Foreword

I was born in 1955, the same year that the Salk polio vaccine went into wide distribution. If you talk to anyone old enough to remember the scourge of polio and the terror it engendered, you begin to get a sense of just how remarkable that breakthrough was and how it changed the lives of millions of people for the better.

That event changed the world, and I grew up in an environment where vaccines for polio, diphtheria, whooping cough, and other contagious diseases were simply taken for granted. Today, the risk of polio has been markedly reduced, having dropped from an estimated 350,000 cases and 125 endemic countries in 1988 when eradication began to fewer than 100 cases and three endemic countries (Pakistan, Afghanistan, and Nigeria) in 2015. Yet as long as polio remains endemic anywhere, the risk of exporting virus, more outbreaks, and more disabled people remains. How is it possible that more than a half-century after Salk's vaccine, polio has still not been eradicated?

Some of this is attributable to the biology of the pathogen. But a lack of political will and a failure of health systems to deliver polio vaccines to children at risk have also prevented the eradication of this scourge. We are 99% of the way there and I am optimistic we will succeed, but only if we combine the best of medicine, logistics, education, and community outreach. Similarly, *S. pneumoniae* has been studied for more than a century. Nevertheless, invasive pneumococcal disease kills more than 800,000 children each year. But since 2000, Gavi (The Vaccine Alliance) has been making effective pneumococcal conjugate vaccines available to the world's poorest countries. Between 2008 and 2015, more than 50 Gavi-eligible countries introduced the vaccine via their routine programs at a rapid rate.

There has been significant progress in the case of measles as well. The vaccine for measles was licensed in the 1960s, but its uptake was frustratingly slow in many places. Even 30 years after its introduction, three-quarters of a million children were dying from measles every year. However, since 2000, measles vaccine coverage has substantially increased, and measles deaths have declined by about 80%. This translates into more than 1500 children each day who live instead of die because the measles vaccine is being delivered regularly almost everywhere in the world.

While the greatest focus of vaccination programs has been on children in the first few years of life, some of the most vulnerable children are newborn infants who are too young for vaccines to induce immediate active immunity. There have been increasing efforts to protect these young children from diseases such as pertussis and influenza by vaccinating pregnant women with transplacental transfer of protective antibodies. This new platform is likely to expand as promising candidates to prevent respiratory syncytial virus and other serious pathogens of the neonatal period prove to be safe and effective in clinical trials.

The simple truth is that vaccines save lives.

They are overwhelmingly safe, are remarkably cost effective, and remain the single best tool we have in global health. They protect the human potential that is sapped by rampant sickness in developing countries. As a result, vaccines are one of the best means we have to promote not just global health, but global development. A recent study showed that low- and middle-income countries can see a return of between $16 and $44 for every $1 invested in vaccines. That's smart economics, not just smart science.

If vaccines are this singularly important tool, then the seventh edition of *Plotkin's Vaccines* is a singularly important resource in extending the power of prevention to the largest possible audience worldwide. *Plotkin's Vaccines* is the most respected source of reliable information on the vaccine tools we now have available, summarizing the scientific basis and rationale for vaccine use as well as the directions being taken to expand this power of prevention to other infectious diseases. It is an honor to have been asked to write this introduction to the latest edition.

It is also an honor to be able to speak to the scientists, researchers, and medical and public health professionals who will take up this volume. Your work is critically important. At a time when irresponsible claims about vaccines sometimes garner as much attention as the facts, it is vital to have informed advocates for the power and necessity of comprehensive vaccination worldwide.

As I write this in 2016, it is an exciting time in the field of vaccines. Last year, we witnessed a remarkable event as donors pledged more than $7.5 billion to Gavi, even in the face of a global financial crisis. The generosity of governments, foundations, and private sector entities that participated in this pledging round will substantially expand the ability of poor countries to vaccinate their children. Through expanded vaccine programs, Gavi projects that it will prevent 5 to 6 million deaths with its vaccination programs in 2016 to 2020. On the research front, we are seeing some promising signs in the decades-long search for an AIDS vaccine. Similarly, we are seeing progress with next-generation vaccines for malaria. The need for this in the poorest parts of the world cannot be overstated. The devastating costs of malaria in lives lost, sickness, diminished capacity, and reduced productivity are incalculable.

Pneumococcus and Rotavirus vaccines, with the potential to save millions of lives over time, are increasingly used in poor countries. Significantly, the time lag between vaccine introduction in rich countries and their availability in poor countries has been shortened from more than a decade to only a few years.

The world has seen the introduction of the first-ever vaccine developed specifically for the developing world—a meningococcal A conjugate vaccine that can end a terrifying threat for millions of people who live in Africa's meningitis belt. Over 250 million people have been vaccinated with the vaccine in large-scale campaigns, and now the vaccine is recommended for use in routine immunization programs.

But much remains to be done. We need new vaccines. The work to develop effective vaccines for tuberculosis, malaria, and HIV must continue.

We need better vaccines. The currently licensed BCG vaccine for tuberculosis has been administered 4 billion times over the last 90 years. It is safe and it protects against severe disease in infants. However, its efficacy is quite limited and it does not

protect against adult pulmonary tuberculosis. Other vaccines such as the oral polio vaccine, the rotavirus vaccine, and other orally administrated vaccines are often less effective in children living in extreme poverty.

We need to better understand mechanistic immune markers that correlate with protection to accelerate discovery and introduction of improved vaccines.

We need to secure faster vaccine introduction and adoption of currently approved vaccines. We are still not reaching a significant number of children, resulting in an intolerable number of preventable deaths.

We need affordable and sustainable supplies of vaccines, particularly for developing countries. The high cost of producing vaccines such as the pneumococcal conjugate vaccine and the human papillomavirus (HPV) vaccine has been an obstacle to incorporating these highly effective vaccines into the immunization programs of developing countries with the highest burden of disease. The HPV vaccine is an extremely effective vaccine that prevents cancer in men and women, but its availability is limited, particularly in developing countries. Gavi is playing a major role in making these vaccines available to the poorest countries, but efforts to simplify the manufacturing and regulation of these vaccines can also help ensure a sustainable, affordable supply for everyone.

But we need to do more than just develop these vaccines and make them affordable; we must also focus on driving near-term improvements in the mechanics of delivering these vaccines to the hardest to reach places, to the people who need them the most. This can include advancing innovative solutions for cold chain equipment, expanded use of the controlled-temperature chain, and in some cases, improvements in thermostability.

Vaccines save lives. But that is not their only benefit. When health improves, poor countries can spend more on schools, roads, and other investments that drive growth, which makes them less dependent on aid.

Vaccines deliver all this for, in some cases, just pennies per shot. That is why I say that if you want to save and improve lives around the world, vaccines are a fantastic investment.

We must use every tool at our disposal to continue to develop, improve, and deploy these miracles of science. It is a matter of the most basic human justice that we do all we can to extend these livesaving interventions around the globe.

Bill Gates
Bill Gates is the founder and co-chair of the Bill & Melinda Gates Foundation.

Preface to the First Edition

Since a first attack, which strengthens the host, often provides valuable safeguards for the future, it must be considered desirable, on condition, of course, that it does not produce too much serious damage. Artificially putting the host into a state comparable to that in which it would be if it had been cured of a spontaneous attack of the particular illness is the object of active immunization or vaccination.

Jules Bordet, Traite de l'Immunite dans les Maladies Infectieuses, 1920

A little over a hundred years ago the first vaccines were specifically developed in laboratories. During that time the success of vaccination has been nothing short of phenomenal. Of the major scourges of humankind, malaria and helminthic disease remain without useful vaccines, although they have now been joined by human immunodeficiency virus infection. Of course, there are many endemic diseases, chiefly respiratory, for which vaccines are badly needed, and there is great activity in hundreds of laboratories seeking to develop immunologic prophylaxis against them.

Indeed, ever since the time of Pasteur the medical world and to some extent the lay world have realized that prevention by vaccination is the El Dorado of research in infectious diseases.

Despite this awareness, there have been curiously few books on the subject of vaccines in actual use, as distinct from the basic immunology of vaccination and from the vaccines in developmental stages. In addition, our experience is that physicians and students often know much less about the vaccines they use than about antibiotics and other forms of treatment, although the impact of vaccines on their patients is likely to be just as great. Despite the proven success of vaccines, only in the United States and other developed countries are there well-vaccinated populations. In this country success has been due to the education and resultant practices of pediatricians. Other segments of the medical community, even in this country, seldom use or think of vaccination.

Moreover, vaccination is always under attack by civil libertarians who claim the right to be ill, by religious zealots who believe the will of God includes death and disease, and by a legal system that profits from the failure of most people to understand risk-benefit ratios or public health issues. Short memories also ensure that people do not recall the way it was before vaccination.

To these problems may be added an attitude that pervades the thinking of both physicians and patients: cure is more interesting than prevention. Minute attention is focused on the heart transplant, the surgery of separating Siamese twins, the high technology of intensive care and why not? These are where the drama is perceived to be. And yet no single physician can in his or her career hope to save more than a small fraction of the lives saved by a single vaccine.

We therefore decided to put together a textbook on vaccines and their use, directed at the physicians who employ them, emphasizing licensed products in the United States, but we also included chapters on vaccines far along in development. In a few cases, where we thought the subjects sufficiently important, chapters on vaccines still in the early stages were admitted. Our hope is that this book will serve as a reference source for all who are interested in vaccines in the prevention of disease.

The Greeks had two gods of health: Aesculapius and Hygieia, therapy and prevention, respectively. Medicine in the twentieth century retains those two concepts, and vaccination is a powerful means of prevention. What follows is information on the vaccines that, together with sanitation, make modern society possible, and that if wisely used will continue to bestow on humankind the gift of prevention, which according to proverb is worth far more than cure.

Stanley A. Plotkin, MD
Edward A. Mortimer Jr, MD

Preface to the Seventh Edition

Since the last edition of this book six new vaccines have been licensed in the United States: a live attenuated oral vaccine to protect against cholera; a human papillomavirus (HPV) vaccine containing antigens against an additional five serotypes to enhance protection against HPV-associated cancers; two protein-based meningococcal Group B vaccines, one of which is the product of reverse genetics technology; an adjuvanted influenza vaccine for use in the elderly; and a combination vaccine for use in 4- to 6-year-olds to protect against diphtheria, tetanus, pertussis, and polio. This time interval has also been marked by important global advances in the delivery of previously licensed vaccines against rotavirus diarrhea, cancer caused by HPV, hepatitis A, cholera, and pneumococcal infections. Of particular note has been the progress on global polio eradication. Type 2 polio has been officially declared eradicated, marking in a sense the second human virus ever to have been eradicated through the use of vaccines (the other being smallpox). There is promise that type 3 polio may have been eradicated with the last case detected in 2012, and type 1 polio is at record low levels. In addition, steady progress is being made in exploiting genetic engineering to make new vaccines, and there have been notable, though partial, successes against HIV, dengue, and malaria.

However, challenges remain as new pathogens emerge or reemerge such as the Ebola outbreak in West Africa and more recently the Zika virus in the Western Hemisphere, neither of which have available licensed vaccines. The need to anticipate and rapidly develop vaccines for these and other emerging pathogens is taking on greater importance.

Vaccines remain one of the most effective and economical prevention measures available and the only medical procedure recommended repeatedly for all children and some adults. But vaccines do not save lives; vaccinations save lives. It is critical to ensure that safe and effective vaccines are delivered to all persons for whom they are recommended.

Since the last edition there has been much progress on maternal vaccination. By vaccinating pregnant women, protection is afforded to both the mother and the infant. In fact, universal vaccination of all pregnant women against influenza and pertussis has been implemented in several countries. The potential for administering respiratory syncytial virus and group B streptococcal vaccines to pregnant women to prevent these common diseases in their infants is also being studied. Much progress has been made.

Vaccine availability is also paramount. The advent of new manufacturers in Asia and Latin America has enhanced the availability of vaccines for developing countries, and their growing economic strength has enabled more people than ever to be immunized. Critical to the successful introduction of new vaccines into developing countries has been Gavi, the Vaccine Alliance, with strong advocacy and financial support from the Bill & Melinda Gates Foundation. Nevertheless, the problem of financing for both old and new vaccines remains.

Moreover, with the increase in vaccination throughout the world, resistance to vaccines has also grown as misinformation retailed by the Internet is rife. It is helpful to have the perspective that vaccine hesitancy is as old as Jenner's smallpox vaccine despite the fact that it succeeded in eradicating a terrible disease. Perhaps it is not surprising that prevention by vaccination in healthy people is more difficult for the public to accept than treatment of established disease, but the proverb "better prevention than cure" is still as sound as it ever was.

Finally, a word to our authors and to our readers. We are grateful to our authors for all their work and for their expertise, which allows us to be sure that the information in the book is correct, and we apologize for harassing them to be on time! We are also grateful to our readers, who by their laudatory comments have given us the enthusiasm to manage the editorial tasks. We regret that the references had to move online (available at ExpertConsult.com), but it was necessary to maintain the affordability of the book.

In any case, we hope this edition will be considered the best yet, and that it will be read by all those, young and old, who recognize the value of vaccines.

Acknowledgments

Dr. Plotkin thanks Ms. Wendy D'Arcy for her faithful work.

Many thanks to Ms. Dianne Miller and Amy Kinsey for their assistance in preparing, revising, and tracking submission of manuscripts and proofs. Their countless hours of work were critical to the successful completion of this revision.

Dedication

To Susan, the love of my life, and to my sons Michael and Alec.

Stanley A. Plotkin

To my wife, Bonnie, who made dreams come true. And to our children, Will and Emily, who make everything worthwhile.

Paul A. Offit

To my loving wife, Diane, and our children, Eleza and Evan, whose support has made my life's work possible.

Walter A. Orenstein

To my supportive family, who have generously shared their time with my work.

Kathryn M. Edwards

SECTION 1 General Aspects of Vaccination

1 A Short History of Vaccination

Susan L. Plotkin and Stanley A. Plotkin

Vaccination as a deliberate attempt to protect humans against disease has a short history when measured against the thousands of years that humans have sought to rid themselves of plagues and pestilence. Only in the 20th century did the practice flower into the routine vaccination of large populations. Yet, despite its relative youth, the impact of vaccination on the health of the world's peoples is hard to exaggerate. With the exception of safe water, no other intervention, not even antibiotics, has had such a major effect on mortality reduction and population growth.

Since the first vaccine was introduced by Edward Jenner (Fig. 1.1) in 1798, vaccination has controlled 14 major diseases, at least in parts of the world: smallpox, diphtheria, tetanus, yellow fever, pertussis, *Haemophilus influenzae* type b disease, poliomyelitis, measles, mumps, rubella, typhoid, rabies, rotavirus, and hepatitis B. For smallpox, the dream of eradication has been fulfilled; naturally occurring smallpox has disappeared from the world.[1] Cases of poliomyelitis have been reduced by 99% and this disease also is targeted for eradication. Rubella and congenital rubella syndrome have been officially declared eliminated from the Americas as of 2015.[2] Vaccinations against many other diseases have made major headway. The path to these successes is worth examining.[3–5]

EARLY DEVELOPMENTS

Attempts to "vaccinate" began long before Edward Jenner's smallpox vaccination. While the precise origin of **variolation** remains unknown, it seems to have developed somewhere in Central Asia in the early part of the second millennium and then spread east to China and west to Turkey, Africa, and finally Europe.

In the 7th century, some Indian Buddhists drank snake venom in an attempt to become immune to its effect. They may have been inducing antitoxin-like immunity.[6] In the 16th century, Brahmin Hindus in India practiced a form of variolation by introducing dried pus from smallpox pustules into the skin of a patient.[7] Writings that cite the use of inoculation and variolation in 10th-century China[8–10] make interesting reading but apparently cannot be verified.[11] There is, however, 18th-century documentation of Chinese variolation. *The Golden Mirror of Medicine*, a medical text dated 1742, listed four forms of inoculation against smallpox practiced in China since 1695:

- The nose plugged with powdered scabs laid on cotton wool
- Powdered scabs blown into the nose
- The undergarments of an infected child put on a healthy child for several days
- A piece of cotton smeared with the contents of a vesicle and stuffed into the nose[8,11]

This text, endorsed by the Imperial Court, raised the status of variolation in China, which previously had been considered just a folk remedy. Another Chinese text, published a century before Jenner's work, stated that white cow fleas were used for smallpox prevention.[9] The fleas were ground into powder and made into pills.

Variolation was introduced into England by Lady Mary Wortley Montagu in 1721, after her return from Constantinople, where she lived for 2 years with her husband, the British Ambassador to the Ottoman Empire. Lady Montagu had been disfigured by smallpox earlier in life and her 20-year-old brother had died of the disease. While living in Turkey, she frequently observed variolation and wrote to a friend back home: "The small-pox, so fatal, and so general amongst us, is here entirely harmless, by the invention of engrafting, which is the term they give it…. Every year, thousands undergo this operation…they take the small-pox here by way of diversion, as they take the waters in other countries. There is no example of any one that has died in it…."[12] So impressed was she that she had her own son variolated while still living in Turkey. Dr. Charles Maitland, who performed the procedure on her son in Constantinople, later performed the first variolation in England in 1721 on Lady Montagu's daughter. The treatment was effective, but results were erratic, and 2% to 3% of persons treated died of smallpox contracted from the variolation itself.[13]

The English medical community had previously learned of variolation in 1713 when Emanuel Timoni, MD, a graduate of Oxford University living in Turkey, sent a letter to the Royal Society about variolation. Another physician, Giacomo Pilarino, also reported Turkish variolation to the Royal Society in 1716.[14] The reports did not seem to be significant, and the procedure was not adopted.[15] An earlier hint of variolation is made by the Danish physician Thomas Bartholin of Copenhagen in 1675, who mentioned that there was a "market" in Copenhagen where people would go to buy the poxvirus from enterprising housewives. It is unclear whether these purchases were for the prevention of smallpox in healthy persons or for the treatment of persons already infected.[15–19] Voltaire lauded the variolation of Circassian women to maintain their beauty in his *Lettres Philosophiques* in 1721.

Most intriguing, at the same time that Charles Maitland variolated Lady Montagu's daughter in England (1721), variolation was practiced in America at the instigation of Cotton Mather who first learned of it from his African slave, Onesimus.[15] Mather subsequently read about variolation in volume 29 of the *Philosophical Transactions of the Royal Society of London*, 1714 to 1716, which contained the aforementioned articles by Timoni and Pilarino. There was a smallpox epidemic in Boston at that time, and Mather used the authority and prestige of his position to urge all Boston-area physicians to consider the practice of variolation (letter, June 24, 1721). Physician

Figure 1.1. Edward Jenner. *(Courtesy the Institute of the History of Medicine, The Johns Hopkins University, Baltimore, MD.)*

response was negative, except for Dr. Zabdiel Boylston, who successfully inoculated his own 6-year-old son and two black slaves shortly thereafter. Six weeks later, Dr. Boylston variolated Mather's son, Sammy, and publicized its success. Mather continued to harangue recalcitrant physicians and the public about variolation to the point where a grenade was thrown into his house in utter exasperation![20,21]

Despite the known risks, George Washington was compelled in the 1770s to order that Continental Army recruits undergo variolation against smallpox, to which the Americans were highly susceptible; the great majority of their English enemies were immune from early childhood exposure or from variolation.[22] In the mid-18th century, several treatises were written on inoculation against measles as well; the Scottish physician Francis Home successfully inoculated humans against measles and published his results (1758).[23–25]

In 1774 in Yetminster, England (Dorset County), a cattle breeder named Benjamin Jesty, himself immune to smallpox after contracting cowpox from his herd, deliberately inoculated his wife and two children with cowpox to avoid a smallpox epidemic.[14] This was no spur-of-the-moment idea; like many country farmers in the area, he knew that dairymaids seemed to be protected from smallpox after they had contracted cowpox. He had considered the possibility of deliberately using the inoculation technique with cowpox for quite some time and acted only when there was an imminent threat of a smallpox outbreak. He took his wife and two children to a nearby field where he knew he could find cattle with cowpox. He inoculated all three of them. His experiment succeeded; they were unaffected by the outbreak, and his two sons were still immune 15 years later, when they were deliberately variolated with smallpox.[26–28]

Jesty's story is interesting; although neither a physician nor a scientist, he nevertheless reflected on the evidence of local dairymaids' immunity to smallpox because of prior infection with cowpox and saw the principle involved: inoculation with one moderately harmless disease (cowpox) could provide protection against another far more dangerous disease, smallpox. When Jesty's neighbors learned that his wife had developed inflammation at the site of the inoculation and had to be treated by a physician because he had "vaccinated" her, they vehemently scorned him.[28] Jesty retreated in the face of their disapproval and never attempted to publicize his experiment or to vaccinate anyone else.[27] Truly, Jesty's actions constituted the first known real **vaccination**—the use of cowpox to protect against smallpox.

Some 30 years later, after Jenner had popularized vaccination, and thanks to the intercession of an enthusiastic vaccinator named Rev. Andrew Bell, Jesty was invited to London in 1805 by the Original Vaccine Pock Institute to tell the story of his 1774 "experiment" before the Institute's examiners. At the end of the visit, they issued a public statement in the *Edinburgh Medical & Surgical Journal* recognizing Jesty's cowpox vaccination. They commissioned his portrait as well, which was hung in the Institute.[27,28] This was a vindication of sorts, but he did not share in the significant monetary award that Jenner received. When Jesty died in 1816, his wife made certain that his tombstone recorded for all posterity his central role in the great endeavor (see frontispiece).

Despite Jesty's successful vaccination of his family, Jenner's work with cowpox vaccination still holds title to the first scientific attempt to control an infectious disease on a large scale by means other than transmitting the disease itself.[29]

Cowpox was not a widespread infection. It appeared sporadically in certain rural counties of England. Thus, the local wisdom that persons who contracted cowpox "did not take the smallpox" was not widely known. Jenner knew it because he had been an apothecary apprentice in Chipping Sodbury in 1768, where a milkmaid told him about using cowpox against smallpox. Indeed, he discussed the possible association between the two with John Hunter, with whom he studied in London from 1770 to 1773. For unknown reasons, Jenner did not return to the subject of cowpox/smallpox until 1796. His first manuscript to the Royal Society on vaccination was rejected because his experiment involved only one person, not enough to establish a principle.[20,27] Within 2 years, he expanded his studies and proved that cowpox could be passed directly from one person to another, thereby providing "large-scale" inoculation against smallpox without depending on the sporadic outbreaks of natural cowpox. Jenner self-published his results in *Variolae Vaccinae* in 1798.[29] This publication brought to the attention of the entire medical community the merits of inoculation with the relatively obscure animal disease, cowpox, to prevent one of humankind's deadliest scourges. Fortunately for the world, Jenner had the connections that Jesty did not, and vaccination rapidly replaced variolation. While Jenner did use the term "vaccine," he is not the originator of the term *vaccination*; that honor belongs to his friend Richard Dunning, who used it in 1800.[30,31] By 1810, Jenner realized that immunity against smallpox by vaccination was not lifelong, but he did not know why.[13]

Curiously, the vaccinia virus used in current smallpox vaccine is not the cowpox virus that Jenner used. Vaccinia, cowpox, and variola are all related orthopox viruses, suspected to have been derived from a common ancestor.[32] S. Monkton Copeman[33–35] gave considerable attention to this issue in the Milroy Lectures of 1898, which make fascinating reading. He documents the many ways, times, and methods by which cows were inoculated to keep the supply of cowpox intact, further adding to the confusion of when and how vaccinia replaced cowpox.[33–35] It has been suggested that vaccinia may have originated in a now extinct horsepox.[36] What is clear is that

the exact origin of vaccinia remains unknown, as does how it became substituted for cowpox.

For the first several decades of the 19th century, arm-to-arm transfer was the primary method of human vaccination.[37] Other recognized diseases, such as syphilis and tuberculosis, were known to be occasionally transmitted along with the "cowpox" virus, so a search was underway to find an alternative way to vaccinate and to ensure a steady supply of cowpox vaccine. The concept of "passages" of the immunizing agent (transmission from one human or animal to another) was well known, and in 1836, Edward Ballard[38] argued for choosing new strains of cowpox for vaccination because the old strains were too weak (too attenuated) from so many arm-to-arm passages. He recommended that the lymph (vesicle fluid) be passed back through a calf to regain strength.

According to Ballard, the idea to use animals to propagate cowpox vaccine, as opposed to human arm-to-arm propagation, was first practiced in Naples, Italy, in 1805. Troja used vaccine virus derived from humans to inoculate cows and then used the lymph from the cows' pocks to vaccinate humans. This was referred to as *retrovaccination*. Troja's successor, Galbiati, stated that he used bovine lymph specifically to avoid transmission of other human diseases. By 1842, a third Italian, Negri, gave up the practice of retrovaccination entirely. He started what was called *animal vaccination*, that is, inoculating from one cow to another cow to keep a steady supply of cowpox lymph. But the initial virus source that he inoculated into the cow was from a human! When a natural outbreak of cowpox occurred in Calabria, Negri switched to that source for his lymph, but because he was running a commercial activity, he bought a third "cowpox strain" from London. Its origin was questionable, but Negri used it anyway, from 1858 onward. By mid- century, arm-to-arm vaccination was essentially replaced by animal vaccination but it is easy to understand why the origin of the vaccinia virus is difficult to trace.[35,38]

In 1864, a French physician named Lanoix studied animal vaccination in Naples and brought back to France a calf inoculated by Negri. He and Chambon set up a business in France for production of calf-to-calf lymph vaccine for humans.[15,35,38] Subsequently, the French government became interested and ordered a study of animal vaccination. The lymph used in the experiments was obtained from Negri in Italy, but was really from the London cowpox lymph of questionable origin. By chance, there were two outbreaks of cowpox in France in 1866. Lanoix and Chambon collected cowpox from both, mixed them together, and used the mixture to produce their vaccine.[35,38] From these confused beginnings, animal vaccination spread rapidly throughout the continent.

Following Robert Koch's recommendation, German scientists began to use glycerin to kill bacteria and to preserve the lymph.[39] This generated a ready supply of a stable calf lymph of consistent potency.[13] By the end of the 1890s, the use of glycerinated calves' lymph was standard everywhere, and both arm-to-arm vaccination and unglycerinated animal vaccination were abandoned.

Louis Pasteur and the Age of Vaccination

Louis Pasteur's (Fig. 1.2) work on the attenuation of the chicken cholera bacterium in the late 1870s was the first major advance after Jenner's *Variolae Vaccinae*. Pasteur drew on concepts that had been developing for at least 40 years: attenuation; modification through passage; renewed virulence; and, most important, the need to replace person-to-person (or animal-to-animal) vaccination with something safer, consistent, and less likely to transmit other diseases.[40]

The popular story that Pasteur had a "eureka" moment when he noticed that a chicken cholera culture (*Pasteurella multocida*) left exposed to air during a long holiday period provided immunity when challenged is considerably more complex than originally told. From the moment he obtained the chicken cholera culture from Henry Toussaint in October 1878, Pasteur spoke of wanting to manipulate it to make a vaccine. The culture was virulent, and he killed many chickens trying to keep it alive through passage from chicken to chicken. By January 1879, he found that he could keep the microbe alive in a culture of chicken bouillon. Chickens inoculated from this bouillon culture died, so it had retained the virulence of his original sample. Next, he prepared a bouillon culture using inflamed chicken muscle tissue from the site of inoculation. He noted that this infected muscle tissue culture did not develop normally as the other cultures did; it became acidic. He fed the chickens bread soaked in the first bouillon culture and then fed them bread soaked in the muscle bouillon. They became sick but survived. He then challenged them with virulent organisms and they lived, so he thought he had a vaccine. After the challenge, the chickens sickened again but again survived and eventually returned to health. So by March 1879, Pasteur realized that he had attained "resistance" to disease; he also knew he had not yet found a product that could be safely used as a vaccine. For the next several months, Pasteur subjected the chicken cholera microbe to various conditions, for example, in a vacuum, exposed to air, and various intervals before inoculation. But it was mainly the chickens that had eaten the bread soaked in acidic bouillon that survived.

Pasteur left on vacation at the end of July 1879; he returned in October and again took up his chicken cholera experiments, focusing on the cultures that had become acidic because they seemed to be the ones that conferred immunity. He tinkered with the amount of time the microbe remained in the acidic cultures. On December 18, 1879, he noted that two cultures made from a chicken that died of a pre-vacation inoculation were the only cultures that turned acidic. He focused on them for his vaccine, although he still had many problems with illness in the chickens. By the middle of January 1880, Pasteur realized that the diminution of virulence came from leaving the microbe for a long time in an acid culture.

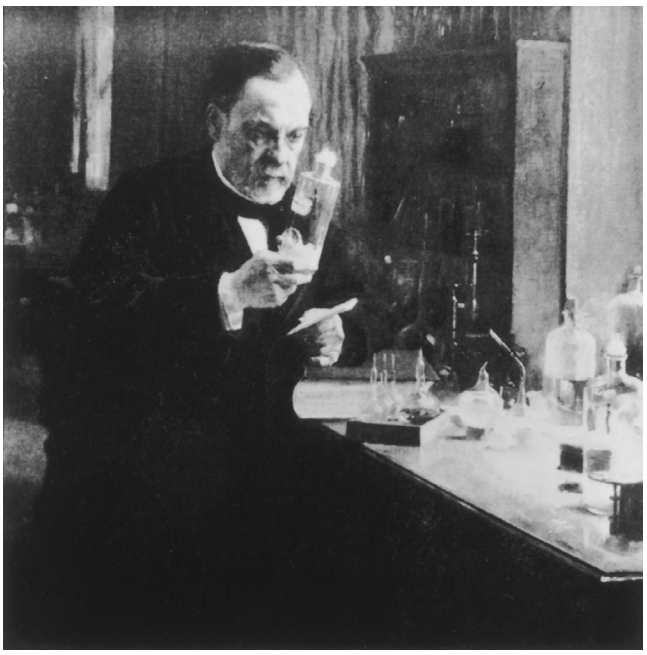

Figure 1.2. Louis Pasteur. *(Courtesy the Pasteur Institute, Paris.)*

Pasteur's definitive test was on January 22, 1880. With highly virulent chicken cholera, he inoculated 19 naïve chickens and 8 that had been previously immunized twice with his acidic cultures. All eight of the previously immunized chickens lived. Most of the naïve candidates did not. So Pasteur's eureka moment was really the result of many months of intensive, deliberate research. Pasteur presented his results at the Académie des Sciences on February 8, 1880, and at the Académie de Médicine on February 10, 1880. He announced that he had achieved successful vaccination against chicken cholera, but he did not reveal his technique. He continued to refine his technique and tried to increase the stability of the final product. Finally, in October 1880, he published at least part of his method for preparation of the vaccine.[20,41] Pasteur's chicken cholera vaccine harkened back to the classic variolation technique, which had used a weakened form of smallpox to inoculate against smallpox. Therefore, the modern concept of vaccination, involving the development of vaccines in the laboratory and using the same agent that caused the disease, was truly introduced with Pasteur's chicken cholera vaccine, 5 years before the famous vaccination of Joseph Meister against rabies. Ironically, the chicken cholera vaccine was never a success; there were frequent vaccine failures. Pasteur was lauded, but the vaccine was eventually discontinued.[20]

Pasteur's research on anthrax began in 1877 and overlapped his work on chicken cholera. Casimir Davaine had seen the anthrax bacillus in 1850, and had postulated it as the cause of anthrax,[42,43] but Koch was the first to obtain pure cultures of anthrax bacillus and to describe its capability to survive indefinitely in the form of spores.[44] He transmitted it to several laboratory animals and proved that there was a causal relationship between this bacillus and the disease anthrax.

Pasteur knew of Davaine's and Koch's work and that of the veterinarian Toussaint (Fig. 1.3).[45] Indeed, he was in a neck-and-neck competition with Toussaint to develop an anthrax vaccine. Toussaint published two articles in July 1880 in the *Comptes Rendus de l'Académie des Sciences* on a live anthrax vaccine that he developed and tested, which induced immunity against anthrax.[20,46–48] He had started his anthrax experiments in May 1880, stating that he was inspired to do so after hearing Pasteur in February 1880 describe his chicken cholera vaccine experiment, although Pasteur had not then revealed his method. Toussaint used the blood of bovines that had died of anthrax, noting that the fluid was full of bacteria, which others thought was extraneous material but Toussaint thought was the causative agent of anthrax. He first attempted to simply "filter" the blood and use it as a vaccine but quickly realized that the bacteria could pass through the filter. He then decided to follow the procedure that Davaine described: to heat the blood for 10 minutes at 55°C or subject the blood to the action of diluted phenol. He used both of these techniques—and a variation on filtering in which he used 12 filters—to produce an attenuated vaccine that he injected in rabbits, sheep, and young dogs. The animals were protected by all three methods, although Toussaint initially thought that the heat-treated was the best.

Figure 1.3. Henry Toussaint.

Toussaint's articles caused quite a stir at the Académie; Pasteur and others challenged their validity and Toussaint was compelled to not only reveal his methods, but also to conduct experiments to prove his claim. On July 28, while still in Toulouse, he took fresh blood from a sheep dying of anthrax and prepared his vaccine in two lots, one with 1% phenol and the other with 1.5%. Both lots were filtered, although by different means. *Neither lot was heat-treated*. He left for Paris with his two lots of "vaccine," where his experiment continued at Vincennes and Alfort under the watchful eyes of several researchers. On August 8, Toussaint inoculated 20 sheep with the first solution (1% and filter papers); 4 of them died very quickly, but the other 16 survived. On August 22, six new sheep were inoculated with material from the second lot (1.5% phenol and rudimentary filtration), and all survived without illness. All 22 sheep were then subjected to challenge with virulent anthrax and all survived. With one injection of a (partially) live vaccine attenuated by filtration and phenol acid, Toussaint had achieved immunity to anthrax![20]

It should be reemphasized that Pasteur did not reveal the method for making chicken cholera vaccine until October 1880. Toussaint's vaccine work was original; it was his own, not Pasteur's. He indeed induced immunity to anthrax, and his was the first anthrax vaccine. Eventually, he received the Prix Vaillant and the Légion d'Honneur for this work.[20,46–49] Toussaint came down with a debilitating neurologic disease in 1881, which prevented him from pursuing his claim as the originator of the first anthrax vaccine. His health continued to decline, and he died in 1890 at age 43 years.[20,46]

The following spring, Pasteur announced the first *public* controlled experiment of anthrax vaccination at Pouilly-le-Fort on May 5,1881.[50] It was initiated by Pasteur in an effort to silence his many critics and to gain recognition for his own anthrax vaccine. Pasteur inoculated 24 sheep, 1 goat, and 6 cows with attenuated anthrax bacilli. On May 17, these same animals were inoculated again with more virulent but still attenuated anthrax bacilli. At the same time, 24 sheep, 1 goat, and 4 cows were kept as control animals and given no inoculations. On May 31, both groups were inoculated with virulent anthrax from spores that Pasteur had kept in his laboratory since 1877.

By the 2nd of June, 21 of the nonvaccinated sheep and the nonvaccinated goat were dead. Two more nonvaccinated sheep died before the spectators' eyes, and the last one died before day's end. All vaccinated sheep, the vaccinated goat, and the six cows remained healthy. (The nonvaccinated cows did not die but showed clear evidence of having contracted anthrax. Their size perhaps had saved them.) At the end of this experiment, the triumphant Pasteur wrote that he had shown

that vaccines could be made that were cultivatable at will by a method that could be generalized, since he had already used the method previously to create a vaccine against chicken cholera. His experiment represented a considerable advancement over Jennerian vaccination, which had not been subjected to the rigors of a controlled experiment.

It has since been documented that Pasteur's results with chicken cholera and anthrax were not as clear-cut as previously thought. Pasteur deliberately withheld critical data (conflicting information on the degree of protection of the vaccine) in his communications to the Académie de Médicine.[51–53] However, this in no way detracts from the significance of his findings, which proved that one could "create" standardized, reproducible vaccines. Pasteur's experiments with chicken cholera and anthrax[41,50] announced to the world that a new, scientific era in vaccination had begun.

By the time the **rabies** vaccine was first administered to humans in 1885,[54] the general public and the scientific community were well aware of the "new vaccination," but only in relation to animals. The reaction when Joseph Meister and Jean Baptiste Jupille became the first humans to be vaccinated against rabies was predictable: outrage. Meister, a 9-year-old boy from Alsace, had been bitten 14 times on the hands and thighs and arrived in Paris some 60 hours after he had been attacked by a rabid dog. The physician working with Pasteur, Dr. Joseph Grancher, was convinced that Meister would die of rabies if left untreated and, therefore, the attempt to vaccinate was justified to save his life. Meister was vaccinated in the same manner that Pasteur was using in his experiments to protect animals (especially dogs) against rabies: with a series of progressively less dried and, therefore, more virulent rabbit spinal cords obtained from rabbits that had died of rabies after having received "fixed virus" injections of rabies virus. A couple of months later, Jean Baptiste Jupille, a 14-year-old from the Jura region of France, arrived 6 days after having been bitten multiple times. (He had fought off a rabid dog that had attacked a number of younger children.) He was given the same course of treatment that Meister received. They both survived.[13]

That Pasteur had deliberately introduced a deadly agent into a human left people aghast. The fact that the rabies virus had been attenuated did not appease the general public or many in the medical community; the cases of rabies that occasionally occurred in subsequent vaccinees were attributed to the vaccine and were viewed as medical murders. Even Émile Roux, one of Pasteur's staunchest allies and a collaborator in the rabies experiments, was appalled at the vaccination of Meister. He thought it was unjustified by the experiments conducted up to that point.

An examination of Pasteur's laboratory notebooks indicates that Roux was right to object.[52] The notebooks tell us that, shortly before vaccinating Meister, in May and June of that same year, Pasteur had seen and recommended vaccination for two other people in local hospitals, each of whom had been admitted with the presumed diagnosis of rabies. The first, an adult, was admitted with an uncertain diagnosis of rabies. The second case was a young girl, 11 years old, who had been bitten by a rabid dog on the lip, remained untreated, and was admitted to a hospital a month later with frank rabies. In both cases, Pasteur used a rabies vaccine made of an emulsion of dessicated spinal cord from a rabid rabbit. Up to this point, he had never published anything about using spinal cords as a vaccine, and in fact, had not yet successfully protected any animal from rabies with such a vaccine. The first patient, the adult whose diagnosis was uncertain, received only one–unauthorized–dose of the vaccine before his doctor forbade the administration of further doses. This patient lived. The young girl, whose rabies diagnosis was not in doubt, received two injections of the same vaccine on her first day in the hospital. When Pasteur and his nephew Adrian Loir arrived the next morning to give the third injection, the young girl died before she could receive it.[52] The death was almost certainly from rabies and not from the two injections she had received. These two cases were never published by Pasteur but were subsequently found in his laboratory notebooks.

Roux left Pasteur's laboratory in protest after Meister's vaccination and did not return until the summer of 1886, after several dozen people who had been bitten by rabid animals had been successfully vaccinated.[13,52,55,56] Ultimately, hundreds were saved from rabies, many more than had died despite the vaccination (presumably from rabies contracted from the bites). Unfortunately, that did not lessen the strenuous opposition to rabies vaccination in humans nor the belief by many that the vaccination itself caused the deaths. After all, only 45 years earlier, once Jenner's vaccination had been accepted, variolation had been made a felony in England for the very same reason: it introduced a deadly live virus into humans (as opposed to cowpox, which was not deadly).[13] Grancher, the physician who administered the rabies vaccine to Meister and many others, was one of Pasteur's staunchest supporters and was invaluable in defending Pasteur before the Académie de Médicine and against recalcitrant physicians.[56] Despite the opposition, and thanks to Grancher and other supporters, Pasteur soon became a worldwide medical hero.

The next major step in vaccine development took place in the United States. It involved a new concept that was equally important: killed vaccines. In 1886, Daniel Elmer Salmon (Fig. 1.4) and Theobald Smith (Fig. 1.5) published their work on a killed hog cholera "virus" vaccine.[57,58] The heated suspension of organisms immunized pigeons against the disease. The vaccine they developed was actually a bacterial vaccine against

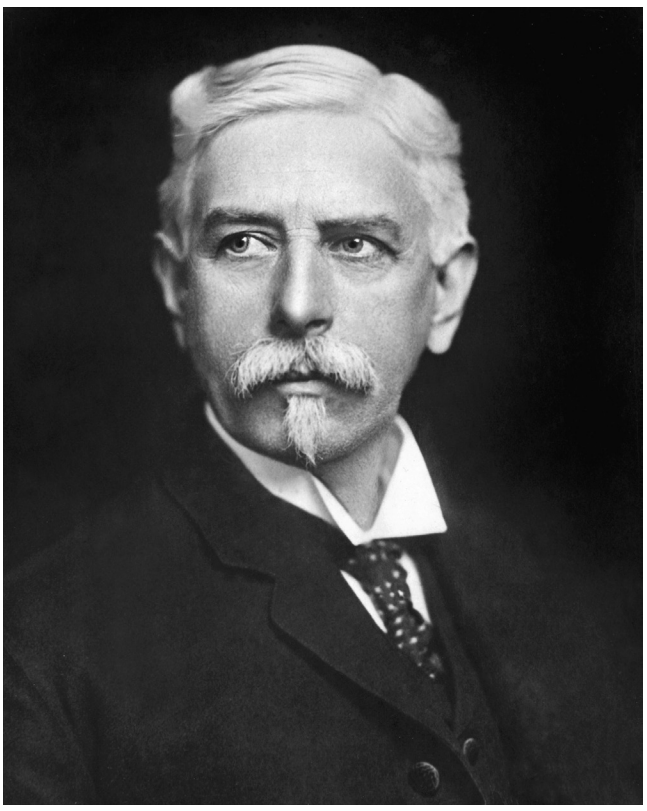

Figure 1.4. Daniel Elmer Salmon. *(Courtesy the American Veterinary Medical Association, Gallery of AVMA Presidents.)*

a cholera-like salmonellosis,[59] but the term *virus* in the latter half of the 19th century did not have the specific meaning it has today; there was confusion about what pathogens could pass through filters. Their report demonstrated that the ideas of **live and killed vaccines** developed almost simultaneously. This seminal work of Salmon and Smith bore fruit for *humans* 15 years later.

Ironically, their competitors in the development of a killed vaccine were Charles Chamberland and Roux from Pasteur's laboratory, who reported on the same topic in December 1887,[60] some 16 months after Salmon and Smith's original paper. In 1888, Salmon read a paper before the American Association for the Advancement of Science (AAAS) defending their 1886 article and their priority in developing the first killed vaccine.[61] However, the Institut Pasteur had just been established in 1887; Pasteur was at the height of his fame and worldwide prestige thanks to the rabies vaccine. Not surprisingly, Salmon and Smith, working for the U.S. Department of Agriculture, saw their claim lost in the aura surrounding Pasteur and his associates. Thus, even 100 years ago, the Institut Pasteur and the U.S. government were involved in disputations about discovery rights, similar to the late 20th-century controversy about who first isolated the human immune deficiency virus: Luc Montagnier at the Institut Pasteur or Robert Gallo at the National Institutes of Health.

Killed vaccines for typhoid, plague, and cholera followed on the heels of Salmon and Smith's research. Richard Pfeiffer and Wilhelm Kolle in Germany and Almroth Wright in England worked independently on killed **typhoid vaccines.**[62–65] To this day, the debate continues about exactly who inoculated the first human with killed typhoid vaccine. In truth, all three deserve credit because it is now clear that several groups were working on typhoid vaccine at that time.[66]

Shibasaburo Kitasato and Alexandre Yersin, each working independently, discovered the causative bacillus of the **plague** in 1894, *Yersinia pestis* (called *Pasteurella pestis* until 1970).[13,15,67,68] With Albert Calmette and Amédée Borelle, Yersin developed a killed plague vaccine for animals,[69] but it was Waldemar Haffkine who took up the task of developing a vaccine against human plague.[70,71] Haffkine was in India working on cholera vaccine when bubonic plague broke out in Bombay. He switched to studies of plague immunization and was himself the first to be injected with his new killed plague vaccine. More than 8000 people were then vaccinated within a few weeks. For a while, Haffkine was a hero. However, the Mulkowal incident in 1902 when 19 people died from contaminated plague vaccine resulted in Haffkine's removal from his post by the Indian government. The contamination (with tetanus bacillus) does not seem to have been his fault.[15] Nevertheless, his scientific career and reputation were severely damaged; he never fully recovered from the incident and retired early from science at age 55 years. Later, with the wisdom of hindsight, the Indian government renamed the Plague Research Laboratory where he had worked *The Haffkine Institute*. Perhaps as important as his development of the plague vaccine was Haffkine's contribution to the literature on the proper way to conduct controlled field trials.[72]

John Snow had shown that cholera was transmitted by contaminated water in 1848,[73] although he did not know the identity of the contaminant. That answer was supplied by Koch, when he isolated *Vibrio cholerae* as the causal organism in 1883.[74] Early attempts at a **cholera** vaccine were made by Jaime Ferrán, Pasteur's pupil, and by Haffkine. Both used live cultures and both vaccines were rejected because of severe reactions.[13] Kolle developed a heat-killed, human cholera vaccine in 1896.[75,76] He grew the vibrios in agar, suspended them in saline solution, heated them at 50°C for a few minutes (later changed to 56°C for 1 hour), and then added 0.5% phenol.

In parallel with the focused research on vaccines, important work on immunity was being pursued at the end of the 19th century. Elie Metchnikoff, another Pasteur protégé, reported his theory of cellular immunity in 1884.[13,77] He named the cells that ingested and destroyed invading microorganisms and other foreign bodies *phagocytes*. Although he did not understand the role of serum and plasma in immunity at this early date, his work was truly pioneering.

In 1888, Roux and Yersin showed that the **diphtheria** bacillus produced a powerful **toxin**.[13,78] Two years later, Emil von Behring and Kitasato, working in Koch's laboratory in Berlin, followed up on early work by Karl Fraenkel; they showed the presence of powerful **antitoxins** in the serum of animals previously injected with low doses of **tetanus** or diphtheria toxins.[79–81] The antitoxin neutralized diphtheria or tetanus toxin in culture. Further experiments showed that the antitoxin protected animals challenged with the tetanus or diphtheria bacillus. Although he did not use the term, what von Behring had found in the serum of animals previously injected with diphtheria or tetanus toxins were **antibodies**. It was Paul Ehrlich, also working in Koch's laboratory, who first referred to these antitoxins as antibodies—"antikorps."[82]

Progress occurred rapidly after these reports; the first child was treated with diphtheria antitoxin just 1 year later, December 1891. Shortly thereafter, commercial production of diphtheria antitoxin began. von Behring referred to the rabbit serum that contained the antitoxin as "immune serum." Soon, the process of inoculating with the immune serum that contained tetanus or diphtheria antitoxin was referred to for the first time as **immunization**.[15,81]

Ehrlich's receptor theory of immunity, which he referred to as the "side-chain theory," made a strong contribution to

vaccine development. When it was first developed in 1897, the theory was used primarily to explain toxin–antitoxin interactions and subsequently the relationship between antigens and antibodies. It soon became one of the cornerstones of 20th-century immunology.[83] Ehrlich's other major contribution was to point out the difference between active and passive immunity.[13,84]

The last decade of the 19th century produced remarkable advancements from remarkable men. von Behring was awarded the first Nobel Prize in Medicine (1901); Koch received it in 1905, and Ehrlich and Metchnikoff shared the Nobel in 1908.

FIRST HALF OF THE 20TH CENTURY

At the beginning of the 20th century, five human vaccines were in use: Jenner's original smallpox vaccine and Pasteur's rabies vaccine (both containing live virus) and three bacterial vaccines: typhoid, cholera, and plague (all killed). In addition, immunization with diphtheria or tetanus antitoxin was an accepted practice. The 19th century's end also saw the end of arm-to-arm lymph inoculation as a vehicle for smallpox vaccination. This technique was replaced by the use of glycerinated calf lymph in 1898.[13] Most of the fundamental concepts of vaccinology had been introduced by the end of the 19th century; the early 20th century would bring refinements to these theoretical underpinnings. Not until the advent of cell culture 50 years later would the field again become so dramatically fertile (Table 1.1).

Wright proposed mass immunization of British troops with killed typhoid vaccine during the Boer War (1899), but there was opposition because of adverse reactions and he was able to vaccinate only 14,000 volunteers. Opposition ran so high that consignments of vaccine were dumped overboard from transport ships in Southampton. The result was catastrophic: more than 58,000 cases of typhoid and 9000 deaths in the British Army.[63] A bitter battle about the merits of the vaccine was waged in the *British Medical Journal* between Wright and the statistician Karl Pearson. Ultimately, at Wright's insistence, the War Board initiated a broad-based trial that showed the overwhelming effectiveness of the vaccine. Wright was then knighted. By the beginning of World War I in 1914, general typhoid vaccination was conducted in the British Army, although it was still not mandatory.[63,85,86]

During the first few decades of the 20th century the use of "bacterins" as human vaccines came into use. Bacterins consisted of killed bacteria (antigens) that were injected parenterally to produce active immunization. Sometimes they were combined with immune serum to become "serobacterins"—the serum would provide short-term immunity before the killed bacterial antigens kicked in to provide long-term immunity. The concept was an outgrowth of Metchnikoff's theory of phagocytosis and Wright's work on opsonins. It was thought that bacterins worked because opsonins induced by the antigens prepared invading bacteria for phagocytosis. Most bacterins were prepared and sold without clinical trials. In its 1908 catalog, HK Mulford Company, a forerunner to Merck, listed nine bacterins that it sold, including those for gonorrhea, typhoid, pneumococcal disease, and streptococcal disease. Bacterins for humans fell into disuse by the late 1930s as more stringent licensing requirements were imposed by the federal government.[87,88] Bacterins for specific herds are still used as targeted vaccines for animals.

In the early 20th century, the *chemical* inactivation of diphtheria and other bacterial toxins led to the development of the first **toxoids**: diphtheria and tetanus. Here again, Theobald Smith had a significant role. In 1907, he determined that toxoids provided immunity in guinea pigs. In a 1909 report on long-lasting immunity against diphtheria in guinea pigs immunized with toxoid, he suggested that toxoids should be considered for humans.[59,89]

In 1923, Alexander Glenny and Barbara Hopkins showed that diphtheria toxin could be transformed into a toxoid by formalin.[90] The discovery came about when the containers in which the batches of diphtheria toxin were kept were cleaned with formalin (they were too large to be autoclaved). The residual formalin in the vats rendered the batch of toxin so weak that 1000 times the normal dose did not kill the guinea pigs. Although this toxoid was certainly safer than the toxin, it could be administered only in conjunction with antitoxin. In that same year, Gaston Ramon developed a diphtheria toxoid that could be used on its own (i.e., without antitoxin) by adding formalin and incubating the mixture at 37°C for several weeks.[91] Ramon and Christian Zoeller used a tetanus toxoid developed in the same manner for the first human vaccinations against tetanus in 1926.[92,93]

The vaccine against **tuberculosis,** bacille Calmette-Guérin (BCG), was the first live vaccine for humans to be produced since Pasteur's rabies vaccine in 1885. Calmette was a protégé of Emile Roux and founder of the Pasteur Institutes at Lille and in Indochina.[13] In 1906, Calmette and Camille Guérin, a veterinarian, started subculturing a strain of mycobacteria obtained from a bovine, which they perhaps thought was *Mycobacterium tuberculosis* but was in reality *Mycobacterium bovis*. They originally focused on producing a serotherapy, along the lines of von Behring's antidiphtheria serotherapy, but quickly realized they could not inhibit the pathogenicity of the bacillus very easily. That began their pursuit of a vaccine. After 13 years of attenuation by 230 passages in beef bile, potatoes, and glycerol, this strain eventually became the BCG strain. In total, Calmette and Guérin spent more than 20 years trying to understand the mechanism of infection of tuberculosis.[94] Clinical trials in children began in 1921, and the vaccine became available for human use in 1927.[13,95–99] Because the original vaccine strain was sent to numerous laboratories around the world, each of which then produced its own variation of BCG vaccine, standardization has proved difficult. Despite the existence of more than a dozen major BCG vaccine strains that vary widely in strength, BCG remains an effective, if imperfect, vaccine against tuberculosis in children.[100]

In 1931, E.W. Goodpasture introduced the use of the chorioallantoic membrane of the fertile hen's egg as a medium for growing viruses.[55,101] This technique represented a major advance because until then it was thought that human viruses could be grown only in animals such as ferrets and mice. Ferrets were expensive, and mouse brain could produce allergic brain encephalitis. The chick embryo proved to be a cheaper and safer medium for the cultivation of viruses. Earlier, in the second Milroy Lecture of 1898, Copeman described conducting an experiment using hens' eggs—successfully—to grow vaccinia virus for the production of smallpox vaccine.[34,102]

Yellow fever virus was isolated in 1927 by two independent groups: researchers at the Rockefeller Foundation working in Nigeria, who isolated the Asibi strain,[103–105] and researchers at the Pasteur Institute in Senegal, who isolated the French strain.[106,107] The French strain was given to various research groups for study.[107] In 1928, A.W. Sellards at the Harvard Medical School began collaborative research on the French strain with Jean Laigret at the Pasteur Institute in Senegal. Max Theiler, working for Sellards at Harvard, developed an animal model to study the virus.[108] Using passage in mouse brain, others were able to "fix" the neurovirulence of the strain,[109] which then was used as a vaccine. This French strain yellow fever vaccine from Theiler's work at Harvard was a live vaccine derived from mouse brain passage.[110] Sellards and Laigret

TABLE 1.1 Outline of the Development of Human Vaccines (Wherever Possible, Date of Licensure Is Indicated)

Live Attenuated	Killed Whole Organism	Native Protein or Polysaccharide	Genetically Engineered
18TH CENTURY			
Smallpox (1798)			
19TH CENTURY			
Rabies (1885)	Typhoid (1896) Cholera (1896) Plague (1897)		
20TH CENTURY, FIRST HALF			
Tuberculosis (bacille Calmette-Guérin) (1927)	Pertussis (1926)	Diphtheria toxoid (1923)	
Yellow fever (1935)	Influenza (1936) Typhus (1938) Tickborne encephalitis (1937)	Tetanus toxoid (1926)	
20TH CENTURY, SECOND HALF			
Polio (oral) (1963)	Polio (injected) (1955)	Pneumococcus polysaccharide (1977)	Hepatitis B surface antigen recombinant (1986)
Measles (1963)	Rabies (cell culture) (1980)	Meningococcus polysaccharide (1974)	Lyme OspA (1998)[b]
Mumps (1967)	Japanese encephalitis (mouse brain) (1992)[b]	*Haemophilus influenzae* type b polysaccharide (1985)[b]	Cholera (recombinant toxin B) (1993)
Rubella (1969)	Tickborne encephalitis (1981)	Meningococcal conjugate (group C) (1999) U.K.[a]

intended to do the human trials on the yellow fever vaccine at the Institut Pasteur in Paris, but Roux, who was then the director, refused to allow the human trials with the murine virus to be conducted. He thought it was too dangerous.[111] Eventually it was used in humans without immune serum by Sellards and Laigret in 1932.[112] However, owing to the strain's passage through mouse brain tissue, the neurovirulence of the French strain did indeed present grave dangers.

Theiler subsequently left Harvard to join the Rockefeller Institute and attempted to develop a more attenuated vaccine, using the Asibi strain. Theiler and Hugo Smith developed the 17D strain from Asibi in fertile hen's eggs chorioallantois per Goodpasture's method. Although the French strain was also highly effective, the 17D strain was both effective and much safer.[55,107,113–115] The French strain certainly saved many lives, especially in French West Africa, where it was used extensively. It remained in production (in modified form) until 1982; however, safety concerns about the use of mouse brain tissue overrode its proven efficacy and 17D won out as the vaccine strain of choice.[107] For this work, Theiler was awarded the Nobel Prize in 1951.

Wilson Smith, Christopher Andrewes, and Patrick Laidlaw isolated human **influenza A** virus in ferrets in 1933.[116] They followed the technique outlined by Richard Shope of the

Rockefeller Institute when he isolated the swine influenza virus in pigs in 1931. Within 5 years, Smith's group and Shope were able to show that swine influenza virus was a surviving virus from the great influenza pandemic of 1918.[117,118] Frank Horsfall, Alice Chenoweth, and colleagues developed a live influenza virus vaccine in mouse lung tissue in 1936.[119,120] Chenoweth claimed that it became inactivated or nonreplicating when it was administered parenterally.[120,121] That same year, 1936, saw the development of two influenza A vaccines grown in embryonated eggs, one (live) by Wilson Smith[122] and the other (killed, whole virus) by Thomas Francis and Thomas Magill.[123,124] Even though these two vaccines were considered safer because they were developed in embryonated eggs, Chenoweth's mouse lung vaccine had contained a higher virus yield and was the first to demonstrate true protection in humans, albeit transient.

In 1937, Anatol Smorodintsev and colleagues in the Soviet Union administered the Wilson Smith strain to humans by the intranasal route, using doses that were lethal when given to mice.[125] This is considered the first *live* human influenza virus vaccine, and although it would not receive a passing grade by today's standards (20% of vaccinees developed febrile influenza), it absolutely demonstrated the role of the virus in the development of influenza.[121,126]

Frank Burnet and D.R. Bull showed in the early 1940s that live attenuated influenza virus could be produced in embryonated eggs but also that the resultant virus mutated rapidly. Therefore, the vaccines that were produced were not consistently attenuated and often produced disease.[127,128] By contrast, the Francis and Magill killed, whole-cell influenza A vaccine did not have the problem of mutated viruses and did not produce disease.

In 1940, Francis and Magill independently isolated **influenza B;** at this point, it was recognized that at least three strains of influenza were circulating at the same time. Francis developed a killed (formaldehyde), trivalent (2As, 1B) vaccine that was mass-produced for the U.S. military in World War II. This conferred a certain "legitimacy" to killed influenza vaccine, as the military did not have to be concerned about "down time" from live vaccine–associated influenza. During this same period, Burnet developed a live aerosolized influenza vaccine, but the influenza season had already begun, so an efficacy trial was inconclusive. By then, the killed vaccine of Francis had been very successful during the war. The Australian government denied Burnet permission to continue trials of a live vaccine as too risky.[121,126,129,130] Except for the Soviet Union, which continued to use live vaccine, killed influenza vaccine became the standard until the 1990s (see subsequent text).

During the 1947 flu season, the influenza vaccine did not protect, definitively proving the concept of antigenic variation of the virus strain from year to year, which had first been proposed by Magill and Francis in 1936. The term itself, "antigenic drift," was introduced by Burnet in 1955 in his *Principles of Animal Virology*.[126]

Many attempts were made to develop vaccines against rickettsiae once Charles Nicolle had discovered in 1909 that they were the cause of **typhus**.[13] The first truly successful typhus vaccine was developed in 1938 by Herald Cox,[131] who used the yolk sac of the chick embryo to grow *Rickettsia rickettsii*. Cox was working on Rocky Mountain spotted fever at the time, but once he found a method to cultivate the rickettsia, killed vaccines for typhus and Q fever quickly followed. There was a heavy demand for the typhus vaccine during World War II.[13,132,133]

Jules Bordet and Octave Gengou first observed the causal agent of **pertussis** in 1900 and cultivated it by 1906.[13,134] Several vaccines were tested in small trials. Thorvald Madsen later carried out the first controlled clinical trials of a pertussis vaccine (i.e., whole killed organisms) on the Faeroe Islands in 1923–1924 and again in 1929.[135,136] During the 1923–1924 epidemic, Madsen reported that the vaccine did not prevent disease but greatly reduced mortality and severity of illness among vaccinated persons. By the 1929 epidemic, the vaccine had been considerably improved but still did not prevent disease.[137] In the 1930s, Pearl Kendrick and Grace Eldering (Figs. 1.6 and 1.7), working for the Michigan Department of

Figure 1.6. Pearl Kendrick. *(From Grand Rapids History & Special Collections, Archives, Grand Rapids Public Library, Grand Rapids, MI.)*

Health, improved the yield of the Bordet-Gengou growth medium and developed a killed (thimerosal) vaccine that they successfully tested in more than 1500 children. Only 4 of 712 vaccinees developed mild cases of whooping cough. They recruited the help of Eleanor Roosevelt to gain additional funds for further research and by 1940, their vaccine was distributed throughout the United States.[138] The American Academy of Pediatrics approved the vaccine in 1943 and the American Medical Association in 1944. Several whole-cell pertussis vaccines were in use by the late 1940s.[139,140] The first **combination vaccine,** DTP (diphtheria, tetanus, pertussis) became available in 1948.[141]

SECOND HALF OF THE 20TH CENTURY TO THE PRESENT

The latter half of the 20th century can truly be called the Golden Age of vaccine development. This occurred primarily because of the ability to grow viruses in stationary **cell culture**. Hugh and Mary Maitland from Manchester University first developed the flask **tissue culture** technique in 1928.[13,59] They succeeded in growing vaccinia virus in sterile cultures of minced rabbit kidney in rabbit serum and mineral salts—a great accomplishment that proved to be a turning point in virus research. George Gey improved the virus yield of this method by continually rolling the tubes, thus increasing the oxygenation of the cells.[59]

After the Second World War, John Enders, Thomas Weller, and Fred Robbins took up research on cell culture at Boston Children's Hospital. After using tissue cultures of the Maitland type (substituting monkey kidney for Maitland's rabbit kidney), they tried to grow viruses in explanted human cells, using fibroblasts grown from the foreskin and muscle tissue of infants who had died soon after birth. Their first success was to grow Lansing type II poliovirus in human cell culture.[142] The ability to grow human viruses in vitro, in a relatively easy and safe manner in monolayer cell cultures, led to an veritable explosion of creativity in vaccinology that continues unabated (see Table 1.1). Indeed, Enders, Weller, and Robbins received the Nobel Prize in Medicine in 1954 for their seminal work.

Paralytic **polio** became an epidemic problem only in the latter half of the 19th century when epidemics broke out in Western Europe and the United States.[143] After the virus was isolated by Landsteiner and Popper,[144,145] there were attempts to make polio vaccines in the 1930s, especially by John Kolmer and Maurice Brodie.[146–148] These vaccines were poorly and hastily tested, and their use resulted in at least six deaths and numerous cases of vaccine-associated paralytic polio. The backlash against these ill-conceived experiments was swift. At the meeting of the American Public Health Association in St. Louis in November 1935, James Leake, medical director of the U.S. Public Health Service, directly accused Kolmer of murder! Kolmer stopped working on vaccines after this disastrous incident and returned to Temple University where he taught Public Health and Preventive Medicine.[31,146] Polio vaccine development for the most part ground to a halt for the next 15 years.[146]

A rare exception to this hiatus was Hilary Koprowski, who did work on polio vaccine during this period and developed the first live oral polio vaccine (OPV) with an attenuated polio variant virus strain grown in mice, not cell culture. It was tested in humans in 1950.[149]

The logjam preventing further polio vaccine research was broken with the aforementioned report by Enders, Weller, and Robbins in *Science* in 1949.[142] All subsequent research on polio vaccine was based on attenuation or passage in cell culture. In rapid succession thereafter, articles appeared showing that the Lansing strain of polio could be grown in a variety of human and other primate tissues,[150–155] and several laboratories began research on polio vaccines.[146] Thus began **"The Polio Wars."**

The first licensed product developed using the cell culture technique was the trivalent, formalin-inactivated polio vaccine (IPV) of Jonas Salk, licensed in 1955.[156] Salk gained his vaccine experience under his mentor Thomas Francis, with whom he developed the first killed influenza vaccine in 1938, which was used to vaccinate the American troops during the Second World War. The majority of Salk's research on killed polio vaccine and the large clinical trial in 1954 (more than 1.8 million children) were funded by the National Foundation for Infantile Paralysis (March of Dimes), founded by Franklin Roosevelt in 1938 and directed by Basil O'Connor. The Foundation's idea on the trial design did not include a placebo-control; on the contrary, Francis insisted on the need for placebo-control. After a shaky start, the clinical trial was designed by a committee that included both points of view, headed by Thomas Francis, Salk's former mentor, who ultimately directed the trial. Although Salk wanted every child in the trial to receive his vaccine, Francis stood his ground and insisted on use of a placebo. The controversial trial design was called a "dual-control" trial. In 11 states, children in grades 1 through 3 received injections of either the polio vaccine or a placebo. In 33 other states, children in grade 2 received injections of the vaccine and all children from grades 1 through 3 were "observed" for the duration of the polio season. In the end, 420,000 children received Salk's vaccine, 200,000 a placebo, and 1.2 million were "observed."[146,157,158]

The quest for a polio vaccine was highly publicized, adding pressure on everyone involved to hurry up and develop a vaccine. Although Salk's public persona generated a lot of animosity from professional colleagues who saw him as a publicity hound, when the overwhelmingly positive results of Salk's trial were announced on April 12, 1955, with great fanfare, ordinary Americans were ecstatic and Salk became an instant "hero." The inactivated Salk vaccine was immediately licensed, and within days, six companies had been granted rights to manufacture the vaccine.[143,146,159]

This haste was understandable, as the "summer polio season" was about to begin and parents were anxious to vaccinate their children. But it was short sighted. Shortly thereafter, the Cutter Incident occurred,[146] in which cases of paralytic polio were detected in vaccine recipients. Epidemiologic evidence showed that the product of one manufacturer, Cutter Laboratories, was implicated in most of these vaccine-related cases. The nation's entire polio vaccination program was put on hold until a review of manufacturing procedures could determine the source of the problem.[146,160,161] More rigorous safety testing was put in place and an additional filtration process added to remove clumps of partly inactivated virus before the vaccination program resumed. The contaminated vaccine resulted in 260 cases of paralytic polio and 10 deaths in recipients, their families, or community contacts. Only one manufacturer was implicated, although several had experienced problems. Because polio was such a widespread and feared disease, there was no lasting boycott of the vaccination program.[143,146]

Despite the success of Salk's killed vaccine, others continued research to develop *live* attenuated polio vaccines in cell culture: Herald Cox at Lederle, Koprowski at the Wistar Institute, and Albert Sabin at Cincinnati Children's Hospital. Like Jenner and Pasteur, these researchers believed that an infection with live virus would provide more long-lasting immunity and greater resistance to disease.[143] Because Salk's vaccine was already in use, Sabin was unable to get funding in the United States for the required clinical trial to prove the efficacy of a

live polio virus vaccine. Despite the Cold War, and probably because he was born in Russia, Sabin was able to collaborate with Russian scientists to do the enormous clinical trials in the Soviet Union. Based on Dorothy Horstmann's favorable review of the Russian trial results, Sabin's vaccine was licensed in the United States in 1960. Until 1963, both vaccines (Salk's killed and Sabin's live) were used in the United States. In 1964, the Committee on the Control of Infectious Diseases of the American Academy of Pediatrics voted a clear preference for Sabin's live OPV, which was grown in monkey kidney cell culture and was easier to administer (vaccine on a sugar cube). As a result, it came into wide use.[143,162]

For the next 30 years OPV was the primary recommended vaccine in the United States and in many, but not all, European countries (Sweden, Finland, and the Netherlands continued using IPV). Although there were reports of vaccine-associated cases of polio with OPV, Sabin adamantly defended his vaccine and refused to believe that it was capable of causing polio. But by the 1990s, the only cases of polio occurring in the United States and Europe were vaccine-associated, caused by mutation of the live virus and reversion to virulence in OPV. In the year 2000, the United States switched to the exclusive use of IPV.

Thanks to both of these vaccines, polio has been eradicated from the Western Hemisphere, and the World Health Organization (WHO) has targeted polio to be the next disease after smallpox to be effaced from the entire world. In the May 2015 WHO report, the recommendation was made to remove Type 2 polio strain (the strain that causes most vaccine-associated polio) from all OPV vaccine by April 2016 and to begin introduction of IPV wherever possible by that same date.[163]

Many others took advantage of cell culture techniques. Samuel Katz, Milo Milanovic, Enders, and colleagues developed the Edmonston strain of **measles** vaccine, grown in chick embryo cell culture,[164] which was attenuated further by Maurice Hilleman and colleagues[165] and by Anton Schwarz.[166] Hilleman also attenuated the Jeryl Lynn strain of **mumps** virus (obtained from and named after his own daughter Jeryl Lynn) in the hen's egg and obtained licensure in 1967.[167] Rubella virus was isolated in 1962, both by Tom Weller[168] and Parkman and associates.[169] The virus was attenuated by passage in cell culture and by 1970, several strains had been developed and were in use: in monkey kidney by Paul Parkman and Harry Meyer (further passaged in duck embryo cells by Hilleman),[170] in rabbit kidney by Abel Prinzie and Constant Huygelen,[171] and in human fibroblasts by Stanley Plotkin.[172] The latter strain (Wistar-RA27/3), the first vaccine made in human fibroblasts, is the sole rubella vaccine in wide use since 1980 because of its better safety and efficacy. In 2015, the Pan American Health Organization (PAHO) announced that rubella was officially declared eliminated from the Western Hemisphere.[2,173]

In the 1950s, the **adenoviruses** were first recovered from adenoids that had been surgically removed.[174] Until their isolation, a great variety of the illnesses they cause were attributed to other diseases. Formalin-inactivated, whole-virus vaccines were made by Hilleman against types 4 and 7; they were licensed for military use only. In the early 1960s, the seed stock was shown to be contaminated with simian virus 40 (SV40)[175]; when all attempts to eliminate SV40 failed, the vaccine was withdrawn in 1963.[176]

Vaccine studies continued, however, using human embryo kidney (HEK) cells and subsequently human diploid cell strains, thus eliminating the SV40 problem. An enteric-coated vaccine tablet was produced for types 4, 7, and 21 by Chanock and colleagues[177–181]; the vaccine was licensed, but again, only for military use. Production ceased in 1996, primarily because of regulatory issues and lack of interest by the military. Not unexpectedly, within a few years significant outbreaks of adenovirus respiratory diseases reoccurred in military recruits. After several years, the U.S. Army signed a contract with another producer to reformulate the original vaccine.[182] In 2011, the U.S. Food and Drug Administration (FDA) again approved a live oral vaccine for adenovirus types 4 and 7 for military populations ages 17 to 50 years.

The live attenuated Oka strain of **varicella** vaccine was developed in the 1970s by Michiaki Takahashi[183,184] and underwent extensive clinical trials before being licensed in Japan and several European countries.[185,186] After a long and convoluted development, licensure was obtained in the United States in 1995.[187] It is now recommended for all children older than 1 year.[188] As of 2009, there has been a 90% decline in varicella-related hospitalizations.[189–193]

The discovery of the relationship between chickenpox and shingles goes back to the late 19th century. A Hungarian scientist, James Bokey, described cases of chickenpox in persons who had been in contact with someone with shingles.[31] Some 30 years later, in an experiment that certainly could not be done today, a German scientist named Kundratitz proved him right by inoculating children with shingles "pus!" They developed chickenpox.[31,194,195] Thus, the attenuated Oka strain in high concentrations could be used as a zoster vaccine.

In May 2006, the FDA granted a license for Zostavax, a higher-potency, live attenuated Oka virus vaccine against **zoster**.[196] This higher-dose vaccine reduces the incidence of shingles and also reduces the severity of postherpetic neuralgia in those cases of shingles that occur in vaccinated persons.[197–201] Originally recommended for those age 60 years and older, it is now recommended for anyone older than age 50 years. A new zoster vaccine based on a viral glycoprotein may be licensed soon.

Influenza vaccines were first licensed in the United States in 1945[202]; the first recommendation for their inclusion in the pediatric schedule did not occur until 2004. By the 1960s, a **live influenza vaccine** that was safe for adults was achieved, the Alice strain (H_3N_2),[203,204] but it could not be used in children, who became febrile.[205] The annually administered *killed* influenza vaccine, which had consistently proved to be safe and effective but without lasting local or cellular immunity, remained the standard.

Newer vaccine design technologies in the 1990s, including reassortment, reverse genetics, and cold adaptation, have again made it possible to develop *live* attenuated influenza vaccines that confer long-term immunity and obviate the need for injections.

Three attenuated master strains were developed for live influenza vaccines: host-range, temperature-sensitive, and cold-adapted mutants. Only the cold-adapted influenza vaccine developed by Hunein Maassab has been licensed in the United States (2003).[206] Other strains were attempted and abandoned because of inconsistent attenuation, instability, and, occasionally, reversion to virulence.[207] Cold-adapted strains allow the vaccine virus to grow in the relative coolness of a subject's nasal passages (32°C) but not in warmer internal organs, particularly the lungs (37°C).[208]

Live attenuated influenza vaccine (LAIV) is administered by nasal spray and is a good example of the advantages of **reassortant technology**, which is possible with viruses that have segmented genomes. Coinfection of cell culture with wild and attenuated strains allows the mixing of genome segments and identification of viruses containing genetic material from both strains. Each year, new influenza vaccine strains for LAIV are made by reassorting the six internal genes from Maassab's master strains with the genes coding for the hemagglutinin and neuraminidase surface glycoproteins of circulating wild strains of influenza viruses.[207,209] (New vaccine strains for *killed*

influenza vaccine also are produced each year by reassortment or by recombinant technology.) The live vaccine was originally shown to be as effective as the killed vaccine in children and offered longer and broader immunity.[207,210–214] Furthermore, the live vaccine is easy to administer and has shown cross-protection against antigenically drifted wild strains.[215,216] However, recent LAIV strains have shown poor immunogenicity, and the vaccine's utility is currently uncertain.

An orally administered, quadrivalent, live **rotavirus** reassortant vaccine developed by Albert Kapikian and associates, was licensed for use in the United States in September 1998.[217–219] Within 10 months of licensure, cases of intussusception among vaccine recipients were reported to the Vaccine Adverse Event Reporting System.[220–222] Based on epidemiological studies, the Centers for Disease Control (CDC) determined that intussusception occurred with significantly increased frequency within the first 2 weeks after vaccination.[223] The vaccine was formally withdrawn from the market in November 1999.[224]

Other rotavirus vaccines were developed by H. Fred Clark, Paul Offit, and Stanley Plotkin at the Wistar Institute and the Children's Hospital of Philadelphia and by Richard Ward and David Bernstein at Cincinnati Children's Hospital. The Wistar/Children's Hospital of Philadelphia rotavirus vaccine is based on a bovine rotavirus (WC-3), attenuated for humans, which has been reassorted with five human rotavirus RNA segments that code for vp4 or vp7 protein, from different serotypes,[225,226] thus producing a pentavalent oral vaccine, which was licensed for use in the United States in 2006.[227] The Cincinnati group developed a vaccine based on a single human rotavirus attenuated by passage in cell culture that contains serotypes G1 and P1a[8]. It was licensed in the United States in 2008.[228–230]

Because concern about intussusception remained strong, both of these vaccines underwent enormous clinical trials (more than 60,000 were tested in each case) to determine whether an association existed. Both vaccines proved highly efficacious, and intussusception was rare.[231–234] Clinical trials expanding the use of these vaccines to developing countries show protection, although not as high as in developed countries. This has led to a global recommendation for the use of rotavirus vaccine by the WHO.[235–239]

Parenteral killed cholera vaccines did not gain wide acceptance because of limited efficacy, fleeting protection, and side effects and were eventually pulled from the market. Several oral vaccines against cholera and its debilitating diarrhea have been developed: two killed and one live. The **killed cholera vaccine** developed by Jan Holmgren and colleagues, combines the whole cell of *V. cholerae* O1 and subunit B of the cholera toxin (WC-rBS).[240,241] The second killed vaccine contains O1 and O139 strains but no recombinant subunit (WC-only). This makes it easier to administer and less expensive to produce. It is currently used primarily in India and Vietnam. Both killed vaccines are prequalified by the WHO, licensed in many countries, and used to prevent travelers' diarrhea as well as for epidemic control.[240–243]

An attenuated **live oral cholera vaccine**, derived from Inada strain 569B has been developed by Myron Levine and colleagues at the University of Maryland.[244–251] This vaccine requires a cold chain and a buffer. The vaccine was licensed and sold in many countries; it offered rapid onset of protection. For reasons unrelated to the vaccine itself, the manufacture was interrupted (bankruptcy proceedings and company takeovers). Ultimately, the rights to the vaccine were returned to the University of Maryland. In 2015, a biotech company reached an agreement with the University of Maryland to bring the live oral cholera vaccine to FDA licensure. In 2016, the vaccine was approved for use in adults aged 18 to 64 years traveling to cholera-affected areas.[251a]

After the early work on killed **typhoid vaccine**, a variety of heat-phenol–killed or acetone-killed, parenteral, whole-cell typhoid vaccines became available.[252–255] All had high rates of adverse reactions and were never considered quite satisfactory. An important advance was made by René Germanier and E. Fürer when they developed an attenuated strain of the Gal E mutant Ty21a of *Salmonella typhi*.[256] After preliminary vaccine studies in the United States,[257] large trials were conducted successfully in Egypt[258] and Chile.[259,260] Protection rates varied; however, there were few adverse reactions, and oral formulation of this vaccine made it less expensive to produce and distribute.[261,262] Typhoid Vi *polysaccharide*, a killed, purified-component vaccine was developed by Landy, Webster, and colleagues[263–265] and later improved by Wong and associates[266] and John Robbins and J.B. Robbins.[267]

The adaptation of **rabies** virus to human diploid cell culture permitted the development of a potent, whole-virus inactivated rabies vaccine by Koprowski, Tadeusz Wiktor, and associates.[268] This vaccine is much more immunogenic than prior rabies vaccines. Since then, many other cell culture rabies vaccines have been developed, including a vaccinia-recombinant rabies vaccine for veterinary use.[269]

The development of a **Japanese encephalitis** (JE) vaccine was attempted during the Second World War,[270] but later a formalin-inactivated whole-virus vaccine, harvested from mouse brain, was developed in Japan in 1965.[271] It was put into use almost immediately to vaccinate Japanese children, although few data regarding its efficacy had been published.

After two Americans who had traveled in Asia died of JE, the U.S. Department of Defense conducted a vaccine trial in northern Thailand[272] that showed an efficacy of 91%. A bivalent vaccine, also in mouse brain, was developed using the Nakayama-NIH strain (from the original vaccine) and the Beijing-1 strain to provide immunity to strains from different geographic areas.[272–274]

X.Y. Yu and coworkers developed live attenuated and inactivated vaccines against JE, each in primary hamster kidney cells.[275–279] The Chinese live vaccine is widely used in Asia, but hamster kidney cells are not approved by the WHO.[280]

The bivalent, inactivated, mouse-brain–derived vaccine needed improvement. An increase in allergic reactions was noted in the 1990s, several doses were required to maintain immunity, and it was developed in animal nervous tissue (mouse brain).[280] In March 2009, the FDA approved a second-generation JE vaccine for adults that is Vero-cell produced, inactivated, and purified. Ixiaro uses the SA_{14}-14-2 strain of virus that had been used in the Chinese live vaccine.[281] In May 2013, the license was extended to include children older than 2 months to 16 years of age. It is the only licensed JE vaccine in the United States; the previous one, made in mouse brain tissue, ceased production in 2006.[281–284]

In 1979, Maurice Hilleman and Phil Provost grew **hepatitis A** virus (HAV) in cell culture,[285] opening the path for the development of a vaccine. Hilleman, Provost, and coworkers developed the first inactivated HAV vaccine in 1986[286]; however, the cell culture used to produce the HAV antigen was not suitable for use in humans. Formaldehyde-inactivated, whole-virion HAV vaccines grown in human fibroblasts were later developed and licensed in the United States in 1995–1996.[287,288] By 2004, HAV infection rates declined to 1.9 per 100,000 population, the lowest rate ever.[289] Universal HAV vaccination for all children was recommended in 2006.[290]

The first killed **tickborne encephalitis** (TBE) vaccine, produced in mouse brain, was developed in the Soviet Union in 1937, shortly after the virus was identified and the tick vector verified.[291,292] In the 1960s, basing their work on Benda and Danes,[293,294] two separate groups, Levkovich in the Soviet

Union[295] and Kunz in Austria,[296] used chick embryo cell culture to develop less-reactogenic, formalin-inactivated vaccines. A **whole virus inactivated vaccine** was developed by Heinz, Kunz, and Fauma in 1980,[297] and is effective against isolates of the TBE virus that share a homologous envelope glycoprotein.[298–300] Since 1999, this vaccine has undergone several changes in the manufacturing process that have improved its purity, especially a switch from mouse brain protein to chick embryo cells.[301] A second inactivated TBE vaccine was licensed in Germany in 1991.[302] After the collapse of the Soviet Union in 1989 and the opening of Eastern Europe, the geographic range of TBE was shown to be quite large; it is now endemic to most European countries, the Russian Federation, and several Asian countries, including China, Japan, and South Korea.

It is clear that by the late 1970s, another transition was occurring in the development of vaccines. Technology had advanced to the point that scientists could identify many components of the infectious agent, viral or bacterial. A new category of vaccines emerged, based on bacterial proteins, polysaccharides, and protein-conjugated polysaccharides. Live attenuated and killed whole-cell vaccines were still important but they did not apply to all diseases. Subunit vaccines were created where the protective antigen could be identified and isolated. Some whole-cell vaccines were replaced by subunit vaccines.

Whole-cell pertussis vaccine from the 1940s caused a number of adverse reactions, mostly mild, but some more serious. In 1975, when two deaths occurred in children shortly after they received whole-cell pertussis vaccine, the Japanese Ministry of Health suspended its use, although a causal relationship was not established. An astronomical increase in the incidence of pertussis followed: 206 reported cases in 1971 grew to 13,105 cases by 1979. Realizing that it had overreacted, the Ministry of Health reinstated use of the vaccine, but only for children older than 2 years.[303] Similar problems occurred in the United Kingdom, where vaccination rates fell to less than 33% by 1977. Three major epidemics followed, causing more than 100,000 cases of whooping cough and 36 deaths.[304] The adverse reactions associated with whole-cell pertussis vaccine led to the development of a Japanese **acellular pertussis** vaccine by Yuji Sato and Hiroko Sato[303,305,306] that is less reactogenic. Based on two of the main protective antigens of *Bordetella pertussis,* toxin and filamentous hemagglutinin,[303,305,307] it was licensed for use in Japan in 1981. Since then, other acellular pertussis vaccines, containing one to five protective antigens, have been licensed in the United States (1996) and other countries.[308] However, despite routine vaccination, an increase in cases of pertussis since 2005 has led to the reevaluation of the acellular vaccines, which give less-persistent immunity. New formulations are being considered to make the acellular vaccine, as well as the use of more frequent boosters.

Modern work on a human **anthrax** vaccine began in the second half of the 20th century. The vaccine, named anthrax vaccine adsorbed (AVA), contains the secreted protein called "protective antigen" that forms part of the toxin. This was obtained from sterile filtrates of an attenuated, unencapsulated, nonproteolytic strain of *Bacillus anthracis*.[309–311] A randomized field study on a similar anthrax vaccine took place from 1955 to 1959 at four mills that processed raw goat hair destined for the clothing manufacturing industry.[312,313] AVA was licensed for use by the U.S. Army in 2002.

Human anthrax had not been viewed as a serious problem in the late 20th century. Worldwide, there were fewer than 2000 cases annually, mostly cutaneous, in the 1980s and 1990s.[314] The bioterrorism incident in 2001, when highly refined anthrax spores were sent through the U.S. postal system, changed that perception. It was considered prudent to ensure the availability and safety of the supply of anthrax vaccine for the military and the general public.[315] Although the FDA has affirmed that the current vaccine is effective, no matter what the route of infection,[316] research has been accelerated to find a new-generation anthrax vaccine based on protective antigen made by recombinant technology or using newer adjuvants. Modern anthrax vaccines will require fewer injections to attain full immunity.[317,318]

During the 1970s and 1980s, several bacterial vaccines consisting of *purified capsular polysaccharides* were developed.

Meningococcal vaccines had been made in the 1940s but failed to protect.[319] Modern work on humoral immunity to meningococcal disease got underway at the Walter Reed Hospital in 1966, ultimately resulting in *capsular polysaccharide vaccines* against meningococcal serogroups A and C by Malcolm Artenstein,[320] Emil Gotschlich,[321] and associates.[320–324]

By the early 1970s, serogroup C meningococcal polysaccharide vaccine was routinely administered to U.S. Army recruits and had virtually eliminated the disease within the military.[318] However, the vaccine did not provide immunity to children younger than 2 years, and the duration of immunity was uncertain. Additional boosters resulted in *reduced* immune responses.[325,326]

Several serogroup A and/or serogroup C meningococcal *conjugates* were developed, conjugated to diphtheria or tetanus toxoid; they provide longer immunity than the polysaccharide vaccine and immunity to children younger than 2 years.[325–330] The serogroup C conjugate was licensed in the United Kingdom in 1999 and placed in the universal immunization schedule in November of that year.[327] After extensive postlicensure studies in the United Kingdom,[326,328–330] a quadrivalent conjugate vaccine against serogroups A, C, Y, and W135 was licensed in the United States in 2005 and a second one in 2010.[331–334]

It took less than 20 years from the time the **pneumococcus** was first isolated (in 1880, by Pasteur and George Sternberg simultaneously)[335,336] to discover the multiplicity of pneumococcal serotypes and appreciate the complexity of developing a vaccine against it. A killed, whole-cell pneumococcal vaccine was made by Almroth Wright in 1911 and tested in South African goldmine workers, but eventually it was abandoned.[337,338] By the late 1940s, extensive work on capsular polysaccharides, notably by Colin MacLeod, resulted in a multivalent capsular polysaccharide pneumococcal vaccine (four-valent and later six-valent).[339–341] However, antibiotics were so successful that the vaccine fell by the wayside.

The current **pneumococcal polysaccharide** vaccine was developed by Robert Austrian and associates.[342] Austrian and Jerome Gold pointed out that pneumococcal disease continued to be a severe problem despite the use of antibiotics.[343] A modern capsular polysaccharide pneumococcal vaccine was subsequently developed for adults by Austrian, initially with 14 antigens (1977) and later increased to 23 antigens (1983).[336,342]

Although the pneumococcal polysaccharide vaccine was effective in adults, it did not protect children younger than 2 years, among whom more than 80% of invasive pneumococcal disease occurs; protein conjugation technology was applied to develop a vaccine that would protect this important group.[344] A *heptavalent pneumococcal conjugate vaccine* (conjugated to a nontoxic mutant of diphtheria) was produced and found to be safe, efficacious, and immunogenic in children younger than 2 years, who are the children most at risk.[345,346] The vaccine was licensed in the United States in February 2000.[347,348] A 1-year postlicensure follow-up study by Steven Black and associates demonstrated a dramatic reduction in age-specific invasive pneumococcal disease incidence.[349] In addition, the use of the vaccine in children has exerted a

marked reduction in adult disease as the result of herd immunity. In February 2010, a 13-valent pneumococcal conjugate vaccine was licensed. PCV13 is recommended for prevention of pneumococcal disease in infants, elderly adults (>50 years of age), and immunocompromised individuals.[350,351]

The first-generation ***H. influenzae* type b** vaccine was developed by Porter Anderson, David Smith,[352] Rachel Schneerson,[353] and their associates. Richard Pfeiffer isolated this bacterium in 1892, but mistakenly thought he had found the causative agent of influenza. For years, it was known as Pfeiffer's bacillus before receiving its current name, *Haemophilus influenzae*.[117] In the 1920s and 1930s, Margaret Pittman had determined that, of the six different polysaccharides of *H. influenzae*, organisms encapsulated with type b caused the largest proportion of serious disease in children. She identified the composition of the capsule as a polymer of ribosylribitol phosphate, now called polyribosylribitol phosphate (PRP).[354] In the 1970s, several teams began research and efficacy studies on an *H. influenzae* type b vaccine, primarily in Finland and North Carolina.[352,353,355–357] This work ultimately culminated in the 1985 licensure of the PRP vaccine.[358] However, the vaccine was not effective for children younger than 18 months, who are most at risk for bacterial meningitis, and it had limited efficacy in older children. Vaccines against *H. influenzae* type b bacteria advanced rapidly to second and third generations.

After it had been shown that the immunogenicity of a capsular polysaccharide could be increased by binding it to a carrier protein,[359,360] Schneerson and John Robbins linked *H. influenzae* PRP to diphtheria toxoid and developed the **first *conjugate* polysaccharide vaccine,** which was licensed in 1987.[361] This vaccine had improved immunogenicity and efficacy and was licensed in 1987 for children older than 15 months. Younger children still remained at risk, but three more immunogenic conjugates soon followed, using nontoxic diphtheria toxoid (HbOC [haemophilus B oligosaccharide-CRM197]) derived from a mutant strain, an outer membrane protein of *Neisseria meningitidis* (PRP-OMP [polyribosylribitol phosphate–outer membrane protein]), or tetanus toxoid.[358,361]

RECOMBINANT PROTEIN VACCINES

The discovery that the particles of **hepatitis B** surface antigen (HBsAg) found in infected people are immunogenic and protective but noninfectious[362–365] provided the basis for efforts to purify these particles from the blood of chronic carriers. Hilleman and colleagues succeeded in licensing a plasma-derived vaccine in the United States in 1981.[365] Although the vaccine was safe and effective,[366] the AIDS epidemic arrived at about the same time as the vaccine licensure; products derived from human blood were considered potentially dangerous. Despite rigorous safety testing and many inactivation processes to kill any foreign agent in the vaccine, the manufacturer could not overcome the reluctance of the public and physicians to use a product that had even a remote risk of containing the AIDS virus. Also, because the vaccine depended on human serum, sources of antigen were limited.

These obstacles prompted the formulation of the **first recombinant vaccine,** HBsAg recombinant, which was licensed in 1986. This was accomplished by Valenzuela, Medina, Rutter, and others at the University of California, San Francisco, and the University of Washington in Seattle, by cloning the gene for HBsAg in yeast (*Saccharomyces cerevisiae*) and in mammalian cells. HBsAg was produced by the cells and then made into vaccine through adsorption on an alum adjuvant.[367–370] In yeast, the surface antigen aggregated into particles similar to the extensively purified surface region antigen from the plasma-derived vaccine.[371] Initial trials and subsequent studies showed the recombinant vaccine to be as effective as the plasma-derived vaccine.[369,372,373] In addition, because it is derived from a gene, it does not bear the stigma of possible contamination with undetected foreign agents.

Lyme disease was first recognized in the United States in 1975, and, within a quarter century, it became the most frequently diagnosed vector-borne disease in the country.[374–377] Named after the town of Lyme, Connecticut, where it was first recognized, it was referred to as "Lyme arthritis" until 1982, when a constellation of associated illnesses was recognized and the name was changed to Lyme disease.[378] Willy Burgdorfer identified the spirochete causing the disease in the United States in 1982,[379] and, subsequently, it was named *Borrelia burgdorferi*.

Personal protection, spraying, and antibiotics[380–383] did not stem the rising tide of Lyme infection. Two vaccine candidates were put into extensive clinical trials.[384–388] Each was based on a recombinant *Escherichia coli* strain containing the gene for outer surface protein A (OspA) of the American Lyme strain.[375] An OspA vaccine was approved by the FDA in 1999 and recommended for use in persons 15 to 70 years old who lived or worked in endemic areas of infection.[377]

Despite the extensive clinical trials and postlicensure surveillance, the vaccine was not well accepted because of a tepid recommendation from the CDC, the alternative of antibiotic treatment after infection, and the need for booster doses. Equally important, a series of class action and individual lawsuits was brought against the manufacturer claiming that the vaccine caused chronic arthritis and other autoimmune problems, although the evidence for vaccine-induced arthritis is absent.[376] In April 2002, the vaccine was withdrawn from the market owing to lack of demand.[389]

A **recombinant, quadrivalent human papillomavirus** (HPV) vaccine was licensed in the United States in 2006, a landmark event because it represents the second vaccine against a human cancer (hepatitis B vaccine being the first) because it is 95% effective in preventing liver cancer caused by hepatitis B infection. The research to develop the HPV vaccine spanned at least 15 years, two continents, several laboratories, and competing claims of priority. The subunit vaccine is based on the capability of self-assembly of virus-like particles (VLPs) in the L1 (major) capsid protein, which is synthesized in yeast.

Using HPV-16, an Australian group under Ian Frazer published data in 1991 showing the synthesis of L1 and L2 genes and the production of VLPs, but only when both L1 and L2 were synthesized together.[390] They recognized that these VLPs could be a potential source material for a vaccine. One year later, John Schiller, Douglas Lowy, and others, at the National Cancer Institute, using a bovine model, established that the L1 capsid protein gene could self-assemble without the need for L2 and produced very high neutralizing antibodies.[391] In effect, the L1 protein made itself into a structure that mimicked the HPV virion.

In 1993, Schiller's group showed that HPV L1 produced in baculovirus was more efficient at self-assembly than the HPV L1 mutant that had been used by Frazer.[392] Laboratories from Georgetown University and Rochester University also made significant contributions to the science underlying this vaccine.[393,394] A concise summary of these various threads has been published by the National Cancer Institute.[395] One HPV vaccine contains VLPs of HPV types 6, 11, 16, and 18. The type 16 and 18 serotypes are responsible for 70% of cervical cancers in the United States. A second, bivalent HPV vaccine was licensed in the United States in 2009. The quadrivalent vaccine is also effective against genital warts, whereas the bivalent targets only cervical cancer.

When first approved in 2006, the quadrivalent vaccine was for use in females only; by 2009 it became clear that boys also

developed cancers induced by HPV and needed to be vaccinated as well, and approval was extended. A nine-valent recombinant HPV vaccine was approved in 2014 to be administered to females ages 9 to 26 years and males ages 9 to 15 years.

The use of proteins, polysaccharides, and recombinant technology broadened the possibilities for vaccine development immensely but challenges remained. Some diseases, such as ***N. meningitidis serogroup B*** had eluded vaccine development via traditional methods, though not for lack of trying. Meningococcus serogroup B did not have readily obvious protective proteins, polysaccharides or antigens. Its capsular polysaccharide was only weakly immunogenic and was thought to cause an autoimmune response.

In 1995 the first complete **genome sequence** was published (*H. influenzae*) and it immediately changed the game in vaccine research.[396] In the decade that followed, more than 100 other pathogen sequences were completed and hundreds more undertaken. **DNA microarray** of these genomes allows for vastly more rapid identification of proteins that could be possible vaccine candidates.[397]

Meningococcus serogroup B is the first disease where genome sequencing has been successful in identifying such vaccine candidates. This was accomplished with **reverse vaccinology**, a technology first pioneered by Rino Rappuoli and colleagues in Siena.[398,399] As the MC58 strain of meningococcus serogroup B was being sequenced, a computer program was used to predict 600 specific antigens as possible vaccine candidates. Of the 600 antigens, 350 (58%) proved workable and 28 (5%) ultimately induced bactericidal antibodies. The technique identified more viable candidates for a meningococcal serogroup B vaccine than had been considered or tested in the preceding 40 years.[397,400]

DNA array analysis and reverse vaccinology have been further aided by the introduction of **proteomics** which allows the identification of subsets of all proteins that are present at any particular point in the life of the bacteria, thus further shortening the time to finding viable vaccine candidates.[397]

The first meningococcal serogroup B vaccine was licensed in the United States in October 2014; it was based on a previously well-known virulence factor, factor H binding protein, two variants of which are contained in the vaccine.[401] The second meningococcal serogroup B vaccine, containing four proteins selected from the 28 that induce bactericidal antibody, was licensed in January 2015, and is the **first vaccine produced by genomics** (also called **reverse vaccinology**.)[402] Both meningococcal serogroup B vaccines are the first licensed vaccines to be approved under the FDA's FAST TRACK program, which was implemented in 2012.

The majority of vaccines now being developed use new technologies that seem to offer greater safety and more possibilities. The focus on subunit (purified protein or polysaccharide), genetically engineered, or vectored antigens has been greatly enlarged by the addition of powerful new techniques such as DNA array analysis, reverse genetics and proteomics. However, older, classic methods such as attenuation and inactivation of whole virus continue to yield new vaccines, as the zoster vaccine demonstrates.

As we continue in the second decade of the 21st century, the prospect for vaccines is stellar. Since 2000, 13 important vaccines have been licensed in the United States and Europe: a heptavalent pneumococcal conjugate vaccine (2000); a cold-adapted influenza vaccine (2003); a meningococcal quadrivalent conjugated polysaccharide vaccine (2005); a high-potency zoster vaccine (2006); the quadrivalent HPV VLP vaccine (2006); a pentavalent rotavirus reassortant vaccine (2006); an attenuated human strain rotavirus vaccine (2008), a second-generation, Vero-cell–produced, inactivated JE vaccine (2009); a bivalent HPV vaccine (2009); a 13-valent pneumococcal conjugate vaccine (2010); a nine-valent HPV vaccine (2014); and, at long last, two meningococcal serogroup B vaccines (2014, 2015). Three cholera vaccines, two killed and one live, have also been licensed in other parts of the world.

This chapter has chronicled the remarkable impact of vaccination on the health of the world's population. In the 21st century, that impact will continue to increase, as a new generation of scientists create, innovate, and plumb the depths of genetic engineering, genomics and the vast array of technologies they have spawned. Despite the vicissitudes of the natural and the political world, the new technologies augur well that the platinum age of vaccinology is indeed upon us.

2 Vaccine Immunology

Claire-Anne Siegrist

To generate vaccine-mediated protection is a complex challenge. Currently available vaccines have largely been developed empirically, with little or no understanding of how they activate the immune system. Their early protective efficacy is primarily conferred by the induction of antigen-specific antibodies (Box 2.1). However, there is more to antibody-mediated protection than the peak of vaccine-induced antibody titers. The quality of such antibodies (e.g., their avidity, specificity, or neutralizing capacity) has been identified as a determining factor in efficacy. Long-term protection requires the persistence of vaccine antibodies above protective thresholds and/or the maintenance of immune memory cells capable of rapid and effective reactivation with subsequent microbial exposure. The determinants of immune memory induction, as well as the relative contribution of persisting antibodies and of immune memory to protection against specific diseases, are essential parameters of long-term vaccine efficacy.

The predominant role of B cells in the efficacy of current vaccines should not overshadow the importance of T-cell responses: T cells are essential to the induction of high-affinity antibodies and immune memory, directly contribute to the protection conferred by current vaccines such as bacille Calmette-Guérin (BCG), may play a more critical role than previously anticipated for specific diseases like pertussis, and will be the prime effectors against novel vaccine targets with predominant intracellular localization such as tuberculosis.

New methods have emerged allowing the assessment of a growing number of vaccine-associated immune parameters, including in humans. This development raises new questions about the optimal markers to assess and their correlation with vaccine-induced protection. The identification of mechanistic immune correlates—or at least surrogates—of vaccine efficacy is a major asset for the development of new vaccines or the optimization of immunization strategies using available vaccines. Thus, their determination generates a considerable amount of interest. During the last decade, the increased awareness of the complexity of the immune system and its determinants, including at the host genetic level, indicated that using system biology approaches to assess how various processes and networks interact in response to immunization could prove more illustrative than trying to isolate and characterize a few components of vaccine responses.[1] Delineating the specific molecular signatures of vaccine immunogenicity is beginning to highlight novel correlates of protective immunity and better explain the heterogeneity of vaccine responses in a population. The tailoring of vaccine strategies for specific vulnerable populations, including very young, elderly, and immunosuppressed populations, also largely relies on a better understanding of what supports or limits vaccine efficacy under special circumstances—at the population and individual levels. Lastly, the exponential development of new vaccines raises many questions that are not limited to the targeted diseases and the potential impacts of their prevention, but that address the specific and nonspecific impacts of such vaccines on the immune system and, thus, on health in general. These immune-related concerns have largely spread into the population, and questions related to the immunological safety of vaccines—that is, their capacity for triggering non–antigen-specific responses possibly leading to allergy, autoimmunity, or even premature death—are being raised. Certain "off-targets effects" of vaccines have also been recognized and call for studies to quantify their impact and identify the mechanisms at play. The objective of this chapter is to extract from the complex and rapidly evolving field of immunology the main concepts that are useful to better address these important questions.

HOW DO VACCINES MEDIATE PROTECTION?

Vaccines protect by inducing effector mechanisms (cells or molecules) capable of rapidly controlling replicating pathogens or inactivating their toxic components. Vaccine-induced immune effectors (Table 2.1) are essentially antibodies—produced by B lymphocytes—capable of binding specifically to a toxin or a pathogen.[2] Other potential effectors are cytotoxic $CD8^+$ T lymphocytes that may limit the spread of infectious agents by recognizing and killing infected cells or secreting specific antiviral cytokines and $CD4^+$ T-helper (Th) lymphocytes. These Th cells may contribute to protection through cytokine production and provide support to the generation and maintenance of B and $CD8^+$ T-cell responses. Effector $CD4^+$ Th cells were initially subdivided into T-helper 1 (Th1) or T-helper 2 (Th2) subsets depending on their main cytokine production (interferon-γ or interleukin [IL]-4), respectively. This dichotomy became outdated as Th cells were increasingly shown to include a large number of subsets with distinct cytokine-producing and homing capacities (see Table 2.1).[3] A recently identified critical subset of vaccine-induced $CD4^+$ Th cells are follicular T-helper (Tfh) cells: they are specially equipped and positioned in the lymph nodes to support potent B-cell activation and differentiation into antibody-secreting-cells[4] and were identified as directly controlling antibody responses and mediating adjuvanticity.[5–7] Another important subset are T-helper 17 (Th17) cells which essentially defend against extracellular bacteria that colonize the skin and mucosa, recruiting neutrophils and promoting local inflammation.[8,9] These effectors are controlled by regulatory T cells (Tregs) involved in maintaining immune tolerance.[10] Most antigens and vaccines trigger B- and T-cell responses, such that there is no rationale in opposing vaccines favoring antibody production ("humoral immunity") and T-cell responses ("cellular immunity"). In addition, $CD4^+$ T cells are required for most antibody responses, whereas antibodies exert significant influences on T-cell responses to intracellular pathogens.[11]

What Are the Main Effectors of Vaccine Responses?

The nature of the vaccine exerts a direct influence on the type of immune effectors that are elicited and that mediate protective efficacy (Table 2.2).

Capsular polysaccharides (PSs) elicit B-cell responses in what is classically reported as a T-independent manner.[12] The conjugation of bacterial PS to a protein carrier (e.g., glycoconjugate vaccines) provides foreign peptide antigens that are presented to the immune system and, thus, recruit

BOX 2.1 Main Immunological Definitions

ADJUVANT

Agents that increase the stimulation of the immune system by enhancing antigen presentation (depot formulation, delivery systems) and/or by providing costimulation signals (immunomodulators). Aluminum salts are most often used in today's vaccines.

AFFINITY, AVIDITY

Antibody affinity refers to the tendency of an antibody to bind to a specific epitope at the surface of an antigen; that is, to the strength of the interaction. Avidity is the sum of the epitope-specific affinities for a given antigen. It directly relates to its function.

AFFINITY MATURATION

Processes through which antigen-specific B cells undergo somatic hypermutation and affinity-based selection, resulting in B cells that produce antibodies with increased affinity over germline antibodies.

ANTIBODIES

Proteins of the immunoglobulin family, present on the surface of B lymphocytes, secreted in response to stimulation, that neutralize antigens by binding specifically to their surface.

ANTIGEN-PRESENTING CELLS

Cells that capture antigens by endocytosis or phagocytosis, process them into small peptides, display them at their surface through major histocompatibility complex (MHC) molecules, and provide costimulation signals that act synergistically to activate antigen-specific T cells. Antigen-presenting cells include B cells, macrophages, and dendritic cells, although only dendritic cells are capable of activating naïve T cells.

B LYMPHOCYTES

Cells that originate in the bone marrow, mature in secondary lymphoid tissues, become activated in the spleen/nodes when their surface immunoglobulins bind to an antigen, and differentiate into antibody secreting cells (plasma cells) or memory B cells.

CARRIER PROTEIN

A protein that is used as a template to which polysaccharide moieties are chemically conjugated to generate glycoconjugate vaccines. It is believed that carrier proteins provide antigenic epitopes for recognition by $CD4^+$ T-helper cells, in particular follicular T-helper cells.

$CD4^+$ T-HELPER 1 LYMPHOCYTES

$CD4^+$ T cells that on activation differentiate into cells that mainly secrete interleukin (IL)-2, interferon (IFN)-γ, and tumor necrosis factor (TNF)-β, exerting direct antimicrobial functions (viruses), and essentially providing support to cytotoxic T cells and macrophages.

$CD4^+$ T-HELPER 2 LYMPHOCYTES

$CD4^+$ T cells that on activation differentiate into cells that mainly secrete IL-4, IL-5, IL-6, IL-10, and IL-13, exerting direct antimicrobial functions (parasites) and essentially providing support to B lymphocytes.

$CD4^+$ T-HELPER 17 LYMPHOCYTES

$CD4^+$ T cells that mainly secrete IL-17, IL-21, and IL-22 are implicated in host defense against extracellular bacteria colonizing exposed surfaces (airways, skin, gut).

$CD8^+$ T CELLS

Lymphocytes that specialize in the killing of infected cells, through direct contact or cytokine (IFN-γ, TNF-α) production.

CENTRAL MEMORY T CELLS

Memory T cells traffick through the lymph nodes, ready to proliferate and generate a high number of effector cells in response to specific microbial peptides.

CHEMOKINES

Small secreted proteins that function as chemoattractants, recruiting cells that express the corresponding chemokine receptors at their surface and thus migrating toward higher concentrations of chemokines.

COSTIMULATORY MOLECULES

Molecules that become expressed at the surface antigen-presenting cells on activation and deliver stimulatory signals to other cells, namely T and B cells.

DENDRITIC CELLS

Cells that constantly sample their surroundings for pathogens such as viruses and bacteria, detect dangers, and initiate immune responses. Immature patrolling dendritic cells (DCs) have high endocytic activity and a low T-cell activation potential. Contact with a pathogen induces maturation and the expression of certain cell-surface molecules, greatly enhancing their ability to activate T cells.

EFFECTOR MEMORY T CELLS

Memory T cells patrol through the body to detect specific microbial peptides and are capable of an immediate cytotoxic function in case of recognition.

EXTRAFOLLICULAR REACTION

B-cell differentiation pathways that occur outside of germinal centers in response to protein or polysaccharide antigens. Extrafollicular reaction is rapid, generates B cells that are short-lived (days), and produces low-affinity antibodies without inducing immune memory.

FOLLICULAR DENDRITIC CELLS

Stromal cells in the spleen and nodes that on activation express chemokines (notably CXCL13) to attract activated antigen-specific B and T cells and thus nucleate the germinal center reaction. Follicular DCs provide antiapoptotic signals to germinal center (GC) B cells and support their differentiation into plasma cells or memory B cells.

FOLLICULAR T-HELPER LYMPHOCYTES

$CD4^+$ T cells that on activation migrate toward follicular DCs and provide critical help to germinal center B cells, influencing isotype switching, affinity maturation, and differentiation.

GERMINAL CENTERS

Dynamic structures that develop in the spleen/nodes in response to an antigenic stimulation and dissolve after a few weeks. GCs contain a monoclonal population of antigen-specific B cells that proliferate and differentiate through the support provided by follicular DCs and T-helper cells. Immunoglobulin class-switch recombination, affinity maturation, B-cell selection, and differentiation into plasma cells or memory B cells essentially occur in GCs.

Continued on following page

BOX 2.1 Main Immunological Definitions (Continued)

ISOTYPE SWITCHING

Switch of immunoglobulin (Ig) expression and production from IgM to IgG, IgA, or IgE that occurs during B-cell differentiation through DNA recombination.

MARGINAL ZONE

The area between the red pulp and the white pulp of the spleen. Its major role is to trap particulate antigens from the circulation and present them to lymphocytes.

PATTERN RECOGNITION RECEPTORS

Germline-encoded receptors sensing the presence of infection via the recognition of conserved microbial pathogen-associated molecular patterns and triggering innate immune responses.

REGULATORY T CELLS

T cells that on activation differentiate into cells that express specific cytokines (IL-10, transforming growth factor [TGF]-β/ surface markers) and act to suppress activation of the immune system through various mechanisms, maintaining immune homeostasis and tolerance to self-antigens.

RESIDENT MEMORY T CELLS

Effector memory T cells residing in specific tissues (lungs, gut, skin) and conferring an immediate-early line of defense against viral and bacterial pathogens.

SOMATIC HYPERMUTATION

A process that introduces random mutation in the variable region of the B-cell receptor (i.e., immunoglobulin) locus at an extremely high rate during B-cell proliferation. This mechanism occurs through the influence of the activation-induced cytidine deaminase enzyme and generates antibody diversification.

T LYMPHOCYTES

Cells that originate in the thymus, mature in the periphery, become activated in the spleen/nodes if their T-cell receptors bind to an antigen presented by an MHC molecule and they receive additional costimulation signals driving them to acquire killing (mainly $CD8^+$ T cells) or supporting (mainly $CD4^+$ T cells) functions.

T-INDEPENDENT B-CELL RESPONSES

Differentiation pathway of B cells, mainly elicited by polysaccharides, that takes place in the marginal zone and extrafollicular areas of the spleen/nodes. Its hallmarks are to be rapid (days), while eliciting the transient (months) production of antibodies of low affinity without inducing immune memory.

T-DEPENDENT B-CELL RESPONSES

Differentiation pathway of B cells elicited by protein antigens that recruit T and B cells into GCs of the spleen/nodes. Its hallmarks are to be slow (weeks), while eliciting long-lasting (years) production of antibodies of high affinity and immune memory.

TOLL-LIKE RECEPTORS

A family of 10 receptors (TLR1 to TLR10), present at the surface of many immune cells, that recognize pathogens through conserved microbial patterns and activate innate immunity when detecting danger.

TABLE 2.1 Effector Mechanisms Triggered by Vaccines

- Antibodies prevent or reduce infections by clearing extracellular pathogens through:
  - Binding to the enzymatic active sites of toxins or preventing their diffusion
  - Neutralizing viral replication (e.g., preventing viral binding and entry into cells)
  - Promoting opsonophagocytosis of extracellular bacteria (i.e., enhancing their clearance by macrophages and neutrophils)
  - Activating the complement cascade
- $CD8^+$ T cells do not prevent infection but reduce, control, and clear intracellular pathogens by:
  - Directly killing infected cells (release of perforin, granzyme, etc.)
  - Indirectly killing infected cells through antimicrobial cytokine release
- $CD4^+$ T cells do not prevent infection but participate in the reduction, control, and clearance of extracellular and intracellular pathogens by their homing and cytokine-production capacities. Their main subsets include:
  - Follicular T-helper (Tfh) cells producing mainly interleukin (IL)-21 and providing B-cell help
  - T-helper 1 (Th1) effector cells producing interferon (IFN)-γ, tumor necrosis factor (TNF)-α/TNF-β, IL-2, and mainly involved in protection against intracellular pathogens (viruses, *Mycobacterium tuberculosis*)
  - Th2 effector cells producing IL-4, IL-5, IL-13, and responding to extracellular pathogens (bacteria and helminths)
  - Th9 effector cells producing IL-9 and also responding to extracellular pathogens
  - Th17 effector cells producing IL-17, IL-22, and IL-26 and contributing to mucosal defense (*Streptococcus pneumoniae, Bordetella pertussis*, *Mycobacterium tuberculosis*)

antigen-specific $CD4^+$ Tfh cells in what is referred to as a T-dependent antibody response.[13,14] A hallmark of T-dependent responses, which are also elicited by toxoid, protein, inactivated, or live attenuated viral vaccines (see Table 2.2), is to induce higher-affinity antibodies and immune memory. In addition, live attenuated vaccines usually generate $CD8^+$ cytotoxic T cells. The use of live vaccines/vectors or of specific novel delivery systems seems necessary for the induction of strong $CD8^+$ T-cell responses. Most current vaccines mediate their protective efficacy through the induction of vaccine antibodies, whereas vaccine-induced $CD4^+$ T cells contribute to macrophage activation and control of *Mycobacterium tuberculosis*[15] and prevent varicella-zoster reactivation. In addition, CD8+ T cells are also elicited.[16]

The induction of antigen-specific immune effectors (and/or of immune memory cells) by an immunization process does not imply that these antibodies, cells, or cytokines represent surrogates—or even correlates—of vaccine efficacy. This requires the formal demonstration that vaccine-mediated protection is dependent—in a vaccinated person—on the presence of a given marker such as an antibody titer or a number of antigen-specific cells above a given threshold.[17,18]

TABLE 2.2 Correlates of Vaccine-Induced Immunity

Vaccines	Vaccine Type	Serum IgG	Mucosal IgG	Mucosal IgA	T Cells
Cholera	Killed	++	+		
Cholera	Live, oral	+	++		
Diphtheria toxoid	Toxoid	++	(+)		
Hepatitis A	Killed	+++			
Hepatitis B (HBsAg)	Protein	++			
Hib PS	PS	++	(+)		
Hib glycoconjugates	PS-protein	+++	++		
Influenza	Killed, subunit	++	(+)		
Influenza intranasal	Live attenuated	++	+	+	+ ($CD8^+$)
Japanese encephalitis	Killed	++			
Measles	Live attenuated	+++			+ ($CD8^+$)
Meningococcal PS	PS	++	(+)		
Meningococcal conjugates	PS-protein	+++	++		
Meningococcal group B	Proteins				
Mumps	Live attenuated	++			
Papillomavirus (human)	VLPs	+++	++		
Pertussis, whole cell	Killed	++			+? ($CD4^+$)
Pertussis, acellular	Proteins	++			+? ($CD4^+$)
Pneumococcal PS	PS	++	(+)		
Pneumococcal conjugates	PS-protein	+++	++		
Polio Sabin	Live attenuated	++	++	++	
Polio Salk	Killed	++	+		
Rabies	Killed	++			
Rotavirus	VLPs	(+)	(+)	++	
Rubella	Live attenuated	+++			
Tetanus toxoid	Toxoid	+++			
Tuberculosis (BCG)	Live mycobacteria				++ ($CD4^+$)
Typhoid PS	PS	+	(+)		
Varicella (chickenpox)	Live attenuated	++			+? ($CD4^+$)
Varicella (zoster)	Live attenuated				++ ($CD4^+$)
Yellow fever	Live attenuated	+++			

BCG, bacille Calmette-Guérin; Hib, *Haemophilus influenzae* type b; PS, polysaccharide; VLP, virus-like particle.
Note: This table may not be exhaustive and includes only currently licensed vaccines.

Antigen-specific antibodies have been formally demonstrated as conferring vaccine-induced protection against many diseases[19] (see Table 2.2). Passive protection may result from the physiological transfer of maternal antibodies (e.g., tetanus) or the passive administration of immunoglobulins or vaccine-induced hyperimmune serum (e.g., measles, hepatitis, varicella). Such antibodies may neutralize toxins in the periphery, at their site of production in an infected wound (tetanus), or in the throat (diphtheria). They may reduce binding or adhesion to susceptible cells or receptors and limit viral replication (e.g., polio) or reduce bacterial colonization (glycoconjugate vaccines against encapsulated bacteria) if present at sufficiently high titers on mucosal surfaces.[20] The neutralization of pathogens at mucosal surfaces is mainly achieved by the transudation of vaccine-induced serum immunoglobulin (Ig) G antibodies. Neutralization requires serum IgG antibody concentrations to be of sufficient affinity and abundance to result in "protective" antibody titers in saliva or mucosal secretions. As a rule, such responses are not elicited by PS bacterial vaccines but achieved by glycoconjugate vaccines, which may prevent nasopharyngeal colonization or nonbacteremic pneumonia[21] in addition to invasive diseases.

Under most circumstances, inactivated vaccines do not elicit sufficiently high and sustained antibody titers on mucosal surfaces to prevent local infection. It is only after having infected mucosal surfaces that pathogens encounter vaccine-induced IgG serum antibodies that neutralize viruses, opsonize bacteria, activate the complement cascade (see Table 2.1), and limit their multiplication and spread, preventing tissue damage and, thus, clinical disease. That vaccines fail to induce sterilizing immunity is not an obstacle to successful disease control, although it represents a significant challenge for

the development of specific vaccines against chronic viral infection.

Current vaccines mostly mediate protection through the induction of highly specific IgG serum antibodies (see Table 2.2). Live oral or nasal vaccines, such as rotavirus, oral polio, nasal influenza, or cholera vaccines, induce serum IgA and secretory IgA, which also help limit viral shedding on mucosal surfaces.

Under certain circumstances, however, passive antibody-mediated immunity is inefficient (tuberculosis). There is conclusive evidence that T cells are the main effectors of BCG, even though specific T-cell frequency and cytokine expression profiles do not correlate with protection in BCG-immunized infants,[15,22] or in zoster immunized adults.[23,24] However, there is indirect evidence that vaccine-induced T cells contribute to the protection conferred by other vaccines. $CD4^+$ T cells seem to support the persistence of protection against clinical pertussis in children primed in infancy, after vaccine-induced antibodies have waned,[25–28] and may contribute to the longer vaccine efficacy of whole-cell pertussis vaccines.[29–31] Another example is that of measles immunization in 6-month-old infants in whom antibody responses largely are not initiated because of immune immaturity and/or the residual presence of inhibitory maternal antibodies, but significant interferon (IFN)-γ–producing $CD4^+$ T cells are generated.[32,33] The infants remain susceptible to measles infection but are protected against severe disease and death, presumably because of the viral clearance capacity of their vaccine-induced T-cell effectors. Thus, prevention of infection may be achieved only by vaccine-induced antibodies, whereas disease attenuation and protection against complications may be supported by T cells, even in the absence of specific antibodies. The understanding of vaccine immunology requires appraising how B- and T-cell responses are elicited, supported, maintained, and/or reactivated by vaccine antigens.

FROM INNATE TO ADAPTIVE IMMUNITY ACTIVATION: THE FIRST STEPS AFTER IMMUNIZATION

Novel adjuvants essentially enhance vaccine responses by modulating innate immunity, which shapes adaptive responses.[34–38] Indeed, the induction of antigen-specific B- and T-cell responses requires their activation in the draining lymph nodes by specific antigen-presenting cells (APCs), essentially dendritic cells (DCs) that must be recruited into the reaction. Immature DCs patrol throughout the body. When exposed to pathogens in the tissues or at the site of injection, they undergo brisk maturation, modulate specific surface receptors, and migrate toward secondary lymph nodes, where the induction of T- and B-cell responses occurs. The central role for mature DCs in the induction of vaccine responses reflects their unique capacity to provide antigen-specific, costimulation signals to T cells; these "danger signals" are required to activate naïve T cells.[39] The very first requirement to elicit vaccine responses is to provide sufficient "danger signals" through vaccine antigens and/or adjuvants (Fig. 2.1) to trigger an inflammatory reaction that is mediated by cells of the innate immune system.[34–37]

DCs, monocytes, and neutrophils express sets of receptors directed against evolutionarily conserved pathogen patterns that are not contained in self-antigens and are readily identified as "danger."[40] Through these pattern-recognition receptors, among which Toll-like receptors fulfill an essential role (Table 2.3),[40] these host cells sense the potential danger when they encounter a pathogen and become activated (Fig. 2.2). They modulate the expression of their surface molecules and produce proinflammatory cytokines and chemokines,[34–37] which result in the extravasation and attraction of monocytes, granulocytes, and natural killer cells and the generation of an inflammatory microenvironment (see Fig. 2.1) in which monocytes differentiate into macrophages and immature DCs become activated.[38] This activation modifies the expression of homing receptors at their surface and triggers DC migration toward the draining lymph nodes (see Fig. 2.2). In the absence of danger signals, DCs remain immature: On contact with naïve T cells, T cells do not differentiate into immune effectors but into regulatory $CD4^+$ T cells that maintain immune tolerance.[10]

Live viral vaccines most efficiently trigger the activation of the innate immune system through multiple pathogen-associated signals (such as viral RNA), allowing their recognition by pattern-recognition receptors (see Table 2.3).[41] Following injection, viral particles rapidly disseminate throughout the vascular network and reach their target tissues. This pattern is very similar to that occurring after a natural infection, including the initial mucosal replication stage for vaccines administered through the nasal and oral routes. DCs are activated at multiple sites, migrate toward the corresponding draining lymph nodes, and launch multiple foci of T- and B-cell activation. This sequence provides a second explanation of the generally higher immunogenicity of live versus "nonlive" vaccines (Table 2.4).[42] Another consequence of this early diffusion pattern is that the site and route of injection of live viral vaccines are of minor importance; for example, the immunogenicity and reactogenicity of measles vaccine is similar following intramuscular or subcutaneous injection,[43] and measles vaccine may be administered by aerosol. Live bacterial vaccines, such as BCG, multiply at the site of injection, where they generate a prolonged inflammatory reaction, but also at a distance, with the preponderance for local draining lymph nodes.

Nonlive vaccines, whether containing only proteins, PS, glycoconjugates, or inactivated microorganisms (see Table 2.2), may still contain pathogen-recognition patterns. In the absence of microbial replication, however, vaccine-induced activation remains more limited, in both time and space. Nonlive vaccines essentially activate innate responses at their site of injection (see Fig. 2.1). Their site and route of administration are, thus, more important. The high number of DCs in the dermis allows a marked reduction (e.g., 10-fold) of the antigen dose with intradermal immunization. This advantage of the dermal DC concentration is applied to the prevention of rabies in many countries and could prove useful against additional targets as novel microneedle and needle-free devices become available for intradermal administration.[44] Patrolling DCs are also numerous in well-vascularized muscles, which is the preferred route of injection for nonlive vaccines. They are fewer in adipose tissues, such that subcutaneous injections may be less effective than intramuscular injections under conditions of limited immunogenicity, as demonstrated for adult immunization against hepatitis B.[45] Despite many efforts, immunization through the mucosal route remains limited to a few live vaccines. The extreme difficulty in producing nonlive mucosal vaccines reflects the need to overcome a large number of physical, immunological, and chemical barriers, which requires the use of live vaccines or strong adjuvants. This fact is not trivial, as unfortunately illustrated by the association of a novel adjuvanted inactivated intranasal influenza vaccine with Bell palsy.[46]

Following their activation, DCs migrate toward the local draining lymph nodes, for example, the axillary and inguinal area following deltoid and quadriceps injection, respectively. That primary immune responses to nonlive vaccines are essentially focal and likely contribute to the fact that the

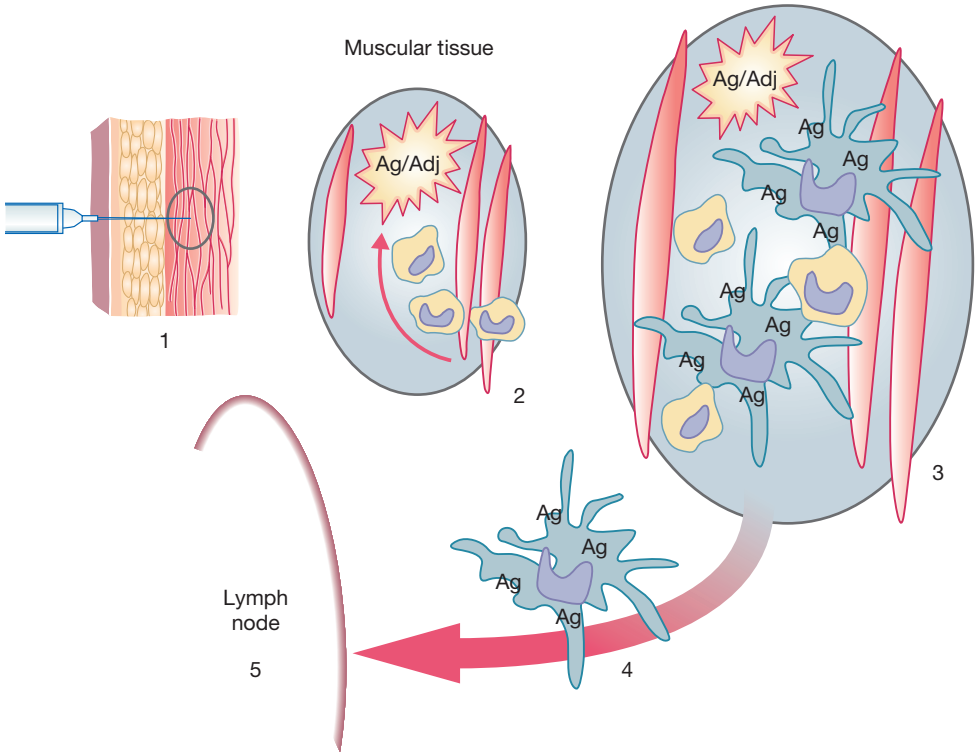

Figure 2.1. Initiation of a vaccine response. Following injection *(1)*, the pathogen-associated patterns contained in vaccine antigens attract dendritic cells, monocytes, and neutrophils that patrol throughout the body *(2)*. Elicitation of sufficient "danger signals" by the vaccine antigens (Ag)/adjuvants (Adj) activates monocytes and dendritic cells *(3)*; the activation changes their surface receptors and induces their migration along lymphatic vessels *(4)*, to the draining lymph nodes *(5)* where the activation of T and B lymphocytes will take place.

TABLE 2.3 Recognition of Vaccine Determinants by Human Pattern-Recognition Receptors

Receptors	Ligands	Demonstrated Ligands in Vaccines
TLR1	Certain bacterial lipoproteins	
TLR2	Peptidoglycan, lipoproteins, glycolipids, lipopolysaccharides	BCG, Hib-OMP, pneumococcal PS
TLR3	Viral double-stranded RNA	Poly I:C (in clinical trial as adjuvant)
TLR4	Bacterial lipopolysaccharides	BCG, pneumococcal PS, HPV-VLPs, AS02, and AS04 adjuvants
TLR5	Bacterial flagellins	Flagellin (in clinical trial as adjuvant)
TLR6	Lipoteichoic acid, lipopeptides	
TLR7	Single-stranded RNA	Yellow fever, live attenuated influenza, whole-cell influenza, TLR7 agonists (in clinical trial as adjuvants)
TLR8	Single-stranded RNA	Yellow fever
TLR9	Unmethylated CpG oligonucleotides	Yellow fever, TLR9 agonists (in clinical trial as adjuvants)
TLR10	Unknown	
NALP3	Multiple	Alum
NOD1, NOD2	Peptidoglycans	Pneumococcal PS

BCG, bacille Calmette-Guérin; CpG, cytosine phosphate guanine; Hib, *Haemophilus influenzae* type b; HPV, human papillomavirus; NALP, Natch domain, Leucine-rich repeat, and PYD-containing protein; NOD, nonobese diabetic; OMP, outer membrane protein; PS, polysaccharide; TLR, Toll-like receptor; VLP, virus-like particle.

simultaneous administration of several distinct vaccines may take place without immune interference if vaccines are administered at distant sites in different limbs draining into distinct lymph node areas. Most nonlive vaccines require their formulation with specific adjuvants to induce danger signals and trigger a sufficient activation of the innate system. The understanding of the mode of action of current and novel adjuvants markedly increased during the last few years, with the long-used aluminum salts revealing some of their secrets.[47] Although the adjuvants currently in use do not trigger the degree of

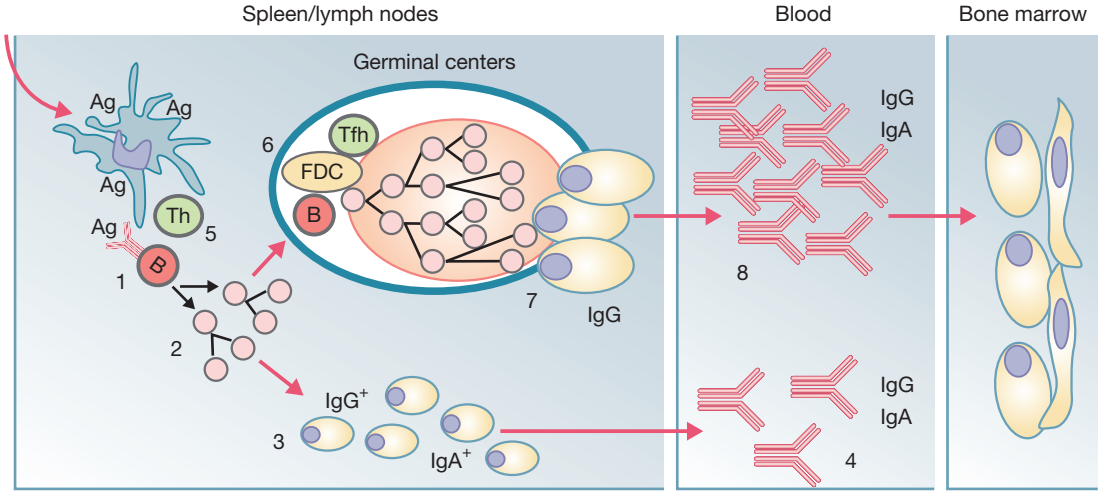

Figure 2.2. Extrafollicular and germinal center responses to protein antigens. In response to a protein antigen reaching lymph nodes or spleen, B cells capable of binding to this antigen with their surface immunoglobulins *(1)* undergo brisk activation. In an extrafollicular reaction *(2)*, B cells rapidly differentiate in plasma cells *(3)* that produce low-affinity antibodies (of the immunoglobulin [Ig] M ± IgG/IgA isotypes) that appear at low levels in the serum within a few days after immunization *(4)*. Antigen-specific T-helper (Th) cells *(5)* that have been activated by antigen-bearing dendritic cells (DCs) trigger some antigen-specific B cells to migrate toward follicular dendritic cells (FDCs) *(6)*, initiating the germinal center (GC) reaction. In GCs, B cells receive additional signals from follicular T cells (Tfh) and undergo massive clonal proliferation; switch from IgM toward IgG, IgA, or IgE; undergo affinity maturation *(7)*; and differentiate into plasma cells secreting large amounts of antigen-specific antibodies *(8)*. At the end of the GC reaction, a few plasma cells exit nodes/spleen and migrate to survival niches mostly located in the bone marrow, where they survive through signals provided by supporting stromal cells.

TABLE 2.4 Determinants of Primary Vaccine Antibody Responses in Healthy People

Determinants	Mechanisms (Presumed)
VACCINE TYPE	
Live vs inactivated	Higher intensity of innate responses through the synergistic activation of several PRRs, higher antigen content following replication, and more prolonged antigen persistence generally result in higher Ab responses to live than to inactivated vaccines.
Protein vs polysaccharide	Recruitment of T-cell help and induction of GCs (i.e., memory induction) results in higher and more prolonged Ab responses to protein or glycoconjugate than to PS vaccines.
Adjuvants	Modulation of antigen delivery and persistence (depot or slow-release formulations) and/or enhancement of Tfh responses (immunomodulator) may support or limit Ab responses.
ANTIGEN NATURE	
Polysaccharide antigens	Failure to induce GCs limits immunogenicity.
Protein antigens	Inclusion of epitopes readily recognized by B cells (B-cell repertoire), inclusion of epitopes readily recognized by Tfh, elicitation of efficient follicular T-cell help, and the capacity of antigen to associate/persist in association with FDCs result in higher Ab responses.
Antigen dose	As a rule, higher Ag doses increase the availability of Ag for B-/T-cell binding and activation and for association with FDCs.
VACCINE SCHEDULE	
Interval between doses	A 3-week minimal interval between primary doses avoids competition between successive waves of primary responses.
Genetic determinants	The capacity of Ag epitopes to associate with a large panel of MHC molecules increases the likelihood of responses in the population. MHC restriction may limit T-cell responses. Gene polymorphisms in molecules critical for B- and T-cell activation/differentiation are likely to affect Ab responses.
Environmental factors	Mostly unidentified
Age at immunization	Early life immune immaturity or age-associated immune senescence

Ab, antibody; Ag, antigen; FDC, follicular dendritic cell; GC, germinal center; MHC, major histocompatibility complex; PRR, pattern-recognition response; PS, polysaccharide; Tfh, follicular T-helper cells.

innate immune activation that is elicited by live vaccines, progress is being made: a single dose of the AS03-adjuvanted influenza H1N1/09 vaccine in healthy children elicited antibody responses similar to those observed in convalescent children[48] and formulating the varicella-zoster-virus IgE protein into the novel AS01b adjuvant system conferred unprecedented vaccine efficacy in the elderly.[24]

VACCINE ANTIBODY RESPONSES

How Are Primary Antibody Responses Elicited?

B cells are essentially activated in the lymph nodes draining the injection site. Vaccine antigens reaching the subcapsular sinus by free-fluid diffusion are taken up by specific subcapsular sinus macrophages and translocated into the B-cell zone. The B cells equipped with surface B-cell receptors[49] capable of binding to the vaccine antigens are activated and migrate to the interface between the B-cell (follicle) and the T-cell zones. There, B cells engage T cells and initiate their proliferation. The cumulative amount of costimulation signals received by B cells determines their fate.[50] Protein antigens (which are taken up and displayed as small peptides on the surface of APCs) activate Tfh cells. This induces a highly efficient B-cell differentiation pathway, through specific structures (germinal centers [GCs]) in which antigen-specific B cells proliferate and differentiate into antibody-secreting plasma cells or memory B cells.[51] Polysaccharide antigens that fail to recruit Tfh cells into the response do not trigger GCs, such that they elicit only short-lived plasma cells resulting in weaker and less durable antibody responses with no immune memory.

T-Dependent Responses to Protein Antigens

The Extrafollicular Reaction. Naïve B cells generated in the bone marrow (BM) reside in lymph nodes until they encounter a protein antigen to which their specific surface IgM receptor binds. Antigen binding initiates B-cell activation and triggers the upregulation of CCR7, a chemokine receptor that drives antigen-specific B cells toward the outer T-cell zone of lymph nodes.[52] At this location, vaccine antigen-specific B cells are exposed to recently (<24 hours) activated DCs and T cells that have upregulated specific surface molecules and, thus, provide B-cell activating signals. This T-cell help rapidly drives B-cell differentiation into Ig-secreting plasma cells that produce low-affinity germline antibodies, in what is called the extrafollicular reaction (see Figs. 2.2 and 2.3).[53]

Ig class-switch recombination from IgM toward IgG, IgA, or IgE occurs during this differentiation of B cells, through the upregulation of the activation-induced deaminase enzyme. Both $CD4^+$ Th1 and Th2 cells exert essential helper functions during the extrafollicular differentiation pathway, and the engagement of their CD40L molecules with CD40 on B cells may skew class-switch recombination into particular Ig classes and subclasses. In rodents, IFN-γ–producing Th1 T cells promote a switch toward IgG_{2a}, whereas Th2 cells essentially support the generation of IgG_1 and IgE (via IL-4) and IgG_{2b} and IgG_3 (via transforming growth factor [TGF]-β).[54] The situation is less clear-cut in humans, where IgG_1 antibodies frequently predominate regardless of the polarization of T-cell help. The extrafollicular reaction is rapid, and IgM and low-level IgG antibodies appear in the blood a few days after primary immunization (see Figs. 2.2 and 2.3). These antibodies are of germline affinity, as there is no hypermutation or selection process during the extrafollicular reaction. This extrafollicular reaction is short-lived, as most cells die by apoptosis within a few days. Consequently, its role in vaccine efficacy is limited to a few months.

The Germinal Center Reaction. Antigen-specific B cells that receive sufficient help from antigen-specific activated Tfh cells proliferate in specialized structures, the GCs, in which they differentiate into plasma cells or memory B cells.[50,55] The induction of GCs is initiated as a few antigen-specific activated B cells upregulate their expression of CXCR5 and migrate toward B-cell follicles, where they are attracted by CXCL13-expressing follicular DCs (FDCs). The FDCs fulfill an essential role in B-cell responses: they attract antigen-specific B and Tfh cells and capture/retain antigen for extended periods. B cells attracted by antigen-bearing FDCs become the founders of GCs (see Fig. 2.2). Receiving additional activation and survival signals from the FDCs and Tfh cells,[56,57] notably through IL-21,[58] B cells undergo massive clonal proliferation—such that each GC is constituted by the progeny of a single antigen-specific B cell. This intense proliferation is associated with two major events: Ig class-switch recombination from IgM toward IgG, IgA, or IgE, and maturation of the affinity of B cells for their specific antigen. This process results in the higher production of antibodies with a higher antigen-binding capacity (see Fig. 2.3).

The maturation of B-cell affinity results from an extensive somatic hypermutation process within the variable-region segments of Ig genes.[50] In a small minority of B cells, the introduction of mutations in their Ig genes increases the affinity of their surface IgG for antigen. This enables these B cells to efficiently compete for binding to the small amounts of vaccine antigens that are associated with the surface of FDCs (see Fig. 2.2). B cells process these vaccine antigens into small peptides that they display at their surface through major histocompatibility complex (MHC) class II molecules. MHC-peptide complexes thus become available for binding by the specific subset of $CD4^+$ Tfh cells.[56,57] These Tfh cells, which express CXCR5, migrate toward CXCL13-expressing FDCs. Differing from Th1 and Th2 cells by their chemokine receptors, transcription factors, surface markers, and interleukins,[56,57] they are uniquely equipped to provide efficient B-cell help through a series of costimulation molecules, including CD40L, ICOS (inducible T-cell costimulator), the IL-10 B-cell growth factor, and IL-21.[56,57] The cellular interactions between antigen-specific GC B cells, antigen-bearing FDCs, and antigen-specific Tfh cells (see Fig. 2.2) result in the proliferation, survival, and selection of B cells that have the highest possible antigen-specific affinity. They also provide the signals required for the subsequent differentiation of GC B cells toward plasma cells secreting large amounts of specific antibodies or toward memory B cells. Tfh cells have thus been identified a major determinant of adult and early life B-cell vaccine responses.[5–7]

The development of this GC reaction requires a couple of weeks, such that hypermutated IgG antibodies to protein vaccine antigens first appear in the blood 10 to 14 days after priming (see Fig. 2.3).[59] Feedback mechanisms terminate GC reactions within 3 to 6 weeks, a period during which a large number of antigen-specific plasma cells will have been generated. It is the magnitude of GC responses, that is, the quality of DC, B-cell, Tfh-cell, and FDC interactions, which controls the intensity of B-cell differentiation into plasma cells and thus the peak of IgG vaccine antibody reached within 4 to 6 weeks after primary immunization (see Fig. 2.3).

T-Independent Responses to Polysaccharide Antigens

Bacterial (*Streptococcus pneumoniae, Neisseria meningitidis, Haemophilus influenzae, Salmonella typhi*) PS antigens released from the injection site reach the marginal zone of the spleen/nodes, an area that is equipped by macrophages exhibiting a unique set of scavenger receptors through the bloodstream. There, PS

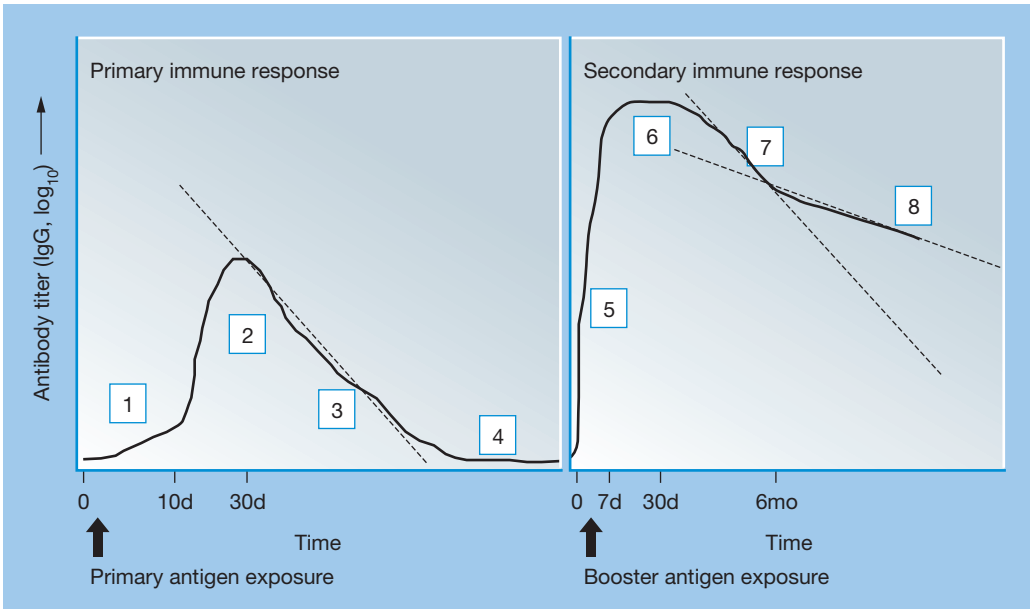

Figure 2.3. Correlation of antibody titers to the various phases of the vaccine response. The initial antigen exposure elicits an extrafollicular response *(1)* that results in the rapid appearance of low IgG antibody titers. As B cells proliferate in germinal centers and differentiate into plasma cells, IgG antibody titers increase up to a peak value *(2)*, usually reached 4 weeks after immunization. The short life span of these plasma cells results in a rapid decline of antibody titers *(3)*, which eventually return to baseline levels *(4)*. In secondary immune responses, booster exposure to antigen reactivates immune memory and results in a rapid (<7 days) increase *(5)* of IgG antibody titer. Short-lived plasma cells maintain peak antibody levels *(6)* during a few weeks—after which serum antibody titers decline initially with the same rapid kinetics as following primary immunization *(7)*. Long-lived plasma cells that have reached survival niches in the bone marrow continue to produce antigen-specific antibodies, which then decline with slower kinetics *(8)*. Note: This generic pattern may not apply to live vaccines triggering long-term IgG antibodies for extended periods.

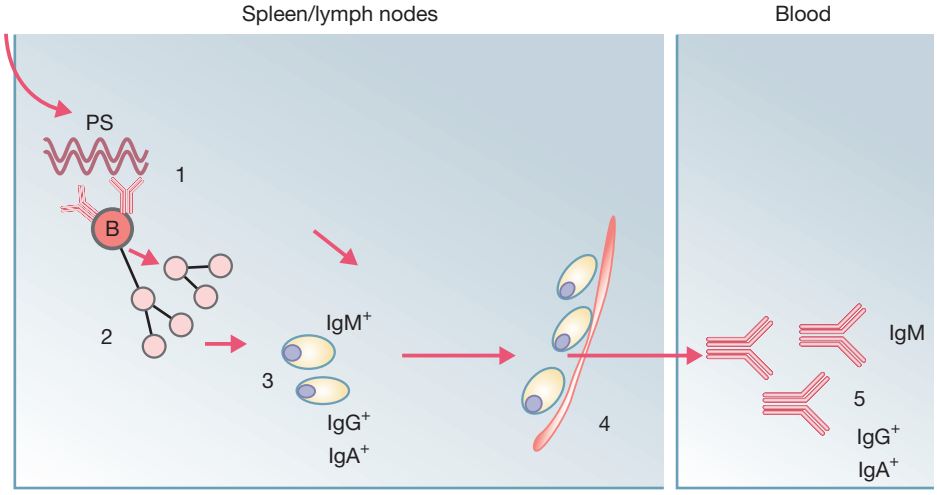

Figure 2.4. Extrafollicular B-cell responses to polysaccharide antigens. B cells use their specific immunoglobulin surface receptors *(1)* to bind to the repetitive structures of polysaccharides reaching the marginal zone of spleen/nodes. In the absence of antigen-specific T-cell help, B cells are activated, proliferate *(2)*, and differentiate in plasma cells *(3)* without undergoing affinity maturation in germinal centers. These plasma cells migrate toward the red pulp of the spleen *(4)*, where they survive for a few weeks/months, secreting low levels of low-affinity immunoglobulin (Ig) M, IgG, or IgA antibodies *(5)*.

bind to marginal zone B cells, and their repetitive structure crosslinks the Ig receptors on the B-cell surface.[53] This activates extrafollicular marginal zone B cells (Fig. 2.4).[53] During the week following immunization, B cells differentiate into plasma cells, undergo some degree of isotype switching from IgM to IgG/IgA, and—in rodents—rapidly produce essentially nonmutated, low-affinity, germline antibodies. Thus, PS vaccines are generally known as triggering T-independent responses characterized by the induction of moderate titers of low-affinity antibodies and the absence of immune memory.

In humans, PS immunization generates the production of intermediate-affinity IgG antibodies bearing some somatic mutations in their variable regions.[60,61] One hypothesis is that PS immunization activates "memory" B cells that have been previously primed by cross-reacting PS bacterial antigens somehow linked to protein moieties—and thus eliciting GC responses.[62] An alternative possibility is that the IgM^+, IgD^+, $CD27^+$ memory B cells that appear in the blood in response to PS immunization may be recirculating splenic marginal zone B cells.[63] This hypothesis is concordant with the fact that bacterial PS vaccines are poorly immunogenic in young children, that is, before the maturation of the splenic marginal zone.[64,65]

After their differentiation in the extrafollicular pathway, PS-specific plasma cells move toward the red pulp of the spleen (see Fig. 2.4) where they persist for some time, before their death by apoptosis and the waning of corresponding antibody responses after a few months. As PS antigens do not induce GCs, bona fide memory B cells are not elicited. Consequently, subsequent reexposure to the same PS results in a repeated primary response that follows the same kinetics in previously primed as in a naïve individual.[66] Revaccination with certain bacterial PS may even induce lower antibody responses than the first immunization, a phenomenon referred to as hyporesponsiveness,[67–69] which is increasingly reported[70–73] and where the molecular and cellular mechanisms include vaccine-induced B cell depletion by apoptosis.[74,75] This phenomenon is time-limited, such that if sufficient time elapses before the administration of a PS vaccine, the B-cell pool would be replenished.

What Are the Determinants of Primary Vaccine Antibody Responses? Numerous determinants modulate the intensity of vaccine-induced GCs and, thus, of peak antibody responses (Table 2.5). The main determinants are the nature of the vaccine antigen and its intrinsic immunogenicity. For example, tetanus toxoid is intrinsically a stronger immunogen than diphtheria toxoid, which becomes more apparent in the face of more limited immunocompetence, such as in preterm infants.[76] Whether this difference reflects a higher capacity of tetanus toxoid to provide antigenic epitopes that bind naïve B cells, the ability to generate cognate Tfh-cell help for B cells, and/or to their association with FDCs is unknown.

The markedly different outcomes of immunization with plain bacterial PS and with protein-conjugated glycoconjugates[67] highlight the differences between the extrafollicular and the GC reactions. It is only when capsular PS are conjugated to a protein carrier driving effective Tfh differentiation that PS-specific B cells are driven toward GC responses, receive optimal cognate help from carrier-specific Tfh cells, and differentiate into higher-affinity antibody-producing cells, longer-lived plasma cells, and/or memory B cells. Protein antigens exhibit markedly distinct carrier properties—regardless of their capacity to induce B- and Th-cell responses.[77,78] That these differences may reflect differences in Tfh induction is a likely hypothesis.[79,80] The limited number of potent carrier proteins implies that an increasing number of conjugate vaccines rely on the same carriers (e.g., CRM_{197}, tetanus or diphtheria toxoids), with the risk of limiting anti-PS responses to individual conjugate vaccines (carrier-mediated epitope suppression) and resulting in vaccine interference.[81,82] This phenomenon may be abrogated by replacing full-length proteins with peptides lacking B-cell epitopes,[83] suggesting that carrier-mediated epitope suppression essentially reflects the competition of carrier- and PS-specific B cells for activation/differentiation signals and factors.

Another determinant of the magnitude of primary vaccine antibody responses (see Table 2.5) is the use of an optimal dose of antigen, which may be determined only experimentally. As a rule, higher doses of nonlive antigens—up to a certain threshold—elicit higher primary antibody responses. This may be particularly useful when immunocompetence is limited, for example, for hepatitis B immunization of patients undergoing dialysis.[84,85] Remarkably, a limiting dose of antigen may restrict primary antibody responses but increase B-cell competition for FDC-associated antigens and, thus, result in a more stringent selection of higher-affinity GC B cells and stronger secondary responses (see subsequent text). Alternatively, adjuvants increasing inflammation at the injection site and, thus, cell recruitment and cell-mediated antigen transport toward lymph nodes, improve antibody responses despite a reduced antigen dose.[86] Little is known about factors that support or limit the affinity maturation process[87,88] which may be modulated by carrier proteins[89] and adjuvants.[90–92]

The nature of the vaccine directly influences the activation of innate immunity and, thus, vaccine responses. The strongest antibody responses are generally elicited by live vaccines that are "naturally adjuvanted," because they activate innate reactions, and, thus, support the induction of adaptive immune effectors in addition to providing a replicating antigen. Nonlive vaccines frequently require formulation with

TABLE 2.5 Determinants of the Duration of Vaccine Antibody Responses in Healthy People

Determinants	Mechanisms (Presumed)
VACCINE TYPE	
Live vs inactivated	Live vaccines generally induce more sustained Ab responses, presumably through Ag persistence within the host.
Polysaccharide antigens	Failure to generate Tfh cells and GCs limits the induction of memory responses and of high-affinity long-lived plasma cells.
VACCINE SCHEDULE	
Interval between primary doses	A minimal interval of 3 weeks between primary doses allows development of successive waves of Ag-specific primary responses without interference.
Interval before boosting	A minimal interval of 4 months between priming and boosting allows affinity maturation of memory B cells and thus higher secondary responses.
Age at immunization	Early life immune immaturity and age-associated immunosenescence limit the induction/persistence of long-lived plasma cells.
Environmental factors	Mostly unidentified.

Ab, antibody; Ag, antigen; GC, germinal center; Tfh, follicular T-helper cells.

adjuvants that enhance and shape vaccine immune responses through a variety of mechanisms.[34–37] The potency of the immune system indeed resides in its highly polymorphic nature, enabling sufficient immunological diversity to overcome a high number of diverse pathogens. This diversity impacts vaccine responses.[93] Probing how host genetic markers may result in variations of vaccine-induced responses is expected to identify gene polymorphisms that predict the likelihood of successful or adverse vaccine outcome, whereas epigenetic studies may help reveal how environmental influences affect innate and adaptive immune responses.[93] This work is still in its infancy, but holds great promise, especially when combined with novel systems vaccinology approaches.[94–96] Immune competence obviously affects vaccine antibody responses, which are limited at the two extremes of life (see subsequent text), and by the presence of acute or chronic diseases, acute or chronic stress, and a variety of factors affecting innate and/or B- and T-cell immunity.

Few nonlive vaccines (e.g., hepatitis A and human papillomavirus [HPV] vaccines) induce high and sustained antibody responses after a single vaccine dose, even in healthy young adults. Primary immunization schedules therefore usually include at least two doses, optimally repeated at a minimal interval of 3 to 4 weeks (longer intervals enhancing rather than reducing the responses) to generate successive waves of primary B-cell and GC responses. These priming doses may occasionally be combined into a single "double" dose, such as for hepatitis A or B and for HPV immunization.[97–101] In any case, vaccine antibodies elicited by primary immunization with nonlive vaccines eventually wane (see Fig. 2.3).

What Controls the Persistence of Vaccine Antibody Responses? Antigen-specific plasma cells elicited in spleen/nodes after immunization have only a short life span, such that vaccine antibodies rapidly decline during the first few weeks and months after immunization. A fraction of plasma cells that differentiated into GCs, however, acquire the capacity to migrate toward long-term survival niches that are mostly located within the BM, from where they may produce vaccine antibodies during extended periods.[102–105]

Some GC-induced plasma cells are attracted toward the BM compartment by cells that provide the signals required for their long-term survival.[50,106–109] In such BM niches, plasma cell survival and antibody production may persist for years. The duration of antibody responses reflects the number and/or quality of long-lived plasma cells generated by immunization[103]: In the absence of subsequent antigen exposure, antibody persistence may be reliably predicted by the antibody titers that are reached 6 to 12 months after immunization, that is, after the end of the short-term plasma cell response (see Fig. 2.3). This is illustrated by the accuracy of mathematical models predicting the kinetics of anti–hepatitis B surface antigen (HBsAg),[110] anti–hepatitis A,[111] or anti-HPV[112,113] antibodies.

A few determinants of the persistence of vaccine antibody responses (see Table 2.5) have been identified. The nature of the vaccine has a crucial role: only live attenuated viral vaccines or virus-like particles induce antibody responses that persist for several decades, if not lifelong, in absence of subsequent antigen exposure and reactivation of immune memory. In contrast, the shortest antibody responses are elicited by PS antigens, which fail to trigger Tfh/GC responses and thus do not elicit high-affinity plasma cells capable of reaching the BM survival niches. Antibody persistence may also be modulated by the use of adjuvants.[114,115] Vaccine schedules also control antibody magnitude and persistence. Closely spaced (1–2 weeks) primary vaccine doses may be administered when a rapid induction of protection is desirable, for example, before travel. However, this raises less-persisting responses than when the same number of vaccine doses are given at longer intervals (1–2 months),[116,117] reflecting the generation of fewer post-GC B cells capable of long-term survival and thus requiring later boosting. Optimal recall and anamnestic responses require longer intervals of at least 3 to 4 months, with longer intervals associated with generally greater responses (see below).

Age at immunization also modulates vaccine antibody persistence, which is shorter at the two extremes of life (see subsequent text). Certain conditions may also limit the persistence of vaccine antibody responses because of enhanced catabolism (as in HIV)[118] or the loss of antibodies in the urinary or digestive tract. The identification of the mechanisms that support or limit the persistence of vaccine antibody responses represents a major challenge.

What Are the Hallmarks of B-Cell Memory Responses? Memory B cells are generated during primary responses to T-dependent vaccines.[50,119] They persist in the absence of antigens but do not produce antibodies (i.e., do not protect), unless reexposure to antigen drives their differentiation into antibody-producing plasma cells. This reactivation is rapid, such that booster responses are characterized by the rapid increase to higher titers of antibodies that have a higher affinity for antigens than do antibodies generated during primary responses (Table 2.6).

Memory B cells are generated in response to T-dependent antigens, during the GC reaction, in parallel to plasma cells (Fig. 2.5).[50,119,120] At their exit of GCs, memory B cells acquire migration properties toward extrafollicular areas of the spleen and nodes. This migration occurs through the bloodstream, in which postimmunization memory B cells are transiently present on their way toward lymphoid organs.

It is essential to understand that memory B cells do not produce antibodies—that is, they do not protect. Their participation in vaccine efficacy requires an antigen-driven reactivation that may occur in response to endemic pathogens, to colonizing or cross-reacting microorganisms ("natural boosters"), or to booster immunization. The activation of memory B cells results in their rapid proliferation and differentiation into plasma cells that produce very large amounts of higher-affinity antibodies.[120] As the affinity of surface Ig from memory B cells is increased, their requirements for reactivation are lower than for naïve B cells: memory B cells may thus be recalled by lower amounts of antigen and without $CD4^+$ T-cell help, although T-cell help supports a second round of GC responses, further magnifying the level/persistence of antibodies.[121] Antigen-specific memory cells generated after primary immunization are much more numerous (and better fit) than naïve B cells initially capable of antigen recognition.[50,119] Thus, the first hallmark of the memory responses (see Table 2.6) is

TABLE 2.6 Hallmarks of Memory B-Cell Responses

Memory B cells:
• Are generated only during T-dependent responses inducing follicular T-helper cells and thus germinal center responses
• Are resting cells that do not produce antibodies
• Undergo affinity maturation during 4–6 months
• Rapidly (days) differentiate into antibody-secreting plasma cells on reexposure to antigen
• Differentiate into plasma cells that produce high(er)-affinity antibodies than do primary plasma cells

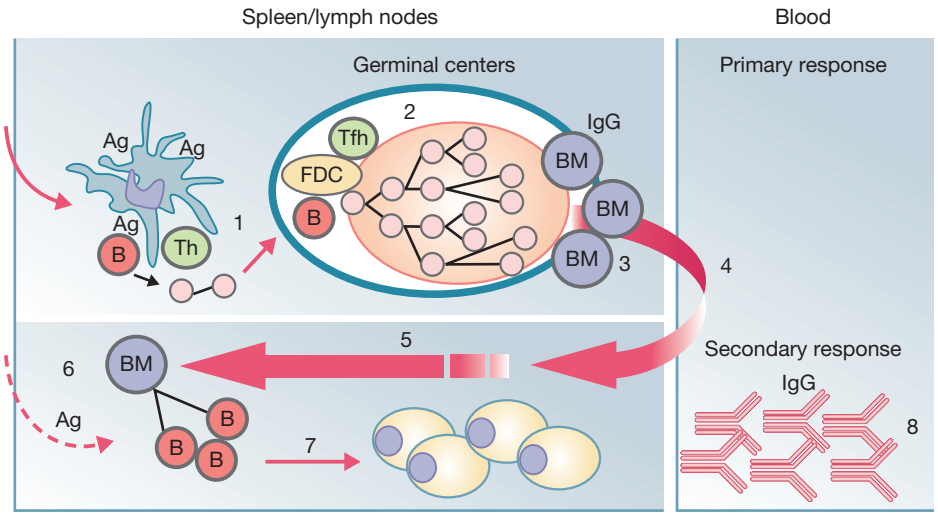

Figure 2.5. Generation of B-cell memory responses. Memory B cells are generated in response to T-dependent antigens *(1)*, during the germinal center (GC) reaction *(2)*, in parallel to plasma cells. At their exit of GCs, these B cells do not differentiate into antibody-secreting plasma cells but into memory B cells *(3)* that transiently migrate through the blood *(4)* toward the extrafollicular areas of spleen and nodes *(5)*. They persist there as resting cells until reexposed to their specific antigens *(6)*. On secondary antigen exposure, memory B cells readily proliferate and differentiate into plasma cells *(7)* secreting large amounts of high-affinity antibodies that may be detected in the serum *(8)* within a few days after boosting. Ag, antigen; BM, bone marrow; FDC, follicular dendritic cell; IgG, immunoglobulin G; Th, T-helper.

to generate significantly higher antibody levels than primary immunization. Should this not be the case, the effective generation or persistence of memory B cells should be questioned.

The reactivation, proliferation, and differentiation of memory B cells occur without requiring the induction and development of GC responses. This process is, thus, much more rapidly completed than that of primary responses. A window of 4 to 7 days after *H. influenzae b* (Hib) PS immunization was reported as sufficient for high levels of PS-specific vaccine antibodies to appear in the blood of previously primed infants.[122] The rapidity with which antigen-specific antibodies appear in the serum is, thus, another hallmark of secondary responses (see Table 2.6). Slower antibody kinetics suggests that memory B-cell induction, persistence, and/or reactivation may have been suboptimal.

Another hallmark of memory B cells is that they display and secrete antibodies with a markedly higher affinity than those produced by primary plasma cells, as a result of somatic hypermutation and selection. The affinity maturation process that is initiated within the GCs extends for several months after the end of the GC reaction. Consequently, vaccine antibodies with higher than baseline avidity (defined as the sum of epitope-specific affinities) for antigen are induced only when sufficient time has elapsed after priming.[123–125] A "classical" prime-boost immunization schedule is, thus, to allow 4 to 6 months to elapse between priming and booster doses, hence the generic "0-1-6 month" (prime-prime-boost) schedule. Secondary antigen exposure (see Table 2.6) thus results in the production of higher-affinity antibodies than primary responses.[126] Notably, this may not be the case when "natural" priming, for example, through cross-reactive bacteria, has occurred prior to immunization.

What Are the Determinants of B-Cell Memory Responses?
The factors that drive the differentiation of antigen-specific GC B cells toward plasma cells or memory B cells are poorly understood.[50] In response to protein antigens, both cell populations are generated in the same GCs, and their differentiation pathway differs only late in the GC reaction. As a rule, factors enhancing plasma cell differentiation and primary antibody responses (such as increasing the antigen dose or using adjuvants) also support the induction of memory B cells (Table 2.7). Postbooster antibody titers are, therefore, higher in people with stronger primary responses. For example, higher postbooster anti-HBsAg responses are observed in people with high (e.g., ≥100 IU/L) rather than intermediate (10–99 IU/L) anti-HBsAg after their primary vaccination.[127,128] This is likely to reflect the induction of a larger pool of memory B cells.

The dose of antigen is also an important determinant of memory B-cell responses (see Table 2.7). At priming, higher antigen doses generally favor the induction of plasma cells, whereas lower doses may preferentially drive the induction of immune memory.[129] Closely spaced primary vaccine doses may be beneficial for early postprimary antibody responses but not for postbooster antibody responses, as illustrated with meningococcal group C glycoconjugates.[130] As a rule, accelerated schedules in which a 4- to 6-month window is not included between priming and boosting result in significantly lower booster responses[125] (see Table 2.7). At the time of boosting, a higher antigen content raises stronger booster responses, presumably by recruiting more memory B cells into the response. This is illustrated by higher antibody responses of children immunized with a higher-antigen-dose pertussis vaccine[131] or primed with a glycoconjugate vaccine and boosted with a higher concentration PS (20–50 μg of PS) when compared with the glycoconjugate (1–3 μg of PS) vaccines.[132,133]

Residual titers of vaccine antibodies present at time of boosting directly influence vaccine antibody responses. As a rule, secondary responses to live attenuated viral vaccines are minimal, since preexisting antibodies neutralize the vaccine virus before in vivo replication. Consequently, even multiple doses of live attenuated vaccines do not have undesirable effects. Responses to nonlive vaccines are also negatively influenced by residual vaccine antibody titers. This may reflect the formation of antigen–antibody complexes that reduce the load of antigen available for B-cell binding and/or antibody-mediated negative feedback mechanisms acting directly on B cells through, for example, fragment c (Fc)

TABLE 2.7 Determinants of Secondary B-Cell Responses

Determinants	Mechanisms (Presumed)
Postprimary antibody titers	As plasma cells and memory responses are generated in parallel in GCs, higher postprimary Ab titers reflect stronger GC reactions and generally predict higher secondary responses.
Residual antibodies at boosting	Neutralization of live viral vaccines; negative feedback mechanisms on nonlive vaccines.
Lower antigen dose at priming	A limited quantity of antigen may induce B-cell differentiation away from PCs and toward memory B cells (?).
Longer intervals before boosting	A minimal interval of 4–6 months is required for optimal affinity maturation of memory B cells.
Higher antigen dose at boosting	A higher availability of antigen may drive higher numbers of memory B cells into differentiation.
ANTIGEN AVAILABILITY	
Exogenous exposure	Exposure to exogenous antigens may reactivate or favor the persistence of memory B cells.
Localization	Memory B cells reactivation requires antigens to reach the draining lymph nodes and not be restricted on mucosal surfaces (HPV, pertussis [?]).
In vivo persistence	Antigen persistence may reactivate or favor the persistence of memory B cells.

Ab, antibody; GC, germinal center; HPV, human papillomavirus; PC, plasma cell.

receptors. Consequently, people with residual antibodies to a given antigen may show only a limited increase of their antibody responses.

The persistence of memory B cells is of utmost importance for long-term vaccine efficacy. Antigen persistence may extend for prolonged periods on the surface of FDCs (see Table 2.7) and contribute to the duration of immune memory.[134] This is likely to contribute to the extended (indefinite?) memory to live attenuated vaccines, recently exemplified by repeated administration of smallpox vaccines decades after priming.[135] Fortunately, memory B cells survive for prolonged periods (e.g., several decades), even in the absence of reexposure to antigen.[136] It has been suggested that memory B cells undergo a certain degree of homeostatic polyclonal activation.[137] Although this does not seem sufficient to maintain antibody responses,[138] it likely contributes to their persistence and the replenishment of BM plasma cells.

The demonstration of the persistence of memory B cells long after vaccine antibodies have eventually disappeared, and of their brisk reactivation on antigen exposure, has direct consequences for immunization programs. First, it implies that an immunization schedule should never be started all over again—but continued where interrupted, regardless of the duration of the interruption. Second, it implies that certain immunization schedules may not need to include booster doses, if the individual is exposed to regular natural boosters. It is intriguing to note, that in the absence of childhood boosters, up to 50% of adolescents or young adults primed against tetanus or hepatitis B in infancy might not raise anamnestic responses, suggesting that infant-induced vaccine memory may not last forever.[139,140]

Immune Memory and Vaccine-Induced Protection: A Race Between Reactivation and Microbial Invasion? All existing vaccines, except T-independent PS, induce immune memory. Nevertheless, vaccine efficacy may be short-term, as illustrated following infant immunization against group C meningococcus.[141] Demonstration of priming—or "boostability"—is therefore not a surrogate marker for long-term vaccine efficacy. This requires identifying the determinants that contribute to—or limit—the persistence of vaccine efficacy. One hypothesis is that this essentially results from the race between the reactivation of immune memory and disease pathogenesis.[142]

It is generally considered that protection by toxoid-based vaccines requires the presence of antitoxin antibodies at time of toxin exposure/production. Persisting immune memory is also not sufficient to protect against *acute* hepatitis B after the waning of vaccine-induced antibodies.[143–145] However, progression to chronic liver disease has not been reported in fully immunized vaccine responders. That immune memory is sufficient to protect against chronic hepatitis B suggests that viral replication and reexposure to HBsAg efficiently drive vaccine-induced memory cells into effector cells before the end of the viral incubation period (4–12 weeks). This process requires enough HBsAg-specific memory B cells to be stimulated, to persist, and to be capable of reactivation even several decades after infant priming. It remains to be defined whether T-cell memory responses contribute to the maintenance of vaccine-induced protection after waning of anti-HBsAg antibodies.

Glycoconjugate vaccines against encapsulated bacteria illustrate the importance of immune memory for vaccine efficacy and some of its limitations. Glycoconjugate priming elicits a bona fide GC reaction, with the induction of high-affinity memory B cells that can be rapidly (4–7 days) recalled on PS immunization.[122] Efficient priming (i.e., induction of immune memory) is readily demonstrated in children primed in infancy.[146,147] However, immune memory can be seen in children with Hib vaccine failure,[148] indicating that their reservoir of memory B cells did not protect them against invasive disease, perhaps through a failure of avidity maturation.[149] The discrepancy between the existence of memory B cells and the lack of protection may again reflect the race against microbial invasion: the time required for production of sufficient levels of circulating antibodies could be too long to interrupt bacterial invasion. Notably, secondary vaccine failures have been relatively rare and primarily observed in countries using an early accelerated infant schedule without a booster dose,[150] the use of diphtheria, tetanus, and acellular pertussis (DTaP)/Hib vaccines with lower Hib immunogenicity is also associated with vaccine failure.[151] Similarly, glycoconjugate vaccines against group C meningococcal disease proved much more efficacious during the first year after infant priming than during the following 3 years.[141] Thus, infant immunization fails to induce sustained protection against group C meningococcus, despite the induction and persistence of immune memory.[152] The requirement for boosters to confer long-term vaccine protection is also well illustrated for pertussis, for which boosters are required to extend protection beyond childhood.[153] An interesting observation is that vaccine-induced memory persists following pertussis immunization—as illustrated by anamnestic responses to a booster dose—but is not sufficient for protection. Yet the incubation period of pertussis exceeds

4 to 7 days. An interesting hypothesis is that as *Bordetella pertussis* bacteria essentially remain on the mucosal surfaces, antigens may fail to efficiently reach the vaccine-induced B and T cells residing in the lymph nodes. For example, the prompt reactivation of immune memory is not sufficient to control polio viral replication in the digestive tract.[154]

Live attenuated viral vaccines (measles, rubella) are considered the prototype inducers of lifelong immunity, although prolonged immunity is also induced by certain nonlive vaccines (hepatitis A, HPV, inactivated poliovirus vaccine, rabies). This derives in part from the induction of sustained antibody responses, which, however, tend to slowly decline in the absence of recurrent exposure,[155] and might eventually result in a growing proportion of seronegative vaccinated young adults, including women of childbearing age. Whether the reactivation of immune memory will be sufficient to curtail the replication process and confer protection against measles, rubella, or varicella, and whether adult booster doses may become needed after microbial control, are essential questions. The resurgence of mumps outbreaks in fully vaccinated young adults may reflect the induction of low numbers of memory B cells[156] and demonstrates that secondary vaccine failure may occur even with live attenuated vaccines.[157] The questions, which are central to sustained vaccine efficacy, are usually unresolved at the time of registration of a new vaccine. For example, to vaccinate young girls against HPV requires reassurance that vaccine protection will extend during several decades. HPV infection of the basal epithelial cells can occur within minutes and is not followed by any antigen exposure to the immune system. Thus, antibody persistence will be required for sustained protection. Remarkably, however, the concentration of vaccine antibodies required to neutralize HPV at the site of entry is so minute[158] and vaccine-induced community-protection so efficient that boosters may indeed not be needed.

Thus, one may expect questions related to the nature (size, type, responsiveness) of the pool of memory cells elicited by various immunization schedules and the relative contribution of long-term antibodies and immune memory to protection to be at the core of many vaccine studies in the next decades.

T-Cell Vaccine Responses

How Do Vaccines Induce CD4⁺ and CD8⁺ T-Cell Responses? The generation of CD4⁺ Th-cell response begins when DCs capture antigen in peripheral tissue and migrate to draining lymph nodes, where T-cell vaccine responses are elicited in parallel to B-cell responses (see Table 2.1). Thus, DCs fulfill a pivotal role in initiating and shaping the immune response to vaccine antigens.

Protein vaccine antigens are taken up by immature DCs activated by local inflammation, which provide the signals required for their migration to draining lymph nodes (see Fig. 2.1). During this migration, DCs mature and their surface expression of molecules changes.[159] Simultaneously, antigens are processed into small fragments and displayed at the cell surface in the grooves of MHC (human leukocyte antigen [HLA] in humans) molecules. As a rule, MHC class I molecules present peptides from antigens that are produced in the cytosol of infected cells, whereas phagocytosed antigens are essentially displayed on MHC class II molecules.[160–163] Thus, mature DCs reaching the T-cell zone of lymph nodes display MHC–peptide complexes and high levels of costimulation molecules at their surface.[164] CD4⁺ T cells recognize antigenic peptides displayed by class II MHC molecules, whereas CD8⁺ T cells bind to class I MHC-peptide complexes (Fig. 2.6).[165] Their recognition is restricted to short peptides (8–11 [CD8⁺] or 10–18 [CD4⁺] amino acids) displayed on specific MHC class I or II molecules, respectively. Antigen-specific T-cell receptors may bind only to specific MHC molecules

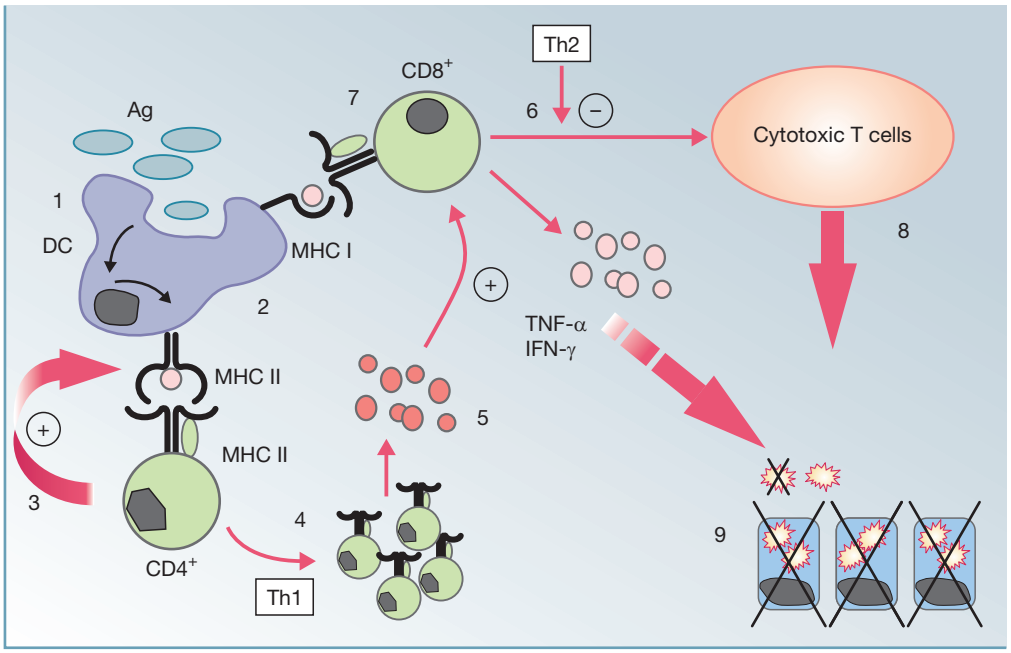

Figure 2.6. Generation of T-cell effector responses. Antigens are phagocytosed by dendritic cells (DCs) *(1)*, processed into small peptides, and displayed at the cell surface in the groove of major histocompatibility complex (MHC) class I and/or class II molecules *(2)*. CD4+ T cells with the appropriate MHC-peptide specificity are activated, provide activation signals to DCs *(3)*, and differentiate in effector cells *(4)* that produce preferentially T helper (Th)1 or Th2 cytokines. Th1 CD4⁺ T cells support *(5)* CD8⁺ T-cell differentiation, which is in contrast inhibited *(6)* by Th2-like cytokines. CD8⁺ T cells recognize MHC class I-peptide complexes *(7)* and differentiate into cytotoxic effector cells *(8)* capable of killing infected cells *(9)* or pathogens. Ag, antigen; IFN, interferon; TNF, tumor necrosis factor.

(e.g., HLA-A2), which differ among individual people and populations. Consequently, T-cell responses are highly variable within a population. These T-cell epitopes may be generated from any region of the vaccine antigens, whether the peptide sequence is located within or at the surface of the protein. This is in contrast with B-cell recognition, which is essentially limited to conformational determinants constituted by amino acids at the antigen surface. This MHC-peptide signal (signal 1) is not sufficient for activation of T cells, which remain anergic or become tolerized in absence of costimulation (signal 2). This ensures that only naïve T cells binding to the surface of activated DCs (i.e., DCs that have sensed danger signals through their Toll-like receptors and responded by a modulation of their surface or secreted molecules) receive the costimulation signals required for their activation.[164]

Activated $CD4^+$ T cells essentially exert supportive functions for DCs, to which they provide signals (CD40L, etc.) resulting in further activation, for B cells (see Fig. 2.2) and for $CD8^+$ cytotoxic T cells (see Fig. 2.6 and Table 2.8). They are elicited by each vaccine type, except plain PS, which are not properly displayed by MHC molecules. Thus, the demonstration of postimmunization $CD4^+$ T-cell responses does not imply a direct role in vaccine efficacy. $CD4^+$ T-cell activation by DCs triggers their differentiation along distinct differentiation pathways.[164,166] By default, DCs essentially trigger the induction of Th2-type $CD4^+$ T cells producing IL-4, IL-5, and IL-13, which are implicated in the defense against extracellular pathogens such as helminths.[167] More potently activated DCs release IL-12p70, which induces the differentiation into Th1 cells that essentially produce IFN-γ and tumor necrosis factor (TNF)-α and, thus, contribute to the elimination of intracellular pathogens directly (cytokine responses) and indirectly through macrophage activation and support to $CD8^+$ T-cell differentiation (see Fig. 2.6).[168] Th1 and Th2 cells support B-cell activation and differentiation during extrafollicular responses, whereas Tfh $CD4^+$ cells provide critical help to GC B cells (see Fig. 2.3).[169] Under certain conditions, activated DCs may also release IL-23, supporting the induction of inflammatory Th17 cells by TGF-β and IL-6.

Numerous factors influence the preferential differentiation of $CD4^+$ T cells toward the Th1, Th2, Tfh, or Th17 pathway.[170] The main determinant of $CD4^+$ T-cell differentiation is the extent and type of DC activation by the innate system,[164] although a recent observation suggests that polarized $CD4^+$ T-cell responses may result from preferential expansion rather than priming.[171] Consequently, DCs are the primary target for specific adjuvants, which may preferentially skew $CD4^+$ responses toward Th1, Th2, or Th17 responses and impact the differentiation of Tfh cells, requiring their careful design and selection.[34–37,39,172]

$CD8^+$ T-cell responses are essentially induced as a result of cross-presentation elicited by infectious, live attenuated vaccines that introduce antigens within the cell cytosol, ensuring their access to MHC class I molecules.[163,173] However, novel delivery systems such as live-vectored vaccines or DNA vaccines delivering antigens directly into the cytosol are now in human trials.[174]

The activation of naïve T cells by vaccine-bearing DCs may also induce their differentiation into Tregs (see Table 2.8), a heterogeneous population with many levels of complexity.[10,175] Vaccine-induced Tregs may use multiple mechanisms to suppress T-cell induction or proliferation: in draining lymph nodes, they may prevent DC maturation, block the priming of effector T cells, or destroy antigen-bearing DCs. These Tregs may be elicited as feedback mechanisms to avoid excessive and, thus, potentially harmful inflammatory responses. By suppressing immune responses, Tregs may limit the efficacy of vaccines, for example, when danger signals are insufficient to elicit immunity, as in chronic infections and cancer.[176–178] Defining the determinants of Treg differentiation may be needed for novel immunization strategies such as therapeutic vaccines. Preclinical studies indicate that adjuvants improving the ratio of antigen-specific effector to Tregs enhance vaccine immunity,[179] opening interesting possibilities.

TABLE 2.8 T-Cell Responses to Vaccines

Type	Mechanisms (Presumed)	Function
$CD4^+$ T-helper cells		
Th1	IFN-γ production	Extrafollicular B-cell help
Th1	Cell contact, IFN-γ	Activation of $CD8^+$ T cells
Th1/Th2	Cell contact, CD40L	Dendritic cell activation
Th2	IL-4, IL-5, IL-13	Extrafollicular B-cell help
Th2	Cell contact, IL-4	Suppression of $CD8^+$ T cells
Th17	IL-17, IL-21, IL-22	Mucosal inflammation
$CD4^+$ follicular T-helper cells		
Tfh1	IFN-γ	Germinal center B-cell help
Tfh2	IL-4, IL-5, IL-13	Germinal center B-cell help
$CD4^+$ regulatory T cells	Multiple mechanisms	Suppression of $CD4^+$/$CD8^+$ responses
$CD8^+$ T cells	IFN-γ, TNF-α	Killing of infected cells
Memory T cells		
Effector memory T cells	Th1/Th2 cytokines, perforin, granzyme	Rapid secondary effectors responses in periphery
Central memory T cells	IL-2, IL-10, CD40L	Delayed activation/proliferation in lymph nodes
Tissue-resident memory T cells	Th1/Th2 cytokines, perforin, granzyme	Tissue localization enabling immediate-early reactivation

IFN, interferon; IL, interleukin; Th, T-helper; TNF, tumor necrosis factor.

What Are the Determinants of Vaccine-Induced T-Cell Memory?

Effector T-cell responses are short-lived, and most (>90%) effector T cells die by apoptosis within a few days. Thus, immune memory is essential to T-cell vaccine efficacy. It is dependent on four main parameters: the frequency of antigen-specific memory T cells, their phenotype, their persistence, and their localization, a recently identified parameter (Table 2.9).[174,180,181] Memory T cells may persist lifelong, even in the absence of antigen exposure and despite their quality and amount being set during the primary immune response.

The frequency of memory T cells directly reflects the magnitude of the initial T-cell expansion and that of its subsequent contraction during which few surviving cells differentiate toward memory T cells. The main determinant of the expansion phase is the level of or duration of antigen stimulation present during priming.[182] This is a major limitation for nonreplicating vaccines, which fail to reach sufficient antigen content and typically require the presence of an adjuvant and/or booster doses. The contraction phase and the transition toward memory cells take place soon after antigen is cleared, which occurs faster for nonreplicating vaccines. Current efforts are, thus, oriented toward the optimization of the primary expansion phase through adjuvants and/or booster administration. As vaccine-induced immunity limits the subsequent "take" of a live vaccine by inducing its rapid neutralization, one attractive approach is the use of distinct vaccines for priming and boosting, as the adenovirus priming–modified vaccinia virus Ankara (MVA) boosting combination currently considered against Ebola virus.[183–186]

The phenotype of memory T cells is also important. Two main types of memory T cells have been identified (see Table 2.8) based on their phenotype and function, central memory cells and effector memory cells.[187] Central memory T cells (Tcm), like naïve T cells, but better equipped, preferentially traffic through lymph nodes and BM and do not exhibit much cytotoxic capacity but have a high proliferative potential. Their role is to recognize antigens transported by activated DCs into lymph nodes and to rapidly undergo massive proliferation and differentiation, generating a delayed but very large wave of effector cells.[188] Effector memory T cells (Tem), closer in phenotype to recently activated T cells, have a high cytotoxic potential that enables them to immediately recognize the pathogen. As they essentially lack lymph nodes homing receptors, it was proposed that Tem recirculate from the blood through nonlymphoid organs, monitoring tissues for the presence of specific microbial peptides.[188] A third type of memory T cells (resident memory T cells [Trm]) was recently recognized as populations of memory T cells which remain settled within specific organs such as the intestine, the lungs, the skin.[189] How Trm cells are induced and maintained in the specific organs is not yet fully deciphered, but as Trm were demonstrated as central for the protection against mucosal infections, novel vaccine strategies against viral (influenza, respiratory syncytial virus [RSV]) or bacterial (pertussis) mucosal pathogens will attempt their induction/maintenance.[190]

Antigen persistence essentially controls the proportion of Tcm and Tem memory cells (see Table 2.9): Tcm cells predominate when antigen is rapidly cleared, whereas Tem/Trm cells become preponderant when antigen persists, such as in chronic infections.[174,180,181] This is a challenge for novel nonreplicating vaccines that should induce and maintain sufficient Tem/Trm cells for immediate clearance in infected tissues. The long-term persistence of memory T cells is well established. Through homeostatic proliferation, memory T cells may persist lifelong, even without antigen exposure.[180,181,191] Studies of the persistence of vaccinia-induced immune memory have confirmed this observation in humans.[192–194]

TABLE 2.9 Determinants of Memory T-Cell Responses

Main Factors	Determinants
Frequency of memory T cells	Magnitude of T-cell expansion (initial antigen load, antigen persistence)
Phenotype of memory T cells	
Effector memory	Induction favored by prolonged antigen persistence
Tissue-resident memory	
Central memory	Induction favored by rapid antigen clearance
Persistence of memory T cells	Supported by interleukin (IL)-15, IL-7

How Specific Are Vaccine Immune Responses?

The specificity of vaccine responses is at the center of many debates. Ideally, one would want vaccine-induced responses to be sufficiently broad to extend protection to nonvaccine strains (e.g., for influenza, rotavirus, *S. pneumoniae*, or HPV vaccines) and sufficiently restricted to not elicit cross-reactions to allergens or self-antigens or other undesirable nonspecific effects. The specificity of vaccine responses has received added interest as a number of studies have also reported both positive and negative "nonspecific" effects of vaccinations in low income countries.[195,196]

As B cells recognize conformational epitopes constituted by distant amino acids, they may bind to antigenic peptides with distinct sequences: It has been estimated that roughly 5% of monoclonal antibodies made against 15 viruses cross-reacted with human proteins.[197] That any viral infection is not followed by the induction or flare of an autoimmune disease highlights the importance of regulatory mechanisms suppressing responses directed against self-antigens. Indeed, the specificity of antibody responses is well controlled. Although polyclonal stimulation has been suggested to activate memory B cells of distinct specificities,[137] this response is not associated with antibody responses. Vaccination with tetanus toxoid was found to expand specific and bystander memory T cells but did not modulate antibody responses to unrelated antigens.[198] Altogether, this indicates that the induction of cross-reactive antibody responses is extremely limited, which may be important in preventing undesirable reactions, but which limits the efficacy of vaccine-induced antibody responses to very few cross-reacting nonvaccine serotypes.[199]

T cells need to recognize only a few amino acids of antigenic peptides displayed by MHC molecules, which offers a much greater potential for cross-reactivity. It has been estimated that each T lymphocyte could potentially bind to a million different peptides.[197] In addition, memory T cells readily respond to homeostatic cytokines, such that bystander memory T cells of distinct antigen specificity may be transiently activated and expand during a flu-like illness or an immunization process.[198,200] However, vaccine-induced exacerbations of autoimmune diseases are very uncommon, probably reflecting the efficacy of regulatory mechanisms limiting the intensity, scope, and duration of the immune responses.[201,202]

The induction of cross-protective T-cell–mediated responses has been repeatedly observed in murine experimental models,

which suggests that cross-reacting viral vaccines could be based on T-cell responses.[203] Yet, convincing examples of heterologous protective immunity in humans are much more limited, including neonatal BCG protects against leprosy,[204] and smallpox vaccine protects against monkeypox.[205] In contrast, the sharing of several T-cell determinants is not sufficient for a single oral polio vaccine strain or influenza strain to confer cross-protection. Consequently, it is tempting to conclude that heterologous protective immunity essentially comes into play for T-cell–mediated rather than for antibody-mediated protective responses. Accordingly, the heterosubtypic immunity conferred by live attenuated influenza vaccines[206,207] could be mediated by T cells and/or by mucosal IgA antibodies.

Nonspecific effects of vaccines are occasionally associated with the fear of immune overload and subsequent enhanced vulnerability to infections, a theory not supported by evidence.[208,209]

In addition to B and T cells, it was recently recognized that innate cells such as natural killer (NK) cells and monocytes acquire a "trained immunity phenotype" upon exposure to certain pathogens and have given support to the idea that vaccines can have off-target effects. The epidemiological studies on this subject have been done mainly by a group working in Guinea-Bissau and their thesis is that live vaccines (including BCG, measles, and oral polio vaccine [OPV]) can reduce mortality caused by respiratory viral infections, whereas killed vaccines, notably diphtheria, tetanus, and pertussis (DTP), can reverse those effects and even increase mortality.[210–213] Data from some other regions are supportive of this theory.[214,215] As most of the epidemiological studies have been nonrandomized studies, this idea has been met with skepticism, particularly as the causes of mortality have been ill-defined. Following a systematic review, the World Health Organization (WHO) Strategic Advisory Group of Experts (SAGE) on immunization concluded that the available data suggest that BCG "has" and measles vaccine "may have" beneficial effects on all-cause mortality, whereas it neither excluded nor confirmed the possibility of beneficial or deleterious nonspecific effects of DTP vaccines on all-cause mortality.[216,217]

Immunologists have now begun to study this issue more comprehensively. Evidence has accrued that BCG strongly stimulates cytokine production and enhances responses to other antigens,[218,219] and NK cells—which can develop memory[220]—are stimulated by BCG to respond to antigens other than mycobacterial.[221] The Danish strain of BCG used in Guinea-Bissau is particularly strong in this respect.[222] Humans given BCG respond with Th1 and Th17 responses and their stimulated monocytes show increased receptor expression.[223,224] Wild measles virus infection in monkeys abolishes immune memory to other antigens,[225,226] making it possible that measles vaccine in addition prevents abolition by the natural virus of the child's ability to respond to other infections.[227] The proposed negative effects of killed vaccines on mortality remains for the moment based only on observation,[228] although nonlive vaccines typically elicit preferential Th2 responses which might hypothetically reduce the Th1 polarization elicited by live vaccines. This subject is one in evolution and a randomized study has begun in Denmark that should shed light on the importance, if any, of nonspecific or off-target effects in a developed country.[228]

Vaccine Responses at the Extremes of Age

The Challenges of Neonatal and Early Life Immunization. According to UNICEF estimates, 4 million infants younger than 6 months die yearly of acute infections.[229] In more developed countries, mortality has been reduced, but infections represent a significant proportion of infant hospitalizations. This disease burden is caused by a limited number of pathogens, such that the availability of a few additional vaccines that would be immunogenic soon after birth would make a huge difference. Early life responses markedly differ from those elicited in mature hosts. The blunting of neonatal immune responses has been regarded for many years as resulting from "neonatal tolerance," reflecting the antigen naïveté of the immune system and, subsequently, its immaturity. Recent work has prompted a change of perspective, leading to the recognition that the neonatal and early life immune system is, in contrast, specifically adapted to the unique challenges of early postnatal life and develops over time through poorly defined but tightly regulated processes.

These specific neonatal features first affect innate responses as pattern-recognition receptors elicit responses biased against the induction of proinflammatory cytokines, which could cause harmful alloimmune reactions against maternal antigens or excess inflammatory reactions.[230,231] In addition, many factors determine the quality and quantity of infant antibody responses: this includes the state of prenatal and postnatal development of the immune system, the type of vaccine and its immunogenicity, the number of doses and their spacing, and the influence of maternal antibodies.[232–234]

Early life immune responses are characterized by age-dependent limitations of the magnitude of responses (Table 2.10). Antibody responses to most PS antigens are not elicited during the first 2 years of life, which is likely to reflect numerous factors, including the slow maturation of the splenic marginal zone,[65,235] limited expression of CD21 on B cells, and limited availability of the complement factors.[236] Although this may be circumvented in part by the use of glycoconjugate vaccines, even the most potent glycoconjugate vaccines elicit markedly lower primary IgG responses in young infants.[237]

Early life antibody responses are directly determined by the prenatal (e.g., gestational age[238]) and the postnatal age at immunization.[236] Accelerated infant vaccine schedules in which three vaccine doses are given at 1-month intervals (2, 3, 4 or 3, 4, 5 months) result in lower immune responses than schedules in which more time elapses between doses (2, 4, 6 months) or between the priming and boosting dose (3, 5, 12 months). However, the magnitude of infant antibody responses to multiple dose schedules reflects the interval between doses, with longer intervals eliciting stronger responses, and the age at which the last vaccine dose is administered. That postnatal immune maturation is required for stronger antibody responses is best demonstrated by comparing antibody responses to single-dose vaccines given to antigen-naïve infants of various ages.[239,240] These studies may be confounded by the persistence of maternal antibodies, which negatively influence infant antibody responses in both epitope and titer specific manners.[241,242] Thus, multivariate analyses of the data for a large number of infants are required to identify the main determinants of vaccine antibody responses.[243]

The induction of B-cell responses is critically dependent on components of the local microenvironment. However, blood is the only accessible compartment in infants and the factors that specifically limit the magnitude of early life antibody responses are difficult to study. Studies in which vaccines routinely administered to human infants were administered at various stages of the postnatal maturation to infant mice indicated that the same limitations of antibody responses are seen in both humans and mice, reflecting similar postnatal constraints.[236] These animal models showed that limitations of antibody responses in early life result from the limited and delayed induction of GCs in which antigen-specific B cells proliferate and differentiate. This was first shown to essentially reflect the delayed development of FDCs required to nucleate

TABLE 2.10 Limitations of Vaccine Responses at the Extremes of Life (Mechanisms Presumed)

In Early Life	
Limited magnitude of Ab responses to PS	Immaturity of marginal zone; low CD21 expression on B cells; limited availability of complement
Limited magnitude of Ab responses to proteins	Limited GC responses (delayed FDC development?); inhibitory influence of maternal antibodies
Short persistence of Ab responses to proteins	Limited establishment of bone marrow plasma cell pool (survival niches?)
Shorter duration of immune memory (?)	Limited GC responses (magnitude of initial memory B-cell pool?)
Limited IFN-γ responses	Suboptimal antigen-presenting cell/T-cell interaction (IL-12, IFN-α)
Limited $CD8^+$ T-cell responses (?)	Insufficient evidence
Influence of maternal antibodies	Inhibition of B-cell but not T-cell responses
In Elderly People	
Limited magnitude of Ab responses to PS	Low reservoir of IgM^+ memory B cells; weaker differentiation into plasma cells
Limited magnitude of Ab responses to proteins	Limited GC responses: suboptimal $CD4^+$ helper responses, suboptimal B-cell activation, limited FDC network development?; changes in B-/T-cell repertoire
Limited quality (affinity, isotype) of antibodies	Limited GC responses; changes in B-/T-cell repertoire
Short persistence of Ab responses to proteins	Limited plasma cell survival?
Limited induction of $CD4^+$/$CD8^+$ responses	Decline in naïve T-cell reservoir (accumulation of effector memory and $CD8^+$ T cell clones)
Limited persistence of $CD4^+$ responses	Limited induction of new effector memory T cells (IL-2, IL-7)

Ab, antibody; FDC, follicular dendritic cell; GC, germinal center; IFN, interferon; Ig, immunoglobulin; IL, interleukin; PS, polysaccharide.

and support GC reactions[244] and subsequently to result from the limited induction of Tfh cells in the draining lymph nodes.[7,245] Direct evidence for a similar mechanism is difficult to obtain[235] in human infants. Efforts are ongoing to identify adjuvants for use in early life. The capacity of the MF59 adjuvant to induce strong Tfh/GC responses in infant mice[7] could also be relevant to the ability of the adjuvant to improve the efficacy of influenza vaccines in young children.[246]

In contrast with this blunting of early life antibody responses, the neonatal immune system readily allows the induction of immune memory, thus reflecting preferential differentiation of early life GC B cells toward memory rather than Ig-producing plasma cells. Neonatal priming may, thus, be used to initiate vaccine responses against hepatitis B or poliomyelitis. Recent work demonstrated that acellular pertussis vaccines may similarly effectively prime neonatal responses, resulting in faster acquisition of infant immunity.[247–249] However, neonatal priming with a combined DTaP vaccine blunted rather than primed subsequent infant pertussis responses,[250] and somewhat reduced Hib and HBsAg responses were also seen following neonatal acellular pertussis priming.[248,251] Thus, vaccine interference issues may be exacerbated in early postnatal life, requiring further studies.[252]

The persistence of immune memory has important implications, especially for infant immunization programs such as for hepatitis B that are intended to protect throughout adult life. The duration of such responses (e.g., the boostability of hepatitis B vaccine antibody responses primed in infancy) extends for at least one decade. However, in the absence of childhood boosters, the boostability of infant-induced immunity may not persist lifelong.[139,140]

Antibody responses elicited before 12 months of age rapidly wane, and antibody titers soon return to near baseline levels,[152,253] which may be associated with a resurgence of vulnerability to infection.[141] This likely reflects the limited survival of antigen-specific plasma cells, as confirmed in infant mice[244] in which early life BM stromal cells provided insufficient survival signals to plasma cells reaching BM niches.[254] Isotype switching and somatic hypermutation (i.e., the affinity maturation of vaccine induced B cells) are already functional in the first year of life,[124,255–257] including in preterm infants.[238] However, several months are required for affinity maturation even in adults,[90] such that high-affinity responses are not observed in very young infants.

Neonatal and infant T-cell responses also differ from those elicited later in life, in particular in the induction of lower IFN-γ[236] and higher Th2 and/or Th17 responses.[258] As examples, IFN-γ responses to OPV are significantly lower in infants than in adults[259]; hepatitis B vaccine induces lower primary IFN-γ responses and higher secondary Th2 responses in early life than in adults[260]; and tetanus-specific IFN-γ $CD4^+$ T-cell responses progressively increase with age.[261] Comparing neonatal and infant priming with acellular pertussis vaccines indicated the preferential induction of Th2 responses on neonatal priming.[262] Whether this results from the fact that neonatal APC responses to Toll-like and other pathogen-associated molecular pattern receptors produce less IFN-α, IFN-γ, and IL-12p70, and more IL-10 than adult cells,[263–265] or result from complex epigenetic controls or the predominance of recent thymic emigrants in neonatal blood,[266] is unknown. The contribution of other factors, such as the predominance of Tregs that are abundant during fetal life[267] and the role of CD71+ immunosuppressive erythroid cells,[268] remains to be defined. Remarkably, adult-like Th1 neonatal responses are notoriously elicited by BCG.[269] Whether neonatal T cells have higher intrinsic requirements for antigen-specific activation require further investigations.

Importantly, the induction of early life B- and T-cell vaccine responses takes place in an environment that may be influenced by the presence of antibodies of maternal origin. IgG antibodies are actively transferred through the placenta, via the FcRn receptor, from the maternal to the fetal circulation.[270] After immunization, maternal antibodies bind to their specific epitopes at the antigen surface, competing with infant B cells and, thus, limiting B-cell activation, proliferation, and differentiation. The inhibitory influence of maternal antibodies on

infant B-cell responses affects all vaccine types, although its influence is more marked for live attenuated viral vaccines that may be neutralized by even minute amounts of passive antibodies.[271] This inhibition is epitope-specific.[272] As a rule, maternal antibodies to carrier proteins (e.g., to tetanus toxoid) blunt infant responses to tetanus toxoid, but not to the PS moiety.[273,274] However, responses to conjugate vaccines may be blunted if anticarrier immunity is required for immunogenicity (e.g., for CRM_{197} conjugates) and maternal antibodies interfere with its induction.[275] Maternal antibodies were reported as inhibiting cotton-rat B-cell responses by interaction with the inhibitory/regulatory FcγRIIB receptor on antigen-specific B cells.[276,277] The extent to which this mechanism accounts for the inhibition of human infant responses remains undefined.

The inhibitory influence of maternal antibodies is dependent on the antibody titer and reflects the ratio of maternal antibodies to vaccine antigen.[90] This was elegantly demonstrated in a study in which Israeli infants were immunized with hepatitis A vaccine at 2, 4, and 6 months.[278] Overall, infant responses were elicited only when maternal antibodies declined to a threshold of 300 to 400 mIU/mL.[278] The maternal antibody titer at which infant responses may be elicited can be defined only experimentally, by comparing antibody responses in infants stratified according to maternal antibody titers at the time of priming. Few vaccines have these precise antibody levels determined by such experimental studies.

The extent and duration of the inhibitory influence of maternal antibodies, therefore, increase with gestational age,[238] for example, with the amount of transferred immunoglobulins, and decline with postnatal age, as maternal antibodies wane.[90] Increasing the dose of vaccine antigen may be sufficient to circumvent the inhibitory influence of maternal antibodies, as illustrated for hepatitis A,[279] measles,[280] and the higher content of pertussis toxin in acellular versus whole-cell pertussis[281] vaccines. However, the higher titers of maternal antibodies elicited by maternal immunization eventually interfere, even with responses to acellular pertussis vaccines.[275,282]

Maternal antibodies usually allow a certain degree of priming (i.e., of induction of memory B cells) through yet undefined mechanisms. As a rule, the blunting of infant antibody responses by maternal antibodies disappears after boosting. Importantly, maternal antibodies do not exert their inhibitory influence on infant T-cell responses, which remain largely unaffected or even enhanced.[283–285] This is best explained by the fate of maternal antibody–vaccine antigen complexes: immune complexes are taken up by macrophages and DCs, dissociate into their acidic phagolysosome compartment, and are processed into small peptides. These peptides are displayed at the surface of APCs and are available for binding by $CD4^+$ and $CD8^+$ T cells.

Thus, the main challenge for further improvement of early life immunization strategies are to identify vaccine formulations and strategies capable of inducing, after one or two early doses, the strong primary antibody responses required against certain early life pathogens—despite the presence of maternal antibodies. Importantly, these formulations/strategies will have to be demonstrated as safe in immunologically immature hosts, adding to the challenges.[286]

Age-Associated Changes in Vaccine Responses. Innate and adaptive antibody and T-cell–mediated cellular immune responses decline with age, which increases the frequency and severity of infections and reduces the protective effects of vaccinations.[287] Aging affects the magnitude and the persistence of antibody responses to protein vaccines,[288,289] as reflected by lower serum antibodies to influenza,[290,291] tetanus, and tick-borne encephalitis (TBE) vaccines.[292] It also affects responses to pneumococcal PS vaccines, although differences in methodological issues have yielded contradictory results.[293] Remarkably, the limitation of antibody responses by aging occurs early: After the age of 20 years, each 10-year period reduced antibody titers elicited by a potent adjuvanted pandemic influenza vaccine in healthy control subjects and immunosuppressed patients by 31%.[294] Limitations of antibody responses in elderly people are also associated with qualitative changes that affect antibody specificity, isotype, and affinity, that is, functional efficacy (see Table 2.10).[295,296]

They result from the influence of a large number of underlying events.[232,297] Responses to PS vaccines are conditioned by a decline in the reservoir of IgM^+ memory B cells that differentiate less efficiently into antibody producing cells, and, thus, limit the IgM responses of aged people.[298] Antibody responses relying on the induction of GCs are also limited,[299] affecting the magnitude of antibody responses and resulting into antibodies of weaker affinities/functional capacities[296] and distribution of subclass antibodies.[300] Numerous factors contribute to limiting the induction of GCs in elderly persons, including factors that are intrinsic to B cells[301] and that affect other cell types, including Tfh cells.[302] For example, studies in aged mice have convincingly demonstrated the existence of age-related changes in FDCs.[303,304] The limited ability of aged subjects to generate high-affinity antibody responses also reflects changes in their antibody repertoire.[304,305]

Age-associated changes in T-cell responses are reflected by a progressive decline in naïve T cells, reflecting declining thymic output. This is associated with a marked accumulation of large $CD8^+$ clones presumably resulting from prior infections. These large T-cell clones (e.g., elicited in response to cytomegalovirus) have reached a state of replicative senescence, and homeostatic mechanisms negatively influence the size of the naïve and effector memory T-cell subsets.[289] In response to influenza immunization, healthy elderly people mount $CD4^+$ responses initially similar to those of young adults but that fail to maintain or expand.[306] This does not reflect a functional impairment of $CD4^+$ T memory cells,[307] but a shift of the T-cell pool from naïve to memory effector $CD4^+$ T cells. The failure to maintain $CD4^+$ responses reflects a lower induction of new Tem cells in relation to lower IL-7 levels.[306,307] Other studies indicated that frail elderly subjects mount blunted and delayed Th1 responses to influenza vaccination, which correlated positively with their reduced total and IgG1 antibody response.[308] Limitations also affect the expansion of infection-driven influenza-specific $CD8^+$ T cells.[308] Strategies to enhance vaccine-induced protection in aging people include the use of higher vaccine doses[309] and/or specific adjuvants. This was recently demonstrated by formulating the IgE glycoprotein of varicella-zoster in the novel AS01E adjuvant.[24] Nevertheless, limitations of effector memory and of GC responses may continue to require the more frequent administration of certain vaccine boosters (e.g., against tetanus or TBE[308]) to compensate for the brevity of B- and T-cell vaccine-induced responses in elderly people.

3 Correlates of Protection

Stanley A. Plotkin and Peter Gilbert

The determination of a correlate of protection (CoP) by a vaccine is often critical to its development, as its measurement permits a number of both theoretical and practical extrapolations. Aside from the intellectual interest in identifying the immune response that is protective, knowledge of a CoP permits measurement of consistent lot potency of a vaccine and differentiation of susceptible from immune individuals. If an infection is uncommon or deadly, such that an efficacy trial is not feasible or ethical, a CoP may yet enable licensure of a vaccine, and once established, a CoP will allow bridging from one vaccine preparation to another.

The terminology in this field is confusing, as various definitions have been published, but semantics are important and confusion will be avoided if the definitions used are understood. Table 3.1 gives the terminology used in this chapter, and is crucial to its understanding. Whereas a CoP is simply a variable immune response that is statistically associated with protection, the important distinction is between a mechanistic correlate of protection (mCoP) that is directly responsible for protection and a nonmechanistic correlate of protection (nCoP) that is easy to measure but which may only be a substitute for an mCoP that is unknown or difficult to measure. In addition, a CoP may be absolute, in the sense that there is a threshold value above which protection is certain, or relative in the sense that higher values are quantitatively more protective than lower values but there are occasional failures even at high levels and occasional protection at lower levels. Last, and importantly, there are cocorrelates, meaning that more than one immune function induced by a vaccine correlates with protection in an additive or synergistic way. The reader who wishes to learn more on this subject is referred to previously published articles.[1–6]

The determination of a CoP is sometimes established early in vaccine development, which is the ideal circumstance in that it makes later vaccine development easier, but sometimes a Phase III trial analysis is necessary to identify the CoP. In the latter case, immune responses of vaccine failures are compared with a sample of subjects who did not become infected. Ideally, the immune responses would be measured at the time of exposure to the infection, but most often samples are available only immediately after vaccination. Nevertheless, a useful CoP is often extracted from those data. Other ways in which CoP are inferred include definition of protective levels of passive antibody given parenterally or acquired by an infant from its mother through the placenta, observations made on vaccinated immunodeficient or immunosuppressed individuals exposed to the infection, challenge of vaccinated volunteers by the agent in question, and rarely by extrapolation from challenge of vaccinated animals. Human challenge models have often given critical information about CoP, and should be employed if the challenge is sufficiently attenuated to be ethically acceptable and if a broad range of immune responses are studied. Examples of human challenge that have yielded important information include influenza, cholera, dengue, and cytomegalovirus.

Chapter 2 of this book describes the immunology surrounding vaccination, but the point to bear in mind regarding CoP is that many different functions may serve as a CoP. Serum and mucosal antibodies come in different isotypes and functionality, and T cells, whether $CD4^+$ or $CD8^+$, can act in a variety of ways, including direct action on infected cells, help to B or other T cells, secretion of cytokines, and even down-regulation of immune responses by T regulatory cells. This chapter seeks to simplify immunology in order to identify principles of protection, although the reader should keep in mind that the immune system is complex and redundant.[3] In addition, the reader is directed to chapters on specific vaccines for more extended analysis of each case.

PRINCIPLES OF PROTECTION

Principle 1: Protection Must Be Defined in Relation to Specific Phenomena

Protection against infection may relate to different immune markers than protection against disease. Polio is an example in which paralysis can be prevented by serum antibodies, as the virus must pass from the pharynx or intestines to the central nervous system via blood, whereas infection is prevented by antibodies at the mucosal level, either locally produced immunoglobulin (Ig) A antibodies or diffusion of IgG antibodies onto the mucosal surfaces of the nasopharynx and intestine. Another instructive example is pneumococcal infections. Prevention of bacteremia can be mediated by antibodies in the range of 0.20 to 0.35 µg of antibody as measured by enzyme-linked immunosorbent assay (ELISA). However, prevention of pneumonia, otitis media, and nasopharyngeal carriage may require levels 10 times higher.[7,8]

Principle 2: The Mechanism of Protection by Vaccination Is Not Necessarily the Same Mechanism as Recovery From Infection

The level of antibodies that protect against measles has been defined. A level of 120 mIU of antibody measured by ELISA indicates protection against clinical measles and infection.[9] A level between 200 and 1000 mIU confers protection against measles disease, but not always against infection as indicated by antibody rises; a level of 1000 mIU does provide protection even against subclinical infection. However, vaccinated B-cell–deficient humans do recover from disease, whereas T-cell–deficient humans may suffer continued viremia leading to serious and fatal measles. It has been shown in monkeys that the $CD8^+$ T cells specific for measles are required to suppress viremia.[10]

The poxviruses provide another example. An individual given vaccinia virus requires both B and T cells to overcome the replicating virus and to become immune. However, in a previously vaccinated person only neutralizing antibodies at levels between 1/20 and 1/32 are required for protection, although $CD8^+$ T-cell responses are helpful in the absence of antibodies. Inasmuch as antibody titers decline by 20 years postvaccination, the presence of antipoxvirus T cells enables the vaccinee to have a mild secondary infection in case of exposure.[11–13]

Principle 3: A Large Challenge Dose Can Overcome Immunity

Vaccination against poliomyelitis is usually highly effective in the prevention of paralysis, as stated above, because of the induction of serum antibody. However, gut immunity is imperfect and can be overcome by large infectious doses. A study challenged subjects previously given live vaccine and killed vaccine with two different doses of the oral live vaccine: 800 or 600,000 $TCID_{50}$ (median tissue culture infective dose). The live vaccine recipients were infected by the low-dose challenge 3% of the time and by the high-dose challenge 15% of the time, whereas 30% of the killed vaccine recipients could be infected by a low dose and 70% by a high dose, indicating that high challenge doses can overcome intestinal immunity.[14]

Another challenge study involved an experimental cytomegalovirus vaccine. Seronegative, naturally seropositive, and previously vaccinated subjects were challenged parenterally with 10, 100, or 1000 PFU of a low-passage natural strain of cytomegalovirus. Seronegative subjects were infected with the lowest dose, whereas naturally seropositive subjects were resistant to 10 or 100 PFU; however, some could be infected by 1000 PFU. The vaccine prevented infection by 100 PFU of the challenge virus, but not by 1000 PFU.[15]

TABLE 3.1 Definitions of Terms Used in This Chapter

Term	Definition
Correlate of protection (CoP)	An immune response that is statistically correlated with protection.
Mechanistic correlate of protection (mCoP)	The immune response that is responsible for protection.
Nonmechanistic correlate of protection (nCoP)	An immune response that substitutes for the true immunologic correlate of protection, which may be unknown or not easily measurable.
Absolute correlate	A specific level of response highly correlated with protection; a threshold.

Principle 4: Most Current Vaccines Protect Through Antibodies

Table 3.2 lists the commonly used licensed vaccines and their predominant mechanisms for causing disease. Many viral and bacterial agents reach target organs through viremia or bacteremia; consequently, it is easy to understand that antibodies can prevent that passage. Some agents replicate only on the mucosa, but there, too, the local presence of antibody is preventive. The pathogenesis of toxin-producing bacteria such as diphtheria and tetanus can be restricted by antitoxic antibodies. In the case of rabies, replication occurs in the subcutaneous tissue before attachment to neurons and elicitation of antibodies before that attachment prevents rabies. Only in the cases of zoster and tuberculosis vaccines does it appear that antibodies are not the primary mechanism of control, but that stimulation of specific T-cell subsets correlate with protection.[16] Aside from these theoretical arguments, the fact is that passive administration of antibody works for many infections also preventable by vaccination. Indeed, the efficacy of hepatitis A vaccine was predictable from the fact that induced antibody levels are a thousand times higher than those shown to protect after administration of gamma globulin.[17] As mentioned under Principle 1, higher levels of antibody are necessary to prevent mucosal colonization than disease, as for example, in the case of pharyngeal colonization after *Haemophilus influenzae* type b vaccine.[18]

Principle 5: Correlates May Be Relative

Although high levels of antibodies are more protective than lower levels, after some vaccines breakthroughs may occur at high levels, even if less frequently than at lower levels. Fig. 3.1 shows a retrospective analysis of the relationship between antibody responses to influenza hemagglutinin and protection against disease. At an anti-HA (hemagglutinin) titer of 1/40, generally thought to be an acceptable response, only approximately 50% of vaccine recipients are protected; even at titers four times higher, breakthrough infections occur.[19] Similarly, high levels of pertussis antitoxin after immunization was related to protection both in household exposures and nonhousehold exposures, but mild disease occurred at intermediate levels of antibody. Owing to greater exposure, more

TABLE 3.2 Major Licensed Viral and Bacterial Vaccines for Humans According to the Mechanism of Disease Prevented by the Vaccine

VIRAL		
	Viremia:	Smallpox, yellow fever, measles Mumps, rubella, polio, varicella Hepatitis A, hepatitis B Japanese encephalitis, tickborne encephalitis
	Mucosal replication:	Influenza, rotavirus, human papillomavirus
	Neuronal invasion:	Rabies
	Neuronal reactivation:	Zoster
BACTERIAL		
	Bacteremia:	*Haemophilus influenzae* type b, Meningococcal, Pneumococcal, Typhoid (Vi)
	Mucosal replication:	Pertussis, typhoid (Ty 21a)
	Toxin production:	Diphtheria, tetanus, pertussis Cholera, anthrax
	Macrophage replication:	Tuberculosis

Severe	79 U/mL	99 U/mL
Mild	156 U/mL	124 U/mL
None	246 U/mL	155 U/mL

antibody was required to prevent infection within households than outside households (Table 3.3).[20]

Principle 6: Antibodies Must Be Functional

Although neutralization of viruses and killing of bacteria are often mCoP, it has been increasingly realized that there are other important antibody functions. First, Fig. 3.2 shows a case in which neutralization was definitely important, where titers were measured by neutralization or by hemagglutination-inhibition after vaccination with two different strains of rubella vaccines. As can be seen, both strains induced hemagglutination inhibiting antibodies, but RA27/3 stimulated considerably more neutralizing antibodies and proved to be the more protective vaccine.[21]

A study of meningococcal Group C polysaccharide vaccine conducted in Quebec showed the difference in function between antibodies measured by ELISA or by bacterial killing. Adults produced both types of antibodies and were highly protected; children 2 to 5 years old produced more antibodies and had moderate protection; and 1-year-old infants generated ELISA but little bactericidal antibody and had no protection.[22]

A striking example of the importance of antibody function has been reported after an HIV vaccine trial in Thailand. A regimen of priming with a canarypox vector presenting the viral envelope followed by a boost with envelope protein generated little neutralizing antibody, but did generate significant levels of antibody-dependent cellular cytotoxic antibody that potentiates natural killer cell activity. IgG3 antibody-dependent cell-mediated cytotoxicity (ADCC) antibodies directed against the V1-V2 loops of virus were shown to correlate with protection. This illustrated that there are many mechanisms by which antibody may protect.[23–26]

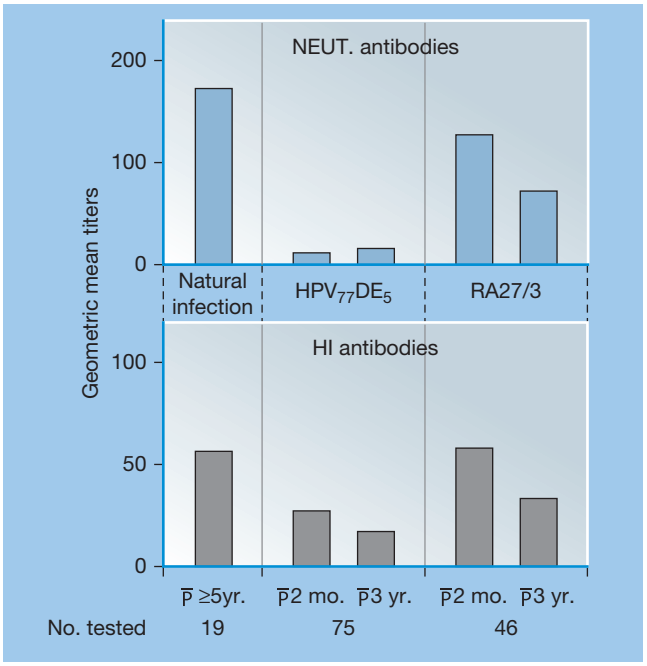

Figure 3.2. Antibody response to rubella vaccines. HI, hemagglutination inhibition; NEUT., neutralization.

Principle 7: T-Cell Responses May Be Correlates

It has usually been assumed that T-cell responses are the important protective correlate for bacille Calmette-Guérin (BCG) vaccine and tuberculosis in general, but it has been difficult to prove that assumption. Interferon-γ secretion has been thought to be important. A study of *Mycobacterium bovis* showed a correlation between interferon-γ–secreting T cells and protective immunity in cows.[27] However, although presumably related to T-cell function, it is uncertain as to which, and the mCoP for tuberculosis vaccine in humans remains elusive.[28–30] On the other hand, malaria is an example where T-cell responses appear to be crucial, and although antibodies to circumsporozoite protein (CSP) are also generated, they do not appear to be a CoP.[31,32] The RTS,S particle containing CSP generates tumor necrosis factor (TNF)-α producing $CD4^+$ cells that appear to predict protection.[33] In contrast, a vaccine based on intravenous injection of irradiated sporozoites depends for efficacy on CSP induction of $CD8^+$ T cells that produce interferon in the liver, where natural sporozoites must first replicate to launch infection.[34]

Although vaccination against chlamydia and tularemia bacteria is still experimental, there is abundant evidence that T-cell responses will be necessary for efficacy.[22,35–37]

There is clearly much still to be learned about T-cell responses as correlates because of the numerous functional classes of these cells. Although $CD8^+$ T-cell cytotoxicity is clearly one of the most important protective functions, $CD4^+$ T cells exist in many varieties with different helper functions for B and T cells that influence protection directly or indirectly through cytokine secretion.[38]

Principle 8: More Than One Factor May Protect as Cocorrelates

A good example of cocorrelates may be derived from studies of influenza. The live, attenuated intranasal vaccine generates both serum antibody and nasal IgA mucosal antibody.[39–41] In

vaccinated children challenged with another dose of the intranasal vaccine, virus shedding occurred at a high rate in vaccinees lacking both responses, at a low rate in vaccinees having both responses, and at an intermediate rate if only one response was present. Thus, the two responses were synergistic, or at least additive. In the case of inactivated influenza vaccine, two separate antibody responses seem important: that against the viral hemagglutinin and that against viral neuraminidase.[42–44] The former block virus entry and the latter block virus exit from the cell. Antibody responses may be poor in the elderly, but granzyme produced by $CD8^+$ cytotoxic T cells are also protective against symptomatic infection by limiting replication.[45–48]

Pertussis vaccines, whether whole cell or acellular, contain multiple components of the bacteria. Toxins and adherence factors are important in pathogenesis, and studies show that whereas antibodies against any of these reduces risk, antibodies against multiple virulence factors reduce risk even more.[49–51] T-helper cell (Th) 1 and Th17 responses also are important for duration of protection.[52–54]

A recent illustration of probable cocorrelates is the chimpanzee adenovirus vectored vaccine against Ebola virus. Whereas monkeys that generate ELISA titers of 2000 or more almost always survive an Ebola challenge, passive antibody did not protect and it appeared that $CD8^+$ T cells are needed for protection, particularly of antibody responses are low.[55–58]

Principle 9: Memory May Be a Mechanistic Correlate of Protection

Hepatitis B vaccine is highly immunogenic at birth, but antibodies are frequently lost later in life. Nevertheless, vaccinees are usually protected because they have an anamnestic antibody response when exposed to the virus.[59–62] Indeed, memory B cells are demonstrable in hepatitis B vaccinees in the absence of serum antibody.[63,64]

An interesting discovery was made recently in simian immunodeficiency virus (SIV)–infected rhesus monkeys. A rhesus cytomegalovirus vector containing various genes of SIV was constructed. The vector induced effector $CD8^+$ T cells directed against the SIV proteins and was able to abort early SIV infections in the monkeys.[65–67] Thus, effector memory of T or B cells is important in diseases for which dissemination occurs early, such as HIV, *H. influenzae* type b and meningococcus, but central memory is important in long incubation period diseases such as hepatitis B that allow for mobilization of an anamnestic response.

Principle 10: There Are Convenient Nonmechanistic Correlates

Zoster is the result of reactivation of varicella virus from dorsal spinal ganglia. The current vaccine consists of live varicella virus in large quantity or the gE protein of the virus. In both cases the vaccines elicit both antibodies and cellular responses. The best CoP is a $CD4^+$ T-cell lymphocyte proliferation index, but there is also a statistical correlation with antibodies to viral glycoproteins.[68,68a,68b] This suggests that the cellular immunity is an mCoP, whereas the antibody is an nCoP, which makes sense if the vaccines maintain the viral latency in the dorsal root ganglia, but it is not impossible that the neutralization of virus by antibody in the skin is also important.

Another example is from rotavirus vaccination. IgG antibodies can prevent infection when given orally or induced by inactivated rotavirus but the replicating live virus vaccines induce mucosal antibody and are effective.[69] However, measurement of mucosal responses is difficult, whereas measurement of serum IgA antibodies is easy. Thus, in the absence of a generally agreed mCoP, serum IgA provides a very useful nCoP.[70–72]

STATISTICAL ISSUES IN DEVELOPING IMMUNE CORRELATES OF PROTECTION

Developing CoPs involves statistical issues in two main areas: (a) development and selection of immunological assays and associated immune response biomarkers meriting study as correlates in preventive vaccine efficacy trials; and (b) statistical evaluation of the selected biomarkers in efficacy trials for their utility as CoPs. For area (a), statistical power for detecting a CoP is eroded for biomarkers with low signal-to-noise ratios[73,74] (e.g., from technical assay measurement error), making the standardized statistical evaluation and optimization of assays within and prior to efficacy trials fundamental for developing CoPs.[25,75–78] Moreover, with systems vaccinology research measuring high-dimensional data on immune responses to vaccination,[79–87] an important area of statistical research is classification of vaccinees into low-dimensional biomarker signature groupings[79,88–90] for assessment as CoPs. From now on we focus on area (b).

In the clinical trials statistical literature, a CoP is an immune response biomarker measured after vaccination that can be used to reliably predict vaccine efficacy (VE) against a clinical end point. Several approaches to defining and statistically evaluating CoPs based on efficacy trials have been proposed.[4,91–103] For CoP assessment, these approaches have been applied to search for thresholds of the biomarker that discriminate vaccinees into disease cases (and hence unprotected) versus undiseased controls (and hence putatively protected),[9,104–108] or to study how protection depends on the distribution of response.[109–111] However, many of these CoP methods do not define protected biomarker subgroups in terms of a causal effect of vaccination, such that an association of the biomarker with disease may not reflect a correlation with VE but rather with pathogen exposure or intrinsic susceptibility to the disease.[4,112–115] Addressing this limitation, the "VE curve" approach directly assesses how VE varies across vaccinated subgroups defined by the level of the biomarker.[4,113–119] With this approach, the most useful CoP has VE of zero for vaccinees with negative/absent immune response and VE near 100% for vaccinees with response above a threshold. A varicella zoster vaccine (VZV) efficacy trial[120] illustrates this approach, where VE to prevent herpes zoster varied widely with fold rise in VZV antibody titers ($P < .001$), with estimated VE of 90% for vaccinees with a 5.26-fold rise compared to 70% and 0% for vaccinees with a 2.39- and zero-fold rise, respectively.[6] These results provide a benchmark for high protective efficacy. As noted above, a useful CoP may or may not be a mechanism of protection.[6]

The major challenge of the VE curve approach is that it requires estimation of how the risk of the clinical end point for a placebo recipient depends on an unmeasured variable—the immune response to the vaccine that the individual would have had, if, counter to fact, the individual had been randomly assigned to receive the vaccine. Consequently, the VE curve statistical methods incorporate techniques for "filling in" the counterfactual immune responses of placebo recipients.[113,114,117,119,121–127] The "baseline immune response predictor" technique develops a model from vaccine recipients predicting individual immune response biomarkers from baseline variables, and applies this model to placebo recipients using these baseline variables. The "closeout placebo vaccination" technique crosses over placebo recipients at the end of study follow-up to receive the vaccine and have the immune response directly measured. Crucially, effective use of these approaches requires storing baseline samples in (almost) all

efficacy trial participants, to make possible measurement of preimmunization predictors of the candidate CoP in most disease cases; unavailability of baseline samples has been one of the greatest limiting factors for CoP assessment in efficacy trials.

We conclude by listing five other statistical issues that are faced in developing CoPs in efficacy trials. First, immune responses are typically only measured in a case-control[128–130] or case-cohort[131–134] subsample, motivating research into optimal sampling design[117,135–139] and analysis[129,130,140] methods.

TABLE 3.4 Correlates of Protection After Vaccination[a]

Vaccine	Immune Function	Protection Level	Type
Adenovirus	Nt Ab	1/4	M
Anthrax	Toxin Nt Ab, anti-PA IgG	1/3000, 10 μg/mL	M
Cholera	Vibrioicidal Ab	?	NM
Dengue	Nt Ab	Variable	M

[b]Depending on the specific vaccine, protection against typhoid is mediated by antibodies to flagella, the Vi capsule, O antigen, as well as cell-mediated immunity.
[c]Cellular responses also important.
[d]Surrogate for neutralizing antibodies.
Ab, antibodies; CMI, cell-mediated immunity; ELISA, enzyme-linked immunosorbent assay; FIM, fimbrial agglutinogens; GP, glycoprotein; HI, hemagglutination inhibition; Ig, immunoglobulin; LNI, log neutralization index; M, mechanistic; MNt, microneutralization; ND, not defined; NM, nonmechanistic; Nt, neutralization; OPA, opsonophagocytic; Prn, pertactin; PT, pertussis toxin.

Second, statistical methods are needed to develop cocorrelates, for example, by estimating VE surfaces across vaccinee subgroups defined by the level of two immune response biomarkers[114,119] or estimating VE curves for a univariable composite biomarker.[126] Moreover, for assessing complex correlates[3] based on high-dimensional immune response biomarkers, supervised machine learning methods are needed to estimate the best models of VE.[88,89,141,142] Third, two types of CoP analyses are defined by measuring the immune response biomarker at a fixed time point shortly after vaccination or at serial time points including just before exposure and infection or disease. Both analyses are important, the former primarily for developing practicable VE-predictive end points and the latter primarily for generating clues about mechanistic CoPs. Fourth, a highly predictive CoP for a particular disease end point, vaccine, and study population may fail for a different end point, vaccine, or study population,[143] indicating that metaanalysis of multiple efficacy trials combined with knowledge of mechanisms of protection is needed for bridging CoPs to new settings.[4,55,94,97,106,115,144,145]

Lastly, for genetically diverse pathogens, the whole discussion above applies to assessing CoPs against particular phenotypes or genotypes of the pathogen (e.g., through pathogen type-specific VE curves), with common application historically to assess serotype- or biotype-specific antibody titers as CoPs against disease with the same type.[146–151] In contemporary efficacy trials, pathogen genomes infecting study participants are sequenced, enabling a statistical sieve analysis that assesses how VE varies with sequence characteristics.[152] Immune response data can inform the sieve analysis by focusing the analysis on putatively protective epitopes such as highly vaccine-reactive peptides or specific reagents that were identified as CoPs.[153,154] Moreover, host characteristics other than immune responses (such as demographics, ecological factors, or genetics such as human leukocyte antigen [HLA] types restricting epitope-specific T-cell responses) may affect VE or type-specific VE, such that the overarching goal of VE curve CoP analysis may be stated as estimation of how VE varies jointly in pathogen sequence characteristics, immune response biomarkers, and any other host characteristics.[3,73,87,155]

COMPLEXITY OF CORRELATES

As Einstein said, "Everything must be made as simple as possible, but not simpler." We have attempted above to reduce this subject to simple principles, but one must recognize that in practice the determination of CoPs is difficult. First, it is necessary to repeat that CoP are not restricted to neutralizing IgG antibody or $CD8^+$ T cell cytotoxicity. Other immunologic responses, such as antibodies that stimulate natural killer cells,[156] Th17 T cells that prevent mucosal infection,[157] and T cells that secrete cytokines are examples of possible CoP.[158]

The CoP for influenza vaccine appears at first to be straightforward: hemagglutination-inhibiting antibody or perhaps neutralizing antibody. However, in children it appears that higher levels of antibody are necessary, perhaps because of the absence of prior influenza infections.[159] In the elderly the situation is even more complex, owing to immunosenescence, such that the presence of cytotoxic T cells may be necessary to protection against serious disease in the presence of a weak antibody response.[46]

A CoP for pertussis vaccine has long been controversial, but the use of acellular vaccines with a variable number of components has been educational. As stated above it appears that high-titered antibodies against pertussis toxin, pertactin, and fimbrial hemagglutinogens each provide some degree of protection and that there is synergy among those antibodies.[52] However, a T-cell response is critical to duration of antibody and to prevention of nasopharyngeal carriage, and Th17 cells are also important based on evidence from mouse and baboon models.[160,161] Thus, B and T cell responses act together for the best efficacy.[162]

The importance of $CD4^+$ T cell immunity to protection by the RTS,S malaria vaccine based on CSP was discussed above. However, protection induced by the liver stage multiple epitope-thrombospondin–related adhesion protein (ME-TRAP) antigen is mediated by $CD8^+$ T cells[163] and the merozoite MSP2 and -3 antigens act by induction of opsonophagocytic antibodies.[164,165]

In line with the doctrine that the immune system is redundant, there are multiple situations in which antibody is the first line of defense and therefore an mCoP, but where cellular immunity provides a backup in the event antibodies are low. Such may be the case for Ebola virus and yellow fever virus.[56,166] For some other agents the two arms of the immune system are synergistic, as in the case of the RTS,S malaria vaccine that induces both types of response against the circumsporozoite antigen of the parasite.[167,168] In other cases, the CoP varies with the type of vaccine. Whereas as described above, the canarypox vector/HIV protein vaccine for HIV depends for its efficacy on an ADCC antibody response,[156] a rhesus cytomegalovirus vectored vaccine that protected monkeys against SIV acts through induction of effector T cells.[66,67] In the case of human cytomegalovirus antibody to surface proteins protect against acquisition by contact,[169] but cellular immunity to internal antigens seems to be key in preventing transplant-associated disease in hematogenous stem cell recipients.[170]

Also still to be defined are CoP relating to mucosal immune responses. Mucosal IgA antibody produced by vaccination has been identified to be important to protection against influenza[39,171] polio,[172] and respiratory syncytial virus,[173] and probably is important for rotavirus vaccine.[70,174] Serum IgG antibody diffusing onto respiratory, gastrointestinal, and genital mucosae undoubtedly also can prevent infection but is poorly characterized.

CONCLUSIONS

The immune system is redundant, but the mCoP after vaccination in most cases is antibody that blocks the agent in the blood. Antibodies have varying functions and the mCoP will vary according to the vaccine. Cellular immunity may synergize with antibody or make up for its lack. Effector T-cell memory may be necessary for short incubation period diseases, whereas central memory with an anamnestic response is sufficient for long incubation period diseases. For some vaccines we do not know the true mCoP but we can use a nCoP that is not protective but is statistically correlated with protection. In general, there is a spectrum of correlates, ranging from pure antibody to the protective antigen in anthrax vaccine to the resurrection of cellular immunity to varicella virus that results from immunization with zoster vaccine.

Table 3.4 gives our best estimates of CoPs for currently licensed vaccines.

4 The Vaccine Industry

R. Gordon Douglas and Vijay B. Samant

The vaccine industry is composed of companies that are engaged in any of the following activities: research (including that performed in industry and biotech), development, manufacture, or sales, marketing, and distribution of vaccines. They receive their revenue chiefly from sales of vaccine products or expectations thereof. The vaccine industry is relatively small, compared to the pharmaceutical industry, but growing. We estimate that total infectious disease vaccine sales in 2013 were more than $25 billion worldwide and expected to grow to about $35 billion by 2020. Although components of the vaccine industry are found in 50 countries worldwide, the large vaccine companies are primarily U.S.- or European-based and have the dominant share of vaccine business on a revenue basis; but regional companies are gradually growing their market share on a dose basis (Table 4.1).[1]

In the past 20 years, the vaccine business, a former laggard in the pharmaceutical business, has shown remarkable growth powered by new innovative vaccines coupled with superior pricing strategies (Fig. 4.1).[2] Specifically contributing to this spectacular growth were the varicella, hepatitis A, pneumococcal conjugate, shingles, rotavirus, meningococcal conjugate for A, C, Y, W, and human papillomavirus (HPV) vaccines, as well as myriad combination vaccines.

This projected growth may plateau in the early 2020s unless the vaccine industry continues to introduce new innovative products targeting diseases that impact the Western world. Sustaining this growth will be a challenge because of dwindling numbers of high-value vaccine targets for which the biology of protection is well understood (see Table 4.7).

The vaccine business is a capital-intensive business that requires considerable ongoing investment in manufacturing assets, facilities, and people to maintain compliance with ever-increasing regulatory directives. The recent departure of Baxter and Novartis from the vaccine industry is an ominous sign that reflects the continued financial pressure on the remaining four major vaccine makers. Further consolidation of this business is likely. In addition, new alliances will be formed between the big four manufacturers and emerging companies in India, China, and Brazil, to take advantage of increasing immunization rates in those countries as well as growth of their private markets.

The United States has been extraordinarily successful in vaccine research and development (R&D).[3,4] In the past 20 years, most new vaccines approved worldwide were developed in the United States. Approximately 15 new vaccines were approved in the United States between 1995 and 2014.[5,6] Since then, combinations of existing vaccines have been introduced for simplified pediatric vaccination resulting in a wider adoption of acellular pertussis vaccination. A polyvalent pneumococcal conjugate vaccine for infants introduced by Wyeth (now a subsidiary of Pfizer) has been widely adopted and has made Pfizer a major force in the vaccine business. Since 2006, several new vaccines have been licensed, including a combination of measles, mumps, and rubella (MMR) and varicella, as well as new vaccines against rotavirus, herpes zoster, HPV, meningococcus, influenza, and others. The HPV vaccines developed by Merck and GlaxoSmithKline significantly expanded the field of adolescent vaccines and confirmed market acceptance of premium pricing.

In the last 10 years, the vaccine industry in the United States and Europe has considerably improved its reliability as a supplier. Chronic shortages are a thing of the past; this turnaround has primarily been achieved by modernization of vaccine manufacturing and distribution infrastructure supported and funded by the profitability of the vaccine business. The Centers for Disease Control and Prevention (CDC) stockpiling of pediatric vaccines has alleviated some concerns of critical shortages in case of supply interruptions. But the industry's vulnerability because of dependence on single-sourced vaccines continues to be an unresolved concern. The regulators and the industry must proactively develop a solution to this critical challenge and avoid any future public health crisis resulting from vaccine shortages during a prolonged supply interruption.

VACCINE DEVELOPMENT

Vaccine development is difficult, complex, highly risky, and costly, and includes clinical development, process development, and assay development. The risk is high because most vaccine candidates fail in preclinical or early clinical development and less than 1 in 15 vaccine candidates entering Phase II achieves licensure. The high failure rate is the result of a variety of reasons:

1. Not fully understanding the biology of protection.
2. Lack of good animal models to predict vaccine behavior in humans.
3. Unpredictability of human immune system reactions to antigens as it relates to immunogenicity or safety.
4. The unpredictability of the impact of combining multiple components in a vaccine.

Vaccine development requires strong project management systems and controls and requisite skill sets among scientists and engineers. A key strategic document that guides the stakeholders in vaccine development is the "target product profile" (TPP). The TPP summarizes the desired characteristics and features of the product under development, the key attributes of the product that provide competitive advantage, and, finally, a topline roadmap of nonclinical and clinical studies required to evaluate the products efficacy and safety in the target population. A well-defined TPP provides all the stakeholders, including research, process development, manufacturing, clinical, regulatory, and senior management, with a clear statement of the desired outcome of the product development program.

Process development involves making preparations of the test vaccine that satisfy regulatory requirements for clinical testing including clinical lots, preclinical toxicology testing, and analytical assessment, and finally, scale-up methods that lead to a consistent manufacturing process at one-tenth of full scale. Usually three consecutive lots are tested in the clinic for immunogenicity. Assay development involves the definition of specific methods to test the purity of raw materials, stability and potency of the vaccine product, and immunologic and other criteria to predict vaccine efficacy. Go/no-go decisions must be made at each stage of clinical and process development and

must be data driven. Clinical, process, and assay development tasks must be closely integrated. Clinical development involves studies of the effects of vaccines on patients for safety, immunogenicity, and efficacy through a staged process: phase 1, early safety and immunogenicity in small numbers; phase 2, safety, dose ranging, and immunogenicity in 200 to 400 individuals; sometimes phase 2b, nonlicensure, proof-of-concept trials for efficacy; and phase 3, safety and efficacy trials that permit licensure, which generally require thousands of subjects.

"Process" can be broadly divided into two categories: bulk manufacturing and finishing operations. Bulk manufacturing includes cell culture and/or fermentation-based manufacturing followed by a variety of separation processes to purify the vaccine. The finishing operations include formulation with adjuvant/stabilizer followed by vial or syringe filling (including lyophilization in the case of live viral vaccines) followed by labeling, packaging, and controlled storage. Process development may be as costly as clinical development and is critically important to the overall success of a vaccine development program. As development proceeds toward licensure, costs escalate as clinical studies become larger, manufacturing scales up, and facilities must be built. Postlicensure studies of safety and efficacy (phase 4) of vaccines are essential and represent a large additional cost. It is important to note that, unlike pharmaceuticals, vaccines that pass early proof-of-concept studies in humans have a very high probability of achieving licensure.

Clinical activities are more visible than bioprocess development and clearly drive the go/no-go decisions that direct progress. The two are interwoven and each has rate-limiting steps, so they must be done in concert.

The first stage of vaccine development involves acceptance of a candidate from a basic research laboratory and development of a small-scale process and formulation to make material for Phase I study, analytical release assays, preclinical toxicology, immunological assays to evaluate clinical responses, an investigational new drug (IND) filing, and well-designed Phase I/IIa studies.

The second step is to complete the definition of product and process prior to initiation of Phase II dose-ranging studies, which may take a year or more. Product definition includes methods of synthesis/bioprocess steps, number of components, and stability/formulation. Stability, release, and raw material assays must be in place. Immunologic and other assays must be established to support dose-ranging studies, and a regulatory plan for vaccine process and product submissions must be written.

The third step is to define the clinical dose and arrive at the appropriate manufacturing scale, which may take 2 years or more. It results in the identification, manufacture, filling, and release of clinical-grade vaccine—usually in a pilot plant—demonstration of safety and a dose response in a Phase II clinical study; validation of critical assays to support Phase III clinical studies; consistency of lot manufacture (ability to produce three or more consecutive production-scale lots that meet all product specifications based on validated analytical methods); and completion of technology transfer to final site

TABLE 4.1 Market Shares of Vaccine Companies, 2014

Company	Year-End Earnings ($ Billion)[a]	Market Share (%)

of manufacture of full-scale lots, including process and analytical procedures. For vaccine targets for which animal studies are not predictive of efficacy in humans, such as HIV, malaria, and tuberculosis (TB), small Phase IIb proof-of-concept studies based on adaptive clinical trial designs may be used to gain confidence before committing significant resources for process development, analytic development, and factory construction.

In general, the analytical and release assays are particularly difficult to develop because, in most cases, vaccines are considered "not well-characterized" biologicals by regulatory agencies. The release assays initially involve functional potency assays such as animal immunogenicity prior to acceptance of more robust and precise in vitro assays that correlate with these functional potency assays. In general, variability of biological assays is a major hurdle in achieving process scale-up and manufacturing consistency.

The fourth stage is the completion of Phase III pivotal clinical studies and corresponding consistency lot studies, which requires 3 to 5 years. Keys to successful Phase III clinical studies are an accurate estimate of sample size based on disease incidence, low dropout rates, precise clinical end point definitions related to future label claims, and rigorous data management to the highest standards. In addition to clinical studies, scale-up and manufacture of consistency lots, including transfer to the facility of all assays, facility validation, demonstration of consistency and real-time stability are needed to support adequate shelf-life claims.

The final stage is Biologics License Application (BLA) preparation, licensure, and vaccine launch, which requires 1.5 to 2 years. Thus the total elapsed time for development is 10 to 15 years, assuming all activities proceed as planned.

Manufacturing plants are very expensive to construct, ranging from $50 million to $300 million depending on the size (dose requirements) and manufacturing complexity, with an additional expenditure of approximately 20% of that cost for cleaning and process validation activities that are now required under the current good manufacturing practices regulations. With few exceptions, each vaccine requires a different plant because of unique manufacturing requirements and the regulatory difficulties associated with changing over to a different product. Some processes are scalable, such as bacterial or yeast fermentation, so that increasing the size of the manufacturing unit (i.e., fermenter) will greatly increase the yield; unit cost will decrease with volume increase. Other manufacturing processes, for example, those dependent on viral growth in embryonated hen eggs or cell lines, are not scalable. Additional plants or modules within plants must be built to increase the throughput, so unit costs do not appreciably decrease with volume increases. Despite the complexity of bulk vaccine manufacturing, 3 to 5 years post–product launch, the fully burdened bulk cost of production for most of the older vaccines declines to as little as $0.50 to $1.00 per dose, and significant elements of product cost are primarily driven by activities related to filling, vialing, and packaging (Table 4.2). Established vaccines with a limited number of suppliers can generate very high profit margins over the product life cycle.

The commitment to build a plant must be made early (4 to 6 years before expected licensure) including a 6- to 12-month finished goods inventory build-up to expedite product to the market. Otherwise a gap of 1 to 5 years between licensure and product launch will occur.

Furthermore, it is far better to produce consistency lots in the final vaccine production factory to demonstrate the ability to manufacture the vaccine reliably and to use those lots in the Phase III efficacy trials. Otherwise, immune studies will be required for "bridging" the product used in the efficacy trial to material manufactured in the commercial factory. This is especially difficult if immune studies are not highly reproducible, as is the case with most cellular immune assays. Such decisions pose large financial risks if the product in development fails and requires access to large amounts of capital, an attribute usually restricted to large pharmaceutical companies.

TABLE 4.2 Vaccine Product Cost

	$/Dose
Bulk[a]	0.20–3.00
Fill/finish[b]	1.00–1.50
Syringe fill (optional)[c]	1.00–2.00
Total cost[d]	2.20–6.50

[a]Bulk range reflects older vaccines such as measles-mumps-rubella (MMR) and hepatitis B, at the low end, to newer vaccines such as shingles and live attenuated influenza at the high end.
[b]Fill/finish range reflects differences in speed, volume, and efficiency of operations.
[c]Syringe-filled product reflects cost of syringe and reduced line efficiency.
[d]Estimated fully burdened manufacturer's cost for U.S.-based operations in 2012.

TABLE 4.3 Vaccine Development Time Lines

Vaccines	Years to Approval

FluMist	25–30
Human papillomavirus[a]	14–16
Rotavirus[a]	14–16
Pediatric combination vaccines	10–12

[a]From filing of first investigational new drug to approval.

Estimates of cost of development of a new drug or vaccine have risen from $231 million in 1991, to $802 million in 2003, to $1 billion in 2010.[7–9] These estimates take into account all costs, including R&D costs of products that fail, postlicensure clinical studies, and improvements in manufacturing processes. Approximately 50% of the cost is for construction; the remainder is the cost of capital interest. These numbers have been debated (others estimate $100 million to $200 million); however, the higher estimates have been validated in two ways. First, the number of new vaccines brought to licensure annually by a company or the industry is very small compared with other products, and correlates with R&D expenditures of $600 million to $800 million for each new product. Thus, if a company spends $100 million annually for vaccine R&D, one might expect one new product every 6 to 8 years, and this appears to hold true. Second, biotechnology companies that are focused on one vaccine and have successfully brought it to market have spent $500 million to $700 million on R&D as exemplified by the development of the live attenuated influenza vaccine by Aviron, now Medimmune. In summary, vaccine development from concept to licensure is a lengthy process as illustrated by timelines for some of the currently licensed vaccines (Table 4.3).

ROLE OF PARTNERS

To understand the predominant role of major pharmaceutical companies in the development of vaccines, one must examine the role of a vaccine development company in relation to its

TABLE 4.4 U.S. Network Partners' Relative Contributions to Vaccine Research and Development

partners. The relative contributions of the various partners to the delicate fabric of vaccine R&D is shown in Table 4.4.[10] Several branches of the U.S. government play major roles in vaccine R&D.

The U.S. National Institutes of Health (NIH) is the major funding source via intramural and extramural (largely academic) programs of fundamental research (e.g., gene-based vaccines or T-cell memory studies) and directed research on pathogens (e.g., HIV), which may lead to new vaccine candidates. The NIH, through its vaccine trials network, has increased its role in clinical development domestically and internationally. In addition, the Dale and Betty Bumpers Vaccine Research Center at the NIH was established in 1999 primarily to pursue the development of HIV vaccines.

The Centers for Disease Control and Prevention (CDC) is the primary government agency responsible for epidemiological monitoring of disease trends. The CDC conducts disease surveillance and epidemiological studies to ascertain the prevalence and incidence of specific diseases; this information provides a rationale for prioritizing vaccine development. These studies by the CDC are performed in addition to studies conducted by the vaccine companies, such as Phase IV studies. Through the Advisory Committee on Immunization Practices (ACIP), the CDC recommends usage of vaccines, and is responsible for most of the public purchases (directly through the Vaccines for Children program for approximately 41%, and indirectly through other federal, state, and local government purchases for approximately 16%, together totaling approximately 57% of all childhood vaccines in the United States), thereby playing a major role in determining the demand and potential profit associated with vaccines. Professional organizations such as the American Academy of Pediatrics and the American Academy of Family Physicians also make recommendations for vaccine usage. There is no federal vaccine program for adults, although Medicare does reimburse for influenza and pneumococcal conjugate vaccines. Historically, many adults with private insurance were not covered for immunizations. However, the Affordable Care Act of 2010 requires health plans to cover vaccines recommended by the ACIP prior to September 2009 with no copayments or other cost-sharing requirements when those services are delivered by an in-network provider.

The Department of Defense (DOD) does targeted vaccine R&D to help it perform its mission of protecting deployable personnel and their families against infectious disease threats in the United States and abroad. Thus, the DOD assesses infectious disease risks in specific theaters and establishes prioritization of vaccine targets, especially those not being funded and developed in the private sector.

The U.S. Army Medical Research and Materiel Command (USAMRMC) is a major DOD organization conducting basic and applied medical research programs supporting military operations. The U.S. Army Medical Material Development Activity is its advanced product development agency, which aligns closely with the Walter Reed Army Institute of Research, the U.S. Army Medical Research Institute for Infectious Diseases, and the Naval Medical Research Center in conducting or supporting surveillance studies and vaccine trials. USAMRMC's longstanding overseas laboratories (e.g., in Thailand and Kenya) provide opportunities for the United States to partner with host nations in the development and evaluation of vaccines of shared interest. Some of the more recent efforts have focused on vaccines against malaria, dengue, HIV, norovirus, and Ebola. The Biomedical Advanced Research and Development Authority (BARDA) within the Health and Human Services Department was established in 2006 to facilitate development and purchase of vaccines and other products for public health emergencies. BARDA also manages Project Bioshield for the procurement of advanced medical countermeasures for biological as well as other threats and has successfully developed medical countermeasures against smallpox, anthrax, and botulinum toxin. In addition, BARDA is funding a variety of early stage novel vaccine approaches for pandemic influenza. BARDA essentially is intended to overlap with and close the gap between NIH-funded preclinical or initial Phase I trials and the more advanced Project Bioshield programs that are in late stage Phase III or licensure stages of development.

The U.S. Agency for International Development (USAID) supports limited R&D targeted toward those vaccines that potentially will have the greatest impact on children younger than age 5 years in developing countries. The Center for Biologics Evaluation and Research (CBER), a division of the U.S. Food and Drug Administration (FDA), is responsible for licensing new vaccines. CBER establishes standards for manufacturing processes, facilities, and pre- and postlicensing clinical studies to ensure that licensed vaccines are safe and effective (see Table 4.4). These standards have a profound

impact on the nature and direction of vaccine development and its costs. In addition, CBER maintains a strong research base internally, so it is better positioned to evaluate data from various studies. CBER remains the premier vaccine regulatory agency in the world.

Nongovernmental organizations (NGOs) are playing an increasing role in vaccine research. The Bill and Melinda Gates Foundation supports several organizations including the International AIDS Vaccine Initiative, the Malaria Vaccine Initiative, Aeras (dedicated to developing TB vaccines), and others with significant funding for development of vaccines that would have the greatest impact on diseases of developing countries. In addition, a related organization, Programs for Appropriate Technology in Health (PATH), is a nonprofit group that forges private sector partnerships to develop vaccine technologies suitable for the developing world. These product development partnership organizations (PDPs; essentially not-for-profit biotech companies) bring together specialized knowledge, animal models, immunologic assays, and field sites for vaccine testing as well as early capital investment to reduce the scientific technical risks, opportunity costs, and financial risk to their biotech and large pharma industrial partners. They also provide opportunities for validation of novel vaccine technologies and platforms.

The role of large, full-service vaccine companies (Table 4.5)[12] is predominantly in development. They engage

in some limited basic research and significant amounts of targeted research regarding specific organisms, but the preponderance of activity is in clinical and process development. Sufficient personnel and expertise in process development and chemical engineering reside almost exclusively in these companies; there is no other resource for such development. Clinical development that will satisfy FDA standards is also done mostly by the large companies, performed by academia and contract research organizations. Personnel and expertise in clinical research, regulatory affairs, data management, statistics, project management, and all other required disciplines also exist within the large companies. Perhaps most importantly, their management is structured to make rapid go/no-go decisions required to minimize risk and assess efficient vaccine development.

Many smaller organizations, often referred to as biotechnology companies, are engaged in vaccine research. They are often started by university scientists, supported by venture capitalists, and are capable of basic research on a vaccine idea. At this early stage, they usually have limited capacity in process development, manufacturing, and clinical development, and none in distribution, sales, or marketing. If research results are favorable, capacity in process engineering, clinical studies, and manufacturing must be enhanced or obtained by partnering. Because of the large cost of adding new capacities and expertise, many biotech companies in advanced product development will opt to partner with large, full-scale companies.

Although 60 or so small companies claim engagement in vaccine R&D, only about a dozen or so consider it a major activity, and only a very few, such as MedImmune, have made it to the market or close to the market on their own. More have licensed their products or technology platforms to larger companies that have then completed development, yielding new vaccines such as those for hepatitis B and *Haemophilus influenzae* type b. For example, the hepatitis B innovation came from the research laboratories of Chiron Corporation that succeeded in making hepatitis B surface antigen in yeast, and thus enabling Merck and GlaxoSmithKline to commercialize the modern hepatitis B vaccines. In the case of *H. influenzae* type b (Hib), Praxis Biologics and Connaught Laboratories pioneered the development of Hib polysaccharide and conjugate vaccines. These companies were eventually acquired by Sanofi and Wyeth-Lederle, respectively.

The greatest contributions of the biotechnology companies have been the introduction of multiple ideas into early vaccine development, and testing them to determine if they should be rejected or carried forward. These small companies are dependent on several factors for their success:

1. A vibrant basic research environment that allows for creation of new ideas, an environment that exists in well-funded (NIH) academic research programs.
2. A strong venture capital and investment community that views vaccine companies as potentially financially rewarding as other investment opportunities.
3. Strong patent laws providing the intellectual property protection that is essential for commercial success.

FUNDING SOURCES FOR VACCINE RESEARCH AND DEVELOPMENT

Funding sources for vaccine R&D include government, profits from sales of product, risk capital, and charitable foundations. The NIH competes with other federal agencies and programs for taxpayer support, and, in general, has been more successful than most. Similarly, vaccine R&D sponsored through the DOD, FDA, CDC, and USAID is competitive with other public needs as determined by the executive and legislative branches of government. Recent funding for bioterrorism vaccines (anthrax, smallpox) and emerging pathogens (Ebola, West Nile virus, severe acute respiratory syndrome [SARS], Middle East respiratory syndrome [MERS], pandemic influenza) could have long-reaching impact on vaccine research and manufacturing and could potentially create new entrants into the vaccine business.

Risk capital from private investors is the primary source of funds for small companies. Investors are attracted to the potential profits of a new vaccine, a forecast determined in part by sales of current vaccines. Large vaccine companies, which are divisions of much larger pharmaceutical companies, seek a profit by selling products. On average, pharmaceutical companies reinvest approximately 18% of their profits from product sales into R&D, and this proportion applies to vaccine sales as well as other pharmaceutical products (Pharmaceutical Research Manufacturers Association, personal communication, 2001).

Because vaccine companies are subsidiaries of large companies, vaccine R&D and manufacturing must compete with other product areas for resources. Comparisons of the economics of the vaccine industry with the pharmaceutical industry in Europe, and separately in the United States, were performed by the Mercer Consulting Company in 1995 (Fig. 4.2).[13] These studies in the United States showed that the

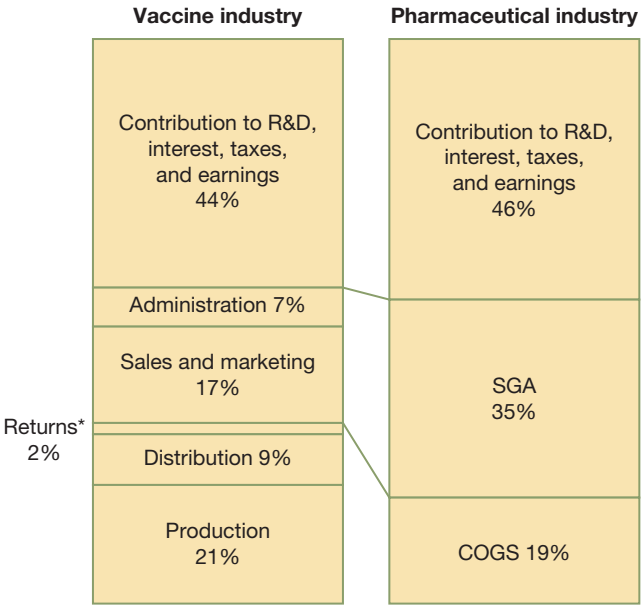

Figure 4.2. Major U.S. vaccine suppliers value-added chain (versus pharmaceutical industry averages). COGS, cost of goods sold; R&D, research and development; SGA, sales, general, and administrative costs. *Negligible returns (products that are sold and subsequently returned for a refund) in the pharma business. *(From Mercer Management Consulting Testimony on vaccine policy before the U.S. House of Representatives Committee on Commerce, June 15, 1995.)*

contributions to R&D, interest, taxes, and earnings after expenses were similar for the two industries (44% vs. 46%, respectively). However, the expenses were quite different. Significantly more was spent on production and distribution (32%, which includes production, distribution, and returns of product) in the vaccine industry compared with the pharmaceutical industry (19%), whereas the pharmaceutical industry spent more than the vaccine industry on sales, marketing, and administrative expenses (35% vs. 24%, respectively).

Consequently, within companies, there is an expectation that sales-to-expense ratios for vaccines will be similar to those of other pharmaceutical products, and that revenues will increase every year. Although some of this increase may be accomplished with sales volume, prices stabilize as vaccine products mature, and increased revenues are no longer possible; hence, the requirement for a steady rollout of new products. However, unlike pharmaceuticals, old vaccines continue to be profitable for a variety of reasons, including:

1. The absence of a regulatory pathway for generic vaccines deters potential entrants from engaging in a complex and expensive approval process.
2. In most cases, access to knowhow, such as proprietary cell lines, virus strains, and internally developed processes, is far more valuable than patent protection.
3. The birth cohort is renewable, providing an ongoing unmet need for vaccines.

As a result, sole-sourced vaccines, manufactured in fully depreciated assets, are profitable for pharmaceutical companies. One such example is the MMR vaccine, which after 40 years still has no competition in the United States. A typical vaccine company will have several vaccine candidates in early development, defined as all R&D through Phase I clinical testing (Table 4.6).[14-17] Those that are most promising in terms of technical feasibility, strong patent protection, and potential market size will be taken forward into development (post–Phase I). In addition, other candidate vaccines might be licensed from small companies. Even in the largest companies, only a few products can be in development at the same time. Thus, go/no-go decisions must be made and market size is a major determinant of the choice between two candidate vaccines, otherwise equal in technical feasibility and likelihood of success (Table 4.7).

This system works extremely well for vaccines with large potential markets in the developed world when technical feasibility is demonstrated. It does not work for vaccines for diseases that exist predominantly in the poorer regions of the world (e.g., TB); it works imperfectly for diseases of the developed world that affect relatively few persons because of geographic restriction (e.g., Lyme disease) or diseases limited to specific risk groups (e.g., cytomegalovirus [CMV] in transplant recipients), and it does not work when technical feasibility has not been demonstrated (e.g., HIV). The last problem has to be solved by a strong basic program in vaccine-related sciences, particularly for HIV, *Staphylococcus aureus*, malaria, and other challenging targets. Niche vaccines for developed-world markets are much more attractive to biotech than to large pharmaceutical companies as evidenced by recent biotech vaccine efforts for West Nile virus, Japanese encephalitis virus, the CMV-transplant indication, and dengue.

To involve large companies in development and manufacturing of vaccines to meet needs such as biodefense or health needs of poorer countries, incentives must be established to convince these companies that they should develop and manufacture such products. Such incentives might take the form of guaranteed purchase of certain volumes of a vaccine if specified standards are met, direct contracting by a government agency, or some other publicly funded mechanism.[18,19] The use of Advanced Market Commitments to create a funding mechanism for vaccines needed in the developing world has been endorsed by the G8 and pilot projects may be starting soon. This will not solve the problem of the high technical risk and opportunity costs associated with such vaccines, but it may contribute to the solution if combined with early investment. Companies may be willing to engage in such work. Indeed, they may already have donated or sold vaccines at very low prices to poorer countries. However, such practices alone will not solve the enormity of the health problems worldwide. Without special incentives, it is unrealistic to expect companies to engage in R&D on diseases that only, or predominantly, affect the poorer regions of the world.[13]

Manufacturers in developing countries (initially in India and China, and more recently in Brazil) are playing an increasing role in meeting these needs. Indeed, they already supply the majority of doses of older vaccines for such countries. As their expertise and capacity in vaccine R&D increases they will perhaps evolve into major participants in supplying new vaccines to the developing world. There are numerous manufacturers in these emerging countries, but a few truly stand out.

India

The vaccine industry has slowly mushroomed in India with several key companies emerging including Bharat Biotech, Biological E., Panacea Biotec, and others, but the largest one is the privately held Serum Institute of India. The Indian vaccine industry has significantly benefited from technology transfer from the West. Despite the industry's success, the available estimates suggest that R&D spending remains relatively low as a percentage of sales.[20]

Serum Institute of India is the world's largest producer of vaccines by number of doses, producing 1.3 billion doses

a year; its products are used in more than 140 countries. Serum Institute is also one of the largest suppliers of measles-containing vaccines and the diphtheria-tetanus-pertussis (DTP) vaccines to U.N. agencies (UNICEF and Pan American Health Organization [PAHO]). The Institute makes its measles vaccine in MRC-5 cells instead of chick embryos and has productivity estimated at 10- to 20-fold higher than the measles vaccines made by Merck and GlaxoSmithKline. This privately held vaccine company has relentlessly invested in production facilities/infrastructure that surpasses some of the best biotech manufacturing facilities in the United States. So powerful has its growth been that one out of every two children immunized worldwide get at least one vaccine produced by the Serum Institute.

Vaccines recently developed by the Serum Institute are Nasovac (live attenuated trivalent influenza vaccine), MenAfriVac (meningococcal A conjugate vaccine), Pentavac (DTP Hepatitis B-Hib vaccine), and inactivated polio vaccine. The Institute continues to invest in R&D and is currently working on a rotavirus vaccine, a polyvalent meningococcal conjugate vaccine, a pneumococcal conjugate vaccine, and HPV Vaccine, combination vaccines containing acellular pertussis, and others.

China

China ranks as the world's largest vaccine consuming and manufacturing country, with an estimated annual output of 1 billion doses.[21] The original six government-owned regional biological institutes are now part of the China National Biotec Group (CNBG) consolidated under the China National Pharmaceutical Group Corporation (Sinopharm Group Co., Ltd.). CNBG has a large R&D center in Beijing that maximizes the synergies of the six affiliated institutions. Today, CNBG/Sinopharm supplies 85% of the doses of the 14 Chinese National Immunization Program vaccines. China's vaccine manufacturing capabilities are currently intensely focused on supplying their own domestic needs for the pediatric birth cohort of 17 million newborns annually. There are 46 registered vaccine manufacturers in China and 24 licensed vaccines. Several of the manufacturers are members of the Developing Countries Vaccine Manufacturers' Network (DCVMN). In 2013, the World Health Organization prequalified the Chinese-made Japanese encephalitis virus vaccine made by the Chengdu Institute for Biological Products in collaboration with PATH.[22] China became the first country ever

to approve a hepatitis E vaccine, which was developed by Xiamen Innovax Biotech.

Brazil

Brazil has four notable vaccine manufacturing companies. Bio-Manguinhos/Fiocruz is a government-owned entity that supplies the full demand for most vaccines under the Brazilian National Immunization Program (NIP). They also have a R&D collaboration with GlaxoSmithKline for a dengue vaccine. Butantan Institute is another government-owned institution that supplies the full demand for a smaller number of vaccines under the Brazilian NIP. Ataulfo de Paiva Foundation is nonprofit private institution that primarily supplies the BCG vaccine for the Brazilian market. Ezequiel Dias Foundation (FUNED) is a public institution and part of Minas Gerais state. Since 2009, it has supplied the meningococcal conjugate vaccine after transferring the technology from Novartis.

Summary

The Indian vaccine industry is the most advanced among these three developing countries, and is already providing a significant portion of the world's vaccine supply as well as developing new vaccines. China is on the verge of the transition from a domestic-only provider to a vaccine exporter, and is demonstrating solid progress in vaccine innovation. Brazil is approaching the point of supplying its own domestic needs, largely with technology transferred from the developed world. Together, these emerging players from middle-income countries will have increasing influence in the global vaccine industry during the coming years.

PRICING OF VACCINES

Pricing is a critical component of success for large companies and for venture funding of small companies since potential sales determine the desirability of an investment decision. The public expectation is for low vaccine prices, although this has changed somewhat in recent years with the introduction of several new, higher priced vaccines, such as varicella, rotavirus, pneumococcal conjugate vaccine, zoster vaccine, and HPV vaccine (Fig. 4.3). Large companies believe that vaccines should be priced according to value to society such as reduction in health care and related costs, relief from pain and suffering, and/or prevention of death, and that they should be rewarded for taking the enormous risks inherent in early vaccine development. Such prices far exceed manufacturing costs, but are essential to produce the revenue streams that allow vaccines to be competitive for R&D and manufacturing resources within large pharmaceutical companies or that make biotech companies attractive investment opportunities. In general, vaccine prices have declined when more than two companies have competed in a single vaccine market and profitability has fallen sharply. The influenza vaccine market highlights this cyclical ebb and flow of competitors, most recently with the H1N1 outbreak and shortages in 2009 leading to expanded competition and a vaccine surplus, followed by lower prices in 2010.

A vigorous large-company vaccine industry is dependent upon several factors:

1. A rich research environment sponsored largely by the NIH and mostly carried out in academia, as the source for new creative ideas.
2. Strong patent laws and protection of intellectual property.
3. Freedom to price products at fair levels related to value of product to society.
4. Well-implemented immunization practices.

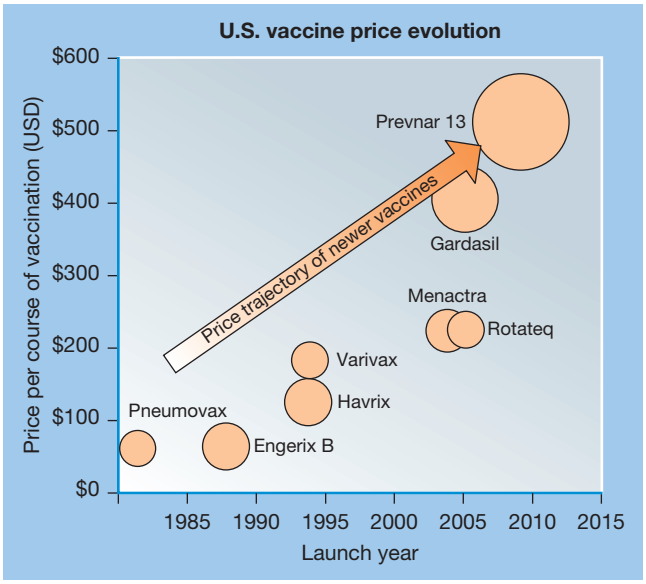

Figure 4.3. U.S. vaccine price evolution. Prices for vaccines are increasing relative to traditionally mandated products. USD, U.S. dollars. *(Data from U.S. CDC, IMS Knowledge Link, and NY Pharma Forum–Global Vaccines Outlook. Courtesy Kevin Fitzpatrick and Nitin Mohan of IMS.)*

Although the first two of these factors have been consistently present in recent years, downward pressure on price is a major threat to current companies and a disincentive to new companies. Freedom to price vaccines is restricted to the private market. Less than 50% of the vaccines for children sold in the United States are sold in the private market; the rest are sold to the federal or state governments at reduced prices. Controls are even greater in Western Europe and Japan, and internationally there is strong downward pressure on prices as one moves from well-developed to less-developed regions of the world.

In addition to the burden of partial price controls, the vaccine industry is subject to intense regulation. It cannot sell products until the vaccine and the facility in which it is manufactured are approved by the FDA or other regulatory authorities; each batch must be released by the appropriate regulatory agency; and the usage, and therefore market size, is largely determined in the United States by the CDC and in Europe by national regulatory authorities. Thus, the vaccine industry does not operate in a free-market environment, and its behavior reflects these constraints.

Vaccine business growth in the future will have three important drivers:

1. New vaccines for CMV, herpes simplex virus (HSV), respiratory syncytial virus (RSV), norovirus, *Clostridium difficile*, enterotoxigenic *Escherichia coli* (ETEC), "improved influenza," and others that will gradually shift the focal point of immunization activities from the pediatric sector to the adolescent and adult sectors.
2. Private market expansion in India and China driven by "high-income family" birth cohorts of 2 million and 6 million, respectively. This birth cohort roughly equals the combined birth cohort of 8 million in the United States and Europe. These high- and even middle-income individuals have shown the desire and ability to pay for vaccines at relatively high prices in relation to their incomes in these and other countries.

3. Public–private partnerships, or PDPs, on emerging pathogens such as pandemic flu, anthrax, SARS, botulism, Ebola, and others, will lead to large-scale manufacturing opportunities for these products. Toward the end of the 2020s, the PDPs for TB, malaria, and HIV are expected to produce effective vaccines for these diseases. A Boston Consulting Group study reports a surprising greater than $600 million per year market for a new TB vaccine (personal communication, 2012). Assuming such vaccines become reality, there is little doubt that the international donor community, working through organizations such as the Global Alliance for Vaccines and Immunization, will provide adequate funds for purchase of effective malaria, HIV, and TB vaccines, all of which are cost-effective, both in terms of cost per life saved and macroeconomic development of poor countries.

Vaccine Market

Estimates of the total worldwide vaccine market revenue are $25 billion. The top four Western suppliers (see Table 4.1) account for approximately 85% of these sales; the remainder comes from regional vaccine companies, the largest of which are located in middle-income countries such as India, China, and Brazil (see Table 4.5). The top four companies are slowly losing market share in doses to the DCVMN sourced doses and when polio eradication is achieved their dose share will drop to less than 20% of worldwide dose volume. In the coming years, as the eradication of polio becomes a reality, the developing country manufacturers will phase out their oral polio vaccine production. However, the need for inactivated polio vaccine will grow as developing countries adopt it into their pediatric immunization plans. As the demand for injected polio vaccine grows in developing countries, alternative approaches for local production will be explored, including access to bulk injected polio vaccine, tech transfer by big pharma as a part of their strategic alliances in developing markets, and potential introduction of alternative injected polio vaccine strains such as the Sabin strain. Another key driver will be the expansion of vaccine markets in India, China, and Brazil. Vaccine uptake rates in India, China and Brazil are still low compared with western countries (e.g., India's flu vaccine uptake in 2014 was 1.0 million doses vs. 140 million doses in the United States).[23,24] The immunization rates are also expected to increase in other low-income countries, which will increase vaccine dose requirements substantially. Most of this demand in low-income countries is expected to be met by manufacturers of DCVMN network. As the DCVMN expands its role, one would expect significant downward pressure on vaccine prices.

The delicate balance between innovation, government support, industrial expertise, and market forces has led to the establishment of a robust vaccine industry that will continue into the future. The industry is changing, however, with the growth of new markets in emerging economies and with the pressing need for new vaccines for the developing world. The current efforts of PDPs and public creation of markets in response to this need will be successful if lessons learned from the industrial vaccine effort are incorporated into these government and philanthropically driven expectations.

5 Vaccine Manufacturing

Phillip L. Gomez and James M. Robinson

The vast majority of the more than 1 billion doses of vaccines manufactured worldwide each year are given to perfectly healthy people.[1–4] It is this fact that drives the requirements for vaccines to be among the most rigorously designed, monitored, and compliant products manufactured today. The ability to manufacture these vaccines safely and consistently is built on four competencies:

1. The manufacturing process that defines how the product is made;
2. The compliance of the organization to successfully complete that process;
3. The testing of the product and supporting operations; and
4. The regulatory authorization to release and distribute the product.

This chapter examines how each of these components is established during the development of a new vaccine and how the field of vaccine manufacturing is responding to emerging challenges for increased capacity (e.g., pandemic influenza vaccine), increased safety assurance (e.g., barrier isolator filling), and increasing complexities of manufacture (e.g., conjugate vaccines). All of this must be accomplished while consistently delivering more than 1 billion doses annually at the relatively low cost of similar therapeutic products.

In the United States, vaccines are regulated as biological products. The U.S. Food and Drug Administration's (FDA) Center for Biologics Evaluation and Research (CBER) is responsible for regulating vaccines. Current authority for the regulation of vaccines resides primarily in Section 351 of the Public Health Service Act and specific sections of the Federal Food, Drug and Cosmetic Act.[5,6] Section 351 of the Public Health Service Act gives the federal government the authority to license biological products and the establishments where they are produced.[7] Vaccines undergo a rigorous review of laboratory, nonclinical, and clinical data to ensure safety, efficacy, purity, and potency. Vaccines approved for marketing may also be required to undergo additional studies to further evaluate the vaccine and often to address specific questions about the vaccine's safety, effectiveness, or possible side effects.[8]

In the European Union, animal and human vaccines are regulated by the European Medicines Agency (EMA), whose main responsibility is the promotion of public and animal health. The EMA's Committee on Medicinal Products for Human Use through its Vaccine Working Party has oversight for human vaccines. Vaccines are licensed through a centralized procedure that allows for simultaneous licensure within all countries within the European Union. Human vaccines manufacturing is regulated under a Good Manufacturing Practices (GMP) Directive 200/94/EEC, Annex 16, and Annex 2.

Harmonization of licensing and regulating procedures for vaccines worldwide has obvious benefits in rapidly delivering safe and effective vaccines to the market. Impediments to harmonization include lack of standardized regulatory procedures and mutual recognition of licenses and inspections between countries and worldwide regulatory agencies. Harmonization of regulation continues to progress as joint FDA-EMA establishment inspections programs have become a reality and adherence to International Conference on Harmonisation (ICH) guidance is expected.

New vaccines are subjected to a well-defined regulatory process for approval. The approval process consists of four principal elements:

- Preparation of preclinical materials for proof-of-concept testing in animal models; manufacture of clinical materials according to current GMP; and toxicology analysis in an appropriate animal system.
- Submission of an investigational new drug (IND) application for submission to FDA for review.
- Testing for safety and effectiveness through clinical and further nonclinical studies (Phase I to Phase III clinical studies).
- Submission of all clinical, nonclinical, and manufacturing data to the FDA and EMA in the form of a Biologics License Application (BLA) for final review and licensure.

This chapter outlines the basics of manufacturing a vaccine and a description of some examples of currently licensed products. It then moves to the regulatory requirements for vaccine manufacturing including current GMP compliance, and then discusses the development of new vaccines. The final section examines the great challenges in the field to deliver a product held to an ever-increasing standard of safety while providing sufficient doses at reasonable costs for an ever-increasing number of diseases.

MANUFACTURING BASICS

The manufacture of vaccines is composed of several basic steps that result in the finished product. Table 5.1 summarizes these steps with examples for pathogens that have a licensed vaccine. The first step is the generation of the antigen used to induce an immune response. This step includes the generation of the pathogen itself (for subsequent inactivation or isolation of a subunit) or generation of a recombinant protein derived from the pathogen. Vaccines under development use additional methods that will be discussed later. Viruses are grown in cells, which can be either primary cells, such as chicken fibroblasts (e.g., yellow fever vaccine), or continuous cell lines, such as MRC-5 (e.g., hepatitis A vaccine). Bacterial pathogens are grown in bioreactors using medium developed to optimize the yield of the antigen while maintaining its integrity. Recombinant proteins can be manufactured in bacteria, yeast, or cell culture. The viral and bacterial seed cultures and the cell lines used for viral production are carefully controlled, stored, characterized, and, often, protected. The first step in manufacture is the establishment of a "master cell bank." This is a collection of vialed cells that form the starting material for all future production. It is extensively characterized for performance and the absence of any adventitious agents. From this bank, working cell banks are prepared that are used as the routine starting culture for production lots. The final vaccine is a direct function of its starting materials, and a change in this seed can be as complicated as initiating a new product development altogether.

TABLE 5.1 Examples of Licensed Vaccine Manufacturing Processes

Disease	Trade Name	Generic Name	Cell Culture/Fermentation	Isolation	Purification	Formulation	Preservative
Anthrax	BioThrax	Anthrax Vaccine Adsorbed	Chemically defined protein-free media growing a microaerophilic culture of avirulent, nonencapsulated *Bacillus anthracis*	ND	Sterile filtrate of culture medium	Aluminum hydroxide	Benzethonium and formaldehyde
Haemophilus influenzae	ActHIB	*Haemophilus* b Conjugate Vaccine (Tetanus Toxoid Conjugate)	Grown of *Haemophilus influenzae* type b strain 1482 grown in a semisynthetic medium	Centrifugation	Phenol extraction and alcohol precipitation; Hib polysaccharide conjugated to tetanus toxoid	Lyophilized	None
Hepatitis A	Havrix	Hepatitis A Vaccine, Inactivated	Hepatitis A (strain HM175) propagated in MRC-5 human diploid cells	Cells lysed to form a suspension	Purification by ultrafiltration and gel permeation chromatography followed by formalin inactivation	Adsorbed onto aluminum hydroxide	2-Phenoxy-ethanol
Hepatitis B	Recombivax HB	Hepatitis B Vaccine (recombinant)	Recombinant hepatitis B surface antigen (HBsAg) produced in yeast cells grown in a complex medium of extract of yeast, soy peptone, dextrose, amino acids, and mineral salts	Released from yeast by cell disruption	Series of chemical and physical methods (ND) followed by treatment with formaldehyde	Coprecipitation of HBsAg with amorphous aluminum hydroxyphosphate sulfate	None
Influenza	Fluzone	Inactivated Influenza Virus Vaccine	Propagation on embryonated chicken eggs	Low-speed centrifugation and filtration	Purification/concentration on linear sucrose density gradient using continuous flow centrifugation followed by additional purification by chemical means	Phosphate-buffered saline with gelatin as stabilizer	Thimerosal in some package configurations
Japanese encephalitis	JE-VAX	Japanese Encephalitis Virus Vaccine Inactivated	Intracerebral inoculation of mice	Harvest of brain tissue/ homogenization	Centrifugation, supernatant collection followed by formaldehyde inactivation; further purification by ultracentrifugation through 40% sucrose	Lyophilized	Thimerosal
Measles, mumps, rubella, and varicella	ProQuad	Measles, Mumps, Rubella and Varicella (Oka/ Merck) Virus Vaccine Live	Measles virus propagated in chick embryo cell culture; mumps virus in chick embryo cell culture; rubella virus propagated in WI-38 human diploid lung fibroblasts; varicella virus propagated on MRC-5 cells	ND	ND	Lyophilized	None

Meningococcal	Menactra	Meningococcal (groups A, C, Y, and W-135) Polysaccharide Diphtheria Toxoid Conjugate Vaccine	Meningococcal strains are cultured individually on Mueller-Hinton agar and grown in Watson-Scherp media; *Corynebacterium diphtheriae* grown on modified Mueller and Miller medium	Extraction of polysaccharide from cell	Polysaccharide purified by centrifugation, detergent precipitation, alcohol precipitation, solvent extraction, and diafiltration; diphtheria purified by ammonium sulfate fractionation and diafiltration; conjugate purified by serial diafiltration	Sodium phosphate–buffered isotonic sodium chloride	None
Pneumococcal	Prevnar	Pneumococcal 13-valent Conjugate Vaccine (Diphtheria CRM197 Protein)	*Streptococcus pneumoniae* serotypes 1, 3, 4, 5, 6A, 6B, 7 F, 9 V, 14, 18 C, 19A, 19 F, and 23 F individually grown on soy peptone broth; *C. diphtheriae* strain containing CRM197 grown in casamino acids and yeast extract–based medium	Polysaccharides isolated by centrifugation; CRM197 ND	Polysaccharides purified by precipitation, ultrafiltration, and column chromatography; CRM197 purified by ultrafiltration, ammonium sulfate precipitation, and ion-exchange chromatography; conjugation done by reductive amination and the conjugate purified by ultrafiltration and column chromatography	Aluminum hydroxide suspension	None
Polio	IPOL	Poliovirus Vaccine Inactivated	Types 1, 2, and 3 poliovirus individually grown in Vero cells on microcarriers using Eagle MEM modified medium supplemented with newborn calf serum	Clarification (method ND) and concentration	Purification by three chromatography steps: anion exchange, gel filtration, and anion exchange; inactivation by formalin	Medium M-199	2-Phenoxy-ethanol
Rabies	RabAvert	Rabies Vaccine	Rabies virus grown in primary culture of chicken fibroblasts in synthetic cell culture medium with the addition of human albumin, polygeline, and antibiotics	Inactivated with β-propiolactone	Purification by zonal centrifugation in a sucrose density gradient	Stabilized with buffered polygeline and potassium glutamate; lyophilized	None
Streptococcus pneumoniae	Pneumovax	Pneumococcal vaccine polyvalent	ND	ND	ND	Isotonic saline	Phenol
Typhoid fever	Vivotif	Typhoid Vaccine Live Oral Ty21a	Fermentation using medium containing a digest of yeast extract, an acid digest of casein, dextrose, and galactose	Centrifugation	ND	Enteric-coated capsule containing lyophilized product	None
Yellow fever	YF-Vax	Yellow Fever Vaccine	Strain 17D-204 of yellow fever is cultured on living avian leukosis virus-free chicken embryos	Homogenization	Centrifugation	Lyophilized product containing gelatin and sorbitol as stabilizer	None

Data from vaccine package inserts.
ND, not disclosed.

The next step is to release the antigen from the substrate and isolate it from the bulk of the environment used in its growth. This can be isolation of free virus or of secreted proteins from cells or of cells containing the antigen from the spent medium. The next step is purification of the antigen. For vaccines that are composed of recombinant proteins, this step may involve many unit operations of column chromatography and ultrafiltration. For an inactivated viral vaccine, there may simply be inactivation of isolated virus with no further purification. The formulation of the vaccine is designed to maximize the stability of the vaccine while delivering it in a format that allows efficient distribution and preferred clinical delivery of the product. The formulated vaccine may include an adjuvant to enhance the immune response, stabilizers to prolong shelf life, and/or preservatives to allow multidose vials to be delivered.

Formulation consists of combining all components that constitute the final vaccine and uniformly mixing them in a single vessel (Fig. 5.1). Operations are conducted in a highly controlled environment with employees wearing special protective clothing to avoid contamination with adventitious agents. Control monitoring of the environment and critical surfaces is conducted during operations. Quality control (QC) testing at this stage usually consists of safety, potency, purity, sterility, and other assays specific to the product.

During this phase, individual, scrupulously cleaned, depyrogenated, single-dose or multidose containers are filled with vaccine and sealed with sterile stoppers or plungers. If the vaccine is to be lyophilized, the vial stoppers are inserted only partially to allow moisture to escape during the lyophilization process, and the vials are moved to a lyophilization chamber. All vials receive outer caps over the stopper for container closure integrity. To preclude the introduction of extraneous viable and nonviable contamination, all filling operations must take place in a highly controlled environment where people, equipment, and components are introduced into the critical area in a controlled manner. After filling, all containers are inspected using semiautomated or automated equipment designed to detect any minute cosmetic and physical defects. As with the formulation phase of the vaccine manufacturing operation, extensive control and monitoring of the environment and critical surfaces are conducted during operations. QC testing at this stage also consists of safety, potency, purity, sterility, and other assays that may be specific to the product.

Vaccine efficacy can be adversely affected by improper distribution and storage conditions. The sensitivity of vaccines to adverse environmental conditions, particularly temperature extremes, varies depending on their composition. Live attenuated vaccines tend to be more susceptible than inactivated vaccines and toxoids.[1] Vaccines are formulated such that the potency at the end of shelf-life remains above the effective dose demonstrated in human clinical trials. As the product may degrade over the 2 to 3 years of shelf life, the release target potency may be significantly above the specified end-of-shelf-life specification. This "overformulation" can represent a significant production yield loss and cost-of-goods increase for the final product in order to support the necessary lead times to deliver and store the vaccines, especially if they are used as a rotating stockpile to protect against supply interruption or an emergency use that does not materialize. The addition of stabilizers or lyophilization, when feasible, tends to improve the thermal resistance of vaccines. Storage at very low temperatures within the manufacturing supply chain may be used to reduce potency loss during storage.

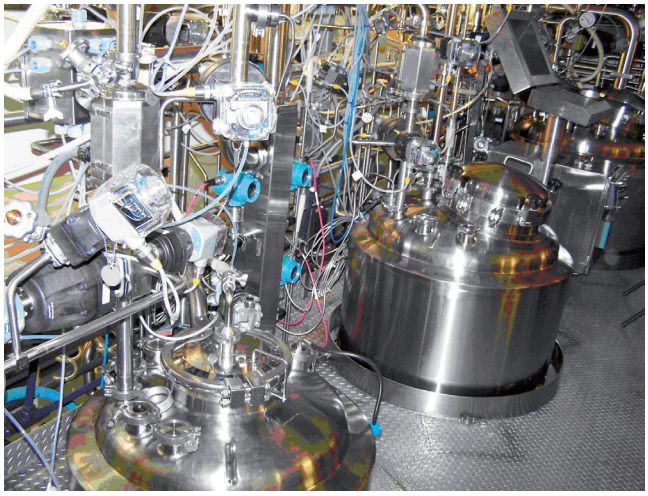

Figure 5.1. Automated vaccine formulation vessels.

Although recommended storage conditions for many vaccines have been detailed,[9] the vaccine manufacturers are responsible for developing data before and after licensing that demonstrate the stability of their vaccines under recommended storage conditions for the claimed shelf life. Generally, these programs provide data in excess of the claimed shelf life (up to 3 years) to support the development of new products intended for clinical use, as well as routine support of currently marketed products, expiration date extension, and supporting distribution conditions.[10,11] Accelerated studies conducted at elevated temperatures are commonly applied to better understand the impact of transient temperature excursions on the vaccine. Manufacturers are required to assure that products under their control are maintained under appropriate conditions so that the identity, strength, quality, and purity of the products are not affected.[12]

Currently, only a limited number of vaccines are required by federal regulation to have specified shipping temperatures.[10] Although most vaccine manufacturers use insulated containers and other precautions for the brief (usually 24 to 72 hours) shipping time, occasional, unanticipated temperature excursions may occur that could have a detrimental impact on the shipped product. Before accepting any vaccine shipment, users should look for any evidence of improper transportation conditions, including excessive transport time and possible adverse ambient temperature conditions.[1]

EXAMPLES OF VACCINE PRODUCTION

Inactivated Virus (Influenza)

Influenza virus vaccine for intramuscular use is a sterile suspension prepared from influenza viruses propagated in chicken embryos. This vaccine is the primary method for preventing influenza and its more severe complications.[13]

Typically, influenza vaccine contains two strains of influenza A viruses (H1N1 and H3N2) and a single influenza B virus. An additional strain of the influenza B virus was added, with the first four-antigen-containing-vaccine licensed in 2012.[14] The two type A viruses are identified by their subtypes of hemagglutinin and neuraminidase. The hemagglutinin and neuraminidase glycoproteins of influenza A virus comprise the major surface proteins and the principal immunizing antigens of the virus. These proteins are inserted into the viral envelopes as spike-line projections in a ratio of approximately 4 : 1.[15]

The trivalent subunit vaccine is the predominant influenza vaccine used today. This vaccine is produced from viral strains that are identified early each year by the World Health Organization, the Centers for Disease Control and Prevention

(CDC), and CBER. For U.S.-licensed manufacturers, the viral strains are normally acquired from CBER or CDC. European strains are typically provided by the National Institute for Biological Standards and Control, and Southern Hemisphere strains by the Therapeutic Goods Administration of Australia. These viral strains are used to prepare cells banks at each manufacturer, which cell banks are ultimately used as the inoculums for vaccine production.

The substrate most commonly used by producers of influenza vaccine is the 11-day-old embryonated chicken egg. A monovalent virus (suspension) is received from CBER or the CDC. The monovalent virus suspension is passed in eggs. The inoculated eggs are incubated for a specific time and temperature regimen under controlled relative humidity and then harvested. In the European Union, the number of passages from the original sample is limited. The harvested allantoic fluids, which contain the live virus, are tested for infectivity, titer, specificity, and sterility. These fluids are then stored wet frozen at extremely low temperatures to maintain the stability of the monovalent seed virus (MSV).[16] This MSV is also certified by CBER.

Once the MSV is introduced into the egg by automated inoculators, the virus is grown at incubated temperatures, and then the allantoic fluid is harvested and purified by high-speed centrifugation on a sucrose gradient or by chromatography. The purified virus is often split using a detergent before final filtration. The virus is inactivated using formaldehyde before or after the primary purification step, depending on the manufacturer. This is repeated for three or four strains of virus, and the individually tested and released inactivated viral concentrates are combined and diluted to final vaccine strength. Fig. 5.2 outlines the overall process.

The inactivated virus vaccine described above is used for the majority of flu vaccine produced and sold today. In recent years, the inactivated influenza vaccine produced on mammalian cell culture has been approved in a number of countries. The process replaces the egg-based virus expansion with a certified cell line; the downstream processes are similar, but focused on removing the host cell protein and DNA to below designated thresholds. A recombinant influenza vaccine, produced in insect cells infected with a recombinant baculovirus to express the hemagglutinin protein has also been approved in the United States.

Recombinant Protein (Hepatitis B)

In July 1986, a recombinant hepatitis B vaccine was licensed in the United States. This vaccine built on the knowledge that heat-inactivated serum containing hepatitis B virus (HBV) and hepatitis B surface antigen (HBsAg) was not infectious, but was immunogenic and partially protective against subsequent exposure to HBV.[17] HBsAg was the component that conferred protection to HBV on immunization.[18] To produce this vaccine, the gene coding for HBsAg, or "S" gene, was inserted into an expression vector that was capable of directing the synthesis of large quantities of HBsAg in *Saccharomyces cerevisiae*. The HBsAg particles expressed by and purified from the yeast cells have been demonstrated to be equivalent to the HBsAg derived from the plasma of the blood of hepatitis B chronic carriers.[17,19,20]

The recombinant *S. cerevisiae* cells expressing HBsAg are grown in stirred tank fermenters. The medium used in this process is a complex fermentation medium that consists of an extract of yeast, soy peptone, dextrose, amino acids, and mineral salts. In-process testing is conducted on the fermentation product to determine the percentage of host cells with the expression construct.[7] At the end of the fermentation process, the HBsAg is harvested by lysing the yeast cells. It is separated by hydrophobic interaction and size-exclusion chromatography. The resulting HBsAg is assembled into 22-nm–diameter lipoprotein particles. The HBsAg is purified to greater than 99% for protein by a series of physical and chemical methods. The purified protein is treated in phosphate buffer with formaldehyde, sterile filtered, and then coprecipitated with alum (potassium aluminum sulfate) to form bulk vaccine adjuvanted with amorphous aluminum hydroxyphosphate sulfate. The vaccine contains no detectable yeast DNA but may contain not more than 1% yeast protein.[7,19,21] In a second recombinant hepatitis B vaccine, the surface antigen expressed in *S. cerevisiae* cells is purified by several physiochemical steps and formulated as a suspension of the antigen absorbed on aluminum hydroxide. The procedures used in its manufacturing result in a product that contains no more than 5% yeast protein. No substances of human origin are used in its manufacture.[20] Vaccines against hepatitis B prepared from recombinant yeast cultures are noninfectious[20] and are free of association with human blood and blood products.[19]

Each lot of hepatitis B vaccine is tested for safety, in mice and guinea pigs, and for sterility.[19] QC product testing for purity and identity includes numerous chemical, biochemical, and physical assays on the final product to assure thorough characterization and lot-to-lot consistency. Quantitative immunoassays using monoclonal antibodies can be used to measure the presence of high levels of key epitopes on the yeast-derived HBsAg. A mouse potency assay is also used to measure the immunogenicity of hepatitis B vaccines. The effective dose capable of seroconverting 50% of the mice (ED_{50}) is calculated.[21]

Hepatitis B vaccines are sterile suspensions for intramuscular injection. The vaccine is supplied in four formulations: pediatric, adolescent/high-risk infant, adult, and dialysis.

All formulations contain approximately 0.5 mg of aluminum (provided as amorphous aluminum hydroxyphosphate sulfate) per milliliter of vaccine.[19] Table 5.2 summarizes the QC testing requirements for the release of recombinant hepatitis B vaccine.

Most vaccines are still released by CBER on a lot-by-lot basis; but for several extensively characterized vaccines, such as hepatitis B and human papillomavirus (HPV) vaccines, which are manufactured using recombinant DNA processes, this requirement has been eliminated.. Their manufacturing process includes significant purification, and they are extensively characterized by their analytical methods. In addition, hepatitis B vaccine had to demonstrate a "track record" of continued safety, purity, and potency to qualify for this exemption.[7,22]

TABLE 5.2 Testing Requirements for the Release of Recombinant Hepatitis B Vaccine

Type of Test	Stage of Production
Plasmid retention	Fermentation production
Purity and identity	Bulk-adsorbed product or nonadsorbed bulk product
Sterility	Final bulk product
Sterility	Final container
General safety	Final container
Pyrogen	Final container
Purity	Final container
Potency	Final container

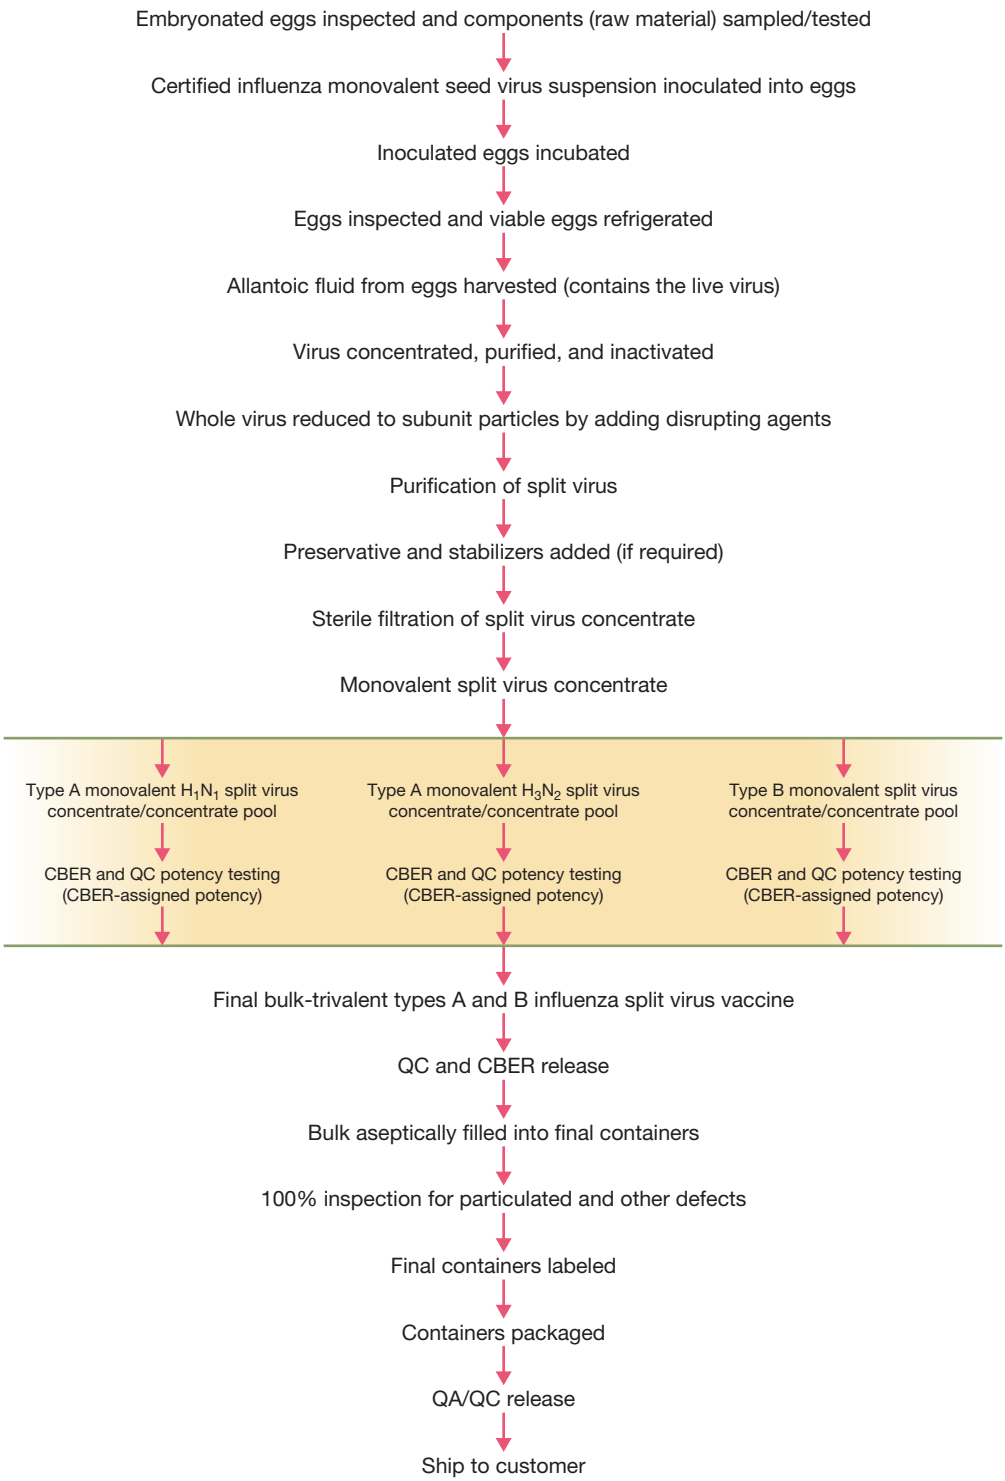

Figure 5.2. Egg-based influenza vaccine manufacturing process flow. CBER, Center for Biologics Evaluation and Research (of the U.S. Food and Drug Administration); QA, quality assurance; QC, quality control.

Conjugate Vaccine (*Haemophilus influenzae* Type B)

The production of *Haemophilus influenzae* type b (Hib) conjugate includes the separate production of capsular polysaccharide from Hib and a carrier protein such as tetanus protein from *Clostridium tetani* (i.e., purified tetanus toxoid), CRM protein from *Corynebacterium diphtheriae,* or outer membrane protein complex of *Neisseria meningitidis*.

The capsular polysaccharide is produced in industrial bioreactors using approved seeds of Hib. A crude intermediate is recovered from fermentation supernatant, using a cationic detergent. The resulting material is harvested by continuous-flow centrifugation. The paste is then resuspended in buffer,

and the polysaccharide is selectively dissociated from disrupted paste by increasing the ionic strength. The polysaccharide is then further purified by phenol extraction, ultrafiltration, and ethanol precipitation. The final material is precipitated with alcohol, dried under vacuum, and stored at −35°C for further processing.

Tetanus protein is prepared in bioreactors using approved seeds of *C. tetani*. The crude toxin is recovered from the culture supernatant by continuous-flow centrifugation and diafiltration. Crude toxin is then purified by a combination of fractional ammonium sulfate precipitation and ultrafiltration. The resulting purified toxin is detoxified using formaldehyde, concentrated by ultrafiltration, and stored at between 2°C and 8°C for further processing.

The industrial conjugation process was initially developed using tetanus toxoid by a team headed by J.B. Robbins at the National Institute of Allergy and Infectious Diseases (NIAID), Bethesda, Maryland.[23]

Conjugate preparation is a two-step process that involves: (a) activation of the Hib capsular polysaccharide and (b) conjugation of activated polysaccharide to tetanus protein through a spacer. Activation includes chemical fragmentation of the native polysaccharide to a specified molecular weight target and covalent linkage of adipic acid dihydrazide. The activated polysaccharide is then covalently linked to the purified tetanus protein by carbodiimide-mediated condensation using 1-ethyl-3(3-dimethylaminopropyl)carbodiimide. Purification of the conjugated material is performed to obtain high-molecular-weight conjugate molecules devoid of chemical residues and free protein and polysaccharide. Conjugate bulk is then diluted in an appropriate buffer, filled into unit-dose and/or multidose vials, and lyophilized.

Live Attenuated Vaccine (Measles)

The measles virus, isolated in 1954, is part of the genus *Morbillivirus* in the family Paramyxoviridae. Current vaccines are derived from Edmonston, Moraten, or Schwarz strains. Such vaccines have been on the market since the 1960s and in combination (measles, mumps, rubella [MMR]) since the 1970s. The final vaccine is a live attenuated viral vaccine inducing immunity in more than 90% of recipients.

For one measles vaccine, the manufacture of the vaccine starts with specific pathogen-free embryonated chicken eggs that are incubated several days. The embryos are collected and treated with trypsin to prepare the chick embryo fibroblasts for cell culture. All of the operations are done under strict aseptic conditions, performed by well-trained operators.

Cell culture are grown in roller bottles using fetal calf sera and M199 Hanks media for optimal cell growth. Chick embryo fibroblast cells are further infected by the viral working seed and incubated several days for viral culture. At the end of the viral culture, the cells are disrupted by mechanical lysis to release the virus. The virus is purified by centrifugation and filtration and stored frozen. After release of all QC tests, the vaccine is formulated alone or with mumps and rubella vaccines and lyophilized to obtain the stable product. The vaccine is reconstituted just before use.

Other manufacturers use different cell substrates; for example, the Serum Institute of India uses human diploid cells to manufacture their measles vaccine (see http://www.seruminstitute.com/content/products/product_mvac.htm).

Virus-Like Particle–Based Vaccines

Traditional viral vaccines rely on attenuated virus strains or inactivation of infectious virus. Subunit vaccines based on viral proteins expressed in heterologous systems have been effective for some pathogens, but have often had poor immunogenicity because of incorrect folding or modification.[24] Virus-like particles (VLPs) are designed to mimic the overall structure of virus particles and, thus, preserve the native antigenic conformation of the immunogenic proteins. VLPs have been produced for a wide range of taxonomically and structurally distinct viruses and have unique *potential* advantages in terms of safety and immunogenicity over previous approaches.[1] Attenuation or inactivation of the VLP is not required; this is particularly important as epitopes are commonly modified by inactivation treatments.[25] However, if a viral vector (e.g., baculovirus) is used as the expression system, inactivation may be required if the purification process cannot eliminate residual viral activity.

For a VLP to be a realistic vaccine candidate, it needs to be produced in a safe expression system that is easy to scale up to large-scale production[1] and by an accompanying purification and inactivation process that will maintain native structure and immunogenicity and will meet the requirements of today's global regulatory authorities. A number of expression systems manufacture multimeric VLPs, including the baculovirus expression system (BVES) in Sf9 and High Five cells, *Escherichia coli*, *Aspergillus niger*, Chinese hamster ovary cells, human function liver cells, baby hamster kidney cells, transgenic plants (potato, tobacco, soybean), *S. cerevisiae*, *Pichia pastoris*, human embryonic kidney 293 (HEK293) cells, and lupin callus (a plant-cell production system) with yields ranging from 0.3 to 10 μg/mL or as high as 300 to 500 μg/mL with *E. coli* and HEK293 (purified).[2]

The BVES has proven quite versatile, demonstrating the capability of preparing vaccine candidates for papillomavirus, feline calicivirus, hepatitis E virus, porcine parvovirus, chicken anemia virus, porcine circovirus, SV40 (simian virus 40), poliovirus, bluetongue virus, rotavirus, hepatitis C virus, HIV, simian immunodeficiency virus, feline immunodeficiency virus, Newcastle disease virus, severe acute respiratory syndrome (SARS) coronavirus, Hantaan virus, influenza A virus, and infectious bursal disease virus.[1]

Many pathogenic viruses, such as influenza, HIV, and hepatitis C, are surrounded by an envelope, a membrane that consists of a lipid bilayer derived from the host cell, inserted with virus glycoprotein spikes. These proteins are targets of neutralizing antibodies and are essential components of a vaccine. Owing to inherent properties of the lipid envelope, assembly of VLPs in insect cells for these viral vaccines is a different type of technical challenge to those produced viruses with multiple capsids.[1] For these targets, production of VLPs is a challenging task because the synthesis and assembly of one or more recombinant proteins may be required. This is the case for VLPs of rotavirus, which is an RNA virus with capsids formed by 1860 monomers of four different proteins. In addition, the production of most VLPs requires the simultaneous expression and assembly of several recombinant proteins, which, in the case of RLP, needs to occur in a single host cell.[26] Purification of VLPs also constitutes a particularly challenging task. VLPs are structures of several nanometers in diameter and of molecular weights in the range of 10^6 Da. Also, for guaranteeing the quality of the product, it is not sufficient to demonstrate the absence of contaminant proteins; it is also necessary to show that proteins are correctly assembled into VLPs.

Production of HPV VLPs represents another challenge. The HPV type 16 major 55-kDa capsids protein, L1, when produced in certain recombinant expression systems such as *S. cerevisiae*, can form irregularly shaped VLPs with a broad size distribution. These HPV VLPs are inherently unstable and tend to aggregate in solution. The primary challenge of HPV vaccine

formulation development was the preparation of aqueous HPV VLP solutions that are stable under a variety of purification, processing, and storage conditions. By treating the HPV VLPs through a process of disassembly and reassembly, the stability and in vitro potency of the vaccine are enhanced significantly. In addition, the in vivo immunogenicity of the vaccine was also improved by as much as approximately 10-fold, as shown in mouse potency studies.[27] The disassembly and reassembly of particles may also be important to remove residual proteins from the expression system or host cells used in the production and is a serious processing challenge, particularly for enveloped VLPs.

PRODUCT DEVELOPMENT

Vaccine development involves the process of taking a new antigen or immunogen identified in the research process and developing this substance into a final vaccine that can be evaluated through preclinical and clinical studies to determine the safety and efficacy of the resultant vaccine. During this process, the product's components, in-process materials, final product specifications, and manufacturing process are defined. The manufacturing scale used during development is usually significantly smaller than that used in the final manufacturing process. Phase I and, sometimes, Phase II clinical trial vaccines are typically produced in product development, but it is usually anticipated that at least one of the three or more consistency lots used for Phase III clinical trials will be manufactured at full-scale production volume. The product manufactured during the development phase is manufactured according to current GMP.[28]

INDUSTRY'S RESPONSE TO NEW CHALLENGES

Manufacturing Flexibility in Scale-Up: New Trends in Single Use

Early vaccines were produced in vivo (e.g., infecting calves with cowpox or rabbits with rabies virus; indeed, most influenza virus vaccines are still made in chicken embryos) and used neat or purified with largely glass lab equipment. Later, the animal cells used for viral vaccines were grown in vitro (e.g., roller bottles) and then infected to amplify virus for viral vaccines; later these cells were grown on microcarriers in deep culture to enable high manufacturing volumes and efficiencies. Microbial vaccines have been produced in large (500 to 5000 L) bioreactors at larger scale. These products were processed in stainless steel equipment for purification. Large-scale production was used to increase capacity to meet the increased demand for these lifesaving products. The cost of these facilities was increasingly expensive through the past few decades, and systems were increasingly complex to automate, clean, sterilize, and validate the facilities for manufacturing. Large central manufacturing facilities enabled lower cost of manufacturing; higher volumes were needed to lower the high fixed cost of construction, validation, and operation. The large central facilities were increasingly efficient, but also limited the manufacturing to a limited number of sites in developed countries.

Higher production yields and new manufacturing techniques, and an increasing focus on personalized medicine and niche products (e.g., low-volume products for rare diseases),[29] has allowed a new paradigm of smaller manufacturing facilities and bioreactors. The advent of disposable single-use equipment has eliminated the high cost of cleaning and sterilizing manufacturing equipment, reducing the complexity and cost of manufacturing facilities, and allowing economical manufacturing at smaller scale. Manufacturing systems that were enabled by 100% single-use technology enabled competitive pricing and a significant time advantage in smaller facilities.[30] The promise of the technology is clear and has triggered a significant investment by equipment developers into the single-use space.

The single-use promise is significant; however, there are a number of hurdles as in any new technology format. Glass and stainless steel equipment of historical manufacturing processes is generally inert and do not contribute impurities to the manufacturing process. The polymers used in single-use equipment may have different reactivity with the product (extractables and leachables), have been shown to shed particulate, and have shown a tendency to leak. Many of these concerns are being overcome in time through polymer engineering, and altering production techniques. Next, the ability to eliminate the high cost of cleaning and sterilizing equipment requires that the entire system be single-use. Many processes have not been able to make this conversion because of yield (low yield means high volume; volumes >2000 L are challenging because of weight and hydrostatic pressure), pressure (high O_2 demand, aeration volume, or flow rate), solvent use, and temperature control (heat transfer limitations). Chromatography also has been a challenging process in single-use systems, although there are promising advances and increasing options for prepacked columns.[29]

With the promise and dynamic pace of advancement in single-use systems, manufacturers are faced with a plethora of options and a jigsaw puzzle of parts to connect effectively. As the industry is rather new, the standards necessary to allow interconnectivity of parts are still marginal but gaining attention.[31] Standards are in development for extractables and leachables, particulate classification and management, integrity, supplier evaluation, and interchangeability. Governing and sponsoring agencies include Parental Drug Associate, BioProcess Systems Alliance, Extractables and Leachables Safety Information Exchange, Product Quality Research Institute, International Society of Pharmaceutical Engineers, American Society for Testing Materials, and United States Pharmacopeia, to name a few. Managing standards will be key to an effective use and integration of technologies supporting the vision of 100% single-use, reliable contingency supplies, robust supply chains, and limited surprises in change management.

Promise and Challenges of Distributed Manufacturing

One major advantage of the right-sized, single-use process is the ability to support distributed manufacturing. Today, a vast majority of supply of vaccines comes from a handful of developed countries because of the cost and complexity of the large-scale facilities and the profitability of those markets that support the significant manufacturing and clinical investment of public companies necessary to license and manufacture a vaccine. Once a large facility is built, duplicating it is a significant challenge as the complexity of the support systems essentially makes every facility unique. The advent of low-capital, single-use manufacturing platforms supports "scale-out" of processes built with "off-the-shelf" single-use systems, truly duplicating the original licensed process and minimizing the challenge of providing equivalence of the product from new facilities to the original facility. One can also imagine making clinical materials at modest scale and avoiding the challenge of scale-up for all markets, which could leverage addition of multiple single-use bioreactors instead of a large stainless system as demand grows. The approach supports a "pay-as-you-go" capital approach, avoiding large investments prior to demonstrating proof of concept and has the promise to make

product available more broadly and more quickly after license through global partnerships and distribution of facilities nearer to the market they will serve. It is well aligned with the current developing policies of multiple emerging economies to be self-reliant for essential services like vaccine supply. For example, a 2009 agreement between GlaxoSmithKline and Brazil describes the sale of GlaxoSmithKline pneumococcal conjugate vaccine to Brazil for 8 years, with an agreement to transfer the manufacturing process to Brazil for potential use in future years.[32]

The distributed manufacturing approach has many benefits including limiting global supply shortages from a catastrophic event at a single plant, the ability to customize a product for a region (e.g., strain of organism changing by region), and offsetting some of the cost of manufacturing (potentially paid by government) with tax-generating local jobs. There are some challenges to be considered. Maintaining alignment of the process among multiple facilities can be challenging in biological manufacturing processes. A process can "drift" in any single plant; having multiple manufacturing plants increases the chances that at least one plant will drift from the licensed, proven process. Likewise, control of raw material quality and source, single-use component supply, changes in supplier's materials in components, and similar unintended, unexpected consequences can leave a region without supply until the issue is identified and resolved. Single-use systems are ever improving; keeping the very specific needs of a process may be challenging with multiple small purchasers of the equipment versus a large central organization. Managing the regulatory files of a diverse production approach within a single company or across companies for a single product may also be difficult for regulators.

In spite of the challenges noted, the benefits of the distributed model, the advancement of standards within single-use manufacturers and the solutions that come with the experience of expanded use are sure to make this a reality in time.

Future Challenges in Polio Vaccine Manufacturing

The manufacture of polio vaccines began in 1955, and ultimately resulted in two products that have been widely distributed: the Salk inactivated polio vaccine (IPV) and the Sabin live attenuated polio vaccine (OPV). The OPV is manufactured typically on a cell line with minimal purification postharvest. This combined with the relatively high productivity of doses/liter of capacity results in a lower cost of manufacture. Because the risk of vaccine-associated paralytic poliomyelitis (VAPP) is estimated at 0.42 per million[33] over a three-dose schedule, there is a planned transition to the Salk IPV as the polio comes closer to eradication. To ultimately make this switch, however, will require substantial increases in the capacity to manufacture IPV, and without productivity improvement, it would require substantial increases in the cost of delivering polio vaccines to the target populations.

The production of IPV as described in Table 5.1 shows that the virus must be grown in cell culture, and then purified using three chromatography steps, followed by inactivation. As with any bioprocess, each steps results in loss of material that reduces the overall productivity. Alternatively, OPV is manufactured on cell lines with minimal purification. In addition, the dose of a live viral vaccine is typically much lower than an inactivated one, also helping the productivity of the process. This is reflected in the pricing of these vaccines. UNICEF publishes the prices of vaccine procured, and in 2014 OPV in a 20-dose vial from the Serum Institute of India was $0.14/dose, whereas IPV from Bilthoven Biologicals/Serum Institute of India in a five-dose vial was $1.90/dose.[34]

An additional challenge is the World Health Organization (WHO) guidelines on the use of wild-type polio virus necessary for the manufacture of IPV. Given the potential for an accident in manufacturing that could release wild-type poliovirus into the environment, the WHO has recommended limiting wild-type manufacturing of IPV to geographies with high IPV coverage in the surrounding community (>90% and at least three doses), and in environments with low transmission potential.[35] Currently, most of the vaccines for global vaccination come from India and China, where the suppliers of vaccines have focused on low-cost production and delivery of vaccines, and these geographies are currently not an option for IPV manufacture based on the WHO GAPIII recommendations.

A variety of strategies are currently being developed in the field to address these challenges, including a focus on the manufacturing technologies utilized to manufacture IPV, and opportunities to increase productivity and reduce unit costs. Existing polio vaccine manufacturing processes were developed years ago and use stainless steel fixed infrastructure manufacturing processes. Newer single-use technologies allow lower costs for initial facility design and could be used for polio vaccine manufacturing. An analysis by Lopes and colleagues shows that using newer facility design approaches that include single-use technologies can reduce bulk IPV costs by 40%, predominantly by reducing the capital costs of the facility.[36] Another approach to decreasing the cost is to increase the productivity of the manufacturing process.

Optimization of cell culture conditions and use of alternative cell lines are being evaluated, which suggest much higher titers of wild-type virus that could drive down the costs of the vaccine. Thomassen and colleagues showed that Vero cell culture can be further optimized to increase the production of D-antigen threefold.[37] Crucell has presented data that show its PER.C6 human-derived cell line has productivity 30 times higher than the Vero cells that are currently used to manufacture IPV.[38]

To allow broader manufacture of polio vaccines, an alternative vaccine using the Sabin attenuated strains but then inactivating them is also being pursued (Sabin-IPV [sIPV]). These viruses have shown lower yields in cell culture, but further work is being done to optimize their expression and purification yields.[39,40] This work again is focusing on cell-line selection, optimization, and facility design. Most importantly, the use of sIPV will allow a broader geographic set of potential locations for manufacturing, including India and China where there is substantial manufacturing infrastructure for vaccines focused on low-cost manufacturing.

Just as the initial discovery of polio vaccines required innovation in manufacturing methods to enable their launch, the ultimate eradication of polio will require innovation in manufacturing to enable the full public health impact of the vaccines.

Prime-Boost Vaccines

Given the complexities of developing vaccines for difficult targets like HIV, tuberculosis (TB), and malaria, a new tool has emerged that uses a "prime-boost" strategy for vaccination. The concept uses one vaccine as a prime, followed by the use of an entirely different vaccine for the boost. Most notably, an HIV vaccine efficacy trial in Thailand had a positive result using this approach. The Thai trial primed with a recombinant canarypox vector and followed with a recombinant gp120 protein boost.[41] Neither the canarypox nor the recombinant protein had shown efficacy on its own, but when combined gave a positive result in the trial. This approach has been used

in additional HIV vaccine efficacy testing,[42] TB vaccines,[43] and malaria,[44] among others.

Several challenges arise in the use of prime-boost vaccines that will need to be overcome if they are to be used in future licensed vaccines for distribution. The first is the complexity of multivalent vaccines. To have a successful batch release, prime-boost vaccines, like multivalent vaccines require successful manufacture and release of multiple components. For example, the HIV vaccines developed by the Vaccine Research Center at the National Institutes of Health (NIH) for HIV and tested for efficacy contained six plasmid DNA components in the prime, and five recombinant adenovirus vectors in the boost.[43] This requires the production of 10 separate active pharmaceutical ingredients, which must then be combined into two separate formulations and tested. Failure of any one component will delay both the ability to combine materials and the manufacturing of the final products. Yields of individual components and consequent costs can vary widely, requiring unique manufacturing supply chain designs that provide consistent supply of the projected demands.

A critical component of assay development for any vaccine is the development of a potency assay for release. With two vaccines required for efficacy testing, defining exactly what the potency requirements are from each component will be important during clinical studies to ensure that future batches for distribution meet these criteria. It may require a prime-boost immunogenicity evaluation in animals for batch release, which has decreased with improved in vitro methods for potency evaluation of vaccines.

Finally, most of the prime-boost approaches often involve multiple organizations or companies. Most vaccine companies focus on a core set of vaccine platform technologies, which allow them to build expertise in process development, assay development, and manufacturing facilities. Nearly all of the vaccines cited for HIV, TB, and malaria use products from separate organizations. Ultimately, if the vaccines prove successful, there needs to be a single regulatory license holder responsible for the distribution of the vaccine, which requires careful collaboration between the different organizations for licensure and life-cycle management of the vaccines.

Most of the prime-boost vaccines being tested are for early clinical trials that are designed to see an early efficacy signal from the vaccine. Given this, there is limited focus on the future manufacturing supply chain and production costs. Even at these early stages of clinical studies, however, it is important to ensure partnerships are clearly defined among vaccine developers, and the clinical studies are designed to demonstrate the true requirement for the prime-boost regime and the characteristics that each component must elicit after immunization. Early cost modeling can help target investments in process development to ensure that a successful signal in efficacy testing can ultimately result in a vaccine that can be successfully manufactured and distributed to the target populations.

A final challenge will be the coordination of the supply chains. As two separate vaccines are required for complete immunizations and potentially different immunization times, deployment and supply of the vaccines have to be synchronized to demand. For routine immunizations this is relatively straightforward; but for any catch-up or mass vaccination campaigns, it requires care management of expiration dates and planning. Vaccine supply shortages are unfortunately not uncommon, and a requirement for multiple vaccines increases the possibility that one might not be continuously available, creating partially immunized and potentially off-schedule immunized individuals. The implications of these scenarios may have to be explored during Phase II dosing studies or postmarketing surveillance.

6 Evolution of Adjuvants Across the Centuries

Nathalie Garçon and Martin Friede

Adjuvants are substances that are added to vaccine antigens to enhance and modulate the immunogenicity of the antigen. The first adjuvants developed focused on increasing antibody responses, and this has often been sufficient for the vaccines considered. During the last 2 decades, however, it has been realized that simply increasing antibody responses is not always sufficient for candidate vaccines to be effective. It has been observed that adjuvants can be used very effectively to:

- provide a strong priming response in naïve populations, effectively reducing the number of doses required to induce protection.
- increase the duration of the immune response.
- enhance specific arms of the immune response such as cell-mediated immunity (CMI), a critical target for many of the remaining infectious diseases for which we do not have vaccines.
- increase the breadth of the immune response to variable antigens, enabling broader cross-protection.
- enhance the immune response in poorly responsive populations, such as elderly and immunosuppressed populations.
- allow for dose sparing of antigens where antigen supply is limited.

Generally speaking, adjuvants are useful for antigens such as inactivated, subunit, and recombinant proteins, which can lose, during the purification process, some of the immunological information present in the pathogen that are needed to trigger an immune response. They have not yet been required for live attenuated vaccines, which carry the necessary immune-stimulating signals themselves. As discussed later, however, some preliminary research suggests that adjuvants can have an effect on live vaccines as well.

CHANCE AND NECESSITY: THE DISCOVERY OF ADJUVANTS

The use of adjuvants has been known for more than a century, and it is only recently that their mechanism of action was elucidated, in part owing to the progress in microbiology and immunology. The first recorded observation of immune potentiation by "adjuvants" is probably that of Coley, who in 1893 observed that administration of killed bacteria (Coley toxins) could in some cases cure certain forms of cancer. It was only in the 1990s that it was determined that this effect was the result of immune stimulation mediated by bacterial DNA. From there on, the specific oligonucleotide sequences that could stimulate the immune response and enhance it to a coadministered antigen were discovered.

It took another 2 decades to recognize the usefulness of adjuvants to enhance humoral immunity. In 1925, Ramon[1] observed that administering diphtheria toxoid to horses with a variety of substances, including starch, plant extracts, or fish oils, substantially enhanced the antibody response to the toxoid. A year later, Glenny[2] observed a similar effect with aluminum potassium sulfate, or alum. Alum was used thereafter as an adjuvant for numerous human vaccines, and to this day, other aluminum salts, in the form of aluminum oxyhydroxide or hydroxyphosphate, are the most widely used adjuvants in human vaccines. The starch and fish oils shown by Ramon to act as adjuvants have, in recent decades, been tested in vaccines in the form of inulin and squalene, respectively.

During the 80 years following the first use of aluminum salts as adjuvants, a wide variety of substances were tested as adjuvants, but many of them failed to be accepted for human use. In the 1940s, Jules Freund developed a water-in-oil emulsion, the Freund adjuvant, in which the vaccine antigen is emulsified as water droplets in a continuous mineral oil phase, containing killed mycobacterium (Freund complete adjuvant) or not (Freund incomplete adjuvant). The latter was briefly used for a commercial influenza vaccine in the United Kingdom in the 1960s, but was soon withdrawn owing to unacceptable reactogenicity. This, however, led to the development of oil-in-water emulsions, in which oil droplets are present in a continuous aqueous phase.

The first oil-in-water emulsions were based on a nonmetabolizable oil (squalane) and replaced later with metabolizable oils (squalene), as opposed to mineral oils as in the original Freund adjuvant. However, a water-in-oil emulsion similar in structure to the Freund adjuvant has been introduced in a cancer vaccine, using mineral oil with a higher degree of purity that allows for use in human vaccine candidates.

In the 1970s liposomes and virosomes that adsorb or encapsulate antigen were developed. Liposomes consist of lipid layers that form nanospheres or microspheres and can encapsulate or integrate antigens into their membranes. Several licensed vaccines contain virosomes, which are reconstituted empty envelopes of influenza viruses similar in structure to liposomes.

A TURNING POINT: BETTER UNDERSTANDING OF IMMUNOLOGY AND ITS IMPACT ON THE DEVELOPMENT OF ADJUVANTS

For most of the 20th century, adjuvant discovery and development was based on observations and experimentation with no clear immunological knowledge of the mechanism behind the adjuvant effect. This, however, dramatically changed in 1996 with the discovery of the Toll-like receptors (TLR) family in *Drosophila* and their relation to fungal resistance by Lemaitre and colleagues.[3] One year later, in 1997, Janeway[4] identified the link between human TLR4 and its key role in initiating an adaptive immune response, the first necessary step to a long-lasting immune response. The discovery by Poltorak and colleagues[5] that TLR4 functioned as a lipopolysaccharide (LPS)-sensing receptor and, hence, the use of LPSs or their derivatives as adjuvants, brought the final piece to the understanding of the mechanism of actions of TLR agonist molecules.[6]

In the early 1980s, Edgar Ribi[7] established that it was possible to produce a molecule that retained the immune potentiation activity of LPS without the associated toxicity. Approximately 30 years later, in 2009, the molecule monophosphoryl lipid (MPL) A was the first new adjuvant in a vaccine (Cervarix vaccine against human papillomavirus

[HPV]) approved for use by the U.S. Food and Drug Administration.

It is now well understood that the immune system uses pathogen-associated molecular patterns (PAMPs) to activate pathogen-recognition receptors such as TLR, and also a host of other more recently discovered receptors: retinoic-acid–inducible gene-based-I–like receptors (RLRs),[8] and cytosolic nucleotide oligomerization domain (NOD)-like receptors (NLRs).[9,10] These receptors bind various pathogen ligands (ranging from, for example, bacterial cell wall and cell membrane components to bacterial or viral nucleotides, to fungal lipids) to trigger different types of immune responses and, if combined with an antigen, can initiate and enhance specific arms of the immune responses to that antigen. For the purpose of brevity, readers are directed to other sources for a detailed description of how pathogen components stimulate various cytokine pathways and how they direct different arms of the immune response[11]; Fig. 6.1 shows this information schematically. As shown in Fig. 6.1, different TLRs, located on the plasma membrane or intracellularly, respond to different pathogen-derived signals to induce proinflammatory cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-6, or type 1 interferon, leading to a predominantly T-helper cell 1 (Th1) response. However, certain TLR2 agonists have been reported to activate Th2 responses.[12]

Table 6.1 lists the various agonists that activate the TLRs, as well as the adaptor molecules, also known as TLR agonists, and examples of adjuvants, which function through these receptors.

Based on this understanding, it is possible to recognize today how most of the adjuvants function. This knowledge should allow rapid screening of compound libraries for molecules that bind these receptors and that may have adjuvant activity leading to the rational design of new adjuvants aimed at stimulating specific arms of the immune response. The level of knowledge associated with the mechanism of action of those specific molecules and, as a consequence, the pattern of cytokines induced should also allow an assessment of the impact of an adjuvant on the safety of a vaccine. However, this has not yet led to the discovery of new molecules with defined

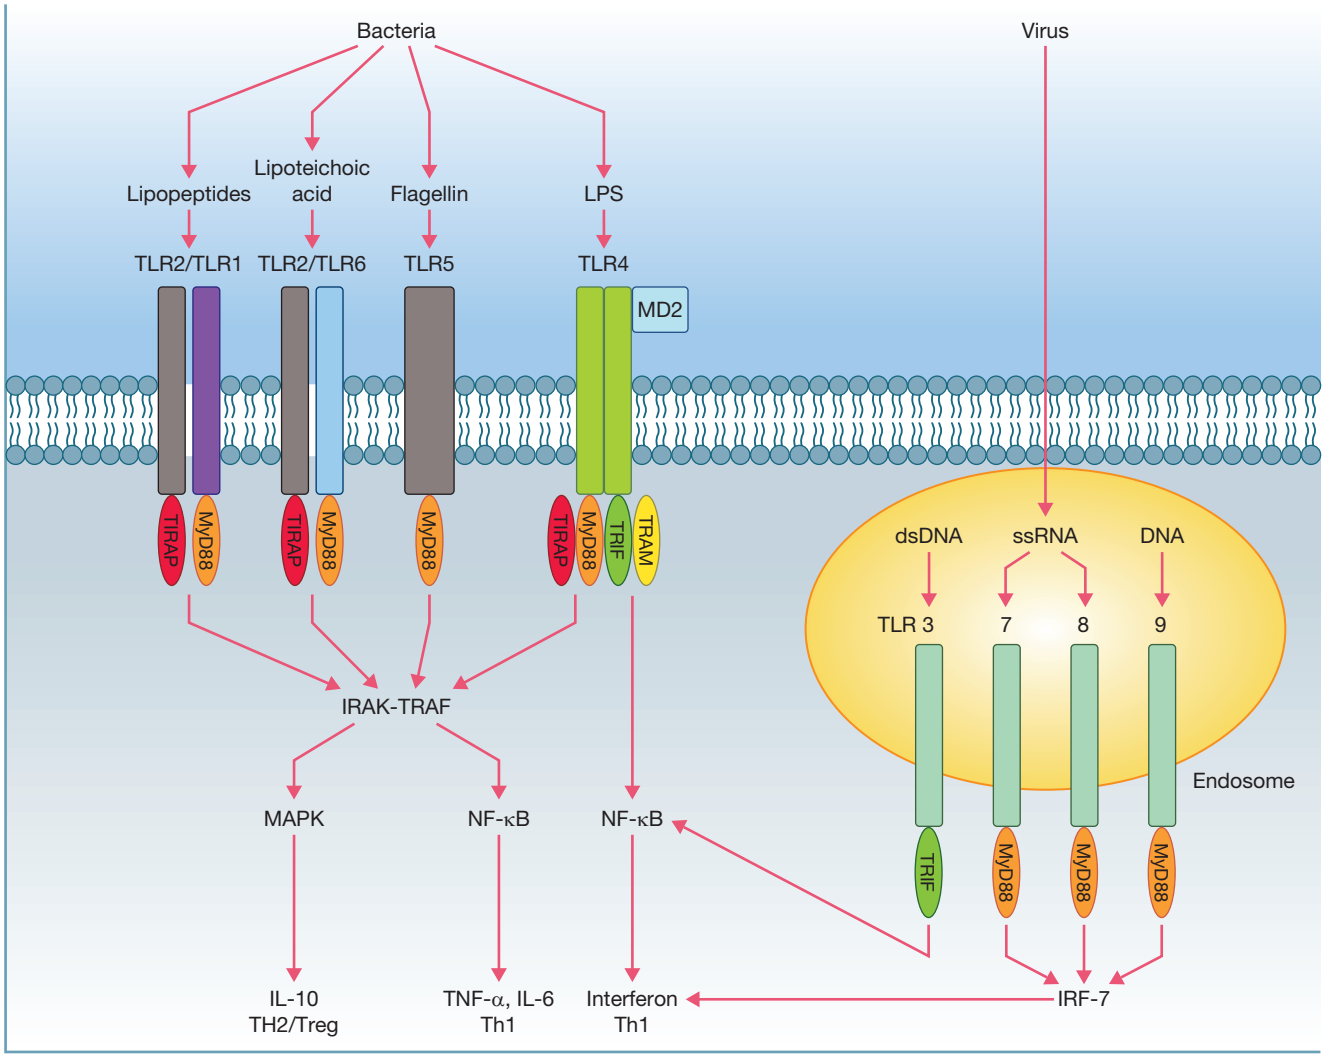

Figure 6.1. Activation of the innate immune system via interaction of bacterial or viral components with specific Toll-like receptors (TLRs), messaging through the myeloid differentiation 88 (MyD88) or TRIF pathway, and subsequent secretion of interleukin (IL)-10, tumor necrosis factor (TNF)-α and IL-6, or type 1 interferon. dsDNA, double-stranded DNA; IRAK, interleukin receptor–associated kinase; IRF, interferon regulatory factor; LPS, lipopolysaccharide; MAPK, mitogen-activated protein kinase; NF-κB, nuclear factor κB; ssRNA, single-stranded RNA; Th, T-helper cell; TRAF, TNF receptor–associated factor; Treg, T-regulatory cell; TRIF, TIR domain–containing adapter-inducing interferon-β.

TABLE 6.1 Agonists That Activate the TLRs, Adaptor Molecules, and Examples of Adjuvants

TLR	Ligand	Ligand Location	Adaptor	Adjuvant
1	Tripalmitoyl-cysteine lipopeptides	Bacterial membranes	MyD88 MAL	
2	Lipopeptides, β-glucan, glycolipids	Bacterial membranes	MyD88 MAL	
3	Double-stranded RNA	Viral RNA	TRIF	Poly(I:C); poly(A:U)

CpG, cytosine phosphate guanine; GLA, glucopyranosyl lipid adjuvant; MAL, MyD88 adaptor-like; MPL, monophosphoryl lipid A; MyD88, myeloid differentiation 88; TLR, Toll-like receptor; TRIF, TIR domain-containing adaptor-inducing IFN-β.

activities, but in certain cases has enabled a better understanding of the mode of action of specific adjuvants and helped to support their safety profile within a given vaccine.[13] A clear understanding of the pathogenesis of immune-mediated disorders and their triggers is required, however, to ascertain the potential impact of the adjuvant. For several adjuvants the exact mechanism of action remains elusive (such as the saponins, which are described later) or may present multiple modes of action (such as aluminum salts).

This is only the first step in defining the value of a molecule as an adjuvant. Further evaluation of the compound in vivo and its safety profile will define its real potential as an adjuvant for vaccines.[14,15]

DEFINING ADJUVANTS: CLASSIFICATION AND EVALUATION

This section is limited to a review of the types of adjuvants that are incorporated in licensed vaccine formulations or for which there is extensive clinical experience.

A Categorization of Adjuvants Based on Mechanism of Action

The majority of adjuvant reviews during recent decades have tried to classify adjuvants according to their mechanism of action and typically classified adjuvants as *vehicles* or *immunostimulants*. Immunostimulants are substances that act directly on the immune system, such as TLR ligands. Vehicles are thought to act primarily by presenting antigens to the immune system. In this group are various aluminum salts, emulsions, immunostimulatory immune complexes (ISCOMs), and biodegradable microparticles. It is now known that most of the vehicles act directly on the immune system, and antigen presentation may be only a minor component of the adjuvant activity (e.g., see the later discussions of modes of action of aluminum salts ["Aluminum Salt Adjuvants"] and oil-in-water emulsions ["Oil-in-Water Emulsions"]). This classification seems outdated, and it may be preferable to classify adjuvants according to their receptor or, when the receptor is unknown, by their physical or chemical nature.

Currently 10 adjuvants are approved for use in vaccines (three aluminum salts with different counter-ions, four oil-in-water emulsions, aluminium/MPL combination, virosomes, and polyoxidonium). Table 6.2 lists the approved vaccines containing these adjuvants. Numerous other adjuvants are in vaccines that are under development. Noteworthy, AS01, the combination of liposome, MPL and QS21, will most likely be the next new adjuvant present in a licensed vaccine, in this case the malaria RTS,S vaccine. These and their classifications by receptor or physicochemical nature are presented in Table 6.3 and discussed in the following sections. Many more adjuvants are in preclinical development; however, they are too numerous to discuss in this chapter.[16]

Aluminum Salt Adjuvants

Aluminum-containing adjuvants have historically served as immunostimulants in vaccines and continue to be the most widely used adjuvants. Several aluminum compounds are used and are known as aluminum hydroxide, aluminum phosphate, and alum. All three of these commonly used names are scientific misnomers. Although this family of adjuvants has been used the longest, it is only recently that we have begun to understand their mechanism of action and the complexity of formulating them with antigens.

The following sections summarize the structure and properties of different aluminum salts, the mechanisms by which they stimulate the immune response, and the effect of freezing on aluminum-adjuvanted vaccines.

Structure and Properties. Aluminum hydroxide adjuvant is not $Al(OH)_3$, but rather crystalline aluminum oxyhydroxide (AlOOH).[17] This difference is important because crystalline aluminum hydroxide has a low surface area (approximately 20 to 50 m^2/g) and as such is a poor adsorbent. Crystalline aluminum oxyhydroxide has a surface area of approximately 500 m^2/g,[18] which makes it an excellent adsorbent. This high surface area is a result of its morphology. The primary particles are fibers having dimensions of approximately $5 \times 2 \times 200$ nm.

Aluminum oxyhydroxide is a stoichiometric compound. The surface is composed of Al-OH and Al-O-Al groups. The Al-OH surface groups can accept a proton, resulting in a positive surface charge, or donate a proton, resulting in a negative surface charge. As shown in Fig. 6.2, the isoelectric point (IEP) of Al-OH is 11.4. Thus, aluminum oxyhydroxide exhibits a positive surface charge at pH 7.4, which is the pH of interstitial fluid.

TABLE 6.2 Types of Licensed Vaccines Containing Adjuvants

Vaccine	Trade Name[a]	Adjuvant
Diphtheria and tetanus vaccine (DT)	Diphtheria and Tetanus Toxoid Adsorbed USP (1)	Aluminum potassium phosphate
DT acellular pertussis (DTaP)	Tripedia (1)	Aluminum potassium phosphate
Haemophilus influenzae type b (Hib)	Liquid PedvaxHIB (2)	Aluminum hydroxyphosphate sulfate
DTaP + Hib	TriHIBit (1)	Aluminum potassium phosphate
Hepatitis B	Recombivax HB (2)	Aluminum hydroxyphosphate sulfate
Hepatitis B	Engerix-B (3)	Aluminum hydroxide
Hepatitis B + Hib	Comvax (2)	Aluminum hydroxyphosphate sulfate
Hepatitis A	Havrix (3)	Aluminum hydroxide
Hepatitis A	Epaxal (6)	Virosomes
Hepatitis A + hepatitis B	Twinrix (3)	Aluminum hydroxide/phosphate
Pneumococcal conjugate vaccine	Prevnar (4) Synflorix (3)	Aluminum phosphate
Influenza vaccine	FLUAD (4)[b]	MF59
Influenza vaccine	Inflexal V (6)[b]	Virosomes
Pandemic influenza vaccine	Pandemrix	AS03
Pandemic influenza vaccine	Focetria	MF59
Pandemic influenza vaccine	Humenza	AF03
Human papillomavirus (HPV)	Gardasil (2)	Aluminum hydroxyphosphate sulfate
HPV	Cervarix (3)	Aluminum hydroxide + MPL
Hepatitis B	Fendrix (3)[b]	AS04 (MPL + aluminum phosphate)
Hepatitis B	SUPERVAX (7)[b,c]	RC529

MPL, monophosphoryl lipid A.
[a]Manufacturers are as follows: 1, Sanofi Pasteur; 2, Merck; 3, GlaxoSmithKline; 4, Wyeth now Pfizer; 5, Novartis; 6, Crucell; 7, Dynavax Europe.
[b]Licensed in Europe.
[c]Licensed in Argentina.

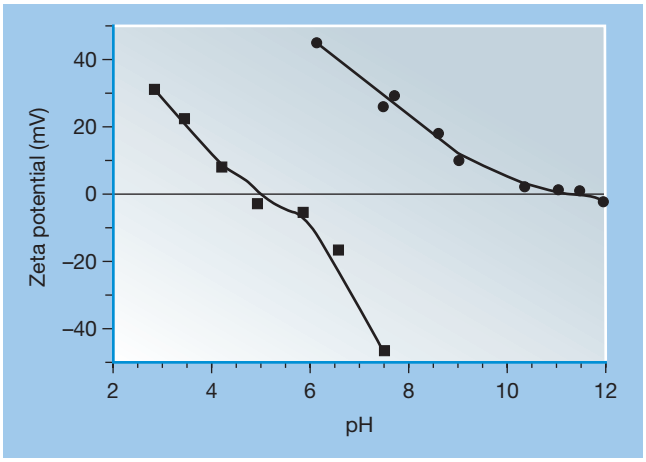

Figure 6.2. Isoelectric points of aluminum hydroxide adjuvant *(right)* and aluminum phosphate adjuvant *(left).* *(From Rinella JVJ, White JL, Hem SL. Effect of pH on the elution of model antigens from aluminum-containing adjuvants.* J Colloid Interface Sci. *1998;205: 161–165.)*

Aluminum phosphate adjuvant is a chemically amorphous aluminum hydroxyphosphate in which some of the hydroxyl groups of aluminum hydroxide are replaced by phosphate groups. The disordered, amorphous state is responsible for the high surface area and high adsorptive capacity.

The surface of aluminum phosphate adjuvant is composed of Al-OH and Al-OPO_3 groups. The IEP varies from 9.4 to 4.5 depending on the degree of phosphate substitution.[19] Commercial aluminum phosphate adjuvants have IEP values in the 4.5 to 5.5 range. In contrast with aluminum oxyhydroxide, commercial aluminum phosphate adjuvants are negatively charged at pH 7.4 (see Fig. 6.2).

Alum, which is water-soluble, is chemically aluminum potassium sulfate, $AlK(SO_4)_2$. The earliest vaccines containing aluminum adjuvants were prepared by in situ precipitation. A solution of alum was mixed with a solution of the antigen dissolved in a phosphate buffer. It is common practice to refer to the adjuvant produced by in situ precipitation as alum. The precipitate is amorphous aluminum hydroxyphosphate and has similar composition and properties as aluminum phosphate adjuvant.[17,20]

The techniques that can be used to characterize aluminum-containing adjuvants have been reviewed by White and Hem.[21]

Effect of Freezing. Vaccines containing aluminum hydroxide adjuvant or aluminum phosphate adjuvant should not be allowed to freeze and should not be used if suspected of having been exposed to freezing temperatures.[22] Freezing may affect the aluminum-containing adjuvant and the adsorbed antigen. Coagulates, which cannot be redispersed by shaking, form when aluminum-containing adjuvants are frozen. Thermostability of vaccines is of increasing importance, and as demonstrated for aluminium salts does not only concern excursion at high temperature, but also at low temperature, such as freezing.

TABLE 6.3 Nonexhaustive List of Adjuvants in Vaccines Under Development or Approved

Class (By MOA)	Component	Adjuvant Name and Other Compounds	Manufacturer	Phase I	Phase II	Phase III	Licensed
		Hiltonol (polylysine)	Oncovir	Cancer			
TLR4	MPL	AS04 (alum)	GSK				HPV, HBV
	MPL	AS02 (emulsion, QS21)	GSK		Cancer		
	MPL	AS01 (liposome, QS21)	GSK			Malaria, zoster	
	MPL	AS15 (liposomes QS21, CpG)	GSK			Cancer	
	MPL	(tyrosine)	ALT			Allergy	
	RC529	RC529 (alum)	GSK				HBV
	GLA	SE-GLA (emulsion)	IDRI	Influenza			
		Stimuvax	Biomira/Oncothyreon			Cancer	
		E6020	Esai				
TLR5	Flagellin	Fusion to influenza hemagglutinin	VaxInnate	Influenza			
TLR7	Imiquimod	Topical		Cancer			
	Imiquimod	Combined with ISA51			Cancer		
TLR9	CpG	1018 ISS	Dynavax		Allergy	HBV	
		CpG 7909	Coley/Pfizer	HBV	Cancer		
		CpG 7909 + alum	NIAID	Malaria			
		AS15 (liposomes, MPL, QS21)	GSK		Cancer		
	dI:dC	IC31 (cationic peptide)	Intercell	Influenza, TB			
Saponins	QS21	AS01 (liposome, MPL)	GSK			Malaria	
	QS21	AS15 (MPL, CpG)	GSK			Cancer	
	QS21	QS21	Universities	HIV, influenza	Cancer		
	Quil fractions	ISCOM (cholesterol)	CSL				
		Iscomatrix (cholesterol)	CSL	HPV, influenza	Cancer		
	GPI-0100			Cancer			
Oil-in-water emulsion	Squalene	MF59	Novartis	HIV	HBV, CMV		Seasonal influenza, pandemic influenza
	Squalene	AF03	Sanofi Pasteur	Influenza			
		SE	IDRI	Influenza			
	Tocopherol	AS03 (squalene)	GSK				Pandemic influenza
	Squalane	CoVaccine (acyl sucrose sulfate)	Protherics	Angiotensin			
			Nobilon	Influenza			
Water-in-oil emulsion	Squalene	ISA 720	Seppic			Malaria, cancer	
		ISA 51	Seppic	Malaria		Cancer	
Polysaccharides	Inulin	Advax (alum)	Vaxine	HBV, influenza			
Cationic liposomes	DDA	CAF (TDM)	SSI	TB			
		JVRS-100 (DNA)	Juvaris	Influenza			
Virosomes			Crucell				HAV, influenza
			Pevione	Malaria			
Polyelectrolytes		Polyoxidonium	Microgen				Influenza

Classified according to adjuvant receptor or adjuvant physicochemical nature (alum-derived adjuvants excluded for clarity).
ALT, alanine aminotransferase; CMV, cytomegalovirus; CpG, cytosine phosphate guanine; DDA, dimethyldioctadecylammonium; GLA, glucopyranosyl lipid adjuvant; GSK, GlaxoSmithKline; HAV, hepatitis A virus; HBV, hepatitis B virus; HPV, human papillomavirus; IDRI, Infectious Disease Research Institute; ISCOM, immunostimulatory immune complex; MOA, mechanism of action; MPL, monophosphoryl lipid A; NIAID, National Institute of Allergy and Infectious Diseases; SE, stable emulsion; TB, tuberculosis; TLR, Toll-like receptor.

Adsorption Mechanisms. The major mechanisms responsible for the adsorption of antigens are electrostatic attraction, hydrophobic forces, and ligand exchange. Electrostatic attraction is probably the most frequently used adsorption mechanism.

Electrostatic attraction can be optimized by determining the IEP of the antigen and then selecting an adjuvant that will have the opposite surface charge at the desired pH. For example, at pH 7.4, aluminum hydroxide adjuvant (IEP = 11.4) adsorbs albumin (IEP = 4.8) but does not adsorb lysozyme (IEP = 11.0). In contrast, aluminum phosphate adjuvant (IEP = 4.0) adsorbs lysozyme but not albumin at pH 7.4.[23]

Care must be taken in selecting a buffer for an aluminum hydroxide adjuvant–containing vaccine. Electrostatic attraction for an acidic antigen may be reduced or reversed if a phosphate buffer is used. Acetate and tromethamine (TRIS) are examples of buffers that do not alter the IEP of aluminum hydroxide adjuvant.[17]

Aluminum hydroxide adjuvant can also be pretreated to lower the IEP to optimize electrostatic adsorption of basic antigens.[24]

Hydrophobic forces can also contribute to the adsorption of antigens by aluminum-containing adjuvants. The contribution of hydrophobic attractive forces can be determined by observing the effect of ethylene glycol on adsorption.[25] Ethylene glycol stabilizes the hydration layer of proteins, which renders hydrophobic interactions thermodynamically unfavorable.

Mechanisms of Action of Aluminum Salt Adjuvants. There is still no consensus regarding the mechanisms by which aluminum-containing adjuvants potentiate the immune response. Several mechanisms are frequently cited to explain how aluminum-containing adjuvants increase antibody production. The depot mechanism was initially thought of as the dominant one; later the promotion of uptake of antigens by antigen-presenting cells (APCs)[26] and, more recently, a direct immune-stimulating mechanism were proposed.

- The depot mechanism postulates that the aluminum-containing adjuvant and the adsorbed antigen remain at the site of injection. The antigen is released slowly to stimulate the production of antibodies. This hypothesis is supported by the observation with some antigens that stronger binding to the aluminum salt crystals can result in higher immune responses. This hypothesis is, however, inconsistent with the observation that alum injection sites can be excised shortly after injection with no impact on immunogenicity.[27]
- It has also been proposed that adsorption of antigen to aluminum-containing adjuvants converts the soluble antigen to a particulate form. APCs take up particulate matter more efficiently by phagocytosis. Thus, antigen, which remains adsorbed, is taken into macrophages and dendritic cells. A dendritic cell culture study[28] revealed that antigens that elute from the aluminum-containing adjuvants are internalized by macropinocytosis, while those that remain adsorbed are internalized by phagocytosis. Antigen internalization by dendritic cells was enhanced when the antigen remained adsorbed to the aluminum-containing adjuvant following administration and when the aggregate size of the adjuvant was smaller than dendritic cells.
- Several groups have identified a role for a direct stimulation of the immune system through innate immune receptors and identified activation of the Natch domain, leucine-rich repeat, and PYD-containing protein (NALP)-3 inflammasome pathway by alum as the mechanism of action.[29–31] The precise mechanism by which alum stimulated NALP3 remained unknown. This has been refined and alum crystals have been shown to interact directly with membrane lipids on the surface of dendritic cells. The resulting lipid sorting triggers signaling cascades, independent of the inflammasome, that promote $CD4^+$ T-cell activation.[32]

It is likely that all three proposed mechanisms contribute to the immunostimulation produced by aluminum-containing adjuvants.

Safety of Aluminum-Containing Vaccines. Aluminum salts as adjuvants have the longest and largest safety track record of all adjuvanted vaccines, with more than 3 billion vaccine doses used during the past 80 years with a positive risk-to-benefit ratio. Focal histologic lesions were observed in patients with diffuse muscular symptoms that included persistent myalgias, arthralgias, and persistent fatigue. In the approximately 130 cases studied, these lesions were identified as macrophagic myofasciitis (MMF).[33] Intracytoplasmic inclusions in the infiltrating macrophages have been identified as containing aluminum by electron microscopy, microanalysis, and atomic adsorption spectroscopy. The presence of aluminum in the deltoid muscle biopsies suggested to Gherardi and colleagues that the source of the aluminum was aluminum hydroxide adjuvant.[34] However, no relationship between the presence of aluminum and MMF and the clinical symptoms has been established. The Vaccine Safety Advisory Committee of the World Health Organization (WHO) reviewed MMF at a meeting in 1999. The committee found that there was no basis for recommending a change in vaccination practices involving vaccine selection, schedule, delivery practices, or information involving aluminum-containing vaccines. The committee recommended that "research studies be undertaken to evaluate the clinical, epidemiological, and basic science aspects of MMF."[35] The U.S. Food and Drug Administration, while recognizing the desirability of new adjuvants, confirmed its support of aluminum salts in vaccines.[36] Research studies undertaken to assess the neurotoxicity of aluminum when it is administered intramuscularly or in a vaccine, showed a difference between the control group and the aluminum-based vaccine tested.[37] A repeat of the experiment, however, did not confirm any differences between the control group and the two vaccines containing aluminum. To date, even though it is established that aluminium salt can be recovered at the injection site months or years after intramuscular injections, no link between the presence of aluminium salt and the MMF syndrome has been clearly established.

Water-in-Oil Emulsions

Water-in-oil emulsions, of which the Freund adjuvant is the best-known example, were included in a commercial influenza vaccine in the United Kingdom in the 1960s. The vaccine was later withdrawn owing to occasional abscesses observed at the site of injection. Initial large-scale clinical studies on 18,000 military recruits conducted in 1953[38,39] resulted in some nodules at the injection sites, which were attributed to impurities (short-chain fatty acids) in the Arlacel-A surfactant. However, when this surfactant was purified, the incidence of cysts was reduced. A 10-year follow-up on these volunteers[40] showed that cyst-like reactions had required hospitalization in 0.1% to 0.6% of the volunteers, but otherwise there were no adverse effects of the vaccine. A subsequent 35-year follow-up[41] demonstrated that not only were there no adverse correlations with different diagnoses, including autoimmune diseases, but also, for some of the disease categories, there was decreased mortality. In contrast with these data from a large clinical trial, studies in rodents in 1972 demonstrated that when male Swiss mice were injected with mineral oil–based

emulsions, the mice developed tumors,[42] and the unacceptability of mineral oil–based emulsions for human use was concluded.

As a result, water-in-oil emulsions based on metabolizable oil were developed using squalene instead of mineral oil. The best-known examples of these are the Montanide adjuvants such as ISA 720 produced by the company Seppic. ISA 720 water-in-oil emulsion has been widely tested in more than 70 clinical trials in which it was often shown to induce immune responses rarely surpassed by other adjuvants. However, as with mineral oil–based emulsions, cysts or sterile abscesses at the site of injection are not infrequent and tend to increase in frequency on boosting.[43] In addition, instability of the antigen in contact with the emulsion was observed.[44] Finally, the difficulty in performing reproducible formulation at the time of administration led to a preformulation that may be incompatible with antigen stability. These challenges suggest that for prophylactic vaccines, researchers should, when possible, avoid using water-in-oil emulsions. For therapeutic vaccines, however, the risk of cysts and the challenges of formulation may be less significant. Such a vaccine (CIMAvax), which contains a mineral oil–based water-in oil-emulsion, Montanide ISA 51, has been licensed in Cuba for non–small cell lung cancer.[45]

Oil-in-Water Emulsions

Oil-in-water emulsion adjuvants were initially developed as an alternative to water-in-oil emulsions; the lower viscosity makes them easier to inject. The first emulsion of this class to be developed for human use was the SAF adjuvant made by Syntex Corporation. This emulsion was based on nonbiodegradable squalane, the catalytically hydrogenated form of squalene, and was designed as a vehicle to carry a synthetic immunostimulant, threonyl muramyl dipeptide (MDP).[46] The SAF adjuvant, while displaying strong adjuvant activity, was too reactogenic for use, partially because of MDP. However, because it was less effective without the immunostimulant, the emulsion was abandoned. Later, Chiron Corporation developed a range of oil-in-water emulsions by replacing squalane with squalene as another vehicle for muramyl derivatives. One of these emulsions (MF59) demonstrated some adjuvant properties and was further evaluated. MF59 and the majority of the later-developed oil-in-water emulsions used squalene, a natural, metabolizable product found in all plant and animal cells where it is a precursor of cholesterol. The commercial source is generally from shark liver, where it is abundant; alternative sources such as phytosqualene are being explored.[47] However, to date, only squalene from shark origin allows for a product with a purity level acceptable for human use.

Despite extensive clinical studies with a wide range of antigens, MF59 was approved only in one vaccine, FLUAD, an influenza vaccine for older adults, and licensed in several European countries from 1997 onward. While there was benefit of the adjuvanted vaccine in terms of antibody response to the influenza hemagglutinin in the target population,[48] the really significant benefit of MF59 and other oil-in-water emulsions became clear during investigations on pandemic influenza vaccines. The emergence of avian H5N1 influenza with occasional human-to-human transmission and the fear that this could become a pandemic led to intensive research in academic and pharmaceutical environments for ways to immunize a largely immunologically naïve population in the context of limited antigen supplies. This was especially critical when it was shown that for an H5N1 pandemic strain, sixfold more antigen was required to induce an immune response to a level equivalent to the seasonal influenza vaccine (90 μg compared with 15 μg).[49] It was shown that MF59 enabled immunization with significantly reduced doses of antigen, down to 7.5 μg, nearly a 12-fold dose reduction.[50]

In parallel to the development of MF59, several other oil-in-water emulsions were developed. For example an oil-in-water emulsion containing α-tocopherol as the immunostimulating compound was formulated by GlaxoSmithKline. This emulsion was tested earlier as part of the initial development of a malaria vaccine, alone (AS03) or in combination with the immunostimulants MPL and QS21 (described later).[51] AS03 demonstrated potent dose-sparing potential for pandemic influenza antigens, allowing for dose sparing down to 3.75 μg.[52]

In response to the need for dose sparing and the demonstrated potential of oil-in-water emulsions, Sanofi Pasteur developed AF03. This adjuvant is also squalene based; however, unlike the other emulsions, which are made by microfluidization of the components, the emulsification of AF03 is achieved without mechanical energy and uses a temperature-induced self-emulsification process (PCT application WO2007080308).

With the outbreak of the H1N1 influenza pandemic, European regulatory authorities approved three oil-in-water emulsions containing pandemic influenza vaccines, with MF59, AS03, and AF03 as adjuvants.

Other emulsions are under development, such as SE (stable emulsion), a squalene-based emulsion, originally developed by researchers at Corixa as a vehicle for MPL and synthetic TLR4 agonists.[53] This emulsion differs from the others in that the emulsifier is a natural phospholipid rather than a surfactant such as Tween-80. SE has been tested in clinical trials in combination with MPL in the context of a *Leishmania* vaccine,[54] as well as in combination with the TLR-4 agonist GLA (glucopyranosyl lipid adjuvant) in a schistosomiasis vaccine,[55] and in an influenza vaccine.[56] CoVaccine is an experimental adjuvant comprising sucrose fatty acid sulfate ester, combined with squalane, in the form of an oil-in-water emulsion. This adjuvant has been reported to allow for dose sparing in the context of influenza vaccines.[57] A single immunization with CoVaccine HT-adjuvanted H5N1 influenza virus vaccine induces protective cellular and humoral immune responses in ferrets and is undergoing clinical evaluation.

Table 6.4 gives an overview of oil-in-water emulsions used as adjuvants in licensed and investigational vaccines.

Adjuvant Effect of Oil-in-Water Emulsions on Naïve Versus Primed Persons. Oil-in-water emulsion adjuvants are highly effective at enhancing immunogenicity and allowing for dose reduction in pandemic influenza vaccines when the vaccinees are naïve. In contrast, the adjuvant effect for seasonal vaccines in healthy adults is quite poor.[58] This suggests that these adjuvants are excellent for priming but do not boost efficiently preexisting immune responses. The benefit for priming is also evident in the studies on the use of MF59-adjuvanted seasonal vaccine in infants, who usually respond poorly to a single administration of seasonal vaccine. These studies show a strong effect of MF59 on immunogenicity[59] and on efficacy of seasonal influenza vaccines, with the effect being strongest in the youngest ages.[60] The adjuvanted vaccine demonstrated 89% efficacy against vaccine-matched strains during two influenza seasons compared with 45% for the nonadjuvanted seasonal influenza vaccines group. On the basis of these data, Canada approved in early 2015 the use of MF59-adjuvanted seasonal influenza vaccine (FLUAD Pediatric) for the pediatric population (6 months to 2 years of age).

The situation is slightly different in the elderly population. Older adults have, in general, been primed to seasonal influenza; however, immunological senescence results in a decreased ability to induce sufficient antibody responses to

TABLE 6.4 Composition of Various Oil-in-Water Emulsions

Name	Components	Regulatory Status
SAF	Squalane; block copolymer; MDP	Abandoned
MF59	Squalene; Tween-80; Span 85	Approved for seasonal influenza for elderly people; approved for pandemic influenza (by the EMA); clinical benefit demonstrated for seasonal influenza in infants
AS03	Tocopherol; squalene; Tween-80	Approved for pandemic influenza (by the EMA)
AF03	Squalene; Tween-80; trometamol	Approved in pandemic influenza (by the EMA)
SE	Squalene; lecithin; block copolymer; glycerol; vitamin E	Clinical evaluation for *Leishmania*, influenza
CoVaccine	Squalane; sucrose fatty acid sulfate; Tween-80	Clinical evaluation for hepatitis

EMA, European Medicines Agency; MDP, muramyl dipeptide; SE, stable emulsion.

conventional influenza vaccines. FLUAD, the MF59-containing seasonal influenza vaccine that has been licensed in numerous countries for the past decade, has been shown to enhance the immune response in this nonresponder population.[61] A similar candidate vaccine using the AS03 oil-in-water emulsion has been tested in elderly adults for impact on influenza symptoms, demonstrating that the adjuvanted vaccine had advantages over the nonadjuvanted vaccine.[62]

Enhancing the Breadth of the Immune Response. Possibly one of the most important breakthroughs in adjuvant research during the last few years was the observation during the development of H5N1 pandemic influenza vaccines that oil-in-water adjuvants not only enhance the immune response and allow for dose reduction, but also enhance diversity and affinity of the antibodies induced.[63] This qualitative and quantitative expansion of the antibody repertoire has tremendous relevance for vaccination against pathogens, which undergo frequent antigenic drifts, such as influenza, as this would reduce the need for a perfect match between the antigen and the circulating pathogen strain.

This observation was first demonstrated in the ferret challenge model with the AS03-adjuvanted H5N1 vaccine through cross-neutralizing antibodies and lethal challenge.[64] The cross-neutralizing antibodies were confirmed later in clinical settings using the same AS03-adjuvanted H5N1 vaccine.[65] Data published with MF59-adjuvanted H5N1 vaccine showed the induction of epitope spreading from HA2 to HA1 hemagglutinin and to neuraminidase, suggesting that this is a common feature of this family of adjuvants. MF59 adjuvant enhances diversity and affinity of antibody-mediated immune response to pandemic influenza vaccines.[66]

Mode of Action. For many years oil-in-water emulsions were classified as vehicles, and it was assumed that the mode of action was primarily through enhanced delivery of the antigen to APCs or to the lymph nodes, even though most antigens do not associate physically to the oil droplets. It has, however, been shown that these emulsions stimulate the immune response indirectly. Using gene microarray analysis, Mosca and colleagues[67] demonstrated that skeletal muscle fibers are the target of MF59, where the adjuvant induces production of PTX3 and JunB, which, in turn, stimulate production of TNF-α, IL-1B, and CCLs (chemokines C-C ligands), resulting in activation of resident APCs and recruitment and activation of circulating APCs. A similar mechanism has also been demonstrated for the α-tocopherol–containing oil-in-water emulsion, AS03. Morel and colleagues[68] showed that similarly to MF59, AS03 induces expression of a range of cytokines, granulocyte recruitment at the injection site, and increased antigen uptake by monocytes and migration to the draining lymph node. In this adjuvant, however, the expression of some of the cytokines, such as IL-6, was modulated by the presence of α-tocopherol, which also enhanced the magnitude of the immune response, suggesting an immunomodulatory action of α-tocopherol independent of the oil emulsion. The same authors also demonstrated that the adjuvant effect is local and that temporal and spatial colocalization of antigen and adjuvant were required; that is, injecting the adjuvant in a site distant to the antigen or at a later time resulted in no adjuvant effect, consistent with a local and short-lived direct impact of the immune system.

Safety of Squalene-Containing Oil-in-Water Emulsions. During the H1N1 pandemic, two influenza vaccines containing an oil-in-water emulsion as adjuvant were approved and distributed in Europe (Pandemrix and Focetria); however, the uptake of these vaccines was hampered by broad media claims of the dangers of squalene. Many of these concerns seem to have arisen from a 2002 report that soldiers returning from the Gulf War with the so-called Gulf War syndrome had antisqualene antibodies that had been induced through receiving vaccines allegedly containing squalene.[69] Although the vaccines in question did not apparently contain squalene, the WHO Global Advisory Committee on Vaccine Safety reviewed all available data, including data from clinical trials with the squalene-containing FLUAD vaccine. Animal studies have also suggested that squalene can induce arthritis.[70] However, in the animal model used, the requirement for a specific breed and the use of a complex protocol irrelevant to the vaccination practice make it difficult to assess the relevance of these data for safety evaluation in humans. The committee concluded that there was no evidence that squalene could induce pathological antisqualene antibodies. Before recommending the use of squalene-containing oil-in-water emulsion for the H1N1 pandemic, the WHO also reviewed all clinical data from more than 35,000 volunteers of all ages and concluded that there were no significant safety concerns.

Thorough safety surveillance by authorities during the 2009–2010 pandemic season showed a positive benefit-to-risk profile for the vaccines. Since August 2010 however, an increased number of cases of narcolepsy has been reported in children and adolescents vaccinated with an AS03-adjuvanted H1N1 pandemic vaccine in three northern European countries. Interim reports of epidemiologic studies conducted in those countries have suggested an increased risk of narcolepsy in some vaccinated persons.[71]

The European Medicines Agency Committee for Medicinal Products for Human Use (CHMP) undertook a thorough

review of all available data as of July 2011, and concluded that the overall benefit-to-risk profile of the AS03-adjuvanted H1N1 vaccine remains positive. The CHMP acknowledged that further research in the areas of genetic and environmental factors in particular need to be explored before definitive conclusions can be drawn. In October 2013, based on the safety and efficacy results obtained for the pandemic H5N1 vaccine, the H5N1/AS03 adjuvanted vaccine received a positive opinion from the Vaccines and Related Biological Products Advisory Committee (VRBPAC) for use in adults older than age 18 years.

Although it is not known how the adjuvanted vaccine could cause narcolepsy, several hypotheses have been proposed, including the potential role of viral proteins such as the nucleoprotein,[72,73] suggesting that it is the presence of influenza viral nucleoprotein in the vaccine, rather than the adjuvant, that may be responsible. There are, however, no data clearly establishing a link between the adjuvant and the onset of the disease.

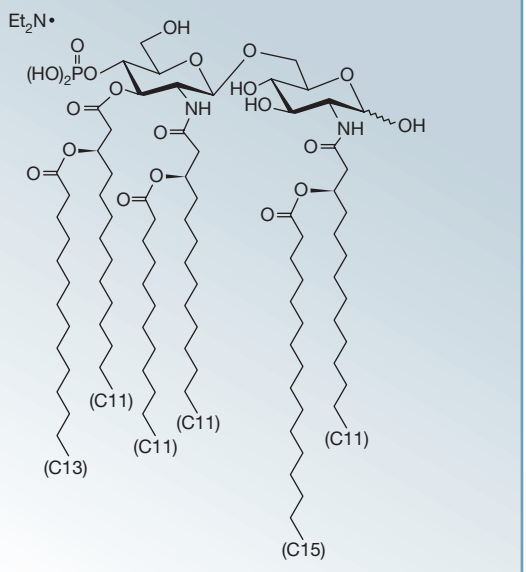
Other Oil Alternatives for Squalene. Little investigation into alternative metabolizable oils has been reported. As mentioned earlier, squalane was used in the SAF emulsion and is included in the CoVaccine adjuvant; however, it is not clear whether this oil can be metabolized or whether it is eliminated through the skin.[74] Miglyol, a metabolizable semisynthetic mixed triglyceride, has been evaluated as an oil-in-water emulsion adjuvant[75] and was shown to enhance immunity but at lower titers than a nonmetabolizable mineral oil. In the future, synthetic oils may overcome some of the challenges associated with the use of animal-derived squalene.

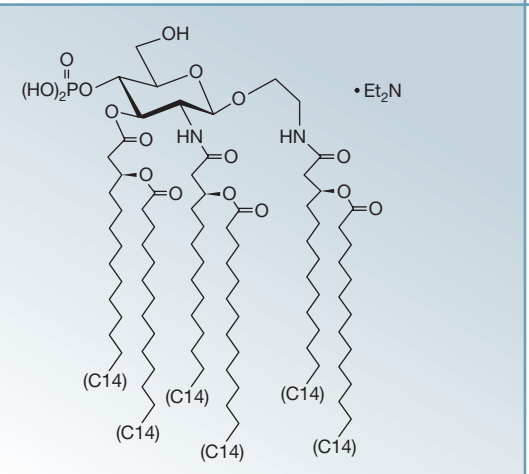
Toll-Like Receptor Agonists

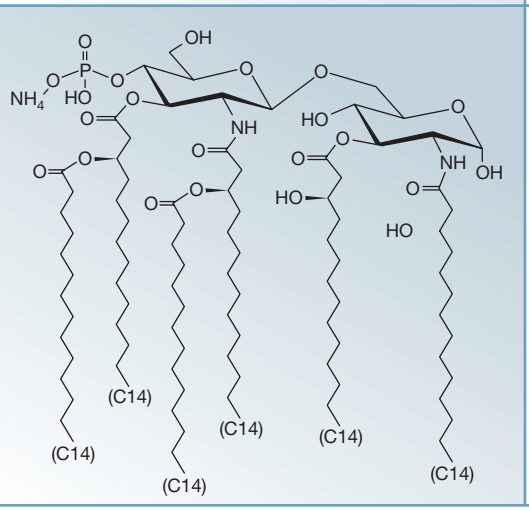
Although TLRs and their role in triggering the innate immune response were understood only after their ligands were identified as adjuvants, it is useful to classify these adjuvants through their specific receptor.

TLR4 Agonists

Although LPS, a major component of the outer membrane of Gram-negative bacteria, has long been known to be a potent stimulator of the immune system, its use in adjuvants has been curtailed by its toxic effects. Early studies demonstrated that removing the core carbohydrate, generating lipid A, reduced the pyrogenicity without reducing the immune-stimulating activity. Lipid A was still too pyrogenic for use; however, it was shown that formulating lipid A in liposomes reduced the pyrogenicity a further 100- to 1000-fold, and liposomal lipid A formulations were used in clinical trials for candidate malaria vaccines without severe adverse events.[76] In 1984, Ribi[77] demonstrated that a significantly less-toxic molecule could be obtained from LPS through sequential acidic and basic hydrolysis steps. The phosphate from the reducing-end glucosamine of lipid A derived from *Salmonella minnesota* RC595 is removed by mild acid hydrolysis, resulting in a molecule, referred to as monophosphoryl lipid A (MPLA, referring to all other TLR4 agonists) that was significantly less toxic than the lipid A and that still stimulated the immune response.[7] Ribi and colleagues then observed that if this MPLA was subjected to a further mild alkali hydrolysis, which selectively removed the acyl chain from the 3′ position of the disaccharide backbone, the resulting molecule, 3-deacylated MPLA (3d-MPL, or MPL), was even less pyrogenic but still exhibited adjuvant activity. GlaxoSmithKline developed a combination of adjuvants, AS04, in which MPL is formulated with aluminum salt. The adjuvant system AS04 is used in two approved vaccines (Cervarix [HPV vaccine] and Fendrix [hepatitis B vaccine for hemodialyzed patients]). Cervarix is aimed at preventing HPV infection and subsequent development of cervical cancer. Extensive clinical trials demonstrated an acceptable safety profile and efficacy of the vaccine against the vaccine strains during a period of more than 8 years in clinical trial follow-up,[78] as well as against divergent HPV strains not present in the vaccine.[79]







Mechanism of Action of TLR4 Agonists. Immune recognition of TLR4 agonists, such as LPS or MPL, is initiated by extraction of monomers from the aggregates by LPS-binding protein in the serum.[80] Monomeric LPS is transferred from LPS-binding protein to another accessory protein, CD14, which, in turn, transfers LPS to MD2, a secreted glycoprotein that associates with the extracellular domain of TLR4 to form the heterodimeric receptor that is responsible for the physiological recognition of LPS.[81] Lipid A bound to the TLR4–MD2 complex activates two distinct intracellular signaling pathways, which have come to be known by the names of the TLR4-proximal adaptor proteins, myeloid differentiation 88 (MyD88) and TIR domain-containing adaptor-inducing IFN-β (TRIF).[82] The Myd88 pathway leads to the activation of mitogen-activated protein kinase– and nuclear factor-κB–dependent proinflammatory responses, whereas the TRIF pathway activates kinases responsible for type I interferon responses.[83] Fig. 6.1 shows this schematically. To this extent, the TLR4 receptor is unique among the TLRs by its ability to induce two distinct signaling pathways. The activation of these pathways is dependent on the structure of the agonist, where minor changes in the number and length of the acyl chains can have a major effect on pathway activation. MPL has been reported to activate the TLR4-TRAM (TRIF-related adaptor molecule)-TRIF–based signaling pathway and the TLR4-MAL (MyD88 adaptor-like)-MyD88 pathway.[84]

Species Specificity of TLR4 Receptor. One challenge exists, however, in the development of TLR4 agonists for use in humans—the variability in the receptor specificity across species. Human, but not murine, TLR4–MD2 transmits proinflammatory signals in response to hexaacylated but not pentaacylated LPS.[85] Moreover, in humans, but less so in rodents, tetraacylated and pentaacylated forms can inhibit the adjuvant activity. As a result, molecules shown to work in rodents will not necessarily function the same way in humans. One example of this is the OM-174 molecule, a triacylated molecule that functioned in mice,[86] but apparently did not function in humans.

Other TLR4 Agonists. As MPL is isolated from a Gram-negative bacterium, *S. minnesota*, and such extraction can present manufacturing hurdles, many groups started to develop MPL analogs by chemical synthesis. Fig. 6.3 illustrates the structure of MPL and its analogs.

RC529, a member of the aminoalkyl glucopyranosides developed by Corixa scientists to provide a synthetic alternative to MPL, is structurally similar to a hexaacyl MPL, but the reducing terminal glucosamine has been replaced by a nonsaccharide backbone.[87,88] This molecule, formulated with alum, is in a hepatitis B vaccine approved in Argentina (SUPERVAX) that is reported to increase immune response compared with nonadjuvanted vaccine.[89]

Glucopyranosyl lipid adjuvant (GLA) is a synthetic hexaacyl form of MPL, but it is designed on the *Escherichia coli* form of LPS rather than the *S. minnesota* LPS. The molecule has a single acyl chain on the 2′ amine and has an acyl chain on the 3′ hydroxyl.[90] Clinical studies are in progress in different area such as tuberculosis (TB)[91] and influenza.[92]

E6020 is a synthetic TLR4 agonist that is not based on a saccharide backbone, but it is able to stimulate the TLR4–MD2 pathway.[93] E6020 is in Phase I trials.

Butantan, the Brazilian vaccine manufacturer, has initiated a program to produce MPL from the LPS extracted from *Bordetella pertussis*, a side product of the whole-cell pertussis vaccine process. This has been reported to enhance immunity to influenza vaccines.[94] Heptaacyl sulphonyl sucrose, a component of the CoVaccine HT adjuvant, currently in clinical development, bears strong resemblance to the backbone structure of TLR4 agonists and is thought to also act through TLR4.[57] One question remains, however, concerning the ability of synthetic TLR4 agonists to overcome polymorphism associated with the TLR4 receptor.[95] Indeed, it is not clear whether all recipients will respond equally to a given TLR4 agonist molecule and whether a mix of various molecules, as present in the different naturally produced TLR4 agonists, will be necessary to compensate for human diversity.

Formulation Challenges. Ensuring an optimal and reproducible adjuvant effect requires some formulation knowhow. In the currently approved vaccines with TLR4 agonists (Cervarix and Fendrix), the MPL is combined with an aluminum salt, and the combination of the two adjuvants is referred to as AS04. The combination of MPL with an aluminum salt adjuvant demonstrates some of the challenges of using MPL and analogous multiacylated disaccharide TLR4 agonists. Only a well-defined and controlled process can ensure that those molecules, which are insoluble in water, will not clump into aggregates that would lead to difficulty during sterilization by filtration or variability in the adjuvant activity. Various other approaches have been adopted to formulate TLR4 agonists, such as their incorporation into small unilamellar liposomes permitting a stable formulation. However, the activity is dependent on the ratio of lipid to agonist and how the agonist is combined with the liposomes.[96] Other alternatives include the incorporation of the agonists into oil-in-water emulsions or application of thermal or sonic energy to form colloids, which can be further stabilized by the addition of small quantities of lipids. The immune enhancement induced by TLR4 agonists is highly dependent on the physical structures, and determination of the consistency and stability of these requires detailed physicochemical characterization.[97] Successful use of these adjuvants, therefore, requires careful consideration of how to formulate them and how these amphipathic molecules will interact with other components of the vaccine, such as surfactants, aluminum salts, and antigens.

Safety of TLR4 Agonists. MPL, by far the most widely used of the TLR4 agonists, has demonstrated an acceptable safety profile. A metaanalysis of data from 11 clinical trials and more than 74,000 volunteers (two-thirds of whom received the vaccine that contains AS04 and one-third the control) shows no increase in severe adverse events over aluminum alone or hepatitis A vaccine controls.[78] It has been administered to millions of young women worldwide with few reported severe adverse events. This was further supported by the mechanism of action of AS04, which demonstrated that the adjuvant effect is local and that temporal and spatial colocalization of antigen and adjuvant were required; injecting the adjuvant in a site distant to the antigen or several hours after injection of the antigen resulted in no adjuvant effect.[13]

RC529 (see Fig. 6.3), a synthetic TLR4 agonist in an approved hepatitis B vaccine, has a limited history of clinical use, but as for MPL, no severe adverse events are associated with vaccine containing it. It is, however, not certain that other TLR4 agonists will have the same safety profile. Minor changes in the structure of TLR4 agonists can modify the way they activate the MyD88 or TRAM–TRIF pathway, promoting type 1 interferon or proinflammatory responses, and, as described earlier, the difference in receptor specificity between rodent and human TLR4 receptors may prevent these being detected in preclinical models. The acceptability and extensive history of whole-cell pertussis vaccines, which contain residual bacterial LPS, suggests that this is a pathway that can be stimulated without long-term adverse effects.

TLR9 Agonists

Bacterial DNA is recognized by mammalian species as a PAMP and serves as a potent activator in the innate immune system through interaction with the intracellular TLR9. Fragments of bacterial DNA and synthetic single-stranded oligodeoxynucleotides (ODNs) containing unmethlyated cytosine phosphate guanine (CpG) motifs (CpG ODNs) found in bacterial DNA have also been demonstrated to be powerful adjuvants.[98,99] In vivo, however, the lability of phosphodiester bonds results in rapid degradation of DNA oligonucleotides, and it has been found that replacing these labile ester bonds in the oligonucleotide sequences with phosphorothioate bonds stabilizes the oligonucleotides and significantly enhances the activity.[100] Most preclinical and clinical studies with CpG-containing oligonucleotides contained this modification.

Although obtaining pure CpG-containing oligonucleotides is easy, the development of this class of molecules as adjuvants for human vaccines is severely hampered by the fact that the specific hexameric CpG motifs inducing optimal immune enhancement differ between species.[98] Hence, evaluation of efficacy and safety in rodents is not readily translated to humans. Furthermore, the distribution of the TLR9 receptor and the pathways that its activation promotes also differ across species. In humans, CpG motifs are recognized by TLR9 found on natural killer (NK) cells,[101] B cells, and plasmacytoid dendritic cells,[98] but are not recognized by myeloid dendritic cells and monocytes. In contrast, in mice, those cells express TLR9, which recognizes CpG motifs. In both species, CpG motifs trigger B-cell activation and induce directly or indirectly the production of Th1 and proinflammatory cytokines, including IL-1, IL-6, IL-18, TNF-α, and interferon-γ; in some cases, CpG can redirect preestablished Th2 responses toward Th1.[102] CpG ODNs also act as adjuvants for antigens delivered by the mucosal route of administration.[103]

Numerous clinical evaluations of CpG as an adjuvant have been performed, most commonly with a sequence of CpG referred to as 7909, a sequence found to be optimal for human use. CpG has been evaluated with and without alum for malaria vaccines,[104,105] conjugate pneumonia vaccines,[106] and hepatitis B vaccines[107,108] and in HIV-infected patients in whom CpG permits rapid and long-term seroprotection.[107] Furthermore, it has been demonstrated in an elderly target population that when chemically conjugated CpG (1080 sequence) to the HBV (hepatitis B virus) antigen, the seroprotection induced was faster, superior, and more durable than three doses of a licensed comparator HBV vaccine (Engerix-B).[109]

CPG has also been used in cancer vaccines, such as non–small-cell lung cancer or melanoma, but as of this writing, with no significantly positive results in humans.[110] In addition, an improved hepatitis B vaccine containing CpG (Heplisav B), which demonstrated higher and faster immune responses than the current alum adjuvanted vaccine, did not get a positive opinion from VRBPAC (October 2013) because of the too-small size of the intended population safety database and was requested to extend it before potential licensure.

Other TLR9 Agonists. TLR9 receptors were thought for a long time to be specific for unmethylated CpG sequences; however,

it has been shown that poly(dI:dC), a DNA version of the well-known TLR3 agonist poly(I:C), is also a potent adjuvant, acting through the TLR9/MyD88-dependent pathway.[111] This oligonucleotide, in conjunction with a cationic peptide, is being developed as an adjuvant termed IC31 in clinical trials with recombinant TB antigens, and is reported to induce long-lasting T-cell responses to the antigens.[112] The mode of action thought to be independent of IC31 is dependent not only on the poly(dI:dC) TLR9 agonist, but also on the interaction of the oligonucleotide with the coformulated cationic peptide. The complex formed entraps the antigen and acts as a physical depot at the site of injection, resulting in sustained antigen and adjuvant release.[113] As for the examples given with TLR4, this demonstrates how critical formulation parameters are to successful adjuvant development

Other Toll-Like Receptor Ligands

The molecules described in the preceding sections account for the vast majority of late-stage clinical trials and approved vaccines containing adjuvants. However, numerous other TLR agonists are entering or are in early phase clinical trials. These are briefly described in the following paragraphs.

Flagellin is a protein that polymerizes to form the flagella of flagellated bacteria and is recognized by TLR5. This protein has been expressed as a fusion partner to influenza hemagglutinin or influenza M2e, in which it serves as an adjuvant, enhancing the immune response to the influenza antigen as shown in clinical trials.[114–116]

Numerous small molecules have been found to act as agonists of TLR7 and TLR8. The best known of these are the small-molecule nucleoside analogs, imiquimod and resiquimod (R-848),[117,118] that are TLR7 and TLR7/TLR8 ligands, respectively (both produced by 3M). Other well-known agonists include loxoribine[119] and bropirimine.[120] The use of these molecules as adjuvants is complicated by their low molecular weight and rapid removal from the site of injection. Several formulation methods enable these molecules to be used as adjuvants. Aldara cream, a 5% topical preparation of imiquimod that is licensed for treatment of genital warts and basal cell carcinoma, has been tested as an adjuvant for topical administration at the site of subcutaneous or intradermal injection of antigens.[121,122] This has been shown to have some adjuvant activity in human clinical trials for cancer.[123]

Other Adjuvants

Several other adjuvants are in advanced clinical development and do not fall into any of the aforementioned categories. The best known of these are the saponins, for which the mechanism of action is not fully understood. In this category, however, one could also include adjuvants such as virosomes, cationic liposomes, and polyelectrolytes, a class of polymers that includes polyoxidonium (a component of the Grippol influenza vaccine produced in Russia) and polyphosphazenes, which are being evaluated in several clinical trials.

Saponins. Saponins are triterpenoid molecules with a complex sugar backbone extracted from a variety of plants. The most widely used of these extracts is the saponin extract from the South American tree *Quillaja saponaria* Molina, referred to as Quil-A, which has been used as an adjuvant in veterinary vaccines since the 1970s. This mixture of saponins, with varying adjuvant activity and toxicity, was found to be too reactogenic for use in humans. The Quil-A saponins have an exquisite affinity for cholesterol, and when in contact with membranes containing cholesterol, they form a complex creating pores in the membrane. At the site of injection, this results in considerable reactogenicity. However, this affinity for cholesterol has also enabled the development of two adjuvants for human use based on the Quil-A saponins: ISCOMS and AS01.

ISCOMS are complexes of partially purified saponins from Quil-A, combined with cholesterol, to form small porous particles 50 to 60 nm in diameter with a characteristic buckminsterfullerene shape and a high density.[124,125] Originally, the antigen was associated with these structures through entrapment, conjugation, or hydrophobic interaction, processes that were tedious and not readily applicable to large-scale manufacturing. Subsequently, it was shown that association of the antigen with the particle is not required, and simple coadministration with antigen is adequate. As a result, simpler formulations (ISCOMATRIX and ISCOPREP), which can be simply mixed with the antigen, were developed by CSL (Australia).[126,127] These cholesterol–saponin complexes are less reactogenic than the parent saponin, yet maintain a strong adjuvant effect. Clinical trials have shown them to be slightly more reactogenic than placebo or active control; however, the reactogenicity is generally mild and acceptable. No other vaccine-related severe adverse events have been reported.[128]

An alternative approach to reduce the toxicity of Quil-A saponins was taken by Kensil and colleagues,[129] who isolated from the mixture of saponins a pure component, termed QS21, that was less toxic yet retained adjuvant activity. QS21, however, had two drawbacks: It was chemically unstable at even mildly alkaline conditions, and, while less toxic than the parent mixture, it was still reactogenic. It was found that by combining QS21 with liposomes that contained cholesterol, the stability of the molecule was significantly enhanced and the reactogenicity abrogated.[130] The adjuvant activity of this combination could be further enhanced by the addition of the TLR4 agonist MPL, and the resulting combination of adjuvants is termed AS01 by its developers, GlaxoSmithKline. This formulation has been tested in the clinical setting and shown to induce higher CD4 T-cell responses to a plasmodium antigen than the same immunostimulants combined with an oil-in-water emulsion.[131] Further challenge studies demonstrated the higher efficacy induced by this formulation, which led to the selection of AS01 for the Phase III efficacy study of the candidate malaria vaccine.[132,133] This again demonstrates the critical aspect of formulation and the challenges to identifying appropriate formulations for optimal activity of adjuvants. QS21 in its pure form is also being used as an adjuvant for cancer vaccines.[134]

The exact mechanism of action of QS21 has not been fully elucidated. The loss of adjuvant and lytic activity when the molecule is hydrolyzed suggests that membrane lysis has a role.[129] However, the adjuvant activity is also lost when the aldehyde function on the triterpenoid backbone is removed.[135] Several synthetic analogs have been developed that may permit a more detailed analysis of critical components of the molecule and a better understanding of its mechanism of action.[136,137] In addition to the malaria vaccine, AS01 has been used as the adjuvant of choice for a herpes zoster vaccine, based on a recombinant antigen. The zoster vaccine demonstrated a reduced risk of shingles of 97.2% in adults age 50 years and older compared to placebo,[138] and is the first recombinant adjuvanted vaccine to demonstrate such a level of efficacy against disease reactivation in individuals with latent virus.

There is renewed interest in saponin-based adjuvants from other plant sources, particularly from researchers in China and India.

Virosomes. Virosomes are reconstituted liposomes containing viral (typically influenza virus) proteins in the liposomal

membrane and, optionally, with additional antigens incorporated in the liposomal membrane or attached to the membrane.[139] Virosomes have been used for influenza vaccines (licensed in Europe as Inflexal) and as adjuvants for hepatitis A vaccine (licensed in Europe as Epaxal). They are under investigation as adjuvants for numerous other targets.[140]

Polyelectrolytes and Polycations. The influenza vaccine Grippol licensed in Russia contains polyoxidonium,[141] a polyelectrolyte copolymer of N-oxide 1,4-ethylene piperazine and (N-carboxyethyl)-1,4-ethylene piperidium bromide, that has immunostimulatory properties.[142] Even though little has been published about this specific polymer and its use as an adjuvant, an analogous polymer, poly(carboxylatophenoxy) phosphazene (PCPP) has been widely investigated as an adjuvant for vaccines and has been shown to exert adjuvant activity.[143,144]

Polycations such as polyarginine,[145] chitosan,[146,147] and cationic lipids[148] have also been shown to exert adjuvant activity. As for polyelectrolytes, the mode of action is not fully understood but is likely to involve interaction with cell membranes similar to that described for alum.[32] Another cationic adjuvant, CAF01, is a liposome-based adjuvant composed of the cationic quaternary ammonium lipid dimethyldioctadecylammonium (DDA) and the synthetic analog of mycobacterial cord factor; trehalose-dibehenate (TDB). CAF01 was originally developed as a CMI-promoting adjuvant for a subunit vaccine against TB, but the adjuvant has since been demonstrated to promote a diverse immune response resulting in CMI and humoral responses[149,150] and is in clinical evaluation.

Mucosal Adjuvants. There is a strong interest in the vaccine community in administering vaccines via the mucosal route. This route offers the advantages of being easier to administer and not requiring trained health care workers, but also has the potential of inducing mucosal immunity at the portal of entry of many pathogens. While mucosal delivery and induction of mucosal immunity can easily be achieved with live attenuated vaccines (e.g., oral poliovirus vaccines, oral rotavirus vaccines, nasally administered live attenuated influenza vaccines), inducing systemic or mucosal immunity with nonlive antigens is much more difficult. These tend to be nonimmunogenic or poorly immunogenic via the mucosal routes; consequently, numerous adjuvants have been evaluated to enhance the immunogenicity.

The most widely investigated are the bacterial adenosine diphosphate (ADP)-ribosylating exotoxins such as cholera holotoxin and *E. coli* heat-labile enterotoxin.[151] Even though these are potent mucosal adjuvants, their toxicity has, for the most part, precluded their use as adjuvants. Consequently, mutations have been introduced in an attempt to reduce their toxicity while aiming to retain some adjuvant activity.[152] These include adjuvants such as mLT(R192G), dmLT,[153] and LTK63.[154,155] For nasal delivery, these adjuvants have, however, presented unacceptable safety concerns. The native toxin was used as an adjuvant in an intranasal influenza vaccine that was licensed in Switzerland but was associated with occasional severe adverse events in the form of Bell palsy (partial facial paralysis) ascribed to the adjuvant,[156] and similar effects were seen in an experimental vaccine using the LTH63 detoxified mutant.[157] These adjuvants all contain the pentamer B subunit of the toxin, which binds ganglioside GM_1 on nerves and can be transported through retroaxonal transport to the root of the nerve; it is thought that the neurological adverse events may have arisen through such an interaction.[157] An alternative adjuvant, which does not contain the B subunit and, hence, does not bind GM_1 gangliosides, is CTA1-DD, which is currently in development.[158,159] These exotoxins also have been evaluated for oral delivery in several clinical trials; however, their susceptibility to acidic environments requires enteric formulations. The double mutant dmLT is currently being investigated as an adjuvant for oral or sublingual vaccination against enterotoxigenic *E. coli* (ETEC).[160]

FUTURE DIRECTIONS

The past decade has seen an unprecedented surge in understanding how adjuvants work. While the history of adjuvant discovery and development has evolved through serendipity, we are now in a position in which identification, selection, and use of adjuvants can be rationalized. This has opened the door to vaccine candidates against as yet unmet medical needs—vaccines that will not only prevent infectious diseases, but might also treat life-threatening diseases such as cancers or enable management of chronic disorders such as Alzheimer disease. Adjuvants appear also as a potential route to improve on current licensed vaccines that may be less efficient in a specific target population that requires a stronger stimulation on the immune system to develop a protective immune response.

There are a number of factors and unknowns that need to be considered. The most important of these is how to demonstrate the safety of adjuvants. As pointed out several times, there is an underlying concern that is not necessarily based on sound science that adjuvants can induce immune-mediated disorders. The absence of suitable animal models and the differences in receptors and receptor distribution between animals and humans can make it difficult in some cases to demonstrate that this is not the case.

Despite the occurrence of autoimmune reactions in the general population, the fear that adjuvants can induce or exacerbate autoimmune disorders is one that is at the forefront of follow-up and surveillance. Holding clinical development of a vaccine based on a single adverse event demonstrates the challenges of developing vaccines with novel adjuvants. The risk-to-benefit balance associated with the vaccine being developed will always be the guiding principle for ascertaining the value of a given approach. A large safety database to demonstrate rare events in such studies is not always possible, which underlines the difficulty introducing new approaches into the field of vaccines. The paucity of epidemiologic data on such immune-mediated disorders, which are key to establishing the background rate of disease, needs to be addressed so that factual analysis can be undertaken when such events occur.

The safety evaluation of a vaccine encompasses all constituents of the product. It cannot be assumed that an adjuvant that is safe in one vaccine with a given antigen will be safe when added to another vaccine, even if the latter vaccine is safe without adjuvant. A rational approach requires nonclinical toxicology, determination of the mode of action of the adjuvant, an evaluation of differences in receptors and activity in animal and human cells, controlled clinical trials, and postmarketing surveillance.[161]

Also, adequate formulation is critical for the activity of many adjuvants. Yet the knowhow for adjuvant formulation is not widely available, even though predicting how the physicochemical parameters of an adjuvant and its interaction with the antigen affect immune responses is key to its selection. All these points emphasize the criticality of process development, robustness, and reproducibility, and the ability to characterize adjuvants in a relevant and efficient way.

A host of adjuvants are now in clinical development; however, none tested in humans so far has the ability to induce functional $CD8^+$ T-cells to a level that can be seen with live viral vaccines. Live viral vaccines have their limitations, in particular with respect to repeated boosting and their use in

immune-suppressed persons. There is, therefore, a need to pursue research into adjuvants capable of inducing $CD8^+$ T-cell responses.

Finally, because vaccines are built on the combination of antigen(s) and adjuvant(s), the need for relevant and immunogenic antigens should not be overlooked. Because more and more vaccines will require the induction of both humoral immunity and CMI, there is a need for researchers to seek to improve the intrinsic immunogenicity of the antigen and to ensure optimum immune responses if the addition of an adjuvant is required.

It is only through the appropriate combination of antigen and adjuvant, selected on the basis of the targeted disease, relevant protective immune response, and target population, that adjuvants will fulfill their promises and find their place as a relevant and effective tool for improving human health.

7 Vaccine Additives and Manufacturing Residuals in Vaccines Licensed in the United States

Theresa M. Finn and William Egan

In addition to one or more immunogens,* a vaccine may contain any of several added substances such as an adjuvant or a preservative. Residual components from the manufacturing process, in varying amounts, are also present in the vaccine. This chapter addresses the types and amounts of additives that are present in vaccines, the rationale for their inclusion, and the applicable federal regulations. Additionally, residual materials from the manufacturing process that are present in the final formulation of the vaccine, as well as relevant federal regulations regarding these residuals, are discussed. Finally, albeit to a limited extent, several issues and concerns that currently pertain to the use of, or presence of, some of these additives and residuals are examined.

This chapter focuses on vaccines licensed in the United States; vaccines licensed outside the United States may contain the same types of additives and residuals, although the amounts that are present in any given vaccine may differ. For the purposes of this chapter, the term "additives" refers to materials that are added to the immunogen by the manufacturer for a specific purpose. Additives include adjuvants, preservatives (i.e., antimicrobial agents), and stabilizers, as well as materials that are added to affect pH and isotonicity. In addition to additives, vaccines contain residuals that remain from the licensed manufacturing process. The final formulation—immunogen plus additives and residuals—defines the specific vaccine; although not all manufacturing residuals can be identified and quantified, their presence and quantity is assumed to be constant because of the constancy of the manufacturing process. Some information regarding additives and residuals is considered to be a trade secret and thus confidential, and cannot be discussed in this chapter.

Vaccine manufacturing includes in-process and release tests, along with their respective specifications, for the allowable quantity of additives and certain residuals that may be present in the vaccine. These tests and their accompanying specifications are detailed in the product's Biologic License Application (BLA); some of the specifications may be provided in the vaccine's package insert. A manufacturer must report each change in the manufacturing process, including removal or adjustment in the quantity of an additive, to the U.S. Food and Drug Administration (FDA). FDA biologics regulations, found in 21 CFR §610.61, address whether the use of, and quantity of, additives and residuals must be disclosed in vaccine labeling. These regulations state:

> *The following shall appear on the label affixed to each package containing a product …*
>
> *(e) The preservative used and its concentration …*
> *(l) Known sensitizing substances, or reference to an enclosed circular containing appropriate information;*
> *(m) The type and calculated amount of antibiotics added during manufacture;*
> *(n) The inactive ingredients when a safety factor, or reference to an enclosed circular containing appropriate information;*
> *(o) The adjuvant, if present;*
> *(p) The source of the product when a factor in safe administration;*
> *(q) The identity of each microorganism used in manufacture, and, where applicable, the production medium and method of inactivation ….*

VACCINE ADDITIVES

Preservatives

Preservatives are added to vaccine formulations to prevent the growth of bacteria or fungi that may inadvertently be introduced into the vaccine during use. In some cases, preservatives are used during the manufacturing process (e.g., in buffers and column washes) to prevent microbial growth. Improvements in manufacturing technology, however, have decreased this need for the addition of preservatives to control bioburden during the manufacturing process. The Code of Federal Regulations (CFR) requires that, with certain defined exceptions, or with the approval of the Center Director (discussed later), preservatives must be added to multidose vials of vaccines. In the past, tragic consequences followed the use of multidose vials that did not contain a preservative, and served, in part, as the impetus for this requirement (see Wilson[1] for a discussion of incidents related to the lack of preservatives in vaccines). Specifically, 21 CFR §610.15(a) states; "Products in multiple-dose containers shall contain a preservative, except that a preservative need not be added to Yellow Fever Vaccine; Polio-virus Vaccine Live Oral; viral vaccines labeled for use with the jet injector; dried vaccines when the accompanying diluent contains a preservative; or to an Allergenic Product in 50 percent or more volume in volume (v/v) glycerin."

Although the regulation does not specify a quantity, it does require that the preservative used "shall be sufficiently nontoxic so that the amount present in the recommended dose of the product will not be toxic to the recipient, and in the combination used it shall not denature the specific substances in the product to result in a decrease below the minimum acceptable potency within the dating period when stored at the recommended temperature."

The CFR does not, however, provide a definition of a preservative. The definition (i.e., antimicrobial effectiveness) that has been used by the FDA for vaccines and other biologicals is found in the U.S. Pharmacopoeia (USP).[2] This is a functional definition, wherein the final formulation of the vaccine, including the preservative, is challenged with specified quantities of the following organisms: *Candida albicans, Aspergillus brasiliensis, Escherichia coli, Staphylococcus aureus,* and *Pseudomonas aeruginosa*. The test sample (preservative-containing vaccine plus the microorganism) is incubated at 20° to 25°C,

*An immunogen is a preparation consisting of all or a portion of a disease-containing organism, or the nucleic acid that encodes one or more of the proteins from that organism, or all or a portion of a human tissue, and it is administered to an individual to induce an immune response to the immunogen for the treatment or prevention of a disease or condition.

and the number of viable microorganisms is determined on days 7, 14, and 28. A preservative is deemed acceptable if the following are achieved:

- Bacteria: a reduction of not less than 1.0 $\log_{10}$ from the initial count at 7 days, and not less than a 3.0 $\log_{10}$ reduction from the initial count after 14 days, and no increase in the 14-day count at 28 days.
- Yeasts and molds: remain at or below the level of the initial inoculum on days 7, 14, and 28.

Note that the antimicrobial agent is not tested by itself; rather, it is the final vaccine formulation that is tested.

Preservatives cannot completely eliminate the risk of bacterial or fungal contamination of vaccines; moreover, they do not address any potential viral contamination. Although it occurs rarely, and not in the recent past, the scientific literature does contain reports[3,4] (see also Wilson[1]) of bacterial contamination of vaccines despite the presence of a preservative, emphasizing the need for meticulous attention to technique when withdrawing vaccines from multiuse vials. At present, the following preservatives are used in U.S.-licensed vaccines: phenol, benzethonium chloride plus formaldehyde, 2-phenoxyethanol, and thimerosal (termed *thiomersal* in some other countries). Recently, the FDA amended the biologics regulations to permit exceptions or alternatives to the regulation for constituent materials (21 CFR §610.15), which includes preservatives and adjuvants. The following section was added to the regulation: "(d) The Director of the Center for Biologics Evaluation and Research (CBER) or the Director of the Center for Drug Evaluation and Research (CDER) may approve an exception or alternative to any requirement in this Section. Requests for such exceptions must be in writing."

The amended regulation could, as an example, allow the use of particular vial adaptors to prevent contamination of products in multidose vials without the use of preservatives. As noted in the final rule,[5] the Director of CBER or the Director of CDER "would not approve an exception or alternative when the data or conditions of use, including the indication and patient population, do not provide a sufficient scientific and regulatory basis for such an approval." The amended regulation took effect in May 2011.

As noted, a preservative "shall not denature the specific substances in the product to result in a decrease below the minimum acceptable potency within the dating period when stored at the recommended temperature." Certain preservatives are not compatible with certain antigens; compatibility must be established. For example, it has been known for a number of years that thimerosal has a deleterious effect on the potency of inactivated poliovirus vaccine (IPV).[6,7] An alternative preservative is necessary for IPV. A preservative that is used in other products, 2-phenoxyethanol,[8] has been found to be compatible with IPV vaccine formulations; it is used as a preservative in both of the currently U.S.-licensed IPV vaccines (IPOL [Sanofi Pasteur SA] and Poliovax [Sanofi Pasteur Ltd.; not currently marketed in the United States]).

Phenol is currently used in three U.S.-licensed vaccines: the polysaccharide vaccines Pneumovax 23 (a 23-valent pneumococcal polysaccharide vaccine manufactured by Merck Sharp & Dohme Corp.) and Typhim Vi (*Salmonella typhi* capsular polysaccharide vaccine manufactured by Sanofi Pasteur SA), and ACAM2000 (the smallpox vaccine from Sanofi Pasteur Biologics Co.); each of these vaccines contains 0.25% phenol as a preservative (phenol is contained in the diluent for ACAM2000). According to the Minimum Requirements of the National Institutes of Health (NIH),[9,10] phenolic compounds (such as phenol or the various creosols) are not permitted as preservatives in diphtheria- and tetanus toxoid–containing products.* This requirement is also reflected in other regulations or requirements, such as those of the World Health Organization (WHO).[11] It has been reported that phenol affects diphtheria toxoid, "so that its immunizing power falls rapidly."[12] Benzethonium chloride with formaldehyde is currently used in only one U.S.-licensed vaccine, anthrax vaccine adsorbed (BioThrax; the preservative is 25 μg/mL benzethonium chloride and 100 μg/mL formaldehyde), manufactured by Emergent BioDefense Operations Lansing LLC.

In recent years, considerable controversy has surrounded the use of thimerosal, an organomercurial, in vaccines. Although allergic responses to thimerosal have been described,[13] a controversy, arising in the late 1990s, centered on the hypothesis that exposure to thimerosal, a derivative of ethyl mercury, may be causally linked to autism and other neurodevelopmental disorders in children. Although there were no clear or definitive data to support a link between thimerosal and neurodevelopmental disorders, the U.S. Public Health Service (PHS), first in July 1999[14] and again in June 2000,[15] in an effort to reduce mercury exposure in children from all sources, recommended that thimerosal be removed from pediatric vaccines as expeditiously as possible. The July 1999 PHS statement was issued jointly with the American Academy of Pediatrics; the June 2000 PHS statement was issued jointly with the American Academy of Pediatricians, the American Academy of Family Physicians, and the Advisory Committee on Immunization Practices (ACIP). Letters from CBER of the FDA, in 1999[16] and again in 2000,[17] to the various vaccine manufacturers noted that the removal of thimerosal from vaccines was merited and requested manufacturers' timelines for thimerosal removal or submission of an explanation as to why thimerosal removal was not currently feasible.

In 2004, the Institute of Medicine (IOM)'s Immunization Safety Review Committee of the National Academy of Science's IOM issued its final report, examining the hypothesis that, inter alia, thimerosal-containing vaccines are causally associated with autism. The committee concluded that the body of evidence favors rejection of a causal relationship between thimerosal-containing vaccines and autism, and that the hypotheses that were generated concerning a biological mechanism for such causality were theoretical only.[18] The European Medicines Agency also noted, as a precautionary measure, "that, although there is no evidence of harm caused by the level of exposure from vaccines, it would be prudent to promote the general use of vaccines without thiomersal and other mercury-containing preservatives."[19] Of note, the WHO continues to recommend the use of vaccines containing thimerosal because the need for multidose preservative-containing vaccines and, thus, the benefit of using such vaccines outweighs the theoretical risk of toxicity.[20] Additionally, the Global Advisory Committee on Vaccine Safety has stated that it remains of the view that there is no evidence supporting a causal association between neurobehavioral disorders and thimerosal-containing vaccines.[21] A more comprehensive update on the thimerosal-autism hypothesis for vaccines may be found in Chapter 82.

At present, with the exception of the inactivated influenza vaccine, all of the U.S.-licensed, routinely recommended pediatric vaccines (hepatitis B, diphtheria–tetanus toxoid–acellular pertussis [DTaP], *Haemophilus influenzae* type b, IPV, pneumococcal conjugate, human papillomavirus [HPV], hepatitis A, rotavirus, measles-mumps-rubella [MMR] and varicella) are thimerosal free or contain only trace amounts (<1 μg

*At the time of the writing of these requirements for diphtheria and tetanus toxoids, U.S. vaccine regulation was the responsibility of the NIH.

TABLE 7.1 Preservatives, Adjuvants, and Inactivation Residues Noted in Labels of Selected U.S.-Licensed Vaccines

Vaccine	Trade Name	Preservative (Amount/ Dose) and μg Hg/Dose[a] (if Noted)	Adjuvant and Aluminum Content Per Dose	Inactivation Residues (Amount Per Dose if Noted)
BACTERIAL VACCINES				
Td (adult)	DECAVAC	None ≤0.3 μg Hg	Alum [$KAl(SO_4)_2$] Al: ≤0.28 mg	Formaldehyde (≤0.1 mg)
	None/MassBiologics	None ≤0.3 μg Hg	$AlPO_4$ Al: ≤0.53 mg	Formaldehyde (<0.1 mg)
DTaP	DAPTACEL	None	$AlPO_4$ Al: 0.33 mg	Formaldehyde (≤0.5 μg) Glutaraldehyde (<50 ng)
	Infanrix	None	$Al(OH)_3$ Al: ≤0.625 mg	Formaldehyde (≤0.1 mg) Glutaraldehyde (%NN)
Tdap	Adacel	None	$AlPO_4$ Al: 0.33 mg	Formaldehyde (≤5 μg) Glutaraldehyde (<50 ng)
VIRAL VACCINES				
Hepatitis A	Havrix 0.5-mL pediatric dose	None	$Al(OH)_3$ Al: 0.25 mg	Formalin (≤0.05 mg)
	VAQTA 0.5-mL pediatric dose	None	Aluminum (mixed salt) Al: 0.225 mg/dose	Formaldehyde (<0.4 μg)
Human papillomavirus	Cervarix	None	AS04 (MPL + $Al(OH)_3$): 0. 5mg Al: 0.17 mg	N/A
	Gardasil 9	None	Aluminum (mixed salt) Al: 0.5 mg/dose	N/A
Influenza	Afluria (2014-2015) (0.5 mL, single dose)	None	None	β-Propiolactone (≤2 ng)
	Afluria (2014-2015) (multidose vial)	Thimerosal 24.5 μg Hg	None	β-Propiolactone (≤2 ng ng)
	Agriflu (2013-2014) (0.5 mL, single dose)	None	None	Formaldehyde (≤10 μg)
	Fluarix (2014-2015) (0.5 mL, single dose)	None	None	Formaldehyde (≤5 μg)
	Fluvirin (2014-2015) (0.5 mL, single dose)	None ≤1 μg Hg	None	β-Propiolactone (≤0.5 μg)
	Fluvirin (2014-2015) (multidose vial)	Thimerosal 25 μg Hg	None	β-Propiolactone (≤0.5 μg)
Japanese encephalitis virus	Ixiaro	None	Al $(OH)_3$ (250 ug) Al: NN	Formaldehyde (≤200 ppm, ≤0.1 mg/0.5 mL dose)
Polio	IPOL	2-Phenoxyethanol (2.5 mg) + formaldehyde (≤0.1 mg)	None	Formaldehyde ≤0.1 mg

DTaP, diphtheria–tetanus toxoid–acellular pertussis; MPL, 3-*O*-desacyl-4′-monophosphoryl lipid A; NN, not noted on label; %NN, amount in final container not noted on label; Td, tetanus-diphtheria vaccine for adolescents and adults; Tdap, tetanus, diphtheria, and pertussis for adolescents and adults.

[a]Dose is 0.5 mL.

of mercury per dose) as a residual from the manufacturing process (Table 7.1). Of the U.S.-licensed trivalent injectable influenza vaccines, six are approved for pediatric use: Fluzone (Sanofi Pasteur Inc.), for use in infants 6 months of age and older; Fluvirin (Seqirus Vaccines, Ltd.), for use in children 4 years of age and older; Afluria (Seqirus Pty Ltd.), for use in children 5 years of age and older; Fluarix (GlaxoSmithKline Biologicals), for use in children 3 years of age and older; FluLaval (ID Biomedical Corporation of Quebec), for use in children 3 years of age and older; and Flucelvax (Seqirus, Inc.), for use in children 4 years of age and older. These six inactivated influenza vaccines are available in either thimerosal-free presentations (Fluzone, Fluarix, Afluria, FluLaval, and Flucelvax) or with trace thimerosal (≤1 μg of mercury per 0.5 mL dose) (Fluvirin). Additionally, there are four U.S.-licensed quadrivalent inactivated influenza vaccines (FluLaval Quadrivalent, Fluzone Quadrivalent, Fluarix Quadrivalent, and Flucelvax Quadrivalent) available for children; the age indications are as above for the trivalent presentations and single-dose presentations of these vaccines contain no thimerosal. FluMist Quadrivalent (MedImmune, LLC) is a live, attenuated quadrivalent influenza vaccine and does not contain thimerosal.

Two Tdap (tetanus, diphtheria, and pertussis for adolescents and adults) vaccines (tetanus, diphtheria, and acellular pertussis vaccines, with the lowercase letters indicating a reduced antigen content for the diphtheria toxoid and one or more of the pertussis antigens) for use in adolescents and adults, Adacel (Sanofi Pasteur Ltd.) for use in persons 10 through 64 years of age, and Boostrix (GlaxoSmithKline Biologicals) for use in persons 10 years of age and older, are licensed in the United States. Neither product contains thimerosal. The quadrivalent (Groups A, C, Y, and W135) meningococcal conjugate vaccines, Menactra (Sanofi Pasteur Inc.) and Menveo (Novartis Vaccines and Diagnostics S.r.l.) do not contain any preservative. MenHibrix (GlaxoSmithKline Biologicals) is a bivalent meningococcal conjugate vaccine

(against serogroups C and Y), additionally containing an *H. influenzae* type b capsular polysaccharide (polyribosyl-ribitol-phosphate) conjugate, and is likewise thimerosal free. Similarly, the two meningococcal serogroup B vaccines BEXSERO (Novartis Vaccines and Diagnostics S.r.l.) and TRUMENBA (Wyeth Pharmaceuticals Inc.) and the HPV vaccines Gardasil 9 (Merck Sharp & Dohme Corp.) and Cervarix (GlaxoSmith-Kline Biologicals) do not contain any preservative.

A diphtheria and tetanus toxoid vaccine (DT) for use in children younger than 7 years of age is available from Sanofi Pasteur Inc. It contains only a trace amount of thimerosal as a manufacturing residual.

Adjuvants

Adjuvants are materials that enhance and direct the immune response (see Chapter 6). Vaccine adjuvants are not licensed separately; rather, the adjuvant is a constituent of the licensed vaccine, and it is the vaccine formulation, in toto, that is tested in clinical trials and is licensed. An adjuvant cannot be added or removed, or its amount in a licensed vaccine changed, without submitting a supplement to the vaccine license and obtaining approval from the FDA. The various aluminum salts (aluminum hydroxide, aluminum phosphate, alum [potassium aluminum sulfate], or mixed aluminum salts) are the most commonly used adjuvants in U.S.-licensed vaccines. One vaccine, Cervarix (GlaxoSmithKline Biologicals), which contains AS04, an adjuvant system composed of an aluminum salt and monophosphoryl lipid A, a detoxified lipopolysaccharide (LPS), has been licensed. In 2013, as part of the U.S. government's national pandemic preparedness initiative, an H5N1 monovalent influenza vaccine, approved for use in persons 18 years of age and older, containing the unique adjuvant, AS03, manufactured by ID Biomedical Corporation of Quebec was licensed. The AS03 adjuvant is an emulsion composed of squalene, DL-α-tocopherol, and polysorbate 80. In 2015, an inactivated influenza vaccine, Fluad (Seqirus Vaccines Ltd.), which contains the squalene-based adjuvant MF59C.1, was licensed.

Despite worldwide use of aluminum salts for more than 50 years, surprisingly little has been known about their mechanism of action as adjuvants (see, e.g., Chapter 6 and Hogenesch[22]). For many years, the prevailing thought was that the aluminum salts functioned as depots for the vaccine immunogens. More recently, it was shown that the aluminum salts also activate inflammasomes, clusters of proteins found inside certain cells. Inflammasomes respond to stresses such as infection or injury by releasing cytokines, which, in turn, stimulate an immune response.[23]

Table 7.1 presents the specific aluminum salt (hydroxide, phosphate, sulfate, or mixed) and the quantity of aluminum that is contained in a number of commonly used vaccines. (The aluminum content that is listed for some vaccines noted in Table 7.1 represents the upper limit of the specification; the vaccine may routinely contain less aluminum.) By regulation (21 CFR §610.15[a]), the aluminum content of a vaccine cannot exceed 0.85 mg of aluminum per dose if the amount is assayed, or 1.14 mg/dose if determined by calculation based on the amount of the aluminum compound that is added. To harmonize with WHO recommendations, this regulation was amended in 1981 to permit up to 1.25 mg of aluminum per dose. However, the higher amount was permitted only "provided that data demonstrating that the amount of aluminum used is safe and necessary to produce the intended effect are submitted to and approved by the Director, Center for Biologics Evaluation and Research" (21 CFR §610.15[a]). The European Pharmacopoeia likewise restricts the aluminum content to 1.25 mg per dose. It should be noted that the above regulation for aluminum content refers to an individual dose of a biological product; thus, for example, for a hypothetical combination vaccine derived from licensed components, the aluminum content for the combination vaccine may still not exceed 0.85 mg.

Recently, the FDA amended the CFR requirements[5] for constituent materials including adjuvants to permit, when justified, exceptions or alternatives such as the use of an increased aluminum content in a vaccine; this change may have a greater impact on certain therapeutic vaccines than on the preventive vaccines.

Concerns have been raised in recent years about the use of aluminum in vaccines and potential adverse outcomes that may be associated with its use at the levels that exist in individual vaccines and through the additive effects of multiple vaccinations. These concerns about the use of aluminum in vaccines prompted a workshop that was sponsored by the National Vaccine Program Office in May 2000. The general use of aluminum salts in vaccines[24] and aluminum toxicokinetics[25] were reviewed during the workshop. In their overall summary of the workshop, Eickhoff and Meyers[26] noted that "based on 70 years of experience, the use of salts of aluminum as adjuvants in vaccines has proven safe and effective." A more recent study by FDA scientists, using updated parameters for toxicokinetic assessments, including current recommended vaccines and aluminum excretion data, concluded that the risk from aluminum exposure from vaccines and the environment to infants was extremely low.[27]

Stabilizers

Various stabilizers are added to vaccines to help protect them from adverse conditions such as the freeze-drying process (for those vaccines that are freeze-dried) or heat. For freeze-dried (lyophilized) preparations of vaccines, it is also necessary to add materials that provide a bulk matrix for the vaccine. The amount of an immunogen that is contained in a vaccine can be extremely small, on the order of tens of micrograms or less. If sufficient amounts of various materials were not added to the vaccine before lyophilization, the vaccine would not be readily observable and would most likely adhere to the vial wall. By way of illustration of vaccine immunogen masses, ActHIB (Sanofi Pasteur SA), a polysaccharide conjugate vaccine that is marketed in a freeze-dried presentation, contains approximately 10 μg of purified polysaccharide conjugated to 24 μg of tetanus toxoid. The immunogen mass for live viral vaccines is even less, on the order of nanograms (approximately 10^3 to 10^5 viral particles per dose). Thus, there is a need to provide a matrix to contain these vaccines during freeze-drying.

The types of material that are added to vaccines as stabilizers include sugars (such as sucrose or lactose), amino acids (such as glycine or the monosodium salt of glutamic acid), and proteins (such as gelatin). Table 7.2 lists the stabilizers that are used for a number of common vaccines.

Added proteins may be of concern for two principal reasons. The first concern arises from the potential for animal- and human-derived protein to contain one or more adventitious agents. The second concern arises from the potential for these proteins to elicit an allergic reaction. The two animal- or human-derived proteins that are currently used as stabilizers in U.S.-licensed vaccines are human serum albumin (HSA) and gelatin. The FDA has, as of this writing, required that, if blood-derived HSA is used in vaccine manufacture, only U.S.-licensed HSA may be used. Additionally, an FDA guidance recommends that the following statement appear in the Warnings section of the package insert for blood-derived HSA-containing products[28]: "This product contains albumin, a

TABLE 7.2 Vaccine Stabilizers, Manufacturing Residuals, and Cell Lines Noted in the Labels of Selected U.S.-Licensed Vaccines

Vaccine	Trade Name	Stabilizers Per Single Dose[a]	Manufacturing Residuals (Except Inactivating Agents) Per Dose[a]	Cell Line
LIVE BACTERIAL VACCINES				
Typhoid	Vivotif (1 capsule)	3.3–34.2 mg Sucrose; 0.2–2.4 mg ascorbic acid; 0.3–3.0 mg amino acid mixture	NN	NA
LIVE VIRAL VACCINES				
Mumps, measles, rubella	MMR-II	1.9 mg Sucrose 14.5 mg hydrolyzed gelatin; 14.5 mg sorbitol; 0.38 mg monosodium L-glutamate; sodium phosphate; ≤0.3 mg recombinant human albumin	25 μg Neomycin; <1 ppm fetal bovine serum albumin; other buffer and media components[b]	Chick embryo cell culture (measles and mumps) WI-38 cells (rubella)
Yellow fever	YF-Vax	Sorbitol and gelatin (%NN)	NN	Chicken embryos
INACTIVATED VIRAL VACCINES				
Polio	IPOL	NN	<5 ng Neomycin; <200 ng streptomycin; <25 ng polymyxin B; <1 ppm calf serum protein	Vero cells
Japanese encephalitis virus	Ixiaro	None added	≤50 ng Bovine serum albumin; ≤100 pg host cell DNA; ≤200 ppm sodium metabisulfite; host cell proteins (≤300 ng/6 μg of protein); ≤0.5 μg protamine sulfate	Vero cells
Hepatitis A	Havrix (1mL dose)	NN	≤5 μg/mL MRC-5 cellular proteins; ≤40 ng/mL neomycin sulfate	MRC-5 cells
	VAQTA (1 mL dose)	70 μg sodium borate/mL	<0.1 μg Nonviral protein/mL; <4×10^{-6} μg DNA/mL; <10^{-4} μg bovine albumin/mL	MRC-5 cells
Rabies	RabAvert	<12 mg polygeline; 1 mg potassium glutamate	<0.3 mg Human serum albumin <3 ng ovalbumin; <1 μg neomycin; <20 ng chlortetracycline <2 ng amphotericin B	Chicken fibroblasts
	Imovax	NN	<100 mg Human serum albumin; <150 μg neomycin sulfate; <20 μg phenol red	MRC-5 cells
RECOMBINANT PROTEIN VIRAL VACCINES				
Human papillomavirus	Gardasil 9	NN	<7 μg Yeast protein	*Saccharomyces cerevisiae*
	Cervarix	NN	<40 ng Insect cell and viral proteins; <150 ng bacterial proteins	*Trichoplusia ni*
Hepatitis B	Engerix-B (1 mL dose)	NN	≤5% Yeast protein	*S. cerevisiae*
	Recombivax HB (1 mL dose)	NN	<1% Yeast protein	*S. cerevisiae*
Influenza	Flublok	NN	≤28.5 μg Baculovirus and insect cell proteins; ≤10 ng baculovirus and insect cell DNA; ≤100 μg Triton X-100	*Spodoptera frugiperda*

TABLE 7.2 Vaccine Stabilizers, Manufacturing Residuals, and Cell Lines Noted in the Labels of Selected U.S.-Licensed Vaccines *(Continued)*

Vaccine	Trade Name	Stabilizers Per Single Dose[a]	Manufacturing Residuals (Except Inactivating Agents) Per Dose[a]	Cell Line
VIRAL VACCINES				
Influenza (trivalent)	Afluria	NN	≤10 ppm Na taurodeoxycholate; <1 μg ovalbumin; ≤3 ng neomycin sulfate; ≤0.5 ng polymyxin B	Embryonated chicken eggs
	Flucelvax	NN	≤8.4 μg MDCK cell protein; ≤120 μg non-HA protein; ≤10 ng MDCK cell DNA; ≤1125 μg polysorbate 80; ≤13.5 μg cetyltrimethylammonium bromide	Madin-Darby Canine Kidney (MDCK) cells
	Fluarix	NN	≤0.0016 μg Hydrocortisone; ≤0.15 μg gentamicin sulfate; ≤0.05 μg ovalbumin; ≤50 μg sodium deoxycholate	Embryonated chicken eggs
	Fluzone	NN	≤150 μg octylphenol ethoxylate	Embryonated chicken eggs

NA, not applicable; NN, none noted; %NN, percentage not noted in labeling.
[a]Each vaccine dose listed in the Table is 0.5 mL unless otherwise noted.
[b]Amounts of all ingredients not specified in labeling.

derivative of human blood. Based on effective donor screening and product manufacturing processes, it carries an extremely remote risk for transmission of viral diseases. Although there is a theoretical risk for transmission of Creutzfeldt-Jakob disease (CJD), no cases of transmission of CJD or viral disease have ever been identified that were associated with the use of albumin."

For HSA produced as a recombinant DNA protein, it would not be necessary for the albumin to be separately licensed by the FDA nor would the above-quoted warning be included in the package insert (as it is not derived from blood). In August 2005, the FDA approved a license supplement for use of recombinant HSA in MMR-II (Merck Sharp & Dohme Corp.).

Gelatin or processed gelatin is also used as a stabilizer. Gelatin may be bovine or porcine derived. Despite the use of a harsh manufacturing procedure (extremes of heat and pH) in the production of gelatin, there is concern about the presence of the bovine spongiform encephalopathy (BSE) agent in bovine-derived material. Thus, any bovine-derived gelatin that is added to vaccines, or used in the vaccine manufacturing process, must not be sourced from countries reporting BSE *or* from countries that do *not* meet the latest BSE-related standards of the Office International des Epizooties (OIE) (see "Transmissible Spongiform Encephalopathy Agents" later).[29]

A second concern for gelatin relates to allergic responses. Allergic responses to gelatin, although rare, have been described in the medical literature.[30–33] It has been hypothesized that in Japan, use of partially hydrolyzed gelatin, which contained a small amount of high-molecular-weight gelatin, contributed to an increase in the incidence of allergic reactions.[33,34] Nakayama and Aizawa noted that a change to hydrolyzed modified porcine gelatin, together with discontinuation of the use of gelatin-containing DTaP vaccines, may have contributed to a decrease in the incidence of allergic reactions after administration of monovalent measles and mumps vaccine in Japan.[34] A severe allergic reaction to gelatin is a contraindication to receiving gelatin-containing vaccines.

Various buffers (e.g., phosphate buffer) are also used in vaccines to maintain a particular pH range, and salts (e.g., NaCl) may be added to achieve isotonicity.

MANUFACTURING RESIDUALS

In principle, any or all of the materials that are used in the manufacturing process may be present in the final vaccine formulation. For the purposes of this chapter, materials that are present in the final vaccine formulation that derive from the manufacturing process are termed *residuals*. Various steps in the manufacturing process may remove or reduce the amounts of many of these residuals. However, for various vaccines, an acceptable technology to remove these manufacturing residuals may not exist, or there may be no perceived need (e.g., with regard to safety or a potential for an adverse effect on efficacy) for their removal. Additionally, and as a general principle, it is not possible to remove a particular substance completely, nor is it possible to demonstrate that a particular substance has been removed completely. For many substances, the residual amount may be below the limits of detection by current analytic technologies, and may, for practical reasons, be considered absent.

Bacterial and viral inactivation substances must be noted in the package label (21 CFR §610.61[q]). Residual bacterial or cellular culture components, such as antibiotics that are used during manufacture, as well as sensitizing substances (generally proteins), and other inactive ingredients when considered a safety factor, also must be noted in the label (21 CFR §610.61 [l][m][n]). There may be some overlap between these categories; however, they are grouped in this manner for convenience and to aid a discussion of these materials as they are affected by current regulations. Residual bacterial or cell culture components may be included in these categories, but other residuals, such as DNA and endotoxin, are not generally noted in labeling.

Inactivation Residuals

Various agents may be used to inactivate bacteria and viruses or to detoxify bacterial toxins. The goal of these chemical treatments is to inactivate the bacterium or virus or to remove toxic activity while still preserving the antigenicity of the product against the homologous organism or toxin. After inactivation, a virus or bacterium may be processed further to furnish particular antigens. For example, after inactivation, influenza

viruses may be split by various chemical treatments (e.g., detergent) so that more purified inactivated influenza vaccines can be produced.

Formaldehyde has a long and extensive history of use in the preparation of bacterial and viral vaccines. It was used by Ramon in 1923 to detoxify diphtheria, yielding a diphtheria toxoid vaccine termed an *anatoxine*.[35] Requirements for the use of formaldehyde and the permitted residual amount of formaldehyde that is allowed for diphtheria toxoid are provided in the NIH Minimum Requirements.[9] Similar NIH Minimum Requirements exist for tetanus toxoid.[10] These documents note that residual, free formaldehyde in the finished product should not be in excess of 0.02% (i.e., 0.1 mg for a 0.5-mL vaccine dose). Formaldehyde is also used to inactivate viruses (e.g., polio and influenza viruses) when preparing vaccines. Table 7.1 lists the amount of residual formaldehyde that is present or allowed in these and various other U.S.-licensed vaccines; in the diphtheria and tetanus toxoids, the amount does not exceed 0.02%.

Similar requirements for residual formaldehyde exist elsewhere, for example, in Europe, as noted in the European Pharmacopoeia for various vaccines. Concern about the presence of residual formaldehyde in vaccines stems from the known toxic effects of formaldehyde, and from its carcinogenicity potential. The U.S. Environmental Protection Agency (EPA) has established a reference dose (RfD) for formaldehyde through the oral route.[36] The RfD is defined by the EPA as "an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure or a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious noncancer effects during a lifetime."[37] The RfD for formaldehyde (oral administration) is 0.2 mg/kg of bodyweight per day.[36] The amount of residual formaldehyde in vaccines (which are administered infrequently, not daily) is below this level.

Formaldehyde has been further classified by the EPA as a "probable human carcinogen" (the EPA's B1 classification).[36] The bulk of the carcinogenicity studies on formaldehyde have focused on chronic respiratory exposure because this is the primary route of industrial and routine household exposure. There are fewer data regarding ingested or parenteral exposure to formaldehyde, and the EPA has not developed a risk estimate for either oral or parenteral exposure.[36] Data regarding carcinogenicity studies may be found in documents from the EPA[36] and the International Agency for Research on Cancer.[38]

One point regarding formaldehyde should be made. Formaldehyde is naturally present in the human body as the result of various biochemical processes[38,39] and the steady-state level of formaldehyde in the bloodstream of humans is approximately 2.6 mg/L.[40] The amount of formaldehyde that is naturally, continuously present in the blood of humans, or turned over in a particular day, is markedly in excess of the amount that is present as a vaccine residual. A 2013 FDA-authored study[41] of the risk posed by the residual formaldehyde in vaccines concluded, "In the absence of any known adverse health effects from endogenously produced formaldehyde, which exists in blood and extravascular water at steady-state concentrations that are more than 100-fold higher [than are residual in vaccines], we consider vaccine-related, exogenous formaldehyde to be a miniscule part of the daily formaldehyde turnover by the body, and, therefore, do not find it plausible that vaccine-related formaldehyde represents an unsafe component of infant vaccines."

Inactivating agents other than formaldehyde are used in various U.S.-licensed vaccines and include glutaraldehyde, which is used to inactivate pertussis toxin (PT) in seven acellular pertussis-containing vaccines (Adacel [Sanofi Pasteur Ltd.], Boostrix [GlaxoSmithKline Biologicals], DAPTACEL [Sanofi Pasteur Ltd.], Infanrix, KINRIX, Pediarix [each manufactured by GlaxoSmithKline Biologicals], and Pentacel [Sanofi Pasteur Ltd.]), and β-propiolactone, which is used in the inactivation of three seasonal influenza virus vaccines (Afluria [Seqirus Pty Ltd.] and Fluvirin and Flucelvax [manufactured by Seqirus Vaccines Ltd. and Seqirus, Inc., respectively]), and two rabies vaccines (RabAvert [Novartis Vaccines and Diagnostics GmbH] and Imovax [Sanofi Pasteur SA]).

Residual Cell Culture Materials

Antibiotics

The CFR permits the addition of antibiotics (with the exception of penicillin) in viral vaccine manufacture (21 CFR §610.15[c]). Antibiotics that have been used include streptomycin, polymyxin B, neomycin, and gentamicin. Although a manufacturer need not specifically test for these antibiotics in the final container, the calculated amount of residual antibiotics (based on dilutions of the amount that was added) must be noted on the package label (21 CFR §610.61[m]). Table 7.2 lists the amount of residual antibiotics in several U.S.-licensed vaccines. Although the amended regulation for Constituent Materials[5] (21 CFR §610.15) applies equally to antibiotics, no examples of potential changes for the antibiotic regulation, unlike for preservatives and adjuvants, were presented in the *Federal Register* notice.

SENSITIZING SUBSTANCES

The CFR's biologics labeling regulations (21 CFR §610.61[l]) provide that "known sensitizing substances" should be listed on the product label. Furthermore, 21 CFR §610.15(b) states that "extraneous protein known to be capable of producing allergenic effects in human subjects shall not be added to a final virus medium of cell culture produced vaccines intended for injection." These regulations address the possibility that animal-derived proteins present in the final formulation of a vaccine can cause allergic reactions in some vaccine recipients. (Other sensitizing substances, such as preservatives, are addressed in other sections of these regulations.) Animal-derived materials are used extensively in vaccine manufacturing, particularly in viral cultures. When viral vaccines are grown in embryonated chicken eggs (influenza and yellow fever vaccines) or chick embryo cell culture (measles or mumps virus vaccines), the label will state that residual chicken proteins may be present in the final formulation (see Table 7.2). Although hypersensitivity to any component of the vaccine is a contraindication, the MMR-II and yellow fever vaccine (YF-Vax) package inserts address the vaccination of persons with hypersensitivity to eggs or egg protein.

The two U.S.-licensed hepatitis B vaccines, Engerix-B (GlaxoSmithKline Biologicals) and Recombivax HB (Merck Sharpe & Dohme Corp.), are recombinant DNA–derived proteins and are produced in yeast; their package inserts note that residual yeast protein may be present (Engerix-B contains not more than 5% and Recombivax HB not more than 1% yeast protein). Hepatitis B vaccine is contraindicated in persons with a history of hypersensitivity to yeast; however, the ACIP has noted that "no evidence exists that documents adverse reactions after vaccination of persons with a history of yeast allergy."[42] The HPV vaccines, Gardasil (Merck Sharp & Dohme Corp.) and Gardasil 9 (Merck Sharp & Dohme Corp.), are also manufactured in yeast cells; according to the package inserts, both vaccines contain less than 7 μg of yeast proteins per dose; hypersensitivity to yeast is given as a contraindication to

receiving the vaccine. The other HPV vaccine, Cervarix (GlaxoSmithKline Biologicals), is manufactured in insect cells; levels of insect cell proteins are reduced to less than 40 ng/dose.

It has been reported[43] that anaphylactic reactions to DTaP and Tdap vaccines may be caused by the presence of residual amounts of casein, a milk protein that is used in the culture media for these vaccines; the reactions occurred in children who already had high levels of milk allergy. The authors[43] note, however, that these anaphylactic reactions are exceedingly rare, and that many highly sensitive children with milk allergy tolerate the vaccines. Further studies will be necessary to define whether there is a subpopulation of children with milk allergies who might be at risk for an anaphylactic reaction. Slater and colleagues[44] have, however, noted several potential confounding factors in this analysis.

Vaccine vial stoppers or syringe components (plunger or tip caps) may contain latex, a component of natural rubber; certain persons are sensitive to latex. Vaccine presentations that contain or may contain latex have statements in the Warning and Precautions section of the package insert to the effect that the vaccine may cause allergic reactions in latex-sensitive individuals.

The Food, Drug and Cosmetic Act (Section 502[e][1][A][iii]) states that all inactive ingredients should be noted in labeling; it also states that this requirement is not necessary if trade secret information would be disclosed. The CFR additionally notes that an inactive ingredient should be listed in the labeling if the ingredient's presence is considered a safety factor (21 CFR §610.61[n]). In some cases, even in the absence of any evidence that a particular material might pose a safety factor, manufacturers have elected to disclose the presence of residual materials such as detergents, solvents, and chelating agents (see Table 7.2 for examples of manufacturing residuals). In addition, many manufacturers provide a brief summary of manufacturing methods, including the reagents used in various steps, such as precipitation (ammonium sulfate) or bacterial culture (e.g., an antifoam agent such as polydimethylsiloxane). Many of these substances are removed or markedly reduced in subsequent manufacturing steps.

Bacterial and Cellular Residuals

For bacterial vaccines, manufacturing residuals may include various bacterial cell constituents. Naturally, whole-cell vaccines—such as the previously used whole-cell pertussis vaccine—contain high levels of these components. At present, no parenteral whole-cell bacterial vaccine is in use in the United States; an oral, live attenuated bacterial vaccine, Typhoid Vaccine Live Oral Ty21a (Vivotif, Crucell Switzerland Ltd.), is approved for use.

Vaccines derived from gram-negative bacteria may contain LPS, commonly termed *endotoxin*, a component of the bacterium's outer membrane. Stimulation of the innate immune system by LPS can produce an inflammatory response that can result in fever, shock, and death.[45] Different organisms have different LPS structures, so their respective response potentials differ. Two tests are currently used to detect LPS in vaccines: the rabbit pyrogen test (which is a test for all pyrogens) and the limulus amebocyte lysate (LAL) test. The lysate from the amebocytes of the horseshoe crab, *Limulus polyphemus*, clots in the presence of LPS and forms the basis for this test.[46,47] In cases where pyrogenicity would be attributable to the presence of LPS, the LAL test is more commonly used. The limulus lysate that is used to test for bacterial endotoxin in U.S.-licensed vaccines (and other FDA-regulated biological products) is itself a U.S.-licensed product. The amount of endotoxin remaining in a final vaccine formulation depends on a number of factors, including the purification steps that are used in vaccine production. Although endotoxin testing of antigens derived from gram-negative bacteria is performed during the manufacturing process—and there may be a release specification for this test—the labeling may not contain this information. One of the DTaP vaccine labels (Tripedia [Sanofi Pasteur Inc.], which is no longer available) includes the amount of endotoxin contributed by the inactivated pertussis components (<50 endotoxin units/mL).

Residual bacterial protein may be present in the final vaccine formulation of bacterial vaccines. The consequences of this residual protein can vary, and its presence may be neutral or harmful. For example, it has been recognized for many years that the presence of residual protein may contribute to increased reactogenicity of diphtheria toxoid.[48,49] However, it has also been held that any such protein contributed to the immunogenicity of the vaccine.[50]

Polysaccharide, conjugated polysaccharide, and purified protein vaccines undergo a number of purification steps that reduce the amount of residual bacterial protein. However, these purification steps may not totally eliminate cellular or media protein components. During development of the product, a number of assessments of purity are performed, such as silver staining or polyacrylamide gel electrophoresis (PAGE) gel immunoblotting. After licensure, purity and quality of the vaccine antigen is often assessed by sodium dodecylsulfate (SDS)–PAGE as a release test. However, there is a limit to the sensitivity of these methods, as is illustrated in publications of the National Institute of Allergy and Infectious Disease–sponsored multicenter acellular pertussis trial,[51,52] which show that some children vaccinated with a fourth and fifth dose of Tripedia (DTaP [Sanofi Pasteur Inc.]; a two-component pertussis vaccine containing PT and filamentous hemagglutinin [FHA]), after previous doses of Tripedia, or a fourth dose of Tripedia after a primary series with whole-cell pertussis vaccine, had a booster response to pertactin and fimbriae, suggesting that there was sufficient antigen in Tripedia to stimulate an immune response.

Cell substrates used in viral vaccine manufacture include two diploid cell strains of human origin (MRC-5 and WI-38); a simian-derived, continuous cell line (Vero cells); a dog kidney derived cell line (MDCK [Madin-Darby canine kidney] cells); and chick embryo cells. Several recombinant DNA-derived viral vaccines are manufactured in insect cell lines. Residual protein from these differing cell lines is present to varying degrees in the vaccines produced from them. There is a concern, as noted previously, for residual egg proteins in sensitive individuals.

Residual cellular DNA from normal primary diploid cells or diploid cell strains, as well as from bacterial cells, may be present in the final vaccine formulation, and this DNA is not considered to pose a risk. Residual DNA from continuous cell lines, such as Vero cells, has been considered by a WHO study group.[53] The WHO Expert Committee on Biological Standardization assessed the risk of a transformational event as negligible and concluded that levels of up to 10 ng/dose of injected product are acceptable.[52] This limit was a revision of an earlier, more conservative limit (≤100 pg per parenteral dose) proposed by the 1986 WHO Expert Committee.[54] In revising this limit, the 1997 Expert Committee considered data from human and animal experience. This included data from nonhuman primates showing that milligram amounts of DNA containing an activated oncogene from human tumor cells had not caused a tumor during 10 years of evaluation; consideration that human blood contains substantial amounts of DNA in plasma; and consideration that contaminating DNA in a biological product would probably be in small fragments that are unlikely to encode a functional gene.[53] The committee concluded that continuous-cell-line DNA could be considered

a contaminant rather than a significant risk factor requiring removal to extremely low levels; hence the revised limit of 10 ng/dose.

Manufacturers do not necessarily need to demonstrate that each lot meets this specification through specific testing on each lot; they may be able to validate that the purification process can remove DNA to this level or below. This limit of 10 ng of residual DNA per dose does not apply to products derived from microorganisms, diploid cell strains, or primary animal cells, or to oral vaccines made with continuous cell lines.[53] The U.S.-licensed Japanese encephalitis virus vaccine (Ixiaro, Valneva Scotland Ltd.), IPV vaccine (IPOL, Sanofi Pasteur SA), and the IPV component of the DTaP-HepB-IPV vaccine, Pediarix (GlaxoSmithKline Biologicals) are produced in the continuous Vero cell line. IPOL contains less than 10 pg of DNA per dose.[55] One influenza virus vaccine, Flucelvax (Seqirus Inc.), is produced in MDCK cells, a canine continuous cell line; the vaccine contains less than 10 ng of MDCK DNA per dose.

Adventitious Agents

Use of animal-derived materials, such as gelatin, fetal bovine serum (commonly referred to as fetal calf serum), or primary animal-derived cells, in vaccine manufacture raises concerns about the potential presence of adventitious contaminants. Regulations (21 CFR §610.18) require that cultures used in the manufacture of products be free from extraneous organisms, and that cell lines should be tested for the presence of detectable microbial agents. A 1993 FDA guidance document[56] stated that master cell banks should be tested for adventitious agents and that animal-derived materials should be free from contaminants and adventitious agents, including viruses and the agent of BSE. A final guidance was published in February 2010.[57]

Manufacturers are required to perform such testing as necessary, and to ensure that the certification provided with any raw material is adequate (e.g., documentation that bovine-derived ingredients have been tested for extraneous viruses). Adventitious agent testing, performed to ensure that cell substrates used in vaccine manufacture are free from bacteria, fungi, mycoplasma, and mycobacteria, is described in detail in U.S.[56,57] and international[58,59] guidance documents. The use of polymerase chain reaction–based reverse transcriptase assays to test for adventitious retroviruses is addressed in a CBER letter to manufacturers.[60] The testing that has been carried out for adventitious agents is not described in the product labeling. However, the manufacturing method, including the cell lines and culture media used, are described.

Transmissible Spongiform Encephalopathy Agents

The lack of sensitive, specific, or readily accessible premortem diagnostic tests for transmissible spongiform encephalopathies (TSEs), such as BSE or CJD, limits surveillance and the ability to test for contamination of products for these agents. Diagnosis of a TSE disease is definitively confirmed by postmortem examination of brain tissue. However, even this examination is limited in sensitivity because, at earlier stages of disease, the TSE agent may be present in undetectably low concentrations. Because of these limits on testing, potential contamination of animal-derived materials with TSE agents is controlled through restricted sourcing.[29]

In 2013, the U.S. Department of Agriculture (USDA) published a final rule to base the conditions for importation of products derived from bovines with regard to BSE on the inherent risk of the particular product, as well as the BSE risk status of the region the product came from (9 CFR §92). This rule removed the USDA list of countries where BSE exists or that present an undue risk of BSE, and describes regions of risk generally similar to those classified by the OIE. A proposed rule, published in January 2007, harmonizes requirements for bovine materials for pharmaceutical products with those of USDA-regulated meat and FDA-regulated foods and animal feeds.[61]

SUMMARY

A final vaccine contains materials in addition to the active immunogen. Some of these materials are added by the manufacturer to effect a specific purpose—for example, stabilizers and adjuvants. Others are residual materials from the manufacturing process. Although not all of the results of all final release and in-process testing are contained in the labeling that accompanies a product, the CFR does specify which information should be included. Package inserts also contain information on manufacturing methods and growth conditions.

8 Passive Immunization

Mark K. Slifka and Ian J. Amanna

Passive immunization, passive immunity, and passive immunotherapy all refer to the transfer of antibodies to an unprotected individual for the prevention or treatment of disease. The first formal demonstration of passive immunization for successfully treating diphtheria and tetanus dates back to animal studies published in *Deutsche Medizinische Wochenschrift (German Medical Journal)* in 1890.[1] The technique was quickly adapted to clinical use and as early as the mid-1890s, diphtheria-specific antitoxin was used successfully in the hospital setting to reduce mortality during diphtheria outbreaks.[2–4] Indeed, in 1901 Emil von Behring was awarded the first Nobel Prize for Physiology or Medicine for the discovery of this important medical intervention.[5] The significance of this clinical advance cannot be overstated; Behring estimated that 45,000 lives were saved each year using diphtheria-specific passive immunotherapy in Germany alone.[6] In the 1890s, the mortality rate of hospitalized cases ranged from 47% to 60%,[7] and the work of Emil von Behring and his colleague, Shibasaburo Kitasato, provided the only hope for diphtheria patients in the preantibiotic era.

According to Behring, the discovery of passive immunization would not have occurred if it were not for his earlier work that focused on characterizing the protective mechanisms of active immunization against diphtheria[5,8] and through the work of his collaborator, Kitasato, on the mechanisms of vaccine-mediated immunity against tetanus.[1] When guinea pigs were infected with *Corynebacterium diphtheriae*, the animals routinely died of the disease. However, when Behring vaccinated animals and they mounted neutralizing antibodies to diphtheria toxin, he found that they were protected from a normally lethal dose of *C. diphtheriae*. To determine if protection was now an intrinsic property of the immune host that could be transferred to a susceptible host, he injected naïve guinea pigs with diphtheria toxin and then successfully treated them with immune serum from vaccinated animals. Likewise, injection of *Clostridium tetani* or purified tetanus toxin was typically lethal, but through a method developed by Paul Ehrlich,[5] animals could eventually become immune to high doses of tetanus toxin by sequentially inoculating them with lower, nonlethal doses of tetanus toxin. Kitasato used this approach to demonstrate that the blood of vaccinated, tetanus-immune rabbits could be transferred to naïve mice and fully protect them from a normally lethal dose of virulent *C. tetani* or from filtered *C. tetani* culture supernatant containing tetanus toxin.[1] Behring and Kitasato may have said it best in the final sentence of their landmark 1890 study, "The result of our experiments remind us forcibly of these words: Blut ist ein ganz besonderer Saft [blood is a very unusual fluid]."[1]

Technology has advanced substantially in the more than 125 years since Behring and Kitasato's first formal demonstration of protective passive immunotherapy.[1] In those early days, it was infeasible to use human immune serum to treat diphtheria, so the first large-scale production of polyclonal diphtheria-immune serum was prepared by vaccinating dairy cows.[5] To this day, commercial antisera used to treat a broad range of toxins are still produced in animals (Table 8.1). Passive immunotherapy with animal-derived antibody preparations should only be used under close medical supervision[9] or the resulting host immune response to the foreign immunoglobulins and serum proteins may trigger serum sickness, urticaria, and/or anaphylaxis following administration. Fortunately, the advent of several innovative technologies that reduce the need for animal-derived antibodies have forged new paths in terms of safety, feasibility, and the protective efficacy afforded by passive immunization. Following the discovery of monoclonal antibody technology,[10,11] further refinements have been made, including use of various display techniques (e.g., phage display, yeast display) to screen large antibody libraries.[12] Other technological advances include the development of chimeric monoclonal antibodies in which the murine antibody is "humanized" by genetically replacing the heavy chain region of the molecule with the human immunoglobulin counterpart and the use of transgenic mice in which the endogenous murine immunoglobulin genes have been replaced by human immunoglobulin genes.[12] This latter approach has the advantage that hybridomas from immunized transgenic mice produce fully human monoclonal antibodies without requiring further genetic modifications. Recently, development of Epstein-Barr virus (EBV)-transformed human memory B cells for the production of monoclonal antibodies has led to yet another surge in the production of new human monoclonal antibodies with rare antigenic specificities to uncommon pathogens and these can be produced directly from immune human subjects.[12,13] Before the era of antibiotics, antibody-based therapy was the only option available for combating many bacterial diseases. Even today, there are only a handful of antiviral drugs available and no therapeutic options exist for most viral diseases. However, new antibody-based therapies are continuing to be developed with the potential to provide protection against a broad array of bacterial and viral pathogens. In this chapter, we describe the role of passive immunity in the protection of the naïve host, discuss the parameters involved with successful immunotherapy, and provide examples of protective efficacy in animal models as well as in human clinical studies.

MATERNAL ANTIBODIES: THE ORIGINAL PASSIVE IMMUNOTHERAPY

Maternal antibodies represent a natural form of passive immunotherapy in which the immunoglobulin (Ig) G repertoire of the mother's preexisting humoral immune response is transferred to the fetus through the placenta. Acquisition of maternal antibodies varies widely among mammalian species.[14] Maternal IgG is transferred in utero to the fetus of humans and monkeys through the placenta with no evidence of postnatal transport, and reaches serum concentrations that are similar between mother and infant. In contrast, there is no prenatal transport of maternal IgG in mink, cows, horses, sheep, goats, and pigs, and although the animals are born with serum that is nearly devoid of IgG, these antibodies are transferred from ingested colostrum into the bloodstream within the first 24 to 48 hours after birth across the gastrointestinal tract. Transmission of maternal IgG in mice, rats, and dogs occurs in utero as well as across the gastrointestinal tract after birth, indicating that they differ from humans and non-human primates as well as being different from mink and the

TABLE 8.1 Licensed U.S. Antibody Products for Passive Immunity to Infectious Diseases or Toxins

Product	Brand Name	Manufacturer	Licensed Indications[a]
STANDARD IMMUNOGLOBULINS (HUMAN)			
Immunoglobulin, intravenous	Bivigam Carimune Flebogamma Gammagard Gammaplex Gamunex-C Octagam Privigen	Biotest Pharmaceuticals CSL Behring Instituto Grifols Baxter BPL Grifols Biotherapeutics Pharmazeutika Produktionsges CSL Behring	Primary humoral immunodeficiency; multifocal motor neuropathy; chronic idiopathic thrombocytopenic purpura; Kawasaki syndrome; chronic inflammatory demyelinating polyneuropathy
Immunoglobulin, subcutaneous	Hizentra Hyqvia Gammagard Vivaglobin	CSL Behring Baxter Baxter CSL Behring	Primary humoral immunodeficiency; multifocal motor neuropathy
Immunoglobulin, intramuscular	GamaSTAN	Grifols Biotherapeutics	Hepatitis A; measles; varicella; rubella
HYPERIMMUNOGLOBULINS (HUMAN)			
Anthrax immunoglobulin intravenous (human)	Anthrasil	Cangene Corporation	Treatment of inhalation anthrax
Botulism immunoglobulin intravenous (human)	BabyBIG	California Department of Health Services	Treatment of infant botulism (type A or type B *Clostridium botulinum*)
Cytomegalovirus immunoglobulin intravenous (human)	CytoGam	CSL Behring	Prophylaxis of cytomegalovirus (CMV) disease associated with organ transplantation
Hepatitis B immunoglobulin intravenous (human)	HepaGam B Nabi-HB	Cangene Corporation Nabi Biopharmaceuticals	Prevention and postexposure prophylaxis for hepatitis B
Rabies immunoglobulin (human)	HyperRab S/D	Grifols Biotherapeutics	Postexposure treatment of rabies, administered in conjunction with the rabies vaccine
Tetanus immunoglobulin (human)	HyperTET S/D	Grifols Biotherapeutics	Prophylactic or therapeutic treatment of tetanus
Vaccinia immunoglobulin intravenous (human)	N/A	Cangene Corporation	Treatment and/or modification of complications resulting from smallpox vaccination
Varicella zoster immunoglobulin (human)	VariZIG	Cangene Corporation	Varicella postexposure prophylaxis in high-risk groups
ANIMAL-DERIVED IMMUNOGLOBULIN PRODUCTS			
Antivenin (*Latrodectus mactans*) (equine)	Black widow spider antivenin	Merck & Co, Inc.	Treatment of bites by the black widow spider (*Latrodectus mactans*)
Botulism antitoxin bivalent (equine) types A and B	N/A	Sanofi Pasteur Ltd	Treatment of botulism (types A or type B)
Botulism antitoxin heptavalent (A, B, C, D, E, F, G)-(equine)	BAT	Cangene Corporation	Treatment of botulism (types A, B, C, D, E, F, or G)
Centruroides (scorpion) immune F(ab')2 (equine) injection	Anascorp	Rare Disease Therapeutics, Inc.	Treatment of scorpion envenomation
Crotalidae immune F(ab')2 (equine)	Anavip	Instituto Bioclon S.A. de C.V.	Treatment of rattlesnake envenomation
Crotalidae polyvalent immune Fab (ovine)	CroFab	Protherics, Inc.	Treatment of rattlesnake and cottonmouth/water moccasin envenomation
Digoxin immune Fab (ovine)	DigiFab	Protherics, Inc.	Treatment of digoxin toxicity or overdose
Diphtheria antitoxin (equine)	DAT	Instituto Butanta[b]	Prophylactic or therapeutic treatment of diphtheria
MONOCLONAL ANTIBODIES			
Palivizumab	Synagis	MedImmune	Prevention of lower respiratory tract disease caused by respiratory syncytial virus (RSV) in high-risk children
Raxibacumab	N/A	Human Genome Sciences/ GlaxoSmithKline	Treatment of inhalation anthrax

N/A, not applicable.
[a]Indications as listed by the manufacturer. Indications have been grouped for each product type.

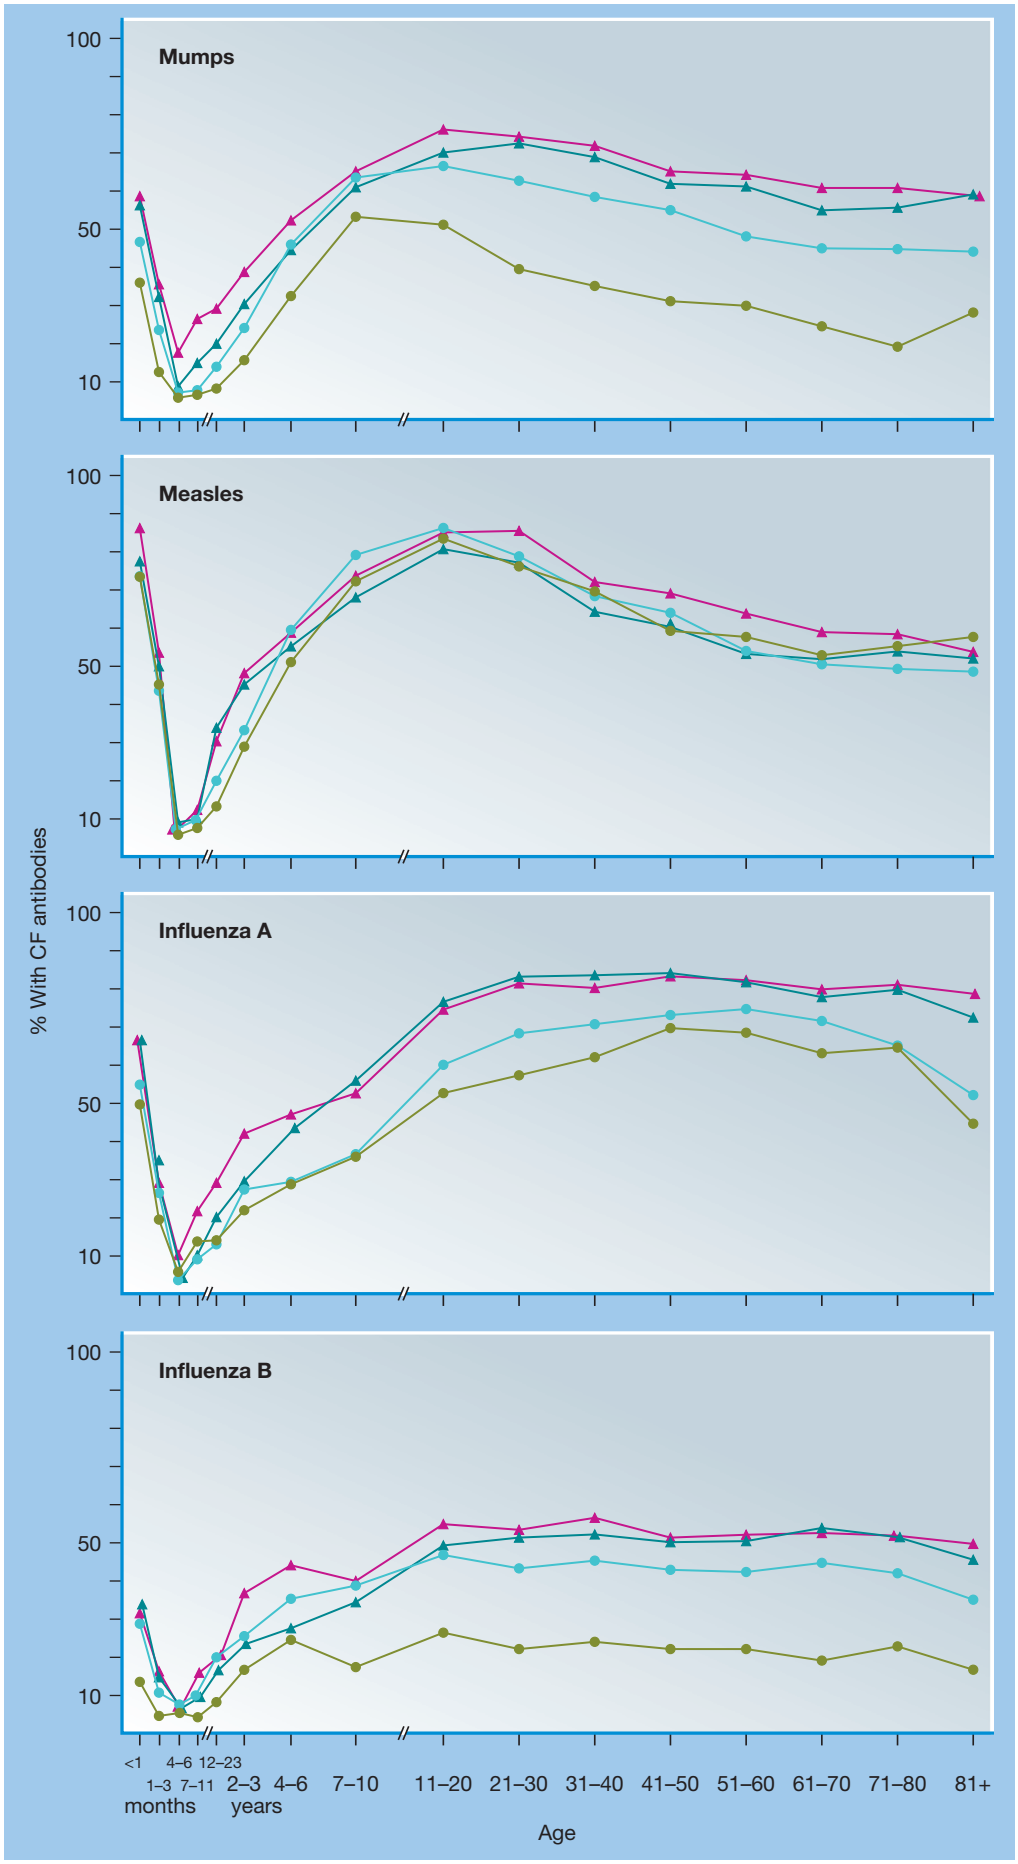
ungulates. These differences also indicate that care should be taken when choosing an appropriate animal model for studying the role of maternal antibodies against infectious disease as the mechanisms may be more species-specific than typically realized.

In a comprehensive study involving the analysis of antibodies to 16 viruses using samples from 58,500 patients, the relationship between maternal immunity and infant immunity is clear (Fig. 8.1).[15] The prevalence of antibodies to each viral antigen among infants less than 1 month old is remarkably similar to those observed in the 20- to 40-year old adults who represented the main age group of the mothers. For instance, immunity to common childhood diseases such as measles and mumps was comparable between newborns and their mothers. Immunity to less-common viral pathogens, such as influenza B, was relatively low among infants and adults in the cohorts examined in 1971–1972, but higher among those sampled in 1973–1974,1975–1976, and 1977–1978, coinciding with an influenza B epidemic that had occurred in 1974.[15] This shows that the prevalence of maternal antibodies is dynamic and that recent outbreaks involving a specific pathogen will result in a higher frequency of pathogen-immune mothers and a concomitant increase in the number of infants who are likewise bestowed at least transient immunity to that particular microbe. As expected, maternal antibodies wane rapidly during the first 6 months of life and then exposure to pathogens over the following months and years results in an accumulation of different antibody specificities as children reach adulthood (see Fig. 8.1). The overall protective efficacy of maternal antibodies is perhaps most pronounced among children with genetic immunodeficiencies such as severe combined immunodeficiency (SCID), resulting in the lack of functional T and B cells or agammaglobulinemia, in which patients lack functional B cells while still having the ability to mount pathogen-specific T-cell responses. The clinical presentation of SCID is not apparent at birth but relatively uniform diagnosis occurs at a mean of 6.59 months of age,[16] which is also about the age that maternal antibodies have reached their lowest levels[15] (see Fig. 8.1). Likewise, agammaglobulinemic patients also begin to present with symptoms of immunodeficiency around this same age.[17] Maternal antibodies represent an immunological "double-edged sword" in the sense that they are known to interfere with live attenuated virus vaccines such as the MMR (measles, mumps, rubella)[18–20] and rotavirus vaccines,[21,22] whereas direct immunization of mothers in the third trimester of pregnancy can significantly increase protection of infants against common respiratory viruses such as influenza.[23–25] Indeed, maternal vaccination may result in a 45% to 91% reduction in influenza-related hospitalizations among infants younger than 6 months of age.[23–25] Likewise, the importance of maternal vaccination against *Bordetella pertussis* (i.e., whooping cough) was recognized as early as the 1930s to 1940s with studies showing higher antibacterial antibody responses and potential protection from exposure to whooping cough among infants born to vaccinated mothers.[26–29] Recent studies verify these earlier results, demonstrating a 90% to 91% vaccine efficacy against whooping cough among infants younger than 2 months of age who were born to mothers who received pertussis vaccination during pregnancy,[30,31] thus lending further support to the current recommendations for the vaccination of pregnant mothers against *B. pertussis*.[32] The age limit of younger than 2 months was chosen as this is the age at which primary pediatric vaccination is recommended and analysis beyond this age might be confounded by the protective effects of direct vaccination of the child. Nevertheless, the protection afforded by maternally derived IgG against respiratory infections involving viral (e.g., influenza) or bacterial (e.g., *B. pertussis*) pathogens together demonstrate the broad impact that maternal vaccination and the subsequently increased transfer of maternal antibodies can have on the health of young infants.



CRITICAL PARAMETERS FOR PASSIVE IMMUNOTHERAPY

Before vaccines and antibiotics revolutionized modern medicine, antibody-based therapies represented the only effective medical treatment for many life-threatening diseases including diphtheria, scarlet fever, bacterial meningitis, and bacterial pneumonia.[33,34] Today, most commercial forms of antibody-based immunotherapy for infectious disease still rely on polyclonal antibodies of human or animal origin, with the notable exceptions of the monoclonal antibodies, palivizumab and raxibacumab (see Table 8.1). The main advantage of using polyclonal antibodies for passive immunotherapy is that this approach will include antibodies to multiple epitope specificities that may work in an additive or synergistic manner with the potential contribution of multiple immunoglobulin isotypes and subclasses that have different biological functions (Table 8.2).[35] On the other hand, there are several potential challenges to using polyclonal antibodies for immunotherapy including low antigen-specific activity, supply limitations (especially for rare diseases), variability between manufacturing lots, and safety as well as quality control issues that are often associated with the use of human blood products. In

TABLE 8.2 Comparison of Polyclonal and Monoclonal Antibody Therapy

	Polyclonal Antibodies	Monoclonal Antibodies
Advantages	Polyvalent specificity Multiple isotypes with different effector functions	High specific activity Standardized potency Unlimited availability Minimal biohazard potential
Disadvantages	Low specific activity Broad variation in potency Limited availability Biohazard risk of human blood products	Monovalent specificity Single isotype Potential to select for escape mutants

Figure 8.1. Age-specific prevalence of antibodies to mumps, measles, influenza A, and influenza B viruses in patients screened with 16 viral antigens during the years 1971–1978. The prevalence curves represent four 2-year periods: 1971–1972 (green line), 1973–1974 (aqua line), 1975–1976 (red line), and 1977–1978 (blue line). contrast, monoclonal antibodies are, by definition, limited to a single epitope specificity but they have several advantages over polyclonal antibodies since they can be manufactured in vitro at large scale, with inherently high specificity and lot consistency (Table 8.2). For example, the combination of 0.7 mg of two tetanus-specific human monoclonal antibodies has the same neutralizing capacity observed with administration of 100 to 170 mg of polyclonal tetanus immunoglobulin.[36] Likewise, administration of 0.023 mg of a vaccinia virus-specific monoclonal antibody provides the same level of protection afforded by 5 mgs of vaccinia immunoglobulin (VIG).[37] Although neutralization escape mutants are a valid concern when using monoclonal antibody therapy,[38,39] this has not yet been a major problem during clinical use of palivizumab for respiratory syncytial virus (RSV). Initially, sequencing of 371 RSV isolates demonstrated that there were no mutations in the neutralizing epitope of the F protein.[40] Subsequent studies identified RSV escape mutants in approximately 5% of 146 breakthrough cases, indicating that selective pressure for escape mutations is still relatively uncommon under current conditions of use.[41] This suggests that monoclonal antibodies can remain effective when used clinically in the long-term, as long as they are specific for a stable epitope for that particular pathogen.

The functional characteristics of the immunoglobulins used for passive immunization is an important consideration in determining protective efficacy in vivo.[35] For example, serum IgG molecules equilibrate into extravascular space whereas IgM is largely confined to intravascular space.[14] IgM molecules also have a short half-life (5 days[14]) and are typically of low affinity, which is why IgM is not an optimal choice for passive immunotherapy. Serum IgA is monomeric and, although it also equilibrates into extravascular space,[14] it has only a 6-day half-life[14] and does not appear to contribute significantly to functional IgA in the lungs of mice.[42,43] Human IgG on the other hand, has an average half-life of approximately 21 days (except IgG_3, which has a 7-day half-life),[14,44] is typically of high affinity, and transudation across mucosal barriers can protect against pathogens that invade through mucosal routes. Interestingly, serum IgG (and serum IgA) responses elicited in response to vaccination against *Neisseria meningitidis* correlate strongly with the levels of antibacterial antibodies present in the saliva at 1 month and 1 year after vaccination,[45] indicating that circulating serum antibodies may be an important contributor to the antibodies released in mucosal secretions. Indeed, after intravenous administration of an HIV-specific monoclonal antibody into rhesus macaques, serum antibody titers of 690 to 725 μg/mL resulted in mucosal antibody titers of 17 to 30 μg/mL in vaginal fluids and provide complete protection against intravaginal challenge with SHIV (chimeric simian immunodeficiency virus expressing HIV envelope).[46] Influenza virus is another mucosal pathogen with strict tropism to the respiratory tract, but influenza-specific serum antibody titers correlate with protection in humans.[47] In mice, the relative roles of influenza-specific polymeric IgA and IgG were compared in terms of antiviral protection in the upper respiratory tract versus the lung after influenza challenge.[42] When polymeric IgA was transferred 4 hours prior to influenza infection, this prevented pathology in the upper respiratory tract but was not effective in the lung, whereas transfer of IgG prevented pathology in the lung, but required higher doses to protect against infection of the upper respiratory tract. The authors concluded that different antibody isotypes may function preferentially at different anatomical sites in vivo. These results are in contrast to experimental influenza infection in humans in which inactivated influenza vaccine-derived IgG is believed to be a major contributor to protection of the nasal compartment.[48] Overall, the ability of IgG to enter nonlymphoid tissues and to penetrate mucosal sites of infection is likely to explain why it is often considered the best immunoglobulin isotype for routine passive immunization and has shown clinical benefit ranging from reduced clinical symptoms to nearly complete protection from lethal infection in a number of infectious disease models (Table 8.3).

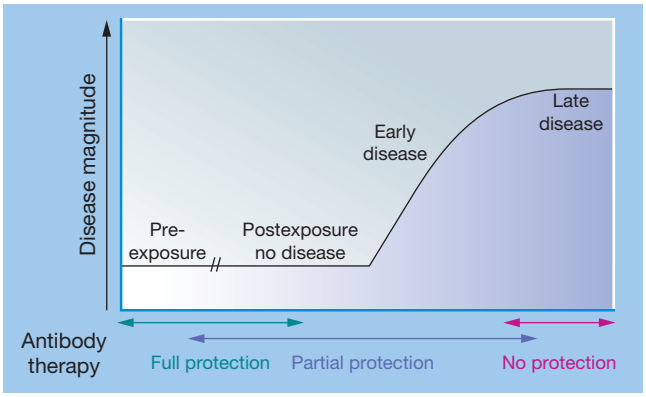

Figure 8.2. Efficacy of passive immunity decreases with disease progression. Full protection from symptomatic disease is best achieved through prophylactic administration of antibody therapy prior to exposure or infection. However, antibody therapy may also be highly effective at early points postexposure, prior to the onset of disease symptoms. Passive immunity is generally less effective when administered after the onset of symptomatic disease, and typically shows little to no clinical benefit once severe late-stage disease has occurred.

Over the last century, it has been well established that high specific antibody titers and early timing of antibody transfer in relation to disease onset are the two most important parameters involved with determining the protective efficacy of passive immunization (Fig. 8.2). In one account of the early days of clinical diphtheria-specific immunotherapy developed by Behring and Ehrlich,[5] initial failures in patients after treatment with weak or unstandardized diphtheria-immune serum brought Ehrlich to describe three points that he believed were important for successful immunotherapy: (a) treatment has to be initiated at the onset of disease; (b) the more the disease has progressed, the higher the serum quantities necessary for cure; and (c) depending on the severity of the case, certain minimal doses can be specified. Later studies confirmed these results: if diphtheria immunotherapy was initiated on the first day of disease, there was 0% mortality ($n = 183$).[49] However, if therapy was delayed to 2, 3, or 4 days after disease onset, then the accompanying diphtheria case-fatality rate subsequently increased to 1.6% ($n = 905$), 4.4% ($n = 632$), and 6.9% ($n = 436$), respectively.[49] These results are similar to those observed during antibiotic-based therapy of bacterial sepsis. In an ideal setting, it is recommended that antibiotics be administered within 1 hour of diagnosis of severe sepsis or septic shock as these drugs provide clinical benefit only if administered early in the course of disease and are generally ineffective during late-stage disease.[50]

The importance of high-dose immunotherapy given at the earliest sign of disease is not unique to bacterial anti-toxin therapy. The same rules apply to preventing or treating viral infections as well. During a measles epidemic in 1931–1932, 72% of exposed individuals ($n = 32$) who received no passive immunization contracted measles. If convalescent serum was administered within 10 days of exposure, then the attack rate was reduced to 16% ($n = 219$) whereas if therapy was not initiated until 12 to 16 days postexposure, approximately 80% of

[a]For animal studies, prophylaxis is defined as antibody administration prior to experimental infection and treatment is defined as antibody administration after infection. For clinical studies, prophylaxis is defined as antibody administration prior to disease onset and treatment is defined as antibody administration after disease onset.
[b]Evidence provided through maternal immunization studies.
[c]Anecdotal results are defined as small studies that indicate passive immunization may provide clinical benefit but are too limited in scope to be conclusive.
[d]Not available, although two studies[433,434] demonstrated prophylaxis by direct mixing of mumps virus and antibody prior to inoculation.

contacts subsequently contracted measles (n = 5).[51] In a study published in 1945 involving 1024 cases of measles exposure, 36% of the individuals who received immunotherapy within 0 to 2 days of exposure contracted measles compared to 48% for those whose treatment was delayed to 6 to 8 days postexposure.[52] The dose used in these studies was also critical: 67% of patients who received 0.01 mL/kg of gammaglobulin contracted measles whereas only 16% of patients who received 0.06 mL/kg of gammaglobulin contracted the disease. The titer of virus-specific antibodies will often differ between lots of polyclonal immunoglobulin preparations (see Table 8.2). In another study, when the measles-specific titer of gammaglobulin from different lots decreased from 33 IU/mL to 16 IU/mL, the postexposure incidence of measles increased from 17% to 57% despite either lot being administered within 5 days of exposure.[53] Likewise, the timing of passive immunotherapy is also important for enteric (e.g., polio) and respiratory pathogens (e.g., RSV). An outbreak in 1934 involving 2992 polio patients showed that if convalescent serum was administered within 0 to 2 days of meningitis, then paralysis was reported in 5.4% of patients (n = 2367). If treatment was delayed until 3 to 6 days after meningeal disease onset, 15.5% reported paralysis (n = 536), and if treatment was delayed for more than 6 days, then paralysis was noted in 30.3% of polio patients (n = 89).[54] For RSV, polyclonal RSV-immunoglobulin reduced the incidence of RSV-associated hospitalization by

41% among children with a history of prematurity or bronchopulmonary dysplasia.[55] Prophylactic administration of a neutralizing monoclonal antibody, palivizumab, was shown to significantly improve clinical outcome by reducing RSV-associated hospitalizations of children with congenital heart disease by 45%.[56] Among premature infants or those with bronchopulmonary dysplasia, RSV-associated hospitalizations were reduced by 55%.[57] A third palivizumab study confirmed these results by showing a 70% reduction in hospitalizations among premature infants and infants with chronic lung disease.[58] Another monoclonal antibody, motavizumab,[59] demonstrated a further 26% relative reduction in RSV hospitalizations compared with patients receiving palivizumab-based prophylaxis.[60] In contrast, once RSV infection has been established, the use of palivizumab,[61] motavizumab,[59] or RSV-immunoglobulin[62] shows no clinical benefit, although RSV-immunoglobulin may provide limited protection in the most severe cases.[62]

Passive immunotherapy can be highly successful for severe, even life-threatening human diseases such as smallpox, or hemorrhagic fever caused by arenaviruses including Junin or Lassa fever virus (see Table 8.3). Successful intervention, however, typically requires initiating treatment before or very shortly after symptom onset. When convalescent serum from smallpox survivors was administered to smallpox patients during the late stages of confluent or hemorrhagic smallpox, there was no clinical benefit observed in comparison to untreated controls (80% vs. 72% mortality, respectively).[63] When vaccinia-immune gammaglobulin (VIG) was administered to smallpox contacts prior to disease onset in addition to postexposure vaccination (i.e., standard of care), the number of smallpox cases was reduced by 70% compared to contacts who received postexposure smallpox vaccination alone.[64] Likewise, administration of vaccinia-immune serum of animal origin along with postexposure vaccination resulted in 0 of 13 cases (0%) of smallpox among close contacts compared to 13 of 29 cases (45%) among controls who received smallpox vaccination alone.[65] During a smallpox outbreak in 1941, 3 of 10 patients (30%) died while undergoing standard clinical care.[66] To determine if addition of passive immunotherapy would reduce mortality after smallpox diagnosis, 250 cases of smallpox were treated with convalescent serum or blood, with no smallpox-associated deaths reported (0 of 250). Approximately 75 patients were described as having severe or hemorrhagic smallpox at the time of treatment and yet all survived. This appears to be the result of using convalescent serum obtained at the peak of the humoral immune response shortly after recovery from smallpox and the use of an optimized dosing schedule with higher doses administered to patients with the more severe disease manifestations.[66]

Argentine hemorrhagic fever is caused by infection with the Junin virus and untreated cases result in 15% to 40% mortality.[67–69] Convalescent serum is protective in animal models of Junin infection[70–72] and when administered within 8 days of symptom onset, the mortality rate among human cases drops to 1% to 3%.[68,69] Likewise, in 35% to 50% of hospitalized cases, Lassa fever virus causes severe disease including diffuse capillary leakage and hemorrhagic diathesis.[73] Prophylactic administration of immune serum protects guinea pigs[74,75] and nonhuman primates[76,77] from subsequent lethal challenge, indicating that antibodies play a clear role in protection against this virulent viral pathogen. In one small clinical study, if passive immunotherapy was administered within 0 to 5 days after admission to the hospital, 4 of 4 (100%) patients survived whereas if immunotherapy was initiated 7 to 9 days after hospitalization, 0 of 3 (0%) patients survived.[78] In another study,[79] patients with virologically confirmed Lassa fever who received immune serum within 10 days of hospitalization survived (4 of 4; 100%). However, if treatment was not initiated until more than 10 days after hospitalization, then only 1 of 4 (25%) patients survived, similar to the untreated group in which only 1 of 5 (20%) patients with virologically confirmed Lassa fever survived.

PASSIVE IMMUNITY AGAINST RESPIRATORY AND ENTERIC PATHOGENS

Although passive immunity against toxins and systemic infections such as measles[51,53,80–84] and smallpox[64–66] is well established, the impact of this approach for the prevention or amelioration of disease caused by respiratory and enteric pathogens may not be as well recognized. However, several studies support the role of passive immunity against mucosal pathogens (see Table 8.3), including examples such as influenza (respiratory virus), *Haemophilus influenzae* (respiratory bacterium), rotavirus (enteric virus), and *Escherichia coli* (enteric bacterium). Influenza is a significant cause of morbidity and mortality throughout the world, including both seasonal transmission and pandemic outbreaks.[85–88] The clinical correlation between homotypic influenza immunity and vaccine-associated protection was recognized early in the development of the influenza vaccine.[89–91] Early animal studies confirmed this result, with passive transfer of antibodies (both systemic and mucosal delivery) able to protect naïve animals against subsequent challenge, or provide therapeutic benefit when administered postexposure.[92–94] More recent animal studies with defined monoclonal antibodies continue to support and extend these earlier results.[95,96] Passive immunization against influenza in humans has also been successful. In a comprehensive retrospective metaanalysis of eight passive immunization studies performed during the Spanish Influenza outbreak (1918–1925), a significant 21% decrease in mortality (95% confidence interval [CI], 15–27%; $P < .001$) was observed.[97] Subset analysis of studies that recorded early (treatment initiated within 4 days of pneumonia complications) versus late intervention (>4 days) showed a significant advantage for early treatment, with mortality decreasing from 59% (49 of 83) to 19% (28 of 148) with earlier intervention, consistent with general considerations for effective passive immunity against infectious diseases (see Fig. 8.2). In a recent double-blinded, randomized controlled study during the 2009 influenza pandemic, the use of hyperimmune intravenous immunoglobulin (IVIG) (from recovered convalescent donors) was compared to normal IVIG in the treatment of severe infection in 34 subjects.[98] The hyperimmune treated group ($n = 17$) demonstrated more rapid viral clearance than the control group ($n = 17$), with a greater than 90% drop in viral loads by day 5 posttreatment. In those patients receiving immunoglobulin within 5 days of symptom onset ($n = 22$), all 12 who received hyperimmune IVIG survived (12 of 12), whereas only 60% of patients receiving normal IVIG survived (6/10, $P = .02$).

H. influenzae type b (Hib) is an extracellular gram-negative bacterium that initially infects the host via the respiratory tract and represents another important human pathogen that can be controlled through passive immunization. Several early reports described the use of concentrated rabbit immune serum as a successful adjunct therapy to sulfonamide treatment for patients suffering from Hib meningitis.[99–101] Indeed, a full course of serum therapy (in addition to antibiotics) was able to reduce mortality to 14% (3 of 19) when compared to 78% mortality rate (7 of 9) in those patients only receiving sulfonamides.[101] A more recent study established the prophylactic

use of human immunoglobulin in at-risk populations.[102] Santosham and colleagues administered hyperimmunoglobulin ($n = 353$), or saline placebo ($n = 350$) to infants at 2, 6, and 10 months of age and examined the rates of invasive Hib. For the first 90 days following the passive immunization protocol, none of the treated infants experienced invasive Hib (0% incidence), compared to 7 of 350 placebo-treated children (2.0% incidence, $P = .007$).[102]

Rotavirus represents an enteric viral pathogen wherein protective passive immunotherapy has been demonstrated.[103–108] In one example of postexposure treatment in infants, oral administration of hyperimmune antibody (in addition to standard supportive care) was able to efficiently reduce rotavirus shedding compared to placebo controls; treated patients ($n = 26$) exhibited no evidence of viral shedding by day 8 posttreatment as compared to 25% of controls ($n = 26$).[105] In a separate study, prophylactic passive immunity using orally administered bovine colostrum from immunized animals was tested in a blinded and randomized trial among infant children (3–15 months old) admitted to a hospital, typically for respiratory conditions.[103] Following admission, infants were given a 10-day course of the bovine colostrum or placebo. Infants who received placebo contracted symptomatic rotavirus at a rate of 14% (9 of 65) whereas no symptomatic rotavirus disease was observed in the colostrum-treated infants (0 of 55; $P < .001$). Analysis of rotavirus vaccine failures also indicates that maternally derived antibodies play a role in passive immunity to rotavirus infection. In a study involving 177 vaccinated infants, a strong inverse correlation was observed between maternally derived rotavirus antibodies and the ability of infants to seroconvert following vaccination with a live rotavirus vaccine.[21] This is an important demonstration not only of passive immunity to an enteric pathogen, but also has broader implications on the timing of vaccine administration, especially in developing countries where preexisting immunity is relatively high, and rotavirus vaccine immunogenicity appears impaired.[109]

E. coli is a significant enteric pathogen wherein prophylaxis through passive immunity has been demonstrated in several clinical studies.[110–113] Tacket and colleagues were able to passively protect human subjects against experimentally induced *E. coli* diarrhea with specific bovine antibody.[110] Using heat-inactivated or glutaraldehyde-inactivated *E. coli* for vaccination, pregnant cows were hyperimmunized with a large number of enterotoxigenic O serogroups. Milk collected during the first 10 days of lactation was purified, concentrated, lyophilized, and formulated for oral administration. As a control, a similar preparation was made using rotavirus as the immunizing antigen. Subjects received daily treatment (3 times daily) for 7 days, with *E. coli* challenge administered 3 days into the treatment regimen. Of the 10 subjects who received the *E. coli* antibody prophylaxis, all remained disease-free following challenge, compared with clinical diarrhea in 9 of 10 placebo subjects ($P < .0001$). Using a closely related clinical protocol, Otto and colleagues also demonstrated good efficacy with hyperimmune bovine colostrum tablets.[111] In the first study conducted in this trial, 11 of 15 (73%) of placebo subjects contracted diarrhea following challenge, but this was reduced to only 1 of 15 (7%) in treated subjects ($P = .0005$). In a second study investigating the impact of omitting buffer to the oral prophylaxis, the authors also examined dose sparing. In these studies, the standard dose still conferred significant protection with 3 of 15 (20%) treated subjects contracting diarrhea, compared with 12 of 14 (86%) of controls. Interestingly, if the dose was reduced by one-half then disease incidence increased to 5 of 14 subjects (36%), indicating a key role played by treatment dose in achieving successful passive immunotherapy.

PASSIVE IMMUNIZATION: A PARADIGM SHIFT IN PROGRESS?

With any new scientific advance, there is controversy. In 1890, when Behring demonstrated that immune serum therapy could protect against diphtheria, it went against the current dogma at that time in which the cellular theory of phagocytosis was believed to be the primary mechanism of host protection.[5] There were also skeptics who, as early as 1896, discussed why antibody immunotherapy would not work.[114] However, the science not only prevailed but today a number of passive immunotherapy products are in clinical use (see Table 8.1) and an ever-increasing number of human diseases benefit from the use of this technology (see Table 8.3). Some believe that antibody plays a more important role in protection against cytopathic viruses and extracellular bacteria, but that T cells must be required for protection against infection by noncytopathic viruses and other intracellular pathogens.[115] Although this is partially refuted by the protective efficacy of maternal antibodies and IVIG therapy in SCID patients who do not have functioning T cells, it is important to bear in mind that antibody-mediated protection by passive immunotherapy in immunocompetent individuals does not function in isolation, but instead works best in conjunction with other immune defenses, including host T cells, B cells, natural killer (NK) cells, etc. Although the role of antibody-mediated protection against intracellular bacteria and chronic viral infections was thought to be relatively minor, there are examples in each of these instances in which passive immunity provides substantial clinical benefit.

As noted previously, prior to the advent of antibiotics, passive immunotherapy was the only option for clinical treatment of most bacterial infections including *Francisella tularensis*, a facultative intracellular bacterium that causes tularemia, a severe disease associated with up to 30% mortality in untreated cases.[116,117] When streptomycin became available, a comparative study in 1946 was performed with 542 tularemia patients who received only symptomatic treatment, 832 who received immune equine serum, 60 who received hyperimmune equine serum, and 9 who received streptomycin.[118] The untreated tularemia cases required an average of 3.78 months to recover and only three modes of therapy showed substantial improvement—treatment with immune serum within 9 days of disease onset (2.41 months until recovery), treatment with hyperimmune serum (2.15 months until recovery), and treatment with streptomycin (2.40 months until recovery). Two clinical cases were extensively described, with the following summary: "The clinical responses to each agent [i.e., immune serum, and streptomycin] were similar, prompt amelioration of the symptoms of intoxication–headache, mental dullness or lethargy, sense of prostration and severe malaise; reduction of fever and of the sizes of the buboes, acceleration in the healing of ulcers and in the resolution of pulmonary exudates." In other words, passive immunotherapy appeared in many ways to mimic antibiotic therapy in terms of protective efficacy. However, it was noted that treatment with equine serum caused serum sickness in 51% of the patients and had a more variable outcome than the antibiotic approach, leading to the recommendation that streptomycin would be the agent of choice for future treatment of this disease.[118] With the recent development of polyclonal and monoclonal antibodies that show protective efficacy against tularemia in animal models,[119–121] it may be possible to incorporate both passive immunotherapy and antibiotic treatment into clinical practice not only for tularemia, but for other bacterial diseases, especially in cases in which antibiotic resistance is becoming more widespread.[122,123]

Mycobacterium tuberculosis is another intracellular bacterium that, despite the availability of antibiotics, remains one

of the most common human diseases and it is estimated to infect up to one-third of the world's population.[124] The development of strains of extensively drug-resistant (XDR) tuberculosis (TB),[125] some of which are resistant to all current antibiotic therapies,[126,127] is also a growing concern, especially as there are few antibiotic drugs in the pipeline.[122,123] There is considerable debate over the role of antibodies in controlling TB, with many believing that antibody plays little or no role in protective immunity (reviewed in references 124 and 128). In a comprehensive historical review by Glatman-Freedman and Casadevall,[128] the clinical benefit of antibody-mediated immunotherapy, albeit quite variable, provides evidence to suggest that antibody plays a role in protection against TB. In studies reported by Paquin in 1895, a group of patients with pulmonary TB confirmed by the presence of bacterium in their sputum showed clinical benefit. After 2 months of passive immunotherapy, 82% of patients showed reduced cough, reduction in bacterial load in sputum, clearance of pulmonary infiltrates, reduction in hemoptysis, improved appetite, and weight gain.[128,129] At 6 months after initiating treatment, all the treated patients were alive and more than half were discharged from the hospital. In contrast, more than 30 untreated TB patients from another ward in the hospital had died within 4 months of starting the study. Experimental proof of antibody-mediated protection against TB was also published in 1897 by Fisch.[128,130] After lethal TB challenge of guinea pigs, administration of immune serum was performed on days 4, 7, and 10, with further doses administered every other day for 4 weeks and once a week after that. Fisch reported that 16 of 18 treated animals were alive after 2.5 months (89% survival). If treatment was delayed until day 14 postchallenge, then 2 of 3 (66%) animals survived but showed signs of illness. If no antibody treatment was performed, then 0 of 3 (0%) of the animals survived past day 28. The same approach was used to treat 50 patients with pulmonary TB.[131] All of the 19 patients treated at the earliest stages of disease improved rapidly after passive immunotherapy and were tuberculin negative at the end of the study. Of the 11 patients treated at the "incipient" stage of disease, 36% no longer had bacilli in their sputum and were considered cured and 64% showed substantial improvement in disease symptoms. The 20 patients with advanced TB showed only modest or no improvement after therapy and it was concluded that immune serum was only beneficial in early but not advanced cases of disease.[131]

EBV is a common human pathogen that causes a chronic infection and is a leading cause of posttransplant non-Hodgkin lymphoma resulting from the uncontrolled proliferation of EBV-infected B lymphocytes in patients undergoing immunosuppressive therapies.[132] In a large retrospective study involving 44,828 kidney transplant patients, the effect of prophylactic treatment for cytomegalovirus (CMV) on posttransplant incidence of non-Hodgkin lymphomas was examined.[133] The standardized incidence ratio (SIR) for non-Hodgkin lymphoma was expressed as the number of lymphoma cases per 100,000 persons and calculated after normalizing for age, sex, and geographical origin. The 30,255 patients who did not receive CMV prophylaxis had a SIR = 26.4, which remained unchanged (SIR = 24.2, $P = .62$) among the 12,470 patients who received antiviral drugs (acyclovir or ganciclovir). In striking contrast, the 2103 patients who received anti-CMV immunotherapy showed a complete absence of lymphomas during the first year after transplantation (SIR = 0, $P = .016$ vs. antiviral treatment). The most common anti-CMV immunoglobulin products were shown to contain antibodies against EBV and it is believed that this is the mechanism of action for the protection afforded during the first year posttransplantation.[133] In the subsequent 5 years of follow-up, new cases of lymphoma developed at similar rates among all three groups ($P = .97$). However, because administration of immunoglobulin is typically only performed during the first 4 months after transplantation and antiviral antibody half-life is estimated to be approximately 25 days,[134] it is not surprising that the protective effects of passive immunotherapy were only maintained through the first year. Nevertheless, the inadvertent discovery of the protective role of antibodies in preventing EBV-induced non-Hodgkin lymphoma represents a potential breakthrough in clinical management of this vulnerable patient population.

Despite decades of research aimed at finding a vaccine or a cure for HIV infection, this virus remains a scourge of global proportions. Early attempts at passive immunotherapy using first-generation HIV-specific monoclonal antibodies were not highly effective[135–137] and this approach was not further pursued until a new generation of highly potent and broadly neutralizing antibodies were identified.[138,139] In particular, a recent Phase I clinical trial[140] involving a single administration of a broadly neutralizing antibody, 3BNC117, has renewed interest in the study of passive immunotherapy for HIV prevention and therapeutic intervention. 3BNC117 is an anti-CD4 binding site antibody that neutralizes 195 of 237 HIV strains comprising six different clades and was tested in a dose-escalation study among HIV-positive patients with different levels of viremia. At a dose of 10 or 30 mg/kg, patient viral load was reduced by up to 2.5 $\log_{10}$ (average decline: 1.48 $\log_{10}$) in 10 of 11 individuals. The subject that did not respond to antibody treatment at 10 mg/kg was infected with a resistant strain of HIV. Although the effect of antibody therapy on viremia was mainly transient after a single administration, the viral load remained lower than their preexisting set point in 3 of 10 patients at 56 days and one subject exhibited viremia levels that remained near the limits of detection throughout the 56-day study. It is currently unclear if HIV viremia in these patients will eventually rebound to their original levels. Similar results were observed during antibody-based therapy of SHIV-infected rhesus macaques in which most animals showed a rebound in viral replication after the transferred monoclonal antibodies declined to undetectable levels but a subset of animals maintained virological control in the absence of further infusions.[141] Combinations of antiretroviral drugs are currently the standard of care for treatment of HIV infection and it is unlikely that one dose of a single monoclonal antibody will be sufficient to have a long-term clinical benefit among a broad patient base. However, there is growing optimism that combining a cocktail of potent, broadly neutralizing monoclonal antibodies with antiretroviral drugs and/or agents that activate latent virus reservoirs could theoretically provide long-term reduction in viral load and reduce the rates of transmission.

FUTURE OF PASSIVE IMMUNIZATION

With substantial advances in monoclonal antibody technologies and an increasing appreciation for the role of antibodies in the control of infectious disease, the development of sophisticated new passive immunotherapies is likely to continue at an accelerated pace. Antibiotic resistance among clinically relevant bacteria including multidrug-resistant (MDR) and XDR *M. tuberculosis*, methicillin-resistant *Staphylococcus aureus* (MRSA), and dominant strains of antibiotic-resistant *Salmonella typhi* and other gram-negative bacterial species is a growing concern.[122,125,142–144] This, coupled with the knowledge that fewer new antibiotics are moving through the drug pipeline,[122,123] may further motivate research into the development of antibody-based therapies to overcome these challenges to clinical intervention against microbial disease. One drawback to passive immunization is that antibody half-life in vivo

often provides only transient protection unless repeated administrations are performed. This may change as new technologies that increase the half-life of monoclonal antibodies are employed. For example, the Fc region of an anti-RSV monoclonal antibody, motavizumab, was mutated to increase its binding to the neonatal Fc receptor (FcRn), resulting in serum antibody pharmacokinetics in human subjects that increased from a typical 19- to 34-day half-life to up to a 100-day half-life while still retaining virus-specific neutralizing activity.[144a] Nevertheless, while passive immunization may be sufficient for protection or therapeutic intervention of acute or remittent disease, active immunization through improved vaccine design may still be needed to train the host immune system to maintain long-term levels of protective immunity. Importantly, examples of successful passive immunization approaches may provide a useful framework for developing new and improved vaccines that elicit the most protective antibody responses.

9 General Immunization Practices

Andrew T. Kroger, William L. Atkinson, and Larry K. Pickering

Recommendations for immunization practices are based on scientific knowledge of vaccine characteristics, biology of immunization, epidemiology of specific diseases, and host characteristics. In addition, experience and judgment of public health officials and specialists in clinical and preventive medicine play a key role in developing recommendations that maximize benefits and minimize risks and costs associated with immunization. General guidelines for immunization practices are based on evidence and expert opinion of benefits and risks of vaccinations as they apply to the current epidemiology of disease and use of vaccines in the United States. However, many of the principles are universal and are applicable to other countries where different public health infrastructures may exist.

VACCINE STORAGE AND HANDLING

Vaccines must be properly shipped, stored, and handled to avoid loss of their biologic activities. Recommended storage and handling requirements for each vaccine are given in each manufacturer's product information.[1] Correct shipping, storage, and handling practices also are published in recommendations of the major vaccine policymaking committees, such as the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC), the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP), and the World Health Organization (see Chapter 76).[2–5] Failure to adhere to these requirements can result in loss of vaccine potency, leading to an inadequate immune response in the vaccinee. Visible evidence of altered vaccine integrity may not be present. The state/local health department or the manufacturer should be contacted when questions arise about the correct handling of a vaccine. New vaccines or new formulations of an existing vaccine may have different shipping, storage, and handling requirements. The recommended storage practices for the most commonly used vaccines in the United States are described in the Vaccine Storage and Handling Toolkit.[6]

Refrigerators without freezers and standalone freezers are usually most effective at maintaining the precise temperatures required for vaccine storage and are preferred to combination refrigerator/freezer units. Freezer storage units may be manual defrost or automatic defrost ("frost-free"). Automatic defrost freezers periodically and transiently increase the freezer temperature to reduce the formation of ice. This type of freezer unit is acceptable for storage of vaccines that must be stored in a frozen state (varicella, measles-mumps-rubella-varicella [MMRV], oral polio, zoster).

Exposure to higher or lower temperatures than recommended can damage a vaccine. For example, live virus vaccines, such as oral poliovirus vaccine (OPV), varicella, combination MMRV, and zoster vaccine, are sensitive to temperatures above freezing and should be kept frozen until just before administration. Measles-mumps-rubella (MMR without varicella) vaccine may be stored at either refrigerator or freezer temperature. Rotavirus vaccine and yellow fever vaccine should be stored at refrigerator temperature (2–8°C).[3,7] Some vaccines composed of purified antigens or inactivated microorganisms, such as hepatitis A, hepatitis B, *Haemophilus influenzae* type b (Hib), human papillomavirus (HPV), and inactivated influenza, can lose their potency if frozen and should be kept at refrigerator temperature and never frozen.[3,4] Diluents should not be frozen and may be kept at room or refrigerator temperature. Maintenance of a "cold chain" from vaccine production to use helps ensure vaccine potency at the time of administration. Temperature monitoring and control are important for storage and handling of all vaccines, particularly during transport and field use. Temperatures should be monitored at least twice a day, using a thermometer that records current, maximum, and minimum temperatures. Whereas maintenance of cold and freezing temperatures may be a problem in tropical climates, data suggest that inappropriate freezing of inactivated vaccines is a problem in maintaining vaccine stability in cold and temperate climates. Shipping containers should be sturdy, the correct size for the amount of vaccine to be shipped, and contain a temperature monitor. Appropriate insulation (e.g., panels and boxes of polystyrene, isocyanurate, or polyurethane) and cold source (e.g., bottles with frozen liquid) should be used to maintain the recommended temperature. Dry ice should not be used to transport frozen vaccine, because it might expose the vaccine to temperatures lower than recommended for storage. Loose fillers do not provide reliable temperature insulation.[3]

Vaccines should not be reconstituted until immediately before use. If not administered within the interval recommended by the manufacturer, reconstituted vaccine should be discarded.[5] Only the diluent provided by the manufacturer should be used to reconstitute a lyophilized vaccine. With the exception of OPV, live virus vaccines should not be refrozen after thawing.

Certain vaccines are distributed in multidose vials. When opened, the remaining doses from partially used multidose vials can be administered until the expiration date printed on the vial or vaccine packaging unless otherwise specified by the manufacturer, provided that the vial has been stored correctly and that the vaccine is not contaminated.[5]

VACCINE ADMINISTRATION

Complete and accurate records documenting administration of all vaccines should be maintained by healthcare providers who administer vaccines and vaccine recipients (or their parents). For each immunization, the following information should be recorded: (a) date of vaccination; (b) product administered, manufacturer, lot number, and expiration date; (c) site and route of administration; and (d) name, address, and title of healthcare provider administering the vaccine.

Infection Control and Sterile Injection Technique

Infection resulting from administration of vaccines is unlikely if appropriate precautions are utilized. Hands should be washed with soap and water or cleansed with an alcohol-based waterless antiseptic hand rub before each patient contact to reduce the risk of bacterial contamination and transmission of microorganisms between vaccine recipients and healthcare personnel. In general, use of protective gloves is not necessary when administering vaccines unless the healthcare provider

will have contact with potentially infectious body fluids or has open lesions on the hands.[2,5]

Failure to follow relevant infection control guidelines can result in transmission of bloodborne pathogens or bacterial infection and abscess formation. Contamination of an injection site can occur from bacteria on the skin at the site of injection. To prevent such contamination, skin at the injection site should be prepared with isopropyl alcohol (70%) or another disinfecting agent and allowed to dry before injection. Transmission of pathogens also can occur if needles, syringes, vaccines, or other equipment used to administer vaccines becomes contaminated. To prevent such contamination, syringes and needles must be sterile. A separate needle and syringe should be used for each injection. Disposable needles and syringes should be discarded after a single use in a labeled, puncture-proof container to prevent inadvertent needle-stick injury or reuse. Because recapping and removing a used needle from a syringe can result in injury to the user, needles should not be recapped after use.[5] The needle and syringe should be discarded as a single unit without removing the needle from the syringe. Single-use disposable needles and syringes should not be sterilized and reused.

If only reusable (i.e., nondisposable) needles and syringes are available, they must be thoroughly cleaned and sterilized after each injection to prevent transmission of bloodborne or other pathogens between patients. Reusable syringes are usually glass rather than plastic. Because of its inert characteristics, glass can be cleaned and sterilized more easily than plastic. Because hypodermic needles enter deep tissues, great care must be taken to ensure that all contaminants are removed from the needle and syringe.[8] Liquid germicides alone are insufficient for needle sterilization because of the restricted access of the chemical agent to the lumen of the needle. Strict adherence to the recommended time and temperature for the sterilization procedure used must be observed.

Most vaccines have a similar appearance after they are drawn into a syringe. Cases in which the wrong vaccine was administered often are attributable to the practice of prefilling syringes or drawing doses of a vaccine into multiple syringes before their immediate need.[5] The routine practice of prefilling syringes should be discouraged because of the potential for such administration errors. To prevent errors, vaccine doses should not be drawn into a syringe until immediately before administration. In certain circumstances in which a single vaccine type is used (e.g., in a community influenza vaccination campaign), filling a small number (10 or fewer) of syringes before their immediate use may be considered. Care should be taken to ensure that the cold chain and sterility are maintained until the vaccine is administered. When the syringes are filled, the type of vaccine, lot number, and date of filling must be labeled accurately on each syringe, and the doses should be administered as soon as possible after filling, by the same person who filled the syringes. Manufacturer prefilled-syringes that are activated (i.e., syringe cap removed or needle attached) but unused should be discarded at the end of the clinic day. Likewise, vaccine drawn into syringes by the user (i.e., not by the manufacturer) should be discarded at the end of the clinic day.

Route of Administration

One or more routes of administration (e.g., intramuscular, subcutaneous, intradermal, intranasal, and oral) are recommended for each vaccine and are listed in the manufacturer's product label and in published recommendations of immunization advisory committees (Table 9.1).[2,5] These routes usually are determined during prelicensure vaccine studies and are based on vaccine composition and immunogenicity. Vaccines should be administered in sites where they elicit the desired immune response and where the likelihood of local tissue, neural, or vascular injury is minimal.[2] To avoid unnecessary local and systemic adverse events and to ensure the appropriate immune response, people administering vaccines should not deviate from the recommended route of administration in the product label. A route of administration or anatomic site of injection different from that recommended can result in an inadequate immune response. For example, the immunogenicity of hepatitis B vaccine and rabies vaccine is substantially lower when the gluteal instead of the deltoid vaccination site is used.[9,10] The reduced immunogenicity presumably is a result of inadvertent injection into subcutaneous or deep fatty tissue rather than into muscle.

Deep intramuscular injection generally is recommended for adjuvant-containing vaccines because subcutaneous or intradermal administration can cause marked local irritation, induration, skin discoloration, inflammation, and granuloma formation.[5] However, subcutaneous injection can lessen the risk of local neurovascular injury and is recommended for vaccines that are less reactogenic but immunogenic when administered by this route, such as live virus vaccines. Intradermal administration is preferred for live bacille Calmette-Guérin (BCG) vaccine and one brand of inactivated influenza vaccine.[11]

Aspiration before injection of vaccines or toxoids (i.e., pulling back on the syringe plunger after needle insertion, before injection) is not necessary because there are no large blood vessels at the recommended injection sites. Also, the process of aspiration can be painful, especially for infants.[12]

Subcutaneous Injections

Vaccines recommended for subcutaneous injection usually are administered into the thigh of infants younger than 12 months of age and into the upper, outer triceps area of persons 12 months of age or older. Subcutaneous injections also can be administered into the upper, outer triceps area of an infant. A $\frac{5}{8}$-inch, 23- to 25-gauge needle is recommended in most situations.[2,5] The needle is inserted into the tissues below the dermal layer of the skin. To avoid administering the vaccine into a muscle, the skin and subcutaneous tissue should be held gently between the thumb and fingers to raise these tissues from the muscle layer. The needle is inserted into the resulting skinfold at an approximately 45-degree angle.[5]

Intramuscular Injections

Selection of the site of injection and needle size is based on the volume of vaccine to be administered, the thickness of the overlying subcutaneous tissue, the size of the muscle, and the desired depth below the muscle surface into which the material is to be injected.

The quadriceps muscle mass in the anterolateral thigh is most commonly used for intramuscular injection in infants, whereas the deltoid muscle of the upper arm is the usual recommended site for older children and adults. After a child begins to walk, the upper arm is the preferred site.[13] By this age, the child's deltoid muscle is usually large enough to be used for intramuscular injection. Although the anterolateral thigh is also an acceptable site, intramuscular injection into the thighs of 18-month-old children has been reported to cause transient limping.[14,15] For infants and younger children, if more than two vaccines are injected in a single limb, the thigh is the preferred site because of the greater muscle mass; the injections should be sufficiently separated (i.e., ≥1 inch) so that any local reactions can be differentiated.[13,14]

TABLE 9.1 Dose and Route of Administration for Selected Vaccines

Vaccine	Dose	Route
Diphtheria, tetanus toxoids, and acellular pertussis (DTaP); diphtheria and tetanus toxoids (DT); tetanus and diphtheria toxoids (Td); tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap)	0.5 mL	IM
DTaP–hepatitis B (HepB)–inactivated poliovirus (IPV)	0.5 mL	IM
DTaP-IPV/*Haemophilus influenzae* type b (Hib)	0.5 mL	IM
DTaP-IPV	0.5 mL	IM
Hib	0.5 mL	IM
Hib-MenCY	0.5 mL	IM
Hepatitis A (HepA)	≤18 y: 0.5 mL ≥19 y: 1 mL	IM
HepB	≤19 y: 0.5 mL[a] ≥20 y: 1 mL	IM
HepA-HepB	≥18 y: 1 mL	IM
Live attenuated influenza vaccine (LAIV)	0.2 mL divided dose between nares	Intranasal spray
Inactivated influenza vaccine (IIV)	6–35 mo: 0.25 mL ≥3 y: 0.5 mL	IM
IIV intradermal	18–64 y: 0.1 mL	Intradermal (ID)
Measles, mumps, and rubella (MMR)	0.5 mL	Subcutaneous (SC)
MMR and varicella (MMRV)	0.5 mL	SC
Quadrivalent meningococcal conjugate vaccine (MCV4)	0.5 mL	IM
Quadrivalent meningococcal polysaccharide vaccine (MPSV4)	0.5 mL	SC
Serogroup B meningococcal vaccine	0.5 mL	IM
Pneumococcal conjugate vaccine (PCV)	0.5 mL	IM
Pneumococcal polysaccharide vaccine (PPSV)	0.5 mL	IM or SC
Human papillomavirus (HPV; bivalent vaccine, 2vHPV, quadrivalent vaccine, 4vHPV, or 9-valent vaccine, 9vHPV)	0.5 mL	IM
IPV	0.5 mL	IM or SC
Rotavirus (RV1 or RV5)	(1 or 2 mL)	Oral
Varicella	0.5 mL	SC
Herpes zoster	0.65 mL	SC

[a]Persons age 11–15 y may be administered Recombivax HB (Merck), 1 mL (adult formulation) on a two-dose schedule.
Modified from Immunization Action Coalition: http://www.immunize.org.

Because of the potential risk of injury to the sciatic nerve, the gluteal region is not recommended for routine vaccination.[2,5] This recommendation is based primarily on reported cases of sciatic nerve injury resulting from injection of antimicrobial agents or antiserum into the gluteus.[16,17] No reports of direct nerve injury resulting from gluteal injection of current childhood vaccines have been published.

If injections are given in the gluteal site, care must be taken to avoid nerve injury. The central region of the buttocks should be avoided. The needle should be inserted into the upper, outer quadrant and directed anteriorly (i.e., not caudally or perpendicular to the skin surface). If the gluteal muscle is chosen, injection should be lateral and superior to a line between the posterior superior iliac spine and the greater trochanter or the ventrogluteal site (i.e., the center of the triangle bounded by the anterior superior iliac spine, the tubercle of the iliac crest, and the upper border of the greater trochanter of the femur). These areas are free of major neurovascular structures. Because of the large volume that must be injected and its large muscle mass, the gluteal site often is used for passive immunization with immunoglobulin preparations.[2,5]

A 22- to 25-gauge needle is appropriate for intramuscular administration of most vaccines. The ideal needle length may depend on the vaccination technique.[18] One technique for intramuscular injections consists of gently bunching the muscle in the free hand while the needle is inserted perpendicular to the skin. A second technique consists of using the thumb and index finger to stretch the skin flat over the injection site while inserting the needle perpendicular to the skin and injecting the vaccine.[18,19]

The subcutaneous tissue and muscle layer thickness of the anterolateral thigh and deltoid region have been determined by ultrasonography.[18,20,21] On the basis of the resulting data, a ⅝-inch (16-mm) needle used according to the second technique described above is estimated to be adequate for intramuscular injection in the thigh of infants and toddlers and in the deltoid of toddlers.[18] However, when using the "bunching" technique described above, a ⅞- to 1-inch (22- to 25-mm) needle would be necessary for adequate intramuscular

penetration of the thigh of a 4-month-old infant and of the thigh and deltoid of toddlers and older children.[2,5,18,20] For injection into the thigh of children 3 years through 10 years of age, the needle length must be 1- to 1.25-inches in length.[22]

For adolescents and adults, the ideal needle length for intramuscular injection depends on the weight and sex of the vaccinee. For adolescents the deltoid muscle is preferred; however, the anterolateral thigh may be used, and if used the needle must be 1- to 1.5-inches in length.[23] Poland and colleagues[21] reported that women have a greater deltoid fat pad thickness by ultrasonography and a greater deltoid skinfold thickness than men of an equal body mass index. These authors recommended a 1-inch (25-mm) needle for men for all weight ranges studied (i.e., 59–118 kg); a ⅝- to 1-inch (16–25-mm) needle is recommended for women weighing less than 60 kg, a 1-inch (25-mm) needle is sufficient for women who weigh 60 to 90 kg, and a 1.5-inch (38-mm) needle is recommended for women who weigh more than 90 kg and men who weigh more than 118 kg.[5,21]

Vaccinating Persons With Bleeding Disorders and Persons Receiving Anticoagulant Therapy

Persons with bleeding disorders such as hemophilia and persons receiving anticoagulant therapy can be at increased risk for bleeding after intramuscular injection. If possible vaccination could be scheduled prior to the use of anticoagulant therapy so that the patients' risk of bleeding is not increased by their therapeutic action.

A 23-gauge or smaller needle should be used for the vaccination, and firm pressure without rubbing should be applied to the site for at least 2 minutes following injection. Alternatively, vaccines recommended for intramuscular injection could be administered subcutaneously to persons with a bleeding disorder if the immune response and clinical reaction to these vaccines are expected to be comparable by either route of injection, such as meningococcal conjugate vaccine and hepatitis A vaccine.[2,24,25]

Intradermal Injections

BCG, one influenza vaccine, and smallpox vaccine are the only vaccines in the United States licensed for intradermal administration. Intradermal influenza vaccine is administered near the middle of the upper arm, over the insertion of the deltoid muscle. The intradermal influenza vaccine is administered using a prefilled 1/50-inch microneedle injector system.

Smallpox (vaccinia) vaccine is administered by the intradermal route using multiple punctures with a unique bifurcated needle held perpendicular to the skin (see Chapter 33). A successful vaccination results in a pustular lesion ("Jennerian pustule") at the vaccination site 6 to 8 days after primary vaccination. The skin reaction following revaccination may be less pronounced, with more rapid progression and healing, than that after primary vaccination.[26]

Oral Administration

For vaccines given orally, the vaccine must be swallowed and retained. A dose of oral polio vaccine (OPV) should be repeated immediately if a patient spits out, does not swallow, or regurgitates a dose within 10 minutes after administration.[24] However, readministration of rotavirus vaccine is not recommended if the dose is spat out or regurgitated. No data exist on the benefits or risks associated with readministering a dose of regurgitated rotavirus vaccine. The infant should receive the remaining recommended doses of rotavirus vaccine following the routine schedule (with a 4-week minimum interval between doses).[5,27]

Intranasal Route

Live attenuated influenza vaccine (LAIV) is licensed for healthy nonpregnant persons 2 through 49 years of age and is the only vaccine administered by the intranasal route. The administration device is a nasal sprayer with a dose-divider clip that allows introduction of one 0.1-mL spray into each naris. The tip should be inserted slightly into the naris before administration. Even if the person coughs or sneezes immediately after administration or the dose is expelled any other way, the vaccine dose need not be repeated. Introduction of low levels of vaccine viruses into the environment likely is unavoidable when administering LAIV; however, no cases have been reported of illness or attenuated vaccine virus infections among inadvertently exposed healthcare providers or immunocompromised patients. The risk for acquiring vaccine viruses from the environment is unknown but is likely low; in addition, vaccine viruses are cold-adapted and attenuated and unlikely to cause symptomatic influenza. Severely immunosuppressed persons should not administer LAIV. However, other persons at higher risk for influenza complications can administer LAIV. These include persons with underlying medical conditions placing them at higher risk or who are likely to be at risk, including pregnant women, persons with asthma, and persons 50 years or older.[28]

Needle-Shielding/Needle-Free Devices

Bloodborne diseases (e.g., hepatitides B and C and HIV) are occupational hazards for healthcare providers. In November 2000, to reduce the incidence of needlestick injuries among healthcare providers and the consequent risk for bloodborne diseases acquired from patients, the Needlestick Safety and Prevention Act was signed into law in the United States. The act directed the U.S. Occupational Safety and Health Administration (OSHA) to strengthen its existing bloodborne pathogen standards. Those standards were revised and became effective in April 2001.[29] These federal regulations require the use of engineering and work practice controls to eliminate or minimize employee exposure to bloodborne pathogens.[30] "Engineering controls" mean controls (e.g., sharps disposal containers; self-sheathing needles; and safer medical devices, such as sharps with engineered sharps injury protections and needleless systems) that isolate or remove the bloodborne pathogens hazard from the workplace.[31] Work practice controls mean procedures followed by employers and workers to control hazards in the workplace (e.g., good housekeeping practices; closed transfers/containers/processes; and hygiene procedures).

Needle-shielding or needle-free devices that might satisfy the occupational safety regulations for administering parenteral injections are available in the United States and are listed at multiple websites.[33] Additional information regarding implementation and enforcement of these regulations is available at the OSHA website.[29]

Jet Injectors

Jet injectors (JIs) are needle-free devices that drive liquid medication through a nozzle orifice, creating a narrow stream under high pressure that penetrates skin to deliver a drug or vaccine into intradermal, subcutaneous, or intramuscular tissues.[35,36] JIs have the potential to reduce the frequency of needlestick injuries to healthcare providers and to overcome the improper reuse and other drawbacks of needles and

syringes in economically developing countries.[37,38] JIs have been reported safe and effective in administering different live and inactivated vaccines for viral and bacterial diseases.[39] The immune responses generated are equivalent to, and occasionally greater than, immune responses induced by needle injection. However, local reactions or injury (e.g., redness, induration, pain, blood, ecchymosis, and transient neuropathy at the injection site) can be more frequent when vaccines are delivered by JIs compared with needle injection.[39]

In the 1990s, a new generation of JIs was introduced with disposable cartridges serving as dose chambers and nozzle. With the provision of a new sterile cartridge for each patient and correct use, these devices avoid safety concerns for multiple-use–nozzle devices. These devices should be used in accordance with their labeling for intradermal, subcutaneous, or intramuscular administration. One brand of inactivated influenza vaccine has been approved by the U.S. Food and Drug Administration for use with a JI device.[40,41]

ALLEVIATION OF PAIN AND DISCOMFORT ASSOCIATED WITH VACCINATION

Several methods have been reported to reduce pain and discomfort associated with vaccination injection, but they have not been tested widely.[39] Pretreatment with topical lidocaine-prilocaine emulsion cream or patch can decrease the pain of diphtheria and tetanus toxoids and pertussis (DTP and DTaP) vaccination in infants by causing superficial anesthesia.[42–44] This product does not interfere with the immune response to MMR[43] or to inactivated vaccines.[45]

Evidence does not support use of antipyretics before or at the time of vaccination; however, antipyretics can be used for treatment of fever and local discomfort that might occur following vaccination. Studies of children with previous febrile seizures have not demonstrated antipyretics to be effective in the prevention of febrile seizures.[46]

A topical refrigerant spray can reduce the short-term pain associated with injections and can be as effective as lidocaine-prilocaine cream.[46,47] Oral administration of sweet-tasting fluid just before injection may cause a calming or analgesic effect in some infants.[48] Breastfeeding is a potent analgesic intervention for infants during blood collection and may, by extrapolation, help decrease injection pain during immunization. Distraction techniques such as listening to music or "blowing away pain" also may help children cope with the discomfort associated with vaccination.[49,50] Swaddling and slow lateral swaying also help as comfort measures.[51]

AGES FOR ADMINISTRATION OF IMMUNOBIOLOGICS

Recommendations for the age and timing of vaccination are based on multiple considerations and may vary in different countries. Optimal response to a vaccine depends on a number of factors, including the nature of the vaccine and the age and immune status of the recipient. Recommendations for the age at which vaccines are administered are influenced by age-specific risks for disease and complications, ability of persons of a certain age to respond to the vaccine, and potential interference with the immune response by passively transferred maternal antibody or previously administered antibody-containing blood products. Vaccines usually are recommended for members of the youngest age group at risk for experiencing the disease for whom efficacy and safety have been demonstrated. These principles are demonstrated with the following examples.

The optimal timing for administration of measles vaccine depends on the rate of disappearance of passively acquired maternal antibody and the risk of exposure to measles virus. At birth and through the first 6 months of life, most infants have passive immunity to measles because of transplacentally acquired maternal measles antibodies. These antibodies interfere with the immune response to live virus measles vaccine by limiting vaccine virus replication. In many developing countries, where measles is highly endemic and frequently affects infants, routine measles vaccination is recommended at 9 months of age (see Chapter 21).[52] However, in the United States, where measles is less common and measles among infants is infrequent, measles vaccine is recommended routinely at 12 through 15 months of age, ages at which almost all infants will have no residual maternal antibody.[2,53]

Another example is the recommended age of pertussis vaccination. Early infancy is the time of greatest risk of serious complications from pertussis, but infants who are younger than 1 month of age do not respond as well immunologically to whole-cell pertussis vaccine (and presumably acellular vaccines) as do older infants.[54–56] Initiation of routine immunization with pertussis vaccine in the United States is recommended at 2 months of age.[57,58] This scheduling represents a compromise between factors affecting the immune response and the epidemiology of the disease necessitating early protection against pertussis. Tdap (tetanus, diphtheria, and pertussis) given to pregnant women will stimulate the development of maternal antipertussis antibodies, which will be transferred to the fetus by the placenta, likely providing the newborn with protection against pertussis in early life.[59] Tdap also will protect the mother from pertussis around the time of delivery, making her less likely to become infected and transmit pertussis to her infant.[59] Vaccination too early in life also may affect the immune response to subsequent doses of vaccine. For example, neonatal administration of diphtheria and tetanus toxoids (DT) may result in suppression of antibody responses to subsequent doses of Hib conjugate vaccines covalently linked to forms of those toxoids.[60] When children who receive measles vaccine before the age of 1 year are revaccinated, they develop vaccine-induced immunity against disease but may have a somewhat diminished antibody response compared with children vaccinated initially after their first birthday.[61,62]

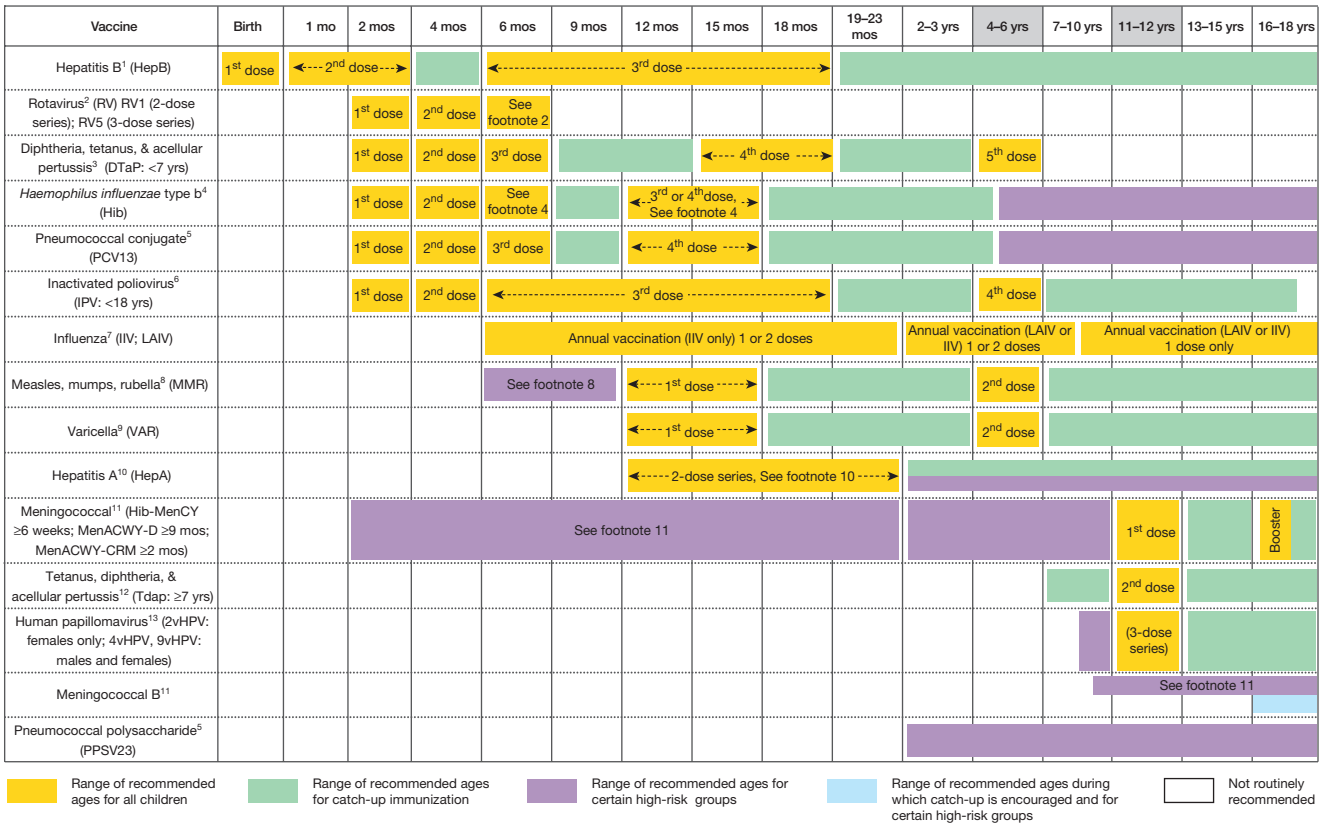
In the United States, the recommended childhood, adolescent, and adult immunization schedules are revised annually and are approved by the ACIP, the AAP (for the childhood and adolescent schedule), the American Academy of Family Physicians, the American Congress of Obstetricians and Gynecologists, the American College of Physicians (for the adult schedule), and the American College of Nurse Midwives (for the adult schedule).[63,64] A recent U.S. childhood vaccination schedule is shown in Fig. 9.1.[63] The most current vaccination schedules for children and adults are available from the CDC Vaccines and Immunizations website (http://www.cdc.gov/vaccines/schedules/index.html).[65] Table 9.2 lists the recommended and minimum ages and recommended and minimum acceptable intervals between doses of vaccines used in the United States. Other vaccination schedules are discussed in Chapters 74, 75, and 76.

SPACING OF VACCINE DOSES

Spacing of Multiple Doses of the Same Vaccine

Although administration of one dose of some vaccines may induce a protective antibody response, most vaccines require administration of multiple doses in a primary series for development of immunity. Examples of the former are rubella and yellow fever vaccines; examples of the latter are poliovirus,

hepatitis B, and pertussis vaccines. In addition, periodic revaccination ("booster doses") with certain vaccines may be necessary to maintain immunity. Examples are typhoid vaccines and tetanus and diphtheria toxoids.



Because of immunologic memory, intervals longer than routinely recommended between doses do not impair the immunologic response to live and inactivated vaccines that require more than one dose to achieve primary immunity. Similarly, delayed administration of recommended booster doses does not adversely affect the antibody response to such doses.[2,5] As a result, interruption of a recommended primary series or an extended interval between booster doses does not necessitate reinitiation of the entire vaccination series. For example, lengthening the interval between two doses of inactivated poliovirus vaccine (IPV) may increase the antibody response to the second dose.[66] In the case of oral typhoid (Ty21a) vaccine, an exception has been proposed. The impact of a lapse in the series of oral typhoid vaccine is not known. However, as a rule of thumb for Ty21a, if fewer than 3 weeks have passed since the last dose, the series may be completed with the missing dose or doses. If more than 3 weeks have passed, the full series should be repeated.

Vaccination providers should strive to adhere as closely as possible to recommended childhood, adolescent, and adult immunization schedules. Clinical studies confirm that recommended ages and intervals between doses of multidose antigens provide optimal protection or have the best evidence of efficacy. Table 9.2 lists recommended intervals between doses of commonly used vaccines.

In certain circumstances, administering doses of a multidose vaccine at shorter than the recommended intervals might be necessary. Examples include when a person is behind schedule and needs to be brought up-to-date as quickly as possible and cases of impending international travel. In these situations, an accelerated schedule with intervals between doses shorter than intervals recommended for routine vaccination can be used.[63] Although the effectiveness of all accelerated

Text continued on p. 106

Recommended immunization schedule for persons aged 0 through 18 years – United States, 2016.
(FOR THOSE WHO FALL BEHIND OR START LATE, SEE THE CATCH-UP SCHEDULE [FIGURE 2]).
These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Figure 1. To determine minimum intervals between doses, see the catch-up schedule (Figure 2). School entry and adolescent vaccine age groups are shaded.

This schedule includes recommendations in effect as of January 1, 2016. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at **http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.** Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (**http://www.vaers.hhs.gov**) or by telephone (**800-822-7967**). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (**http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm**) or by telephone (**800-CDC-INFO** [**800-232-4636**]).

This schedule is approved by the Advisory Committee on Immunization Practices (**http//www.cdc.gov/vaccines/acip**), the American Academy of Pediatrics (**http://www.aap.org**), the American Academy of Family Physicians (**http://www.aafp.org**), and the American College of Obstetricians and Gynecologists (**http://www.acog.org**).

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Figure 9.1. Immunization schedules. Available at www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html. *Continued*

Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind —United States, 2016.

The figure below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this table in conjunction with Figure 1 and the footnotes that follow.

Children age 4 months through 6 years					
Vaccine	Minimum age for dose 1	Minimum interval between doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Hepatitis B[1]	Birth	4 weeks	**8 weeks** *and* at least 16 weeks after first dose. Minimum age for the final dose is 24 weeks.		
Rotavirus[2]	6 weeks	4 weeks	4 weeks[2]		
Diphtheria, tetanus, and acellular pertussis[3]	6 weeks	4 weeks	4 weeks	6 months	6 months[3]
Haemophilus influenzae type b[4]	6 weeks	**4 weeks** if first dose was administered before the 1st birthday. **8 weeks (as final dose)** if first dose was administered at age 12 through 14 months. **No further doses needed** if first dose was administered at age 15 months or older.	**4 weeks**[4] if current age is younger than 12 months **and** first dose was administered at younger than age 7 months, **and** at least 1 previous dose was PRP-T (ActHib, Pentacel) or unknown. **8 weeks** *and* **age 12 through 59 months (as final dose for healthy children)**[4] if current age is younger than 12 months **and** first dose was administered at age 7 through 11 months (wait until at least 12 months old); **OR** if current age is 12 through 59 months **and** first dose was administered before the 1st birthday, **and** second dose administered at younger than 15 months; **OR** if both doses were PRP-OMP (PedvaxHIB; Comvax) **and** were administered before the 1st birthday (wait until at least 12 months old). **No further doses needed** if previous dose was administered at age 15 months or older.	**8 weeks (as final dose)** This dose only necessary for children age 12 through 59 months who received 3 doses before the 1st birthday.	
Pneumococcal[5]	6 weeks	**4 weeks** if first dose administered before the 1st birthday. **8 weeks (as final dose for healthy children)** if first dose was administered at the 1st birthday or after. **No further doses needed** for healthy children if first dose administered at age 24 months or older.	**4 weeks** if current age is younger than 12 months and previous dose given at <7months old. **8 weeks (as final dose for healthy children)** if previous dose given between 7–11 months (wait until at least 12 months old); **OR** if current age is 12 months or older and at least 1 dose was given before age 12 months. **No further doses needed** for healthy children if previous dose administered at age 24 months or older.	**8 weeks (as final dose)** This dose only necessary for children aged 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age.	
Inactivated poliovirus[6]	6 weeks	4 weeks[6]	4 weeks[6]	6 months[6] (minimum age 4 years for final dose).	
Measles, mumps, rubella[8]	12 months	4 weeks			
Varicella[9]	12 months	3 months			
Hepatitis A[10]	12 months	6 months			
Meningococcal[11] (Hib-MenCY >6 weeks; MenACWY-D >9 mos; MenACWY-CRM >2 mos)	6 weeks	8 weeks[11]	See footnote 11	See footnote 11	
Children and adolescents age 7 through 18 years					
Meningococcal[11] (Hib-MenCY >6 weeks; MenACWY-D >9 mos; MenACWY-CRM >2 mos)	Not applicable (N/A)	8 weeks[11]			
Tetanus, diphtheria; tetanus, diphtheria, and acellular pertussis[12]	7 years[12]	4 weeks	**4 weeks** if first dose of DTaP/DT was administered before the 1st birthday. **6 months (as final dose)** if first dose of DTaP/DT or Tdap/Td was administered at or after the 1st birthday.	**6 months** if first dose of DTaP/DT was administered before the 1st birthday.	
Human papillomavirus[13]	9 years	Routine dosing intervals are recommended.[13]			
Hepatitis A[10]	N/A	6 months			
Hepatitis B[1]	N/A	4 weeks	**8 weeks and** at least 16 weeks after first dose.		
Inactivated poliovirus[6]	N/A	4 weeks	4 weeks[6]	6 months[6]	
Meningococcal[11]	N/A	8 weeks[11]			
Measles, mumps, rubella[8]	N/A	4 weeks			
Varicella[9]	N/A	**3 months** if younger than age 13 years. **4 weeks** if age 13 years or older.			

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Figure 9.1. cont'd

Footnotes — Recommended immunization schedule for persons aged 0 through 18 years—United States, 2016
For further guidance on the use of the vaccines mentioned below, see: **http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.**
For vaccine recommendations for persons 19 years of age and older, see the Adult Immunization Schedule **www.cdc.gov/vaccines/schedules/hcp/adult.html**.
Additional information

- For contraindications and precautions to use of a vaccine and for additional information regarding that vaccine, vaccination providers should consult the relevant ACIP statement available online at **http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.**
- For purposes of calculating intervals between doses, 4 weeks = 28 days. Intervals of 4 months or greater are determined by calendar months.
- Vaccine doses administered 4 days or less before the minimum interval are considered valid. Doses of any vaccine administered ≥5 days earlier than the minimum interval or minimum age should not be counted as valid doses and should be repeated as age-appropriate. The repeat dose should be spaced after the invalid dose by the recommended minimum interval. For further details, see *MMWR, General Recommendations on Immunization and Reports* / Vol. 60 / No. 2; Table 1. *Recommended and minimum ages and intervals between vaccine doses available* online at **http://www.cdc.gov/mmwr/pdf/rr/rr6002.pdf**.
- Information on travel vaccine requirements and recommendations is available at **http://wwwnc.cdc.gov/travel/destinations/list**.
- For vaccination of persons with primary and secondary immunodeficiencies, see Table 13, *"Vaccination of persons with primary and secondary immunodeficiencies," in General Recommendations on Immunization* (ACIP), available at **http://www.cdc.gov/mmwr/pdf/rr/rr6002.pdf**.; and American Academy of Pediatrics. "Immunization in Special Clinical Circumstances," in Kimberlin DW, Brady MT, Jackson MA, Long SS eds. *Red Book: 2015 report of the Committee on Infectious Diseases. 30th ed.* Elk Grove Village, IL: American Academy of Pediatrics.

1. Hepatitis B (HepB) vaccine. (Minimum age: birth)
Routine vaccination:
At birth:

- Administer monovalent HepB vaccine to all newborns before hospital discharge.
- For infants born to hepatitis B surface antigen (HBsAg)-positive mothers, administer HepB vaccine and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) at age 9 through 18 months (preferably at the next well-child visit) or 1 to 2 months after completion of the HepB series if the series was delayed; CDC recently recommended testing occur at age 9 through 12 months; see **http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6439a6.htm**.
- If mother's HBsAg status is unknown, within 12 hours of birth administer HepB vaccine regardless of birth weight. For infants weighing less than 2,000 grams, administer HBIG in addition to HepB vaccine within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if mother is HBsAg-positive, also administer HBIG for infants weighing 2,000 grams or more as soon as possible, but no later than age 7 days.

Doses following the birth dose:

- The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks.
- Infants who did not receive a birth dose should receive 3 doses of a HepB-containing vaccine on a schedule of 0, 1 to 2 months, and 6 months starting as soon as feasible. See Figure 2.
- Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks), administer the third dose at least 8 weeks after the second dose AND at least 16 weeks after the **first** dose. The final (third or fourth) dose in the HepB vaccine series should be administered **no earlier than age 24 weeks**.
- Administration of a total of 4 doses of HepB vaccine is permitted when a combination vaccine containing HepB is administered after the birth dose.

Catch-up vaccination:

- Unvaccinated persons should complete a 3-dose series.
- A 2-dose series (doses separated by at least 4 months) of adult formulation Recombivax HB is licensed for use in children aged 11 through 15 years.
- For other catch-up guidance, see Figure 2.

2. Rotavirus (RV) vaccines. (Minimum age: 6 weeks for both RV1 [Rotarix] and RV5 [RotaTeq])
Routine vaccination:
Administer a series of RV vaccine to all infants as follows:

1. If Rotarix is used, administer a 2-dose series at 2 and 4 months of age.
2. If RotaTeq is used, administer a 3-dose series at ages 2, 4, and 6 months.
3. If any dose in the series was RotaTeq or vaccine product is unknown for any dose in the series, a total of 3 doses of RV vaccine should be administered.

Catch-up vaccination:

- The maximum age for the first dose in the series is 14 weeks, 6 days; vaccination should not be initiated for infants aged 15 weeks, 0 days or older.
- The maximum age for the final dose in the series is 8 months, 0 days.
- For other catch-up guidance, see Figure 2.

3. Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. (Minimum age: 6 weeks. Exception: DTaP-IPV [Kinrix, Quadracel]: 4 years)
Routine vaccination:

- Administer a 5-dose series of DTaP vaccine at ages 2, 4, 6, 15 through 18 months, and 4 through 6 years. The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
- Inadvertent administration of 4th DTaP dose early: If the fourth dose of DTaP was administered at least 4 months, but less than 6 months, after the third dose of DTaP, it need not be repeated.

Catch-up vaccination:

- The fifth dose of DTaP vaccine is not necessary if the fourth dose was administered at age 4 years or older.
- For other catch-up guidance, see Figure 2.

4. *Haemophilus influenzae* type b (Hib) conjugate vaccine. (Minimum age: 6 weeks for PRP-T [ACTHIB, DTaP-IPV/Hib (Pentacel) and Hib-MenCY (MenHibrix)], PRP-OMP [PedvaxHIB or COMVAX], 12 months for PRP-T [Hiberix])
Routine vaccination:

- Administer a 2- or 3-dose Hib vaccine primary series and a booster dose (dose 3 or 4 depending on vaccine used in primary series) at age 12 through 15 months to complete a full Hib vaccine series.
- The primary series with ActHIB, MenHibrix, or Pentacel consists of 3 doses and should be administered at 2, 4, and 6 months of age. The primary series with PedvaxHib or COMVAX consists of 2 doses and should be administered at 2 and 4 months of age; a dose at age 6 months is not indicated.
- One booster dose (dose 3 or 4 depending on vaccine used in primary series) of any Hib vaccine should be administered at age 12 through 15 months. An exception is Hiberix vaccine. Hiberix should only be used for the booster (final) dose in children aged 12 months through 4 years who have received at least 1 prior dose of Hib-containing vaccine.
- For recommendations on the use of MenHibrix in patients at increased risk for meningococcal disease, please refer to the meningococcal vaccine footnotes and also to *MMWR* February 28, 2014 / 63(RR01);1–13, available at **http://www.cdc.gov/mmwr/PDF/rr/rr6301.pdf**.

Catch-up vaccination:

- If dose 1 was administered at ages 12 through 14 months, administer a second (final) dose at least 8 weeks after dose 1, regardless of Hib vaccine used in the primary series.
- If both doses were PRP-OMP (PedvaxHIB or COMVAX), and were administered before the first birthday, the third (and final) dose should be administered at age 12 through 59 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a third (and final) dose at age 12 through 15 months or 8 weeks after second dose, whichever is later.
- If first dose is administered before the first birthday and second dose administered at younger than 15 months, a third (and final) dose should be administered 8 weeks later.
- For unvaccinated children aged 15 months or older, administer only 1 dose.
- For other catch-up guidance, see Figure 2. For catch-up guidance related to MenHibrix, please see the meningococcal vaccine footnotes and also *MMWR* February 28, 2014 / 63(RR01);1–13, available at **http://www.cdc.gov/mmwr/PDF/rr/rr6301.pdf**.

Vaccination of persons with high-risk conditions:

- Children aged 12 through 59 months who are at increased risk for Hib disease, including chemotherapy recipients and those with anatomic or functional asplenia (including sickle cell disease), human immunodeficiency virus (HIV) infection, immunoglobulin deficiency, or early component complement deficiency, who have received either no doses or only 1 dose of Hib vaccine before 12 months of age, should receive 2 additional doses of Hib vaccine 8 weeks apart; children who received 2 or more doses of Hib vaccine before 12 months of age should receive 1 additional dose.
- For patients younger than 5 years of age undergoing chemotherapy or radiation treatment who received a Hib vaccine dose(s) within 14 days of starting therapy or during therapy, repeat the dose(s) at least 3 months following therapy completion.

4. *Haemophilus influenzae* type b (Hib) conjugate vaccine. (cont'd)

- Recipients of hematopoietic stem cell transplant (HSCT) should be revaccinated with a 3-dose regimen of Hib vaccine starting 6 to 12 months after successful transplant, regardless of vaccination history; doses should be administered at least 4 weeks apart.
- A single dose of any Hib-containing vaccine should be administered to unimmunized* children and adolescents 15 months of age and older undergoing an elective splenectomy; if possible, vaccine should be administered at least 14 days before procedure.
- Hib vaccine is not routinely recommended for patients 5 years or older. However, 1 dose of Hib vaccine should be administered to unimmunized* persons aged 5 years or older who have anatomic or functional asplenia (including sickle cell disease) and unvaccinated persons 5 through 18 years of age with HIV infection.

* *Patients who have not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.*

5. Pneumococcal vaccines. (Minimum age: 6 weeks for PCV13, 2 years for PPSV23)
Routine vaccination with PCV13:

- Administer a 4-dose series of PCV13 vaccine at ages 2, 4, and 6 months and at age 12 through 15 months.
- For children aged 14 through 59 months who have received an age-appropriate series of 7-valent PCV (PCV7), administer a single supplemental dose of 13-valent PCV (PCV13).

Catch-up vaccination with PCV13:

- Administer 1 dose of PCV13 to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- For other catch-up guidance, see Figure 2.

Vaccination of persons with high-risk conditions with PCV13 and PPSV23:

- All recommended PCV13 doses should be administered prior to PPSV23 vaccination if possible.
- For children 2 through 5 years of age with any of the following conditions: chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy); diabetes mellitus; cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; solid organ transplantation; or congenital immunodeficiency:
  1. Administer 1 dose of PCV13 if any incomplete schedule of 3 doses of PCV (PCV7 and/or PCV13) were received previously.
  2. Administer 2 doses of PCV13 at least 8 weeks apart if unvaccinated or any incomplete schedule of fewer than 3 doses of PCV (PCV7 and/or PCV13) were received previously.
  3. Administer 1 supplemental dose of PCV13 if 4 doses of PCV7 or other age-appropriate complete PCV7 series was received previously.
  4. The minimum interval between doses of PCV (PCV7 or PCV13) is 8 weeks.
  5. For children with no history of PPSV23 vaccination, administer PPSV23 at least 8 weeks after the most recent dose of PCV13.
- For children aged 6 through 18 years who have cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; generalized malignancy; solid organ transplantation; or multiple myeloma:
  1. If neither PCV13 nor PPSV23 has been received previously, administer 1 dose of PCV13 now and 1 dose of PPSV23 at least 8 weeks later.
  2. If PCV13 has been received previously but PPSV23 has not, administer 1 dose of PPSV23 at least 8 weeks after the most recent dose of PCV13.
  3. If PPSV23 has been received but PCV13 has not, administer 1 dose of PCV13 at least 8 weeks after the most recent dose of PPSV23.
- For children aged 6 through 18 years with chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure), chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy), diabetes mellitus, alcoholism, or chronic liver disease, who have not received PPSV23, administer 1 dose of PPSV23. If PCV13 has been received previously, then PPSV23 should be administered at least 8 weeks after any prior PCV13 dose.
- A single revaccination with PPSV23 should be administered 5 years after the first dose to children with sickle cell disease or other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; generalized malignancy; solid organ transplantation; or multiple myeloma.

6. Inactivated poliovirus vaccine (IPV). (Minimum age: 6 weeks)
Routine vaccination:

- Administer a 4-dose series of IPV at ages 2, 4, 6 through 18 months, and 4 through 6 years. The final dose in the series should be administered on or after the fourth birthday and at least 6 months after the previous dose.

Catch-up vaccination:

- In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk of imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).
- If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years and at least 6 months after the previous dose.
- A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age. If only OPV were administered, and all doses were given prior to 4 years of age, one dose of IPV should be given at 4 years or older, at least 4 weeks after the last OPV dose.
- IPV is not routinely recommended for U.S. residents aged 18 years or older.
- For other catch-up guidance, see Figure 2.

7. Influenza vaccines. (Minimum age: 6 months for inactivated influenza vaccine [IIV], 2 years for live, attenuated influenza vaccine [LAIV])
Routine vaccination:

- Administer influenza vaccine annually to all children beginning at age 6 months. For most healthy, nonpregnant persons aged 2 through 49 years, either LAIV or IIV may be used. However, LAIV should NOT be administered to some persons, including 1) persons who have experienced severe allergic reactions to LAIV, any of its components, or to a previous dose of any other influenza vaccine; 2) children 2 through 17 years receiving aspirin or aspirin-containing products; 3) persons who are allergic to eggs; 4) pregnant women; 5) immunosuppressed persons; 6) children 2 through 4 years of age with asthma or who had wheezing in the past 12 months; or 7) persons who have taken influenza antiviral medications in the previous 48 hours. For all other contraindications and precautions to use of LAIV, see *MMWR* August 7, 2015 / 64(30):818–25 available at **http://www.cdc.gov/mmwr/pdf/wk/mm6430.pdf.**

Figure 9.1. cont'd

Continued

7. **Influenza vaccines. (cont'd)**
For children aged 6 months through 8 years:
- For the 2015–16 season, administer 2 doses (separated by at least 4 weeks) to children who are receiving influenza vaccine for the first time. Some children in this age group who have been vaccinated previously will also need 2 doses. For additional guidance, follow dosing guidelines in the 2015–16 ACIP influenza vaccine recommendations, *MMWR* August 7, 2015 / 64(30):818–25, available at http://www.cdc.gov/mmwr/pdf/wk/mm6430.pdf.
- For the 2016–17 season, follow dosing guidelines in the 2016 ACIP influenza vaccine recommendations.

For persons aged 9 years and older:
- Administer 1 dose.

8. **Measles, mumps, and rubella (MMR) vaccine. (Minimum age: 12 months for routine vaccination)**
Routine vaccination:
- Administer a 2-dose series of MMR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
- Administer 1 dose of MMR vaccine to infants aged 6 through 11 months before departure from the United States for international travel. These children should be revaccinated with 2 doses of MMR vaccine, the first at age 12 through 15 months (12 months if the child remains in an area where disease risk is high), and the second dose at least 4 weeks later.
- Administer 2 doses of MMR vaccine to children aged 12 months and older before departure from the United States for international travel. The first dose should be administered on or after age 12 months and the second dose at least 4 weeks later.

Catch-up vaccination:
- Ensure that all school-aged children and adolescents have had 2 doses of MMR vaccine; the minimum interval between the 2 doses is 4 weeks.

9. **Varicella (VAR) vaccine. (Minimum age: 12 months)**
Routine vaccination:
- Administer a 2-dose series of VAR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose. If the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.

Catch-up vaccination:
- Ensure that all persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007 / 56 [No. RR-4], available at **http://www.cdc.gov/mmwr/pdf/rr/rr5604.pdf**) have 2 doses of varicella vaccine. For children aged 7 through 12 years, the recommended minimum interval between doses is 3 months (if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid); for persons aged 13 years and older, the minimum interval between doses is 4 weeks.

10. **Hepatitis A (HepA) vaccine. (Minimum age: 12 months)**
Routine vaccination:
- Initiate the 2-dose HepA vaccine series at 12 through 23 months; separate the 2 doses by 6 to 18 months.
- Children who have received 1 dose of HepA vaccine before age 24 months should receive a second dose 6 to 18 months after the first dose.
- For any person aged 2 years and older who has not already received the HepA vaccine series, 2 doses of HepA vaccine separated by 6 to 18 months may be administered if immunity against hepatitis A virus infection is desired.

Catch-up vaccination:
- The minimum interval between the 2 doses is 6 months.

Special populations:
- Administer 2 doses of HepA vaccine at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children, or who are at increased risk for infection. This includes persons traveling to or working in countries that have high or intermediate endemicity of infection; men having sex with men; users of injection and non-injection illicit drugs; persons who work with HAV-infected primates or with HAV in a research laboratory; persons with clotting-factor disorders; persons with chronic liver disease; and persons who anticipate close personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. The first dose should be administered as soon as the adoption is planned, ideally 2 or more weeks before the arrival of the adoptee.

11. **Meningococcal vaccines. (Minimum age: 6 weeks for Hib-MenCY [MenHibrix], 9 months for MenACWY-D [Menactra], 2 months for MenACWY-CRM [Menveo], 10 years for serogroup B meningococcal [MenB] vaccines: MenB-4C [Bexsero] and MenB-FHbp [Trumenba])**
Routine vaccination:
- Administer a single dose of Menactra or Menveo vaccine at age 11 through 12 years, with a booster dose at age 16 years.
- Adolescents aged 11 through 18 years with human immunodeficiency virus (HIV) infection should receive a 2-dose primary series of Menactra or Menveo with at least 8 weeks between doses.
- For children aged 2 months through 18 years with high-risk conditions, see below.

Catch-up vaccination:
- Administer Menactra or Menveo vaccine at age 13 through 18 years if not previously vaccinated.
- If the first dose is administered at age 13 through 15 years, a booster dose should be administered at age 16 through 18 years with a minimum interval of at least 8 weeks between doses.
- If the first dose is administered at age 16 years or older, a booster dose is not needed.
- For other catch-up guidance, see Figure 2.

Clinical discretion:
- Young adults aged 16 through 23 years (preferred age range is 16 through 18 years) may be vaccinated with either a 2-dose series of Bexsero or a 3-dose series of Trumenba vaccine to provide short-term protection against most strains of serogroup B meningococcal disease. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.

Vaccination of persons with high-risk conditions and other persons at increased risk of disease:
Children with anatomic or functional asplenia (including sickle cell disease):
Meningococcal conjugate ACWY vaccines:
1. Menveo
   - *o Children who initiate vaccination at 8 weeks:* Administer doses at 2, 4, 6, and 12 months of age.
   - *o Unvaccinated children who initiate vaccination at 7 through 23 months:* Administer 2 doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
   - *o Children 24 months and older who have not received a complete series*: Administer 2 primary doses at least 8 weeks apart.
2. MenHibrix
   - *o Children who initiate vaccination at 6 weeks:* Administer doses at 2, 4, 6, and 12 through 15 months of age.
   - *o* If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
3. Menactra
   - *o Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart. If Menactra is administered to a child with asplenia (including sickle cell disease), do not administer Menactra until 2 years of age and at least 4 weeks after the completion of all PCV13 doses.

Meningococcal B vaccines:
1. Bexsero or Trumenba
   - *o Persons 10 years or older who have not received a complete series.* Administer a 2-dose series of Bexsero, at least 1 month apart. Or a 3-dose series of Trumenba, with the second dose at least 2 months after the first and the third dose at least 6 months after the first. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.

Children with persistent complement component deficiency (includes persons with inherited or chronic deficiencies in C3, C5-9, properidin, factor D, factor H, or taking eculizumab (Soliris®):
Meningococcal conjugate ACWY vaccines:
1. Menveo
   - *o Children who initiate vaccination at 8 weeks:* Administer doses at 2, 4, 6, and 12 months of age.
   - *o Unvaccinated children who initiate vaccination at 7 through 23 months:* Administer 2 doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
   - *o Children 24 months and older who have not received a complete series*: Administer 2 primary doses at least 8 weeks apart.
2. MenHibrix
   - *o Children who initiate vaccination 6 weeks:* Administer doses at 2, 4, 6, and 12 through 15 months of age.
   - *o* If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
3. Menactra
   - *o Children 9 through 23 months*: Administer 2 primary doses at least 12 weeks apart.
   - *o Children 24 months and older who have not received a complete series*: Administer 2 primary doses at least 8 weeks apart.

Meningococcal B vaccines:
1. Bexsero or Trumenba
   - *o Persons 10 years or older who have not received a complete series*. Administer a 2-dose series of Bexsero, at least 1 month apart. Or a 3-dose series of Trumenba, with the second dose at least 2 months after the first and the third dose at least 6 months after the first. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.

For children who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic, including countries in the African meningitis belt or the Hajj
- administer an age-appropriate formulation and series of Menactra or Menveo for protection against serogroups A and W meningococcal disease. Prior receipt of MenHibrix is not sufficient for children traveling to the meningitis belt or the Hajj because it does not contain serogroups A or W.

For children at risk during a community outbreak attributable to a vaccine serogroup
- administer or complete an age- and formulation-appropriate series of MenHibrix, Menactra, or Menveo, Bexsero or Trumenba.

For booster doses among persons with high-risk conditions, refer to *MMWR* 2013 / 62(RR02);1–22, available at **http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6202a1.htm**.
For other catch-up recommendations for these persons, and complete information on use of meningococcal vaccines, including guidance related to vaccination of persons at increased risk of infection, see *MMWR* March 22, 2013 / 62(RR02);1–22, and *MMWR* October 23, 2015 / 64(41); 1171–1176 available at **http://www.cdc.gov/mmwr/pdf/rr/rr6202.pdf, and http://www.cdc.gov/mmwr/pdf/wk/mm6441.pdf.**

12. **Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine. (Minimum age: 10 years for both Boostrix and Adacel)**
Routine vaccination:
- Administer 1 dose of Tdap vaccine to all adolescents aged 11 through 12 years.
- Tdap may be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
- Administer 1 dose of Tdap vaccine to pregnant adolescents during each pregnancy (preferred during 27 through 36 weeks gestation) regardless of time since prior Td or Tdap vaccination.

Catch-up vaccination:
- Persons aged 7 years and older who are not fully immunized with DTaP vaccine should receive Tdap vaccine as 1 (preferably the first) dose in the catch-up series; if additional doses are needed, use Td vaccine. For children 7 through 10 years who receive a dose of Tdap as part of the catch-up series, an adolescent Tdap vaccine dose at age 11 through 12 years should NOT be administered. Td should be administered instead 10 years after the Tdap dose.
- Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter.
- Inadvertent doses of DTaP vaccine:
  - – If administered inadvertently to a child aged 7 through 10 years may count as part of the catch-up series. This dose may count as the adolescent Tdap dose, or the child can later receive a Tdap booster dose at age 11 through 12 years.
  - – If administered inadvertently to an adolescent aged 11 through 18 years, the dose should be counted as the adolescent Tdap booster.
  - For other catch-up guidance, see Figure 2.

13. **Human papillomavirus (HPV) vaccines. (Minimum age: 9 years for 2vHPV [Cervarix], 4vHPV [Gardasil] and 9vHPV [Gardasil 9])**
Routine vaccination:
- Administer a 3-dose series of HPV vaccine on a schedule of 0, 1–2, and 6 months to all adolescents aged 11 through 12 years. 9vHPV, 4vHPV or 2vHPV may be used for females, and only 9vHPV or 4vHPV may be used for males.
- The vaccine series may be started at age 9 years.
- Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks); administer the third dose 16 weeks after the second dose (minimum interval of 12 weeks) and 24 weeks after the first dose.
- Administer HPV vaccine beginning at age 9 years to children and youth with any history of sexual abuse or assault who have not initiated or completed the 3-dose series.

Catch-up vaccination:
- Administer the vaccine series to females (2vHPV or 4vHPV or 9vHPV) and males (4vHPV or 9vHPV) at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals (see Routine vaccination above) for vaccine series catch-up.

Figure 9.1. cont'd

TABLE 9.2 Recommended and Minimum Ages and Intervals Between Vaccine Doses[a,b,c,d]

Vaccine and Dose Number	Recommended Age for This Dose	Minimum Age for This Dose	Recommended Interval to Next Dose	Minimum Interval to Next Dose
Diphtheria and tetanus toxoids and acellular pertussis (DTaP)-1[e]	2 mo	6 wk	8 wk	4 wk
DTaP-2	4 mo	10 wk	8 wk	4 wk
DTaP-3	6 mo	14 wk	6–12 mo[f]	6 mo[f]
DTaP-4	15–18 mo	15 mo	3 y	6 mo[e]
DTaP-5	4–6 y	4 y	—	—
Haemophilus influenzae type b (Hib)-1[e,g]	2 mo	6 wk	8 wk	4 wk
Hib-2	4 mo	10 wk	8 wk	4 wk
Hib-3[h]	6 mo	14 wk	6–9 mo	8 wk
Hib-4	12–15 mo	12 mo	—	—
Hepatitis A (HepA)-1[e]	12–23 mo	12 mo	6–18 mo	6 mo
HepA-2	≥ 18 mo	18 mo	—	—
Hepatitis B (HepB)-1	Birth	Birth	4 wk–4 mo	4 wk
HepB-2	1–2 mo	4 wk	8 wk–17 mo	8 wk
HepB-3[i]	6–18 mo	24 wk	—	—
Herpes zoster[j]	≥ 60 y	60 y	—	—
Human papillomavirus (HPV)-1[k]	11–12 y	9 y	8 wk	4 wk
HPV-2	11–12 y (+2 mo)	9 y (+4 wk)	4 mo	12 wk[r(l)]
HPV-3[l]	11–12 y (+6 mo)	9 y (+24 wk)	—	—
Inactivated poliovirus (IPV)-1[e]	2 mo	6 wk	8 wk	4 wk
IPV-2	4 mo	10 wk	8wk–14 mo	4 wk
IPV-3	6–18 mo	14 wk	3–5 y	6 mo

TABLE 9.2 Recommended and Minimum Ages and Intervals Between Vaccine Doses[a,b,c,d] *(Continued)*

Vaccine and Dose Number	Recommended Age for This Dose	Minimum Age for This Dose	Recommended Interval to Next Dose	Minimum Interval to Next Dose
Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap)[v]	≥11 y	7 y	—	—
Varicella-1[p]	12–15 mo	12 mo	3–5 y	12 wk[w]
Varicella-2[p]	4–6 y	15 mo[x]	—	—

[a]Combination vaccines are available. Use of licensed combination vaccines is generally preferred to separate injections of their equivalent component vaccines. When administering combination vaccines, the minimum age for administration is the oldest age for any of the individual components (exception: the minimum age for the first dose of MenHibrix is 6 weeks); the minimum interval between doses is equal to the greatest interval of any of the individual components.

[b]Information on travel vaccines, including typhoid, Japanese encephalitis, and yellow fever, is available at http://www.cdc.gov/travel. Information on other vaccines that are licensed in the United States but not distributed, including anthrax and smallpox, is available at http://www.bt.cdc.gov.

[c]In the recommended interval and the minimum interval columns, "months" refers to calendar months.

[d]Within a number range, a dash refers to "through."

[e]Combination vaccines containing the HepB component are available (see Table 9.1). These vaccines should not be administered to infants <6 weeks because of the other components (i.e., Hib, DTaP, HepA, and IPV).

[f]The minimum recommended interval between DTaP-3 and DTaP-4 is 6 months. However, DTaP-4 need not be repeated if administered at least 4 months after DTaP-3. This is a special grace period of 2 months which can be used if evaluating records retrospectively. An additional 4 days should not be added to this grace period.

[g]For Hib and PCV, children receiving the first dose of vaccine at age ≥7 months require fewer doses to complete the series.

[h]If polyribosylribitol phosphate-meningococcal outer membrane protein conjugate (PRP-OMP; Pedvax-Hib, Merck Vaccine Division) was administered at ages 2 and 4 months, a dose at age 6 months is not necessary.

[i]HepB-3 should be administered at least 8 weeks after HepB-2 and at least 16 weeks after HepB-1 and should not be administered before age 24 weeks.

[j]Herpes zoster vaccine is recommended as a single dose for persons aged ≥60 years.

[k]Bivalent HPV vaccine is approved for females age 9–25 years. Quadrivalent HPV vaccine is approved for males and females age 9–26 years. Nine-valent HPV vaccine is approved for females age 9–26 years, and males age 9–15 years.

[l]The minimum age for HPV-3 is based on the baseline minimum age for the first dose (i.e., 9 years) and the minimum interval of 24 weeks between the first and third dose. Dose 3 need not be repeated if it is administered at least 16 weeks after the first dose and the intervals between dose 1 and dose 2, and dose 2 and dose 3, are maintained at 4 weeks and 12 weeks, respectively.

[m]A fourth dose is not needed if the third dose was administered at ≥4 years and at least 6 months after the previous dose.

[n]One dose of influenza vaccine per season is recommended for most persons. Please see influenza vaccine specific chapter to determine which children age <9 years should receive two doses in a single season.

[o]The minimum age for inactivated influenza vaccine varies by vaccine manufacturer. See package insert for vaccine-specific minimum ages.

[p]Combination MMRV vaccine can be used for children ages 12 months to 12 years.

[q]A second dose of PPSV 5 years after the first dose is recommended for persons age ≤65 years who are at highest risk for serious pneumococcal infection and for persons likely to have a rapid decline in pneumococcal antibody concentration. (Source: CDC. Prevention of pneumococcal disease: recommendations of the Advisory Committee on Immunization Practices [ACIP]. *MMWR Recomm Rep.* 1997;46[RR-8]:1–24).

[r]Revaccination with meningococcal conjugate vaccine is recommended for previously vaccinated persons who remain at high risk for meningococcal disease. (Source: CDC. Updated recommendations from the Advisory Committee on Immunization Practices (ACIP) for revaccination of persons at prolonged increased risk for meningococcal disease. *MMWR Morb Mortal Wkly Rep*. 2009;58:1042–1043).

[s]MenACWY-D (Menactra) can be given as young as 9 months of age for high-risk persons, MenACWY-CRM (Menveo) can be given as young as 2 months of age for high-risk persons. Hib-MenCY can be given as young as 6 weeks of age for high-risk persons. Hib-MenCY is a four-dose series at ages 2 months, 4 months, 6 months, and 12 to 18 months.

[t]The first dose of rotavirus must be administered at age 6 weeks through 14 weeks and 6 days. The vaccine series should not be started for infants age ≥15 weeks, 0 days. Rotavirus should not be administered to children older than 8 months, 0 days of age regardless of the number of doses received between 6 weeks and 8 months, 0 days of age.

[u]If two doses of Rotarix (GlaxoSmithKline) are administered as age appropriate, a third dose is not necessary.

[v]Only one dose of Tdap is recommended for nonpregnant persons. Subsequent doses should be given as Td. For management of a tetanus-prone wound in persons who have received a primary series of tetanus-toxoid–containing vaccine, the minimum interval after a previous dose of any tetanus-containing vaccine is 5 years.

[w]The minimum interval from varicella-1 to varicella-2 for persons beginning the series at age ≥13 years is 4 weeks. For persons younger than 13 years, a special grace period of 2 months can be applied to the minimum interval, so the minimum interval would also be 4 weeks for this age cohort. However, an additional 4 days should not be added to this grace period for this age cohort.

[x]A special grace period of 3 months, based on expert opinion, can be applied to the minimum age of 15 months when evaluating records retrospectively, which results in an acceptable minimum age of 13 months. An additional 4 days should not be added on to this grace period.

schedules has not been evaluated in clinical trials, immune responses with accelerated intervals are likely to induce adequate protection.[5] Table 9.2 lists accelerated, or minimum, intervals and ages that can be used for scheduling catchup vaccinations.

Administration of doses of a vaccine at intervals less than the minimum intervals or earlier than the minimum age (see Table 9.2) may result in a reduced immune response with diminished vaccine efficacy and should be avoided.[2,5] Multiple doses of some live vaccines are recommended to stimulate an immune response to different types of the same virus, such as poliovirus types 1, 2, and 3, or to induce immunity in persons who failed to mount an immune response to an earlier dose of vaccine, such as measles.[53,67] These multiple doses constitute a primary vaccination series and are not booster doses.

Spacing of Different Vaccines

Table 9.2 includes guidelines for spacing administration of different vaccines.[5] Inactivated vaccines are not known

to interfere with the immune response to other inactivated vaccines or to live vaccines (see below for exceptions). An inactivated vaccine can be administered simultaneously or at any time before or after a different inactivated vaccine or live vaccine.

The possibility that two doses of the same or different live virus vaccines administered within too short an interval may inhibit the immunologic response to the second dose is based on evidence from animal and human studies. Petralli and colleagues[68,69] reported that the immune response to smallpox vaccination was affected by prior administration of live attenuated measles vaccine. Interferon produced in response to the initial dose of measles virus vaccine has been postulated to inhibit replication of vaccinia virus in the subsequent vaccine dose. In a study in two U.S. health maintenance organizations, persons who received varicella vaccine less than 30 days after MMR vaccination had an increased risk of varicella vaccine failure (i.e., varicella disease in a vaccinated person) of 2.5-fold compared with persons who received varicella vaccine before or 30 days or more after MMR.[70] In contrast, Stefano and colleagues[71] determined that the response to yellow fever vaccine is not affected by monovalent measles vaccine administered 1 to 27 days earlier. In general, live virus vaccines administered orally do not interfere with live virus vaccines administered parenterally or orally, although a reduction in the seroconversion rate following the first dose of monovalent rotavirus vaccine has been reported when this dose is administered concurrently with OPV.[72] The effect of nasally administered vaccine on the response to other live vaccines not administered at the same visit is not known.

To minimize the potential risk for interference, parenterally or nasally administered live virus vaccines not administered on the same day should be administered 4 weeks or more apart whenever possible. If parenterally or nasally administered live virus vaccines are separated by less than 4 weeks, the live virus vaccine given second should be readministered 4 or more weeks after the previous dose.[5] Yellow fever vaccine can be administered at any time after single-antigen measles vaccine (single-antigen measles vaccine is not currently available in the United States). Oral and parenteral live virus vaccines can be administered simultaneously or at any interval before or after each other, if indicated.[5]

SIMULTANEOUS ADMINISTRATION OF DIFFERENT VACCINES

Simultaneous administration of all indicated vaccines is an essential component of childhood vaccination programs.[2,5] Simultaneous administration of different vaccines is particularly important when return of the recipient for further vaccination is uncertain, imminent exposure to several vaccine-preventable diseases is expected, or a vaccinee is preparing for international travel on short notice. The Strategic Advisory Group of Experts (SAGE) of the World Health Organization supports multiple vaccine injections in a single visit, and encourages this practice based on the benefits they confer.[73]

Unless specifically licensed for injection in the same syringe, different vaccines administered simultaneously should be injected separately and at different anatomic sites. If both upper and lower limbs must be used for simultaneous administration of different vaccines, the anterolateral thigh is often chosen for intramuscular injections and the triceps region for subcutaneous injections. If more than one injection must be administered in a single limb of an infant or young child, the thigh usually is preferred because of its large muscle mass. The distance separating two injections in the same limb should be sufficient (e.g., 1 inch or more) to minimize the chance of overlapping local reactions.[5,13,14] In general, different vaccines, including live virus products, can be administered simultaneously without reducing their safety and effectiveness (Table 9.3).[74] Studies of cortisol concentration and behavioral responses to vaccination indicate that responses are similar in infants who receive two injections during one visit and infants who receive a single injection, suggesting that a second injection does not increase stress.[76,77]

TABLE 9.3 Guidelines for Spacing of Live and Inactivated Antigens

Antigen Combination	Recommended Minimum Interval Between Doses
Two or more inactivated[a,b]	Can be administered simultaneously or at any interval between doses
Inactivated and live	Can be administered simultaneously or at any interval between doses
Two or more live intranasal or injectable[c]	4-wk minimum interval if not administered simultaneously

[a]The American Academy of Pediatrics suggests a 1-month interval between tetanus toxoid, reduced diphtheria toxoid, and reduced acellular pertussis vaccine and tetravalent meningococcal conjugate vaccine if these vaccines are not administered on the same day.[75]
[b]In persons with functional or anatomic asplenia, MenACWY-D (Menactra) and PCV13 should not be administered simultaneously and should be spaced by 4 weeks. Likewise, for persons with immunosuppressive high-risk conditions for invasive pneumococcal disease, if both PCV13 and PPSV23 are indicated, PCV13 should be administered first and PPSV23 should be administered 8 weeks later. For persons with immunocompetent high-risk conditions for invasive pneumococcal disease and healthy persons aged ≥65 years indicated for both PCV13 and PPSV23, PCV13 should be administered first, and PPSV23 should be administered 1 year later.
[c]Live oral vaccines (e.g., Ty21a typhoid vaccine and rotavirus vaccine) can be administered on the same day or at any interval before or after inactivated or live injectable vaccines.

Increased severity or incidence of adverse reactions has not been observed after simultaneous administration of the most widely used vaccines.[5] Similarly, simultaneous administration of vaccines generally does not cause immunologic interference, with two exceptions. Pneumococcal conjugate vaccine and Menactra brand meningococcal conjugate vaccine should not be administered simultaneously in children with functional or anatomic asplenia, because Menactra interferes with the immune response to the seven-valent pneumococcal conjugate vaccine (and presumably PCV13 as well). Children with functional or anatomic asplenia are at high risk for pneumococcal infection. All doses of pneumococcal conjugate vaccine should be administered first and then a dose of Menactra should be administered 4 weeks after the last dose of pneumococcal conjugate vaccine. Interference is not known to occur with other brands of meningococcal conjugate vaccine and pneumococcal conjugate vaccine. Pneumococcal polysaccharide vaccine may interfere with the immune response to pneumococcal conjugate vaccines. If both doses are indicated, they should not be administered simultaneously. For persons with immunosuppressive high-risk conditions indicated for both PCV13 and PPSV23, PCV13 should be administered first, with PPSV23 administered 8 weeks later. For persons with immunocompetent high-risk conditions for invasive pneumococcal disease or for healthy persons aged 65 years or older indicated for both PCV13 and PPSV23, PCV13 should be administered first, with PPSV23 administered 1 year later. Pneumococcal conjugate vaccine should be administered first, followed by pneumococcal polysaccharide vaccine at least 8 weeks later.[74,77,78]

INTERFERENCE BY IMMUNOGLOBULINS

Passively acquired antibodies can interfere with the immune response to certain vaccines, both live and inactivated, and to toxoids. The result can be the absence of seroconversion or a blunting of the immune response with lower final antibody concentrations in the vaccinee. This potential for interference underlies the recommendation that hepatitis B vaccine and hepatitis B immunoglobulin be administered at separate sites when administered simultaneously. Passively acquired antibody does not affect the immune response to all vaccines.

Interference With Live Virus Vaccines

To elicit an adequate immune response, live vaccine virus must replicate in the recipient. The probable mechanism by which passively acquired immunoglobulin blunts the immune response is neutralization of vaccine virus, resulting in inhibition of viral replication and insufficient antigenic mass.[79] For example, persisting transplacentally acquired maternal measles antibodies inhibit the response to live measles vaccine in infants for as long as 12 months and perhaps longer.[80,81] The age to which inhibition persists has been correlated with concentrations of maternal or cord blood antibodies.[82–84] Rubella vaccine virus may be less susceptible than measles vaccine virus to these transplacentally acquired maternal antibodies.[83,85] The effect of blood and immunoglobulin preparations on the response to mumps and varicella vaccines is unknown, but commercial immunoglobulin preparations contain antibodies to these viruses. The effect of blood and immunoglobulin preparations on the response to live rotavirus and influenza vaccines is unknown.

Intramuscular or intravenous administration of immunoglobulin–containing preparations (e.g., immunoglobulin, hyperimmunoglobulins, intravenous immunoglobulin, and blood) before or simultaneously with certain vaccines also can affect the immune response to live virus vaccines. When partially attenuated Edmonston B measles vaccine, which is no longer available in the United States, was administered concurrently with measles immunoglobulin in an effort to reduce the incidence of adverse events associated with this vaccine, the rate of seroconversion was not affected but the geometric mean titer of serum measles antibody was diminished.[86] In a study of an investigational bacterial polysaccharide immunoglobulin (BPIG), children had a reduced immune response to live measles vaccine for as long as 5 months after receipt of BPIG.[87] The measles antibody seroconversion rate and geometric mean titer were lower among children who received BPIG compared with children who received placebo. Blunting of the immune response to live rubella vaccine also occurred after receipt of BPIG but was less marked and of shorter duration.

Although passively acquired antibodies can interfere with the response to rubella vaccine, the low dose of anti-Rh(D) globulin administered to postpartum women has not been demonstrated to inhibit the immune response to RA27/3 strain rubella vaccine.[88] Parenterally administered immunoglobulin preparations also do not seem to adversely affect the immune response to yellow fever vaccine.[89] Although high concentrations of passively acquired antibodies may reduce the serum antibody response to live poliovirus vaccine, they have little effect on replication of vaccine virus and development of gastrointestinal tract immunity.[55,89–91] Data are insufficient to determine the extent to which passively acquired antibodies interfere with the immune response to other live viral or bacterial vaccines, such as varicella, mumps, LAIV, zoster, and typhoid (Ty21a strain). A humanized mouse monoclonal antibody product (palivizumab) is available for prevention of respiratory syncytial virus infection among infants and young children. This product contains only antibody to respiratory syncytial virus; hence, it will not interfere with immune response to live vaccines.[92]

Interference With Inactivated and Component Vaccines

Interference with current inactivated and component vaccines is less marked than with live vaccines and requires exposure to large doses of passively acquired antibodies.[93] The mechanism by which passively acquired antibodies interfere with the immunologic response to inactivated and toxoid vaccines is not clear. Moderate doses of parenterally administered immunoglobulins have not inhibited development of a protective immune response to DTP, tetanus toxoid, and Hib conjugate vaccines.[94,95] Although the concurrent administration of inactivated hepatitis A vaccine and immunoglobulin can result in lower serum antibody concentrations than if vaccine alone is administered, seroconversion rates have not been diminished.[96,97] Infants with high concentrations of passively acquired maternal antibody to hepatitis A virus had lower serum antibody concentrations after receipt of hepatitis A vaccine but had seroconversion rates similar to those of vaccinated infants without maternal antibodies.[98] Similarly, seroconversion rates to inactivated polio vaccine given on a 2-, 4-, and 6-month schedule were lower among infants who had high maternal antibody levels for all three poliovirus types.[99]

RECOMMENDATIONS FOR SPACING ADMINISTRATION OF VACCINES AND IMMUNOGLOBULINS

Interference of immunoglobulins with the immune response to vaccines is dose-related and more likely to occur and to persist for a longer period after receipt of larger doses of immunoglobulins.[87,100] The recommended interval between administration of immunoglobulin preparations and vaccines is based on whether evidence suggests interference between immunoglobulin and the vaccine, the dose of the immunoglobulin administered, and the expected half-life of immunoglobulin G. Tables 9.4 and 9.5 list the recommended intervals between administration of immunoglobulin preparations and various live and killed vaccines.

In the United States, inactivated and component (subunit) vaccines may be administered simultaneously with or at any time before or after receipt of an immunoglobulin preparation.[2,5] The vaccine and immunoglobulin preparation should be administered at different sites, and the standard recommended doses of the corresponding vaccines should be given. Supplemental doses are not indicated.

Recommendations for administration of live virus vaccines vary on the basis of the aforementioned considerations. After receipt of an immunoglobulin preparation or other blood product, measles vaccine should be deferred during the intervals listed in Table 9.5.[5,91,101] Human blood and immunoglobulin preparations also contain rubella, mumps, and varicella antibodies. High doses of passively acquired antibodies can inhibit the immune response to live rubella vaccine for as long as 3 months.[87,102] The effect of immunoglobulin preparations on the response to live mumps and live varicella vaccines has not been defined. To reduce the possibility of interference, postponement of administration of rubella,

TABLE 9.4 Guidelines for Administering Antibody-Containing Products[a] and Vaccines

Simultaneous Administration (During Same Clinic Day)	
Products	**Recommended Minimum Interval Between Doses**
Antibody-containing products and inactivated antigen[b]	Can be administered simultaneously at different anatomic sites or at any interval between doses
Antibody-containing products and live antigen	Should not be administered simultaneously.[c] If simultaneous administration of measles-containing vaccine or varicella vaccine is unavoidable, administer at different sites and revaccinate or test for seroconversion after the recommended interval (see Table 9.5)

Nonsimultaneous Administration Products		
Administer First	**Administer Second**	**Recommended Minimum Interval Between Doses**
Antibody-containing products	Inactivated antigen	No interval necessary
Inactivated antigen	Antibody-containing products	No interval necessary
Antibody-containing products	Measles, mumps, rubella vaccine, varicella vaccine, and combined measles, mumps, rubella, varicella vaccine	Depends on dose of antibody received[c,d]
Measles, mumps, rubella, varicella vaccine, and combined measles, mumps, rubella, varicella vaccine antigens	Antibody-containing products	2 wk[c]

[a]Blood products containing substantial amounts of immunoglobulin include intramuscular and intravenous immunoglobulin, specific hyperimmunoglobulin (e.g., hepatitis B immunoglobulin, tetanus immunoglobulin, varicella zoster immunoglobulin, and rabies immunoglobulin), whole blood, packed red blood cells, plasma, and platelet products. Pneumococcal polysaccharide and pneumococcal conjugate vaccines should be separated by at least 8 weeks in high-risk immunosuppressed persons and by 1 year in healthy or immunocompetent high-risk persons. In persons with asplenia, pneumococcal conjugate vaccine and Menactra brand meningococcal conjugate vaccine should not be given simultaneously. The series of PCV13 should be administered first, with Menactra administered 4 weeks after the final dose of PCV13.
[b]Hepatitis B immunoglobulin (HBIg) and hepatitis B vaccine need to be administered at separate sites.
[c]Yellow fever vaccine, rotavirus vaccine, oral Ty21a typhoid vaccine, live attenuated influenza vaccine, and zoster vaccine are exceptions to these recommendations. These live attenuated vaccines can be administered at any time before or after or simultaneously with an antibody-containing product.
[d]The duration of interference of antibody-containing products with the immune response to the measles component of measles-containing vaccine, and possibly varicella vaccine, is dose-related (see Table 9.5).

mumps, and varicella vaccines for the intervals indicated in Table 9.5 is prudent.[5]

Immunoglobulin preparations administered too soon after vaccination with MMR or varicella vaccines can interfere with the immune response. If administration of an immunoglobulin preparation becomes necessary less than 2 weeks after receipt of MMR, its component vaccines, or varicella vaccine, readministration of the vaccine is recommended after the appropriate interval listed in Tables 9.4 and 9.5, unless serologic testing indicates an antibody response.[5,53] For example, if whole blood is administered less than 14 days after receipt of varicella vaccine, the vaccine should be readministered at least 6 months after the whole blood unless serologic testing indicates an adequate immune response to the initial dose of varicella vaccine.

Although data are not available on the effect of passive antibody on the response to rotavirus vaccine, the ACIP recommends that live rotavirus vaccine may be administered at any time before, concurrent with, or after administration of any blood product, including antibody-containing products.[27] Because the immune responses to OPV, zoster, and yellow fever vaccines have not been demonstrated to be adversely affected by immunoglobulin preparations, these vaccines can be administered at any time in relation to receipt of immunoglobulin preparations.[89] Live oral typhoid (Ty21a) vaccine also is recommended for administration irrespective of the receipt of immunoglobulin preparations.[5,103] LAIV can be administered at any time before or after receipt of an antibody-containing blood product.[5]

INTERCHANGEABILITY OF VACCINES FROM DIFFERENT MANUFACTURERS

Combination and monovalent vaccines against the same diseases with similar antigens and produced by the same manufacturer are considered interchangeable in most situations.[2,5] However, supporting data on the safety, immunogenicity, and efficacy of using comparable vaccines from different manufacturers for different doses of a vaccination series frequently are limited or unavailable. When the same vaccine cannot be used to complete an immunization series, similar vaccines produced by different manufacturers or produced by the same manufacturer in different countries generally have been considered acceptable to complete the immunization series provided each vaccine is given according to licensed recommendations.

Some diseases have serologic correlates of immunity that can be used to evaluate vaccine interchangeability. For example, in studies in which one or more doses of hepatitis B vaccine produced by one manufacturer were followed by doses from another manufacturer, the immune response was comparable to that resulting from use of a single vaccine type.[104–106] Whereas Hib conjugate vaccines differ in antigen composition, interchangeability of different products has been validated on the basis of the accepted serologic correlate of immunity against Hib invasive disease.[107–109]

Determination of vaccine interchangeability is more difficult for diseases without serologic correlates of immunity. When feasible, acellular pertussis vaccine from the same

TABLE 9.5 Recommended Intervals Between Administration of Antibody-Containing Products and Measles- or Varicella-Containing Vaccine, By-product and Indication for Vaccination

Product/Indication	Dose (Including Milligrams of Immunoglobulin G/kg of Body Weight) and Route[a]	Recommended Interval Before Measles- or Varicella-Containing Vaccine[b] Administration (Mo)
Blood transfusion		
Red blood cells (RBCs), washed	10 mL/kg (negligible) IV	None
RBCs, adenine-saline added	10 mL/kg (10 mg IgG/kg) IV	3
Packed RBCs (hematocrit 65%)[c]	10 mL/kg (60 mg IgG/kg) IV	6
Whole blood (hematocrit 35%–50%)[c]	10 mL/kg (80–100 mg IgG/kg) IV	6
Plasma/platelet products	10 mL/kg (160 mg IgG/kg) IV	7
Botulinum immunoglobulin intravenous (human)	1.5 mL/kg (75 mg IgG/kg) IV	6
Cytomegalovirus intravenous immunoglobulin (IgIV)	150 mg/kg maximum	6
Hepatitis A Ig		
Contact prophylaxis	0.02 mL/kg (3.3 mg IgG/kg) IM	3
International travel, <3 mo stay	0.02 mL/kg (3.3 mg IgG/kg) IM	3
International travel, ≥3 mo stay	0.06 mL/kg (10 mg IgG/kg) IM	3
Hepatitis B Ig	0.06 mL/kg (10 mg IgG/kg) IM	3
IGIV		
Replacement therapy for immune deficiencies[d]	300–400 mg/kg IV[d]	8
Immune thrombocytopenic purpura treatment	400 mg/kg IV	8
Postexposure varicella prophylaxis[e]	400 mg/kg IV	8
Postexposure measles prophylaxis for immunocompromised contacts	400 mg/kg IV	8
Immune thrombocytopenic purpura treatment	1000 mg/kg IV	10
Kawasaki disease	2 g/kg IV	11
Measles prophylaxis Ig, standard (i.e., nonimmunocompromised contact)	0.50 mL/kg (80 mg IgG/kg) IM	6
Monoclonal antibody to respiratory syncytial virus F protein (e.g., Synagis [MedImmune])[f]	15 mg/kg IM	None
Rabies Ig	20 IU/kg (22 mg IgG/kg) IM	4
Tetanus Ig	250 U (10 mg IgG/kg) IM	3
Varicella Ig (VariZIG)	125 U/10 kg (60–200 mg IgG/kg) IM, maximum 625 U	5

[a]This table is not intended for determining the correct indications and dosages for using antibody-containing products. Unvaccinated persons might not be protected fully against measles during the entire recommended interval, and additional doses of Ig or measles vaccine might be indicated after measles exposure. Concentrations of measles antibody in an Ig preparation can vary by manufacturer's lot. Rates of antibody clearance after receipt of an Ig preparation also might vary. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80 mg IgG/kg.
[b]Does not include zoster vaccine. Zoster vaccine may be given with antibody-containing blood products.
[c]Assumes a serum IgG concentration of 16 mg/mL.
[d]Measles vaccination is recommended for children with mild immunosuppression from HIV infection, and varicella vaccination may be considered for children with mild immunosuppression, but both are contraindicated for persons with severe immunosuppression from HIV or any other immunosuppressive disorder.
[e]Licensed VariZIG, similar to licensed varicella-zoster immunoglobulin (VZIG), is a purified human Ig preparation made from plasma containing high levels of antivaricella antibodies (IgG).
[f]Contains antibody only to respiratory syncytial virus.

manufacturer is preferred for the entire primary vaccination series.[58] In the absence of a correlate for *Bordetella pertussis* infection, interchangeability of acellular pertussis vaccines is difficult to assess. Available data from one study indicate that, for the first three doses of the DTaP series, one or two doses of Tripedia (manufactured by Aventis Pasteur) followed by Infanrix (manufactured by GlaxoSmithKline) for the remaining doses(s) is comparable to three doses of Tripedia with regard to immunogenicity, as measured by antibodies to diphtheria, tetanus, and pertussis toxoids and filamentous hemagglutinin.[110] However, in the absence of a clear serologic correlate of protection for pertussis, the relevance of these immunogenicity data for protection against pertussis is unknown. Any DTaP vaccine can be used to complete the DTaP series if the

product(s) administered for earlier doses are unknown or unavailable.[5,58,111]

HYPERSENSITIVITY TO VACCINE COMPONENTS

Types of Reactions

Hypersensitivity reactions after vaccination can be local or systemic and can vary in severity from mild discomfort at the site of vaccination to severe anaphylaxis. Onset can be immediate or delayed. Serious allergic reactions are rare. Whether a specific hypersensitivity reaction is caused by a vaccine component or an unrelated environmental allergen can be difficult to determine. However, symptoms occurring immediately after vaccination that are suggestive of an anaphylactic reaction generally contraindicate further administration of that vaccine to the recipient.[2,5]

Urticaria and anaphylactic reactions have been reported after administration of DTP, DT (diphtheria and tetanus toxoids–pediatric), Td (diphtheria and tetanus toxoids–adult), and tetanus toxoid.[112–114] A severe allergic reaction (e.g., anaphylaxis) to a previous dose of vaccine or to a vaccine component is a contraindication to the respective vaccine. Although immunoglobulin E–type antibodies to tetanus and diphtheria antigens have been identified in some patients with these symptoms, transient urticaria-like rashes are not a contraindication to subsequent vaccination because they are unlikely to be anaphylactic unless they appear within minutes after vaccination.[114–116] A serum sickness–type reaction caused by circulating complexes of vaccine antigen and previously acquired antibody is the probable cause of these reactions, and subsequent vaccination at a 10-year interval is unlikely to result in the necessary ratio of antigen-to-antibody concentration to form immune complexes.[114,117]

Tetanus toxoid is contraindicated in persons who experienced an immediate anaphylactic reaction to tetanus toxoid–containing vaccine, unless the person can be desensitized to the toxoid.[2] Because of the importance of tetanus immunization and the uncertainty about which vaccine component might be the cause of the reaction, the patient may be referred to an allergist for evaluation and possible desensitization.[114,118,119] On occasion, a history of an allergic reaction to tetanus vaccine may refer to a reaction to tetanus antitoxin of equine origin given for tetanus prophylaxis before human-derived tetanus immunoglobulin became available in the 1960s. Before use of tetanus toxoid is discontinued because of an alleged episode of anaphylaxis, skin testing and possible desensitization should be considered.[118,120]

Urticaria also has been reported following pneumococcal conjugate, MMR, varicella, and smallpox vaccines.[121–124]

Immediate or delayed onset of generalized urticaria and angioedema that can progress to respiratory distress and hypotension has been reported after receipt of inactivated mouse brain-derived Japanese encephalitis vaccine.[125–127] The pathogenesis of these reactions is not known. Mouse brain–derived Japanese encephalitis vaccine is no longer available in the United States. A vero cell–derived Japanese encephalitis vaccine is available in the United States for people 2 years of age and older.[128,129]

VACCINE COMPONENTS CAUSING HYPERSENSITIVITY

Proteins

Egg protein is a constituent of vaccines prepared with use of embryonated chicken eggs, such as influenza and yellow fever vaccines. On rare occasions, these vaccines can induce anaphylaxis or other immediate hypersensitivity reactions, and these reactions are sometimes attributed to egg protein antigen.[2,5,130–132] As a result, yellow fever vaccine generally is contraindicated in persons with a history of anaphylactic reactions to egg ingestion unless desensitization has been successfully completed. For example, persons needing yellow fever vaccine who have a history of systemic anaphylaxis-like symptoms after egg ingestion can be skin tested with yellow fever vaccine before vaccination and desensitized if necessary.[130]

While a history of anaphylaxis following influenza vaccine is a contraindication to further doses of influenza vaccine, evidence does not support allergy to egg as a cause of anaphylaxis following influenza vaccine. A history of allergy to eggs is not a contraindication to vaccination with influenza vaccine; however, influenza vaccination should only occur under the supervision of a provider who is able to recognize and manage severe allergic conditions. Measles and mumps vaccines are produced in chick embryo fibroblast cell culture. Persons with hypersensitivity to eggs are at low risk for anaphylactic reactions to these vaccines, and skin testing with vaccine is not predictive of allergic reaction after immunization.[2,133–135] Neither skin testing nor administration of gradually increasing doses of vaccine is required when these vaccines are administered to persons who are allergic to eggs.[2,5,53,101,133]

Live virus vaccines, such as measles, mumps, rubella, yellow fever, and varicella, contain gelatin as a stabilizer. Persons with a history of allergy to gelatin have experienced, on rare occasions, an anaphylactic reaction after vaccination with such a vaccine.[121,124,134–136] Skin testing of persons with a history of systemic anaphylaxis-like symptoms after gelatin ingestion may be useful to identify persons at risk for severe hypersensitivity reactions to vaccination. A regimen for administering particular vaccines to persons with anaphylaxis to components contained in those vaccines has been published.[137] Because gelatin used as a vaccine stabilizer may be of porcine origin, whereas ingested food gelatin may be of bovine origin, absence of a history of allergy to gelatin-containing foods does not eliminate the possibility of a gelatin-mediated reaction to vaccine.

Approximately 6% of persons who receive a booster dose of human diploid rabies vaccine have a serum sickness–type illness.[138,139] This reaction is thought to be caused by sensitization to human albumin that has been altered chemically by a virus-inactivating agent used in the production of the vaccine.[2,140]

Anaphylaxis following recombinant hepatitis B vaccines rarely has been reported and usually is attributed to hypersensitivity to residual yeast protein in the vaccine.[141]

Latex

Latex is liquid sap from the commercial rubber tree. Latex contains naturally occurring impurities (e.g., plant proteins and peptides), which are believed to be responsible for allergic reactions. Latex is processed to form natural rubber latex and dry natural rubber. Natural rubber latex and dry natural rubber might contain the same plant impurities as latex but in lesser amounts. Natural rubber latex is used to produce medical gloves, catheters, and other products, whereas dry natural rubber is used in syringe plungers, vial stoppers, and injection ports on intravascular tubing. Synthetic rubber and synthetic latex also are used in medical gloves, syringe plungers, and vial stoppers, but they do not contain natural rubber or natural latex or the impurities linked to allergic reactions.

The most common type of latex sensitivity is contact-type (type IV) allergy, usually as a result of prolonged contact with

natural rubber latex–containing gloves.[142] Although injection procedure–associated latex allergies among patients with diabetes mellitus have been described,[143–145] allergic reactions, including anaphylaxis, after vaccination procedures are rare. Only one report of an allergic reaction after administering hepatitis B vaccine in a patient with known severe allergy (anaphylaxis) to latex has been published.[146]

If a person reports a severe (anaphylactic) allergy to latex, vaccines supplied in vials or syringes that contain natural rubber should not be administered, unless the benefit of vaccination outweighs the risk of an allergic reaction to the vaccine. For latex allergies other than anaphylactic allergies, such as a history of contact allergy to latex gloves, vaccines supplied in vials or syringes that contain natural rubber latex or dry natural rubber can be administered.[5]

Antimicrobial Agents

Live virus vaccines may contain trace amounts of one or more antimicrobial agents, such as neomycin, streptomycin, and polymyxin B. Vaccine contents are listed in each manufacturer's product label for each vaccine. The most common allergic response to neomycin is a delayed-type (cell-mediated) local contact dermatitis consisting of an erythematous, pruritic papule that occurs 48 to 96 hours after vaccine administration.[2,5,147] Such delayed-type reactions are not contraindications for vaccination.[2,5,147,148] However, persons who have experienced an anaphylactic reaction to neomycin or to another vaccine constituent should not receive vaccines containing that antimicrobial agent.[2,5,149,150] No vaccines licensed in the United States contain penicillin or penicillin derivatives.

Thimerosal

Thimerosal is an organic mercurial compound in use since the 1930s and added to certain immunobiologic products as a preservative. A joint statement issued by the U.S. Public Health Service and the AAP in 1999[151] established the goal of removing thimerosal as soon as possible from vaccines routinely recommended for infants. Although no evidence exists of any harm caused by low concentrations of thimerosal in vaccines and the risk was only theoretical,[152] this goal was established as a precautionary measure.

Since mid-2001, vaccines produced in the United States that are recommended routinely for infants younger than 6 months of age have been manufactured without thimerosal as a preservative and contain no thimerosal or only trace amounts. Thimerosal as a preservative is present in certain other vaccines. Examples are tetanus toxoid, Td, DT, certain formulations of influenza vaccine, and meningococcal polysaccharide vaccine in multidose vials.[153] Formulations of influenza vaccine with a reduced concentration of thimerosal or no thimerosal as a preservative are available in the United States.[153]

Receiving thimerosal-containing vaccines has been postulated to lead to induction of allergy in some persons.[154,155] However, there is limited scientific evidence for this assertion. Hypersensitivity to thimerosal usually consists of local delayed-type hypersensitivity reactions.[156–158] Thimerosal elicits positive delayed-type hypersensitivity patch tests in 1% to 18% of persons tested, but these tests have limited or no clinical relevance.[159,160] Most patients do not experience reactions to thimerosal administered as a component of vaccines, even when patch or intradermal tests for thimerosal indicate hypersensitivity.[156,160] A localized or delayed-type hypersensitivity reaction to thimerosal is not a contraindication to receipt of a vaccine that contains thimerosal.[2,5]

MANAGEMENT OF ACUTE VACCINE ADVERSE REACTIONS

Although rare after vaccination, the immediate onset and life-threatening nature of an anaphylactic reaction require that personnel and facilities providing vaccination be capable of providing initial care for suspected anaphylaxis. Epinephrine and equipment for maintaining an airway should be available for immediate use.

Anaphylaxis usually begins within several minutes of administration of vaccine. Rapid recognition and initiation of treatment are required to prevent possible progression to cardiovascular collapse. If flushing, facial edema, urticaria, itching, swelling of the mouth or throat, wheezing, difficulty breathing, or other signs of anaphylaxis occur, the patient should be placed in a recumbent position with the legs elevated. It is important to note that urticaria might not be present in all cases of anaphylaxis. Aqueous epinephrine (1 : 1000) should be administered intramuscularly and can be repeated within 5 to 15 minutes.[161] A dose of diphenhydramine hydrochloride may shorten the reaction, but it will have little immediate effect. Maintenance of an airway and oxygen administration may be necessary. Arrangements should be made for immediate transfer to an emergency facility for further evaluation and treatment. All patients should be observed for 4 to 24 hours after onset of symptoms.[161]

Syncope (vasovagal or vasodepressor reaction) can occur after vaccination and is most common among adolescents and young adults. In 2005, the Vaccine Adverse Event Reporting System (VAERS) detected a trend of increasing syncope reports that coincided with licensure of three vaccines for adolescents: HPV, quadrivalent meningococcal vaccine (MCV4), and Tdap.[162] Of particular concern among adolescents has been the risk for serious secondary injuries, including skull fracture and cerebral hemorrhage after a fall and subsequent head injury. Of 463 VAERS reports of syncope between January 1, 2005 and July 31, 2007, 41 listed syncope with secondary injury with information on the timing after vaccination, and most of these syncope reports (76%) occurred among adolescents. Among all age groups, 80% of reported syncope episodes occur within 15 minutes of vaccine administration (additional information is available at http://www.cdc.gov/concerns/fainting.html). Providers should take appropriate measures to prevent injuries if a patient becomes weak or dizzy or loses consciousness. Adolescents and adults should be seated or lying down during vaccination. Vaccine providers, particularly when vaccinating adolescents, should consider observing patients (with patients seated or lying down) for 15 minutes after vaccination to decrease the risk for injury should they faint.[162] If syncope develops, patients should be observed until the symptoms resolve.

SPECIAL CONSIDERATIONS

Vaccination of Preterm Infants

The immune response to vaccination is a function of postnatal rather than gestational age.[163–165] Transplacentally acquired maternal antibody is present in lower concentrations and, thus, persists for a shorter interval in preterm infants than in gestationally mature infants.[164,166–168] Because preterm infants have less transplacentally acquired maternal antibody, inhibition of the immune response in preterm infants may be less than that in full-term infants.[164,169]

In most cases, infants born prematurely, regardless of birth weight, should be vaccinated at the same chronological age and according to the same schedule and precautions as full-term infants and children.[5] Birth weight and size are not factors in deciding whether to postpone routine vaccination

of a clinically stable preterm infant,[170–174] except for hepatitis B vaccine. The full recommended dose of each vaccine should be used. Divided or reduced doses are not recommended.[175]

Decreased seroconversion rates might occur among certain preterm infants with birth weights of less than 2000 g after administration of hepatitis B vaccine at birth.[176] However, by chronological age 1 month, all preterm infants, regardless of initial birth weight or gestational age, are likely to respond as adequately as older and larger infants.[177–180] Infants weighing less than 2000 g born to hepatitis B surface antigen (HBsAg)-negative mothers should receive the first dose of the hepatitis B vaccine series at chronological age 1 month or hospital discharge, if hospital discharge occurs when the infant is younger than 1 month of age. Low-birth-weight infants born to HBsAg-positive mothers should receive hepatitis B vaccine within 12 hours after birth. The initial vaccine dose should not be counted toward completion of the hepatitis B series, and three additional doses of hepatitis B vaccine should be administered, beginning when the infant is 1 to 2 months of age. For mothers with unknown HBsAg status, hepatitis B vaccine is recommended within 12 hours of birth, regardless of low-birth-weight status.

In addition to hepatitis B vaccines, hepatitis B immunoglobulin (HBIG) is recommended for infants whose mothers are HBsAg-positive or unknown. If the mother is HBsAg-positive, HBIG should be given within 12 hours of birth. If the mother is HBsAg-unknown, providers should first attempt to determine the mother's status. However, if the infant's birth weight is less than 2000 g, HBIG should be given within 12 hours of birth. If the infant's birth weight is 2000 g or greater, providers need to continue determining the mothers' status but should administer a dose of HBIG as soon as possible but before 7 days passes unless the mother is found to be HBsAg-negative.

Several studies suggest that the incidence of adverse events after vaccination of preterm infants is the same as or lower than that of full-term infants vaccinated at the same chronological age.[168,181,182] A temporal association between receipt of DTP and HibTITER Hib vaccine and a transient increase or recurrence of apnea in premature infants has been reported, although the significance of this finding is unclear.[183] Neither of these vaccines is currently available in the United States.

A preterm infant who is still hospitalized at 2 months of age can receive the vaccines routinely scheduled at that age. However, in countries in which OPV is used, IPV may be considered for hospitalized infants. Because poliovirus vaccine strains are excreted after receipt of OPV, IPV will decrease the risk of transmission of vaccine viruses in the hospital.[67,184] ACIP supports rotavirus vaccination of preterm infants according to the same schedule and precautions as full-term infants and under the following conditions: the infant's chronological age meets the age requirements for rotavirus vaccine (e.g., 6 weeks through 14 weeks and 6 days of age for dose 1), the infant is clinically stable, and the vaccine is administered at the time of discharge from the neonatal intensive care unit (NICU) or nursery or after discharge from the NICU or nursery. Although the lower level of maternal antibody to rotavirus in very preterm infants theoretically could increase the risk for adverse reactions from rotavirus vaccine, ACIP believes the benefits of vaccinating an infant when age-eligible, clinically stable, and no longer in the hospital outweigh the theoretic risks.[27]

BREASTFEEDING AND IMMUNIZATION

Neither inactivated nor live virus vaccines administered to a lactating mother or infant who is breastfeeding have adverse consequences.[2,5] Because inactivated and component vaccines do not multiply in the body, they pose no special risk for lactating women or their infants. Lactating women also may safely receive live virus vaccines, such as MMR, LAIV, OPV, and varicella without interruption of their breastfeeding schedule.[5,53,184,185] Although vaccines that contain attenuated live viruses or bacteria replicate in the vaccine recipient, most live vaccine strains are not known to be secreted in human milk. An exception is rubella vaccine virus, which has been detected in human milk and recovered from the nasopharynx and throat of some breastfed infants after maternal immunization.[186,187] In one study, transient seroconversion to rubella virus without evidence of clinical disease was noted in 25% of the breastfed infants.[186] Breastfed infants who acquired rubella vaccine virus and rubella-specific antibodies from human milk have a normal immune response to rubella vaccine administered at 15 to 18 months of age.[188]

Breastfeeding of infants does not adversely affect their development of a protective immune response and is not a contraindication for any routinely administered vaccine.[2,5] Live oral rotavirus vaccines are less immunogenic and efficacious among children in developing countries compared with middle income and industrialized countries. Higher titers of rotavirus immunoglobulin A and neutralizing activity in human milk consumed by infants at the time of immunization has been proposed as a cause of this reduced immunogenicity.[189] However, a clinical trial found no difference in the proportion of infants who seroconverted to rotavirus vaccine between those who were either breastfeed or not breastfeeding during the 30 minutes prior to and after each vaccine dose was administered.[190] Yellow fever vaccine should be avoided in breastfeeding women. Two cases (one confirmed, one probable) of yellow fever vaccine–associated acute neurotropic disease (YEL-AND) have been detected in infants whose mothers were vaccinated but were not vaccinated themselves. In both infants, vaccine virus was recovered from the cerebrospinal fluid (CSF) of the infant, but the exact mode of transmission was not precisely determined because vaccine was not recovered from human milk. However, when nursing mothers cannot avoid or postpone travel to areas endemic for yellow fever in which risk of acquisition is high, they should be vaccinated.[191] Compared with infants who are formula fed, breastfed infants may have an enhanced immune response to certain oral and parenteral vaccines, such as conjugate Hib vaccine, OPV, and DT.[192–194] However, the significance of such an effect is unclear.

VACCINATION DURING PREGNANCY

Risk for a developing fetus from vaccination of the mother during pregnancy primarily is theoretical. No evidence exists of risk from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids.[195,196] Live vaccines pose a theoretical risk to the fetus. Benefits of vaccinating pregnant women usually outweigh potential risks when the likelihood of disease exposure is high, when infection would pose a risk to the mother or fetus, and when the vaccine is unlikely to cause harm.

Recommendations for vaccination during pregnancy can be found in the annual U.S. adult immunization schedule.[64] Pregnant women who are not immunized or only partially immunized against tetanus should complete the primary series.[197] The number of doses needed to complete the primary series should be administered. One of these doses should be Tdap. Tdap is optimally administered at 27 to 36 weeks' gestation. Women for whom the vaccine is indicated but who have not completed the recommended three-dose series during pregnancy should receive follow-up after delivery to ensure the series is completed. Use of pertussis vaccine in pregnant women may lead to transfer of higher levels of pertussis antibody across the placenta to the fetus and results in protection

from pertussis in the first few months of life when the disease is most severe.[198] Therefore, a dose of Tdap is recommended for pregnant women during every pregnancy, preferably during 27 to 36 weeks of gestation.[59]

Women in the second and third trimesters of pregnancy are at increased risk for hospitalization from influenza. Therefore, routine influenza vaccination is recommended for all women who will be pregnant (in any trimester) during influenza season, usually November through March in the United States.[28] Influenza vaccination of a pregnant woman also reduces the risk of medically-attended respiratory tract illness in the newborn.[199]

IPV can be administered to pregnant women who are at risk for exposure to wild-type poliovirus infection.[75,200] Pregnancy is not a contraindication to hepatitis B vaccine. Current vaccines contain noninfectious HBsAg and should cause no risk to the fetus.[201] Hepatitis A, pneumococcal polysaccharide, meningococcal conjugate, and meningococcal polysaccharide vaccines should be considered for women at increased risk for those infections.[202–206]

Pregnant women who must travel to areas where the risk for yellow fever is high should receive yellow fever vaccine because the limited theoretical risk from vaccination is substantially outweighed by the risk for yellow fever infection.[203,207] Pregnancy is a contraindication for smallpox (vaccinia), measles, mumps, rubella, and varicella-containing vaccines. Smallpox (vaccinia) vaccine is the only vaccine known to cause harm to a fetus when administered to a pregnant woman. In addition to the vaccinee herself, smallpox (vaccinia) vaccine should not be administered to a household contact of a pregnant woman. However, in a postevent setting, or smallpox emergency, pregnancy or having a household contact who is pregnant would not be considered contraindications, because of a different risk/benefit consideration. Although of theoretical concern, no cases of congenital rubella or varicella syndrome or abnormalities attributable to fetal infection have been observed among infants born to susceptible women who received rubella or varicella vaccines during pregnancy.[53,208] Because of the importance of protecting women of childbearing age against rubella and varicella, reasonable practices in any vaccination program include asking women if they are pregnant or might become pregnant in the next 4 weeks, not vaccinating women who state that they are pregnant, explaining the theoretical risk for the fetus if MMR or varicella vaccine were administered to a women who is pregnant, and counseling women who are vaccinated not to become pregnant during the 4 weeks after MMR or varicella vaccination.[53,208,209]

Routine pregnancy testing of women of childbearing age before administering a live virus vaccine is not recommended.[53] If vaccination of an unknowingly pregnant woman occurs or if she becomes pregnant within 4 weeks after MMR or varicella vaccination, she should be counseled about the theoretical basis of concern for the fetus; however, MMR or varicella vaccination during pregnancy should not be regarded as a reason to terminate pregnancy.[185,209]

All pregnant women should be evaluated for immunity to rubella and varicella and should be tested for the presence of HBsAg in every pregnancy.[53,185,201,210] Women susceptible to rubella and varicella should be vaccinated immediately after delivery or after the termination of the pregnancy. A woman found to be HBsAg-positive should be followed carefully to ensure that the infant receives HBIG and begins the hepatitis B vaccine series no later than 12 hours after birth and completes the recommended hepatitis B vaccine series on schedule.[201] No known risk exists for the fetus from passive immunization of pregnant women with immunoglobulin preparations.

VACCINATION OF HOUSEHOLD CONTACTS

Administration of live and inactivated vaccines to household members does not present a known hazard to pregnant women. Although transmission of varicella vaccine virus from a 12-month-old infant to his pregnant mother has been reported, no virus was detected in fetal tissue after an elective abortion.[211] Pregnancy of a household contact is not a contraindication to administration of varicella vaccine or any other vaccine in the childhood immunization schedule to a household member.[185,212]

VACCINES RECEIVED OUTSIDE THE UNITED STATES

The ability of a clinician to determine that a person is protected on the basis of country of origin and the person's records alone is limited. Vaccines administered outside the United States generally can be accepted as valid if the schedule was similar to that recommended in the United States (i.e., minimum ages and intervals; see Table 9.2). Only written documentation should be accepted as evidence of previous vaccination. Written records are more likely to predict protection if the vaccines, dates of administration, intervals between doses, and the person's age at the time of vaccination are comparable to U.S. recommendations.[5] Although vaccines with inadequate potency have been produced in other countries,[213,214] most vaccines used worldwide are produced with adequate quality control standards and are potent.

The number of American families adopting children from outside the United States has increased substantially in recent years.[215] Adopted children's birth countries often have immunization schedules that differ from the recommended childhood immunization schedule in the United States. Differences between schedules used in other countries include the vaccines administered, the recommended ages of administration, and the number and timing of doses (see Chapters 74 to 76). The ACIP has published guidelines for assessing and vaccinating international adoptees.[5] Children adopted in the United States from other countries should receive vaccines according to U.S.-recommended schedules.

Data are inconclusive regarding the extent to which an internationally adopted child's immunization record reflects the child's protection. A child's record might indicate administration of MMR vaccine when only single-antigen measles vaccine was administered. A study of children adopted from the People's Republic of China, Russia, and Eastern Europe determined that only 39% (range: 17%–88% by country) of children with documentation of more than three doses of DTP before adoption had protective serologic concentrations of diphtheria and tetanus antitoxin.[216] This finding raised questions about whether the vaccines received were potent or whether the immunization records purporting to show receipt of at least three doses were an accurate reflection of the true number of doses actually received. However, antibody testing was performed by a hemagglutination assay, which may underestimate protection and cannot directly be compared with antitoxin concentration measured by other tests.[217] A second study measured antibody to diphtheria and tetanus toxins among 51 children who had records of having received two or more doses of DTP. Most of the children were from Russia, Eastern Europe, and Asian countries, and 78% had received all vaccine doses in an orphanage; 94% had evidence of protection against diphtheria (enzyme immunoassay [EIA] >0.1 IU/mL). A total of 84% had protection against tetanus (EIA >0.5 IU/mL). Among children without protective tetanus antitoxin concentrations, all except one had records of three

or more doses of vaccine, and most nonprotective concentrations were categorized as indeterminate (EIA 0.05–0.49 IU/mL).[218] Reasons for the discrepant findings in these two studies probably relate to different laboratory methods; the study using a hemagglutination assay might have underestimated the number of children who were protected. Additional studies using standardized methods are needed.

If a question exists regarding whether vaccines administered outside the United States were immunogenic, several approaches may be considered. Repeating the vaccinations as age-appropriate is an acceptable option; this usually is safe and avoids the need to obtain and interpret serologic tests.[5] If avoiding unnecessary injections is desired, judicious use of serologic testing can help determine which immunizations are needed, particularly for DTP/DTaP vaccine. Although no established serologic correlates exist for protection against pertussis, diphtheria and tetanus antitoxin levels may be used as surrogates to assess whether doses listed on the immunization record actually were received or were potent.[5]

Increased rates of moderate to severe local adverse reactions after the fourth and fifth doses of DTP or DTaP have been reported.[108] If a revaccination option is adopted and a severe local reaction occurs, serologic testing for specific immunoglobulin G antibody to tetanus and diphtheria toxins can be performed before administering additional doses. Protective concentrations indicate that further doses are unnecessary, and subsequent vaccination should occur as age-appropriate.

Instead of revaccinating a child with DTaP when there is a question about the validity of a record that indicates receipt of three or more doses of DTP or DTaP, serologic testing for specific immunoglobulin G antibody to diphtheria *and* tetanus toxin can be obtained. If a protective concentration is present, recorded doses can be considered valid, and the vaccination series should be completed as age-appropriate. Indeterminate antibody concentration might indicate immunologic memory but waning antibody. Serologic testing can be repeated after a booster dose if the vaccination provider wants to avoid revaccination with a complete series.[5]

Children 7 years of age or older who are not considered fully vaccinated for pertussis should receive one dose of Tdap vaccine. "Fully vaccinated" means at least five doses of DTaP before the seventh birthday or at least four doses of DTaP before the seventh birthday if the fourth dose is given after the fourth birthday.

Serologic testing for HBsAg is recommended for all international adoptees born in Asia, the Pacific Islands, Africa, and other regions of high or intermediate endemicity.[218] Children determined to be HBsAg-positive should be monitored for development of liver disease.[201] Household members of HBsAg-positive children should be vaccinated. A child whose records indicate receipt of three or more doses of vaccine can be considered protected, and additional doses are not needed if at least one dose was administered at or after 6 months of age. Children who received their last hepatitis B vaccine dose when younger than 6 months of age should receive an additional dose at 6 months of age or older.[5] Children who have received fewer than three doses should complete the series at the recommended intervals and ages (see Table 9.2).

The simplest approach to vaccinating a child with uncertain polio vaccine records is to revaccinate with IPV according to the U.S. Schedule. Adverse events after IPV are rare.

VACCINATION OF PERSONS WITH A PERSONAL OR FAMILY HISTORY OF SEIZURES

Infants and young children with a personal history of seizures or a parent or sibling with a history of seizures are at increased risk for seizures after receipt of whole-cell pertussis, MMR (or monovalent measles) vaccine, or MMRV vaccine.[53,219–221] In most cases, these seizures are brief, self-limited, and associated with fever. Studies have not established a causal association between these seizures and residual seizure disorders or permanent neurologic sequelae.[222,223] Acellular pertussis vaccines are associated less often with fever than are whole-cell pertussis vaccines; whole-cell DTP is no longer available in the United States.

Because neurologic disorders such as epilepsy and degenerative disorders marked by loss of developmental milestones often become manifest during infancy, pertussis vaccination may coincide with onset or recognition of such disorders and cause confusion about the etiologic role of the vaccine. For infants with a personal history of a seizure, delaying pertussis vaccination is recommended until a progressive neurologic disorder is excluded or the cause of the seizure has been established.[57,58] Because measles vaccine is administered at an age when a child's neurologic status is likely to already have been established, deferring measles immunization of a child with a personal history of a seizure is not recommended.[53,184]

Pertussis and measles vaccinations are not contraindicated in persons with a family history of seizures. Even though children with a parent or sibling who has had a seizure are themselves at increased risk for a seizure, the benefits of administering pertussis and measles vaccine to children with a family history of seizures substantially outweigh the small risks because the seizures are usually febrile in origin, generally have a benign outcome, and are not likely to be confused with manifestations of a previously unrecognized neurologic disorder.[53,58,184,222,224] In June 2009, after consideration of the postlicensure data and other evidence, ACIP adopted recommendations regarding use of MMRV vaccine for the first and second doses and identified a personal or family (i.e., sibling or parent) history of seizure as a precaution for use of MMRV vaccine. For the first dose of measles, mumps, rubella, and varicella vaccines at age 12 to 47 months, either MMR vaccine and varicella vaccine or MMRV vaccine may be used. Providers who are considering administering MMRV vaccine should discuss the benefits and risks of both vaccination options with the parents or caregivers. Unless the parent or caregiver expresses a preference for MMRV vaccine, CDC recommends that MMR vaccine and varicella vaccine should be administered for the first dose in this age group. For the second dose of measles, mumps, rubella, and varicella vaccines at any age (15 months to 12 years) and for the first dose at age 48 months or older, use of MMRV vaccine generally is preferred over separate injections of its equivalent component vaccines (i.e., MMR vaccine and varicella vaccine). This recommendation is consistent with ACIP's 2009 provisional general recommendations regarding use of combination vaccines which state that use of a combination vaccine generally is preferred over its equivalent component vaccines.[5]

VACCINATION DURING ACUTE ILLNESS

The decision to administer or delay vaccination because of an intercurrent or recent acute illness depends on evaluation of the etiology of the disease and the severity of symptoms.[2,5] Mild illness, febrile (temperature ≥38°C) or afebrile, is not a contraindication to vaccination. Although one study reported a lower rate of seroconversion to the measles but not to the rubella or mumps components of MMR vaccine in children with evidence of a recent or current upper respiratory tract infection compared with children without this history,[223] a difference in seroconversion to measles vaccine in healthy children compared with children who are ill has not been found in other studies.[81,225–228]

Acute minor illnesses, such as upper respiratory tract infection, diarrhea, and acute otitis media, are common during infancy and childhood.[229] Postponing vaccination in children with minor febrile or afebrile illness constitutes a missed opportunity to protect a child from disease, can contribute to outbreaks of vaccine-preventable disease, and can significantly impede efforts to immunize infants and young children on schedule.[230–233] Every opportunity should be used to provide indicated vaccines and to avoid missed opportunities in persons who may not return for medical care and administration of recommended vaccines.[2,5,234,235] The potential benefit of preventing disease by timely vaccination far outweighs any small possible risk of vaccine failure.

Vaccination usually is deferred in persons who have moderate or severe illness. A person with signs or symptoms of moderate or severe illness at the scheduled time of vaccination should be requested to return as soon as the illness improves so that vaccines can be administered at the recommended ages. Waiting until after a person has recovered from the acute phase of a moderate or severe illness avoids superimposing a reaction to vaccination on the underlying illness or mistakenly attributing a manifestation of the underlying illness to the vaccine.[2,5]

CONTRAINDICATIONS TO AND PRECAUTIONS REGARDING VACCINATION

Vaccine contraindications and precautions are described in the manufacturer's product labeling and in the recommendations for the use of vaccines developed by national advisory committees such as the ACIP and the Committee on Infectious Diseases of the AAP. In the United States, the content of the product label is regulated by the Food and Drug Administration on the basis of specific studies required of the manufacturer to prove the safety and efficacy of a specific product. Most recommendations of vaccine advisory committees are the same as those in the product label. However, differences sometimes exist because of advisory committees' assessments of the risks and benefits of a given recommendation, their goal to make immunization as practical as possible, and their responsibility to develop recommendations for the use of vaccines in circumstances in which specific safety and efficacy data may be limited but for which physicians, nurses, and public health officials need guidance. For example, the manufacturer's product label recommends that women vaccinated with live varicella virus vaccine avoid becoming pregnant for 3 months, whereas the ACIP and AAP advise waiting only 1 month.[1,185,236] Similarly, the AAP and ACIP advise that pregnancy should not be considered a contraindication to hepatitis B vaccination, whereas the manufacturer's product label states that hepatitis B vaccine should only be given to pregnant women if clearly indicated.[1,201,237,238]

A contraindication indicates that a vaccine should not be administered. In contrast, a precaution specifies a situation in which vaccine may be administered if the benefit of vaccination to the individual patient is judged to outweigh the risk.[5] Contraindications and precautions may be generic and apply to all vaccines, or they may be specific to one or more vaccines (Table 9.6). The following two guidelines apply to all vaccines: (a) An anaphylactic reaction to a vaccine or vaccine constituent

TABLE 9.6 Contraindications and Precautions[a] to Commonly Used Vaccines

Vaccine	Contraindications	Precautions
Diphtheria and tetanus toxoids and acellular pertussis (DTaP)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Encephalopathy (e.g., coma, decreased level of consciousness, or prolonged seizures), not attributable to another identifiable cause, within 7 days of administration of previous dose of diphtheria toxoid, tetanus toxoid, and pertussis (DTP) or DTaP	Progressive neurologic disorder, including infantile spasms, uncontrolled epilepsy, progressive encephalopathy; defer DTaP until neurologic status clarified and stabilized Temperature of ≥40.5°C within 48 h after vaccination with a previous dose of DTP or DTaP Collapse or shock-like state (i.e., hypotonic hyporesponsive episode) within 48 h after receiving a previous dose of DTP/DTaP Seizure ≤3 days after receiving a previous dose of DTP/DTaP Persistent, inconsolable crying lasting ≥3 h within 48 h after receiving a previous dose of DTP/DTaP Guillain-Barré syndrome (GBS) <6 wk after previous dose of tetanus toxoid–containing vaccine History of Arthus-type hypersensitivity reactions after a previous dose of diphtheria-toxoid–containing or tetanus toxoid–containing vaccine; defer vaccination until at least 10 y have elapsed since the last tetanus toxoid–containing vaccine Moderate or severe acute illness with or without fever
Diphtheria and tetanus toxoids (DT), tetanus and diphtheria toxoids (Td)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	GBS < 6 wk after previous dose of tetanus toxoid–containing vaccine History of Arthus-type hypersensitivity reactions after a previous dose of diphtheria-toxoid–containing or tetanus toxoid–containing vaccine; defer vaccination until at least 10 y have elapsed since the last tetanus-toxoid–containing vaccine Moderate or severe acute illness with or without fever
Haemophilus influenzae type b (Hib)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Age <6 wk	Moderate or severe acute illness with or without fever
Hepatitis A	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever

TABLE 9.6 Contraindications and Precautions[a] to Commonly Used Vaccines (*Continued*)

Vaccine	Contraindications	Precautions
Hepatitis B	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component; hypersensitivity to yeast	Infant weight <2000 g[b] Moderate or severe acute illness with or without fever
Human papillomavirus vaccine (2vHPV, 4vHPV, 9vHPV)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever; pregnancy
Inactivated influenza vaccine (IIV, RIV)	Severe allergic reaction (e.g., anaphylaxis) after previous dose of influenza vaccine	GBS <6 wk after a previous dose of influenza vaccine Moderate or severe acute illness with or without fever
Inactivated poliovirus (IPV)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Pregnancy Moderate or severe acute illness with or without fever
Live attenuated influenza vaccine (LAIV)	Severe allergic reaction (e.g., anaphylaxis) after previous dose or to vaccine component, including egg protein Persons aged <2 y or >49 y Those with contraindications listed in the package insert: Children ages 2–17 y who are receiving aspirin or aspirin-containing products; persons who have experienced severe allergic reactions to the vaccine or any of its compounds, or to a previous dose of any influenza vaccine; pregnant women; immunosuppressed persons; persons with a history of egg allergy; children ages 2–4 y who have asthma or who have had a wheezing episode noted in the medical record within the past 12 mo, or for whom parents report that a health care provider stated that they had wheezing or asthma within the last 12 mo Persons who have taken influenza antiviral medications within the previous 48 h[c]	GBS <6 wk after a previous dose of influenza vaccine The safety of LAIV in persons with underlying medical conditions that might predispose them to complications after wild-type influenza infection (e.g., chronic pulmonary, cardiovascular [except isolated hypertension], renal, hepatic, neurologic, hematologic, or metabolic disorders [including diabetes mellitus]) has not been established. These conditions, in addition to asthma in persons age ≥5 y, should be considered precautions for the use of LAIV Moderate or severe acute illness with or without fever
Measles, mumps, and rubella (MMR)[d,e]	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Pregnancy Known severe immunodeficiency (e.g., from hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, or long-term immunosuppressive therapy[f] or patients with HIV infection who are severely immunocompromised)[e]	Recent (≤11 mo) receipt of antibody-containing blood product (specific interval depends on product)[g] History of thrombocytopenia or thrombocytopenic purpura Need for tuberculin skin testing[h] or interferon gamma release assay (IGRA) testing Moderate or severe acute illness with or without fever
Pneumococcal conjugate vaccine (PCV13)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose of PCV13, or any diphtheria toxoid–containing vaccine or to a component of a vaccine (PCV13 or any diphtheria toxoid–containing vaccine)	Moderate or severe acute illness with or without fever
Pneumococcal polysaccharide vaccine (PPSV)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever
Quadrivalent meningococcal conjugate vaccine (MCV4) and monovalent meningococcal b vaccine	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever
Quadrivalent meningococcal polysaccharide vaccine (MPSV4)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever
Rotavirus	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Severe combined immunodeficiency (SCID) History of intussusception	Altered immunocompetence other than SCID Chronic gastrointestinal disease[i] Spina bifida or bladder exstrophy[i] Moderate or severe acute illness with or without fever

Continued on following page

TABLE 9.6 Contraindications and Precautions[a] to Commonly Used Vaccines (*Continued*)

Vaccine	Contraindications	Precautions
Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap)	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Encephalopathy (e.g., coma, decreased level of consciousness, or prolonged seizures), not attributable to another identifiable cause, within 7 days of administration of previous dose of DTP, DTaP, or Tdap	GBS <6 wk after a previous dose of tetanus toxoid–containing vaccine Progressive or unstable neurological disorder, uncontrolled seizures, or progressive encephalopathy until a treatment regimen has been established and the condition has stabilized History of Arthus-type hypersensitivity reactions after a previous dose of diphtheria toxoid-containing or tetanus toxoid–containing vaccine; defer vaccination until at least 10 y have elapsed since the last tetanus toxoid–containing vaccine[j] Moderate or severe acute illness with or without fever
Varicella	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Known severe immunodeficiency (e.g., from hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, or long-term immunosuppressive therapy[f] or patients with HIV infection who are severely immunocompromised)[e] Pregnancy	Recent (≤11 mo) receipt of antibody-containing blood product (specific interval depends on product)[k] Moderate or severe acute illness with or without fever
Zoster	Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Known severe immunodeficiency (e.g., from hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, or long-term immunosuppressive therapy or patients with HIV infection who are severely immunocompromised[e,f] Pregnancy	Moderate or severe acute illness with or without fever

[a]Events or conditions listed as precautions should be reviewed carefully. Benefits of and risks for administering a specific vaccine to a person under these circumstances should be considered. If the risk from the vaccine is believed to outweigh the benefit, the vaccine should not be administered. If the benefit of vaccination is believed to outweigh the risk, the vaccine should be administered. Whether and when to administer DTaP to children with proven or suspected underlying neurologic disorders should be decided on a case-by-case basis.

[b]Hepatitis B vaccination should be deferred for infants weighing <2000 g if the mother is documented to be hepatitis B surface antigen (HBsAg)-negative at the time of the infant's birth. Vaccination can commence at chronological age 1 month or at hospital discharge. For infants born to HBsAg-positive women, hepatitis B immunoglobulin and hepatitis B vaccine should be administered within 12 hours after birth, regardless of weight.

[c]Source: Fiore AE, Uyeki TM, Broder K, et al; Centers for Disease Control and Prevention (CDC). Prevention and control of influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices (ACIP), 2010. *MMWR Recomm Rep*. 2010;59(RR-8):1–62.

[d]HIV-infected children may receive varicella and measles vaccine if $CD4^+$ T-lymphocyte count is >15%. (Source: Adapted from American Academy of Pediatrics. Passive immunization. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015.

[e]MMR and varicella-containing vaccines can be administered on the same day. If not administered on the same day, these vaccines should be separated by at least 28 days.

[f]Substantially immunosuppressive steroid dose is considered to be ≥2 weeks of daily receipt of 20 mg or 2 mg/kg body weight of prednisone or equivalent.

[g]See Table 9.5 for details.

[h]If active tuberculosis is suspected, MMR should be delayed. Measles vaccination might suppress tuberculin reactivity temporarily. Measles-containing vaccine can be administered on the same day as tuberculin skin testing. If testing cannot be performed until after the day of MMR vaccination, the test should be postponed for ≥4 weeks after the vaccination. If an urgent need exists to skin test, do so with the understanding that reactivity might be reduced by the vaccine.

[i]For details, see Cortese MM, Parashar UD; Centers for Disease Control and Prevention (CDC). Prevention of rotavirus gastroenteritis among infants and children: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2009;58(RR-2):1–25.

[j]With the exception of pregnant woman who should be vaccinated during every pregnancy regardless of interval since last tetanus toxoid–containing dose.

[k]Vaccine should be deferred for the appropriate interval if replacement immunoglobulin products are being administered (see Table 9.5).

contraindicates further use of that vaccine or vaccines containing that constituent (see "Vaccine Components Causing Hypersensitivity" above). (b) Moderate or severe acute illness, regardless of the absence or presence of fever, is a precaution to vaccination (see "Vaccination During Acute Illness" above).

Immunosuppression resulting from underlying disease or therapy is a contraindication for receipt of most live vaccines.[5,53,184] MMR vaccine is recommended for HIV-infected persons who are not severely immunosuppressed.[172,209,217,239] Varicella vaccine can be considered for HIV-infected persons not severely immunosuppressed.[185] Rotavirus vaccine is contraindicated in infants diagnosed with severe combined immunodeficiency (SCID).[240,241] Corticosteroid therapy can suppress the immune system of an otherwise healthy person, although the minimal dose and duration of therapy necessary to cause immunosuppression are not well defined. Underlying disease, concurrent therapies, and the frequency and route of administration of corticosteroids also can affect immunosuppression. Steroid therapy does not usually contraindicate administration of live vaccines when given in low to moderate doses administered daily or on alternate days, physiologic

TABLE 9.7 Conditions Commonly Misperceived as Contraindications to Vaccination

Vaccine	Conditions Commonly Misperceived as Contraindications (i.e., Vaccination May Be Administered Under These Conditions)
General for all vaccines, including diphtheria and tetanus toxoids and acellular pertussis (DTaP), pediatric diphtheria and tetanus toxoids (DT), adult tetanus and diphtheria toxoids (Td), adolescent–adult tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap), inactivated poliovirus (IPV), measles, mumps, and rubella (MMR), *Haemophilus influenzae* type b (Hib), hepatitis A, hepatitis B, varicella, rotavirus, pneumococcal conjugate vaccine (PCV), trivalent inactivated influenza vaccine (IIV) live, attenuated influenza vaccine (LAIV), pneumococcal polysaccharide vaccine (PPSV 23), quadrivalent meningococcal conjugate vaccine (MCV4), quadrivalent meningococcal polysaccharide vaccine (MPSV4), serogroup B meningococcal human papillomavirus (HPV) vaccine, and herpes zoster	Mild acute illness with or without fever Mild-to-moderate local reaction (i.e., swelling, redness, soreness); low-grade or moderate fever after previous dose Lack of previous physical examination in well-appearing person Current antimicrobial therapy[a] Convalescent phase of illness Preterm birth (hepatitis B vaccine is an exception in certain circumstances)[b] Recent exposure to an infectious disease History of penicillin allergy, other nonvaccine allergies, relatives with allergies, or receiving allergen extract immunotherapy History of Guillain-Barré syndrome[c]
DTaP	Temperature of <40.5°C, fussiness, or mild drowsiness after a previous dose of diphtheria toxoid, tetanus toxoid, and pertussis (DTP)/DTaP Family history of seizures Family history of sudden infant death syndrome Family history of an adverse event after DTP or DTaP administration Stable neurologic conditions (e.g., cerebral palsy, well-controlled seizures, or developmental delay)
Tdap	History of temperature of ≥40.5°C for <48 h after vaccination with a previous dose of DTP or DTaP History of collapse or shock-like state (i.e., hypotonic hyporesponsive episode) within 48 h after receiving a previous dose of DTP/DTaP History of seizure <3 days after receiving a previous dose of DTP/DTaP History of persistent, inconsolable crying lasting >3 h within 48 h after receiving a previous dose of DTP/DTaP History of extensive limb swelling after DTP/DTaP/Td that is not an Arthus-type reaction Stable neurologic disorder History of brachial neuritis Latex allergy that is not anaphylactic Breastfeeding Immunosuppression
IPV	Previous receipt of ≥1 dose of oral polio vaccine
MMR[d,e]	Positive tuberculin skin test Simultaneous tuberculin skin testing[f] Breastfeeding Pregnancy of recipient's mother or other close or household contact Recipient is female of childbearing age Immunodeficient family member or household contact Asymptomatic or mildly symptomatic HIV infection Allergy to eggs
Hepatitis B	Pregnancy Autoimmune disease (e.g., systemic lupus erythematosus or rheumatoid arthritis)
Varicella	Pregnancy of recipient's mother or other close or household contact Immunodeficient family member or household contact[g] Asymptomatic or mildly symptomatic HIV infection Humoral immunodeficiency (e.g., agammaglobulinemia)
Inactivated influenza vaccine (IIV)	Nonsevere (e.g., contact) allergy to latex, thimerosal, or egg Concurrent administration of Coumadin or aminophylline
LAIV	Healthcare providers who see patients with chronic diseases or altered immunocompetence (an exception is providers for severely immunocompromised patients requiring care in a protected environment) Breastfeeding Contacts of persons with chronic disease or altered immunocompetence (an exception is contacts of severely immunocompromised patients requiring care in a protected environment)
PPSV	History of invasive pneumococcal disease or pneumonia
HPV	Immunosuppression Previous equivocal or abnormal Papanicolaou test Known HPV infection Breastfeeding History of genital warts

Continued on following page

TABLE 9.7 Conditions Commonly Misperceived as Contraindications to Vaccination *(Continued)*

Vaccine	Conditions Commonly Misperceived as Contraindications (i.e., Vaccination May Be Administered Under These Conditions)
Rotavirus	Prematurity Immunosuppressed household contacts Pregnant household contacts
Zoster	Therapy with low-dose methotrexate (≤0.4 mg/kg per week), azathioprine (≤3.0 mg/kg per day), or 6-mercaptopurine (≤1.5 mg/kg per day) for treatment of rheumatoid arthritis, psoriasis, polymyositis, sarcoidosis, inflammatory bowel disease, or other conditions Healthcare providers of patients with chronic diseases or altered immunocompetence Contacts of patients with chronic diseases or altered immunocompetence Unknown or uncertain history of varicella in a U.S.-born person

[a]Antibacterial drugs might interfere with Ty21a oral typhoid vaccine, and certain antiviral drugs might interfere with varicella-containing vaccines and LAIV.

[b]Hepatitis B vaccination should be deferred for infants weighing <2000 g if the mother is documented to be hepatitis B surface antigen (HBsAg)-negative at the time of the infant's birth. Vaccination can commence at chronological age 1 month or at hospital discharge. For infants born to HBsAg-positive women, hepatitis B immunoglobulin and hepatitis B vaccine should be administered within 12 hours after birth, regardless of weight.

[c]An exception is Guillain-Barré syndrome within 6 weeks of a dose of influenza vaccine or tetanus-toxoid–containing vaccine, which are precautions for influenza vaccine and tetanus-toxoid–containing vaccines, respectively.

[d]MMR and varicella vaccines can be administered on the same day. If not administered on the same day, these vaccines should be separated by at least 28 days.

[e]HIV-infected children should receive immunoglobulin after exposure to measles. HIV-infected children can receive varicella and measles vaccine if $CD4^+$ T-lymphocyte count is >15%. (Source: Modified from American Academy of Pediatrics. Passive immunization. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015.)

[f]Measles vaccination might suppress tuberculin reactivity temporarily. Measles-containing vaccine can be administered on the same day as tuberculin skin testing. If testing cannot be performed until after the day of MMR vaccination, the test should be postponed for at least 4 weeks after the vaccination. If an urgent need exists to skin test, do so with the understanding that reactivity might be reduced by the vaccine.

[g]If a vaccinee experiences a presumed vaccine-related rash 7 to 25 days after vaccination, the person should avoid direct contact with immunocompromised persons for the duration of the rash.

maintenance doses, or doses administered topically, by aerosol, or by local (e.g., intraarticular) injection.[5,184] In most cases, persons receiving high doses of systemic corticosteroids (i.e., ≥2 mg/kg per day or 20 mg/day of prednisone or its equivalent) for less than 14 days can receive live vaccines immediately after discontinuation of therapy.[2,5] However, live vaccines usually are not administered to persons who have received high doses of systemic corticosteroids for 14 days or more until at least 1 month after cessation of steroid therapy.[5,184]

Live vaccines usually are contraindicated for pregnant women because of a theoretical risk to the fetus (see "Vaccination During Pregnancy" above). However, the small theoretical risk from administration of a live vaccine to a pregnant woman is sometimes far outweighed by the risk of contracting a disease with serious consequences for mother and fetus (e.g., yellow fever vaccine).

Healthcare providers sometimes inappropriately consider a condition to be a contraindication or precaution to vaccination.[2,5] Withholding vaccine in such situations results in a missed opportunity to administer needed vaccine (Table 9.7).

SECTION 2

Licensed Vaccines and Vaccines in Development

10 Adenovirus Vaccines

Gregory C. Gray and Dean D. Erdman

HISTORY OF DISEASE

In the 1950s, multiple researchers[1,2] identified new viruses as the cause of acute respiratory disease (ARD), pharyngitis, conjunctivitis, and pneumonitis. Soon afterward, these viruses were recognized to be a related group of viruses and given their present name: adenoviruses.[3]

WHY THE DISEASE IS IMPORTANT

The adenoviruses are often the cause of respiratory illness among U.S. military trainees[4,5] and children.[6–13] In the 1960s, adenoviruses were recognized to infect as many as 80% of trainees, with 20% requiring hospitalization.[5] Median attack rates for trainees ranged from 6 to 16.7/100 per month at the most affected northern and Midwestern U.S. military bases, and from 2.3 to 2.6/100 per month for posts in the South and West.[14] Up to 40% of the trainees in a unit were lost to illness within a 2-week period, and many who were hospitalized had to restart training.[15] Adenoviruses were also recognized to cause as much as 15% of instances of gastroenteritis in infants and children, and up to 10% of instances of pneumonia among hospitalized children.[16–18] Adenovirus morbidity can be severe and lead to death, especially in young children, transplantation recipients, and other immunocompromised patients.

The search for vaccines against adenoviruses was driven by adenovirus morbidity among military trainees, their disruption to military training, and their medical care costs.[15] In 1971, after a series of misstarts, military recruits began routinely receiving live oral enteric-coated vaccines for adenovirus types 4 and 7 (Ad4 and Ad7), which were safe and effective.[19] With few exceptions, adenovirus morbidity was markedly controlled. However, in 1996, the sole manufacturer of these vaccines ceased production. As vaccine stores were depleted, U.S. military trainees again experienced large outbreaks of adenovirus disease, with some deaths reminding public health officials of the impact of adenoviruses.[20–22] In one comprehensive 2006 study, Russell and colleagues documented 98% Ad4 attack rates among 180 susceptible military recruits during 4 weeks of training.[23] The importance of these pathogens has been further emphasized through the recent emergence of multiple novel Ad3, Ad7, and Ad14 strains and the subsequent epidemics and deaths they caused.[24–29]

BACKGROUND

Clinical Description

Human adenoviruses have been classically grouped into seven species (A through G) containing as many as 68 unique types (Ad1 through Ad68) and multiple more genotypes often determined by restriction enzyme digests (Ad7a, Ad7d2, etc). However, the nomenclature and classification system is undergoing change. In 2013, the International Committee of Taxonomy of Viruses added a genus prefix (eg, human adenovirus A has become human mastadenovirus A).[30] A number of investigators have additionally argued that it is time to move away from neutralization and hemagglutination assays in determining serotype and to chiefly use a genetic classification approach.[31] Such virologists have used large DNA sequence comparisons to describe as many as 68 novel adenovirus types,[32,33] although this approach has met with some debate.[34–37]

No matter which adenovirus nomenclature or classification system is agreed upon, it is clear that adenoviruses affect most organ systems. Individual adenovirus types often have different tissue tropisms that lead to specific signs and symptoms (Table 10.1).[39,40]

Endemic Respiratory Adenovirus in Children

Although most children become infected with many of the common adenoviruses early in life, only approximately 50% of these infections result in disease.[39,41,42] Isolation studies have indicated that Ad1, Ad2, Ad5, Ad3, and Ad6 are most prevalent types detected,[39,43] and often manifest by pharyngitis, bronchitis, bronchiolitis, croup, or pneumonia.[43,44] The incidence of adenovirus disease is higher in late winter, spring, and early summer, and both sexes are equally affected.[41,45]

Epidemic Respiratory Adenovirus in Children

Occasionally, epidemics occur in daycare facilities, neonatal intensive care units, chronic care facilities, and orphanages, especially with Ad3 and Ad7.[46–49] In addition to causing outbreaks in closed populations, Ad7 can cause large epidemics affecting children in open communities.[50,51]

Acute Respiratory Disease of Military Recruits

In young adults who live in closed communities such as boarding schools and military recruit camps, adenoviruses may cause epidemics of illnesses similar to influenza, including tracheobronchitis and pneumonia severe enough to require hospitalization.[2,4,52,53] Adenovirus pneumonia may be fatal, especially when it is associated with Ad7 strains.[16,54–56] The incubation period of the disease is 4 to 5 days.[53] Before the use of vaccines in the U.S. military, Ad4 and Ad7 accounted for 90% of all respiratory illnesses among recruits who were hospitalized, whereas Ad3, Ad14, and Ad21 were less frequently observed.[4] At some northern basic training sites, rates of 6 to 8 per 100 trainees per week translated into 600 to 800 ARD hospital admissions per week.[15] Recently, the newly

TABLE 10.1 Clinical Syndromes Associated With Human Adenovirus Infections

Clinical Syndrome	Common Types	Population at Risk
Endemic respiratory	1, 2, 3, 5, 6	Infants, children
Epidemic respiratory	7, 14, 55	Children
Acute respiratory disease	3, 4, 7, 14, 21	Military recruits
Pharyngoconjunctival fever	1, 3, 4, 7, 14	School-age children, young adults
Keratoconjunctivitis	8, 11, 19, 37, 53, 54	All age groups
Hemorrhagic cystitis	11, 34, 35	Immunocompromised patients, children
Gastroenteritis	31, 40, 41, 52	Children, immunocompromised patients
Other syndromes	2, 4, 7, 12,19, 32, 37	Children, adults
Immune deficiency	34, 35, 43–49, 50, 51	Transplantation recipients, persons with AIDS, and immunocompromised patients

There is agreement regarding the classification of adenoviruses 1 to 51, which have been classically typed with neutralization and hemagglutination assays. However, the classification of adenoviruses 52 to 68 remains controversial as these have been chiefly identified through genetic sequencing. In particular, adenovirus 55 is a recombination of 11 and 14.[126,148]

recognized Ad55 (Ad11 and Ad14 recombinant) has been documented to have caused significant ARD morbidity among military trainees in China.[57]

Typical ARD is a febrile disease with symptoms of sore throat, fever, cough, coryza, rhinorrhea, headache, and chest pain.[2,39,58] With extension into the lungs, physical examinations can reveal rales and rhonchi with little evidence of consolidation, and chest radiography often shows patchy interstitial infiltrates, principally in the lower lung fields.[2,53,59] Symptoms last 3 to 10 days.[39] The infection is often self-limited, but occasionally deaths occur.[2,60] Routes of transmission are thought to include direct contact or aerosolized virus inhaled into the lung. The virus has been isolated from the oropharynx more than 2 weeks after exposure.[2,61] In a 2006 report, Russell and colleagues demonstrated viable adenovirus was ubiquitous on surfaces in the military trainee barracks.[23]

Pharyngoconjunctival Fever

This syndrome is characterized by pharyngitis, conjunctivitis, and spiking fever.[62] First described in the 1920s as associated with swimming, the cause has been subsequently linked to insufficient chlorination.[63–65] One or both eyes are affected, and diarrhea, coryza, tonsillar exudates, and lymphadenopathy may be observed. The most frequently identified types have been Ad3 and Ad7, but other types, such as Ad1, Ad4, and Ad14, are also associated with pharyngoconjunctival fever.[62] The disease is associated with summer camps, swimming pools, and lakes; occurs in children and young adults; and often spreads to other family members.[62,66,67] The incubation period is 6 to 9 days, and the virus may be isolated from pool water.[62,65] There is little bacterial superinfection and no permanent damage to the eye.[59]

Epidemic Keratoconjunctivitis

Epidemics of conjunctivitis in adults caused by adenoviruses were first described as "shipyard eye."[68,69] The disease was observed at industrial settings where shipbuilding took place and was probably transmitted because of inadequate infection control practices when workers sought care for chemical irritation and minor trauma from paint and rust chips.[68] The disease has an incubation time of 8 to 10 days and is characterized by conjunctivitis, edema of the eye, pain, photophobia, and lacrimation. Superficial erosions and subepithelial infiltrates of the cornea may occur.[39] Preauricular lymph gland swelling and involvement of cervical and submaxillary lymph glands may be observed.[39] Epidemic keratoconjunctivitis (EKC) is associated with Ad8, Ad19, Ad37, and, rarely, other types.[70–74] In addition, Ad19 and Ad37 have been isolated from the genital tract of young adults with EKC, and the possibility of sexual transmission has been considered.[75,76] Numerous epidemics of EKC have been associated with ophthalmology practices, where spread from contaminated ophthalmic solutions, fingers, and instruments has been implicated.[70,72,74,77,78]

Hemorrhagic Cystitis

Hemorrhagic cystitis syndrome in children is caused by adenovirus infections in 23% to 51% of cases in the United States and Japan.[79] Although the specific route of spread is unknown, Ad11 and Ad21 were the most frequently isolated adenoviruses.[79] Boys were two to three times more often affected than girls. Clinical findings included gross hematuria of 3 days' duration. Dysuria, microscopic hematuria, and urinary frequency lasted a few days longer.[79,80] No viremia or structural abnormalities were found. Adenoviral antigen in exfoliated bladder epithelial cells can be demonstrated by immunofluorescence.[79] Cases of acute hemorrhagic cystitis after renal and bone marrow transplantation are increasingly being reported.[81–83] Ad34 and Ad35, as well as species B adenoviruses, were first isolated from renal transplantation recipients, but neither was associated with symptoms of hemorrhagic cystitis.[84]

Gastroenteritis

Adenoviruses are also recognized to cause watery diarrhea with fever. Ad40 and Ad41 are the most prevalent strains, but Ad50, Ad51, and Ad52 have been detected among the immunocompromised. AdV52 has been associated with one outbreak cluster of acute gastroenteritis.[124] These strains often require special cells lines for culture and they may not demonstrate cytopathic effect.[85] Electron micrography or special assays are often necessary for their study.[85] Numerous outbreaks have been described, and adenoviruses may account for up to 12% of all infant diarrhea.[86–88]

Rare Acute Manifestations

A number of case or outbreak reports document other, more unusual manifestations of human adenovirus infection. These occur most frequently among children. Although the studies

are inconsistent, adenovirus is implicated as a possible fetal pathogen.[89,90] Adenovirus infections among children are associated with sudden infant death,[91] encephalitis, meningoencephalitis,[92,93] cerebral edema,[94] acute flaccid paralysis,[95] pertussis-like syndromes,[96,97] mononucleosis-like syndromes,[98] and neonatal disseminated infections.[99] Among adults, adenovirus infections have been associated with a toxic shock–like syndrome,[100] encephalitis, genital lesions, orchitis, urethritis, and cervicitis.[101] Nosocomial transmission to susceptible healthcare workers and patients has been reported. This is likely related to the long periods of viral shedding among adenovirus-infected immunocompromised hosts, the possible aerosolization of the virus, and fomite transmission in the hospital setting.[40,95,102]

Complications

Adenovirus Infections in Immunocompromised Patients

Adenoviruses have been implicated as opportunistic agents in patients with immune deficiency states, such as patients with AIDS, patients receiving cancer chemotherapy, bone marrow transplant recipients, and patients undergoing solid organ transplantation.[11,12,82,103–106] The patients are prone to pneumonia and disseminated adenoviral infection. They have also developed parotitis[107] and urinary tract disease.[108] A number of the more recently described types, such as Ad43 through Ad51, have been recovered from people with AIDS.[108,109]

A review of 201 bone marrow recipients over a 4-year period indicated that adenovirus infections occurred in 20.9% of patients, with a higher incidence in children than in adults (31.3% vs 13.6%).[110] Ad35 was the most common type identified.[110] In 1992, Hierholzer reported that adenovirus infections in immunocompromised patients with pneumonia were associated with case fatality rates as high as 60%, compared with only 15% among immunocompetent hosts with pneumonia.[9] Radiographs of adenovirus-infected patients often demonstrate patchy interstitial infiltrates, usually in the lower lung fields.[111] Fig. 10.1 shows the chest radiograph of a 20-year-old recipient of an autologous bone marrow transplant for diffuse large cell lymphoma (B-cell type) with systemic Ad11 infection, which was obtained on day 45 posttransplantation. He died on day 80. Adenovirus was recovered from conjunctival, urine, and bronchoalveolar lavage cultures. A case fatality rate of 50% occurred in immunocompromised people with hepatitis and associated adenovirus infections, compared with 10% in similarly infected immunocompetent patients with hepatitis.[9] Positive tests of serum by polymerase chain reaction (PCR) for adenovirus has been reported to predict severe disseminated adenovirus infection in immunocompromised patients.[112] Nephritis and kidney failure caused by adenovirus infections have been reported in adults and children receiving bone marrow transplants.[113,114] A study of 532 hematopoietic stem cell transplant recipients between 1986 and 1997 found a 12% incidence of adenovirus infections, with children being more likely than adults to have a positive culture (23% vs 9%).[115]

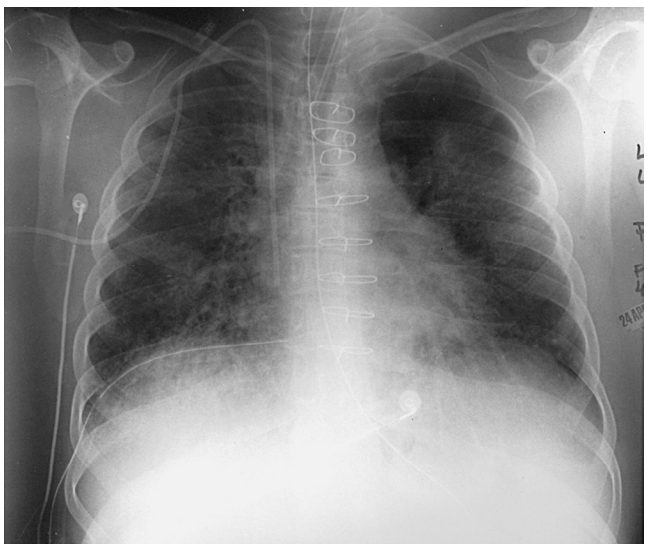

Figure 10.1. Pneumonia caused by adenovirus type 11 in a 20-year-old recipient of an autologous bone marrow transplant. *(Courtesy Stuart Ray, MD, Johns Hopkins University, Baltimore, MD.)*

Chronic Diseases Caused by Adenoviruses

Thanks often to molecular techniques, human adenoviruses have been associated with a number of chronic disease conditions, including chronic airway obstruction,[101] pulmonary dysplasia,[116] myocarditis, and cardiomyopathy.[117] Although the results of studies are mixed, an intriguing series of human and animal studies associate a number of human adenovirus types with obesity.[118–121]

Virology

Human adenoviruses are nonenveloped, double-stranded DNA viruses belonging to the genus Mastadenovirus, family Adenoviridae.[122] They are classified by species (A–G) through hemagglutination properties and by serotype (1–51) with horse or rabbit antisera (Table 10.2).[40,59,123] Different strains within serotypes are further distinguished by whole-genome restriction-enzyme digest patterns. However, as typing serum samples are difficult to acquire and sequencing costs are decreasing, virologists are considering full genome sequencing as a more modern and accurate method to detect unique strains and have described as many as 68 unique adenovirus types.[124–128]

Adenoviruses are considered large viruses, with an estimated diameter of approximately 920 Å.[129] The viruses have an icosahedral capsid shell that is made up of 240 hexon bases, 12 penton bases, and 12 fibers that are associated with the penton bases (Fig. 10.2). Four minor proteins (IIIa, VI, VIII,

Some information for the recently described adenovirus types is not yet available.

Modified from Lion T. Adenovirus infections in immunocompetent and immunocompromised patients. Clin Microbiol Rev. *2014;27(3):441–462.*

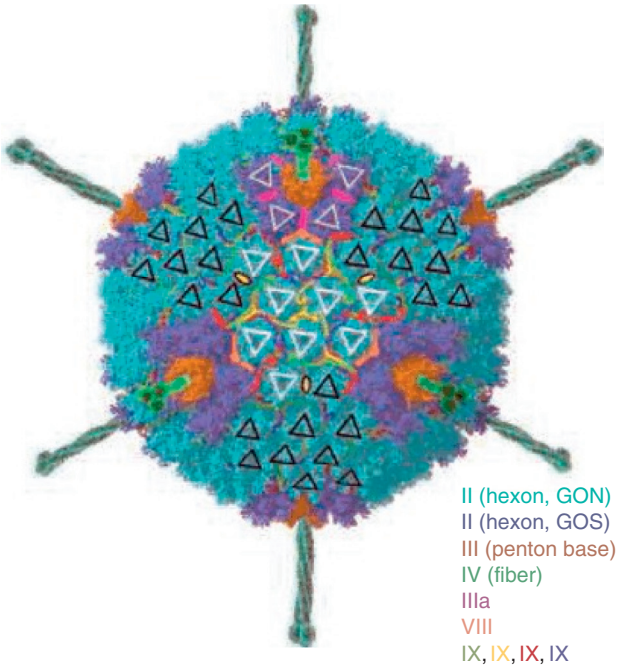

Figure 10.2. Image of adenovirus virion determined by cryoelectron microscopy showing newly understood interactions of the major components (hexon, penton, and fiber proteins) and minor proteins (IIIa, VIII, and IX). The proteins interact in groups of nine (GON) and groups of six (GOS) capsomers. *(Courtesy Hong Zhu, University of California, Los Angeles. Modified from Harrison SC. Looking inside adenovirus.* Science. *2010;329:1026–1027.)*

and IX) add to the complexity of the capsid. The pentons and hexons are each derived from different viral polypeptides.

Adenovirus hexons are both type-specific and species-specific antigens, primarily inducing species-specific complement-fixing antibodies, whereas the pentons are especially active in hemagglutination.[130] The fibers also evoke type-specific antibodies, vary in length among human strains, and are sometimes absent in particular animal strains.[131–134] The genome core of the virus is composed of five more proteins (V, VII, u, Iva2, and terminal protein) and a single molecule of linear, double-stranded DNA of 26 × 106 to 45 × 106 molecular weight. The G + C base compositions of the human virus genomes range from 47% to 60%.[110,122,135,136]

Adenoviruses are unusually stable to physical and chemical agents, as well as adverse pH, and, thus, survive for long periods outside the host, making them available for transmission to others. They can be destroyed by heat at 56°C for 30 minutes, UV irradiation, 0.25% sodium dodecyl sulfate, chlorine at 0.5 μg/mL, and formalin, but are resistant to ether and chloroform.

Adenoviruses replicate in the cell nucleus and tend to be very host-specific. However, there is mounting evidence that humans and animals have exchanged adenoviruses. In 2009, a simian adenovirus epidemic occurred among nonhuman primates at a U.S. research center and subsequently infected the primate caretakers with some evidence of human-to-human transmission.[137,138] A 2011 report documented the recent detection of 45 distinct adenovirus in nonhuman primates most of which mapped phylogenetically very closely to human adenovirus species.[139] In 2012, human infections with a novel avian adenovirus were associated with avian chlamydiosis outbreak in Hong Kong.[140] Finally, it is also important to recognize that Ad4 and Ad52 are thought to have originated from nonhuman primates.[124,141,142] Hence, some virologists have recently reviewed the probability that adenoviruses may be zoonotic.[143]

Some adenovirus types have been determined to be oncogenic in animals and to transform cell lines, but oncogenicity has not been observed in humans. Hybridization or genetic recombination of multiple strains of adenovirus may occur. Sometimes, these recombinant strains or other emergent novel adenovirus strains lead to epidemics. A number of recent examples have been reported in the medical literature.[26,27,29,144–148]

Pathogenesis as It Relates to Prevention

Depending on the route of inoculation, the type of virus, and the immune state of the host, adenoviruses can cause diseases or asymptomatic infections. Respiratory infection is presumed to result from inhalation of aerosolized virus, whereas ocular infection, gastroenteritis, and nosocomial infections may arise from fomites, water, or fecal–oral contact. Reactivation of latent adenovirus is also believed to occur.[53] Some 50% to 80% of tonsils removed surgically may have adenoviruses isolated from the tissue, suggesting that these viruses may remain in a latent state for years.[149,150] Virus has been also isolated from lymphocytes, kidney, blood, cerebrospinal fluid, and most body organs.[9,11,12,54,55,93,151–153] In the lungs, extensive pathology has been found with microscopic necrosis of the tracheal and bronchial epithelium.[39] Acidophilic intranuclear inclusions are seen in bronchial epithelial cells in addition to the basophilic masses of cells surrounded by clear halos, which may indicate aggregations of viral material.[54] A mononuclear infiltrate, rosette formation, and focal necrosis of mucous glands are characteristically seen.

Three types of interaction of adenovirus with infected cells can occur. A lytic infection may take place during which the virus completes an entire replicative cycle.[59] Between 10^5 to 10^6 progeny viruses per cell are produced, of which only 1% to 5% are actually infectious.[59] The second type of interaction is chronic or latent infection, in which small amounts of virus are produced, and an inapparent infection results. Viral shedding from the gastrointestinal tract may occur for years.[39] In fact reactivation of such latent infection likely explains much adenovirus disease in the severely compromised. Correspondingly, monitoring viral loads in the stool of transplant patients has predicted disseminated disease and been useful in guiding antiviral therapy.[154]

In addition to aerosolization, intestinal shedding of respiratory virus is an important factor to consider in the prevention of nosocomial spread in hospitals and chronic care homes.[39,145,155] Persistent infection has been reported in epithelial cells from monkeys.[156] Lymphoid cells are thought to be the reservoir for these persistent infections.[157,158] The third type of interaction is oncogenic transformation, whereby the viral DNA is integrated into the host genome and replicated with the cellular host DNA, but only the early steps in the viral cycle occur and no infectious virions are produced.[159]

The genes from adenoviruses are expressed in the cell nucleus in two phases: "early" (E), which precedes viral DNA replication, and "late."[157] Early genes encode proteins that function to thwart immunosurveillance, especially those from the E3 transcription unit.[157] The late genes primarily encode viral structural proteins. The functions of the E1 proteins include the induction of DNA synthesis in quiescent cells, immortalization of primary cells in cooperation with activated *ras* or with the E1B proteins, transactivation of delayed early genes, induction or repression of several cellular genes, and induction of apoptosis. These proteins modulate the sensitivity of adenovirus-infected cells to tumor necrosis factor (TNF),

a key inflammatory cytokine with antiviral properties.[157] None of the E3 genes are required for adenovirus replication in cultured cells, but several of the E3-coded proteins (10.4 K, 14.5 K, and 14.7 K) inhibit TNF cytolysis.[157,160,161] Because a major function of TNF may be to prevent viral replication, the inhibition of TNF by these viral proteins may be a significant mechanism of pathogenesis.

Another significant E3-coded protein is Gp 19 K. This glycoprotein is located in the endoplasmic reticulum and forms a complex with class I antigens of the major histocompatibility complex (MHC), preventing cells from being killed by cytotoxic T lymphocytes.[157] A cotton rat animal model was used by Ginsberg and colleagues and Ginsberg and Prince to study the pathogenesis of Ad2 and Ad5, which cause pneumonia similar to that seen in humans.[160,162] Two phases of infection were seen; the initial phase, characterized by the infiltration of monocytes and neutrophils, and a later phase associated with the infiltration of lymphocytes. The pathology seemed to reflect the response by host immune defenses to viral infection. The Gp 19 K markedly reduced the transport of the class I MHC to the surface of the infected cells and impeded the attack of cytotoxic T cells.[157,160,161] It is now known that only the early genes are required to induce the complete pathogenesis of adenovirus infection in cotton rats.[161] Although several cytokines, such as TNF-α, interleukin-1, and interleukin-6, were elaborated during the first 2 to 3 days of the infection in the cotton rat model, only TNF-α had a major role in pathogenesis.[161] Steroids almost completely eliminated the pneumonic inflammatory response to infection.[161]

Pathology caused by latent infection with adenoviruses has been linked to chronic obstructive pulmonary disease (COPD).[158,162] Some have suggested that childhood viral diseases represent an independent risk factor for COPD.[163] The adenoviral E1A proteins can stimulate the transcription of many heterologous viral and cellular genes. These proteins have the ability to interact with the DNA binding domains of several cellular transcription factors and activate a wide variety of genes.[164,165] The adenoviral genome has been found to be present in the lungs of more patients with COPD than in control subjects.[166] E1A proteins are expressed in epithelial cells of human lung tissue, and by increasing the expression of several genes important in controlling the inflammatory process, these may contribute to the pathogenesis of COPD. The events described may amplify the airway inflammation associated with cigarette smoking.[161]

The isolation and cloning of a 46-kDa protein adenovirus receptor, which mediates attachment and infection of group B viruses, may facilitate the development of new strategies to limit diseases caused by adenoviruses.[167] The more common receptor is referred to as CAR. This protein has been identified as the receptor for the coxsackie B virus and adenoviruses. Recently, another receptor, desmoglein 2, was identified for Ad3, Ad7, Ad11, and Ad14 strains.[168]

Laboratory Diagnosis

Adenoviral infections generally cannot be diagnosed on clinical grounds alone because the clinical signs and symptoms of these infections are variable and often resemble those caused by other microorganisms.[101] Traditionally, laboratory support and qualified personnel are necessary to accurately diagnose adenoviruses infections. Considerations include specimen type and timing, collection and storage procedures, types of laboratory tests performed, including serological assays, and availability of newer types of diagnostic assays.

Specimen Collection. The optimal specimen for diagnosis of adenovirus infection depends on the clinical presentation and the suspected type.[101] Adenoviruses can be detected in a variety of specimens, including nasal and throat secretions, conjunctival scrapings and swabs, stool, blood, cerebrospinal fluid, and biopsied tissue specimens. Specimens should be collected early in the illness and shipped promptly at 4°C or on dry ice if prompt testing is not possible. Swab and fresh tissue specimens must be transported in appropriate viral transport media[40,58,84,101] whereas fluid samples like urine, stool, and cerebrospinal fluid should not be diluted in transport media. For culture, nonsterile specimens should be treated with antibiotics prior to inoculation. Stool specimens are brought to 10% to 20% suspensions with buffered saline and clarified by low-speed centrifugation. Blood for culture or molecular testing should be collected with an anticoagulant to prevent clotting. Serum separated from clotted blood samples can be used for serological diagnosis (see below).

Cell Culture. Through biological amplification, cell culture offers a sensitive method for adenovirus detection by monitoring for cytopathic effect (CPE). Because adenoviruses are host-specific, isolation of human adenoviruses is most easily accomplished in human cells.[169] Most human adenoviruses have been successfully isolated in cell culture. Several diploid and continuous cell lines, including A549, HeLa, HEp-2, KB, MRC-5 and commercial mixed cell lines with A549 cells, reportedly give good overall recovery and produce typical CPE.[170,171] However, the fastidious enteric adenoviruses Ad40 and Ad41 are an exception. For efficient recovery, most Ad40 and Ad41 strains require the Graham-293 Ad5-transformed secondary HEK (human embryo kidney) cell line for primary isolation.

CPE may develop slowly in monolayers of inoculated cells necessitating several subpassages before becoming visible. Infected cells become rounded, enlarged, and refractile and aggregate into irregular "grape-like" clusters.[40] A 4-week incubation with blind passage is recommended. A rapid procedure for culture identification of adenovirus is the shell vial technique. Here, cell monolayers prepared in glass vials or multiwell plastic culture plates are inoculated with the clinical specimen, centrifuged, and stained after 2 to 3 days incubation with commercial monoclonal antibodies.[172] Cell culture is declining as a routine diagnostic method for detection and identification of human adenoviruses as a result of cost and delays. Antigen and molecular detection techniques have supplanted culture in many laboratories (see below).[169] However, while direct detection methods offer important diagnostic benefits, culture is the only means available for obtaining sufficient virus for immunotyping, assessing virus susceptibility to antivirals, and identifying infectious virus in clinical and environmental specimens.

Direct Visualization of Virus Particles

Electron and immunoelectron microscopy[173] were once commonly used to detect and identify the fastidious adenoviruses in stool specimens from young children, thereby establishing their association with acute gastroenteritis.[40,102,174–177] These methods are still used to localize virus in cells from biopsy and autopsy specimens to confirm disease association and to study disease pathology.

Antigen Assays. Detection of adenovirus antigenic proteins can be accomplished by reacting with virus-specific polyclonal or monoclonal antibodies labeled with various reporter systems. Examples include enzyme immunoassay, immunofluorescence assay, time-resolved fluoroimmunoassay, and latex agglutination.[178–181] These assays can be used to detect adenovirus proteins directly in clinical specimens or to

identify virus isolates. Immunoassays are simple to perform, less costly and provide results more quickly than culture or molecular tests, but are generally less sensitive.[181,182] The immunofluorescence assay is often used in the clinical diagnostic laboratory for rapid identification of adenovirus in cells from unfrozen specimens. Point-of-care antigen immunoassays[181,183] for rapid adenovirus detection and immunohistological staining for adenovirus antigens in biopsy and autopsy specimens are still in common use[182,184]

Molecular Assays. Molecular methods are rapidly replacing classical culture and antigen detection for diagnosis of adenovirus infection. The PCR assay in particular has become a popular diagnostic alternative for these viruses, offering the potential for rapid and sensitive detection and being easily tailored for species-specific and type-specific identification as described below. PCR assays[185] using adenovirus group-specific primers individually[185,186] or combined in assays for multiple human pathogens[187] have proven comparable or better than cell culture or immunodiagnostic methods for detection of adenoviruses in clinical samples. Several commercial multiplex assays for respiratory pathogens including adenovirus have been cleared by the U.S. Food and Drug Administration (FDA) for clinical diagnostic use.[188] Use of quantitative real-time PCR assays have the added benefit of allowing monitoring of adenovirus levels that can be used to predict patient prognosis, manage chemotherapy and monitor efficacy of antiviral therapy.[189]

Adenovirus Typing Assays. Once detected, further identification of adenoviruses to species and type can be accomplished by a variety of immunologic and molecular methods to support outbreak investigations and patient clinical management. For example, adenovirus infections in bone marrow or lung transplant recipients can be rapidly fatal. It is in the patients' interest that healthcare providers determine the species and type of any infecting adenovirus as some are more sensitive to specific antiviral therapy.[190] It is also important to learn if the adenovirus represents a community-acquired strain, a healthcare-acquired strain, a donor-associated strain, or the reactivation of a latent virus. Efforts to further identify adenoviruses have led to the discovery of cross-species infections with simian adenoviruses acquired from nonhuman primate reservoirs.[138,191]

Serum neutralization (SN) using defined hyperimmune animal antisera is the gold standard method used for classifying human adenovirus types.[40] SN targets type-specific neutralizing epitopes on the adenovirus hexon and fiber proteins and to a lesser extent on the penton protein. Hemagglutination inhibition (HI) has also been used of immunotyping adenoviruses. HI targets type-specific epitopes on the adenovirus fiber protein, and when used in combination with SN, can identify hexon/fiber recombinant viruses. Because immunotyping methods require reference antisera that are difficult to obtain and standardize and often difficult to interpret, molecular methods have generally replaced immunotyping for rapid routine adenovirus typing.

Numerous molecular methods for species and type-specific identification of adenoviruses have been described, including conventional[192–194] and real-time PCR[195,196] assays using species-specific and type-specific primers and probes, PCR amplification coupled with restriction endonuclease analysis,[197,198] microarrays,[199] and mass spectrometry[200] and, increasingly, PCR-coupled sequence-based typing strategies that target hypervariable regions of the adenovirus hexon or fiber genes or both.[194,201–208] Several commercial assays have been marketed that use PCR to identify human adenovirus to species.[209–211] As molecular typing strategies often focus only on specific hypervariable regions of the virus genome, potentially important virus strains resulting from recombinations or mutations can be missed. McCarthy and colleagues proposed a molecular typing algorithm that combined examinations of the hexon and fiber genes.[212]

Restriction enzyme analysis (REA) of whole-virus genomes can be used to identify genetic variants of a serotype, aiding epidemiologic studies and outbreak investigations.[213,214] Extensive studies of Ad3, Ad4, and Ad7 using REA have been described[20,215–218] and a number of novel viruses have thus been identified.[26] However, REA is work intensive, dependent on virus isolation to recover genomic DNA and requires expertise to perform and interpret, and is therefore restricted to a few experienced laboratories.

Classical and next generation sequencing technologies are increasingly being used to obtain full genomic sequences of human adenoviruses. Genome sequences are available for all human adenovirus prototype types and sequences of newly identified genomic variants are now routinely placed in public domain providing reference data for adenovirus identification.[126] A new whole genome-based characterization system for adenoviruses is under consideration to replace immunotyping for designating new adenovirus types.[31,36]

Serological Assays. Acute adenovirus infection can also be diagnosed by serological demonstration of a fourfold or greater rise in antibody titer between paired acute-phase and convalescent-phase sera. The first acute specimen should be collected as early as possible after onset of illness and the convalescent specimen should be collected 2 to 4 weeks later. Serologic tests for adenoviruses have included complement fixation (CF), HI, SN, indirect immunofluorescence, and enzyme immunoassay (EIA).[169] The classical CF test measures adenovirus-group specific antibodies, and though once widely used, lacks sensitivity. The EIA also measures adenovirus group-specific antibodies, but is more sensitive than the CF test and is readily automated and therefore more widely used today.[40,101,219] HI and SN assays also are more sensitive than CF, but because they measure type-specific antibodies, they are not suitable for routine diagnosis and most reagents are not commercially available.[40] Although valuable for outbreak investigations and essential for seroprevalence and vaccine efficacy studies, serology is rarely used today for clinical diagnosis because of the inconvenience of serum collection and the 2- to 4-week delay needed to obtain convalescent serum.

Treatment and Prevention With Antimicrobials

Currently, there are no FDA-approved treatment or prophylaxis therapies against adenovirus infections. There are numerous off-label therapeutic case or case series reports, but their results are mixed. There are few, if any, controlled, prospective therapeutic studies.[220] In the 1960s, γ-globulin was studied as prophylaxis against adenovirus infections without good effect.[221] However, Maisch and colleagues found a positive effect of intravenous immunoglobulin therapy in patients with adenovirus-associated inflammatory cardiomyopathy.[222] Some studies suggest that interferon-β may have a beneficial effect on EKC and viral cardiomyopathies.[223,224] More recently, adoptive transfer of adenovirus-specific T-cells has been explored with some success but this is now reserved for immunocompromised patients who do not respond to antiviral therapy.[225]

Off-label antiviral use reports of the antivirals ribavirin, cidofovir, ganciclovir, acyclovir, and vidarabine[220,226] have also been disappointing. Only ribavirin and cidofovir have been used often enough to be worthy of discussion. Nebulized ribavirin was used with some success for two children with pneumonia caused by adenovirus.[227] Intravenous ribavirin has

been reportedly used in immunocompromised patients and in patients with hemorrhagic cystitis and disseminated disease.[219,228–231] Intravenous ribavirin was given to 12 adult blood and marrow transplant recipients without appreciable benefit.[232] The mixed reports may be explained by a recent finding that only human adenoviruses of species C are susceptible to ribavirin.[190] In contrast, all species of human adenovirus appear to be susceptible to cidofovir.[190] Perhaps this finding explains the better results with this antiviral drug. In a retrospective study of 45 bone marrow transplant recipients treated with cidofovir for adenovirus infections, 31 (69%) had successful outcomes; however, in 18 (40%) of the 45 patients, cidofovir-associated toxicity developed.[233]

A new experimental oral antiviral therapy against DNA viruses, brincidofovir (formerly CMX001), shows great promise against adenoviruses.[225,234,235] An analog of cidofovir, it does not have cidofovir's renal toxicity profile. Currently, brincidofovir is being evaluated against DNA viruses including adenoviruses. It has been awarded "Fast Track Designation" by the FDA.

EPIDEMIOLOGY

Incidence and Prevalence Data

Because only approximately 50% of childhood adenovirus infections result in disease, prevalence as detected by antibody studies is high.[42,236,237] Those in species C (Ad1, Ad2, Ad5, and Ad6) are usually endemic and acquired in early childhood, often before 2 years of age.[39] By school age, most children have been exposed to several types of adenoviruses. Infections caused by Ad4, Ad7, Ad14, and Ad21 may occur at a later age. Many of the other types occur sporadically or in epidemics. Many adenovirus infections are subclinical or asymptomatic, especially those in species A and D. Conversely, Ad4, Ad7, and Ad21 usually cause symptomatic respiratory disease.[39]

Most types of adenoviruses are thought to be endemic worldwide.[45] In 1983, Schmitz and colleagues[45] summarized 10 years of adenovirus reports sent to the World Health Organization. They noted an increasing prevalence of Ad7, Ad8, and Ad19 and a declining prevalence of Ad3 and Ad4.[45] Age predilections were highly significant for infants for species A (Ad12, Ad18, and Ad31); for infants and small children for species C (Ad1, Ad2, Ad5, and Ad6); for school children for Ad3; for school children and adults for Ad7; and for adults for Ad4, Ad8, and other types of species B, D, and E.[45] A predilection for males was observed for all types in species B and C and in Ad4 and Ad19.[45]

A summary of 2237 clinical adenovirus submissions to 22 U.S. laboratories during a 25-month period (2004–2006) revealed that Ad3 (prevalence: 34.6%), Ad2 (prevalence: 24.3%), Ad1 (prevalence: 17.7%), and Ad5 (prevalence: 5.3%) explained most illnesses among children. The authors noted an increasing prevalence of Ad21 over time.[177]

Even though most types of adenovirus can be found throughout the world, sometimes marked differences are observed in the geographical distribution of specific genotypes. Of particular note are the distributions of Ad3, Ad4, and Ad7 genotypes, with anecdotal suggestions that some genotypes may be more virulent and have competitive advantage.[238] As yet, no clear markers of increased adenovirus virulence have been identified.

In 2009, Lebeck and colleagues[26] reported on 516 clinical Ad3 isolates from 15 U.S. laboratories with restriction enzyme digests. The most prevalent types were Ad3a2 (36.9%), Ad3a50 (27.1%), Ad3a51, (18.0%), and Ad3a17 (4.6%). Ad3a50 and Ad3a51 were newly described strains that became more prevalent in 2006. Multivariable modeling revealed that children younger than 2 years; persons with chronic disease; and persons infected with Ad3a2, Ad3a50, or multiple or rare strains were at increased risk of severe Ad3 clinical disease. Similarly, beginning in 1986, Chile, Uruguay, and Argentina experienced the emergence of a novel Ad7h strain that supplanted the endemic Ad7c strains.[239,240] Among pediatric patients, the Ad7h strain was associated with longer hospitalizations, higher patient temperatures, greater oxygen requirements, and 55% secondary attack rates among siblings, and it explained 94% of adenovirus mortality.[241,242] Similarly, first detected in 1992 in Israel, Ad7d2 spread to the United States in 1996 and since then has been associated with three of the five documented U.S. civilian outbreaks of Ad7[24] and at least one military outbreak.[20] These Ad7d2 outbreaks led to at least 19 deaths and the suggestion that this new genotype was a more virulent strain. In a 2005 report from Iowa, Ad7d2 had displaced other Ad7 strains.[243]

Most recently, a novel genotype of a seldom-detected Ad14 strain (classified as Ad14p1) emerged in the United States and has spread to other countries causing considerable morbidity and death.[28,146,147,244–249] It differs from the Ad14p prototype strain by markedly greater epithelial cell binding, cell cytotoxicity, plaque morphology, and minor mutations in the fiber knob and E1A genes.[250,251,251a]

High-Risk Groups

As noted, virtually all children have adenovirus infections, and, occasionally, these infections are severe and lead to death. Additionally, adenovirus infections are quite common among the immunocompromised and often associated with significant morbidity. Adenovirus epidemics often occur at intensive care units or long-term care facilities. For instance, in 1999 a novel Ad7b variant caused 84% of the 50 residents (age range: 1–46 years) of a New York long-term care facility to become ill, 26 were hospitalized, and 7 died.[252] In a 2007 national U.S. adenovirus study, the authors found risk factors for severe clinical adenovirus disease included age younger than 7 years, chronic disease, recent transplantation, and infection with Ad5 or Ad21.[177]

Epidemics among military populations, especially when adenovirus vaccines were not available, have been particularly well documented.[4] Before the use of vaccines in the U.S. military, Ad4 and Ad7 accounted for 60% of all ARD among hospitalized recruits. Ad3, Ad14, and Ad21 also occurred, but less commonly.[14] Up to 80% of recruits became infected with adenovirus, while seasoned military personnel experienced lower rates.[4] Such outbreaks have also been reported among military recruits in China, Finland, The Netherlands, The United Kingdom, Turkey, Singapore, and South Korea.[253–261]

Modes of Transmission and Reservoirs of Infection

The disease characteristics of the adenoviruses vary by species and type (see Table 10.1).[39] The reasons for these differences are not well understood. Adenoviruses are transmitted by direct contact, aerosolized virus, the fecal–oral route, and via water. Although recent data suggest that human Ad4 and Ad52 may have simian origins,[124,141] and a novel adenoviruses may have crossed species between humans and animals,[137,262] humans are thought to be by far the primary reservoir for human adenovirus.[263]

Significance as a Health Burden

The most common environment for adenovirus transmission is the home. However, high rates of adenovirus transmission

occur wherever large groups of susceptible people gather. Transmission rates are higher in children's institutions and daycare centers, and in lower socioeconomic groups.[46,47] Enteric adenoviruses may be an important pathogen in the daycare setting.[264] Epidemics associated with Ad3 often occur in association with swimming activities.[66] Ad8 has been associated with transmission in physicians' offices.[70]

Nosocomial outbreaks of adenovirus keratoconjunctivitis have been reported from the accident and emergency department of a major eye hospital in the United Kingdom.[265–267] Nosocomial conjunctivitis, pharyngitis, and pneumonia caused by adenoviruses have been noted in hospital intensive care units.[17,268,269]

With increasing numbers of immunocompromised patients in hospitals, adenovirus infections have become of more frequent cause of severe disease.[9] In addition, reactivation of a latent infection could possibly initiate a nosocomial outbreak. Persons with deficient cell-mediated immunity are at greatest risk for adverse outcomes.[39] Bone marrow transplant recipients are especially susceptible to adenovirus infections.[82,110] The death rate among immunodeficient patients with pneumonia may be as high as 60%.[9]

Chronic diarrhea in patients with AIDS is often a diagnostic problem. A prospective study using extensive diagnostic techniques, such as duodenal, jejunal, and rectal biopsies, demonstrated that 6.5% of the patients had adenovirus infections.[270]

Although the civilian experience has not established a requirement for a vaccine, the epidemic nature and extensive morbidity experienced by military recruits during the 1960s demonstrated an overwhelming need for adenovirus vaccines for military use. One well-studied and typical epidemic at Fort Dix, NJ, exemplified this requirement.[15] A platoon of 48 men was followed up prospectively for their 8 weeks of basic training. Of 92 episodes of respiratory illness, 24 required hospitalization. The documented hospitalization rate for ARD due to adenovirus Ad4 was 5/100 soldiers per week.[15] At large basic training posts, this rate translated to approximately 500 to 800 ARD admissions per week, which had a devastating impact on military hospitals.[15,19] Excess medical costs and the fact that soldiers had to be "recycled" owing to lost training time resulted in significant economic loss to the military. Serious disruptions to training schedules led to administrative attempts to control epidemics, such as sleeping head-to-foot and keeping military units separated (cohorting).[19] The impact of adenovirus infections in the military led to the development of adenovirus vaccines.

PASSIVE IMMUNIZATION

While years ago immunoglobulin therapy was not found to be particularly useful in preventing adenovirus infections among military trainees,[220] modern passive immunization strategies may prove helpful. In particular, recently isolating Ad-specific T cells from stem cell donors have been effective in treating hematopoietic stem cell transplantation recipients who develop severe adenovirus that is nonresponsive to antivirals.[37]

ACTIVE IMMUNIZATION

The first adenovirus vaccine prototype was an injectable bivalent Ad4 and Ad7 vaccine grown in monkey kidney cells and formalin-inactivated.[19] After safety tests, a small trial in 1957 reduced admissions for adenoviruses by 98%, and a large trial of 8238 soldiers was 90% effective in reducing hospitalization.[271,272] A trivalent vaccine, which also included Ad3, was also tested.[273] Large-scale production of vaccine lots led to variation in antigenicity, resulting in a lowering of protection rates, with only a 52% reduction in hospital illnesses caused by adenoviruses.[274] Even this low rate of protection was reported in 1965 to have saved the Army approximately $5 million a year.[274] Adenovirus seed lots were found to be contaminated with simian virus 40 (SV40), a virus oncogenic in animals, and in 1963, the license for the vaccine was rescinded.[15] Although this caused considerable concern at the time, an epidemiologic study of 1959–1961 era U.S. Army male veterans showed no evidence of an increased risk of various cancers that plausibly could be the result of an SV40 exposure.[275]

Use of a live vaccine for ARD caused by Ad7 was investigated, and oral administration was reported to induce high antibody levels in 1960.[276] Couch and colleagues[277] and Chanock and colleagues[278] demonstrated that some adenoviruses infect the gastrointestinal tract but do not produce symptoms in adults. This finding led to the administration of the virus as a vaccine in an enteric-coated capsule, which produced an asymptomatic, intestinal infection and neutralizing antibodies.[277,278] Many safety studies were performed in human volunteers, including the administration of Ad4 and Ad7 vaccines separately and simultaneously.[277] Neutralizing antibodies were elicited, and asymptomatic infections were evidenced by the recovery of virus from rectal specimens. Initial vaccine virus production using HEK cells was later modified to use human diploid fibroblast strains WI-26 and WI-38 because the primary cells were not suitable for large-scale production and there was concern of their contamination with other human pathogens.[278] Because some adenoviruses are oncogenic in animals, much attention was given to safety studies in hamsters and the transformation of cell lines by adenoviruses.[279,280]

Additional field trials for the Ad4 vaccine were conducted at Parris Island, SC, and Great Lakes, IL, indicating that the vaccine was highly protective, safe, and antigenic and showed no evidence of transmission among military trainees. Vaccine use led to reductions in ARD rates by 50%.[281,282] Intrinsic vaccine efficacy was as high as 82%.[282]

Use of the monotypic Ad4 vaccine was followed by the appearance of ARD caused by Ad7 at Fort Dix, NJ.[15] The Army Adenovirus Surveillance Program was initiated to identify the agents of ARD and to assess fluctuations in disease patterns.[14]

Before an Ad7 vaccine could be developed and licensed, numerous studies addressed the oncogenicity potential of Ad7 to humans.[283–286] A trial of the Ad7 vaccine demonstrated safety, infectivity, antigenicity, and lack of communicability similar to that observed for the Ad4 vaccine.[287] Additional trials indicated that when the Ad4 and Ad7 vaccines were given simultaneously, no decrease in immunogenicity occurred, and with mass immunization, there was 95% suppression of Ad7-associated disease.[287–289] Numerous outbreaks of Ad21 in military populations in the United States and Europe led to the initiation of studies using an Ad21 prototype vaccine in safety and immunogenicity trials.[290–294] Trials of Ad1, Ad2, and Ad5 vaccines were also conducted with the goal of protecting children.[295] However, Ad1, Ad2, Ad5, and Ad21 vaccine production was never pursued.

Beginning in 1971, live, enteric-coated, oral vaccines for Ad4 and Ad7 were routinely administered, and adenovirus morbidity was greatly reduced.[19] Ad4 and Ad7 vaccines were licensed by the FDA in 1980 and produced by Wyeth Laboratories. In 1994, the Department of Defense was notified that the sole producer of Ad4 and Ad7 vaccines, Wyeth Laboratories Inc, Marietta, PA, would stop production permanently. Beginning in 1984, Wyeth repeatedly notified the Department of Defense of the need to negotiate a contract that would consider the renovation of the existing vaccine production facility.[296] The contract was not renegotiated.[296] Bulk vaccine production ceased in 1995, and the last vaccine was placed in

tablet form in 1996. Through requests for extensions of expiration dates and use of vaccines only during September through March, rather than year-round, the U.S. Department of Defense attempted to obtain maximum benefit from the remaining supply. By 1999, all vaccine supplies were depleted.

After the loss of the manufacture of the Ad4 and Ad7 vaccines, there were many documented outbreaks of ARD due to adenoviruses in U.S. military training centers. The first recorded epidemic took place during April-May 1995, at Fort Jackson, SC, during a lapse of vaccine administration that occurred because of a logistical error that temporarily interrupted vaccine production.[21] Ad4 was identified as the etiologic agent in unvaccinated soldiers who experienced hospitalization rates of 11.6% during basic training.[21] Numerous additional outbreaks occurred at the other U.S. military camps,[20,22,297] some causing large numbers of hospitalizations[22,297,298] and some spreading to more advanced training camps.[299] Results of a nationwide seroprevalence survey among unimmunized U.S. Army trainees confirmed the lack of protective neutralization antibodies to Ad4 and Ad7, with nearly 90% being susceptible to at least one type.[299,300] Evaluation of the epidemic, clinical, and immunological risk factors for adenovirus infection was performed for a subset of patients, demonstrating that anti-Ad4 immunity was low in new recruits, risk of illness was higher in smokers, and 81% of patients from whom paired serum samples were collected demonstrated a fourfold or higher increase in anti-Ad4 titer after infection.[301]

Gray and colleagues provided a concise overview of population-based surveillance for respiratory disease at four U.S. military training centers as the last of the stores of vaccines were depleted.[302] Between October 1996 and June 1998,53.1% of 1,814 throat cultures from symptomatic trainees yielded adenoviruses.[302] Ad4, Ad7, Ad3, and Ad21 accounted for 57%, 25%, 9%, and 7% of the isolates,[302] respectively (although the prevalence of Ad7 detections has markedly declined in recent years).[303] Russell and colleagues[304] examined an estimated 73,748 clinical cases of adenovirus infection that occurred during the period of 1999 to 2004 among U.S. military trainees at eight training sites. They observed that adenovirus explained from 52.3% to 76.4% of detected febrile respiratory illnesses at these sites.[304] The aggregate number of adenovirus infections among U.S. military trainees has fluctuated with the availability of vaccines and season (Fig. 10.3). In some winter months, more than 2200 preventable clinical infections were documented. Realizing that the detected adenovirus illnesses greatly underestimated true clinical disease, Russell and colleagues[304] posited that the true count of clinical adenovirus disease occurring in these camps was an estimated 45,000 cases per year, 90% of which would be prevented were the adenovirus vaccines available. This realization of preventable morbidity was not lost to public health officials inside and outside the U.S. Department of Defense, with many calling for reacquisition and use of the vaccines.[305–308]

On September 25, 2001, 7 years after Wyeth announced permanent cessation of production of the adenovirus vaccines, two widely publicized adenovirus-associated deaths in nonimmunized recruits,[309] and strongly worded letters from the Institute of Medicine and the Armed Forces Epidemiological Board to expedite contract efforts, induced the Department of Defense to contract for production of adenovirus vaccines.[296,306,310,311] The decision to resume production was based on a continuing low prevalence of antibodies to Ad4 and Ad7 in people coming into the military,[300] the occurrence of documented outbreaks when the vaccines were not given,[20–22,302] and almost 30 years of experience of not having ARD outbreaks when potent adenovirus vaccines were being

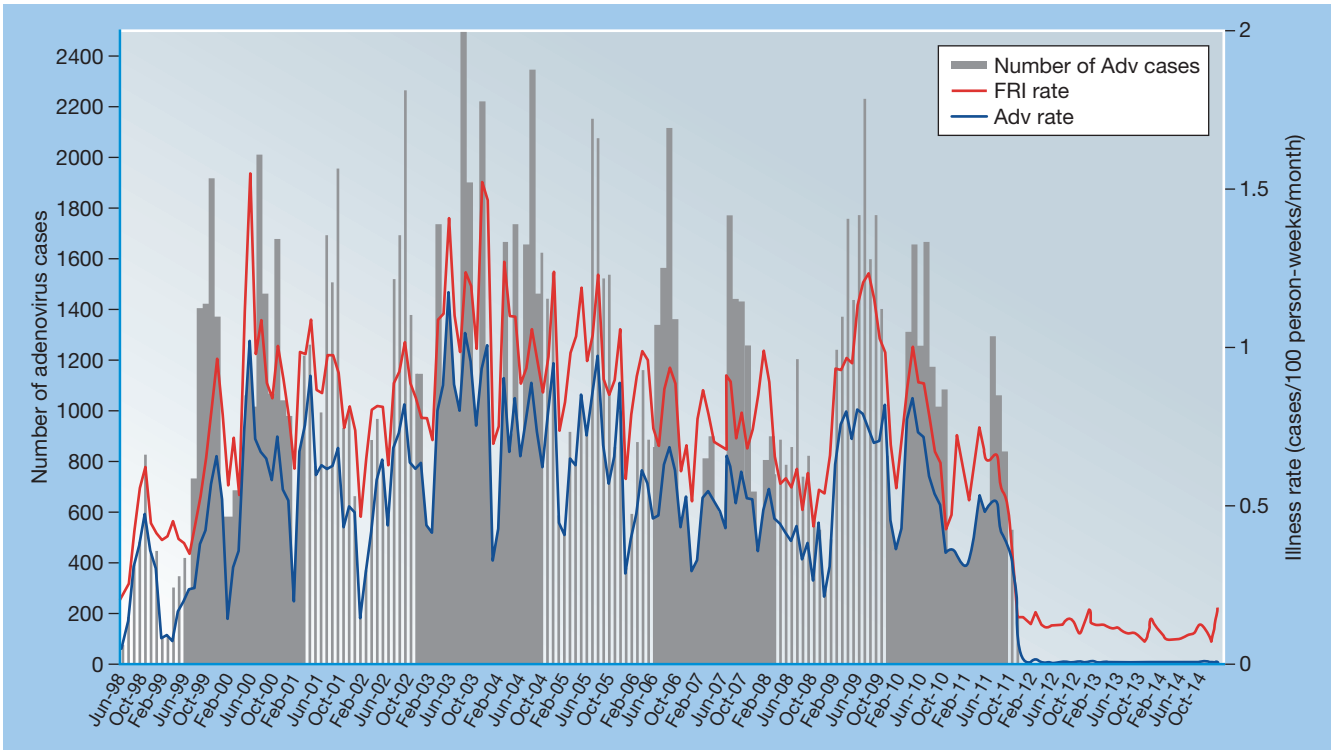

Figure 10.3. Febrile respiratory illness (FRI) and adenovirus (Adv) rates per 100 person-weeks per month with estimated monthly number of adenovirus-associated clinical encounters among trainees at eight U.S. military training sites, June 1998 through December 2014. *(Courtesy Anthony Hawksworth, Naval Health Research Center, San Diego, CA.)*

administered.[19] A genomic analysis of the Wyeth Ad4 and Ad7 vaccine strains show no evidence of attenuation.[312] In 2001 the contract was awarded and seed viruses strains from Wyeth were transferred to Barr Laboratories Inc. (now part of Teva Pharmaceuticals Industries, Inc.).

In the fall of 2004, the Teva Ad4 and Ad7 vaccines were studied in a Phase I double-blind, placebo-controlled trial involving 58 Army medic trainees who had just completed U.S. Army basic training.[313] Among the subjects who had been previously exposed to adenovirus during basic training and before enrollment, 79% and 78% were seropositive to Ad4 or Ad7, respectively. For the trial, 58 initially seronegative subjects were selected. Both vaccines were given to 30, and 28 received placebo tablets. For 32 subjects, final follow-up was permitted at day 180. The participants were closely followed up with cultures, symptom diaries, and clinical examinations during a 56-day period for evidence of vaccine reactions and adenoviral disease. The most commonly reported adverse events in the vaccine recipients were nasal congestion (33%) and dry cough (33%), sore throat (27%), headache (20%), abdominal pain (17%), arthralgia (13%), nausea (13%), and diarrhea (13%). Symptom reporting did not differ between vaccine and placebo groups. Vaccine virus was shed in the stools of 73% and 71% of volunteers seronegative to Ad4 and Ad7, respectively, for as long as 21 days after vaccination. By day 28 after vaccination, 73% of vaccine recipients seroconverted to Ad4, while 63% seroconverted to Ad7. A randomized, double-blind, placebo-controlled Phase II/III trial (NCT00382408) of these vaccines was conducted in 2006–2007 at two military training facilities. Ad4 and Ad7 vaccine or placebo was administered to 4040 U.S. military trainees in a 3 : 1 ratio. As described above the vaccine was found to have excellent efficacy (99.3% for Ad4) and safety profiles similar to the previously manufactured Wyeth vaccine.

In March 2011, after an arduous 10-year vaccine development process, eight likely preventable adenovirus-associated deaths,[314] thousands of hospitalizations, and more than $100 million in funding,[315,316] Teva was awarded FDA licensure for their Ad4 and Ad7 vaccines. The vaccines are indicated for military personnel ages 17 to 50 years of age and contraindicated for persons who are pregnant, who cannot swallow the vaccine tablets without chewing, or who have a severe reaction to the vaccines.

Constituents Including Antibiotics, Preservative, Adjuvants, Etc.

Wyeth vaccine tablets contained live viruses, materials added for the growth and maintenance of viruses and cells, and other pharmaceutical materials. Human-diploid fibroblast cells (strain WI-38) were used for virus preparation, and growth was maintained in Minimal Essential Medium, Eagle solution, antibiotics (neomycin sulfate, gentamicin sulfate, and amphotericin B), fetal bovine serum, and sodium bicarbonate. After harvesting, the viral growth was freed of particulate material by filtration and dried by lyophilization. During drying, additives were used to preserve viability. Before processing into tablets, the virus preparation was diluted with lactose powder.[317]

Using the same Wyeth master seed viruses and a manufacturing process similar to the process Wyeth used, Teva is now producing the Ad4 and Ad7 vaccines. Teva's tablets consist of three layers: a central core containing at least 4.5 $\log_{10}$ tissue culture infective dose ($TCID_{50}$) of lyophilized formulated adenovirus mixed with anhydrous lactose, microcrystalline cellulose, polacrilin potassium, and magnesium stearate, an outer layer of inactive excipients, and a protective enteric coating consisting of cellulose acetate phthalate, alcohol, acetone, and castor oil (Fig. 10.4).[318] The Ad7 vaccine tablet also contains FD&C Yellow #6 aluminum lake dye to give it a distinguishing yellow color.

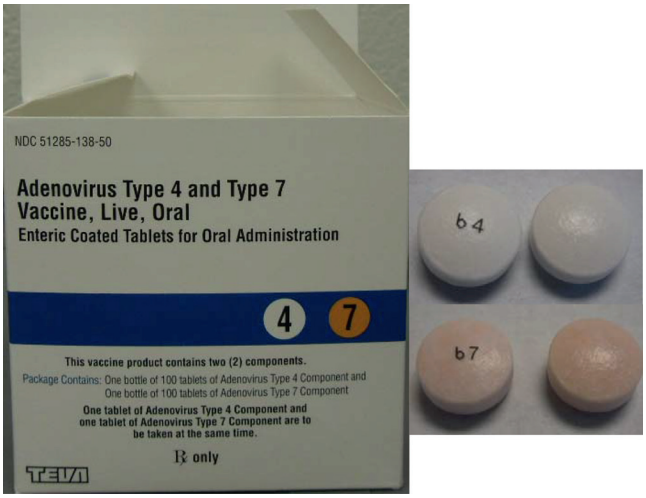

Figure 10.4. Teva Pharmaceuticals Industries Ltd. enteric-coated adenovirus type 4 and type 7 vaccine packaging and tablets. The adenovirus type 7 (b7) tablet is yellow. The enteric coat is designed to resist stomach acid. *(Courtesy John Shaw, Teva Pharmaceuticals, Inc.)*

Preparations Available, Including Combinations

The Teva adenovirus vaccines contain live nonattenuated Ad4 or Ad7 in the form of enteric-coated tablets. They are produced similarly to how the Wyeth vaccines (described above) were produced. The final vaccine is composed of two tablets (one tablet of Ad4 and one tablet of Ad7) designed to pass intact through the stomach and release the live virus in the intestine. Each enteric-coated tablet contains an inner core tablet containing anhydrous lactose, microcrystalline cellulose, polacrilin potassium, magnesium stearate, and live adenovirus, either Type 4 or Type 7, at a potency of no fewer than 32,000 tissue-culture infective doses (4.5 $\log_{10}$ $TCID_{50}$) per tablet. The outer tablet layer contains microcrystalline cellulose, magnesium stearate, and anhydrous lactose, with an enteric coating consisting of cellulose acetate phthalate, alcohol, acetone, and castor oil. The Ad7 tablet also contains FD&C Yellow #6 aluminum lake dye.

The Ad4 vaccine (white tablets) and the Ad7 vaccine (yellow tablets) are packaged in separate bottles and the bottles are combined in a single package.[318] The tablets can be administered simultaneously but have to be swallowed without chewing. Vomiting and diarrhea may interfere with vaccine effectiveness. These vaccines are indicated for military populations shown to be at risk of ARD from the specific adenovirus types represented in the tablets.

The adenovirus vaccines are routinely given to military recruits and U.S. Coast Guard cadets along with numerous other vaccines in the first 8 days after entering training. Type-specific neutralizing antibodies to the adenovirus vaccines are produced in the vaccinated trainees and were associated with protection against ARD. Interference with immune responses when the adenovirus vaccines were given with other vaccines has not been identified.[319]

DOSAGE AND ROUTE: INTRAMUSCULAR, SUBCUTANEOUS, AND ORAL

The initial oral Ad4 vaccine was developed using dried virus contained in enteric-coated capsules and found to be effective in preventing infections.[278] Original trials for Ad7 vaccine were conducted using 0.05 mL of a 1:10 dilution of the Ad7 pool (10^6 $TCID_{50}$) within a hard gelatin capsule and given orally.[277] Time of disintegration within the intestine was assayed roentgenographically using a barium sulfate–containing capsule and varied between 1 and 5 hours.[277] Two small dose ranging studies using vaccine capsules suggested that for both types, nearly 100% seroconversion was achieved by approximately 10^4 $TCID_{50}$ per capsule.[289,313] A 1969 dose-ranging study used three Ad7 doses: $10^{6.8}$ $TCID_{50}$, $10^{4.8}$ $TCID_{50}$, and less than 10 $TCID_{50}$ per capsule.[277,289] There was 100% antibody response with the highest dose, 95% response with the intermediate dose, and 56% response with the lowest dose. Another study evaluated the response when both vaccines were given individually at doses of $10^{5.4}$ $TCID_{50}$ for Ad7 and 10^4 $TCID_{50}$ for Ad4, and simultaneously for both vaccines at the same doses.[287] There was no decrease in the immunogenicity of the Ad4 vaccine when it was given with the Ad7 vaccine.[289] In the mid 1960s, Wyeth Laboratories took over production of the adenovirus vaccines, which were converted to enteric-coated tablets.

Vaccine Stability

The currently licensed Teva vaccines are stored between 2°C and 8°C with a shelf life of 30 months.

IMMUNOGENICITY OF VACCINE

Humoral Responses

Oral adenovirus vaccine recipients routinely shed virus fecally, which can potentially continue for up to 6 weeks.[292,320] Wyeth vaccine recipients developed neutralizing humoral antibody (immunoglobulin [Ig] G, IgM, and IgA).[292] In soldiers who were free of preexisting antibody, an average of 80% to 95% developed a neutralizing antibody level of greater than 1:8, while fewer than 50% demonstrated complement-fixing antibody.[289,321] Neutralizing antibody responses were detected 2 to 3 weeks after vaccination. In general, antibody titers were less than titers achieved after natural infection.[8,282] Local secretory IgA antibody was not induced by the oral vaccine, and reinfection of the respiratory tract was possible, but usually mild or asymptomatic.[322] Since viremia and viruria could occur in patients with febrile disease, invasiveness beyond mucosal surfaces could be important in the pathogenesis of the disease and infection.[323] The serum-neutralizing antibody produced as a result of vaccination may have prevented the typical febrile disease associated with natural infection.[321] Local IgA antibody could be produced experimentally by the intranasal inoculation of an Ad4 vaccine in liquid.[322] A Phase I/II study of the Teva oral Ad4/7 vaccine showed 73% and 63% of immunonaïve subjects seroconverted to Ad4 and Ad7 at 28 days postvaccination.[313] A Phase III study of the same vaccines documented seroconversion at 94.5% (Ad4) and 95% (Ad7).[324]

Cellular Responses

The cellular response to Wyeth Ad4 and Ad7 vaccines has not been well studied. However, the cellular immune responses to some adenovirus-vectored vaccines have been excellent.[325]

Correlates of Protection

A SN assay value of 1:4 against a specific virus is considered as protective.[315] A fourfold rise in titer is considered as evidence of infection.

Special Groups (e.g., Immunosuppressed)

Although some early Ad1, Ad2, Ad4, and Ad5 vaccine trials were conducted among civilians,[320,326,327] the Teva vaccines have not been used in groups other than healthy military trainees.

EFFICACY AND EFFECTIVENESS OF VACCINE

Military recruits who received Ad4 vaccine exhibited increased resistance to respiratory disease caused by this virus.[278,281,328] A number of major well-controlled studies of more than 42,000 soldiers were performed from 1963 to 1966.[329] Use of the vaccine reduced ARD by 50% and adenovirus infection in recruits by more than 90%.

Field trials began in 1969 for the Ad7 vaccine. The trials indicated protection against disease in susceptible persons.[288,289,330] In addition, it was found that the two vaccines (for Ad4 and Ad7) could be administered simultaneously without interference or loss of efficacy.[288,289,331] As a result of using the vaccines at one large Air Force base during a 9-year period, ARD caused by adenovirus disappeared.[332] The adenovirus surveillance program demonstrated that the combination of the two adenovirus vaccines was highly effective in controlling epidemic ARD.[14] From 1971 to 1999, the live enteric-coated Ad4 and Ad7 vaccines were administered to new military recruits and successfully controlled ARD caused by adenoviruses.

The Phase III double-blind, placebo-controlled efficacy trial of the Teva Ad4 and Ad7 vaccines conducted in 2006 found the vaccines to be 99.3% effective in reducing Ad4-caused ARD.[324] Two years after their reintroduction, the Teva vaccines were credited with a 100-fold decline in military trainee adenovirus cases and with the prevention of 1100 to 2700 hospitalizations each year.[303]

Duration of Immunity and Protection, Including Description of Reinfection, If Any

The duration of immunity and persistence of circulating antibody following immunization has not been well studied. The adenovirus vaccines were developed to protect new members of the military (recruits) against Ad4 and Ad7 respiratory disease during the first months of military service. The adenovirus vaccines were very effective in accomplishing that objective, and immunity beyond 56 days has not been studied.

Safety

Common Adverse Events

Four study groups were followed up for inpatient and outpatient episodes of illness during vaccine safety and immunogenicity trials at Lackland Air Force Base, TX, in 1976. In addition to the placebo group, one group received three vaccines simultaneously (Ad4, Ad7, and Ad21), another group received two vaccines simultaneously (Ad4 and Ad7), and the last group received one vaccine only (Ad21).[294] No appreciable differences were noted in the inpatient or outpatient experiences of the different groups.[294]

Studies of the various live adenovirus vaccines have documented fecal and pharyngeal shedding of vaccine virus and

transmission to nonvaccinated study participants.[295,320,321,324,333] Although recent trials of the Teva vaccine demonstrated sparse transmission among military personnel,[324] the possibility of transmission of vaccine virus to other susceptible personnel should be considered for up to 4 weeks after receipt of modern vaccines.

Rare Adverse Events

In 1973, a Navy trainee was hospitalized with fever, malaise, and dyspnea for 11 days after receiving the Ad4 and Ad7 vaccines.[334] The patient died on the 10th hospital day with the diagnosis of Ad7 pneumonia, based on the isolation of the virus by cell culture. However, it was not possible at the time to determine whether his infection was caused by a wild Ad7 before the development of vaccine-induced immunity or to an Ad7 vaccine strain.[334]

Immunocompromised Recipients

As adenoviruses may cause severe disease among immunocompromised persons, when HIV was first discovered, concern grew among U.S. military public health officials that adenovirus vaccine might cause severe disease among HIV-infected military trainees. Subsequently, a study was conducted among HIV-infected and uninfected military trainees. Although significantly fewer HIV-infected subjects responded to the Ad4 vaccine than did soldiers without HIV infection, no clinically apparent adverse reactions were detected.[319] Response to the Ad7 vaccine was difficult to define because many vaccine recipients in both groups had high neutralizing antibody titers at the time of vaccination.[319] More severely immunocompromised persons, who might inadvertently be infected with adenovirus vaccine virus through fecal shedding from "normal" vaccine recipients, have not been studied.

Pregnancy

The live, oral adenovirus vaccines were never subjected to animal reproduction studies because of the lack of a suitable animal model. Therefore, it is not known if these vaccines had the potential to cause fetal damage if given to a pregnant woman or to affect reproductive capacity. Female military trainees are screened with pregnancy tests before they received the adenovirus vaccines. During the recent Teva vaccine trials four of the subjects were found to be pregnant after they had received the Ad4 and Ad7 vaccines.[318] All four subjects delivered healthy babies at 36 to 40 weeks' gestation. Unusual morbidity among pregnant vaccine recipients has not been reported.

Spread to Contacts

Because the virus may be shed fecally for up to 6 weeks, the virus may be spread to family members or very close contacts.[320,326] Hence, vaccine recipients are instructed to maintain good hygiene and to avoid contact with children younger than 7 years of age, the immunocompromised, and pregnant women for 28 days following vaccination.[318] The spread of vaccine virus has not been well studied. In the recent Phase II trial of the Teva vaccines, participants were followed shedding on days 0, 7, 14, 21, 28, and 56. Periodic fecal shedding was noted 7 to 21 days following vaccination.[313]

INDICATIONS FOR VACCINE—WHO AND WHY

Adenovirus vaccines have been indicated for the prevention and control of specific adenovirus-associated ARD in populations with a high risk of exposure, a high level of susceptibility, and a high risk of subsequent infection and disease. Adenovirus vaccines were recommended for use in military populations at risk of developing ARD from adenoviruses. Use of these vaccines was not recommended for other populations. Current and future studies of virus transmission and disease occurrence in pediatric populations, chronic care, and other civilian institutional settings; high-level healthcare organizations; and colleges may identify other potential indications for adenovirus vaccines.

In 1971, the U.S. military began routinely administering both vaccines to males reporting to recruit training centers, but only during the winter months.[15] The incoming recruits were given the vaccines within hours of arrival at a training center to obtain protection as early as possible in the training program. Initially, women were not given the vaccines because ARD outbreaks caused by adenoviruses had never been documented among military women, and there was concern about the possibility of administering the vaccines to women who were pregnant.[19]

The program of administering the vaccines only during the high-risk winter months was directed at control, rather than eradication of ARD caused by adenoviruses.[15] With this schedule, late spring and early fall outbreaks occurred. These outbreaks prompted the U.S. Army and the U.S. Navy to adopt policies of year-round administration of both adenovirus vaccines in 1983.[19] Taking a different course, the U.S. Air Force stopped the administration of adenovirus vaccines at its only recruit training center in Texas in the mid-1980s and adopted a program of surveillance with use of the vaccines only as indicated.[19]

When the military started immunizations to protect against ARD caused by adenoviruses, training programs were segregated by gender. These separate training programs have since been combined, leading to concern that the risk for ARD caused by adenoviruses would be the same for men and women. The U.S. military regulation for immunizations required that, based on risk, Ad4 and Ad7 vaccines be administered simultaneously and only once to Army, Navy, and Marine Corps recruits.[335] In the Air Force and Coast Guard, the vaccines were administered when directed by the appropriate authority.[335] The same regulation described precautions to be taken to avoid unintentional administration of the vaccines during pregnancy and counseling instructions regarding the possibility of pregnancy within 3 months following immunization.[335]

In response to the cessation of adenovirus vaccine production in 1996, the Army, Navy, and Marine Corps modified their policies of year-round vaccine administration to conserve the remaining vaccine for use in higher-risk months only. The modified policies directed that the vaccines be given to arriving military recruits only during the period of September 1 through March 31 until all vaccine stocks were exhausted in 1999.

CONTRAINDICATIONS AND PRECAUTIONS

Teva uses no antibiotics in the virus propagation steps. The vaccine is contraindicated for pregnant women, immunocompromised patients, persons outside the target age range of 17 to 50 years, persons who cannot swallow the tablets whole, or persons who are allergic to the vaccines.

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Effects of Vaccination, Including Herd and Contact Immunity

In the prevaccine era, ARD from adenoviruses caused significant morbidity at military training centers. These outbreaks

were extremely costly in terms of medical care requirements and time lost from training.[19] The routine administration of the Ad4 and Ad7 vaccines, which began in 1971, resulted in an extremely efficacious, cost-effective, and safe immunization program.[19,336–338] Initially, the vaccines were administered only during the high-risk winter months. The occurrence of spring and fall outbreaks prompted a modification of the program to administration of the vaccines year-round.[19] From 1971 to 1999, except for a period in the 1970s when ineffective vaccines thought to be contaminated with solvent were used,[15] there has never been a reported outbreak of ARD caused by Ad4 or Ad7 in U.S. military units that received the vaccines. Outbreaks of ARD caused by Ad14 and Ad21 have occurred, but these have been sporadic.[19,294,339]

A problem in the administrative system used to procure vaccines for the U.S. military resulted in an adenovirus vaccine production delay that began in the spring of 1994 and lasted until late February 1995.[19] There was only one outbreak of ARD caused by adenoviruses reported in conjunction with that production delay.[21] When Wyeth Laboratories announced in 1994 that it would no longer produce the adenovirus vaccines, many in the U.S. Department of Defense and the different military services asked if the vaccines were still needed. Some thought that improved military barracks with modern heating, ventilation, and air-conditioning systems may have significantly reduced the risk of transmission of the adenoviruses and subsequent disease in susceptible people. The assessment of current risk was hampered by the lack of modern seroprevalence data for Ad4 and Ad7 among new military entrants and the lack of studies of adenovirus carriage, transmission, infection, and disease because the vaccines had been so successful. The U.S. Department of Defense also found it had lost the capability to perform serologic studies for adenovirus infections. Unfortunately, with the loss of the vaccines, adenovirus-associated ARD increased in all uniformed services, including the U.S. Air Force.

Disease Control Strategies

Ad4 and Ad7 vaccines have been the primary means for controlling adenovirus-induced ARD among U.S. military trainees. Secondary control measures have included reducing crowding, aligning trainees' beds head-to-foot, making frequent hand washing a requirement, increasing air exchanges, and keeping contact between different cohorts of recruits to a minimum (cohorting).[340–342] Although interventions like frequent hand washing[340] caused a 45% reduction in upper respiratory tract infections among trainees, the numerous attempted interventions fell far short of the effectiveness of administering adenovirus vaccines in reducing ARD.

Cost-to-Benefit Information

The excess morbidity caused by ARD and associated costs are of significant concern to the U.S. military. A number of cost-to-benefit analyses have been performed each showing significant benefit in using the vaccines.[336–338] Using an estimated cost for receipt of both vaccines at $150 and using the vaccines year-round in approximately 200,000 trainees per year, Radin and colleagues,[303] estimated the U.S. Department of Defense would prevent approximately 6000 to 13,000 clinical adenovirus cases and 1100 to 2700 hospitalizations per year, saving the U.S. government approximately $20 million per year in training and medical costs.

FUTURE VACCINES

Subunit Vaccine

In 1963, soluble viral subunit antigens were found to be highly immunogenic on parenteral administration in animals.[321,343] Crystalline hexon and fiber antigens from Ad5 have been shown to induce neutralizing antibody and protection in human volunteers who were challenged.[344] There has been no additional development of these antigens as potential vaccines. However, adenovirus vaccines consisting of soluble viral subunit antigens would be free of DNA and could alleviate fear of the oncogenic potential of adenoviruses.[321]

Recombinant Vaccines

Advances in molecular biology have permitted the in vivo and in vitro gene transfer into mammalian cells using various adenovirus constructs. Genetically engineered adenoviruses have been altered to carry genes from a wide array of other pathogens including influenza A virus,[345] Ebola virus,[346] and Middle East respiratory syndrome–coronavirus,[347] and to introduce genes as a therapy against various chronic diseases. Adenovirus vaccine construct research is quite dynamic. A detailed description is beyond the scope of this textbook. However, excellent reviews have been published discussing the advantages and drawbacks of recombinant adenovirus vaccine strategies.[348–355]

11 Anthrax Vaccines*

Arthur M. Friedlander, John D. Grabenstein, and Philip S. Brachman†

Anthrax, a zoonotic disease caused by *Bacillus anthracis*, has three forms: cutaneous, inhalational, and gastrointestinal. Mortality in untreated cutaneous cases is approximately 20%, but less than 1% if antibiotics are promptly given. Inhalational anthrax is almost 100% fatal if untreated, and gastrointestinal cases have an untreated mortality rate of 25% to 75%. Meningitis may be a complication of any of the three forms of disease. Natural cases are primarily associated with industrial, agricultural, or laboratory exposure. The natural disease is not a major global public health problem, although occasional epidemics occur. However, the intentional use of *B. anthracis* as a bioweapon in the fall of 2001 in the United States irrevocably altered our views of public health, not just for anthrax, but also for many other infections with bioterrorism potential.

Historically, anthrax is considered to have been the fifth and sixth plagues described in *Exodus* (circa 1491 BC). Hippocrates described the disease in approximately 300 BC. Europeans recorded epizootics and epidemics in the 16th century. Between 1750 and 1850, the disease in both humans and animals was described in detail, and the organism was characterized. An epidemic of presumed gastrointestinal anthrax occurred in 1770 in Haiti and involved approximately 15,000 people; it was attributed to the ingestion of contaminated beef during a famine.[1]

In the 1870s, Koch cultured *B. anthracis* on artificial media and demonstrated definitively for the first time the microbial etiology of an infectious disease. In 1881, Pasteur attenuated the organism and conducted a successful field test of his attenuated vaccine strain administered for livestock. Greenfield performed similar work at the same time.[2] In the late 1800s and early 1900s, cases of cutaneous and inhalational industrial anthrax involved rag pickers in Germany and woolsorters in England.[3] The term *woolsorters' disease* referred to inhalational anthrax. Because of the large number of reported cases in England, a wool disinfection station was established in Liverpool.[4] All incoming wool and other animal fibers were disinfected using formaldehyde baths before being further processed. Subsequently, the number of cases of anthrax among these workers decreased significantly.

Cases of human anthrax have been reported from almost every country. However, the actual number of cases in the world is at best an estimate. In 1958, Glassman[5] estimated the annual worldwide incidence at 20,000 to 100,000 cases. In the 1980s and 1990s, the total global reported disease decreased to an estimated 2000 cases annually.

Industrial cases occur primarily in European and North American countries, and are associated with the processing of animal materials, such as hair, wool, hides, and bones. Agricultural cases occur primarily in Asian and African countries and result from contact with diseased domesticated animals or their products, such as hair, wool, hides, bones, and carcasses, including meat.

In the United States, the earliest reports of animal anthrax came in the early 1700s from what is now Louisiana. Sporadic animal cases were reported later from almost every state. Areas with more regularly reported animal cases are now called anthrax districts and primarily include the Great Plains states. Human anthrax was first reported from Kentucky in 1824. Human cases subsequently occurred throughout the United States, with the majority reported from industrialized states in the Northeast. However, as the textile industry moved to other parts of the country, human cases arose in the new locations.

Several unusual epidemics have been reported since the late 1970s. The largest epidemic in modern times occurred in Zimbabwe, with approximately 10,000 human cases reported between 1979 and 1985, including approximately 7000 cases occurring in 1979 and 1980.[6–8] Most people had cutaneous lesions, but some gastrointestinal cases also were reported. The source of the infections was infected cattle.

Another unusual epidemic occurred in Sverdlovsk, Russia, part of the Soviet Union, in 1979, after an accidental release of spores from a military microbiology facility. In this epidemic, at least 77 human cases of inhalational anthrax with at least 66 deaths occurred among people exposed to aerosolized *B. anthracis* organisms.[9,10] Some cases also occurred in sheep and cattle grazing as far as 50 km downwind from the facility, possibly as a result of the same release, although natural anthrax outbreaks previously had been reported from the region. In 1995, Iraq admitted to the United Nations that it produced weapons containing anthrax spores and was prepared to launch them during the 1991 Persian Gulf War.[11]

In late September 2001, a Florida man developed inhalational anthrax, the first case in the United States since 1976 and subsequently died.[12] Initially, it was regarded as an isolated case, but it became the first among 11 confirmed inhalational cases and seven confirmed and four suspected cutaneous cases of anthrax reported from Florida, New York, New Jersey, the District of Columbia, and Connecticut.[13–15] Exposure to contaminated mail was the confirmed or apparent source of infection in all these patients.[13–16] Among cutaneous cases, lesions developed on the forearm, neck, chest, or fingers.[17] Of the 11 inhalational cases, the median age was 56 years (range: 43–94 years). The presumed incubation period from exposure to onset of symptoms ranged from 4 to 6 days.[15] Additional details of these cases will be subsequently described. An unusual epidemic of anthrax cases arising secondary to heroin injection began in Europe in 2009 and continues. Since the first report of injectional anthrax in a heroin addict in 2000,[18] there have been more than 70 laboratory confirmed cases with a 37% case fatality rate reported from four European countries, some with unusual clinical syndromes.[19–21] These included cases with compartment syndrome or necrotizing fasciitis and others who presented with acute abdominal pain and signs of peritonitis associated with groin heroin injection. In most cases, the typical lesion consisting of an initial papule progressing to eschar, as described below, was absent.

The incidence of human anthrax in the developed world is extremely low. However, the impetus for the development of an improved human vaccine is the threat of *B. anthracis* used

*Opinions, interpretations, conclusions, and recommendations are those of the authors and are not necessarily endorsed by the U.S. Army.

†Deceased.

as a biological weapon. This worrisome possibility was given credence by the 1979 Sverdlovsk incident and the 1991 Iraqi experience, and prompted the U.S. Department of Defense to begin anthrax vaccinations for some members of the U.S. Armed Forces on March 10, 1998. The 2001 bioweapon attacks in the United States confirmed fears and heightened interest in the effort to develop new vaccines. The specter of anthrax spores used as a bioweapon against civilian populations on a larger scale than that yet experienced poses potential catastrophic consequences.[22] Given that spores can persist in experimentally infected animals after treatment with antibiotics for well over 30 days,[23–26] the major efforts directed to the management of such an event include early diagnosis and postexposure prophylaxis with antibiotics and vaccination.

BACKGROUND

Clinical Description

There are three primary forms of anthrax: cutaneous, inhalational, and gastrointestinal.[27] Secondary meningitis can occur with all three forms but is most often observed with inhalational anthrax. Rarely, meningitis has been reported without a primary site identified. In the United States, approximately 95% of reported cases of clinical anthrax have been cutaneous and 5% inhalational.

Cutaneous Anthrax

The incubation period for cutaneous anthrax is 1 to 7 days (usually 2–5 days). The lesion is first noted as a small, pruritic papule. Within several days, the papule develops into a vesicle 1 to 2 cm in diameter. Occasionally, the initial papule is surrounded by a ring of vesicles, which coalesce to form a large vesicle. The vesicular fluid is clear or serous colored and contains numerous *B. anthracis* organisms and a paucity of leukocytes. Nonpitting edema and erythema may develop around the lesion. Pain is not present unless there is secondary infection. The vesicle may enlarge to 2 to 3 cm in diameter, sometimes becoming hemorrhagic. Systemic symptoms are usually mild and include malaise and low-grade fever. There may be regional lymphangitis and lymphadenopathy. Approximately 5 to 7 days after the skin lesion, the vesicle ruptures, revealing a straight-edged, depressed ulcer crater that develops a black eschar. During a period of 2 to 3 weeks, the eschar loosens and falls off, usually without leaving a scar. The evolution of the eschar is not affected by antibiotic treatment.

The lesions most often occur on an exposed part of the body, such as the face, neck, or arm. Large, irregularly shaped cutaneous lesions have been reported in some industrial cases after many organisms were rubbed into the skin. Occasionally, extensive ocular involvement occurs, with orbital involvement leading to damage to the lids and ductal system.

More severe cutaneous involvement is referred to as malignant edema, in which multiple bullae surround the site of the initial lesion and extensive local edema, induration, and toxemia are present. At times, the edema may be massive, extending from a primary lesion on the neck to the groin.

Rarely, multiple cutaneous lesions have been reported after multiple inoculations of spores through the skin. Reinfections have been rarely reported, but not confirmed.

Cutaneous anthrax in heroin users, arising mainly from IM injection of heroin, has been associated with varying clinical findings from more typical self-limiting skin lesions to atypical abscesses, cellulitis, compartment syndrome, and necrotizing fasciitis with accompanying systemic toxicity and sepsis. The cases of sepsis may result from coinfection with other organisms in the setting of traumatized tissue.[19–21]

Inhalational Anthrax

In 1 to 5 days after inhaling an infectious dose of *B. anthracis* organisms, nonspecific symptoms develop that include malaise, fatigue, myalgia, slight temperature elevation, and minimal nonproductive cough, usually without symptoms of an upper respiratory infection.[28] There may also be a feeling of precordial tightness. Auscultation of the chest may reveal rhonchi. A slight improvement may occur within 2 to 4 days, but then severe respiratory distress develops suddenly, including dyspnea, cyanosis, stridor, and profuse diaphoresis. In some cases, subcutaneous (SC) edema of the neck and chest may be present. Physical examination reveals a patient with toxic symptoms who has an elevated pulse, respiratory rate, and temperature. Physical examination may reveal signs of a pleural effusion. Widening of the mediastinum on radiographic examination of the chest is frequently seen, as are pleural effusions, that may be hemorrhagic. The leukocyte count may be moderately elevated. Shock may develop terminally, and death usually occurs within 24 hours of respiratory distress. Death likely is caused by lymphatic/vascular obstruction in the mediastinum, with pulmonary hemorrhage and edema associated with large hemorrhagic pleural effusions and toxicity.

The patients treated in the 2001 U.S. outbreak frequently reported chills, prolonged and profound fatigue, nausea or vomiting, and chest discomfort.[15] All had abnormal chest radiographs (Table 11.1),[14] with paratracheal and hilar fullness, and pleural effusions, infiltrates or both. In some patients, the initial findings were subtle. Among all eight patients who had not received antibiotics before diagnosis, *B. anthracis* grew in blood cultures drawn at initial examination. Of the 11 patients, six (55%) survived with aggressive supportive care and multidrug antibiotic regimens.[14,15] All five patients with fulminant signs of illness, with severe respiratory distress or hypotension, or meningitis at initial examination, died despite receiving appropriate intravenous antibiotics and supportive care.[13,14] In all fatal cases, autopsy revealed classical edematous mediastinitis with hemorrhage.

A literature review of articles published from 1900 to 2005, some of which include the patients from the 2001 U.S. outbreak, reports the clinical features of 82 cases of inhalational anthrax from 106 reports.[29] The symptoms and clinical features in the 2001 patients were similar to the other cases but the 2001 patients were more likely to have had therapy initiated during the prodromal phase, to have received multiple antibiotics, and to have had pleural fluid drainage. Additional cases occurred in drumhead makers in 2006[30,31] and 2008.[32]

From Jernigan JA, Stephens DS, Ashford DA, et al., for the Anthrax Bioterrorism Investigation Team. Bioterrorism-related inhalational anthrax: the first 10 cases reported in the United States. Emerg Infect Dis. *2001;7:933–944.*

Gastrointestinal Anthrax

Symptoms of gastrointestinal anthrax develop 2 to 5 days after the ingestion of contaminated meat. The initial symptoms of disease consist of nausea, vomiting, anorexia, and fever followed by abdominal pain and diarrhea, which may be bloody. Hematemesis, sometimes severe, may develop. In some cases, the presentation is that of an acute abdomen and has prompted surgical exploration of the abdomen. Physical examination reveals an elevated temperature, pulse, and respiratory rate. Sepsis with toxemia, shock, and death may develop.

Oral–oropharyngeal anthrax occurs when ingested organisms gain entrance to the SC tissues through the oral or oropharyngeal tissue. In these cases, local ulcers, fever, anorexia, cervical or submandibular lymphadenopathy, or edema may develop.

Bacteriology

B. anthracis, the causative agent of anthrax, is a large, Gram-positive, spore-forming, nonmotile bacillus (1.0 to 1.5 × 3 to 10 mm). The organism grows readily on sheep blood agar aerobically and is nonhemolytic under these conditions. The colonies are large, rough, and gray-white in color, with irregular, tapered, curving outgrowths that cause the typical "medusa head" appearance. A loop drawn up through a colony makes the disturbed part of the colony stand upright like whipped egg white. In the presence of high concentrations of carbon dioxide, the organisms form antiphagocytic capsules and two exotoxins, and colonies are noted to be smooth and mucoid. In tissue, the bacteria are encapsulated and appear singly or in chains of two or three bacilli. Bacterial identification is confirmed by the production of toxin, lysis by a specific γ bacteriophage, the presence of a capsule and cell wall polysaccharide confirmed by fluorescent antibody testing, and confirmed virulence when injected in mice and guinea pigs. Polymerase chain reaction (PCR) tests for toxin and capsule genes are also confirmatory. Genetic analyses of different isolates reveal that *B. anthracis* is one of the most monomorphic, homogeneous bacterial species known.[33,34]

The spores are quite resistant to environmental extremes and may survive for decades in soil (see "Epidemiology" below). Recent evidence also suggests that *B. anthracis* infected with lysogenic bacteriophage can survive in soil and colonize earthworm intestines for prolonged periods in the vegetative state and may serve as a source of infectious spores.[35] Viable spores were reported to persist for weeks to months within the lungs of rhesus monkeys after inhalation, while receiving antibiotic treatment. After the cessation of antibiotic treatment, residual spores remain viable and can cause fatal disease.[23–26]

Pathogenesis

The major pathogenic virulence determinants of *B. anthracis* are the capsule and two protein exotoxins, lethal toxin and edema toxin. More recently, additional factors have been shown to contribute to virulence, although to a lesser degree than the capsule and toxins. These other factors include a capsule depolymerase responsible for attachment of the capsule to the cell wall peptidoglycan,[36] a manganese adenosine triphosphate (ATP)-binding cassette transporter,[37] siderophore biosynthesis genes,[38] nitric oxide synthase,[39] a caseinolytic protease component (ClpX),[40] a surface protein that may be involved in cell adhesion (BslA),[41] and a high temperature requirement A gene involved in the bacterial response to stress.[42]

The importance of the capsule was appreciated early in the 20th century when Bail[43] demonstrated that organisms without a capsule were avirulent. However, extensive studies by Sterne[44] and others in the 1930s showed that nonencapsulated strains could induce immunity to anthrax. The strains developed by Sterne[45] have proved remarkably effective as live vaccines for domesticated animals and are used worldwide.

As is true for many bacterial virulence factors, the genes encoding the anthrax capsule are carried on an extrachromosomal 96-kb plasmid (pX02).[46,47] Anthrax strains lacking the capsule plasmid fail to produce capsule and are attenuated.[48] The capsule is a homopolymer of poly-D-glutamic acid and enhances virulence by making the organism resistant to phagocytosis and to lysis by cationic proteins.[49,50] Capsule released from the surface may also interfere with resistance[51] and with maturation of antigen presenting cells induced by peptidoglycan resulting in reduced chemotaxis of these cells to chemokines.[52]

A role for toxins in anthrax pathogenesis was suspected from the earliest studies by Koch,[53] but it was not firmly established until 1954, when Smith and Keppie[54] demonstrated that sterile plasma from experimentally infected guinea pigs was lethal when injected into other animals. Evans and Shoesmith[55] showed that *B. anthracis* culture filtrates produced edema after injection into the skin of rabbits. Additional work in the 1950s and 1960s evaluated the impact of toxins in disease and immunity.[56,57] Since the mid-1980s, many advances have been made in the understanding of the molecular biology of the toxins and their effects on multiple cell types in vivo and in vitro.[58] Nevertheless, their precise role in pathogenesis remains undefined. Anthrax has been characterized as being due to a large bacterium that produces a feeble toxin.[59] Although it is clear that anthrax is an invasive disease and that anthrax lethal toxin, when given intravenously, is relatively impotent compared with other bacterial toxins, the lethal and edema toxins are essential for virulence and thought to be important in the establishment of disease by impairing host defenses.

The anthrax lethal and edema toxins, like many bacterial toxins (e.g., diphtheria, tetanus, botulinum), have a binding domain by which they bind to target cell receptors and an active domain that is responsible for the biochemical and usually enzymatic activity of the toxin. However, the anthrax toxins are unusual in that the binding and active domains exist in two distinct proteins, and the two active domain proteins share the same binding protein. This binding protein is called protective antigen (PA). PA combined with a second protein called lethal factor (LF) constitutes the anthrax lethal toxin, which is lethal when injected into experimental animals.[60,61] The same PA combined with a third protein, edema factor (EF), constitutes the edema toxin, which causes edema when injected into experimental animals[60,61] and can also be lethal for some animals.[62] The edema toxin is responsible for the massive edema that may be present in cases of anthrax, whether in the skin or mediastinum. The 89-kDa EF is a calmodulin-dependent adenylate cyclase that raises intracellular cyclic adenosine monophosphate (AMP) levels.[63] The 85-kDa LF is a zinc metalloprotease that inactivates mitogen-activated protein kinase interfering with multiple host cell signaling pathways.[64,65] Toxicity in macrophages appears to be mediated through activation of caspase-1, requires a specific inflammasome protein, and results in lysosomal permeabilization.[66–68] Consistent with this model, each of the individual proteins alone lacks biologic activity.

The crystal structures of PA,[69] LF,[70] and EF[71] have all been determined. The current model, based on cell culture studies, proposes that PA first binds to a host cell toxin receptor (Fig. 11.1). Two of these receptors have now been identified,[72,73] and additional cell-surface proteins may modulate their activity.[74] PA then is cleaved by a cell-surface protease, releasing a

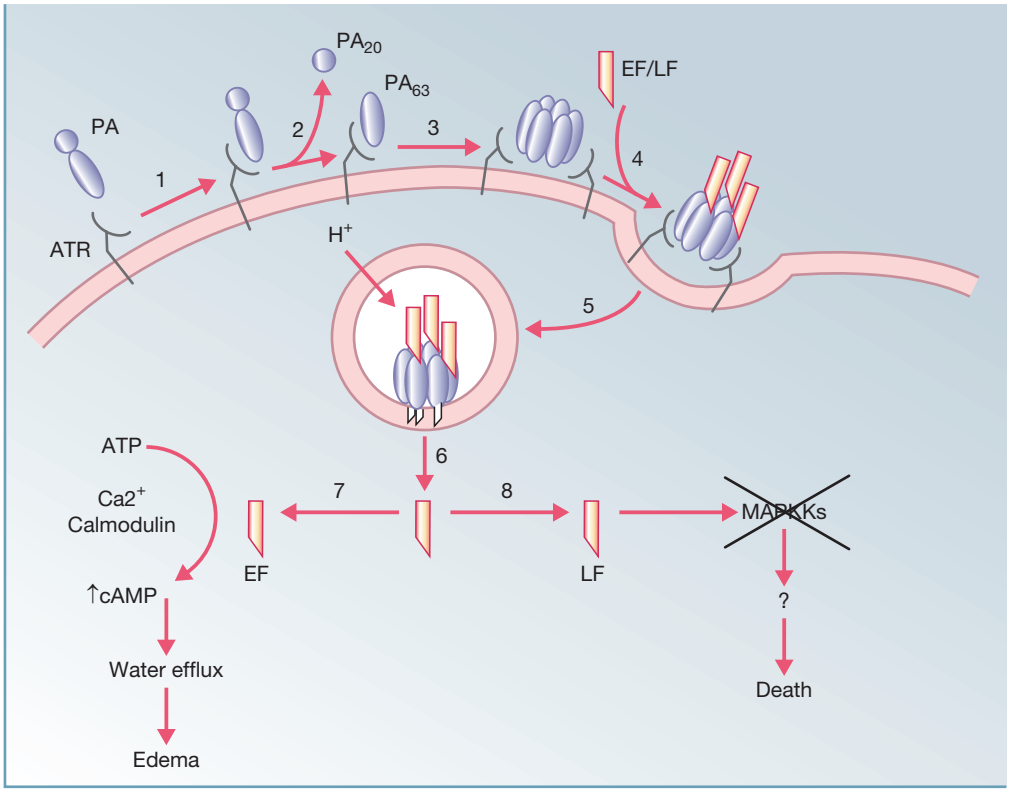

Figure 11.1. Model of anthrax toxin action. Protective antigen (PA) secreted by *Bacillus anthracis* binds to a membrane protein receptor (ATR) *(1)*, two of which have been described. The PA is then cleaved by the protease furin *(2)* with release of a 20-kDa fragment and oligomerization of the remaining 63-kDa monomer *(3)*. The PA_{63} oligomer then binds edema factor (EF) or lethal factor (LF) *(4)*. The complete toxin is then endocytosed *(5)* and trafficked to endosomes. At the low pH of the endosomes, the oligomer inserts into the membrane resulting in translocation of EF/LF to the cytosol *(6)*. EF causes an increase in cyclic adenosine monophosphate (cAMP) *(7)*, while LF cleaves mitogen-activated protein kinases (MAPKKs) *(8)* resulting in host cell damage and death of some cell types. PA can also be cleaved by proteases in the circulation to the 63-kDa monomer and form oligomers with EF/LF which then bind to host cell receptors. *(Modified from Mourez M, Lacy DB, Cunningham K, et al: 2001: a year of major advances in anthrax toxin research.* Trends Microbiol. *2002;10:287–293.)*

20-kDa aminoterminal fragment. The cell-bound 63-kDa carboxyterminal fragment oligomerizes and creates a second binding domain to which either or both of the active proteins (LF or EF) binds. The complex then enters the cell through endocytosis with LF and EF passing through a PA channel induced by the low pH of the endosome, recently visualized by cryoelectron microscopy,[75] to exert their intracellular toxic effects. PA may also be cleaved by proteases in the circulation to form oligomers with LF and EF, which then bind to cell receptors.[58] An alternative pathway has recently been described whereby LF within extracellular vesicles or exosomes can enter and intoxicate cells independently of the PA receptor.[76]

The genes for the toxin production are carried on a second 182-kb plasmid (pX01).[77] Strains deleted of the plasmid coding for the toxin genes remain encapsulated, but are attenuated.[48,77] Of historical significance, it appears that the veterinary vaccine strains produced by Pasteur through passage at high temperature lack the plasmid for the toxin genes, explaining their lack of virulence.[77] It is thought that vaccine preparations consisted of a mixture of organisms, most of which lacked the toxin plasmid together with small numbers of fully virulent organisms that retained the toxin plasmid and were responsible for the vaccine's efficacy. Further work has shown that deleting the PA gene alone eliminates the organism's virulence,[78] thus confirming the central role of PA in the activity of the two toxins and their role in virulence.

Early studies showed that crude toxin preparations or combinations of edema and lethal toxins inhibited neutrophil killing,[79] chemotaxis,[80] or phagocytosis,[49] and that edema toxin inhibits neutrophil phagocytosis[81] and priming of the respiratory burst of neutrophils.[82] At low concentrations, lethal and edema toxins also appear to block the production of proinflammatory cytokines from macrophages,[83,84] directly inhibit macrophage chemotaxis,[85] and interfere with the early protective inflammatory response. At high concentrations, lethal toxin is cytolytic for macrophages from some mouse strains.[86] These mouse studies have shown that the strains with macrophages and neutrophils resistant to lethal toxin, as seen in human cells, are more resistant to infection, with neutrophils more important for resistance than macrophages.[87–89] However, the relevance of these studies in mice with attenuated unencapsulated strains to the mechanism of toxin pathogenesis of human disease remains to be determined. Lethal and edema toxins also have deleterious effects on a multitude of other cells, including lymphocytes and dendritic cells,[90–94] endothelial cells,[95] glucocorticoid receptor–positive cells,[96] and cardiac myocytes,[97] but the physiologically important cell target(s) in the infected host remains to be established. In terms of pathogenesis, the greater importance of lethal toxin versus edema toxin was demonstrated with a mouse model in which an anthrax strain producing the lethal toxin alone retained some virulence, whereas a strain producing only edema toxin was avirulent; the parent strain producing both

toxins was the most virulent.[98] More recent studies show that lethal toxin, but not edema toxin, is essential for virulence in nonhuman primates.[99]

In cutaneous anthrax, infection begins when a spore is introduced through the skin. At the local site, the spore germinates into the vegetative bacillus, which produces the antiphagocytic capsule. The edema and lethal toxins produced by the organism impair leukocyte function and contribute to the distinctive findings of tissue necrosis, edema, and relative lack of leukocytes in the local lesion. If not contained, the bacilli spread to the draining regional lymph nodes, allowing further production of toxins and induction of the typical hemorrhagic, edematous, and necrotic lymphadenitis. From the lymph nodes, the bacteria continue to multiply and enter the bloodstream, producing a systemic infection.

In inhalational anthrax, spores ingested by alveolar phagocytes and lung dendritic cells are transported to the tracheobronchial and mediastinal lymph nodes, where they germinate.[100,101] Local production of toxins by extracellular bacilli leads to the massive hemorrhagic, edematous, and necrotic lymphadenitis and mediastinitis characteristic of this form of the disease. The bacilli then spread to the blood, causing septicemia. In approximately half the cases there may be hemorrhagic meningitis. PA and LF are detectable in the blood early and at high concentrations later,[56,102] with the lethal toxin occurring as a complex of PA and LF at late stages of disease.[103] Capsule is also present at high levels.[102] The site of action and the role of lethal and edema toxins in the mechanism of death from infection remain obscure. Death is a result of respiratory failure with overwhelming bacteremia that is often associated with meningitis and subarachnoid hemorrhage.

Diagnosis

A diagnosis of cutaneous anthrax should be considered after the appearance of a painless, pruritic papule that develops into a 1- to 2-cm vesicle, revealing a black eschar at the base of a shallow ulcer. Examination by Gram stain or culture of the vesicular fluid should confirm the diagnosis, but prior antibiotic therapy quickly renders the infected site culture-negative. Biopsy at the lesion edge, examined by Gram stain, immunohistology, and PCR, may be useful in people who have been treated with antibiotics. The latter two tests are available through the Laboratory Response Network (see below). In addition, there should be a history of exposure to materials contaminated with *B. anthracis*.

The diagnosis of inhalational anthrax is difficult, but should be suspected in cases with a history of exposure to an aerosol containing *B. anthracis*, followed by an initial phase during which symptoms are nonspecific. Once the acute stage develops, a widened mediastinum seen on chest radiograph, often with pleural effusions, should suggest the diagnosis. In untreated cases, culture of blood and pleural effusions will readily establish the diagnosis, and more rapid detection methods, including PCR for the PA gene, immunoassay for PA and capsule antigens, and mass spectrometry for LF or lethal toxin, may all be useful.[102,104] These tests are available through the Laboratory Response Network and state health departments (http://www.cdc.gov/anthrax/labs/labtestingfaq.html). In cases previously treated with antibiotics, these assays for toxin and capsule in blood and pleural fluid, as well as immunohistologic examination of pleural fluid or transbronchial biopsy specimens, are of particular value[14,15,17,105] and may be positive as long as 6 to 8 days after initiation of therapy.[104,106] Because primary pneumonia is not a feature of inhalational anthrax, sputum examinations do not aid diagnosis. The radiographic differential diagnosis should include histoplasmosis, sarcoidosis, tuberculosis, and lymphoma. A computed tomography scan of the chest may be helpful to detect hemorrhagic mediastinal lymphadenopathy and edema, peribronchial thickening, and pleural effusions.

Gastrointestinal anthrax is difficult to diagnose because of its rarity and similarity to other more common severe gastrointestinal diseases. An epidemiologic history of ingesting contaminated meat, particularly in association with other similar outbreak cases, suggests the diagnosis. Microbiologic cultures are not helpful in confirming the diagnosis unless bacteremia is present. The diagnosis of oral-oropharyngeal anthrax can be made from the clinical and physical findings, but the role of bacteriologic cultures in confirming this diagnosis remains unclear.

Treatment and Prevention With Antibiotics

Mild cases of cutaneous anthrax may be treated effectively with oral penicillin, fluoroquinolone, doxycycline, or another antibiotic, depending on antimicrobial susceptibility. If rapid spread or prominent systemic symptoms are present, high-dose parenteral therapy as for inhalational anthrax (see below) should be given until there is a clinical response. Effective therapy reduces the edema and systemic symptoms but does not change the evolution of the skin lesion. In injectional anthrax parenteral antibiotic therapy as for inhalational anthrax (see below) should be initiated and surgical debridement and fasciotomy may be required.

Treatment of inhalational anthrax requires high-dose intravenous therapy (ciprofloxacin or another fluoroquinolone) with at least one or more antibiotics with good central nervous system penetration, for example, meropenem and linezolid, because of the high incidence of meningitis.[14,15,107,108] This approach also applies to gastrointestinal anthrax. Regimens should be altered based on susceptibility testing available at the Laboratory Response Network and state health departments along with the clinical status. The successful treatment of six of the 11 inhalational cases in the 2001 bioweapon attacks suggests that, with rapid antibiotic treatment and modern supportive care, including aggressive management of respiratory distress and pleural effusions, mortality is similar to that of other causes of sepsis.

After exposure to an aerosol of anthrax, postexposure prophylaxis or presymptomatic treatment should include oral antibiotics for 60 days or more, depending on individual circumstances (eg, extent of exposure, vaccination status; see later text).[107,108] Ciprofloxacin or doxycycline are recommended. Other oral antibiotics, including other fluoroquinolones, clindamycin, or amoxicillin or penicillin VK if the strain is susceptible, are alternatives. Levofloxacin is indicated as a second-line drug because of limited safety data beyond 30 days.[108] Amoxicillin is recommended for children and pregnant or lactating women, depending on microbial resistance.[15,107] Preexposure or postexposure vaccination may enable shorter courses of antibiotics (see later text).[107,109] Postexposure vaccination alone would not be expected to protect quickly enough to be effective.[22]

EPIDEMIOLOGY

Several theories explain the ecology of soil contaminated with *B. anthracis* spores. One theory suggests that *B. anthracis* spores can persist for many years in soil rich in nitrogen and organic material with adequate calcium, a pH greater than 6.0, and an ambient temperature greater than 15.5°C. It remains unclear whether there are cycles of germination and replication within the soil or if amplification within mammalian hosts serves to maintain the spore population in the soil.

Animal anthrax results from animals ingesting *B. anthracis* spores by eating contaminated feed or while grazing on pastures. Soil becomes contaminated from contaminated commercial fertilizer, contaminated feed, or diseased animals that contaminate the soil with their secretions before or after death.[110]

The number of reported human anthrax cases in the United States has declined steadily. Between 1916 and 1925, the annual average number of cases was 127; between 1948 and 1957, 44 cases; between 1978 and 1987, 0.9 cases per year; and between 1988 and 2000, 0.25 cases per year. Of the 235 human cases reported in the United States from 1955 to 2000, 20 were fatal (Fig. 11.2). Among these cases, 224 had cutaneous lesions (118 on an arm, 65 on the head or neck, 11 on the trunk, 8 on a leg, and 22 at an unknown site) and 11 were inhalational cases. These cases only include naturally occurring cases and do not include cases related to the 2001 outbreak. As discussed, in 2001, there were a total of 22 cases, 11 inhalational cases that included five deaths, and 11 cutaneous cases associated with contaminated mail. In the years from 2002 to 2014, there have been six cases of anthrax reported in the United States, the last being in 2011.[111] Three of those cases were related to exposure to drumheads made from animal skin; two of these were inhalational anthrax, and one was the first confirmed case of gastrointestinal anthrax reported in the United States. The other cases included two cutaneous cases and one inhalational case associated with travel in four states where anthrax is enzootic.[112]

A new manifestation of anthrax was reported in the United Kingdom in 2009—injectional anthrax. Since then, more than 140 laboratory-confirmed cases of anthrax associated with injecting heroin contaminated with *B. anthracis* have been reported in Europe.[19,21] These cases have demonstrated varying clinical signs and symptoms as well as high mortality rates. It has not been determined whether the heroin itself was contaminated, or *B. anthracis* was present in materials mixed with the heroin.

For naturally occurring anthrax, the basic epidemiologic principles are the same in developing and developed countries. Agricultural anthrax is a more significant problem in developing countries, and industrial anthrax occurs more commonly in developed countries. Industrial anthrax results from exposure of susceptible persons to contaminated animal products including wool, goat hair, hides, or bones. These materials come from animals that were infected with *B. anthracis* before death or contaminated after death (eg, from contaminated soil with which the carcass or animal products came in contact). The wool and hair from infected animals may be clipped from live animals or pulled from carcasses. A hide may be obtained from an animal that has died of anthrax. Bones can be collected from grazing areas on which animals die or from rendering plants that may handle carcasses of animals that have died of anthrax.

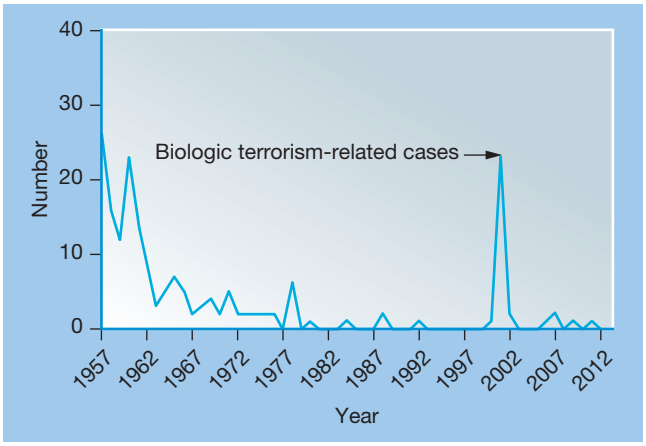

Figure 11.2. Number of both naturally occurring and biological terrorism–related reported cases of anthrax, by year in the United States for the years 1957 to 2012.[111]

Wool and goat hair are processed into yarn used in the textile and carpet industries and in the preparation of other cloth-like materials. Hides are processed into leather goods. Bones are used in preparing bone meal, gelatin, and fertilizer. In industrial cases, cutaneous anthrax results from spores that gain entrance through the skin by entering preexisting wounds or by being rubbed through the skin or on a hair fiber that may penetrate the skin. At times, the processing of goat hair and wool creates infectious aerosols that may result in inhalational anthrax when inhaled. A rendering plant is another source of potential infection.

A case of inhalational anthrax was reported in early 2006 in a 44-year-old male drumhead maker who brought goat skins into the United States from Africa. After cleaning the skins, he developed inhalational anthrax, but with vigorous therapy survived.[27,105] *B. anthracis* was recovered from his work environment. Several additional cases of anthrax associated with drums from Africa have been reported, including one case of disseminated anthrax, another of inhalational anthrax from Europe,[32] and two cutaneous[113] and one presumed gastrointestinal case[114] from the United States.

Cases associated with agricultural settings result from contact with diseased animals or with the products of animals that have died of anthrax. Affected persons are primarily agricultural workers, veterinarians, or people who kill and butcher infected animals or butcher the carcasses of animals that have died of anthrax. This contact results in cutaneous anthrax or, if the infected meat is ingested, gastrointestinal or oral–oropharyngeal anthrax.

Laboratory-associated cases of anthrax are rare. These are essentially all cutaneous, although a few inhalational cases have occurred. Rarely, cases have been reported after contact with contaminated clothing, such as woolen coats or pilots' leather helmets. Table 11.2 presents the sources of infection of the 264 cases reported in the United States from 1955 to 2011. The two vaccine-associated cases of cutaneous agricultural anthrax resulted from the inadvertent injection of live attenuated animal vaccine into the hand of the vaccinator. Two additional vaccine-associated cases of anthrax occurred in persons producing vaccine and were thought to result from contamination of skin lesions with the vaccine strain.[115]

Exposures related to bioterrorist events represent a new category. The anthrax spore attacks in the fall of 2001 resulted in 11 confirmed inhalational cases and seven confirmed and four suspected cutaneous cases reported from Florida, New York, New Jersey, the District of Columbia, and Connecticut.[13–15] Exposure to contaminated mail was the confirmed or apparent source of infection in all patients.[15,16] More than 32,000 people received short courses of prophylactic antibiotics while potential exposures were evaluated,[116] and among the treated people, more than 10,000 continued to receive antibiotics for 60 or more days with or without postexposure vaccination as prophylaxis.[117,118] Exposures likely resulted from opening contaminated letters, from working in buildings with high-speed automated mail-sorting machines, or through direct contact with cross-contaminated pieces of mail or environments contaminated with spores.

PASSIVE IMMUNIZATION

In the era before antibiotics, antisera from convalescent animals were common therapeutic products.[119] One of the first

was anthrax antiserum, developed in France by Marchoux and in Italy by Sclavo in 1895.[120,121] Although it was used initially for prophylaxis and treatment of anthrax among livestock, Sclavo later used his product to treat cutaneous or septicemic human disease. He reported 10 deaths among 164 treated patients (6% mortality, compared with the Italian case-fatality rate of 24% in untreated cases), although these were not controlled clinical trials. Sclavo injected 30 to 40 mL of antiserum subcutaneously, and repeated it 24 hours later. In severe cases, he also injected 10 mL or more intravenously.

Between the 1910s and 1940s, clinicians in Europe and the Americas treated patients with anthrax antiserum using 25 to 300 mL daily for 5 days, sometimes in combination with arsenicals.[119–130] One patient with severe cutaneous anthrax recovered after receiving 2265 mL of antiserum.[131] No controlled studies were performed to demonstrate efficacy. Anthrax antiserum for therapy of cutaneous anthrax was replaced by therapy with sulfanilamide in 1939, followed by penicillin in 1947 and subsequently by other antibiotics.[129,132]

Equine anthrax antiserum produced by live-spore vaccination has been licensed in China,[133] the Soviet Union, and later Russia for decades, and its use continues, although the frequency of its use is unclear. The Lanzhou Institute of Biological Products in China developed a lyophilized antianthrax $F(ab)_2$ formulation of equine immunoglobulin (Ig) G fragments for human use by intracutaneous, IM, or IV administration, but it is rarely used (Dong Shulin, personal communication, 2002). Several other Fab formulations are in early-stage animal testing.

Experimental evidence indicates that passive immunization with equine antibody produced against attenuated Sterne veterinary vaccine strains or against crude toxins prevents disease in animals when given before or shortly after spore challenge.[23,134] Rhesus monkeys were protected with one or two doses of equine antianthrax spore hyperimmune serum when begun 1 day after low-dose aerosol challenge. Of immune serum–treated animals 45% survived, compared with only 10% of control animals.

Studies by Little and colleagues[135] showed efficacy of anti-PA antiserum prophylaxis against an IM challenge in animals. The anti-PA polyclonal antibody protected against death, and anti-PA monoclonal antibody significantly delayed mortality. Reuveny and colleagues[136] similarly found that passive immunization of guinea pigs with polyclonal anti-PA antisera conferred protection against an intradermal challenge dose of 40 median lethal doses (LD_{50}).

Kobiler and colleagues[137] challenged guinea pigs intranasally with a 25 LD_{50} dose of spores and intraperitoneal administration of rabbit anti-PA serum 24 hours after infection protected 90% of animals, with lesser efficacy seen with anti-Sterne and anti-LF antibodies. Beedham and colleagues[138] demonstrated that mice could be protected against live anthrax challenge with antibody from PA-vaccinated animals, but not with their splenic lymphocytes, supporting the longstanding evidence that antibody is the major mechanism of vaccine-induced immunity.

Although the importance of anthrax toxins in pathogenesis suggests that antiserum to toxins could have a role in treatment, no such products were produced, until interest was rekindled by the anthrax bioweapon attacks in fall 2001.[139] Modern experimental evidence shows that passive immunization with antiserum prevents anthrax in animals when given before or shortly after spore challenge.[140] This includes protecting guinea pigs from intradermal challenge, rhesus monkeys from low-dose aerosol challenge, and rats from parenteral challenge. The need for therapeutics other than antibiotics may be especially great in the case of antibiotic-resistant strains of *B. anthracis*, although there remains no definitive evidence to date of efficacy of antiserum to toxin in humans. In 2007, the U.S. government purchased several thousand therapeutic courses of human polyclonal anthrax immunoglobulin from Cangene Corporation (Winnipeg, Canada). This product was manufactured by fractionating the plasma of volunteers given at least four doses of anthrax vaccine adsorbed (AVA [BioThrax]). The formulation, now known by the trade name Anthrasil, was licensed by the Food and Drug Administration (FDA) in March 2015 for use in combination with appropriate antibacterial drugs. The anthrax immunoglobulin formed part of the successful treatment of a 2006 case of inhalational anthrax in a 44-year-old man exposed via African hides[105] and has been used in treatment of anthrax in drug users in Scotland,[141] but definitive evidence of efficacy in humans is unavailable. Efficacy evidence for licensure relied heavily on animal-challenge data, augmented with cross-species pharmacokinetic data,[142] fulfilling the FDA Animal Rule.

Several human monoclonal anti-PA antibodies have been developed. The U.S. government contracted for several thousand intravenous treatment courses of raxibacumab (ABthrax, Human Genome Sciences, Rockville, MD), a monoclonal anti-PA antibody. This antibody protects rabbits and nonhuman primates from death when given prophylactically against an aerosol spore challenge and when given therapeutically.[143]

The FDA licensed raxibacumab in December 2012 for use in combination with appropriate antibacterial drugs. Even though studies with both polyclonal anthrax immunoglobulin (Anthrasil) and raxibacumab showed increased survival over animals treated with antibiotic alone, the difference was not statistically significant.[108,144] Other monoclonal antibodies are also under development, such as MDX-1303 (or Valortim) developed by Pharmathene.[145] It remains unclear whether polyclonal antibodies that neutralize several epitopes might be preferable to monoclonal antibodies that target only one epitope.[146] If bacteria could be reengineered to modify the single binding epitope of a monoclonal antibody, it might be rendered ineffective. Indeed, it has been reported that modifications to PA can result in lack of effectiveness of a neutralizing monoclonal antibody, whereas a polyclonal antibody was still active.[147]

Mouse and humanized chimpanzee monoclonal antibodies to the other major virulence factor, capsule, have also been shown to be protective in mouse models.[148,149]

ACTIVE IMMUNIZATION

History of Vaccine Development

Although there is great historical interest in Pasteur's first effective live bacterial vaccine, and live attenuated veterinary vaccines are still used, human anthrax vaccines licensed in the United States and Europe consist of purified anthrax proteins, and not live attenuated vaccines. Early human anthrax vaccines (presumably live) were used in the 1910s but found little favor.[121] Then, Sterne developed live attenuated strains in the 1930s, which led to worldwide use for domesticated animals.[45] Russian investigators developed similar vaccines for animal and human use. In 1946, Gladstone[150] identified the PA component of cultures of *B. anthracis* as being an effective vaccine, and only later did subsequent studies identify PA as the cell-binding component of the anthrax toxins. Belton and Strange[134] increased the yields of PA to allow large-scale production, leading to the current British vaccine, anthrax vaccine precipitated. Wright and colleagues[151–153] used similar techniques to develop precursors to the American vaccine.

Protective antigen is the term applied to one of the toxin proteins, which is the plasmid-encoded binding component of the anthrax toxins described previously. The major effective immunogen in culture supernatants is PA, although smaller amounts of LF and EF may be present; their contribution to protective immunity has remained controversial.[56] In older studies, EF enhanced the protective efficacy of PA in some experimental animals.[154,155] These studies are difficult to interpret because the preparations used may not have been pure and free of cross-contamination. Studies using the PA gene cloned into *Bacillus subtilis* demonstrated conclusively that PA alone, in the absence of EF, LF, or other *B. anthracis* proteins, protects animals against experimental infection.[156] Although other experiments showed that purer preparations of PA, free of immunologically detectable LF or EF,[157] or recombinant PA,[158] can protect experimental animals, it remains unknown whether adding EF or LF enhances the efficacy of PA. One study reported that a DNA vaccine with the N-terminal domain of LF alone delayed time to death but did not increase overall survival in rabbits challenged with a virulent strain.[159] Similar results were observed with anti-LF serum in guinea pigs,[137] although antibody to LF[160] and vaccination with inactivated LF or the N-terminal domain[161] protected mice from infection with an attenuated strain. In addition, some protection was observed in a mouse model with EF expressed in an adenovirus vector.[162]

Description of Vaccines

The only human anthrax vaccine licensed in the United States, AVA marketed as BioThrax, is produced by Emergent BioSolutions (Rockville, MD) from sterile filtrates of microaerophilic cultures of an attenuated, unencapsulated, nonproteolytic strain (V770-NP1-R) of *B. anthracis*. The cell-free culture filtrate, containing predominantly PA, is adsorbed to aluminum hydroxide, and the final product contains no more than 2.4 mg of aluminum hydroxide per 0.5-mL dose. Formaldehyde, in a final concentration of no more than 0.02%, and 0.0025% benzethonium chloride are included as preservatives. Current product-content standards require 5 to 20 µg/mL of total protein, of which at least 35% is the 83-kDa PA protein, measured by densitometric analysis on sodium dodecyl sulfate–polyacrylamide gel electrophoresis after pooling 12 sublots.[163] The vaccine is stable for 3 years after a successful potency testing.

Some lots produced in the 1980s appeared to contain small amounts of LF and lesser amounts of EF, as determined by induction of antibody responses in animal recipients,[48,157,164,165] although this has not been reported in the limited observations in human vaccinees.[165] Western blot analysis found no detectable EF. Enzyme-linked immunosorbent assay (ELISA) studies found LF to be present in the range of 10 to 30 ng/mL of fermentation filtrate before adsorption.[163] However, analysis by mouse macrophage cytotoxicity assay suggested that LF was present in a biologically inactive form.[153] Although it is clear that PA by itself is an effective immunogen, it remains unresolved whether the small amounts of LF or EF that may be present in some lots contribute to the vaccine's protective efficacy. A 2008 study of serum samples of AVA vaccinees showed that low levels of antibody to LF and EF were present by Western blot, but these did not contribute to toxin neutralization.[166]

Potency testing of AVA is performed by assessing biologic activity after intradermal challenge of vaccinated guinea pigs with a lethal dose of spores. The vaccine is stored at 2°C to 8°C. In December 2008, the FDA approved a revised recommended schedule for vaccination consisting of 0.5 mL given IM at 0 and 4 weeks and at 6, 12, and 18 months instead of the previous schedule with doses given SC at 0, 2, and 4 weeks followed by doses at 6, 12, and 18 months.[109] With continued exposure, booster doses have traditionally been recommended annually. A study of a simplified dosing schedule revealed that at month 43, anti-PA IgG geometric mean concentrations (GMCs) for three reduced-dosage groups were noninferior to the original eight-dose SC group. At month 43, volunteers receiving doses at 0, 1, 6, and 42 months IM or at 0, 1, 6, 18, and 42 months IM had GMC responses greater than those receiving the original eight-dose SC schedule. Solicited injection-site adverse events occurred at lower proportions in the IM group compared to SC. Route of administration did not influence the occurrence of systemic adverse events. A three-dose IM priming schedule with doses administered at months 0, 1, and 6 elicited long-term immunological responses and robust immunological memory that was efficiently stimulated by a booster vaccination at 42 months.[167]

Anthrax Vaccine Precipitated, a similar vaccine produced by the Health Protection Agency (Porton Down, Salisbury, Wiltshire), was developed in the United Kingdom, first administered to humans in the early 1950s, and licensed there in 1979.[168–173] This vaccine is made by precipitating the sterile cell-free culture filtrate of a derivative of the attenuated, unencapsulated Sterne strain 34 F_2 with aluminum potassium sulfate.[172] LF and EF are present in this vaccine at levels higher than believed to be found in the U.S. vaccine from the 1980s.[168,173] The vaccine contains thimerosal as a preservative.

The British vaccine is administered IM in a regimen of three 0.5-mL doses at 0, 3, and 6 weeks, with a booster dose 6 months after the third dose. Subsequent booster doses are given annually.[165] Other schedules of administration of this vaccine are also being studied.

A vaccine consisting of a suspension of live spores, named STI-1 for the Sanitary-Technical Institute, has been used for humans in the Soviet Union and its subsequent independent republics since 1953.[110,174] This strain, similar to the Sterne strain used in veterinary vaccines, is unencapsulated.[174] Although this vaccine has a reputation for causing substantial side effects, its developers assert that it is reasonably well tolerated and shows some degree of protective efficacy.[174,175] This vaccine, manufactured by the Tbilisi Scientific Research Institute of Vaccines & Serums (Tbilisi, Georgia), the Institute of Microbiology (Kirov [Vyatka], Russian Federation), and perhaps at other locations, is given either by scarification through a 10- to 20-mL drop of vaccine containing 1.3 to 4×10^8 spores or SC.[2,110,172,174,176–178] The initial dose is followed by a second dose 21 days later, with yearly boosters.

Another human live spore vaccine given by scarification has been manufactured by the Lanzhou Institute of Biological Products (Lanzhou, Gansu, People's Republic of China) since the 1960s, based on the avirulent strain A16R.[110,133] A single dose contains 1.6 to 2.4×10^8 colony-forming units. A single booster dose is given 6 to 12 months after the first vaccination (Dong Shulin, personal communication, 2002).

Immunogenicity of Anthrax Vaccine Adsorbed Vaccine Produced in the United States

The results of two studies indicated that immunization with the AVA induced an immune response (as measured by indirect hemagglutination) to PA. In the first study, 83% of vaccinees seroconverted 2 weeks after the first three doses.[179] In the other, 91% seroconverted after receiving two or more doses.[180] The titers fell over time, but 100% of vaccinees responded with an anamnestic response to the annual booster dose. Analysis using a more sensitive ELISA against PA demonstrated that seroconversion rates were between 96% to 100% of vaccinees after the second dose.[181,182]

By using a more sensitive validated ELISA assay, Pittman and colleagues[183] found that one dose of AVA evoked detectable anti-PA IgG antibodies in 60% to 84% of vaccinees. After two doses, 95% to 100% of vaccinees developed anti-PA antibodies. Studies also show that providing a missed 6-month dose after a delay as long as 5 to 7 years did not impair the booster response and it is not necessary to restart the series.[184]

A pilot study comparing SC and IM administration of AVA revealed higher titers to PA when a 4-week interval between the first two doses was compared with a 2-week interval, with fewer injection-site or systemic events with the IM route.[182] As described earlier, based on a larger randomized clinical trial,[185] the FDA changed the licensed schedule of 0.5 mL of vaccine given at 0 and 4 weeks and at 6, 12, and 18 months by the IM route from the old schedule of 0, 2, and 4 weeks and 6, 12, and 18 months given SC. The 2014 Wright study[167] may lead FDA to simplify the schedule further, as has been done by German regulatory counterparts who adopted a booster-vaccination interval of 3 years after a three-dose priming series (0, 1, and 6 months).

Although the change in route from SC to IM resulted in fewer solicited injection-site adverse events, it had no effect on the occurrence of systemic adverse events. Most importantly, the change to the IM route and elimination of the 2-week dose resulted in statistically significantly lower concentrations of anti-PA antibody from week 8 through and including month 6. The antibody titers using the new schedule were noninferior to the old schedule at month 7, after the 6-month dose. However, the percentage of responders with a fourfold rise in titer was similar at 8 weeks and 7 months after the 6-month booster with the two schedules. The significance of the lower immune response up to month 7 remains unclear as the serologic correlation with immunity remains to be determined and will require extrapolation from studies in animal models. However, in those instances where rapid onset of an immune response is desired, as when postexposure vaccination is given together with antibiotics (see later), then the original schedule of doses given SC at 0, 2, and 4 weeks should be considered.[186]

There also seems to be some variability in the response of humans to vaccination with AVA as persons with DRB1-DQA1-DQB1 human leukocyte antigen (HLA) class II haplotypes produce significantly lower levels of anti-PA antibody.[187]

Cellular Responses

Soviet scientists developed a skin-test antigen known as anthraxin in 1957, derived from the edematous fluid of infected animals given an unencapsulated *B. anthracis* strain.[178] Licensed in 1962 in Russia, the skin test product is composed of an undefined heat-stable polysaccharide–protein–nucleic acid complex, without anthrax capsular or toxigenic material.[178,188] A positive skin test after a 0.1-mL intradermal injection is defined as erythema of 8 mm or more with local induration persisting for 48 hours.[168] Anthraxin was useful in identifying cases of anthrax[174,189] and identifying STI-1 vaccine-induced immunity in guinea pigs, sheep, and humans.[174] Experimental data show that guinea pigs vaccinated against anthrax that developed a positive anthraxin skin test were immune to a subsequent parenteral challenge.[178] The positive and negative predictive values of the individual test results have not been published and there is limited experience with the skin-test antigen in humans in Western countries. Thus, its usefulness in predicting immunity in humans remains unknown. Contemporary immunologic studies show that humans develop PA-reactive CD4+ T cells with a T-helper cell type 2 (Th2) cytokine profile[190] as well as long-lived PA-specific memory B-cell responses after vaccination with AVA.[191] Another study examined associations between HLA genotypes, haplotypes, and homozygosity and PA-specific cellular immune responses in healthy subjects following vaccination with AVA. Limited associations were observed between individual HLA alleles or haplotypes and variable lymphocyte proliferative (LP) responses to AVA. Individuals homozygous for any HLA locus demonstrated significantly lower PA-specific LP than subjects heterozygous at all eight loci.[192]

Correlates of Protection

After a naturally acquired infection, antibody to PA develops in 68% to 93% of cases as reported in different series, depending on when samples are drawn.[173,180,181,193] Antibody to LF occurs in 42% to 55% of cases, whereas antibody to EF is less frequently observed.[173,181] Antibody to the anthrax capsule occurs in 67% to 94% of cases.[181,193] This reaction contrasts with that after vaccination, in which no response to capsule is expected because the strain used to produce the vaccine is nonencapsulated. In the 2001 epidemic of inhalational anthrax, antibody to PA was detected in all survivors of confirmed cases.

In experimental animals, there is generally a correlation between immunity and antibody titer to PA after immunization with AVA.[194] In a mouse model using an attenuated strain, systemic rather than mucosal antibody correlated better with

protection against inhalational challenge.[195] However, the live veterinary vaccine provides significantly greater protection against similar challenge doses of anthrax in experimentally infected animals than does the human vaccine, even though it often induces lower levels of antibody to PA,[156,164,165] suggesting other antigens may be involved in protection.

More recent studies using live and protein-based vaccines have demonstrated a strong correlation between antibodies to PA and protective immunity. Barnard and Friedlander[196] showed, for the first time using live vaccines producing varying amounts of PA, that protection was strongly correlated with antibody titers to PA, a finding subsequently confirmed by Cohen and colleagues.[197] A similar correlation of immunity to AVA with antibody to PA, measured by ELISA and toxin neutralization, was observed in a rabbit model of inhalational anthrax.[194] Reuveny and colleagues,[136] using a PA vaccine to protect guinea pigs against an intradermal challenge, found that toxin-neutralizing antibodies correlated better with survival than antibodies measured by ELISA, and similar results were observed in rabbits challenged by the intranasal route.[198] However, studies in nonhuman primates showed that anti-PA IgG was more accurate than toxin-neutralizing antibodies as a correlate of protection against inhalational challenge.[199] Further analysis of the antibody response to different epitopes on PA[200] will increase knowledge of the nature of the protective antibodies as monoclonal antibodies to PA with synergistic, additive or antagonistic effects on neutralization have been described.[201] The overall evidence based on passive immunity with the aforementioned antibodies and protection with PA vaccines confirms that humoral immunity is the predominant mechanism of protection. Vaccine-induced protection seems in some animal models to be a function of the rapidity of the infectious process, the level of antibody present at challenge, and the speed of development of an anamnestic response.[202]

More recent studies sponsored by the National Institute of Allergy and Infectious Diseases (NIAID) and the Centers for Disease Control and Prevention (CDC) to further establish the relationship between antibody response and protection in rabbits (NIAID) and in nonhuman primates (NIAID and CDC) have been conducted. Although the NIAID used second-generation anthrax PA vaccines (see later) and the CDC used the licensed AVA vaccine, studies using both types of vaccines have shown that antibody levels in both species correlate with protection against aerosol challenge. Analysis of multiple studies in rabbits and two nonhuman primate species showed that levels of toxin neutralizing antibodies in one species are predictive of vaccine efficacy in the other species.[203,204] The finding that toxin neutralizing antibody levels can predict cross-species survival supports the extrapolation of data from animals to predict anthrax vaccine efficacy in humans. It is hoped this approach will be suitable for licensure of new anthrax vaccines and/or indications using the FDA pathways for licensure of vaccines that cannot be tested for efficacy in humans.[205]

Efficacy of Vaccine

The protective efficacy of different experimental PA-based vaccines derived from culture filtrates of *B. anthracis* has been clearly demonstrated with the use of various animal models and routes of challenge.[56,171] A comprehensive, peer-reviewed evaluation by the National Academy of Sciences reported that "The committee finds that the available evidence from studies with humans and animals, coupled with reasonable assumptions of analogy, shows that AVA as licensed is an effective vaccine for the protection of humans against anthrax, including inhalational anthrax, caused by all known or plausible engineered strains of *B. anthracis*."[163] The FDA independently affirmed that AVA prevents anthrax regardless of route of exposure.[206]

A controlled field trial was conducted in the late 1950s with a less potent vaccine similar to the currently licensed AVA.[207] This vaccine was composed of an alum-precipitated, cell-free culture supernatant from an attenuated, unencapsulated, nonproteolytic strain of *B. anthracis*. This strain differed slightly from that used to produce the licensed vaccine and was grown under aerobic rather than microaerophilic conditions.[152] The study was conducted in a susceptible population working in four mills in the northeastern United States, where raw imported goat hair contaminated with *B. anthracis* was encountered. The results indicated that vaccination, compared with a placebo, provided 92.5% protection against anthrax, combining the cutaneous and inhalational cases (95% confidence interval [CI], 65%–100%). No isolated assessment of the effectiveness of the vaccine against inhalational anthrax could be made because there were too few cases, although the only inhalational cases observed occurred in nonvaccinated persons.

There have been no controlled clinical trials in humans of the efficacy of the currently licensed U.S. vaccine, although the differences between the AVA vaccine and the PA-based vaccine used in the 1950s study by Brachman and colleagues described above[207] are minor from a regulatory perspective.[163] The AVA vaccine has been tested extensively in animals and protects guinea pigs against IM[164,165] and aerosol[157] challenge. More recent experiments show that this vaccine also protected rhesus monkeys against a lethal aerosol challenge with anthrax spores.[158,208–211] Table 11.3 summarizes inhalational challenge studies in nonhuman primates vaccinated with the licensed human vaccine or a recombinant PA vaccine. Additional studies with various formulations of recombinant PA by different manufacturers have confirmed its efficacy in nonhuman primates (E. Nuzum, personal communication, March 18, 2011).

Duration of Immunity

The duration of immunity induced by vaccination has not been clearly established. In the field trials that evaluated a vaccine similar to the currently licensed AVA, one case of cutaneous anthrax occurred 5 months after receipt of three doses within 4 weeks just before the scheduled 6-month boosting dose.[207] This single observation could indicate that immunity induced by the initial dosing series of AVA may not be long lasting but this was a less-potent vaccine than AVA and complete protection against cutaneous inoculation might not be possible. Ongoing studies of clinical correlates of protection may help clarify this point.[163,185,187]

Postexposure Prophylaxis With Vaccination

Postexposure vaccination by itself is unlikely to be of any acute benefit because of the short incubation period and the rapid course of the disease. Animal studies support this conclusion.[22] However, vaccination combined with antibiotic prophylaxis before onset of clinical illness may offer the best possible protection against inhalational anthrax. This is because of the propensity of anthrax spores to persist in the host for long periods and possibly germinate after antibiotics have been discontinued.[19–22] Vaccination allows an immune response to develop during the period of antibiotic prophylaxis. Thus, postexposure vaccination may shorten the period of antibiotic prophylaxis required for prolonged protection. This is supported by recent studies in nonhuman primates demonstrating that addition of postexposure vaccination to antibiotics resulted in a significant increase in survival

TABLE 11.3 Preexposure Efficacy of Anthrax Vaccines Against Inhalational Challenge in Nonhuman Primates

compared with treatment with antibiotics alone.[212] Because the rapid development of an antibody response is particularly critical for postexposure prophylaxis and the new vaccine schedule of 0 and 4 weeks and 6, 12, and 18 months given IM (see earlier) results in a lower anti-PA antibody response at weeks 4 and 8, the FDA recommends using the previously licensed dose schedule and route (0, 2, and 4 weeks given SC) along with antibiotics for a minimum of 60 days until more definitive data are available.[109] Based on initial studies in nonhuman primates,[212] it may be possible to further reduce the recommended duration of antibiotics, but at present, 60 days are recommended. Use of AVA for postexposure prophylaxis along with antibiotics is not licensed at present and will require an investigational new drug protocol or emergency use authorization by the FDA during a public health emergency. Further studies are required to determine the optimal human vaccine dose schedule and duration of antibiotics for licensure for postexposure prophylaxis.

Vaccine Safety

Common Adverse Effects

The licensed AVA vaccine, when first used, gave an incidence of local reactions similar to that of the antecedent alum-precipitated vaccine, although no detailed observations were reported.[153] In an open-label study from 1966 to 1971 with the licensed vaccine given SC, approximately 7000 textile employees, laboratory workers, and other at-risk persons received 15,907 doses.[213] There were 24 reports (0.15% of doses) of severe local reactions (defined as edema or induration >120 mm in diameter or marked limitation of arm motion or axillary node tenderness). There were 150 reports (0.9%) of moderate local reactions (edema or induration 30–120 mm in diameter) and 1373 reports (8.6%) of mild local reactions (erythema only or induration <30 mm in diameter). Four cases of systemic reactions (<0.06%), reported as transient, included fever, chills, nausea, and general body aches. None of these studies used contemporary methods of data collection for signs and symptoms.[214]

The U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) assessed the safety of the licensed AVA vaccine as part of a randomized clinical study between 1996 and 1999.[182] A total of 28 volunteers received SC doses according to the licensed schedule. Each volunteer was observed for 30 minutes after administration of AVA and scheduled for follow-up evaluations at 1 to 3 days, 1 week, and 1 month after vaccination. Four volunteers reported seven acute adverse events within 30 minutes after SC administration. These included erythema (3), headache (2), fever (1), and elevated temperature (1). Of these events, one patient reported simultaneous occurrence of headache, fever, and elevated temperature (38.2°C). The most common local reactions were tenderness, erythema, SC nodule, induration, warmth, local pruritus, limited arm motion, and edema. Local reactions occurred more often in women. No abscess or necrosis was observed at the injection site. Systemic reactions included malaise, headache, myalgia, fever, anorexia, respiratory difficulty, and nausea or vomiting (4%). All local and systemic adverse events reported in this study were transient. There was one report of a delayed-type hypersensitivity reaction beginning 3 days after the first dose.

The USAMRIID also analyzed the occupational health records of 1583 workers (1249 men and 334 women) who reported adverse events after receiving 10,722 SC doses of the licensed AVA vaccine from 32 separate vaccine lots.[215] In this group, 273 people received 10 or more doses and 46 people received 20 or more doses. With regard to injection-site reactions, 3.6% of doses were reported to produce redness, induration, itching, or edema. Most people who reported a reaction received subsequent doses without problems, but people who reported an injection-site reaction were more likely to report a local reaction to a later dose. Systemic events of headache, fever, chills, malaise, and muscle or joint aches were reported after 1% of doses. The most common of these were headache (0.4%), malaise (0.4%), and fever (0.1%). Women noted local (i.e., erythema, induration, edema, swollen lymph nodes, lumps) and systemic (i.e., headache, fever, dizziness, hives) events more commonly than did men. Vaccine recipients younger than age 40 years reported adverse events more often than did recipients age 40 years or older.

Two uncontrolled case series used serial self-administered surveys to assess the local and systemic reaction after SC anthrax vaccine administration. Among 601 healthcare workers at an Army hospital in Honolulu,[163,216,217] after the first, second, and third doses more women reported localized itching (56%–68%) than did men (24%–31%); more SC nodules (81%–93%) than did men (56%–65%); more moderate to large injection-site reactions (erythema >10 cm) (40%–51%) than did men (17%–32%); and more swelling of the lower arm (8%–15%) than did men (7%–10%). Overall, nearly 20% of both men and women reported symptoms that they personally judged could be ignored; 15% reported symptoms that affected their activity for a short time, but did not limit their ability to perform duties; 8% reported symptoms that were relieved by self-treatment with nonprescription medication that affected their activity for a short time; and fewer than 2% reported symptoms unrelieved by medication, with their ability to perform duties limited for a short time. From 1.5% to 2.7% of women and from 1.2% to 2.1% of men reported systemic events that limited work performance. leading to limitation of performing duties. Events in both sexes resolved without intervention and without sequelae.

Differential rates of adverse events between the sexes have been reported for other vaccines.[214,218–220] Other studies suggested that female sex, body mass index, and prevaccination serum progesterone levels were associated with an increased risk of adverse events. Elevated prevaccination anti-PA IgG levels in women were also associated with an increased risk of local reactions after anthrax vaccination.[221,222]

The other uncontrolled case series was conducted at a U.S. Army base in South Korea[163,216,223] where 2214 men and 610 women were given AVA vaccine SC. Women reported SC nodules more frequently (50%–62%) than did men (21%–29%); erythema greater than 12 cm in diameter was self-reported by 2% to 4% of women and 0.4% to 1% of men. Women experienced more itching at the local site (20%–37%) than did men (6%–8%), more fever (2%–4%) than did men (1%), more chills (3%–6%) than did men (1%–2%), and more malaise (8%–15%) than did men (4%–7%). Overall, 0% to 1.9% of vaccine recipients reported restricted work activities or limited duty assignments. From 0% to 1.1% of vaccine recipients reported losing 1 or more days of duty and between 0.4% to 1.7% sought medical care for the reaction. Regardless of sex, almost all vaccine recipients reported that events were localized or minor and self-limited and did not lead to impairment of work performance.

As noted, the change in the route of routine administration for AVA from SC to IM in December 2008 resulted in fewer solicited injection-site adverse events but had no effect on the occurrence of systemic adverse events.[185]

Rare Adverse Effects

The best quality evidence evaluating the overall safety of the licensed AVA vaccine comes from database studies conducted

by the Army Medical Surveillance Activity and the Naval Health Research Center (NHRC).[163,224,225] These studies established that anthrax-vaccinated and unvaccinated personnel of either sex are hospitalized and visit outpatient clinics at the same rates overall for each of 14 major categories within the International Classification of Diseases and for each of several specific diagnoses with speculative association with anthrax vaccination. For example, 1 per 35 anthrax-vaccinated people was hospitalized per year, compared with 1 per 28 unvaccinated people hospitalized per year.

A similar cohort study evaluated disability discharge rates, comparing 154,456 anthrax-vaccinated and 562,377 unvaccinated soldiers during 4.25 years of follow-up.[226] Rates of disability evaluations did not differ significantly between the two groups, with an adjusted hazard ratio of 0.96 (95% CI, 0.92–0.99). Subset analyses similarly found no differences between men and women for permanent disability, temporary disability, musculoskeletal disability, or neurologic disability.

Three reports described the long-term health of 99 male laboratory workers who received a variety of licensed and investigational vaccines (volume range: 52–134 mL), including the early and the current formulation of anthrax vaccine.[227–229] The third study included a small control group. Although there were elevations in liver and kidney function test results and white blood cell counts in some of the male vaccine recipients, none developed unusual diseases or unexplained symptoms attributable to repeated doses of multiple vaccines. A 17-year follow-up study comparing 155 multiply vaccinated laboratory workers (142 of whom received anthrax vaccine) and 265 unvaccinated workers in the surrounding community found no differences in clinical side effects attributable to anthrax vaccine.[230]

All reports to the Vaccine Adverse Event Reporting System (VAERS) involving the licensed AVA vaccine for a multiyear interval were evaluated by the Anthrax Vaccine Expert Committee (AVEC), composed of civilian physicians.[231,232] The AVEC evaluated 1857 VAERS reports and additional medical records corresponding to 1793 recipients of the AVA between March 1998 and February 2002. The 1857 adverse event reports could be grouped into three main categories, based on effect on the vaccine recipient's functional status: hospitalization, inability to work for 24 hours or more, and "other." Of the 1857 reports, 64 involved hospitalization. The civilian panel found that 11 of the 64 "very likely/certainly" or "probably" were caused by anthrax vaccine. All 11 involved allergic or inflammatory reactions at the injection site. Another 172 reports involved inability to work for 24 hours or more (but did not involve hospitalization); 94 of the 172 reactions were certainly or probably caused by anthrax vaccine according to the AVEC. These 94 reports primarily described injection-site reactions, various rashes, acute allergic reactions, and viral-like symptoms. In the balance of the 1857 reports, 1621, involved neither hospitalization nor time off work for 24 hours or more. All were reviewed by the AVEC, which found no patterns of unexpected adverse events. Subsequent analyses of VAERS reporting rates did not identify any serious unexpected risk from the vaccine.[233]

Two cases of optic neuritis were reported in soldiers after anthrax vaccination. Optic nerve antibodies were found in one case, but no epitopes were found in common between optic nerve and the anthrax organism.[234] A later database study found no statistically significant elevation in the risk of optic neuritis in AVA vaccinees compared with similar unvaccinated people.[235]

A cohort study involving 4092 active-duty women in the U.S. Army assessed the effect of the licensed AVA vaccine on pregnancy and childbirth.[236] This cohort contrasted 3135 vaccinated women and 957 unvaccinated women, with 39,549 person-months of follow-up. The anthrax-vaccinated and unvaccinated women had an equivalent likelihood of becoming pregnant and of giving birth. A subsequent NHRC assessment found a slight elevation in the rate of birth defects in first trimester–exposed infants (odds ratio = 1.18; 95% CI, 0.997–1.41) compared with infants of women vaccinated outside of the first trimester, but no specific defect occurred at an elevated rate after adjustment for multiple comparisons.[237]

An analysis of men in the military evaluated at an assisted reproductive technology clinic compared 254 anthrax-vaccinated and 791 unvaccinated men and found no differences in semen concentration, sperm motility, sperm morphology, need for intracytoplasmic sperm injection, rate of fertilization of mature oocytes, embryo transfer, or clinical pregnancy.[238]

AVA was the subject of much controversy in the late 1990s and early 2000s, with assertions that the vaccine was associated with a variety of adverse health effects. To provide an objective basis for assessing the vaccine's safety profile, a large number of postmarketing safety studies were conducted. These studies involved cohort studies of acute symptoms,[167,182,183,185,214,215,217,221,223,224,235] hospitalizations,[163,224,239,240] quality of life,[241,242] disability evaluations,[226] periodic physical-examination and clinical-laboratory parameters,[243] and reproductive outcomes,[236,238,244] as well as primary and secondary review of the spontaneous reports to VAERS.[231–233] Several cohort studies span multiple years after immunization.[163,167,185,224,227,230,231,239–242,245–248] Multiple studies used active surveillance, defined as data collected at fixed time points without relying on the passive reporting of symptoms or conditions.[167,182,184,185,217,221,230,241,242] Other studies featured systematic surveillance where data were collected automatically and electronically, without any reporting action required by the clinician or associated with specific vaccines.[163,224,226,235,237,238–240,243,245–248]

After the National Academies of Sciences heard from anthrax vaccinees and comprehensively reviewed the accumulated scientific data, they concluded that anthrax vaccine has an adverse-reaction profile similar to that of other adult vaccines.[163] However, the anthrax immunization program needed improvements in the methods of communication between the Department of Defense and military personnel with regard to overall clinical immunization services. Concern about the value of anthrax immunization among military personnel largely resolved after the anthrax bio-attacks of the fall of 2001 that demonstrated the lethality of anthrax spores.

Indications for Vaccination

Routine preexposure vaccination with doses given IM at 0 and 4 weeks and at 6, 12, and 18 months plus yearly boosters is recommended for industrial workers who handle potentially contaminated animal products, including wool, goat hair, hides, and bones imported from countries in which animal anthrax is reported. These countries are primarily in Asia and Africa but are occasionally in South America and the Caribbean. A veterinarian or agricultural worker who has contact with potentially infected animals should be vaccinated, as should laboratory workers who work with *B. anthracis*.[109] For postexposure prophylaxis the most rapid immune response is generated in unvaccinated persons with three doses of vaccine that should be given SC at 0, 2, and 4 weeks in conjunction with a 60-day course of appropriate antimicrobial agents.[108,109]

Special circumstances that warrant vaccination with anthrax vaccine include a threat of biologic warfare or terrorism. The U.S. Armed Forces began vaccinating designated service members in 1998 to protect against anthrax arising from the

use of *B. anthracis* as a biologic weapon. Between 1998 and 2016, more than 3 million military personnel received more than 13 million doses of AVA.[249]

Contraindications and Precautions

A contraindication to vaccination is a hypersensitivity reaction to the vaccine. This is uncommon, but several persons who have received the initial dose or doses developed moderately severe local reactions with some systemic response. If it is necessary to immunize persons with such responses, pretreatment with antihistamines and nonsteroidal antiinflammatory drugs may be of value, although this has not been evaluated scientifically.[250] Anaphylaxis is extremely rare after vaccination and is a contraindication to further vaccination.[109]

PUBLIC HEALTH CONSIDERATIONS

The use of the anthrax vaccine in industrialized populations had a significant impact on the reduction of natural anthrax cases among industrial workers and is one of the main methods by which industrial anthrax was controlled. Improvements in the industrial environment, with better manufacturing equipment and environmental control, also have helped reduce the industrial risks of naturally occurring anthrax. In addition, replacement of animal products (primarily goat hair) with synthetic fibers has reduced the occurrence of anthrax infection. It is ironic that mail-processing machines replaced wool-processing machines as a source of industrial risk in the 2001 anthrax bioweapon attacks.

Agricultural cases have been reduced by control of the disease in animals through the use of animal vaccines and better disposal of infected carcasses. The routine immunization of animals in areas with continuing cases of animal anthrax and the immunization of appropriate humans exposed agriculturally and industrially to *B. anthracis* will serve to reduce the number of naturally occurring human cases.

FUTURE VACCINES

Current acellular vaccines against anthrax are less than ideal for several reasons. These vaccines are composed of an incompletely defined culture supernatant adsorbed to aluminum hydroxide. There is only partial quantification of the PA content of the vaccine or other constituents, thus the degree of purity is not fully characterized. Standardization is determined by biologic activity in an animal potency test. The schedule currently licensed for the U.S. vaccine is less than optimal, in that five doses are required during 18 months, followed by annual boosters. Clearly, the ideal anthrax vaccine would be more completely defined and able to produce long-lasting immunity within 30 days.[163] Current research to accelerate and enhance the antibody response to AVA is of particular importance in view of the lower immune response seen with the new schedule eliminating the week 2 dose and changing the route from SC to IM. The most advanced effort involves use of the adjuvant cytosine phosphate guanine (CpG). This has been shown in mice, guinea pigs, and nonhuman primates[251,252] and in an initial Phase I trial in humans[253] to enhance the antibody response to AVA, although increased adverse events were seen in humans after the adjuvant. In a follow up Phase I study using lower doses of CpG there was some increase in local reactogenicity, transient lymphopenia, and increased serum C-reactive protein (CRP) levels with CpG. The peak antibody response was higher and occurred 1 week earlier with CpG and further studies are planned to determine the optimal regimen.[254] Additional studies suggest a regimen of 0 and 2 weeks with AVA plus CpG gives a higher peak antibody response than a 0-, 2-, and 4-week regimen with AVA alone.[255] Further understanding of the molecular pathogenesis of anthrax and of the structure of PA and its interaction with LF and EF would likely lead to significant progress in the development of improved vaccines. For example, genetically defined mutations in the receptor-binding domain,[256,257] the protease-sensitive domain,[258] or other parts of the molecule[259,260] may generate a less toxic more stable PA preparation to be used alone or as a complex with EF and/or LF. Similarly, mutations in the edema or lethal toxin may allow evaluation of nontoxic complexes with PA. Evidence in experimental animals suggests that adjuvants other than aluminum may increase the protective efficacy of PA substantially even after a single dose,[261,262] including CpG as described, and new formulations using microcapsules,[263] liposomes,[264] nanoparticles[265,266] or delivery by the transcutaneous,[264,267] intradermal,[268] or intranasal[265,269] route also may be of value.

Several vaccine candidates based on recombinant PA protected nonhuman primates from inhalational challenge.[158,205,270] These vaccines are in advanced stages of development, undergoing Phase I/II human trials.[271–273] The initial small studies revealed the PA vaccine to be well tolerated with reactogenicity similar to or less than that seen with AVA. In one study, the immunogenicity of PA after two doses of 5 to 75 μg was noninferior to AVA while in another study without an AVA group, antibody titers were higher at 50 μg compared to doses of 5 and 25 μg. Although there is evidence that the efficacy of AVA against parenteral challenge in rodents differs with challenge strains,[164,165,173] AVA protected rhesus monkeys against a more rigorous aerosol challenge with all strains tested.[208,211] Nevertheless, there is concern that naturally occurring or genetically engineered strains might circumvent protection seen with a single component PA-based vaccine.

Another approach has been to develop live vaccines for human as live vaccine protects experimental animals better than does the licensed human PA vaccine.[157,164,165,274] The precedent exists for using such a vaccine in humans in Russia and the former Soviet republics. Live attenuated vaccines known to protect experimental animals against anthrax include aromatic compound-dependent, toxigenic, nonencapsulated strains of *B. anthracis*.[274] as well as strains of *B. anthracis*,[196,197,275] *B. subtilis*,[274] *Salmonella*,[276,277] *Lactobacillus*,[278] and vaccinia,[279–281] that have been constructed to contain the cloned PA gene alone or with mutated and inactivated LF and/or EF. A system using killed but metabolically active *B. anthracis* expressing PA and mutated LF and EF protected rabbits against intratracheal challenge with a virulent strain.[282] Finally, other approaches giving protection in animals using PA alone or with LF or EF have included nonreplicating DNA vaccines,[159,283,284] viral replicons,[285] adenovirus vectors,[162,286] bacteriophage,[261] and hepatitis B core particles.[287] However, in the first human trial, a DNA vaccine expressing a mutated PA and mutated LF was poorly immunogenic and showed dose-limiting adverse events.[288]

Attempts to identify antigens other than the PA component of the toxin that contribute to protection are also underway. Spore components[289] and the capsule[290–292] have been shown to offer additional protection in small-animal models, and a capsule vaccine offers some protection in nonhuman primates.[50,293] In more recent studies, a capsule vaccine completely protected nonhuman primates against inhalational anthrax.[294] While some enhancement of protection was observed when PA was combined with spore components, there was no protection when the spore components were used alone,[295–297] and the search for protective spore antigens continues. A recent study showed some protection in mice against challenge with an attenuated strain after vaccination with glyceraldehyde-3-phosphate dehydrogenase or GroEL

isolated from *B. anthracis.*[298,299] In addition, the recent sequencing of the *B. anthracis* genome[300] is anticipated to advance the search for new vaccine candidates using reverse vaccinology to identify surface exposed or secreted antigens.[301]

Although these efforts are in the experimental stage, they may lead to the production of a vaccine that requires fewer doses and provides a more rapid and enhanced immune response and long-lasting immunity In addition, inclusion of other PAs, such as the capsule, with PA, may protect against a broader range of anthrax strains, provide protection of individuals who do not respond optimally to PA, and perhaps increase the efficacy of PA vaccines.

12 Biodefense and Special Pathogen Vaccines

Phillip R. Pittman and Stanley A. Plotkin

This chapter discusses vaccines for military and biodefense research personnel as well as some vaccines that are in development for uncommon or geographically limited diseases. Military personnel have the potential to be exposed to many infectious agents as endemic diseases and in their unnatural form as biological weapons. Increasingly, civilian populations may be targets for terrorist attacks using microorganisms (or their toxins), as was demonstrated by the purposeful dissemination of anthrax spores following ballistic attacks on the World Trade Center and the Pentagon in 2001.

The U.S. Army has had a longstanding program to develop vaccines to combat these threats. Within the U.S. Department of Defense (DOD), the U.S. Army Medical Research and Materiel Command (USAMRMC), located at Fort Detrick, Maryland, is the principal organization responsible for vaccines and other medical countermeasures against biological warfare agents. Within USAMRMC, the unit with direct responsibility for this defensive mission is the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID), also at Fort Detrick. Before 1969, when the United States maintained an offensive biological weapons program, the U.S. Army Medical Unit within the Walter Reed Army Institute of Research in Washington, DC, served in this capacity.

Many of the biowarfare vaccines currently available at USAMRIID and elsewhere to protect laboratory researchers studying these agents were conceived at the U.S. Army Medical Unit and were further developed at the now closed National Drug Laboratories (also known as The Salk Institute's Government Services Division [TSI-GSD]). Most of the vaccines developed at Fort Detrick, for a variety of reasons, remain investigational new drugs (INDs). However, all these vaccines have undergone extensive preclinical testing and have progressed to Phase II trials that have continued for many years. Meanwhile, USAMRIID researchers and others continue to apply new technology to develop improved vaccines.

Table 12.1 presents all IND vaccine products of military interest developed at USAMRMC/USAMRIID; most of these vaccines are currently available for administration only through USAMRIID's Special Immunizations Program (SIP).[1] One of the vaccines, the Candid #1 Junin (Argentine hemorrhagic fever [AHF]) vaccine, shown to be efficacious in a Phase III trial[2] in Argentina, has been incorporated into that country's public health program and administered to thousands of individuals. Several other vaccines, including Venezuelan equine encephalitis (VEE) TC-83, eastern equine encephalitis (EEE) vaccine, western equine encephalitis (WEE) vaccine, tularemia live vaccine strain (LVS), Rift Valley fever (RVF) inactivated vaccine, and the whole-cell Q fever vaccine, have also been administered to more than 1000 volunteers, primarily through the SIP. In contrast, the chikungunya (CHIK) vaccine strain 181/clone 25, live attenuated RVF vaccine MP-12, Q fever chloroform-methanol residue (CMR) vaccine, and vaccinia/Hantaan vaccine have been administered to no more than a few hundred volunteers each.

Each of the vaccines in active use in USAMRIID's SIP is administered under an approved human use protocol, and all volunteers provide written informed consent before vaccination. These IND vaccines are administered on a voluntary basis to at-risk laboratory and field workers. Most SIP participants are scientists and technicians from USAMRIID, but scientists from academia, other federal and state agencies, and private drug companies also participate.[1] Extramural scientists who wish to receive one of these vaccines must come to USAMRIID for vaccine administration and safety monitoring. The protocols and consent forms are reviewed by the USAMRIID Scientific Review Committee, the Headquarters USAMRMC Institutional Review Board, and the Office of Research Protections (within USAMRMC Headquarters at Fort Detrick) before submission to the U.S. Food and Drug Administration (FDA). Protocols are conducted in accordance with the Belmont Principles, DOD Instruction 3216.02 ("Protection of Human Subjects and Adherence to Ethical Standards in DOD-Supported Research"), and other applicable DOD and FDA regulations and guidelines. Many of these vaccines have been in use since the 1960s and 1970s, and all are subject to periodic potency and lot-release testing as required by FDA.

Continuous monitoring for safety and immunogenicity is conducted through the IND vaccine managing authority: the U.S. Army Medical Materiel Development Activity and the Non-Clinical Studies Division of USAMRIID. Funding for testing of these products is provided through the Medical Countermeasure Systems, Fort Belvoir, Virginia. To date, all vaccines have demonstrated an acceptable safety profile and reasonable immunogenicity (Table 12.2), except the botulinum toxoid pentavalent (ABCDE) vaccine, which is no longer administered.[3] The most reactogenic product is the live attenuated VEE TC-83 vaccine, which frequently induces a short-term systemic reaction.[4] The inactivated vaccines, except the whole-cell Q fever vaccine, require multiple doses for priming and frequent periodic boosting to maintain acceptable levels of neutralizing antibody. All vaccines have been administered to men and nonpregnant women within a broad range of ages, ethnicities, and races. With the exception of Junin vaccine, efficacy of these products is inferred by the absence of laboratory-acquired infection among recipients. However, because laboratory practices and engineering controls have evolved in concert with use of the vaccines, quantifying efficacy on a continuous basis is difficult.

USAMRIID has been proactive in evaluating, not only the short-term reactogenicity, but also the long-term medical safety of its vaccines and other vaccines administered to at-risk laboratory workers. One study[5] was aimed at detecting any long-term medical effects from repeated injections with multiple vaccines; a second study[6] evaluated volunteers who participated in biomedical research as part of Operation Whitecoat.

The first study consisted of 155 volunteers who had participated in a multiple immunizations program (MIP cohort) and 265 community control volunteers who had not participated in a MIP, matched by age, race, and sex.[5] The majority of study volunteers were male (83%) and older in age (average age: 69.4 years). This study did not link any disease or medical condition to repetitive immunization with multiple antigens or any single antigen. Fatigue was noted

TABLE 12.1 Investigational New Drug, Limited-Use Vaccines in Inventory at USAMRIID: Characteristics and Administration

Name	IND Number	Type	Dosage (mL)	Route	Schedule (days)	Boosters
VEE TC-83 (NDBR 102)	BB-IND 142	Live attenuated	0.5	SC	0	Boost with C84 per titer
VEE C-84 (TSI-GSD 205)	BB-IND 914	Inactivated	0.5	SC	0[a]	Yes; based on titer
WEE (TSI-GSD 210)	BB-IND 2013	Inactivated	0.5	SC	0, 7, 28	Mandatory boost at month 6[b]
EEE (TSI-GSD 104)	BB-IND 266	Inactivated	0.5	SC	0, 28	Mandatory boost at month 6[c]
Chikungunya 181/clone 25 (TSI-GSD 218)	BB-IND 2426	Live attenuated	0.5	SC	0	Not determined
RVF (TSI-GSD 200)	BB-IND 365	Inactivated	1.0	SC	0, 7, 28	Yes; based on titer[d]
RVF MP-12, ZH548 (TSI-GSD 223)[e]	BB-IND 4307	Live attenuated	1.0	IM	0	No
Junin, or Candid #1[e]	BB-IND 2257	Live attenuated	0.5	SC	0	No
Q fever (NDBR 105)[e,f]	BB-IND 610	Inactivated	0.5	SC	0	No
Q fever CMR[e] (TSI-GSD 217)	BB-IND 3516	Inactivated	0.5	SC	0	Not determined
Tularemia LVS (NDBR 101, TSI-GSD 213)	BB-IND 157	Live attenuated	0.06	Scarification	0	No

CMR, chloroform-methanol residue; EEE, eastern equine encephalitis; IM, intramuscular; IND, investigational new drug; LVS, live vaccine strain; RVF, Rift Valley fever; SC, subcutaneous; TSI-GSD, The Salk Institute's Government Services Division; USAMRIID, U.S. Army Medical Research Institute of Infectious Diseases; VEE, Venezuelan equine encephalitis; WEE, western equine encephalitis.

[a]C-84 is given only after TC-83 and titer <1:20.

[b]After month 6, boosts of the WEE vaccine are given as needed per titer.

[c]Boosts of the EEE vaccine before and after month 6 are given as needed per titer (as 0.1 mL intradermally).

[d]Initial responders to RVF (inactivated) vaccine: mandatory boost at month 6, then as needed per titer. Initial nonresponders: boost within 90 days of low titer.

[e]These vaccines are currently not in active use at USAMRIID.

[f]A skin test (using Q fever skin test antigen, MNLBR 110, a dilution of the NDBR 105) is conducted 1 week prior to vaccination with Q fever vaccine (NDBR 105).

TABLE 12.2 Assessment of Efficacy and Safety of Selected Limited-Use Vaccines

			Relative Severity and Frequency of Vaccine-Related Reactions	
Name	Tests of Effectiveness	Effective?	Systemic Severity/Frequency	Local Severity/Frequency
VEE TC-83, live	Reduction in laboratory-associated infections	Yes	+++/+++	+/+
VEE C-84, inactivated	Insufficient data	Unknown	+/+	+/+
WEE, inactivated	Reduction in laboratory-associated infections	Probably	+/++	+/+
EEE, inactivated	Reduction in laboratory-associated infections	Probably	+/++	+/++
Chikungunya, live	Insufficient data	Unknown	+/++	+/++
RVF, inactivated	Reduction in laboratory-associated infections	Yes	+/+	+/+
RVF MP-12, live	Insufficient data	Unknown	+/++	+/+
Junin, live	Formal Phase III field trial	Yes	+/+	+/+
Q fever, inactivated	Reduction in laboratory-associated infections	Probably	+/+++	+/+++
Q fever CMR, inactivated	Insufficient data	Unknown	+/++	+/+++
Tularemia LVS, live	Reduction in laboratory-associated infections	Yes	+/+++	+/+++

EEE, eastern equine encephalitis; LVS, live vaccine strain; RVF, Rift Valley fever; VEE, Venezuelan equine encephalitis; WEE, western equine encephalitis.

Severity of reactions: +, most reactions are mild, <5% are severe; ++, most reactions are mild or moderate, <15% are severe; +++, a majority of reactions are mild or moderate, ≥15% are severe.

Frequency of reactions: +, typically occur after <10% of doses; ++, typically occur after ≥10% but <30% of doses; +++, typically occur after ≥30% of doses.

Table displays an overall, qualitative assessment of the severity and frequency of reactions based on published work[2,56,83,92,311–314] as well as unpublished studies conducted at USAMRIID.

more commonly among subjects who had received multiple immunizations, but this finding was not associated with number of shots, number of antigens, or time in the MIP. Although statistically significant increases and decreases in several clinical laboratory tests were observed, none of these findings appeared to be clinically significant.

The single most important finding of this study was the greater frequency of serum monoclonal proteins observed among MIP subjects compared with control subjects. However, no associations between the presence of monoclonal proteins and specific diseases or medical conditions were seen.[5] The significance and implications of this finding are unclear, warranting further investigation. A larger study with more than 1100 volunteers who participated in the SIP has been completed and should, once the results are analyzed, elucidate these findings further. The results of this study are expected to be published in 2017.

The second study involved men entering military service in the early days of the Cold War and the Vietnam War who expressed a conscientious objection to combat. These men were offered the opportunity to serve as medical research volunteers in Fort Detrick's biological warfare defense program. More than 2000 subjects participated in what became known as Operation Whitecoat. A study to assess the current health status of Operation Whitecoat medical research volunteers who served between 1954 and 1973 was developed as a joint effort between DOD and the Seventh-Day Adventist Church.[6]

Many of the volunteers enrolled in this study had been exposed to an infectious agent, vaccine, or other biological product as part of Operation Whitecoat (study group; n = 358); others had participated in research studies as unexposed control subjects or chose not to participate at all (control group; n = 164). Volunteers completed a self-administered questionnaire regarding their health status, clinical signs and symptoms, reproductive outcomes, and diseases or conditions diagnosed by medical providers. Attempts to assess frequencies of clinical signs and symptoms or diseases by individual vaccine, individual virulent agent, and individual antibiotic/inert substance exposure yielded numbers too small for meaningful analysis for all but recipients of VEE vaccine(s) and tularemia vaccine(s) as well as individuals exposed to virulent *Coxiella burnetii*. Among these exposures, a possible association between developing asthma and receipt of tularemia vaccine(s) (but not VEE vaccine or virulent *C. burnetii*) was observed (13.3% of vaccinees vs 2.4% of control subjects). In this same cohort, an association between receipt of a tularemia vaccine and a greater frequency of chronic headaches was suggested (with 35.6% of vaccinees vs 18.3% of control subjects reporting that headaches were occasionally or more frequently a problem as opposed to never or rarely a problem); however, this association did not reach statistical significance. No adverse impact on the overall health of Operation Whitecoat volunteers could be conclusively attributed to participation in research studies at Fort Detrick.[6] Loma Linda University will continue with intermittent follow-up studies.

LIMITED-USE VACCINES AGAINST VIRAL DISEASES

Alphaviruses

The alphaviruses are a group of mosquito-borne, lipid-enveloped, positive-sense, single-stranded RNA viruses belonging to the family *Togaviridae*. Alphaviruses are responsible for two distinct clinical syndromes: fever, chills, headache, myalgias, vomiting, and encephalitis (e.g., VEE, EEE, and WEE) and fever, rash, and polyarthralgias/arthritis (e.g., CHIK, Ross River virus disease [RRVD, formerly called epidemic polyarthritis], and o'nyong-nyong). Several excellent reviews are available on the classification, epidemiology, and clinical features of these agents.[7–9] Although the DOD has developed vaccines against VEE virus (VEEV), WEE virus (WEEV), EEE virus (EEEV), and CHIK virus (CHIKV), these vaccines remain investigational. Ongoing research seeks to develop improved vaccines against these pathogens.[10] For example, a recent study using replicon technology showed that individual replicon vaccine candidates for VEE and EEE or a combined VEEV/WEEV/EEEV replicon particle vaccine elicited strong neutralizing antibodies and protection against aerosol challenge with VEEV subtype I-AB (Trinidad donkey strain) and EEEV. However, the individual WEEV replicon and the combined VEEV/WEEV/EEEV replicon vaccine elicited low levels of neutralizing antibodies to WEEV and conferred poor protection in macaques.[11] In particular, Wolfe and colleagues[12] argue that an FDA-licensed trivalent VEE/WEE/EEE vaccine—one that overcomes the safety, immunogenicity, and immune interference issues of the existing IND vaccines—is required to meet the requirements of the biodefense community. Such a vaccine also would be of great value to the public health and agricultural communities.

Experience with sequential administration of alphavirus vaccines at USAMRIID has led to a number of interesting observations relating to immunologic interference. Prior immunization with inactivated EEE and/or WEE vaccines decreases one's ability to mount a neutralizing antibody response following receipt of live attenuated VEE TC-83 vaccine. However, no interference is observed when the order of administration is reversed, such that VEE TC-83 vaccine is given first.[13] Similarly, interference occurs when two live attenuated alphavirus vaccines, VEE TC-83 and a CHIK vaccine (CHIK 181/clone 25), are administered sequentially.[14] Volunteers initially vaccinated with VEE TC-83 exhibited poor neutralizing antibody responses to live attenuated CHIK vaccine (46% response rate). Among persons initially inoculated with the CHIK vaccine or placebo who then received the live attenuated VEE TC-83 vaccine, geometric mean antibody titers to VEEV, as measured by 80% plaque reduction neutralization test ($PRNT_{80}$), were uniformly depressed in CHIK vaccine recipients compared with placebo recipients.[14] Interference may be an important consideration for the development of next-generation alphavirus vaccines, and particularly for the development of multiagent alphavirus vaccines.

Venezuelan Equine Encephalitis Virus

The two VEE vaccines available for human use as INDs (vaccines)—the live attenuated product, TC-83, and a formalin-inactivated product, C-84—both derive from the same lineage. The live attenuated TC-83 virus, a subtype I-AB strain, was isolated from a donkey brain in Trinidad and was passaged 13 times in embryonated eggs.[15] The virus was attenuated by 78 passages in fetal guinea pig heart (FGPH) cell cultures, plaque-picked in chick embryo fibroblasts (CEFs), and passaged four additional times in FGPH cell cultures.[16] The VEE TC-83 virus designation is a direct reference to the 83 passages in cell culture. VEE C-84 vaccine is formalin-inactivated and is made from the TC-83 production seed, TC-82, that has undergone one additional passage in CEFs.[17] This C-84 production seed is passaged once more in CEFs to derive the C-84 vaccine, which is inactivated with 0.1% formalin and then freeze-dried. The inactivation procedure is based on that used by Salk and colleagues[18] to inactivate the poliovirus. TC-83 and C-84 contain streptomycin and neomycin, each at a concentration

of 50 μg/mL. Laboratory infections with epizootic VEEV strains closely related to the parent strain have essentially been eliminated since the introduction of these vaccines and improvement in personal protective equipment.

At USAMRIID, immunologically naïve people at risk for exposure to VEE receive a single dose of the live attenuated TC-83 vaccine. Those who seroconvert ($PRNT_{80}$ titer ≥1:20) receive a single booster of C-84 as needed based on their titer ($PRNT_{80}$ <1:20); nonresponders to TC-83 receive a booster with C-84. The response rate to TC-83 alone is 82%.[4] When TC-83 is followed by a single boost with C-84, a combined response rate of well over 90% is observed. Female responders to TC-83 tend to have titers similar to those of male responders, but the frequency of nonresponders tends to be higher among women than men; in one study, the initial response rate among recipients of a single dose of TC-83 was 74% and 85%, respectively, for women and men. The nature of this sex difference is not understood.

Approximately 23% of persons receiving the live attenuated TC-83 sustain adverse reactions, including headache, sore throat, malaise, fatigue, myalgias, arthralgias, chills, and fever—a suite of symptoms similar to those seen following natural VEEV infection but less severe.[4] The local reaction rate is less than 5%. The inactivated vaccine C-84 has a local reaction rate of approximately 5%, but essentially no systemic reactions are associated with its administration. Diabetes mellitus, abortion, and teratogenesis have been associated—epidemiologically and/or in animal studies—with natural wild-type VEEV infection.[19–21] Before pregnancy testing prior to vaccination became available, three cases of spontaneous abortion or stillbirth were temporally related to the administration of TC-83.[22] However, VEEV was not recovered from culture of tissues in either case. (Though they were reported to FDA, these cases were never published as case reports.) Since the advent of pregnancy testing, great care has been used to ensure that women are not pregnant before administration of TC-83. Out of an abundance of caution, persons with a family history of diabetes mellitus are considered ineligible for vaccination with TC-83, despite the lack of evidence for a causal association between diabetes mellitus and VEEV infection or vaccination with TC-83.

The ideal VEE vaccine would have a high seroconversion rate (>95%) and a low reaction rate (<5%). By these standards, TC-83 is reactogenic and has a moderate response rate, as measured by neutralizing antibody. In addition, TC-83 does not protect adequately against distantly related VEEV subtype I-AB variants or the other enzootic VEEV subtypes II through VI. Finally, the manufacturing process for TC-83 requires the manipulation of infectious viral particles in a biosafety level 3 containment laboratory.[10]

A new-generation, live attenuated vaccine candidate, V3526, uses twin site-directed mutagenesis of the full-length complementary DNA clone of the virulent virus RNA.[23] V3526 has two deletion mutations—a lethal deletion at the PE-2 cleavage signal site and a suppressor mutation at site 253 of the E1 glycoprotein—that should prevent reversion to wild-type VEEV. This vaccine candidate also has limited potential for transmission by mosquitoes and elicits cross-protection against different viral strains.[10] After showing promise in preclinical studies,[24] V3526 elicited the development of impressive neutralizing antibody levels in human volunteers during Phase I clinical trials. However, the vaccine was associated with a high frequency of fever and other flu-like symptoms; thus, further development was discontinued.[25,26]

Because of the long history of frequent adverse reactions related to live attenuated VEE vaccines, the manufacturer decided to inactivate V3526 and further develop it as an inactivated vaccine to be used as a priming vaccine that would replace C-84. Testing has shown reduced infectivity by both formalin inactivation (fV3526) and gamma-irradiation (gV3526). For example, both inactivated vaccine candidates showed a loss of neurovirulence after intracerebral inoculation of suckling BALB/c mice, suggesting that the vaccines were completely inactivated. Both fV3526 and gV3526 elicited robust immune responses; furthermore, protection was demonstrated by both vaccine candidates against subcutaneous challenge with VEEV I-AB Trinidad donkey strain following two doses of either vaccine. Recently, researchers have been testing these vaccine candidates, using various adjuvants and routes of administration, against subcutaneous and aerosol challenge.[24,27,28]

In addition to fV3526 and gV3526, other technologies are being evaluated for the production of vaccines against VEE. For example, Sharma and colleagues[29] found that the hydrophobic alkylating compound 1,5-iodonaphthylazide can effectively inactivate virulent VEEV strain V3000. The resulting inactivated vaccine candidate was efficacious in protecting mice from virulent VEEV challenge, and its efficacy was enhanced by the use of adjuvants. Rossi and colleagues[30,31] developed a live attenuated vaccine using an encephalomyocarditis virus internal ribosome entry site (IRES)—a construct that inhibits translation of viral proteins in mosquito cells, thus preventing transmission by the natural VEEV vector. This IRES-based VEE vaccine fully protected mice and macaques from clinical disease after aerosol challenge with virulent VEEV.

DNA vaccines are also under development and, in protective efficacy studies, have shown promise in both mice and guinea pigs.[32] One DNA vaccine candidate has also demonstrated protection against aerosol challenge with wild-type VEEV in nonhuman primates.[33,34] A candidate based on a novel approach to DNA vaccine development, infectious DNA (iDNA), was protective in one BALB/c mouse challenge study.[35]

Western Equine Encephalitis Virus

An inactivated WEE vaccine, TSI-GSD 210, has been used at Fort Detrick since the 1970s to immunize at-risk laboratory personnel. The WEE vaccine is a lyophilized product derived from supernatant fluids of primary CEF cell cultures infected with the attenuated CM4884 strain of WEEV.[36,37] The supernatant fluid is harvested and filtered, the virus is inactivated with formalin, and the final product is lyophilized for storage at −20°C. The vaccine contains 50 μg/mL of neomycin. The primary end point used to measure immunogenicity of the WEE vaccine is the $PRNT_{80}$, with a titer of at least 1:40 considered indicative of a response.

In an analysis of data from 363 volunteers who received 0.5 mL of inactivated TSI-GSD 210 vaccine subcutaneously at days 0, 7, and 28, 151 subjects (41.6%) responded with a $PRNT_{80}$ titer of 1:40 or greater, whereas 212 subjects (58.4%) failed to achieve this neutralizing antibody titer. Of 115 initial nonresponders, 76 (66.1%) converted to responder status after a single booster. Kaplan–Meier plots showed that a regimen consisting of three initial doses and one booster induced a $PRNT_{80}$ titer of at least 1:40 lasting 1.6 years in 50% of initial responders. Local and systemic adverse events are uncommon with this vaccine. Among 363 vaccinees receiving three initial injections of the WEE vaccine, only 5 reported local or systemic reactions (P.R. Pittman, P.H. Gibbs, and T.L. Cannon, unpublished data).

No instances of occupational WEE have been documented among laboratory workers who develop neutralizing antibodies following vaccination. WEE vaccine continues to be administered as part of Phase II clinical trials; however, no efficacy trial has been conducted.

A new lot of the WEE vaccine, Western Equine Encephalitis Vaccine, Inactivated, TSI-GSD 210, Lot 3-1-92, was found to be safe and immunogenic in a recent Phase I clinical trial (Dr. Robert Rivard, USAMRIID, personal communication, 2015). In this study, WEE vaccine was administered in 0.5-mL doses subcutaneously in the upper outer aspect of the triceps in a three-dose primary series (days 0, 7, and 28) with a mandatory boost (day 180). All 10 subjects were classified as responders at day 56. For 4 of 10 subjects, the titers had waned below the acceptable level by month 6. Following the month 6 boost, all 10 subjects developed titers above 1:40, and all remained above this level for at least 1 year.

DNA-based vaccines against WEE have shown promise in challenge models in mice. One such study evaluated a DNA vaccine, pVHX-6, expressing the 26 S structural gene of WEEV strain 71 V-1658. All mice receiving four intraepidermal doses of pVHX-6 survived challenge with a homologous strain, but only 62% and 50% survived challenge with Fleming and CBA87 strains, respectively.[38] Other studies have demonstrated, in a murine model, the efficacy of DNA vaccines expressing the capsid and envelope proteins of WEEV in challenge models. In two studies, a replication-defective human adenovirus serotype-5 (HAd5) was used as a vector for vaccine delivery. In the first study, a HAd5 vector encoding E2 and E1, administered as a single dose, conferred protection against challenge with homologous and heterologous WEEV strains.[39,40] In the second study, a HAd5 vector encoding E1 alone, designated adenovirus (Ad) serotype-5-E1 (Ad5-E1), provided total protection against homologous and heterologous strains of WEEV in mice.[41] A potential drawback of this approach in humans is the widespread prevalence of antibodies against adenovirus.

Eastern Equine Encephalitis Virus

The EEE vaccine (TSI-GSD 104) is a lyophilized product originating in primary CEF cell cultures infected with the attenuated PE-6 strain of EEEV. The seed for the EEE vaccine is passaged twice in adult mice and twice in guinea pigs, then passaged nine times in embryonated eggs, followed by three passages in CEFs.[42] The supernatant fluid, which is harvested and filtered, contains 50 μg each of neomycin and streptomycin and 0.25% w/v (weight per volume) of human serum albumin, USP (U.S. Pharmacopoeia). The virus is then inactivated with 0.05% formalin. When inactivation is completed, the residual formalin is neutralized by treatment with sodium bisulfite. The final product is lyophilized for storage at −20°C.

Among 255 volunteers who received the two-dose primary series of EEE vaccine (administered subcutaneously) between 1992 and 1998, 197 (77.3%) responded with a $PRNT_{80}$ titer of 1:40 or greater. Of initial nonresponders, 66% subsequently seroconverted following receipt of an EEE vaccine booster (which is administered intradermally). Among initial responders whose titers waned over time, 98.6% responded to a booster dose of EEE vaccine. Local and systemic side effects are infrequent, occurring in less than 1% of vaccinees after the primary vaccine series and in 3.7% after the first booster. Kaplan–Meier plots show that two primary doses and one intradermal booster of TSI-GSD 104 provide satisfactory neutralizing anti-EEEV antibodies in 50% of initial responders for up to 2.2 years.[43]

Among recent findings regarding next-generation EEE vaccines, a single subcutaneous dose of an EEE vaccine candidate, attenuated via an IRES, protected 100% of vaccinated mice against intraperitoneal challenge.[44] In addition, an EEEV replicon and a combined VEEV/WEEV/EEEV replicon protected macaques from aerosol challenge.[11]

Chikungunya Virus

CHIKV can cause an acute viral syndrome in humans characterized by fever, rash, and arthritis.[45] Some people, especially those who are human leukocyte antigen (HLA)-B27–positive, may develop long-term joint involvement.[46] Although documented epidemics have occurred since the late 18th century, the virus was first isolated during the 1952–1953 Tanzanian epidemic.[47] During 2004–2006, an epidemic ravaged the Indian Ocean islands east of Madagascar—La Réunion, Mauritius–Seychelles, and Mayotte.[48] More than 2 million people have been affected since the start of the epidemic, which has since spread to the Caribbean and India, with cases also occurring in persons from the United States, Europe, and elsewhere who traveled to the Caribbean.[49–52] In December 2014, Kendrick and colleagues[53] reported on the first 11 cases of CHIK originating in the United States (Florida). Genomic sequencing of six isolates from the Indian Ocean outbreak suggests that the strain responsible for the outbreak is related to East African isolates.[49] In addition, evidence from the sequence data suggests that the CHIKV strain responsible for the Indian Ocean outbreak evolved, during the course of the outbreak, into several distinct variants. One mutation may have allowed the CHIKV to be efficiently transmitted by the most abundant mosquito species on La Réunion (*Aedes albopictus*); this may help explain the noted robustness of the epidemic.[49,52,54]

Several attempts were made, with variable success, to develop an efficacious inactivated vaccine using chick embryo cell cultures, suckling mouse brain, and African green monkey kidney.[55] A live attenuated vaccine was made from the seed of the African green monkey kidney vaccine, using CHIKV strain 15561, which had originally been isolated from an infected patient during a 1962 CHIK epidemic in Thailand.[55,56] The 11th African green monkey kidney passage of CHIKV strain 15561, made at the Walter Reed Army Institute of Research, was transferred to USAMRIID and passaged in Medical Research Council (MRC)–5 cells. After 18 passages in MRC-5 cells, CHIKV 181/clone 25 was selected as a vaccine seed strain based on biomarkers. CHIKV 181/clone 25 was efficacious in challenge models in suckling mice and in nonhuman primates.[55]

A randomized, double-blind, placebo-controlled trial of the CHIK 181/clone 25 vaccine documented a seroconversion rate of 98% among alphavirus-naïve volunteers.[56] One year after immunization, 85% of vaccinees remained seropositive. Injection site and systemic symptoms, including flu-like symptoms, were similar in vaccine and placebo recipients. However, the vaccine was temporally associated with arthralgia in 8% of vaccinees. One volunteer in the vaccine group developed a pruritic, eczema-like rash at the injection site. Interference between the CHIK 181/clone 25 vaccine and the live attenuated VEE TC-83 vaccine is discussed above. This live attenuated CHIK vaccine requires additional Phase II and Phase III clinical testing. Current epidemics in the Caribbean, Indian Ocean, and India offer unique prospects for Phase III clinical testing of this vaccine.

Additional strategies for the development of a safe and efficacious vaccine for CHIK are being pursued. These include chimeric alphavirus vaccine candidates using VEEV attenuated vaccine strain TC-83, a naturally attenuated strain of EEEV, or Sindbis virus as a backbone with the structural protein genes of CHIKV. Wang and colleagues[57] found that each of these chimeras produced robust neutralizing antibody responses, and vaccinated mice were fully protected against disease and viremia after CHIKV challenge. One DNA vaccine candidate expressing a component of the CHIKV envelope glycoprotein produced neutralizing antibodies in mice and macaques.[58] A second DNA vaccine candidate uses a plasmid coding for the CHIKV-capsid,

E1 and E2. When injected into mice, this construct induced broad cellular immunity and produced antibodies, detectable by enzyme-linked immunosorbent assay (ELISA), that recognized native antigen.[59] Another group is evaluating a formalin-inactivated Vero cell–adapted vaccine candidate prepared using a strain from the India epidemic.[60] Most recently, a promising virus-like particle (VLP) vaccine containing the viral envelope has elicited high titers of neutralizing antibodies in nonhuman primates and in human volunteers.[61–63] In addition, a single immunization with a measles virus–vectored CHIK vaccine candidate induced high CHIKV antibody titers and protected mice from a lethal CHIKV challenge.[64]

Ross River Virus

RRVD, or epidemic polyarthritis, was first recognized in Australia in 1928; Ross River virus (RRV), its causative agent, was first isolated in 1963 from a pool of mosquitoes.[65–67] RRVD is essentially limited to Australia, Fiji, and the surrounding islands, including American Samoa and the Cook Islands, where several thousand cases occur per year.[68,69] In humans, polyarthritis may be followed by fever, rash, and lethargy; symptoms generally resolve after 3 to 6 months.[69,70] In 1997, U.S. marines participating in Operation Tandem Thrust in Queensland, Australia, had an infection rate of 1.5%; RRVD developed in nine individuals.[71]

A vaccine candidate was derived from a virus isolated from a human case of classical RRVD using the C6-36 cell line (*A. albopictus*).[72] The candidate underwent four serial passages in MRC-5 human fetal lung cells followed by two passages in Vero cells. Cell cultures contained penicillin (100 U/mL) and streptomycin (100 µg/mL). The virus was inactivated using binary ethyleneimine. In mice, the vaccine induced neutralizing antibodies and conferred protection against viremia after intravenous challenge with live RRV.[73]

More recently, a Vero cell–grown, formalin-inactivated, benzonase-digested (to digest host cell DNA), sucrose gradient–purified vaccine candidate induced neutralizing antibodies in mice.[74] Immunized mice and guinea pigs failed to develop viremia following intravenous challenge with the prototype strain of RRV (T48). In a Phase I/II dose escalation study[75] in 382 healthy, RRV-naïve adults, this vaccine was safe and immunogenic when administered as three immunizations (at days 0 and 21 and month 6) at four dose levels, with or without aluminum hydroxide added as an adjuvant; the adjuvanted 2.5-µg dose stimulated the highest immune response. This group recently completed a Phase III study in 1755 healthy younger adults (ages 16–59 years) and 209 healthy older adults (ages 60 and older).[76] The vaccine was well tolerated. Neutralizing antibody titers (≥1:10) were achieved by 91.5% of the younger adults and 76.0% of the older adults after the third vaccination. The potential for antibody-dependent enhancement of disease, which has been described for RRV in vitro, will need to be considered during the development of vaccines against RRV.[69,77]

Bunyaviruses

The Bunyaviridae are a large family of segmented, lipid-enveloped, negative-stranded RNA viruses. Vaccines against human pathogens representing two of the five genera, RVF virus (*Phlebovirus* genus) and Hantaan virus (*Hantavirus* genus), have been developed at Fort Detrick.

Rift Valley Fever Virus

RVF is a mosquito-borne infection endemic to sub-Saharan Africa and primarily affecting ruminant animals. Under appropriate climatologic conditions, however, explosive epizootics among animals and epidemics in humans occur with considerable morbidity and mortality. In recent years, RVF has demonstrated its ability to spread northward to Egypt and into Yemen and Saudi Arabia on the Asian continent. The consequences of further spread into naïve animal and human populations are potentially devastating.[78] The spread of West Nile virus (WNV) has demonstrated that viruses once bounded by the Atlantic Ocean have the potential to overcome that barrier. Thus, the development of a vaccine or other countermeasures against the RVF virus is important for the protection of human and animal populations in Africa and the Middle East, U.S. military personnel involved in campaigns in those regions, and livestock and people in the United States and elsewhere.

The U.S. Army has developed two vaccines to combat this threat: an inactivated RVF vaccine (TSI-GSD 200) and, more recently, a live attenuated product (RVF MP-12; TSI-GSD 223). The Entebbe strain of RVF, isolated from a mosquito pool in Bwamba County, Uganda, is the source for the inactivated vaccine.[79] The virus was passaged 184 times in adult mice, followed by two passages in fetal rhesus lung (FRhL) cells to form the production seed. Although the original vaccine was produced in primary African green monkey kidney cells, the current vaccine lots are produced in FRhL cells.[80,81] The vaccine is inactivated in 0.05% formalin. Following verification of viral inactivation, the residual formaldehyde is neutralized with sodium bisulfite to less than 0.01%. A study of the immunogenicity and safety of inactivated RVF vaccine in humans during a 12-year period showed that the vaccine was safe and immunogenic when the three-dose primary series and one booster are administered.[82,83] In particular, 540 (90%) of 598 volunteers given three 1.0-mL doses of TSI-GSD 200 subcutaneously on days 0, 7, and 28 responded with a $PRNT_{80}$ titer of 1:40 or greater. Three-fourths of the initial nonresponders developed a $PRNT_{80}$ titer of 1:40 or greater after a single booster. However, approximately 10% of recipients of the inactivated RVF vaccine require repeated boosting. In these individuals, a booster typically results in an adequate titer, which wanes over the next year to <1:40, prompting another booster (P.R. Pittman, unpublished data).

An isolated RVF strain recovered from a nonfatal human case that occurred during the first Egyptian epidemic in 1977 was used to derive the live attenuated RVF vaccine. The virus (ZH548) was passaged twice in suckling mouse brain, then once in FRhL cells. It was then attenuated by 12 serial alternating passages in human lung cell cultures (MRC-5 cells, certified for vaccine use) by previously described methods[84] in the presence or absence of 5-fluorouracil. The resulting RVF MP-12 vaccine is a lyophilized product originating from supernatant fluids harvested from the final mutagenesis passage. The vaccine has undergone extensive safety testing and challenge studies in several animal species: rodents, sheep (including pregnant ewes and naïve neonatal lambs), cattle (including in utero–vaccinated bovids), and monkeys.[85–89] Furthermore, Miller and colleagues[90] showed that RVF MP-12 vaccine, administered to sheep, results in long-lasting immunity and has limited potential to be transmitted to mosquitoes feeding on vaccinated animals.

RVF MP-12 has undergone clinical evaluation in human volunteers at USAMRIID. In a Phase I randomized, double-blind, dose-escalation/route-seeking study, 56 healthy, nonpregnant subjects were randomly selected to receive RVF MP-12 ($10^{4.7}$ plaque-forming units [PFU] subcutaneously, $n = 10$; $10^{3.4}$ PFU intramuscularly, $n = 6$; or $10^{4.4}$ PFU intramuscularly, $n = 27$) or placebo ($n = 13$).[91] Only infrequent and minor side effects were seen among placebo and MP-12 recipients. One volunteer had a titer of 1.3 log by direct

plaquing in cell culture. Six vaccinees had transient low-titer viremia detected by amplification only; all six of these volunteers were from the group receiving $10^{4.4}$ PFU intramuscularly. Neutralizing antibodies (measured by $PRNT_{80}$ titer), as well as RVF-specific immunoglobulin (Ig) M and IgG, were observed in 40 (93%) of 43 vaccine recipients. The highest peak geometric mean antibody titers were observed in the group receiving $10^{4.4}$ PFU intramuscularly. Overall, 28 (82%) of 34 RVF MP-12 recipients available for testing remained seropositive ($PRNT_{80}$ = 1:20) at 1 year following inoculation.[91]

A joint program between the University of Texas Medical Branch and USAMRIID for further development of the RVF MP-12 vaccine has been completed. This study, funded by the National Institute of Allergy and Infectious Diseases, involved the administration of a single intramuscular dose of RVF MP-12 vaccine to 19 naïve male and nonpregnant female subjects. The vaccine was safe and immunogenic in this vaccine trial. A total of 18 (95%) of 19 subjects developed neutralizing antibodies against RVF virus, as determined by a $PRNT_{80}$ titer of 1:20 or more. Results suggested that the vaccine resulted in, at most, only low-level viremia. No virus was detected by direct plaque assay; however, during the first 14 days after vaccination, nine MP-12 isolates were recovered from five subjects with the use of amplification by blind, double passage in Vero cells. No single-nucleotide polymorphisms or reversions were observed in the attenuating mutations of the parent virus.[92]

Another RVF live attenuated vaccine candidate is Clone 13. This vaccine candidate is a plaque-purified clone of RVF virus that contains a large deletion in the small (S) genome segment that disrupts the biological functions of the nonstructural proteins NSs. Clone 13 has proven highly immunogenic in mice, sheep, and goats, although it has demonstrated only moderate immunogenicity in cattle.[93,94]

Other approaches to the development of vaccines against RVF virus, all of which are at the preclinical stage, include vaccines based on viral vectors[95–97]; DNA vaccines with molecular adjuvants[98]; subunit vaccines based on purified proteins[99–103]; and vaccines based on single-cycle replicable vaccine mutants.[104]

Hantaviruses

Hantaviruses causing hemorrhagic fever with renal syndrome (HFRS) have been, and continue to be, significant endemic disease threats to U.S. military forces on the Korean peninsula and throughout Europe.[105] At least 14 distinct viral strains of HFRS-causing viruses are distributed worldwide.[106] Three viral proteins are able to induce protection: two surface glycoproteins, G1 and G2 (also called Gn and Gc), and the N nucleocapsid protein. Neutralizing antibodies are protective, although T-cell responses may also be useful.[107] In addition to HFRS, hantaviruses are responsible for hantavirus pulmonary syndrome.[106,108] The hantavirus causing this syndrome in the southwest United States is called Sin Nombre virus (SNV). Humans become infected with hantaviruses via inhalation of aerosolized rodent excreta.[109] The prototype hantavirus, Hantaan, was first isolated in Korea, and the first vaccine also was developed there to protect against HFRS.[108,110,111] This inactivated vaccine, the ROK84/105 strain, harvested from suckling mouse brains, is concentrated by protamine sulfate precipitation and centrifugation. The concentrate is then exposed to formalin inactivation and purified by ultrafiltration and sucrose gradient ultracentrifugation. Aluminum hydroxide is added to the vaccine as an adjuvant, thimerosal as a preservative, and gelatin as a stabilizer. The final product, produced by Rhein Biotech, reportedly has less than 0.01 ng/mL of myelin basic protein. The recommended regimen for this product, Hantavax, is two doses of 5120 ELISA units (0.5 mL) given 1 month apart by the subcutaneous or intramuscular route.

Little has been published on the vaccine, but the manufacturer reports that tolerance is good, although allergic reactions occur, presumably as a result of mouse brain antigens. A serologic response measurable by indirect fluorescence is seen in nearly all vaccinees. Neutralizing antibodies are usually absent after one dose, but are measured in approximately 75% of subjects after the second dose.[112] They decrease to 16% at 12 months, at which time a booster is recommended. Although placebo-controlled data on the efficacy of the vaccine are not available, a similar vaccine made in North Korea reportedly showed 88% to 100% efficacy, and Hantavax itself has been effective in uncontrolled epidemiologic studies done in South Korea and Yugoslavia.[113,114] Although neutralizing antibody responses were not persistent and not stimulated by a booster dose,[107,115] a case-control study conducted in the Republic of Korea estimated efficacies of 46% for two doses and 75% for three doses, but with wide confidence limits.[116]

Vaccines made in cell culture against hantavirus and Seoul virus strains are licensed in China. The substrate is cell cultures of golden hamster kidney or Mongolian gerbil kidney. The efficacy of these bivalent vaccines is reportedly better than 90%, with fewer reactions than after the use of mouse brain–derived vaccine.[113,114]

Another Korean company has developed a hantavirus vaccine made in Vero cells that protected challenged animals by eliciting strong responses to the G1, G2, and N proteins of the virus.[117]

At USAMRIID, advances in technology fueled the development of bioengineered hantavirus vaccines. Two experimental approaches included recombinant vaccinia-vectored Hantaan virus vaccine carrying envelope and nucleocapsid genes[118,119] and the same genes inserted into bacterial plasmids as DNA vaccines. The recombinant vaccinia-vectored Hantaan virus vaccine was efficacious in the hamster infectivity model; even if preexisting immunity to vaccinia virus was present, it could be overcome by a second intramuscular injection of the vaccine candidate.[118] A double-blind, placebo-controlled clinical trial involving 142 volunteers using two subcutaneous injections 4 weeks apart showed that, for vaccinia-naïve volunteers, neutralizing antibodies to Hantaan virus or vaccinia virus were detected in 72% or 98%, respectively, whereas neutralizing antibodies to Hantaan virus were detected in only 26% of vaccinia-immune volunteers, showing the effect of prior vector-directed immunity.[119] This vaccine has been abandoned.

DNA plasmids coding for the G1 and G2 proteins protected monkeys against challenge with a South American hantavirus and elicited antibodies that exerted passive protection in hamsters.[120] Boosting the monkeys 1 to 2 years later showed that immunological memory had been induced.[121] Alphavirus replicons, baculovirus-produced proteins, and chimeric hepatitis B VLPs are all under study as additional hantavirus vaccine candidates.[113,122,123]

Boudreau and colleagues[124] report on a Phase I clinical trial that evaluated Hantaan virus and Puumala virus M-segment DNA vaccines for preventing HFRS. Each volunteer received either Hantaan DNA vaccine (n = 9), Puumala DNA vaccine (n = 9), or both vaccines (n = 9). Three doses (containing 8 μg DNA/4 mg gold per dose), administered 4 weeks apart, were provided to volunteers by particle-mediated epidermal delivery. The single vaccines elicited neutralizing antibodies to Hantaan virus or Puumala virus, respectively, in 30% and 44% of vaccinees. Neutralizing antibodies to one or

both viruses were detected in 56% of volunteers who received the combined vaccine. In an attempt to increase seroconversion, Hooper and colleagues[125] conducted a Phase I clinical trial of these two DNA vaccines delivered by intramuscular electroporation, similar to the Boudreau study. Volunteers (three groups of nine individuals each) received three doses, 28 days apart, of either the Hantaan DNA vaccine, the Puumala DNA vaccine, or a mixture of both vaccines. Each dose of vaccine contained 2 mg DNA in a total volume of 1 mL saline; the combined vaccine contained 1 mg of each DNA vaccine. Neutralizing antibodies were found in 56% and 78% of volunteers who received the Hantaan or Puumala DNA vaccines, respectively. Results of the combined vaccine showed that 78% of vaccinees developed neutralizing antibodies against Puumala virus. The three volunteers with the highest antibody levels against Puumala also developed neutralizing antibodies against Hantaan. No serious adverse events resulting from the vaccines were noted in either study.

Hooper and colleagues[126,127] also found that DNA vaccines encoding the virus envelope glycoproteins of SNV or Andes virus (both of which cause hantavirus pulmonary syndrome) elicit high-titer neutralizing antibodies in animal models. Hamsters vaccinated with three doses of the SNV DNA vaccine were fully protected from lethal challenge with SNV. Further, a pan-hantavirus vaccine using Andes virus, SNV, Hantaan virus, and Puumala virus plasmids elicited neutralizing antibodies against all four viruses.[126]

West Nile Virus

The spread of the flavivirus WNV from its introduction into New York City in 1999 across the United States has been a dramatic example of an emerging infection. WNV is an arbovirus of birds, for which it is often lethal, and is transmitted by multiple mosquito species. Although the incidence of human infections has recently decreased, WNV frequently causes febrile illness, with the complication of meningoencephalitis in about 1% of infections.[128]

WN-VAX, a formalin-inactivated WNV vaccine derived from a strain isolated in New York City in 1999, has been tested in a number of animal models. This vaccine, administered intraperitoneally in two doses, protected 100% of 4-week-old mice against a lethal challenge with WNV.[129] More recently, Muraki and colleagues[130] found that mice passively immunized with serum from WN-VAX–immunized mice were also protected from lethal WNV infection. When administered to macaques, WN-VAX elicited neutralizing antibodies.[130] Clinical trials on this vaccine are planned.

Several Phase I and Phase II clinical trials have been completed on WNV vaccine candidates. The ChimeriVax West Nile vaccine candidate, containing a yellow fever virus backbone and expressing the premembrane and envelope proteins of WNV, was reported to be safe and induced neutralizing antibodies in a Phase I clinical trial.[131,132] In a Phase II clinical trial, ChimeriVax was well tolerated, and more than 96% of vaccinees seroconverted.[133]

In a Phase I clinical trial, a DNA vaccine candidate elicited neutralizing antibodies against WNV.[134] A recombinant subunit vaccine candidate, consisting of an envelope protein truncated at the C-terminal end and containing 80% of the N-terminal amino acids of the native WNV protein (WN-80E) mixed with adjuvant, produced antibodies detectable by ELISA and neutralizing antibody assays. In the challenge experiment, all control rhesus macaques had detectable viremia for at least 3 days after challenge, whereas none of the vaccinated animals showed viremia.[135] A Phase I trial assessing the safety of this vaccine was recently completed.

Arenaviruses

Several members of the *Arenaviridae* family of segmented, negative-stranded RNA viruses are recognized as causative agents for viral hemorrhagic fever syndromes in humans. To date, efforts to develop protective immunogens against arenaviruses have met with limited success.[136] During the 1980s, the first successful vaccine against an arenavirus, Junin virus, was developed through a collaboration between the government of Argentina and the U.S. Army. Efforts to develop vaccines against other pathogenic arenaviruses have resulted in a number of promising candidates, but none of these has progressed to clinical trials.[137]

Junin Virus

Junin virus is the causative agent of AHF, which is endemic to the pampas of north-central Argentina. Humans become infected with the Junin virus by inhalation of infected rodent secretions and excretions.[138–140] Death occurs in 15% to 30% of untreated patients afflicted with AHF.

For several decades, attempts were made in Argentina to develop an efficacious vaccine against AHF. The resulting inactivated and live attenuated vaccine candidates all failed for various reasons.[136] The product developed at USAMRIID, Candid #1, is a descendant of the prototype XJ strain Junin virus, isolated in guinea pig from a fatal AHF case. Following another passage in the guinea pig, the virus underwent 44 newborn mouse brain passages, then was cloned and passaged 19 times in certified FRhL cells.[136,141,142] Candid #1 proved effective in preventing disease in guinea pigs and rhesus macaques after lethal Junin virus challenge.[140,143,144] In Phase I and Phase II clinical testing in humans, Candid #1 was safe and immunogenic.[145,146] More than 90% of volunteers developed antibodies against Junin virus, although at lower levels than those seen after mild natural infection,[147] and 99% developed a Junin virus–specific cellular immune response. In a pivotal efficacy study, 3255 volunteers were randomized to receive the vaccine and 3245 were randomized to receive a placebo. During the trial, 23 volunteers developed an illness that met the clinical case definition for AHF.[148,149] Of these, 22 had received a placebo and 1 had received the vaccine; vaccine efficacy by intent-to-treat analysis was 95% (95% confidence interval, 82%–99%; $P < .001$). Argentina's National Institute of Human Viral Diseases produced its own Junin vaccine, also called Candid #1, against AHF and tested it in 946 human volunteers to compare its safety and immunogenicity with that of the Candid #1 vaccine produced in the United States and used in previous studies.[150] The vaccine was comparable to the U.S.-produced vaccine in terms of safety and efficacy. No severe adverse events were related to the vaccine. As a result of this study, Argentina's national regulatory authority (ANMAT) licensed the locally produced Candid #1 vaccine.[151,152]

Vaccination with Candid #1 is recommended for persons at risk of occupational (agricultural or laboratory) exposure to the Junin virus. The development of this vaccine represents a successful collaboration between USAMRIID and the Argentine Ministry of Health and Social Action, under the auspices of the United Nations Development Programme and the Pan American Health Organization. Over the years, hundreds of thousands of people in Argentina and other countries have been inoculated, with an excellent record of safety and effectiveness.[153]

Lassa Virus

Another important Arenavirus is Lassa virus, transmitted by rodents in West Africa, where there has been a recent large

epidemic. Several candidate vaccines have shown protection in nonhuman primate models, including reassortants, vesicular stomatitis virus-vectored recombinants, and alphavirus replicons.[153a]

Middle East Respiratory Syndrome Virus

The Middle East respiratory syndrome (MERS) virus—like the severe acute respiratory syndrome (SARS) virus that spread from China and caused a worldwide outbreak in 2002–2003—is a coronavirus.[154,155] The reservoir for MERS is camels, particularly young animals, which acquire a respiratory illness that can be transmitted to humans.[156,157] In addition, human-to-human transmission has been repeatedly observed in Saudi Arabia and in South Korea.[158] All coronaviruses possess a glycoprotein spike that induces neutralizing antibodies; both monoclonal antibodies and vaccines based on the spike have shown good protection in experimental challenge models, including macaques.[159] Development of vaccines for camels and for humans is proceeding.

Novavax has developed 0.2-μm nanoparticles consisting of MERS spike protein which, together with ISCOMATRIX adjuvant, have been shown to induce neutralizing antibodies in mice.[160] German workers have used the MVA vaccinia virus as a vector for the MERS spike protein and induced neutralizing antibodies and protection in a mouse challenge model.[161] The Vaccine Research Center at the National Institutes of Health has developed plasmids and recombinant proteins representing the full-length MERS spike or the S1 domain of the spike. When both antigens were administered to mice or macaques, neutralizing antibodies were induced and animals were protected from challenge with the virus.[162] The further development of these candidate vaccines will depend on epidemiology and market size.

LIMITED-USE VACCINES AGAINST BACTERIAL DISEASES

Q Fever

Q fever is a highly infectious zoonotic disease of humans usually caused by aerosol transmission of *C. burnetii* from infected sheep or goats.[163] The organism was thought to be a *Rickettsia* but is now considered to be related to *Legionella* bacteria. Fever and pneumonia are the most frequent clinical manifestations of Q fever, although hepatitis, endocarditis, and a variety of other complications may develop.[164] Antibiotics are effective but may act slowly, and chronic fatigue syndrome after Q fever has been reported, presumably as a result of cytokine dysregulation.[165]

Mechanisms of immunity to Q fever are complex. Although antibodies are important to clear extracellular organisms, it is sensitization of T-cell lymphocytes to Q fever antigen and secretion of lymphokines that clear intracellular infection and provide immunologic memory.[166]

In the development of a Q fever vaccine, *C. burnetii* was adapted to grow in the chick embryo yolk sac, and an early vaccine was made by formalin inactivation of organisms produced in eggs.[167] This vaccine was effective in humans, including in those subjected to experimental challenge, but it also occasionally resulted in severe local reactions that sometimes progressed to abscess formation. Eventually it was shown that reactions were associated with preexisting immunity to Q fever. Accordingly, the practice of screening prospective vaccinees was adopted—using serology for Q fever antibodies and observation for local induration after inoculation with a skin test antigen made from diluted vaccine.

Advances in *Coxiella* biology and vaccinology led to a new generation of vaccines. For example, evidence showed that only Phase I Q fever organisms, analogous to smooth forms of bacteria, were protective, and that a transition to Phase II (rough) would occur if the organism was passaged too many times in chick embryo. Therefore, Q fever vaccines are based on Phase I organisms only.[168] In addition, researchers recognized that purification to remove chicken protein and lipid and isolation of whole inactivated *Coxiella* by extraction, filtration, or centrifugation would result in a cleaner, less reactogenic, and highly immunogenic product. Two whole-cell vaccines came into use in high-risk subjects: an Australian vaccine made and licensed by Commonwealth Serum Laboratories[166,169] and a vaccine (IND 610) made and tested by the U.S. Army.[170] Both are administered as a single 30-μg subcutaneous injection. The Australian vaccine, Q-Vax, is purified using high concentrations of NaCl to remove nonprotective antigens. The U.S. Army vaccine, Whole-Cell, Inactivated, Q-Fever Vaccine NDBR 105, IND 610, is also extracted with NaCl, then subjected to ethanol–Freon 113 extraction; finally, it is purified further on a $CaHPO_4$ $2H_2O$ (brushite) column. Despite these purification processes, however, skin testing of prospective recipients remains necessary to prevent serious reactions in persons who have experienced prior infection.

Whole-cell vaccines have undergone considerable clinical testing. In Australia, a placebo-controlled trial[171] and an open trial in abattoir workers[172,173] showed efficacy approaching 100% (Table 12.3). From 2002 to 2006, during a vaccination program funded by the Australian government, the incidence of Q fever in Australia declined by more than 50%.[166,174] The U.S. Army vaccine was subjected to a controlled challenge in volunteers; this trial also proved highly successful.[175] Two meta-analyses found that Q-Vax was, respectively, 97% and 83% to 100% effective, but the data were considered to be of only moderate quality.[176,177] A Q fever outbreak, apparently caused by dairy goats, occurred in The Netherlands between 2007 and 2011, affecting more than 4000 individuals.[178] Control measures that included Q-Vax vaccination of individuals at high risk for developing chronic Q fever were

TABLE 12.3 Protection by Q Fever Vaccines

Vaccine	Type of Study	No. of Cases of Q Fever		
		Vaccinated	Unvaccinated	Protection (%)
United States	Random, challenge	2/32	5/6	92
Australian	Random, placebo-controlled	0/98	7/102	100
Australian	Observational	3[a]/2716	52/2012	96–100

[a]Vaccinated during incubation period of Q fever.

Data from Ormsbee RA, Marmion BP. Prevention of Coxiella burnetii *infection: vaccines and guidelines for those at risk. In: Marne TJ, ed.* Q Fever: The Disease, *vol 1. Boca Raton, FL: CRC Press; 1990:225–248.*

effective in containing the outbreak despite limited coverage of the vaccination campaign.[179–181]

To eliminate the problem of reactions, third-generation acellular Q fever vaccines have been prepared in the United States[182,183] and in the former Czechoslovakia.[184] These vaccines, extracted with chloroform–methanol or other lipid solvents to remove lipid A (thought to be the chief offending substance in *C. burnetii*), have not yet undergone sufficient clinical testing to determine whether they are equivalent to whole-cell Q fever vaccine in protection of humans. In addition, it is not yet clear if these vaccines overcome the problem of serious reactions in preexposed individuals.[185,186]

A live attenuated Q fever vaccine produced in chick embryo yolk sac has been developed in Russia, but its safety has been questioned. Other vaccine approaches under investigation are based on the P1 29-kDa protein, a 67-kDa antigen, and DNA plasmids coding for various proteins.[187–189]

Better Q fever vaccines are needed that induce antibodies and T-helper type 1 (Th1) cell responses and yet are well tolerated by individuals with preexisting immunity. Elucidation of the key protective antigens is required.[185,189]

Tularemia

Tularemia, a bacterial bioterrorism threat, can be a significant endemic and epidemic human disease.[190] The causative bacterium of tularemia, *Francisella tularensis*, was isolated in 1912; in 1919, Edward Francis made the association with the human disease then known as "deer fly fever."[191]

Andersson and colleagues[192] describe the transcriptional response in peripheral blood following ulceroglandular tularemia in humans. The authors identified seven genes whose changes in expression predict the early phase of tularemia. In addition to identifying how the host defense develops or is turned off by *F. tularensis* invasion, these data are important in identifying potential diagnostic markers for tularemia infection.

Many of the more than 200 cases of *F. tularensis* documented in the American medical literature resulting from laboratory exposure occurred in laboratory personnel who had received one or more injections of a phenol-killed vaccine and/or acetone-prepared vaccine.[193–196] One of these early inactivated products, the Foshay vaccine, showed incomplete protective efficacy against tularemia organisms introduced by the respiratory and intracutaneous routes.[197,198] Although circulating antibodies could be demonstrated following administration of these vaccines, the antibodies generated were not protective. It was concluded that the protective antigen of *F. tularensis* was destroyed in the inactivation procedures used to prepare the vaccines, although now antibodies alone are considered insufficient.

Partly as a result of the experience with killed vaccines, an effort to develop a live vaccine against *F. tularensis* was undertaken. By avoiding destruction of the protective antigen, live vaccines, which cause actual infection, are thought to produce an immunity closer to that caused by the disease itself, in particular by generating persistent antibodies and CD8-mediated cellular immunity, both of which are required for protection against disease.

Soviet investigators initially developed a live tularemia vaccine in 1942.[199] Ampoules of this "viable" tularemia vaccine were brought to the United States from the Russian Institute of Epidemiology and Microbiology (Gamaleia Institute) by Shope[200] in 1956. From an ampoule of this product, Eigelsbach and Downs[201] derived a vaccine strain, which they designated LVS.

Studies done at Fort Detrick in the early 1960s showed that LVS was protective for mice and guinea pigs after a challenge.[201] This protection was subsequently found to be the result of cell-mediated immunity when passively transferred spleen cells from immunized mice provided protection to nonimmune recipients.[202] Similar immunization studies were done in monkeys, which also demonstrated a significant immune response to vaccination with LVS.[203]

LVS initially was given by scarification to volunteers at Fort Detrick in 1958.[204] The vaccination procedure and adverse events after vaccination were evaluated in 29 subjects.[198] Only a pink scar remained 1 month after vaccination. Transient axillary lymphadenitis was observed in approximately half of the subjects, but none of the 29 men exhibited fever or other systemic reactions following immunization with LVS. All persons showed bacterial agglutinin antibodies; peak titers were observed 29 to 59 days after vaccination and were sustained.[205]

After challenge doses of up to 2500 organisms, a significant protective effect was seen in the volunteers vaccinated with LVS, with only 20% of vaccinated persons showing clinical illness compared with 85% of the unvaccinated control subjects. None of the vaccinated persons developed symptoms severe enough to require treatment. At higher challenge doses, however, immunity was overcome; after challenge with 25,000 organisms, 90% of vaccinated persons showed some symptomatology compared with 85% of the control subjects. However, LVS modulated illness severity such that only 60% of vaccinated volunteers had symptoms severe enough to require treatment, compared with 100% of those in the control group.[205]

The efficacy of the live tularemia vaccine, when administered by aerosol, has also been evaluated.[206,207] In one study,[207] aerosol vaccination with LVS protected 6 of 16 subjects against challenge with the virulent SCHU-S4 strain of *F. tularensis*. All protected subjects had measurable circulating antibodies, while only one of the 10 subjects who developed disease had circulating antibodies.

LVS (also referred to as NDBR 101) has been used since the mid-1960s and has been associated with a significant decline in the rate of laboratory-acquired infections at Fort Detrick.[208] In the absence of firm knowledge concerning the attenuating mutations in LVS and its residual virulence, the vaccine remains investigational and is administered only under protocol and with written informed consent. The lots undergo lot-release and potency tests as required by FDA for IND products.

Efforts are underway to develop new-generation vaccines against tularemia using modern technologies. Lipopolysaccharide from *F. tularensis* gives partial protection through the induction of antibodies, but clearly, cell-mediated responses to other antigens will be necessary for an optimal vaccine against highly virulent strains.[209,210] In addition, aerosol delivery may give better protection than peripheral inoculation.[211] Much work is underway to create new live attenuated mutants[211–217] and novel subunit vaccines.[218] In one promising approach, the oxidant-sensitive *emrA1* mutant of *F. tularensis* LVS elicited a strong humoral immune response in mice without causing adverse effects. Mice vaccinated with a single intranasal dose of the *emrA1* mutant of *F. tularensis* LVS were protected against a lethal respiratory LVS challenge; this vaccine also provided partial protection against lethal challenge with the virulent *F. tularensis* SchuS4 strain.[219]

Brucellosis

Primarily a disease of animals, brucellosis first was described in humans in 1859 as "Mediterranean gastric remittent fever" or "Malta fever."[220] The consumption of unpasteurized goat milk was found to be the source in the Malta epidemic.[182]

Bruce[221] isolated the etiologic agent in 1886 from a fatal case of brucellosis. Initially named *Micrococcus melitensis*, the genus later was named for its discoverer and is currently known as *Brucella melitensis*. *Brucella* species are non–spore-forming, Gram-negative coccobacilli that exist worldwide. Several animal species become infected with *Brucella* species. Humans become infected on contact with infected animals, by consuming unpasteurized infected milk or other dairy products, and by working with the organism under laboratory conditions. Brucellosis manifests with nonspecific flu-like symptoms that are often much more prominent than the gastrointestinal symptoms.[222] The feasibility of infection by aerosol makes *Brucella* a possible agent of biowarfare.

Effective vaccines, both live and killed, are available for animals. Use of these vaccines has led to decreases in human disease where animal infection is enzootic. Nevertheless, an estimated 500,000 annual human cases still occur worldwide.[223] A live vaccine, *Brucella abortus* S19, was extensively used in Russia and gave more than 50% protection, although it was somewhat reactogenic.[224]

Ongoing research seeks to further attenuate live vaccines used in animals and to develop subunit vaccines based on membrane and ribosomal proteins or DNA plasmids coding for those proteins.[225–234] For example, protection in animals has been achieved with an outer membrane protein and its gene,[235,236] with periplasmic protein bp26,[237] by intranasal administration of *Brucella* lipopolysaccharide complexed with *Neisseria meningitidis* outer membrane protein,[238,239] and a recombinant glucokinase protein *Brucella* vaccine candidate.[240]

Pseudomonas

Pseudomonas aeruginosa is a common pathogen in ventilated patients and in those with burns; however, it also causes life-threatening infections in people with cystic fibrosis owing to its production of a thick, mucoid capsule. Although antibodies to the lipopolysaccharide develop in people with cystic fibrosis after infection, they are of low affinity and do not protect. In contrast, artificial immunization with lipopolysaccharide from eight different strains coupled chemically with the *Pseudomonas* exotoxin A elicited high-affinity IgG antibodies.[241,242] Studies of cellular immune responses showed induction of antigen-specific lymphocyte proliferation and a Th1-like cytokine secretion.[243] During a 10-year period, people with cystic fibrosis immunized with O polysaccharide conjugated to toxin A had fewer *Pseudomonas* infections and a tendency toward less colonization with mucoid strains (Herzog C. Personal communication to S. Plotkin, November 26, 2002).[244,245] Importantly, lung function was also better in vaccinees.[244,246,247] In a Phase III trial, patients with cystic fibrosis who received four doses of a bivalent *P. aeruginosa* flagella vaccine were significantly less likely to have one or more acute *P. aeruginosa* infections than were those who received placebo (19.6% vs 30.7% among vaccinees and placebo recipients, respectively).[248] However, additional antigens are expected to provide better protection.[249] A vaccine containing formalin-inactivated whole *Pseudomonas* bacteria has been administered orally to healthy volunteers without adverse reactions and with significant serum IgA responses.[250]

Many other experimental vaccines are under development, including ones based on flagellar antigens, outer membrane proteins such as OprF and OprI, and exotoxin A.[251–254] For example, one DNA vaccine encoding *Pseudomonas* exotoxin A and PcrV has shown promise in mice,[255] and a *P. aeruginosa* hybrid outer membrane protein OprE/I (IC43) vaccine was well tolerated and immunogenic in a recent randomized, placebo-controlled Phase I study.[256] The mucoid exopolysaccharide of *P. aeruginosa* has been conjugated with keyhole limpet hemocyanin and found to elicit opsonophagocytic antibodies in mice.[257] An attenuated salmonella vector expressing the O antigen of *P. aeruginosa* lipopolysaccharide given intranasally protected mice against challenge.[258] Interestingly, Th17 responses, as in the case of other mucosal bacteria, may be necessary for protection,[259] and mucosal routes of administration may improve efficacy.[260–262]

The virulence factor alginate is produced by mucoid forms of *P. aeruginosa*. One strategy in *Pseudomonas* vaccine development is to raise opsonic antibodies against alginate. One group conjugated alginate to the outer membrane vesicle of *N. meningitides*. Immunization of mice with this conjugate provided protection against intranasal challenge with *P. aeruginosa*,[263] thus validating the concept.

Helicobacter pylori

Helicobacter pylori, which colonizes the stomach early in life but exerts its effects in adults, is the cause of gastritis, peptic ulcers, and low-grade gastric lymphomas.[264,265] The mechanisms of disease involve stimulation of Th1, regulatory T, and possibly Th17 cells; antibody and cellular mechanisms seem to be involved in the protection demonstrated in animal models. Clinical trials have tested urease, which is secreted by *H. pylori*; the cagA pathogenicity island; the VacA cytotoxin; and the neutrophil-activating protein.[266] The results in the past have not been promising; more recently, however, an aluminum-adjuvanted combination of the latter three antigens stimulated strong antibody and cellular responses in volunteers and will undergo further clinical development.[267] Other approaches, such as VLPs,[268] epitope-based vaccines,[269–271] alkyl hydroperoxide reductase and mannosylated AhpC,[272] and thiolperoxidase,[273] have shown promise in single- and multicomponent vaccine studies using murine models.

Botulism

Botulism is a neurologic intoxication caused by botulinum neurotoxin, the most poisonous agent known. It is produced by the bacterium *Clostridium botulinum*. Seven toxin types (A through G) have been recognized; all but G cause human disease.[274] Botulinum neurotoxin is a significant biowarfare and bioterrorism threat. The neurotoxin binds to the presynaptic membrane and prevents acetylcholine release, resulting in a symmetric, descending flaccid paralysis with classical bulbar palsies characterized by diplopia, dysphonia, dysarthria, and dysphagia.[275] As paralysis progresses, generalized weakness occurs; if untreated, death occurs from airway obstruction and diaphragmatic muscle paralysis. Interestingly, this toxin has many therapeutic uses as well—notably, but not limited to, treatment of blepharospasm, strabismus, cervical torticollis, and various dystonias.[276–278]

Pentavalent (ABCDE) botulinum toxoid (PBT) was available as a prophylactic countermeasure to botulism from 1959 until November 30, 2011, when the Centers for Disease Control and Prevention stopped providing the vaccine under IND 161 because of reduced potency and increased reactogenicity.[3] Although the old methodology for producing toxoids (i.e., the methods used to produce PBT) can be improved by reducing formalin concentrations and increasing the purity of the botulinum proteins, the most advanced candidates are recombinant nontoxic proteins. The Hc subunits of toxin types A and B were immunogenic in a clinical trial and are proceeding in development.[279–282] Other peptides of the toxin, including the light chain and the N terminal of the heavy chain, are also being tested[283] (Fig. 12.1). A nonreplicating

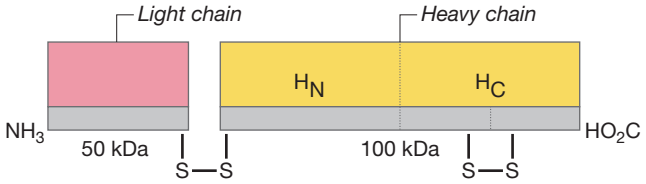

Figure 12.1. Structure of botulinum toxin.

adenovirus-vectored monovalent (C) vaccine, given intranasally or orally, has also been shown to induce serum and secretory antibodies and to protect animals.[284,285] A recombinant bivalent vaccine (rBV A/B) has completed Phase II safety and immunogenicity testing in humans.[286] Inevitably, new vaccines against botulism will have to be licensed through a demonstration of efficacy in animals. Although a titer of antibodies correlating with efficacy is not known for humans, studies in guinea pigs suggest that very low levels (<0.1 U) will be protective.[287]

In March 2013, the FDA approved a heptavalent equine (ABCDEFG) botulism antitoxin to treat individuals with symptoms of botulism after exposure or suspected exposure to botulinum neurotoxin.[288,289] BabyBIG has been available in California to treat infant botulism since 2003.[290] However, no vaccines for prophylactic protection against botulism are currently available in the United States.

Clostridium difficile

Clostridium difficile is an inhabitant of the human gastrointestinal tract that, under certain conditions, produces toxins that cause diarrhea. The precipitating cause of *C. difficile* infection (CDI) seems to be the elimination of other intestinal flora by antibiotic treatment. Incidence of the disease has increased considerably in recent years.[291–294] Antibodies against both of the toxins produced by *C. difficile*, A and B, are needed to prevent illness.[295,296]

Much work is in progress to develop and use monoclonal antibodies against the toxins for prophylaxis and treatment.[297–300] Vaccines against CDI are currently under clinical development at Sanofi Pasteur[301] and Pfizer.[301a] Both candidate *C. difficile* toxoid vaccines are composed of a highly purified formalin or genetically inactivated toxoids together with aluminum adjuvants delivered by intramuscular injection. Early clinical data suggest a relationship between an immune response to toxins A and B with protection against a primary or recurrent case of CDI.[297,302–305] After colonization, a systemic anamnestic response to toxin A, as evidenced by increased serum IgG antitoxin A levels, is associated with asymptomatic carriage of *C. difficile.* Serum IgG antitoxin A levels have also been significantly correlated with IgG levels against toxin B antigens, which were also higher in asymptomatic carriers.[303] In patients with CDI, higher IgG antibodies to toxin A are associated with protection against recurrence.[303] In an initial Phase I study, the candidate vaccine induced IgG antibodies to toxins A and B with resolution of recurrent diarrhea.[304] In a more recent Phase II study, the Sanofi candidate, given in a high dose, elicited functional antibody responses in adult and elderly volunteers for at least 180 days without safety issues.[306]

In addition, work has begun on the use of colonization factors as vaccine antigens. These include a protease (Cwp84) that is an adhesion molecule[307,308] and a cell wall polysaccharide conjugated to the diphtheria toxoid variant CRM.[309] In another approach to vaccine development, Baliban and colleagues[310] created a synthetic DNA vaccine encoding receptor binding domains from *C. difficile* toxin A and toxin B. In mice and nonhuman primates, this vaccine demonstrated robust immunogenicity, and immunized mice were protected from a challenge with *C. difficile* spores from homologous and heterologous strains.

Acknowledgments

We thank Elizabeth S. Brown, PhD, for critical review of this manuscript. George R. French contributed to this chapter in prior editions.

13 Cancer Vaccines

Adrian Bot, Elliot M. Berinstein, and Neil L. Berinstein

THE CONCEPT OF CANCER VACCINES IS ANCHORED IN CLASSICAL VACCINOLOGY

The idea of inducing or enhancing an immune response against cancerous cells is strongly anchored in the concept of prophylactic vaccination against a number of infectious agents, one of the most important and successful achievements of medicine. Adequate preexposure of the immune system to a truncated or surrogate version of a particularly infectious agent reshapes the immune repertoire and enables it to effectively counter a subsequent infectious inoculum. Thus, the immune system is intrinsically endowed with enough plasticity and potency to support an efficient antimicrobial vaccination.

A second line of evidence dating back to Coley[1] proposed the concept of enhancing immunity as a means to cope with cancer. Anecdotal evidence of tumor regression after an infection[2] or exposure to microbial byproducts[3] has been tantalizing enough to encourage study of this approach with increasing effort in the field of "cancer vaccines" during the last two decades.

Nevertheless, even though therapeutic cancer vaccines have proved challenging, with only one vaccine licensed to date[4] out of hundreds of clinical development programs, the field of immune-oncology has expanded greatly based on a deeper understanding of the role of immune system in cancer,[5] successful clinical application of the concept of immune checkpoint blockade,[6] and tantalizing evidence of clinical efficacy of cancer vaccines mediated by tumor antigen-directed T cells.[7]

More specifically, cancer vaccine development has been guided by the paradigm of immunity to viruses.[8] During a successful cell-mediated immune response to a viral infection in a target organ, viral antigens are presented to antigen-reactive T cells by professional antigen-presenting cells (APCs; particularly dendritic cells [DCs]) within secondary lymphoid organs. Activated T cells then proliferate and differentiate to cytotoxic T lymphocytes (CTLs) that secrete cytokines, including interferon (IFN)-γ and tumor necrosis factor (TNF)-α. Activated CTLs enter the circulation and are guided to the site of the viral infection by chemokines and adhesion molecules, where the CTLs kill the virally infected cells by releasing granzymes and perforin or by activating death receptors on the surfaces of the target cells. For example, in the case of Epstein-Barr viral infection[9] the magnitude of the CTL response must be sufficiently strong (on the order of 1 to 10 virus-specific CTLs per 100 CTLs) to clear the infection and must be maintained for a sufficient time (at least weeks to months[10]) to be effective. The former requirement is usually mediated by high-avidity T cells and the latter requirement is fulfilled by the induction of memory T cells.[11] Cancer vaccines should ideally mimic the same steps as those seen with viral infections (Fig. 13.1), except that the ultimate targets are cancer cells instead of virally infected cells. These steps are discussed in more detail as they apply to cancer vaccines.

Although the field of immunotherapy is rapidly expanding and diversifying in oncology, our focus in this chapter remains on "vaccines" that provide exogenous antigens to the immune system to reshape, direct, and empower it to destroy cancerous cells. Nevertheless, we anticipate that various therapeutic platforms in immune-oncology, including both vaccines and immunotherapy, will be used in conjunction with each other, leveraging their strengths and complementing their mechanisms of action leading to more effective and durable protection against the disease process. Thus, based on all evidence to date, vaccines can no longer be seen as a standalone therapeutic platform, but must be seen as a component of a broader, integrated therapeutic armamentarium against cancer that is still under development.

UNDERSTANDING TUMOR IMMUNOBIOLOGY IS KEY TO DESIGNING EFFICACIOUS CANCER VACCINES

Several aspects of tumor immunobiology are very important to appropriately design cancer vaccines. Until recently, the lack of adequate understanding of tumor immunology, especially mechanisms of immune tolerance and evasion, has hampered cancer vaccine development.

Tumor Antigens

Cancer antigens can be recognized by T cells. Like viral antigens, they are peptides derived from degraded proteins that are associated with human leukocyte antigen (HLA) molecules on the surface of APCs.[12] Peptides from intracellular proteins, degraded by the proteasome and bound to HLA class I heavy-chain domains in the endoplasmic reticulum, are recognized by CD8+ T cells. Peptides from "endocytosed" membrane or extracellular proteins are degraded in endosomes where they bind to HLA class II proteins and are subsequently recognized by CD4+ T cells.[12]

In a few instances, cancers are caused by oncogenic virus infections. In these situations, foreign viral proteins can serve as targets for cancer vaccines. More commonly, DNA damage, faulty DNA repair, or aberrant chromosomal rearrangements can lead to mutant self-proteins or new breakpoint regions that are found only in tumor cells. These are called tumor-specific antigens (e.g., m-Ras, bcr-abl) as they are not encountered in noncancerous cells. Most recently these have been termed neoantigens and may or may not play a role in oniogenesis. This is in contrast to the broad category of tumor-associated antigens (TAAs), which also comprise unmodified self proteins that are selectively upregulated or expressed in cancerous cells (e.g., "cancer-testes antigens"). TAAs may also arise through oncogenic signaling processes that increase the expression of proteins or polysaccharides that are otherwise weakly or transiently expressed.[13] Because tumor-specific antigens are novel proteins they are unlikely to be seen by developing T cells in central lymphoid organs (which is more common with tumor-specific antigens), they do not induce tolerance, and they can be recognized by peripheral T cells. More details on tumor antigens are provided below.

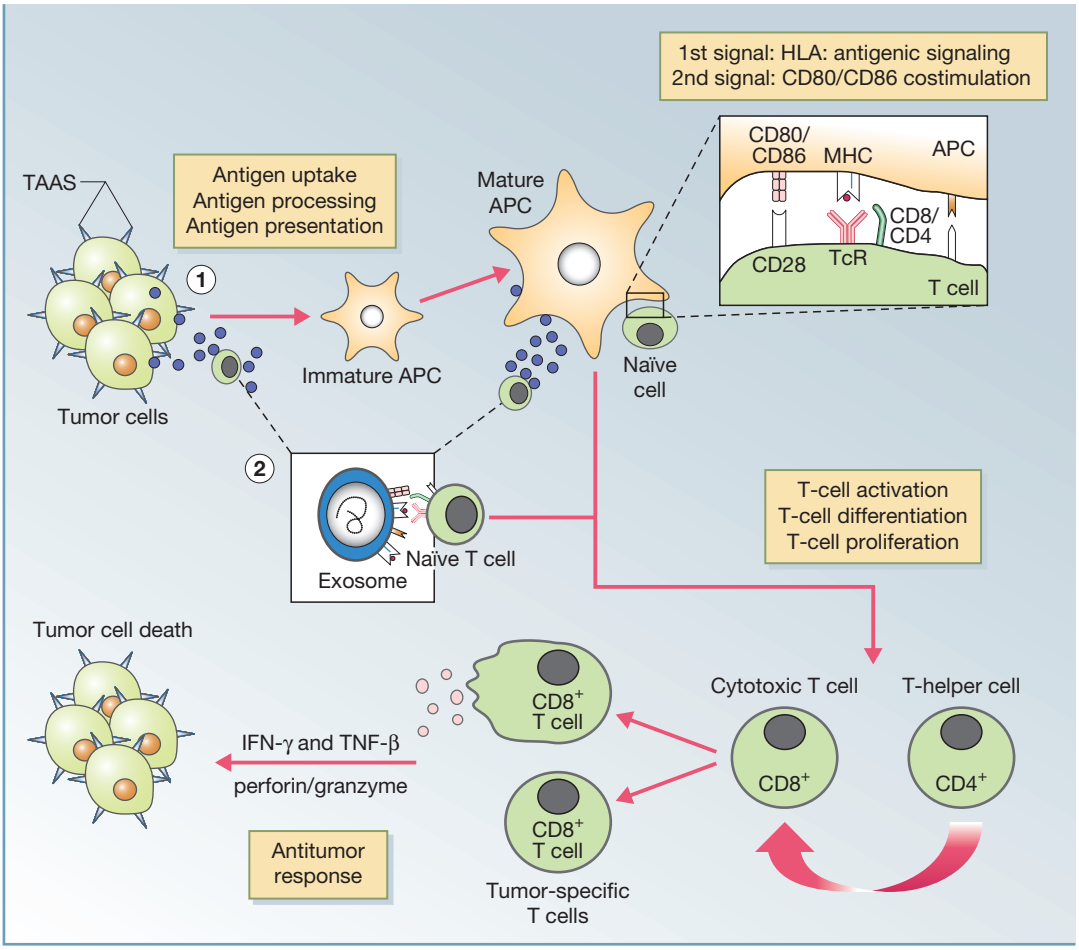

Figure 13.1. Generation of an effective antitumor response. In general, tumor-associated antigens (TAAs) are taken up by immature professional antigen-presenting cells (APCs). The APCs must become activated and process and present TAA epitopes within the binding groove of human leukocyte antigen (HLA) molecules on the surface of APCs. Mechanisms of APC activation are: (1) Immunogenic tumor cell death: Immune modulation (vaccination), radiation, and chemotherapy can cause tumor cell death, which can induce early calreticulin translocation to the cell surface, heat shock protein (HSP)70 and HSP91 release and exposure, late chromatin binding protein high-mobility group box 1 protein (HMGB1), and nucleic acids and their degradation products (such as adenosine triphosphate) release. These danger-associated molecular patterns are recognized by pattern recognition receptors on APCs. (2) Exosome recognition: APC-derived and tumor-derived exosomes activate naïve T cells by displaying HLA molecules, CD80 or CD86, and adhesion molecules. Both of these pathways lead to APC maturation and T-cell activation through T-cell receptor (TCR) recognition of processed epitopes presented on HLA molecules. For activation, T cells require two signals: antigenic peptide/major histocompatibility complex (MHC) (first signal) and costimulation through CD80 and CD86 ligation of CD28 (second signal). Activated T cells then proliferate and differentiate into CD4+ T-helper cells and CD8+ cytotoxic effector T cells. Activated tumor-specific CTLs enter the circulation and are guided to the site of transformation by chemokines and adhesion molecules, where they kill tumor cells by secreting interferon (IFN)-γ and tumor necrosis factor (TNF)-β and by releasing granzymes and perforin.

Antigen Presentation and T-Cell Proliferation

To increase tumor-reactive CTLs to sufficient numbers and to sufficient exposure times to clear tumor cells, it is necessary to provide more than the antigenic signal, or signal 1.[14] Costimulatory, or second signals, in the form of cell surface molecules, cytokines, and chemokines, must also be provided at the same time by APCs. In general, the costimulatory signals required to activate T cells to enter the cell cycle are found on professional APCs, with the most potent being DCs.[15] However, even fibroblasts can stimulate T cells to proliferate in vivo under appropriate circumstances.[16]

Important costimulatory molecules, including the B7-family members, CD80 (B7.1) and CD86 (B7.2) that bind to CD28 on T cells, orchestrate the glycolytic metabolism required by rapidly proliferating cells.[17] Other important costimulatory molecules on APCs deliver signals to antigen-activated T cells, allowing them to survive and progress through the cell cycle. For example, adhesion molecules such as CD54, CD48, and CD58 bind to LFA1, CD2, and CD24 on T cells, respectively, whereas members of the TNF receptor family, CD40 and CD70, bind to CD40L and CD27, respectively.[18]

Tumor-Derived Exosomes

Exosomes are small membranous vesicles that fuse to the plasma membrane, resulting in the release of their vesicular cargo into the extracellular space.[19] B cells and DC-derived exosomes display abundant major histocompatibility complex (MHC) class I and class II molecules, costimulatory molecules CD80 and CD86, and adhesion molecules such as CD54 and CAM-1.[20,21] APC-derived exosomes expressing these ligands mediate antitumor immunity through MHC class II–restricted CD4+ T-cell activation and MHC class I–restricted

CTL activation. Tumor cells also secrete exosomes that have immunostimulatory and immunosuppressive properties depending on the conditions. Tumor-derived exosomes contain abundant TAAs that are processed and presented by DCs to CTLs, initiating tumor-specific immune responses.[22] Tumor-derived exosomes, however, may also promote tumor evasion through initiation of apoptosis of tumor-specific CTL (mediated by exosomes expressing FAS ligand) and through T-cell activation and signaling suppression.[23]

Immunogenic and Nonimmunogenic Cell Death

Cell and tissue death occurs constantly from homeostatic tissue turnover (nonimmunogenic cell death) or through suicide of virus-infected, bacteria-infected, and transformed cells (immunogenic cell death) (see Fig. 13.1).[24] The DCs are responsible for distinguishing between nonimmunogenic and immunogenic cell death and subsequently initiating the appropriate immune response. Pattern recognition receptors on DCs recognize distinct immunogenic damage-associated molecular patterns (DAMPs) that exist on the surface or are released from dying cells.[25] Immunogenic tumor cell death is characterized primarily by early translocation of calreticulin to the cell surface,[26] release and exposure of heat shock protein (HSP) 70 and HSP91,[27] and late release of chromatin-binding protein high-mobility group box 1 protein (HMGB1).[28] Nucleic acids and their degradation products also function as immunogenic DAMPs. DC recognition of these biochemical markers leads to apoptotic body phagocytosis (initiated by calreticulin), DC activation (initiated by HSP70 and HSP91), antigen processing and presenting (initiated by HMGB1). Tumor-specific HMGB1 ligation of Toll-like receptor (TLR) 4 facilitates TAA processing and presentation along with MHC classes I and II and costimulatory molecule expression by inhibiting fusion of phagosomes with lysosomes.[29,30] Similarly, HSPs facilitate DC activation through ligation to CD91. Nucleotides from degraded DNA or RNA act on TLR2, TLR7, TLR8, and TLR9, as well as on intracellular receptors RIG-1, MDA5, and LGP2.[29] Adenosine triphosphate (ATP) and its degraded products activate purinergic P2RX7 receptors.[31] Nucleotide product recognition facilitates DC inflammasome-driven production of inflammatory cytokines such as interleukin (IL)-1, IL-18, and IL-33, which is required for the adequate polarization of IFN-γ–producing CTLs.[32,33]

Chemotherapy-Induced Immunogenic Apoptosis

Chemotherapy indiscriminately kills rapidly dividing tumor cells, including hematopoietic and immune cells, thus producing immunosuppressive side effects. Cancer chemotherapeutics, such as anthracyclines, oxaliplatin, and ionizing irradiation, induce immunogenic cell death despite their immunosuppressive nature. In contrast, agents such as etoposide, mitomycin C, staurosporine, mitochondrial poisons, and endoplasmic reticulum stressors fail to elicit immunogenic cell death.[34] Chemotherapeutic agents that induce immunogenic cell death do so by exposing and releasing calreticulin, HMGB1, HSP70, HSP91, and ATP22, exposing DAMPs, and initiating an effective antitumor response.[31] Nonimmunogenic chemotherapy-induced tumor death occurs if apoptotic cells do not expose DAMPs or if apoptotic cells modify existing DAMPs through caspase activation and reactive oxygen species release and inactivation of HMGB1.[35] Chemotherapy can also cause dying cells to directly release immunosuppressive cytokines such as IL-10 and transforming growth factor (TGF)-β. Production of these cytokines leads to regulatory T cell (Treg) and T helper cell (Th) 2-driven inhibition of inflammation and DC tolerance to dying tumor cells.[22]

T-Cell Differentiation

Entry into the cell cycle allows antigen-activated T cells to differentiate into effector cells. The major pathways of T-cell differentiation are classed as type 1 (Th1/TC1) or type 2 (Th2/TC2).[36] Th17 cells and Tregs have been identified as novel effector T-cell subtypes. Type 1 responses mediate cell-mediated immunity and are thought to be required for successful antitumor[37] and antiviral[38] responses. Type 1 effector cells secrete cytokines such as IFN-γ and TNF-α, express chemokine receptors such as chemokine-related receptor (CXCR) 3 and chemokine receptor (CCR) 5,[39] and kill via perforin and granzyme release.[40] Type 2 immunity is associated with humoral and allergic responses. Type 2 effector cells secrete IL-4, IL-10, IL-5, and IL-13, and express CCRs such as CCR3, CCR4, and CCR8.[41] Th17 cells promote protective inflammatory responses against infectious agents and fulfill an important role in various autoimmune diseases.[42] Th17 secretion of IL-17 mediates proinflammatory antitumor immunity. Antitumor immunity is primarily facilitated by Th1/TC1 polarization, although Th17 cells may have a role.[43]

Maintenance of Effector Cells

A number of different processes are required to ensure that CTL activity is maintained in sufficient numbers and for sufficient duration to mediate an effective antitumor response. Initially, costimulatory molecules control the survival of effector cells. For example, OX40L on APCs promotes the continued activation of CD4+ Th1 cells,[44] whereas 41BBL binding to 41BB promotes the continued activation of CD8+ TC1 cells.[17] In contrast, Th2/TC2 responses are maintained by interactions of CD30 with CD30L on APCs.[45] In the absence of signals from costimulatory molecules, antigen-activated T cells fail to replicate and clear tumor cells. In addition to maintaining effector T-cell survival, costimulatory molecules may also mediate effector T-cell function. For example, OX40L may be required on tumor cells to activate CTLs.[45] Cytokines also maintain the survival of activated and memory T cells and enhance the activity of effector cells.[46] For example, members of the gamma c cytokine family, such as IL-2 and IL-15, can maintain the responses of activated T cells.[47] Many of these cytokines are made by CD4+ helper T cells. In addition to amplifying CTL responses, the cytokines produced by CD4+ T cells recruit other inflammatory cells, such as eosinophils and macrophages, which may help clear tumor cells.[48]

T-Cell Trafficking to Tumors

The complex process of producing large numbers of type 1 effector T cells requires the cytokine and costimulatory molecule milieu of a secondary lymphoid organ.[49,50] To exert their effector functions, the activated T cells must travel from the lymph node to the site of the virally infected or tumor target cells through the bloodstream. A number of molecular families, including lectins and integrins, are involved in recruiting T cells from the bloodstream to tertiary sites. Chemokines are especially important in localizing the appropriate class of effector cells (e.g., CCL2, CXCL12, CXCL16) as well as Treg cells counteracting those (e.g., CCL22).[51,52,53]

ALL HURDLES FACING CANCER VACCINES NEED TO BE SYSTEMATICALLY ADDRESSED

Although the model of antiviral cell-mediated immunity guides the potential development of cancer vaccines, a number of properties intrinsic to the cancer-bearing state may limit the

effectiveness of vaccines. Thus, additional immunomodulatory treatment strategies may need to be added to enhance the efficacy of cancer vaccines.[54]

In essence, there are three major differences between prophylactic vaccination against infectious agents and therapeutic vaccination against cancer that have slowed translation of the latter to effective medicines. First, cancer vaccines are directed at manipulating the immune system in patients who already have a clinically overt disease or asymptomatic tumor burden. In this stage, the endogenous immune system has already been negatively influenced by the tumor biology (immune editing)—and vice versa, tumor cells with increased resistance to immunity have been selected (immune sculpting)—with negative impact on immune system's responsiveness against therapeutic cancer vaccines.[55]

Second, the target to be eliminated often consists of large tissue masses with antigenic heterogeneity and a plethora of immune inhibiting mechanisms, as opposed to small homogenous microbial inocula.

Third, the suboptimal nature of our preclinical models, platform technologies, and limited understanding of best targets and companion biomarkers to guide adequate development of cancer vaccines, is a problem that hampers efforts in this field and turns initial enthusiasm to skepticism.

Mechanistically, the hurdles that limit the efficacy of cancer vaccines can be grouped as below.

T-Cell–Negative Regulation by Antigen-Presenting, Stromal, and Tumor Cells

Just as the cytokines and costimulatory molecules can positively regulate T-cell activation, proliferation, and effector function, other members of cytokine and costimulatory molecule gene families can act as negative regulators (Fig. 13.2). These can be specific to APCs, tumor cells, or shared between those. For example, TGF-β produced by immune cells or tumor cells acts directly on T cells to inhibit their ability to proliferate.[56] As another example, the major effects of IL-10 are immunosuppressive, in part by suppressing active costimulatory molecule and cytokine expression by APCs.[43]

CD80 and CD86 have positive effects on T-cell activation and proliferation when they bind to CD28. However, when they bind to CTLA-4 (CD152), a member of the CD28 gene family inducibly expressed on the surface of activated T cells, strong inhibitory signals limit further T-cell proliferation and activation.[57] CTLA-4 binds CD80 and CD86 with 10- to 20-fold higher affinity than the costimulatory CD28 molecule[58] and CTLA-4 directly inhibits effector T-cell activation through CD28 signaling pathway disruption and by outcompeting CD28 for CD80 and CD86 ligation.[59] Constitutive CTLA-4 expression on Tregs also mediates tumor-specific T-cell suppression.[60]

Programmed cell death ligand 1 (PDL1) (B7-H1 or CD274) and PDL2 (B7-DC or CD272) on APCs or tumor cells inhibit the activation of T cells that express PD1. PD1 ligation inhibits T-cell receptor (TCR) signaling events and T-cell activation[61] and leads to the so-called exhausted T cell. Upregulation of PDL1 on APCs is a feature of chronic viral and other infections and leads to suppression of the immune and inflammatory response often associated with these infections. Intrinsic tumor expression of PDL1 and PDL2 promotes tumor growth by increasing apoptosis of tumor-reactive T cells.[62]

B- and T-lymphocyte attenuator (BTLA) is a costimulatory receptor functionally similar to PD1 and CTLA-4.[15] Herpes virus entry mediator expressed on APCs can inhibit T-cell activation in T cells that express the BTLA receptor.[63]

Similarly, B7-H4 (B7x or B7S1), a member of the B7 family of costimulatory molecules, is a negative regulator of activated tumor-reactive T cells.[64,65] The receptor, which binds to B7-H4, has not yet been identified. Recently, by using ovarian cancer as a model, it has been shown that Tregs in the tumor microenvironment stimulate B7-H4+ tumor-associated macrophages to inhibit T-cell–mediated antitumor immunity via IL-10 and IL-6 expression.[66]

Inducible T-cell costimulator ligand (ICOSL), a member of the B7 family of costimulatory molecules, is predominantly found on professional APCs[18] and peripheral and endothelial cells.[67] ICOSL upregulation during inflammation promotes IL-10 production by T cells.[67] ICOS, which is induced on activated T cells and constitutively expressed on Tregs, negatively regulates antitumor T cells by inhibiting effector T-cell proliferation.[15]

The lymphocyte activation gene (LAG)-3 (CD223), which is morphologically similar to the CD4 coreceptor, negatively regulates T-cell activity through MHC class II binding.[68] LAG-3 ligation inhibits T-cell proliferation and antitumor cytokine production by downregulating expression of the CD3–TCR complex.[69]

Myeloid-Derived Suppressor Cell T-Cell Inhibition

Myeloid-derived suppressor cells (MDSCs) are potent suppressors of antitumor immunity within the tumor environment. MDSCs are a heterogeneous population of cells of myeloid origin consisting of myeloid progenitor cells and immature DCs, macrophages, and granulocytes.[70] MDSCs suppress antitumor immunity through diverse mechanisms that alter the innate and adaptive immune systems (Fig. 13.3). MDSCs inhibit CD8+ and CD4+ T-cell activation through the upregulation of arginase that subsequently depletes arginine (essential for T-cell proliferation).[71] MDSCs, activated by proinflammatory mediators prostaglandin E (PGE)2, IL-1α, IL6, and vascular endothelial growth factor (VEGF), dampen antitumor immunity by skewing it toward a tumor-promoting Th2 response and by downregulating macrophage secretion of antitumor cytokine IL-12.[72] MDSCs also indirectly inhibit T-cell activation by inducing Tregs.[73]

Regulatory T-Cell Immune Suppression

Tregs are important sources of T-suppressor cytokines and inhibitory signals and fall into two broad classes. The first category of Treg cells (Tr1) may be a separate T-cell lineage that develops in the thymus.[74] These Tr1 cells express the glucocorticoid-induced TNF receptor family-related gene (GITR), CTLA-4, PD1, and the high-affinity IL-2 receptor (CD25), and require IL-2 for growth and survival. They also secrete IL-10 and TGF-β, and their gene expression profile is regulated by the transcription factor, forkhead box P3 (FOXP3).[75] The second category of Treg cells (Tr2 cells) develops in response to antigens in the periphery with several types of induced/adaptive Treg cells described. Some induced Tr2 cells are CD4+/CD25+ and express FOXP3-like Tr1 cells. Others, called Th3 cells, secrete only TGF.[76] Various sources of Tregs within the tumor microenvironment exist. The tumor microenvironment is abundant in CCL22 that acts to traffic Tregs via CCR4 (the receptor for CCL22) surface expression.[77] Tumor factors such as VEGF, IL-10, and TGF-β suppress DC differentiation and DC function and activate plasmacytoid DCs[78] and MDSCs that, in turn, stimulate Treg differentiation and expansion.[79] Tregs suppress antitumor immunity by a variety of mechanisms (see Fig. 13.3). Tregs can induce T-cell cycle arrest through B7-H4+ tumor-associated macrophage negative-regulation pathways.[66] Tregs can selectively kill tumor-specific T cells and tumor-specific APCs through perforin- or granzyme B–dependent pathways.[80,81] CTLA-4+ Tregs

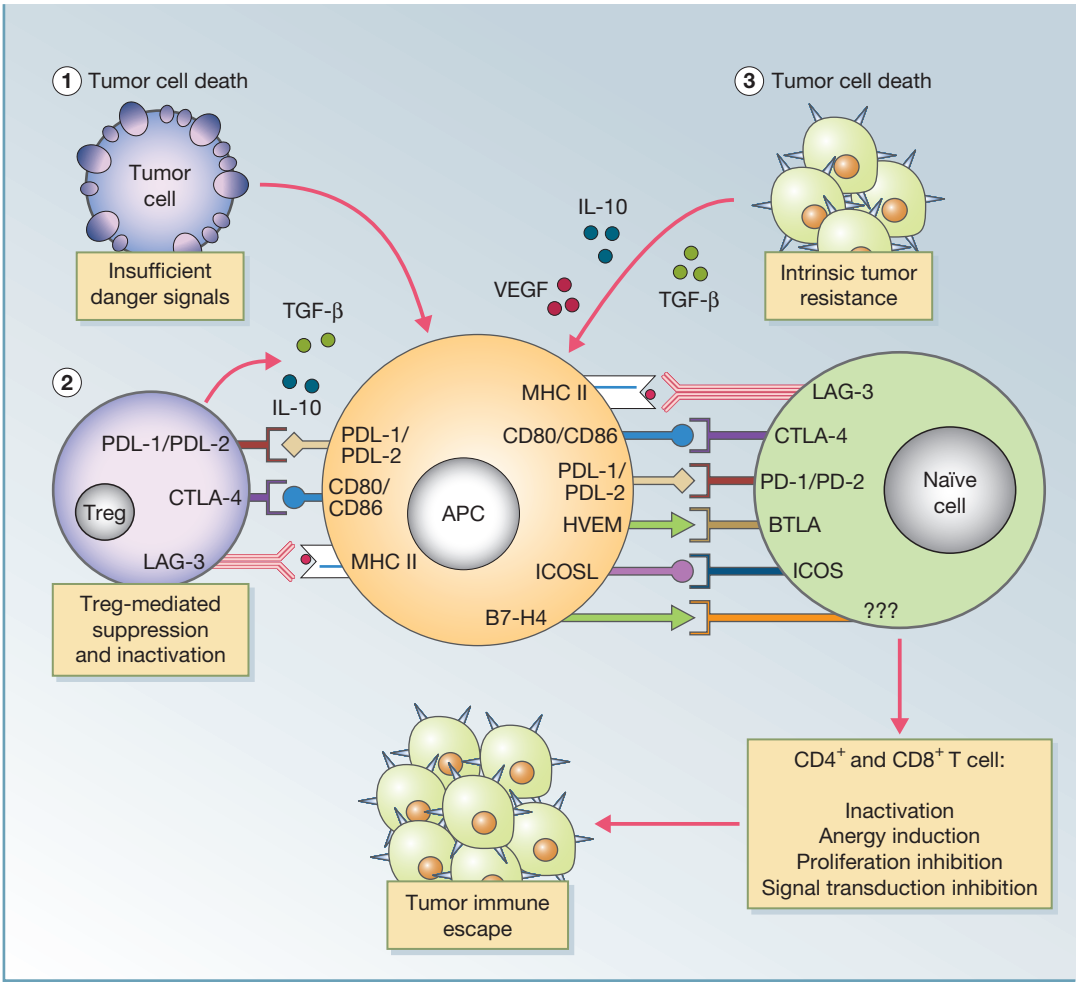

Figure 13.2. Antitumor response suppression by regulatory T cells (Tregs) and antigen-presenting cells (APCs). Under certain conditions, APCs and Tregs can suppress tumor-specific T-cell immunity by a variety of mechanisms. Insufficient APC activation or insufficient danger signals can lead to coinhibitory pathway activation. Tumors can often intrinsically induce expression of cytokines, such as interleukin (IL)-10, transforming growth factor (TGF)-β, and vascular endothelial growth factor (VEGF), that are capable of activating coinhibitory pathways in APCs and Tregs, recruiting additional Tregs to the tumor site, and directly inhibiting cytotoxic effector T-cell function. Treg recruitment to tumor sites suppresses antitumor immunity through a variety of mechanisms. (1) Tregs secrete inhibitory cytokines such as IL-10 and TGF-β, which directly inhibit effector T-cell activation and effector function. (2) Tregs induce T-cell apoptosis through perforin- and granzyme-dependent killing mechanisms. (3) High-affinity CD25 (also known as IL-2 receptor), present on Tregs, deprives tumor-specific T cells of IL-2, a cytokine essential for T-cell survival, leading to cytokine deprivation–mediated death. Negative regulation of T cells diminishes antitumor immunity and can lead to tumor immune escape. (4) Coinhibitory pathways (shown here and described in the text) on APCs and Tregs are responsible for diminishing antitumor immunity by inactivating T cells, anergizing effector T cells, and inhibiting T-cell proliferation.

suppress tumor-specific T-cell activation through induced expression of indoleamine 2,3-dioxygenase (IDO) by APCs, which depletes tryptophan (T-cell activation precursor).[82] Tregs also secrete suppressor cytokines such as IL-10 and TGF-β, which directly inhibit expression of MHC molecules, CD80, CD86, and IL-12 cytokines on APCs.[83] The heterotrimeric IL-2 receptor complex expressed on Tregs has a 100-fold higher affinity for IL-2 than does the dimeric form expressed on conventional T cells. Thus, Tregs can further suppress effector T-cell growth and survival by limiting the available IL-2 in the tumor microenvironment.[84]

Tregs have been found in the blood, lymph nodes, and tumor microenvironments of patients with a number of malignancies and have been shown to limit the activity of antitumor T cells.[52] Selective reduction or elimination of Tregs may enhance immune responsiveness to vaccines. A clinically relevant method to eliminate Tregs involves the use of cytotoxic agents such as cyclophosphamide.[85] CD4+/CD25+ T cells can also be eliminated by CD25 antibodies or Ontak, which consists of a portion of diphtheria toxin coupled to the human IL-2 binding domain, allowing it to bind and kill CD25+ cells.[86] 1-Methyl tryptophan may reduce the suppressive effects of IDO-positive APCs on T cells. CTLA-4 blocking antibodies can reduce inhibitory signaling and increase the proliferation of activated T cells and, potentially, the magnitude of an antitumor response. However, because autoreactive T cells are also activated by this reagent, toxicity from autoimmune disorders is high.[87] In addition, the desired effector T-cell response may be diluted by the activation of other cells. Other methods to increase the number and activity of vaccine-activated tumor-reactive T cells include the use of antibodies against IL-10 or TGF-β.[88]

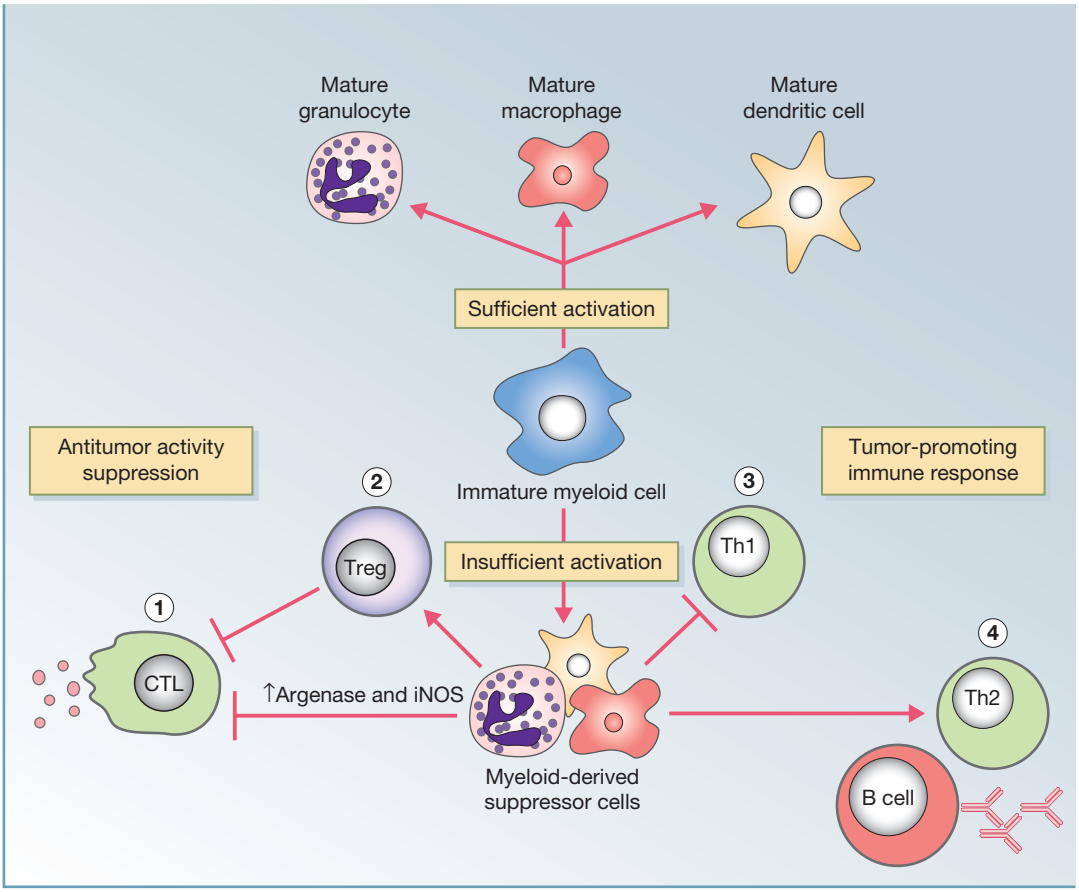

Figure 13.3. Antitumor response suppression by myeloid-derived suppressor cells (MDSCs). Immature myeloid cells that receive sufficient activation differentiate into mature granulocytes, macrophages, and dendritic cells (DCs). However, immature myeloid cells that are not sufficiently activated develop into a heterogeneous population of immature granulocytes, macrophages, and DCs, collectively referred to as MDSCs. MDSCs suppress antitumor immunity through a variety of mechanisms. (1) MDSCs inhibit CD8+ and CD4+ T-cell activation by upregulating arginase, inducing reactive oxygen species (ROS) and peroxynitrite (iNOS) production, and by cysteine sequestering (not shown). (2) MDSCs also indirectly inhibit T-cell activation by activating and recruiting regulatory T cells (Tregs). (3) MDSCs directly promote tumor growth by inhibiting antitumor Th1 cells. (4) MDSCs dampen antitumor immunity by skewing the immune response toward a tumor-promoting Th2 response.

Additional Regulatory Immune Cells

T cells are not the only cells with regulatory function that can suppress adaptive immune responses. CD1-restricted natural killer (NK) T cells with invariant TCRs, nonclassical NK T cells with normal TCRs,[89] T cells,[90] macrophages,[91] and effector B cells[92] also secrete IL-10 and can negatively affect T-cell responses.

Immune-Tolerant T Cells of Low Avidity

As described, tumor antigens are often derived from normal proteins that become accessible to T cells because of increased expression through oncogenic signaling events that drive tumor progression. However, central thymic tolerance mechanisms may result in a TCR repertoire that has only weak affinity for peptides derived from these tumor antigens because they are derived from "self."[93] Clearly, if there are no T cells that can respond to antigens in a vaccine, the vaccine is likely to be ineffective. Adoptive T-cell therapeutic approaches are being developed to overcome this problem.[94] Alternatively, careful selection of tumor antigen vaccine targets is a critical part of any vaccination approach (see "Cancer Vaccine Platform Technologies").

Immune Deviation: Th2 Polarization

Tumor cells often secrete factors such as IL-10, IL-6, and PGE that promote type 2 over type 1 immunity.[56] Because the cytokine milieu at the time of initial encounter with the antigen has a major role in determining the form of the resulting immune response,[36] cancers may, therefore, induce an ineffective (and sometimes tumor-promoting) response. To ensure that a type 1 response ensues, it may be necessary to decrease tumor bulk with cytotoxic chemotherapy to lower the levels of immunosuppressive factors. Alternatively, provision of cytokines (such as IL-12 and IFN-γ) or combinations of multiple cytokines (IRX2)[95] that promote type 1 responses can be used.

Intrinsic Resistance of the Tumor Target to T Cells

The analogy of cancer vaccines and successful viral immunity breaks down almost completely when one considers the nature of the target cell. As intimated in the preceding discussion on chemokines, virally infected target cells do not interact passively with antiviral CTLs. Rather, they cooperate with CTLs

by upregulating the expression of molecules that promote T-cell killing on recognition of antigens. Virally infected cells also secrete cytokines, such as IL-15,[96] that maintain the activity of CTLs and chemokines that guide type 1 effector cells to the region of inflammation.

In contrast, tumors generally arise in response to prolonged cytotoxic insults.[97] To survive, cells become genetically unstable and activate signaling pathways that allow them to grow without regard for social controls.[98] Signaling pathways that are often activated in tumor cells are the antithesis of those that are activated in response to viruses.[56] They include the rat sarcoma viral oncogene homolog (RAS), v-Akt murine thymoma viral oncogene homolog (AKT), and signal transducer and activator of transcription (STAT) proteins, which activate antiapoptotic genes that prevent killing by CTLs and positively regulate the expression of cytokines that inhibit the activity of CTLs, such as IL-10, TGF-β, and VEGF, and chemokines, such as CCL22, that recruit Tregs.[52] STAT3 and STAT5 transcription factors are thought to orchestrate this microenvironment, promoting tumorigenesis and cancer progression by inducing and maintaining a tumor-promoting inflammatory microenvironment.[99]

Suboptimal Immunologic Monitoring

Immunologic monitoring has been long used in both preclinical and clinical studies to evaluate cancer vaccines. However, using such immunologic results has often resulted in faulty decision making, with some vaccines being advanced into further stages of development with modest potential for success.

The immunologic assays developed include enzyme-linked immunospot (ELISPOT) assay, intracellular cytokine staining, and multimer multiparametric flow cytometry assays. The optimal form of immunologic monitoring for cancer vaccines has not been established. Concerns about the assays initially used included issues regarding the reproducibility, sensitivity, standardization, and predictive validation of the assays. There were challenges regarding which assays or combinations of assays were most predictive, and when, where, and which cells to evaluate. Based on these important concerns, leading collaborative networks organized standardization and "harmonization" initiatives for ELISPOT and flow cytometric assays and made recommendations on the types of assays that should be used in cancer immunotherapy/vaccine trials.[87,100] It has been generally agreed that at least two different assays should be performed to confirm an increase in tumor-reactive T cells in response to vaccination as false-positives could be seen when patients are identified as "responders" with only one assay and not another.[101] In addition, steps have been taken to standardize the assay methods and to report in a consistent manner "the minimal information about T-cell assays."[102]

There have been significant advances in various technologic aspects that have improved the type and quality of the antigen-specific immune analyses. These advances include the use of longer peptides spanning the antigen of interest rather than MHC-restricted nonamers and class II binding peptides to obtain a more comprehensive analyses of CD4+ and CD8+ T-cell responses not confined to a single MHC type. In addition, there have been advances in the types of multimers available. These advances offer enhanced sensitivity and improved correlations with functional activity.[103] There have also been advances in the technologies for identifying specific immune subsets, using models that rely on multiple parameters.[104]

Other considerations include the source of T cells (i.e., blood, lymph node, tumor) and methods using either direct ex vivo analysis or in vitro sensitization and culture. This is particularly important as it has been clearly documented that the repertoire of T cells in blood and tumor tissue are not identical,[105] hence overreliance on immune monitoring in blood may lead to misinterpretation of a vaccine's capability to elicit useful immune responses.

Nevertheless, the major issues associated with current immune monitoring remain: (a) standardization; (b) significance from the standpoint of magnitude and profile, particularly in preclinical models that have their own caveats; (c) throughput to also monitor additional T-cell clonotypes recruited to the process through "epitope spreading"; and (d) reliability in clinical studies, as there have been very few benchmarks useful to inform on adequate success criteria for the decision to go, no-go, or optimize a vaccine.

While the above describe major hurdles in front of cancer vaccines, some of them are already addressable but others remain to be elucidated to fully enable the development of this class of vaccines.

CANCER VACCINE PLATFORM TECHNOLOGIES CONTINUE TO UNDERGO SIGNIFICANT DIVERSIFICATION

Based on the preceding discussion, important components required for therapeutic cancer vaccines include the antigen, the adjuvant, and the platform for delivering the antigen and other vaccine components. Immunomodulators to reverse the obstacles that limit immune activation in cancer patients will also be important for maximizing the clinical activity of the vaccine. Adjuvants are not discussed here because they are discussed elsewhere.

The choice of the tumor antigen to be used in a cancer vaccine is a critical. The antigen will determine the specificity of the immune response, influence the overall immunogenicity of the vaccine, and affect the clinical usefulness (efficacy-to-toxicity ratio) of the cancer vaccine.

During the past 15 years, a wide range of different tumor antigens have been identified.[106,107] Most recently, truncated cryptic fragments from TAAs have been identified as tumor specific and highly immunogenic.[108] More commonly, tumor antigens that are associated with certain types of cancers have been evaluated. Tables 13.1 and 13.2 list the major categories and include the cancer testes antigens (CTAs), the differentiation antigens, the overexpressed antigens, and the oncofetal antigens. There also is a class of viral antigens that have been found to be associated with certain malignancies, most notoriously the E6 and E7 proteins of the human papillomavirus.[109] The TAAs have some level of specificity to one or several classes of tumors and are restricted in their expression level in normal tissues and organ systems. Some of these antigens were identified because of their immunogenicity using SEREX (serological expression of complementary DNA expression) or reverse immunology.[110,111] Finally, multiple new technologies, including proteomics, gene array, and immunologic strategies, are being used to identify even more highly expressed, specific, and immunogenic tumor antigens.[112] This search has culminated with the recent discovery of a most exciting class of antigens, that are tumor and patient specific, encompassing strictly tumor specific epitopes resulting from nonsynonymous somatic mutations (their totality representing the cancer mutanome), yielded by genes within the tumor cells.[113,114] Such neoepitopes represent improved targets for vaccines and other immune interventions as they can be "non-self," more immunogenic, and selectively expressed by tumor cells, but not normal tissue. Future strategies encompassing highly personalized vaccines directed at such epitopes are described below.

TABLE 13.1 Categories and Examples of Tumor Antigens

Category of Tumor Antigen	Example
TUMOR SPECIFIC	
Mutated oncogenes	mRas
Immunoglobulin idiotype	Idiotype
Cryptic frameshift sequences	May be tumor-specific
TUMOR ASSOCIATED	
Cancer testis	MAGE-A1, MAGE1, MAGE-A3
Differentiation	gp100, tyrosinase
Oncofetal	CEA
Widely expressed	mP53, 5T4
VIRAL	EBV, HPV

CEA, carcinoembryonic antigen; EBV, Epstein-Barr virus; gp100, glycoprotein 100; HPV, human papillomavirus; MAGE1, melanoma-associated gene 1; MAGE-A3, melanoma-associated gene 3.

TABLE 13.2 Examples of Tumor Types and Antigens

Tumor Type	Example of Tumor Antigen
Colorectal	CEA, KSA, 5T4
Lung	CEA, MAGE-A3, Muc1
Breast	CEA, HER/2-neu, Muc1
Gastric	Gastrin, CEA
Pancreatic	CEA
Melanoma	gp100, Mart1/Melan A, tyrosinase, MAGE-A1, MAGE1, MAGE-A3, NYESO-1
Ovarian cancer	CEA, survivin, NYESO1
Prostate cancer	PSA, PSMA, PAP, 5T4, WT1
Chronic myelogenous leukemia	BCR/ABL, WT1
Lymphoma	Immunoglobulin idiotype

BCR/ABL, breakpoint cluster region/Abelson murine leukemia virus; CEA, carcinoembryonic antigen; gp100, glycoprotein 100; MAGE1, melanoma-associated gene 1; MAGE-A3, melanoma-associated gene 3; NYESO1, New York ESO antigen 1; PAP, prostate acid phosphatase; PSA, prostate-specific antigen; PSMA, prostate-specific membrane antigen; WT1, Wilms tumor antigen 1.

TABLE 13.3 Platforms to Present Antigen

	Peptide	Protein	Carbohydrate	Cellular Tumor	Cellular Dendritic	DNA	Viral
Immune response	CD8+ or CD4+ specific	CD4+	CD4+	CD8+	Mixed	CD8+ and CD4+	CD8+ and CD4+
Antigen specificity	Epitope specific	Antigen specific	Glycosylation specific	Not antigen specific	Potentially broad	Single or multiple defined antigens	Single or multiple defined antigens
Treatment type	Allogeneic	Allogeneic	Allogeneic	Autologous or allogeneic	Autologous	Allogeneic	Allogeneic
Manufacturing	Well defined	Well defined	Well defined	Stability/ characterization	Collection/culture/ characterization	Well defined	Specialized but well defined
Development phase	Phase III complete	Phase III underway	Phase III complete	Phase III complete	Phase III complete; U.S. Food and Drug Administration approved vaccine	Phase I/II	Phase III underway

There are many different platforms that can be used to present the tumor antigen(s) to the immune system (Table 13.3). These platforms can be antigen specific or antigen nonspecific. In the nonspecific approaches, the tumor cell itself is used as an immunogen. In this situation, the tumor cell can be taken from the patient (autologous) or generated from cell lines (allogeneic). To further enhance the immunogenicity, tumor cell vaccines can be genetically modified with immunogenic molecules such as costimulatory molecules, cytokines, or haptens. The antigen-specific vaccines use a particular tumor antigen(s) as the immunogen. These antigens can be any of the tumor-associated or tumor-specific antigens. The tumor antigen(s) can be presented to the immune system in a variety of platforms that may include proteins, carbohydrates, DNA, or viral vectors. In addition, MHC-binding epitopes derived from the proteins can also be presented to the immune system as peptide vaccines.

The choice of platform used to present the antigen to the immune system will influence the characteristics of the immune response. For example, nonamer binding HLA class I peptide immunogens will induce predominantly a CD8+ T-cell immune response and Th1 CD4 type of immune response. On the other hand, an extracellular protein immunogen will undergo endocytosis and be processed through a class II pathway and activate CD4+ T cells and predominantly a Th2 response. Similarly, carbohydrate immunogens will also induce predominantly CD4 and Th2 immune responses. Viral and DC vaccines may generate broader immune responses of CD4 and CD8 types.

Cellular Vaccines—Tumor Cells

Tumor cell–based vaccines were among the earliest cancer vaccines.[115] Tumor cells taken directly from a patient or from allogeneic cell lines were inactivated to enhance the immunogenicity of the tumor cells. This included lysing the cells, radiating the cells, or adding an adjuvant. With tumor cell vaccines, many normal cellular antigens along with tumor antigens were presented to the immune system, with the potential that the large number of normal cellular

immunogens might compete with or dilute out the desired response to the tumor antigens. The potential strength of the approach is that any tumor-specific mutated antigens would be presented to the immune system, particularly with autologous tumor cell vaccine approaches. Both CD4 and CD8 epitopes would be presented to the immune system. Disadvantages of autologous vaccines relate to the logistics of obtaining, processing, manufacturing, and then readministering these autologous vaccine preparations into an individual patient.

Live tumor cells are poorly immunogenic and have been shown to secrete various factors that inhibit various immune responses. Apoptotic or necrotic tumor cells may release factors such as HSPs, HMGB1, uric acid, or ATP (see "Immunogenic and Nonimmunogenic Cell Death") that have various immune-stimulatory properties. There are a number of strategies to kill the tumor cells prior to administration and include freeze-thawing and irradiation. A number of different strategies to genetically modify the tumor cell to make it more immunogenic have also been evaluated.[116,117] These include the introduction of immunogenic haptens, xenogeneic or immunogenic antigens, cytokine molecules, viral oncolysates, and/or costimulatory molecules.

Exosomes are membrane-derived vesicles from multivesicular endosomes that are secreted by many cell types and reflect the protein content of the cells from which they came. Tumor-derived endosomes have been studied as tumor vaccines and, when administered with granulocyte-macrophage colony-stimulating factor (GM-CSF), can activate cytotoxic T cells specific for various tumor antigens. Whole tumor-derived RNA has also been used to pulse DCs, and vaccine-specific T-cell responses have been seen in some patients with melanoma.

Several Phase III trials have been completed with the first generation of tumor cell vaccines (inactivated or cell lysates). These include customized autologous and allogeneic approaches and genetically modified (GM-CSF) tumor cells. In the Phase III trials conducted with various tumor cell vaccines to date, clinical efficacy was not established[118,119] (Table 13.4). However, there has been promising results with the combination of a GM-CSF expressing cellular vaccine (GVAX-Cell Genesis) and ipilimumab, a CTLA-4–blocking antibody that blocks a key immune-inhibiting checkpoint, where a relationship was seen between the induced tumor necrosis and ratio of infiltrating CD8+ T cells over FoxP3 Tregs.[120]

Cellular Vaccines—Dendritic Cells

Technologies to isolate DC precursors or immature DCs from patients and to culture and activate these cells have been developed and optimized.[121,122] These cells can be used to present tumor antigens to the immune system. The type of T-cell activation by DC vaccines is dependent on how the tumor antigens are provided to the DCs. For example, if class I binding peptides are used to pulse these DCs, the immune response will be predominantly a CD8+ T-cell response.[123] Similarly, if tumor antigens are provided through genetic approaches such as plasmid or viral vectors, the tumor antigens will be expressed intracellularly and processed and presented through a class I pathway resulting in a predominantly CD8+ T-cell response. If the tumor antigen is secreted from these genetic expression constructs, the class II pathway may also be used and predominantly CD4+ T-cell responses will be generated. RNA has also been used to provide the tumor antigen, and this will also predominantly use a class I CD8+ T-cell pathway.[123]

There are a number of approaches to load DCs with antigens. Pulsing DCs with autologous tumor cell lysates or tumor cell–derived RNA results in presentation of a wide variety of cellular antigens and the tumor antigens.[123] RNA has certain favorable properties, including the potential for high levels of translation in the cytoplasmic compartment, which can induce CD8+ and CD4+ T-cell responses. One clinical trial showed that vaccines containing multiple peptides can induce a broad immune response to multiple epitopes. As such, a 12-epitope peptide vaccine was shown to be more immunogenic than a four-peptide vaccine.[124] Trials using combinations of class I and class II binding epitopes are underway.

RNA is emerging as an effective way to transduce DCs. This results in effective class I protein processing and presentation.

TABLE 13.4 Vaccines in Phase II or Phase III Development for Prostate Cancer

Vaccine	Company	Type	Tumor-Associated Antigen	Additional Components	Status
Sipuleucel-T or Provenge	Dendreon	Autologous PBMCs specifically activated dendritic cells	PMBCs activated with TAA, PAP	GM-CSF	FDA approved
PROSTVAC-VF	Bavarian Nordic	Primed with vaccina based vector boosted with fowlpox based vector	Both vectors contain the transgene TAA, PSA	Both vectors also contain immune costimulatory transgenes CD80, ICAM-1, and LFA-3. Both viruses are administered with GM-CSF	Phase III
AD5-PSA		In vivo gene therapy mediated by adenovirus	PSA		Phase II
PAP DNA Vaccine		Naked DNA	PAP	Combination therapy with GM-CSF or Sipucel T	Phase II
CV9103	CureVac	TAA mRNAs	PSA, PSCA, PSMA, and STEAP1		Phase IIb
GVAX	Biosante Inc	Two irradiated allogenic prostate cancer cell lines		Cell lines express GM-CSF	Phase III

GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM, intercellular adhesion molecule; LFA, lymphocyte function–associated antigen; mRNA, messenger RNA; PAP, prostate acid phosphatase; PBMC, peripheral blood mononuclear cell; PSA, prostate-stimulating antigen; PSCA, prostate stem cell antigen; PSMA, prostate-specific membrane antigen; STEAP1, six transmembrane epithelial antigen of the prostate 1; TAA, tumor-associated antigen.

In addition, the expression is transient, and RNA will not integrate into the genome. RNAs can be introduced by lipid-mediated transfection, passive transfection, or, as most recently found, by electroporation. Alternatively, the tumor's array of antigens can be presented by producing DC-tumor cell hybridomas in which the antigen processing and presentation capabilities of the DC are used to process and present tumor-derived proteins.[125] Another approach to provide unique antigens to purified DCs is to pulse DCs with exosomes derived from autologous DCs. These are nanometric vesicles that are released from late endosomes and contain multiple antigens, including tumor-derived antigens.[126] DCs can be loaded with common TAAs using genetic approaches or pulsed with MHC class I or class II epitopes from TAAs.[127] Finally, the activity of DCs can be further enhanced by genetically modifying DCs with molecules that may affect DC migration (chemokines), activation (GM-CSF) or T-cell activation (cytokines).[128]

Preclinical data using DC vaccines demonstrate that specific T-cell responses of the desired functional qualities to induce antitumor activity can be induced. Based on these results a number of different DC-based vaccines have been evaluated in the clinic. Phase II studies in myeloma and lymphoma using patient-specific idiotype antigens[129] and in colorectal cancer using carcinoembryonic antigen peptide targets[130] have demonstrated an expected immunologic response—manifested through induction or elevation of antibody or T-cell responses against the immunizing antigens—and some examples of clinical antitumor responses.

Most recently, a Phase III clinical trial using patient-derived DCs pulsed with a prostatic acid phosphatase–GM-CSF fusion protein (Sipuleucel-T [Dendreon]) in patients with hormone-refractory prostate cancer has demonstrated a small but significant survival advantage for patients who received the vaccine versus the placebo.[131–134] An association between the numbers of CD54 APCs and likelihood of improved survival was seen. This is the first example of a survival advantage using a cancer vaccine and provides clinical proof of concept for cancer vaccines in general. It is somewhat debatable whether this vaccine comprises truly differentiated DCs. Nevertheless, confirmatory trials have duplicated this important result, and, recently, this vaccine has become the first therapeutic vaccine approved by the U.S. Food and Drug Administration (FDA) for use in cancer (castrate-resistant prostate cancer).

Although technologies to purify DCs have become more robust and generalized, the customized patient-specific nature of this approach make broad-scale application of DC approaches a challenge. Cell-based vaccines comprising mostly DCs, are very effective in eliciting both T-helper and CTL responses, but less proficient in inducing B-cell responses.

Peptide Vaccines

The epitopes that are presented on class I or class II MHCs can be predicted and synthesized to use as targets for cancer vaccines.[135] With peptide-based approaches, the MHC type of the patient must be known and peptide immunogens must be specific to a particular MHC type. Most recently, peptides that bind to multiple different MHC subtypes or types have been identified (supertopes).[136] Other improvements to the approach include modifying the sequence of the peptides to increase the strength of binding to the MHCs (anchor modifications)[137] or to the TCR (heteroclitic modifications).[138] These improvements have yielded enhanced immunogenicity in preclinical models, and early trials have suggested that there may be enhanced clinical activity. Because peptide immunogens are highly specific, the breadth of the induced immune response can be enhanced by using multiple peptide epitopes from one or more protein antigens. In addition, combinations of class I and class II binding peptides can be used toward coinduction of CTLs and Th cells acting synergistically in vivo.

Although some immunologic and clinical activity has been seen with peptide immunogens formulated in saline without an adjuvant, most data suggest that peptide immunogens will be more efficacious when formulated in adjuvants such as incomplete Freund adjuvant. However, the overall clinical response rate for a variety of class I binding peptides administered as monotherapy to patients with advanced cancer is very low. Combining peptide-based vaccination with immunomodulators such as IL-2 infusions may result in better T-cell migration to tumor sites and enhanced antitumor activity.[139] Improved antitumor activity has been confirmed in a randomized trial with improved response rates and overall survival in patients receiving a gp100 peptide vaccine with high doses of IL-2 versus high doses of IL-2 alone. A trial comparing the same gp100 vaccine with and without the anti–CTLA-4 monoclonal antibody did not show that clinical measurements were improved by the combination over those seen with the anti–CTLA-4 antibody alone.[140] Together with other evidence demonstrating the induction of durable clinical responses ascribable to anti–CTLA-4 antibody, supported the historical approval of the first immune checkpoint blocking antibody.[141] Enhanced clinical and immune responses may be seen with combinations of multiple peptides over single class I and class II binding peptides. The immunologic activity of peptide vaccines may be enhanced with enhanced adjuvant formulations. Addition of cytosine phosphate guanine (CpG) oligodeoxy nucleotides to the MART-1 immunodominant epitope[142–151] in Montanide emulsion resulted in enhanced T-cell responses with more rapid induction of CD8+ T cells and higher peak responses.[101] Similar immune enhancements, manifested through generation of broad integrated antibody and CD4+ and CD8+ T-cell response, were seen with a recombinant New York esophageal cancer-antigen-1 (NYESO-1) protein with ISCOMATRIX adjuvant[152] or with the addition of RNA adjuvants.[153]

Another promising approach involves use of synthetic long peptide (SLP) vaccines. The use of SLPs, generally polypeptides of greater than 30 amino acids, has several theoretical advantages. They may provide multiple epitopes with the potential to bind to multiple MHC types for presentation to CD4+ and CD8+ T cells. A clinical trial using SLPs has been completed in human papillomavirus (HPV)-related diseases with a high frequency of durable clinical regressions seen in patients with HPV-related vulvar intraepithelial neoplasia.[154]

Promising immune results have been seen with a polypeptide vaccine administered in a novel liposomal formulation (DPX-Survivac [ImmunoVaccine]) in patients with high risk or recurrent ovarian cancer. Polyfunctional T-cell responses were seen in all evaluable patients at the optimal dose.[155] Further evaluation of this vaccine in conjunction with metronomic use of cyclophosphamide in survivin-expressing tumors such as ovarian carcinomas is underway.

Peptide-based immunogens are very immunogenic and simple to manufacture. The major limitation of this approach relates to its HLA restriction, the apparently limited capability to elicit robust immunity, and the need to identify and produce multiple peptides to generate broad immune responses to antigens or to generate Th cell and CTL responses.

Protein-Based Vaccines

Tumor antigen proteins used for vaccination will undergo endocytosis by APCs and be processed and presented through the MHC class II pathway. The processed epitopes will be presented to CD4 cells and, in most situations, promote a Th2-focused immune response with generation of humoral

responses. Formulating the protein in some adjuvants may alter the magnitude of the response and may also help promote a Th1-type response. The advantages of using protein-based vaccines are that they are relatively easy to manufacture and they avoid the MHC requirements of peptides. In fact, the processing and presentation of protein immunogens results in multiple epitopes of the tumor antigen being presented on the patient's MHC class I and class II complexes.

There were positive results from a small randomized clinical trial with a vaccine called Stimuvax (Oncothyreon, EMD Serono Inc.).[156] This is a 25-amino-acid polypeptide vaccine (from the MUC1 tumor antigen) formulated in a liposomal formulation containing monophosphoryl lipid (TLR4 agonist). However a randomized trial of this product in locally advanced stage 3a or 3b lung cancer did not meet a significant clinical end point.

A melanoma-associated gene (MAGE)-A3 full-length protein has been evaluated in melanoma and non–small-cell lung cancer (NSCLC) with different saponin adjuvant formulations. This vaccine has the advantage over idiotype and HSP vaccines in that it is an "off-the-shelf" (allogeneic) vaccine and does not need to be synthesized uniquely for each patient. The choice of adjuvant was critical for the activity of the vaccine, and the MAGE-A3 vaccine with this adjuvant induced CD4+ and specific immune responses in many patients with lung cancer, but the MAGE-A3 vaccine alone was less effective. In a small ($n = 182$) randomized clinical trial in patients with lung cancer, a 33% relative reduction of recurrence risk was seen with vaccine treatment.[157] This vaccine-adjuvant combination was subsequently tested in larger, randomized trials but failed to meet the primary clinical end point.[158]

Two kinds of autologous protein-based cancer vaccines have been comprehensively evaluated. The first is the idiotype protein.[159] The immunoglobulin idiotype is a patient-specific customized autologous approach. Strategies have been developed to isolate patient-specific idiotype protein from B-cell lymphomas or myelomas and include hybridoma technology or polymerase chain reaction–based approaches. The idiotype protein can be purified and conjugated to an immunogenic hapten such as KLH (keyhole limpet hemocyanin) to enhance the immunogenicity of the vaccine. In preclinical models, reproducible humoral responses are induced by these protein immunogens.[160] These responses are protective against subsequent tumor challenge with tumor cells expressing the idiotype protein. Depletion of CD4+ T cells in murine models will reduce the therapeutic effect. The immunogenicity of idiotype protein can be enhanced by several techniques, including conjugation of the idiotype variable region to xenogeneic constant region proteins or vaccination with adjuvants such as GM-CSF or GM-CSF–transduced cells.[161]

Idiotype protein vaccines have been studied in the clinic in patients with B-cell lymphoma or myeloma. The approach is feasible, and idiotype protein can be produced for hundreds of patients by hybridoma technology or more easily by polymerase chain reaction techniques.[162] The vaccines are safe, and few serious adverse events have been documented. Although humoral responses are predominantly induced, cellular responses have also been demonstrated. Immunologic responses are more likely to be seen in patients with low tumor burdens and are correlated with longer remissions. In one study, occult lymphoma cells in the peripheral blood were reduced or eliminated after idiotype vaccination.[163] The impact of vaccination with patient-specific idiotype protein has been evaluated in three randomized clinical trials.[164] In two of these trials, clinical benefit was not seen, but in the third, a significant increase in disease-free survival was seen. In this trial, patients' tumors were significantly debulked with aggressive chemotherapy before vaccination, but most of the patients did not receive rituximab, the current standard of care, as part of this debulking chemotherapy. Thus, additional trials to determine whether this vaccine is active in patients after rituximab-based chemotherapy will be important.

The HSPs have also been evaluated as cancer vaccines.[165] HSPs can be isolated from tumor cells after mild heating of the cells. These HSPs are associated with intracellular proteins and peptides. Although many normal peptides will bind to HSPs, TAA peptides will also bind. It is also possible to make recombinant HSPs that bind to specific tumor antigens. Thus, the HSP-peptides isolated from tumors represent patient-individualized vaccines. The HSPs enter APCs through a specific receptor (CD91 on DCs).[166] These HSPs are then internalized and processed and presented through the proteasomal pathway and generate predominantly a CD8 immune response.[167] HSPs have been evaluated in the clinic in various tumor types and been shown to be safe and immunogenic. However, a Phase III trial evaluating HSP in melanoma did not achieve its clinical end point.[168]

A protein vaccine targeting epidermal growth factor receptor (EGFR) (Rindopepimut [Celldex]) had been studied in glioblastoma where EGFRviii is overexpressed in approximately 30% of these tumors. Rindopepimut consists of the EGFRviii protein conjugated to KLH, with both humoral and cellular responses to EGFR generated after vaccination. In three Phase II trials the median overall survival (OS) was between 20.4 and 21.8 months and the OS at 2 years was between 23 and 33%.[169–171] A Phase III trial is underway. Of patients treated, 85% generated significant titers of antibodies to EGFRviii.

Carbohydrate Vaccines

The pattern of glycosylation on tumor cells is different from normal cells, and often carbohydrate antigens on the surface of tumor cells are upregulated.[172] In addition, autoantibody responses to various glycoproteins are often seen in patients with cancer and may be associated with improved outcome.[173] For this reason, several glycoprotein immunogens have been evaluated as potential TAAs for cancer vaccines. A limitation of carbohydrate TAAs is that there may be low-level expression of carbohydrate targets on some normal tissues.[174] In addition, the tumoral expression of carbohydrate antigens may be highly variable.

In early phase clinical trials, carbohydrate immunogens for breast or colon cancer, including the STN moiety, have been shown to be safe and immunogenic inducing predominantly humoral-based immune responses, particularly immunoglobulin (Ig) M and IgG.[175] A Phase III trial with the Theratope STN cancer vaccine for breast cancer has been completed. In this trial, a small dose of cyclophosphamide was given before the vaccination to reduce or eliminate Tregs.[176] However, a clinically significant vaccine effect was not seen in the Phase III trial.

DNA Vaccines

Tumor antigens can be encoded in plasmid vectors and used as immunogens. Cytokines and costimulatory molecules can also be engineered into plasmids.[177,178] After vaccination, DNA will enter cells in the local vicinity, and the engineered transgenes will be expressed. Tumor antigens will, thus, be processed through the class I pathway and epitopes will be presented predominantly on class I MHCs. If the plasmid is expressed in fibroblasts or local muscle cells, the processed tumor antigens will eventually be cross-presented by professional APCs that phagocytose the dying transfated local cells. In some situations, low-frequency APCs will be directly primed

by the plasmid immunogens. In preclinical models, DNA cancer vaccines have been shown to be effective in generating CD8+ T-cell responses and, in some situations, also CD4+ T-cell responses.[179] These responses can be protective against subsequent challenge with syngeneic tumor cells expressing the TAA.

In the clinic, the experience with DNA vaccines for cancer and other diseases has been less impressive. Immune responses are of lower magnitude and require larger quantities of the plasmid immunogen. Strategies to enhance the immunogenicity of DNA vaccines are being developed and include inclusion of different adjuvants, preparation of different formulations, engineering immunogenic molecules into the vector, and using devices (e.g., gene gun) to enhance delivery of the vaccine.[180] In addition, presenting antigen in a RNA virus to produce large quantities of the antigen locally is also being evaluated (AlphaVax).

Finally, the most promising strategies use DNA vaccines in heterologous prime-boost approaches with other platforms such as viral, protein, or peptide immunogens.[181–183] There have been no completed Phase III trials of DNA vaccines for cancer apart from a recent pivotal trial with a naked DNA expressing sequences encoding HLA-B7 and β_2-microglobulin, aimed to enable an immune response against melanoma that failed to meet its primary end point.[142]

Microbial Vaccines

The TAAs can be engineered into various viral vectors and used as cancer vaccines. Because many viruses are efficient at entering cells and expressing their genetic material, viral vaccines have the advantage of producing relatively high levels of the tumor antigen at the vaccination site. Another potential advantage of viral vaccines is the danger signal that is often provided. This will facilitate the activation of professional APCs. A limitation of many but not all viruses is their potential to replicate and cause various types of illnesses after infection including cytokine storms. Finally, the immunogenicity of the virus can result in antiviral responses that can neutralize the virus, cause unwanted inflammation, and reduce or prevent the effectiveness of subsequent vaccinations or compete with the immune response to the TAA transgene.

Various members of the poxvirus family have been found to be attractive vectors for cancer vaccination.[184,185] The modified vaccinia Akara virus and the Avipox (fowlpox) and canarypox viruses have been shown to have no or limited replication potential in human cells. Thus, there is no or little likelihood of illness being caused by the virus. The poxviruses are large viruses and can be engineered to contain many foreign transgenes. They effectively induce CD4 and CD8 responses.

Significant neutralizing responses to some poxviruses, including MVA and avian pox virus, have not been demonstrated and could potentially be used for chronic vaccination. The major limitations of poxvirus-based approaches relate to the specialized engineering and production technologies that are required for these viruses.

In preclinical models, these vectors have been shown to effectively prime CD8 and/or CD4 responses to the inserted transgene. These responses have been associated with tumor protection in various models. In the clinic, there has been significant experience with fowlpox and canarypox (ALVAC) vaccines for cancer. Both of these vaccines are very safe, with the type of immune response induced dependent on the tumor antigen being studied. With ALVAC vaccines containing carcinoembryonic antigen, predominantly CD8 responses have been documented.[186,187,187a] On the other hand, with ALVAC vaccines containing p53, CD8 responses were not seen and CD4 responses were most common.[188] This and some preclinical studies suggest that there may be a high level of central tolerance at the CD8 level to p53. The immune response induced by these vectors may be augmented by inclusion of costimulatory molecules such as B7 or a triad of costimulatory molecules (TRICOM) in the vaccine.[189] The immune responses may also be augmented by prime-boost immunizations and with adjuvants such as GM-CSF or immune modulators such as interferon.[190] A significant 8.5-month increase in OS was seen in patients with hormone-refractory prostate cancer vaccinated with the Prostvac vaccine (Vaccinia PSA TRICOM and Fowlpox PSA-TRICOM [Bavarian Nordic]). However, there was no increase in progression-free survival with the vaccine.[191] A Phase III trial of this vaccine is now underway in hormone refractory prostate cancer. A Phase III trial with a MVA vector expressing 5T4 (Trovax-Oxford Biomedica) did not meet its clinical end point in patients with renal cancer.[143]

Yeast-based vectors have also been used as therapeutic vaccines in cancer. The Tarmogen platform (GlobImmune) consists of heat inactivated yeast containing an antigen of choice. The yeast is taken up by DCs and presented to the immune system. A Tarmogen vector containing carcinoembryonic antigen has been studied in medullary thyroid cancer and based on favorable Phase I results is now being evaluated in a Phase II trial.[144]

Listeria monocytogenes has also been used as a cancer vaccine vector. The live-attenuated, double-deleted (LADD) platform (Aduro) has been modified to improve its safety profile by deleting two genes that control the virulence of *Listeria* and by engineering a target TAA. A LADD expressing mesothelin has been studied in the clinic in pancreatic cancer where mesothelin is often expressed. Based upon results from a combination Phase I trial with the cellular vaccine GVAX, a randomized controlled trial comparing GVAX with GVAX prime followed by LADD-mesothelin (CRS-207) boost was performed.[145] In this trial, a low dose of cyclophosphamide was administered with GVAX in 90 patients to reduce Treg cells. The safety profile was acceptable and a significant increase in OS was seen in the combination arm (9.7 m vs 4.6 m). Patients with enhanced mesothelin-specific CD8 responses had a longer OS. Similar vaccines containing either Her2, prostate-specific antigen (PSA), and HPV are under development.

Another technology using *Listeria*, Advaxis LM (Advaxis Immunotherapies), uses live attenuated *Listeria* that is engineered with a plasmid containing the fusion protein and the target antigen. APCs take up the *Listeria* and produce the fusion protein and antigen that is then processed and presented to the adaptive immune system. Both innate and adaptive immune responses are stimulated. A Phase I trial using Lm-LLO-E7 (live attenuated *L. monocytogenes* [Lm] that secretes the HPV-16 E7 antigen fused to a nonhemolytic fragment of the Lm protein listeriolysin O [LLO]) administered intravenously targeting HPV in cervical cancer has been reported and although there was a 40% incidence of grade 3 adverse events, the treatment was considered safe and a partial clinical response was seen.[146] A randomized trial of ADXS-HPV with or without cisplatin in 110 patients with recurrent cervical cancer has been completed but not reported and further investigation by the Gynecologic Oncology Group is underway. A combination trial of this *Listeria*-based vaccine with a checkpoint inhibitor and with the IDO inhibitor Epacadostat is also underway.

RNA-Based Vaccines

The application of in vitro transcribed (IVT) messenger RNA (mRNA) as a vaccine platform for cancer has been studied

extensively in preclinical models and has reached the Phase III clinical studies. Two different approaches have been investigated: (a) transfer of mRNA to patient's cells ex vivo and (b) direct delivery of IVT mRNA by injection in skin or lymph nodes. In both of these approaches a DNA template is created and the mRNA is transcribed using a cell free system.[147] The mRNA will contain a start and stop codon, 5′ cap and 3′ poly A regions flanked by untranslated regions. These are usually expressed intracellularly and the transcribed protein is then processed and presented through a MHC class I pathway. Strategies to improve the stability and translatability of the mRNAs have been developed. RNAs have immunostimulatory effects and in general induce immune activation by stimulating pattern recognition receptors whose normal function is to identify and respond to viral RNAs. For cellular delivery, formulations (such as lipid materials) have been developed to protect mRNAs against ribonuclease (RNAse)-mediated degradation. Electroporation is a preferred method of transfer. Intradermal or intranodal administration of naked or protamine-complexed RNA vaccines has also been used. Initial studies with DCs transfected with RNA demonstrated the feasibility, and immunogenicity of mRNA transfected DCs and has led to a Phase III trial, now underway by Argos Therapeutics, in patients with advanced renal cancer. Direct intradermal injection of protamine-complexed IVT mRNA with or without GM-CSF is safe and induces CD8 T-cell responses as well as antibody responses. Curevac is studying this approach in clinical trials of patients with prostate or NSCLC. The mRNA self-adjuvanted vaccine CV9103, which contains PSA, prostate stem cell antigen (PSCA), prostate-specific membrane antigen (PSMA), and six transmembrane epithelial antigen of the prostate 1 (STEAP1), was studied in a Phase II trial in patients with hormone refractory prostate cancer.[148] Forty-four patients received up to five intradermal vaccinations in escalating doses and then 32 additional patients were given the vaccine at the recommended Phase II dose. The treatment was well tolerated and immune responses were seen in 26 of 32 patients and responses to multiple antigens were seen in 15 of 33 patients at the recommended dose. The median OS was thought to be favorable at 31.4 months.

Oncolytic Virus Vaccines

Oncolytic viruses are viruses that can selectively replicate in cancerous tissues and not normal tissues.[149,150] They use various oncogenic pathways that are activated for their selective replication including defective interferon pathways (vesicular stomatitis virus [VSV]), deletions of P53 (adenovirus), attenuated PKR (protein kinase regulated by double-stranded RNA) responses (herpes simplex virus [HSV]), deleted thymidine kinase activity *(Vaccinia)*, RAS mutations *(Reovirus)*, and increased expression of nectin-4 (measles virus). Although tumor destruction by replicating virus is an important antitumor mechanism, the induction of a systemic antitumor immune response may be equally as important. Thus strategies to enhance the induction of a systemic immune response are being explored and include engineering immunostimulatory cytokines such as GM-CSF or TAAs and combining administration with other immunomodulators such as checkpoint inhibitors.

There are several oncolytic viruses that look promising based upon initial clinical trials. T-VEC is a HSV1 virus that has been engineered to express GM-CSF (Amgen).[151] The virus is administered through repeated intratumoral injections. In preliminary results from a randomized Phase III trial comparing injections with the virus to injections with GM-CSF alone, the objective response rate was 16% versus 2%, respectively, with trends toward an improved OS. Pexa-Vec (Jennerex) is a *Vaccinia* virus that has also been engineered to express GM-CSF. There is evidence that this virus can replicate in tumor cells after intravenous infusions. In a randomized trial in hepatocellular carcinoma there was a median survival of 14.1 months versus 6.7 months for patients randomized to high-dose Pexa-Vec versus low dose (hazard ratio [HR] 0.39, $P = .02$).[192] In both of these trials there was evidence of viral replication in regressing tumors, so it is difficult to know whether the adaptive immune response played a significant role in the antitumor responses. However evidence of local and distant immunity was seen after T-Vec treatment.[193] Two objective responses of patients with myeloma were seen after treatment with a measles virus (MV-NIS) administered intravenously and there are ongoing trials with this oncolytic virus.[194] Tumor necrosis was seen in two of 21 patients with metastatic melanoma treated with intravenous infusions of the Reovirus Serotype-3-dearing strain (Reolysin [Oncolytics]).[195] Preclinical studies have shown promising results for oncolytic viruses engineered with TAAs and those combined with checkpoint inhibitors or other immunomodulators or cell therapies.

VACCINES IN CLINICAL DEVELOPMENT FOR SPECIFIC CANCERS

A number of vaccines using various platforms are being developed for specific cancers and will be subjected to the usual Phase I to Phase III clinical development pathways through different pharmaceutical companies. The following is a summary of vaccines at more advanced stages of clinical development for common tumor types.

VACCINES IN DEVELOPMENT FOR SPECIFIC TUMOR TYPES

Prostate Cancer

There are many different immunotherapies being tested to treat prostate cancer (see Table 13.4). Leading the way is Sipuleucel-T (Dendreon), an autologous DC vaccine. Recombinant prostatic acid phosphatase (PAP) and GM-CSF are used to activate peripheral blood mononuclear cells (PBMCs), specifically DCs, both ex vivo and in vivo.[196] This product was approved by the FDA after a successful Phase III trial in metastatic castration-resistant prostate cancer. Patients survived 4.1 months longer than those treated with the placebo. In this trial, 73.0% of patients treated with Sipuleucel-T had a T-cell response, compared to 12.1% of patients treated with the placebo.[196] Sipuleucel-T is being tested in Phase II trials in combination with ipilimumab (NCT01804465).

Another promising therapy is PROSTVAC-VF (Bavarian Nordic). This therapy uses two recombinant viruses that have transgenes for the TAA (PSA) and for costimulatory proteins, CD80, intercellular adhesion molecule (ICAM)-1, and lymphocyte function–associated antigen (LFA)-3.[197] Patients are given a *Vaccinia* virus to prime the immune system and a fowlpox virus to boost it. An encouraging Phase II trial showed that 30% of patients treated with PROSTVAC-VF survived 3 years, whereas, only 17% of patients had a 3-year survival when given the placebo.[197] There was also an increase in the median survival by 8.5 months in the vaccine-treated group compared to the control group. PROSTVAC-VF is now being tested in a Phase III trial and in a Phase I trial in combination with ipilimumab (NCT00113984).

Other vaccines being tested in Phase II trials to treat prostate cancer include an adenovirus with a PSA transgene[198] (NCT00583024, NCT00583752), a naked DNA vaccine

that targets the TAA PAP (NCT00849121, NCT01706458), and CV9103 which consists of mRNA for multiple TAAs (NCT00831467, NCT01817738).

Breast Cancer

The protein and peptide vaccines are the most developed platforms for treating breast cancer (Table 13.5). NeuVax (Cancer Insight), a HER-2 derived peptide, E75, was evaluated in a Phase I/II trial when administered with GM-CSF. It had minimal toxicities and showed a marginal increase in 5-year disease-free survival over the control group.[199] A Phase III trial testing NeuVax and GM-CSF is ongoing (NCT0147924) and is also being administered in an ongoing Phase II trial in combination with trastuzumab (NCT01570036).

Theratope (Biomira) consists of carbohydrate antigen, sialyl-Tn, attached to the carrier glycoprotein, KLH protein. This was administered with the adjuvant Enhanzyn in a completed Phase III trial that failed to prolong survival in women with metastatic breast cancer compared to the placebo group[200] (NCT00003638). However, a post hoc analysis revealed a significant increase in time to progression and OS in a stratified group of women who received concomitant endocrine treatment.[201]

Lung Cancer

There were some initial promising results with both a protein and a lipopeptide vaccine in lung cancer.[202] In a Phase III study (NCT00409188), Tecemotide (Stimuvax-EMD Serono), the MUC1 lipopeptide attached to a liposomal delivery system, failed to significantly prolong survival in the overall population of patients with unresectable stage III NSCLC (Table 13.6).[203] However, the group of patients who received concurrent chemoradiotherapy had a prolonged survival of 30.8 months compared to the 20.16 months survival of the placebo group.[203] Another Phase III trial is underway to test patients who have already undergone concurrent chemoradiotherapy (NCT02049151).

The MAGE-A3 antigen is expressed in approximately 35% of patients with NSCLC.[204] MAGE-A3 protein vaccine (GlaxoSmithKline) was delivered with the immune adjuvant AS15 in a Phase II trial and demonstrated trends toward improved outcomes compared to the placebo. However, a Phase III trial was terminated because it failed to meet its primary point of extending disease-free survival (DFS) (NCT00480025).

Another peptide vaccine, GV1001 (GemVax), is a peptide derived from the human telomerase reverse transcriptase and administered with GM-CSF. A Phase II trial showed that the median OS was significantly longer in immune responders than in nonresponders (19 months compared to 3.5 months), and 80% of patients exhibited an immune response.[205] Because of these results, a Phase III trial is in development (NCT01579188).

CIMAvax EGF is a protein vaccine designed to induce a humoral response. The TAA, EGF (epidermal growth factor), is fused with a carrier protein and administered with Montanide ISA 51 adjuvant. In a Phase II study, the OS did not differ significantly from patients given the current standard of care.[206] However, patients who had a good antibody response to the protein survived significantly longer (11.7 months vs 3.6 months).[206]

TABLE 13.5 Vaccines in Phase II or III Development for Breast Cancer

Vaccine	Company	Type	Tumor-Associated Antigen	Additional Components	Status
Nelipepimut-S, E75 or NeuVax	Galena Biopharm	Peptide vaccine	HER2 E75	Administered with GM-CSF	Phase III, Phase II with trastuzumab
Theratope	Biomira	Glycoprotein vaccine	Sialyl-Tn	KLH and Enhanzyn adjuvant	Completed Phase III

TABLE 13.6 Vaccines in Phase II or III Development for Lung Cancer

Vaccine	Company	Type	Tumor Associated Antigen	Additional Components	Status
L-BLP25 or tecemotide	Stimuvax-EMD Serono	Lipoprotein vaccine	MUC1	Monophosphoryl lipid A	Phase III
TG4010	Transgene	Recombinant *Vaccinia* virus	MUC1	Administered with IL-2	Phase IIb
GSK15772932A	GSK	Peptide vaccine	MAGE-A3	Immune adjuvant AS15	Phase III
GV1001	GemVax	Peptide vaccine	Human telomerase reverse transcriptase	Administered with GM-CSF	Phase III
CIMAvax EGF		Peptide vaccine	EGF	Montanide ISA 51 adjuvant	Phase II
Belagenpumatucel-L or Lucanix	NovaRx Corporation	Cancer cell vaccine	TGF-β2		Phase III
Tergenpumatucel-L	NewLink Genetics	Cancer cell vaccine	α-1,3-Galatosyltransferase		Phase II
Racotumomab	Vaxira	Antiidiotype vaccine	Neu-glycolyl–containing gangliosides		Phase III

GM-CSF, granulocyte-macrophage colony-stimulating factor; GSK, GlaxoSmithKline; IL, interleukin; MAGE, melanoma-associated gene; TGF, transforming growth factor.

The TAA MUC1 is also targeted by a recombinant vaccine virus, TG4010 (Transgene). This virus has a transgene for MUC1 and is administered with IL-2. A Phase IIb trial demonstrated a benefit in treating patients with TG4010 with standard chemotherapy over standard chemotherapy alone.[207]

Belagenpumatucel-L (NovaRx), is a cancer cell line vaccine that expresses TGF-β_2. In a Phase II trial, patients who displayed a cellular and humoral immune response survived significantly longer than those who did not (32.5 months vs 11.6 months).[208] A Phase III trial demonstrated an increase in OS in a number of subgroups of patients, including patients who received prior radiation treatment (median survival 28 vs 16 months with placebo)[209] (NCT00676507).

Racotumomab (Vaxira) is an anti-idiotype vaccine that induces an immune response against the TAA neu-glycolyl containing gangliosides. A Phase II study demonstrated a longer median survival over those treated with a placebo (8.23 months vs 6.80 months).[210] A Phase III trial is ongoing (NCT01460472).

Melanoma

gp100 is a peptide vaccine that has been tested in a Phase III trial with IL-2 and the adjuvant, Montanide ISA 51 (Table 13.7). The response rate and median OS was greater with the gp100 vaccine and IL-2 than with IL-2 alone (16% vs 6%, 17.8 months vs 11.1 months, respectively).[211]

Ipilimumab is a fully humanized antibody that targets CTLA-4 and blocks CTLA-mediated T-cell inhibition/anergy. It has gained FDA approval for metastatic melanoma after Phase III trials showed a significant increase in survival in ipilimumab-containing arms. In a trial where ipilimumab was combined with a gp100 peptide vaccine, patients given ipilimumab and placebo had a 28.5% complete response (CR), partial response (PR), or stable disease (SD) compared with 20.1% when ipilimumab was given with gp100 and 11% when gp100 was given alone; the statistically significant differences in objective response and survival between vaccination alone and ipilimumab treatment, supported the approval of this antibody (NCT00094653).[212] Nevertheless, it is unclear why vaccine addition to ipilimumab treatment resulted in a negative trend regarding objective response rate and survival.

GSK2132231A (GlaxoSmithKline) is another peptide vaccine currently being tested in Phase III clinical trials for melanoma (NCT00796445). This consists of a peptide derived from the TAA MAGE-A3 that is administered with Montanide ISA 51. In a Phase II clinical trial, patients treated with GSK2132231A and Montanide ISA 51 showed an increased OS and MAGE-A3 specific antibody titers.[213]

There are multiple allogeneic tumor cell vaccines against melanoma currently being tested in Phase III clinical trials, including the Pol-03A (Polynoma) and CSF470 (Laboratorio Pablo Cassará) vaccines (NCT015465, NCT01729663).

Pancreatic Cancer

The vaccine Algenpantucel-L (NewLink Genetics) is made of allogeneic cancer cell lines that are transduced with α-1,3-galatosyltransferase. In a Phase II trial, the vaccine was administered with the adjuvant gemcitabine plus 5-fluoruracil and the 1-, 2-, and 3-year survival rates were 86%, 51%, and 42% respectively (Table 13.8).[214] This was thought to be superior to that expected based on historical data. A Phase III trial is ongoing (NCT01836432).

GV1001 (GemVax) is the only other vaccine in a Phase III trial to treat pancreatic cancer (NCT00358566, NCT00425360). It is a peptide vaccine derived from the telomerase protein. Two Phase III trials were started based on promising Phase II results. However, one (NCT00425360) was terminated early because of lack of benefit and no survival advantage seen.[215]

Colorectal Cancer

ONCO-VAX (Intracell) is an interesting cellular vaccine that has been studied in a Phase III trial (see Table 13.8). Irradiated autologous tumor cells are returned to the patient with bacille Calmette-Guérin (BCG) adjuvant. A Phase III trial in colon

TABLE 13.7 Vaccines in Phase II or Phase III Development for Melanoma

Vaccine	Company	Type	Tumor-Associated Antigen	Additional Components	Status
gp100 peptide vaccine		Peptide vaccine	gp100	Montanide ISA 51 adjuvant and IL-2	Phase III
GSK2132231A		Peptide vaccine	MAGE-A3	Montanide ISA 51	Phase III
Melanoma TAA pulsed dendritic cells		Adoptive dendritic cell therapy	gp100, MAGE-A1, MAGE-A2, MAGE-A3, MART-1 and tyrosinase		Phase II
Melanoma MHC epitope pulsed dendritic cells		Adoptive dendritic cell therapy	gp100 and tyrosinase		Phase II
Seviprotimut-L or pol-103a	Polynoma	Allogeneic cancer cell vaccine		Bacille Calmette-Guérin adjuvant	Phase III
CSF470	Laboratorio Pablo Cassará	Allogeneic cancer cell vaccine			Phase II/Phase III
Prime boost viral vaccination		Primed with *Vaccinia*-based vector boosted with fowlpox-based vector	Both viruses express NYESO-1		Phase II

IL, interleukin; MAGE, melanoma-associated gene; MART, melanoma antigen recognized by T cell; MHC, major histocompatibility complex; NYESO-1, New York ESO-antigen-1; TAA, tumor-associated antigen.

TABLE 13.8 Vaccines in Phase II or Phase III Development for Other Cancers

Cancer	Vaccine	Company	Type	Tumor-Associated Antigen	Additional Components	Status
Pancreatic cancer	GV1001	GemVax	Peptide vaccine	Human telomerase reverse transcriptase	Concurrent and sequential chemotherapy	Phase III
	Algenpantucel-L	NewLink Genetics	Allogeneic cancer cell vaccine	α-1,3-Galatosyltransferase	Gemcitabine plus 5-fluorouracil	Phase III
	Synthetic RAS peptides		Peptide vaccine	RAS	GM-CSF	Phase I-II
Colon cancer	ONCO-VAX	Vaccinogen	Irradiated autologous tumor cell		Bacille Calmette-Guérin adjuvant	Phase III
	PANVAC		Autologous poxvirus modified dendritic cells	CEA and MUC1	GM-CSF	Phase II
Renal cell carcinoma	AGS-003	Argos Therapeutics	Autologous dendritic cells	Patient-specific tumor RNA	Synthetic truncated CD40 ligand and sunitinib	Phase III
	IMA901	Immatics	Peptide vaccine	9 HLA class I-binding tumor-associated peptides	Cyclophosphamide	Phase III

CEA, carcinoembryonic antigen; GM-CSF, granulocyte-macrophage colony-stimulating factor; HLA, human leukocyte antigen; RAS, rat sarcoma viral oncogene homolog.

cancer found a significant improvement in recurrence-free and overall survival in patients with stage II disease[216] and a Phase IIIb study is currently ongoing to confirm the benefit of this vaccine (NCT02448173).

Renal Cell Carcinoma

AGS-003 (Argos Therapeutics) is a personalized therapy where patient-specific tumor cell RNA is transduced into autologous DCs (see Table 13.8). The patients' DCs are then administered with a synthetic truncated CD40 ligand and sunitinib. The median progression-free survival (PFS) and OS (11.2 and 30.2 months, respectively) in a Phase II trial both exceeded historical data.[217] A Phase III trial for AGS-003 and sunitinib is currently ongoing (NCT01582672).

IMA901 (Immatics) is a combination of nine peptides derived from TAA commonly expressed in renal cell carcinomas. A Phase II study showed that 67% and 54% of patients responded by mounting an immune response to IMA901 and GM-CSF with cyclophosphamide or to IMA901 and GM-CSF alone, respectively.[218] The study showed that IMA901 and GM-CSF reduced the number of Tregs and helped improve OS when the patient had an immune response to the vaccine.[218] A Phase III trial is currently ongoing (NCT01265901).

Advancement to Late-Stage Development Is Not a Success Predictor for Cancer Vaccines

Table 13.9 shows the results of seven promising cancer vaccine trials in which a positive clinical end point was met or approached in the earlier stages of clinical development. Six of the seven trials were randomized.

Despite promising Phase II results, only one vaccine for cancer, sipuleucel-T, has had significantly compelling randomized results to be approved by the FDA. While the initial positive results from other smaller randomized trials predicted successful outcomes, subsequent larger Phase III trials, have not translated to statistically significant positive outcomes for these other vaccines.

These vaccines are characterized by one or more of a number of features that have likely resulted in their successful clinical outcomes in Phase II: (a) clinical development in which the vaccine or vaccine and adjuvant combination have been optimized; (b) combination with an immune modulator; (c) choice of an immunoresponsive patient population; a (d) highly immunogenic vaccine platform; and (e) utilization of surrogate end points to make decisions. In addition, in all these trials the decision to move to Phase III was based on a clinical end point that was supported by biological data. However, the early results may have been misleading as a consequence of nonblinded randomization in some studies, potentially resulting in biases favoring vaccine-dosed cohorts, and the nondefinitive nature of the end points and statistics, such as underpowering, in these exploratory relatively small Phase II trials.

Sipuleucel-T was approved in April 2010 as a therapeutic vaccine for use in castrate-resistant prostate cancer. It is the first cancer vaccine to receive regulatory approval. The pivotal Phase III trial leading to its approval included 512 patients with 2 : 1 randomization ratio and demonstrated a 22% reduction in the risk of death compared with the placebo group ($P = .03$), a 4.1-month improvement in OS (25.8 months in the sipuleucel-T group vs 21.7 months in the placebo group), and a 36-month probability of survival of 31.7% vs 23%. Overall, while statistically significant, the clinical benefit was marginal. The major toxic effects are chills, fever, and headache.[134] This vaccine is manufactured by Dendreon, a Seattle, Washington–based company. This is an autologous approach in which patients undergo three apheresis procedures to obtain sufficient numbers of APCs that are then cultured and incubated with the PAP-GM-CSF fusion protein and subsequently reinfused intravenously into the patient every 2 weeks. Another Phase III trial, called PROTECT, is evaluating the efficacy of sipuleucel-T in patients with prostate cancer with increasing PSA levels after initial local surgery.

The MAGE-A3 vaccine is a recombinant protein vaccine admixed with a proprietary adjuvant. This vaccine has been developed by GlaxoSmithKline. MAGE-A3 is a cancer-testis antigen that is overexpressed in a number of cancers

TABLE 13.9 Phase II Results Do Not Always Predict Phase III Results

Vaccine	Platform Type	Sponsoring Organization	Target Antigen	Tumor Type	Phase II Results	Progression-Free Survival Improvement[a]	Overall Survival Improvement[a]	Stage of Development
Sipuleucel-T	Autologous cellular[134]	Dendreon	Prostatic acid phosphatase	Prostate cancer, castrate resistant	Increased OS by 4 mo (stat sig)—3 trials	2.4 mo in median	4.5 mo in median[b] (25.9 vs 21.4 mo)	FDA approved
Prostvac	Poxvirus[190]	Bavarian Nordic	Prostate-specific antigen	Prostate cancer, castrate resistant	Increased OS by 8.5 mo ($P = .0061$); $n = 82$	Not different	8.5 mo in median[b] (25.1 vs 16.6 mo)	Phase II complete
MAGE-A3	Adjuvanted protein[248]	GlaxoSmithKline	MAGE-A3	NSCLC (stages IB and II)	Increased HR, 66 ($P = .12$); $n = 182$	26% reduction in HR (DFS)	33% reduction in HR	Phase III negative
BLP25	Peptide and immune modulator[156]	EMD Serono	MUC1	NSCLC (stages IIIB and IV)	Increased HR, 73 ($P = .112$); $n = 163$	Not described	4.4 mo in median (17.4 vs 13 mo; greater in IIIB locoregional group)	Phase III negative
HPV-SLP	Long peptide[154]	ISA Pharmaceuticals	HPV-16 and HPV-18 E6 and E7	Vulvar intraepithelial neoplasia	Durable OR 15/20 with corresponding good immune response	Objective response, 79% at 12 mo (not randomized)	Not assessed	Phase III to start
BiovaxID	Autologous protein[164]	Biovest	Immunoglobulin idiotype	Follicular lymphoma	Reductions in MRD in small no. of patients	13.6 mo	Not assessed	Phase III negative
Rindopepimut	Peptide[170]	Celldex	EGFRvIII	Glioblastoma	Promising OS for glioblastoma (21.8 mo) Improved PFS and OS in combination with bevacizumab	Not described	3.2 mo	Phase III negative

DFS, disease-free survival; EGFR, epidermal growth factor receptor; FDA, U.S. Food and Drug Administration; HPV, human papillomavirus; HR, hazard ratio; MAGE, melanoma-associated gene; MRD, minimal residual disease; NSCLC, non–small-cell lung cancer; OR, objective response; OS, overall survival; PFS, progression-free survival; SLP, synthetic long peptide.
[a]Over survival for concurrent control subjects.
[b]Statistically significant.

(melanoma and NSCLC, bladder, head and neck, esophageal, and hepatocellular cancers), but is not expressed appreciably in any normal tissues other than testis and placenta. Thus, a vaccine directed to this antigen should be safe and free of autoimmunity. It is expressed in approximately 35% of patients with NSCLC and in most patients with melanoma. GlaxoSmithKline completed a double-blind, placebo-controlled, randomized Phase II trial in early stage (IB, II) NSCLC. In the trial, 182 patients were treated. The vaccine was well tolerated with mostly injection site–related side effects. An interim Cox regression analysis showed a 33% increased DFS for the group receiving the vaccine (hazard ratio [HR], 0.66; $P = .12$).[157] Based on these results, GlaxoSmithKline initiated a double-blind, placebo-controlled, randomized Phase III trial involving 2300 patients worldwide with stage IB, II, or IIIA NSCLC who had undergone resection and adjuvant chemotherapy, if indicated. However, while some of the biomarker based evaluations of clinical outcomes have been promising,[158] the trial failed to meet its primary end point. There is still a possibility that biomarker identified patient subpopulations will benefit from this approach.

Stimuvax, or L-BLP25, is a vaccine based on a 25-amino-acid repeat found in the broadly expressed tumor antigen MUC1. MUC1 is overexpressed and aberrantly glycosylated in NSCLC. MUC1 is also overexpressed in a variety of other malignancies, including breast, pancreatic, and ovarian cancer. The vaccine is composed of the 25-amino-acid lipopeptide, the adjuvant monophosphoryl lipid A, and three lipids formed into liposomes. The vaccine is administered subcutaneously repetitively, but is preceded by an injection of low-dose cyclophosphamide 3 days before vaccination to reduce Tregs. A Phase IIB trial that included 163 patients randomized to the vaccine or best supportive care was performed. The HR was 0.739 in favor of vaccine-treated patients ($P = .112$).[156] The greatest clinical effect was seen in patients with locoregional stage IIIB disease in whom the HR was 0.524 with a P value of .069. There was no significant toxicity observed. Based on these results, EMD Serono initiated an international randomized Phase III trial comparing L-BLP25 with placebo in patients with stage III NSCLC. However, the vaccine recently failed to achieve its primary end point in this pivotal trial,[203] although patients with earlier-stage disease had better outcomes.

Prostvac-VF is a poxvirus-based vaccine that is being developed for men with castrate-resistant prostate cancer. The vaccine consists of a *Vaccinia* virus and a fowlpox virus, each encoding the prostate TAA, PSA, and the TRICOM costimulatory complex that includes B7.1, LFA-3, and ICAM-1. The TRICOM complex increases the immunogenicity of the vaccine and induces antigen-specific T cells that have higher avidity for the antigen they recognize. The *Vaccinia* vector is used once for priming, and the fowlpox vector is administered repetitively at 2- or 4-week intervals for six administrations. The vaccines are each administered with GM-CSF injected locally. The randomized Phase II trial included 82 patients randomized in a 2:1 ratio to vaccine or placebo injections.[190,191] In this trial, the primary end point was PFS, and there was no difference in this end point between the two arms. However, at 3 years after the study, the Prostvac-VF group had a 25.1-month OS compared with a 16.6-month OS in the placebo group ($P = .0061$). A Phase III trial to confirm these results is being initiated, cosponsored by Bavarian Nordic and BMS, and is ongoing. The results of this trial will take several years, but Prostvac-VF could have several advantages over sipuleucel-T, now approved in the same patient population. Prostvac-VF is not a personalized vaccine and will have manufacturing and likely cost advantages over sipuleucel-T. The sponsor also started Phase II trials combining this vaccine with ipilimumab (CTLA-4 blocking antibody) and enzalutamide (androgen receptor antagonist).

ISA Pharmaceuticals is developing a novel peptide vaccine to the HPV associated tumors. HPV is responsible for a number of genital diseases (genital warts and cervical and vulvar intraepithelial neoplasia) and several cancers, including cervical cancer and some head and neck cancers. The E6 and E7 proteins from certain HPV subtypes are thought to be oncogenic and are often retained in proliferating cancer cells. Panels of SLPs to the HPV E6 and E7 proteins have been tested in patients with HPV-related cellular dysplasia. A high frequency of CD4+ and CD8+ immune responses was documented, and durable regressions in 15 of 20 patients with vulvar intraepithelial neoplasia were seen, including nine complete responses.[154] Patients with the best clinical responses tended to have the best cellular immune responses. Phase III trials with this vaccine are underway.

Rindopepimut (CellDex) is an investigational immunotherapy that targets the tumor-specific oncogene EGFRvIII, a functional and permanently activating mutation of the EGFR, a protein that has been well validated as a target for cancer therapy.[170,219] Rindopepimut is administered via intradermal injection and consists of the EGFRvIII-specific peptide sequence conjugated to the carrier protein KLH. Expression of EGFRvIII correlates with increased tumorigenicity in mouse models and poor long-term survival in clinical studies of glioblastoma patients. EGFRvIII expression may also be associated with tumor stem cells that have been identified in glioblastoma multiformae (GBM). These stem cells contribute to resistance to cytotoxic therapy and tumor recurrence. EGFRvIII is expressed in tumors in approximately 30% of glioblastoma patients. It has not been detected at a significant level in normal tissues; therefore, targeting of this tumor-specific molecule is not likely to impact healthy tissues.

Eighty-five percent of patients in clinical trials evaluating rindopepimut developed significant anti-EGFRvIII antibody titers, which increased with time on study. The majority (67%) of these patients developed titers above 1:12,800. Such immune responses may contribute to the direct destruction of tumor cells expressing EGFRvIII.

Three Phase II trials of rindopepimut have been completed in newly diagnosed EGFRvIII-positive glioblastoma patients with consistent results—ACTIVATE, ACT II, ACT III—and multiple patients continue to be followed for survival. Across all three studies, rindopepimut was generally well tolerated with generation of robust, specific, and durable immune responses. Results from a Phase II study of rindopepimut plus temozolomide in newly diagnosed patients postresection, demonstrated an increase of PFS.[170] However, a recently concluded Phase III randomized trial failed to confirm clinical benefit with temozolomide in patients with newly diagnosed glioblastoma. Rindopepimut and standard adjuvant temozolomide chemotherapy were administered to 65 patients with newly diagnosed EGFRvIII-expressing (EGFRvIII+) glioblastoma after gross total resection and chemoradiation. PFS at 5.5 months (~8.5 months from diagnosis) was 66%. Relative to study entry, median OS was 21.8 months, and 36-month OS was 26%. Extended rindopepimut vaccination (up to 3.5+ years) was well tolerated. Another study evaluating rindopepimut plus bevacizumab versus a control vaccine plus bevacizumab showed encouraging results[219]: for rindopepimut + bevacizumab versus KLH + bevacizumab: progression-free survival at 6 months = 27% (9 of 33) vs 11% (4 of 35); overall response rate (ORR) = 24% (7 of 29) vs 17% (5 of 30). Median OS was also increased: 12 versus 8.8 months in the control group that received bevacizumab alone. Rindopepimut induced robust anti-EGFRvIII antibody titers in 80% of patients. Rapid antibody responses were associated with prolonged OS.

CANCER VACCINES HAVE SUBSTANTIAL POTENTIAL BUT NEED FURTHER OPTIMIZATION AND REPOSITIONING WITHIN THE THERAPEUTIC ARMAMENTARIUM AGAINST CANCER

There have been a number of positive advances in the development of therapeutic vaccines for cancer. Highly specific TAAs have been identified, many of which are immunogenic and capable of inducing immune responses in healthy people and in patients with cancer. With some antigens, there is even evidence of existing antibody or T-cell immune responses that may be further enhanced with vaccination approaches. In addition, a number of promising platforms to deliver tumor antigens to the immune system have been developed with induction of CD4, CD8, or broad CD4 and CD8 immune responses. In addition some vaccines were able to polarize the immune system toward the Th1/CD8 response. T-cell responses approaching those seen in response to viral infections are being generated in some, but not all, patients with some vaccine platforms.

The most promising vaccine technologies and approaches include the following:

- Heterologous prime–boost approaches usually using DNA or viral vectors as priming agents, and distinct viral vectors or recombinant proteins as boosters.[220]
- Long peptides adjuvanted with TLR agonists targeting non-self antigens.[221]
- DC transduced with tumor-derived RNA[222] or other individualized vaccines corresponding to the tumor mutanome, a collection of nonsynonymous mutations in the genome of cancerous cells, corresponding to immunogenic epitopes.[223]
- RNA-based or adjuvanted protein or polypeptide vaccines delivered to APCs within lymphoid organs.[224,225]
- Genetically engineered DCs rendered more potent immunogens than endogenous DCs.[226,227]
- Combinations between vaccines and immune-enhancing agents or checkpoint inhibitors to increase induction of immune effector cells and enable their activity within the tumor environment.

There are opportunities to improve the magnitude and the quality of the response in most patients receiving these vaccines. Strategies to overcome immune-inhibitory pathways induced by the cancer must also be addressed and overcome. These advances, coupled to the improved understanding of the molecular requirements for T-cell activation and the importance of modulating the regulatory T-cell response, are providing rational strategies to enable the T cells primed with therapeutic cancer vaccines to mediate antitumor clinical responses.

Based on developments to date and lessons learned from many vaccines failures, here are some future directions for the research and translation of therapeutic cancer vaccines:

- Understanding the intrinsic limitations of vaccines as single therapy agents, namely the suboptimal capability to elicit clinically efficacious T cells in bulky disease, is a compelling rationale to reposition them. One scenario is to utilize them as single agents in an adjuvant setting, minimal residual disease, or in situ tumors, while considering integrative approaches in later-stage disease, according to the schema described in Fig. 13.4.

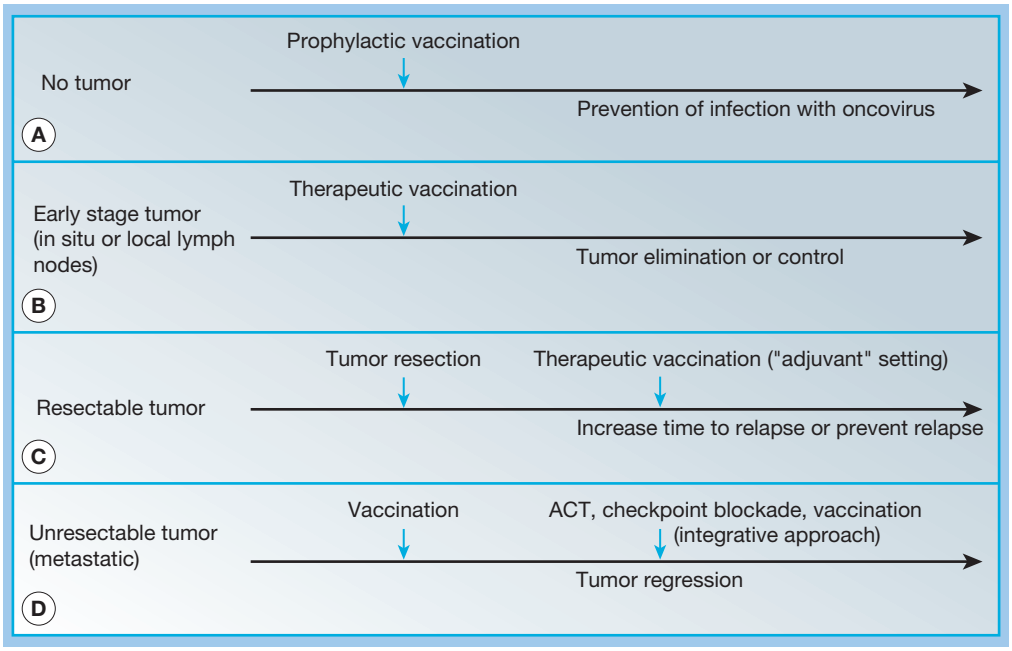

Figure 13.4. Disease stage–dependent applicability of cancer vaccines. Different scenarios where vaccination can be applied to cancer, depending on the disease stage. **A,** Prophylactic vaccination against viruses with oncogenic potential, such as HBV and HPV, could have an indirect but drastic impact on prevalence of liver cancer and cervical or oropharyngeal carcinoma. **B,** Instances where therapeutic vaccination could have an effect by itself are in early stage tumors confined to primary lesions (e.g., CIN, or melanoma with disease confined to locoregional nodes). **C,** The case of resectable tumors, therapeutic vaccination in adjuvant setting could be helpful in eliminating residual cancerous cells. This setting presents an opportunity to generate patient specific epitopes, in a truly individualized manner. **D,** In the case of unresectable, advanced tumors, vaccination could help increase the number of tumor-infiltrating lymphocytes, thus rendering the disease more susceptible to other therapeutic modalities, such as checkpoint blockade. Alternatively, or in addition, vaccines could be used in conjunction with other therapeutic modalities, such as ACT, checkpoint blockade, or other targeted therapies. ACT, adoptive T-cell therapy; CIN, cervical intraepithelial neoplasia; HBV, hepatitis B virus; HPV, human papillomavirus.

- Further optimize for potency and prioritize platform technologies for vaccination developed to date as a joint effort between academia and industry.
- Expand the realm of targets: non-self and neoantigens-viral, immunogenic point mutations, translocations, fusions, alternate reading frames, essentially those categories that correspond to a preserved or functional immune repertoire.
- Biomarker-guided patient stratification and streamlining of clinical development of therapeutic vaccines against cancer.

ENHANCING VACCINE ACTIVITY BY COMBINATION WITH IMMUNE MODULATORS OR OTHER IMMUNOTHERAPIES

During the last several years, Phase III clinical trials using the different vaccine platforms and antigens described have been completed, as described above. Table 13.10 summarizes the results of some of the major trials that have been completed but have not demonstrated evidence of clinical efficacy. As discussed, there are multiple possible reasons for the failure of these trials. These include quality or potency of vaccines; clinical trial design issues, including patient population and extent of disease or number of previous treatments; failure to address cancer-related immune inhibition, and as discussed in the section "All Hurdles Facing Cancer Vaccines Need to be Systematically Addressed," misleading clinical results from small Phase II clinical trials.

As outlined in the section "All Hurdles Facing Cancer Vaccines Need to be Systematically Addressed," effective functional immune responses are limited by various immune-inhibitory pathways in patients with cancer. The major roadblocks are related to suboptimal APC activation, induction of T-cell anergy, induction of T-cell exhaustion, inhibitory cytokines, and induction of Tregs and other inhibitory cells. These pathways may act locally at the tumor site or systemically. The dominant inhibitory pathways may vary from tumor to tumor, stage to stage, and patient to patient. These variations need to be determined for different cancers and different clinical settings.

Clinical strategies could reverse these immune-inhibitory pathways or at least the dominant pathway in a particular clinical setting. This approach would enhance the functionality of T-cell responses induced by cancer vaccination approaches. In the future, it may be possible to obtain patient-specific biomarker profiles of dominant immune-inhibitory pathways to tailor patient-specific immunostimulatory strategies.

A number of immune modulatory treatments are being tested in the clinic and in preclinical models. The National Cancer Institute conducted a workshop to identify and rank the most promising experimental immune modulatory reagents for cancer, such as cytokines and checkpoint blocking agents, that are available for early clinical testing, along with ranking out the most promising antigens.[228,229]

Thus, future cancer vaccine approaches will likely involve a combination of vaccine and immunoadjuvants, immune modulators, and even cell therapies. Vaccines will likely be a critical component of these combinatorial immunotherapies. Agents to optimally activate APCs in combination with the vaccine include TLR agonists, CD40 stimulators, and cytokine combinations. In addition, reagents to reduce Tregs, reverse negative signaling (anti–CTLA-4), or reverse T-cell anergy (anti–PD-1 [programmed death-1]) are examples of immune modulators that are being considered. These approaches, together with optimal patient selection, will be critical for the success of future cancer vaccine approaches.

Vaccines and Checkpoint Inhibitors

Whereas various cancer vaccines may be able to prime immune responses specifically to a cancer, the multiple immune inhibitory mechanisms that cancers may use to avoid immune elimination may prevent meaningful clinical responses, particularly in more advanced disease where these inhibitory mechanisms are even more active. As discussed previously in this chapter, checkpoint inhibition either through CTLA-4– or PD-1–mediated T-cell signaling are important immune inhibitory mechanisms. These pathways can now be addressed and reversed with the checkpoint inhibitor monoclonal antibodies that are under clinical development or approved by the FDA. In summary, both the anti–CTLA-4 monoclonal ipilimumab and the anti-PD-1 monoclonal antibodies pembrolizumab and nivolumab have shown objective tumor responses in patients with metastatic melanoma and lung cancer and have been approved for clinical use for these indications.[230–232] They represent strong candidates for vaccine combination studies.

These checkpoint antibodies work best in tumors where there is some initial evidence of an immune response such as increased numbers of tumor infiltrating lymphocytes and evidence of granzyme and or interferon production. In such situations there is often evidence of increased levels of PDL1 expression on the tumor cells or local APCs. It is postulated that these preexisting T-cell responses are directed against neoantigens generated through tumorigenesis, hence a correlation between mutational load and response to the checkpoints inhibitors. These findings lead to the hypothesis that a therapeutic cancer vaccine and checkpoint inhibitor combination would be an effective therapeutic combination.

Several early phase clinical trials have been performed to assess such immunotherapeutic combinations. In an early trial, ipilimumab was administered after vaccination with the GM-CSF cellular vaccine GVAX.[233] Eleven patients with stage 4 melanoma were treated with ipilimumab infusions every 2 or 3 months starting from 1 to 4 months after GVAX treatment. There were no grade 3 or 4 toxicities. A relationship between therapy induced necrosis and the ratio of intratumoral CD8+/FOXP3+ T cells was discovered, speaking to the detrimental role of Treg cells within the tumor environment. Nine patients with stage 4 ovarian cancer were also similarly evaluated from 1 month to 3 years after treatment. Two cases of grade 3 gastrointestinal toxicities were experienced. Some clinical responses were seen in these patients treated with this combination strategy A similar approach was studied in 30 patients with previously treated pancreatic ductal carcinoma. Patients received ipilimumab every 3 weeks × 4 and then every 3 months alone or with GVAX.[234] Two patients receiving ipilimumab alone had stable disease whereas three patients in the combination treatment group had stable disease. Interestingly, 7 of 15 patients had declines in CA19–9 in the combination arm while no declines were seen in the ipilimumab-alone arm. There was a nonstatistically significant trend toward improved survival in the combination treatment arm. Toxicities were comparable in the two arms.

A Phase III trial of ipilimumab alone, gp100 peptide vaccine alone, or gp100 peptide vaccine and ipilimumab combination was completed in 676 patients with metastatic melanoma[230] that was described in detail in an earlier section of this chapter.

Thirty patients with castration-resistant prostate cancer were treated with the *Vaccinia*-based vaccine Prostvac with escalating doses of ipilimumab. Of the 30 patients, 58% had a decline in PSA.[235] Associations between OS and certain immune cell subsets either before or after therapy were found. There were trends of association between longer OS and certain immune cell subsets before immunotherapy: lower

TABLE 13.10 Summary of Major Phase III Trials That Have Not Shown Clinical Efficacy

Vaccine/Producer	Platform	Antigen	Previous Randomized Phase II?	Disease	Stage	Monotherapy	Immunomodulation
Canvaxin,[249] CancerVax	Cellular	Allogeneic melanoma cell lines		Melanoma	Metastatic; adjuvant	Yes	BCG
Vaccinia melanoma oncolysate[106]	Lysates	Vaccinia and melanoma cell line antigens		Melanoma	II	Yes	BCG
Melacine Ribi[250]	Cellular	Allogeneic melanoma cell lines		Melanoma	Metastatic; adjuvant	Yes	No
OncoVAX, Intracel[251]	Cellular (lysate)	Autologous		Colorectal	II and III	Yes	No
THERATOPE, Biomira[252]	CHO	STn carbohydrate	No	Breast	Metastatic	Yes	Cyclophosphamide
Gastrimmune, Aphton[253]	Peptide-DT conjugate	Gastrin	No	Pancreatic	Metastatic		
Oncophage Antigenics[168]	Protein (heat shock proteins)	Autologous tumor antigens		Renal, melanoma	Renal, nonmetastatic; melanoma, metastatic		
PANVAC, Therion[254]	Viral (poxvirus)	CEA and MUC1	No	Pancreatic	Metastatic	Yes	No
MyVax, Genitope[255]	Protein (anti- idiotype KLH)	Autologous idiotype	No	Pancreatic	Advanced	Yes	No
FavId, Favrille[255]	Protein (anti- idiotype KLH)	Autologous idiotype	No	Non-Hodgkin lymphoma	Advanced	After rituximab	GM-CSF
GVAX, Cell Genesys[256] (autologous)	Cellular (modified with GM-CSF)	Autologous	No	Prostate	Advanced	Yes	No
GVAX, Cell Genesys[256] (allogenic)	Cellular (modified with GM-CSF)	Prostate cell lines	No	Prostate	Advanced	With docetaxel (Taxotere)	No
GMK, Progenics[257]	CHO	GM_2 ganglioside		Melanoma	Adjuvant	Yes	No
TroVax, Oxford BioMedica[34]	Poxvirus	5T4	No	Renal	Advanced	No	No
MAGE-A3 GSK[258]	Protein	MAGE-A3	Yes	Lung	Postsurgery Ib, II, IIIa	Yes	AS15 adjuvant
Stimuvax EMD Serono[203]	Protein	MUC1 (BLP-25)	Yes	Lung	IIb, III	Yes	Cyclophosphamide
Rintega, Celldex (Rindopepimut)[170]	Peptide conjugated to KLH	EGFRvIII	Yes	Glioblastoma multiformae	Recently diagosed	Temozolomide	GM-CSF

BCG, bacille Calmette-Guérin; CEA, carcinoembryonic antigen; CHO, carbohydrate; GM-CSF, granulocyte-macrophage colony-stimulating factor; GSK, GlaxoSmithKline; KLH, keyhole limpet hemocyanin; MAGE, melanoma-associated gene.

PD-1+ Tim-3+ Th cells, higher PD-1− Tim-3+ CTL, and a higher number of CTLA-4− Tregs. They also found that an increase in Tim-3+ NK cells postvaccination versus prevaccination was associated with longer OS.

Based on the scientific rationale and evidence to date, the next steps would be to test combinations of vaccines and licensed checkpoint-blocking agents. Notably, a randomized Phase II trial of combining sipuleucel-T with immediate versus delayed CTLA-4 blockade for prostate cancer has been initiated and is currently accruing (NCT01804465). This is an open-label, randomized, multicenter trial in patients with chemotherapy-naïve metastatic castration-resistant prostate cancer. All patients will be treated with standard vaccination with sipuleucel-T (q2wk × 3). Then, patients will be randomized to one of two arms: an immediate treatment arm comprising ipilimumab q3wk × 4 started 1 day following the final dose of vaccine or a delayed treatment arm comprising ipilimumab q3wk × 4 started 3 weeks following the last dose of vaccine. Following this ipilimumab treatment, patients will then be followed monthly for 3 months and then quarterly until disease progression.

A Phase Ib trial with the herpes virus oncolytic vaccine T-VEC and ipilimumab has been reported in 19 patients with stage IIIb or stage IV melanoma.[236] Grade 3/4 toxicities occurred in six (32%) of the patients. Two patients experienced grade 3/4 autoimmune toxicities commonly seen in patients with ipilimumab, consisting of colitis, hypophysitis, adrenal insufficiency, and elevated amylase and lipase. The objective response rate was 56%, including 33% complete responses. This objective response rate is higher than the objective response rate seen with T-VEC alone (16%) from a historical control trial. There was an increase in CD8+ T cells seen in tumor sites after combination therapy. The results of the randomized trial leading to regulatory approval of T-VEC have been published in the *Journal of Clinical Oncology*[151]: among 436 patients randomly assigned, ORR was significantly higher with T-VEC (16.3%; 95% confidence interval [CI], 12.1% to 20.5%) than GM-CSF (2.1%; 95% CI, 0% to 4.5%; odds ratio, 8.9; $P < .001$). ORR was also higher in the T-VEC arm (26.4%; 95% CI, 21.4% to 31.5% vs 5.7%; 95% CI, 1.9% to 9.5%). Median OS was 23.3 months (95% CI, 19.5 to 29.6 months) with T-VEC and 18.9 months (95% CI, 16.0 to 23.7 months) with GM-CSF (HR, 0.79; 95% CI, 0.62 to 1.00; $P = .051$). T-VEC efficacy was most pronounced in patients with stage IIIB, IIIC, or IVM1a disease and in patients with treatment-naïve disease. These results build a momentum behind combination approaches to further elevate the clinical response rate and durability of clinical benefit. A randomized trial of T-VEC with pembrolizumab is now underway for patients with advanced melanoma.

Some of these trials have been, or are being performed with, anti-CTLA-4 combinations. Given the improved toxicity and clinical activity of the anti–PD-1s and anti-PDL1s it is likely that combination studies with such agents are of increased interest.

Nivolumab, a human IgG_4-blocking antibody against the T-cell PD-1 checkpoint protein, has activity against metastatic melanoma and has been tested in combination with peptide vaccines in melanoma patients. In a Phase I study,[237,238] patients with unresectable stage III or IV melanoma who were ipilimumab naïve and had experienced progression after at least one prior therapy or experienced progression after prior ipilimumab received nivolumab at 1, 3, or 10 mg/kg every 2 weeks for 24 weeks, then every 12 weeks for up to 2 years, with or without a multipeptide vaccine against well characterized antigens such as MART-1 (melanoma antigen recognized by T cell-1) and NYESO-1. While the combination of nivolumab with vaccine was well tolerated and safe at all doses, the objective response rate for both ipilimumab-refractory and ipilimumab-naïve patients was 25%.

The same group investigated nivolumab plus peptide vaccine as adjuvant therapy in resected stage IIIC and stage IV melanoma patients.[239] HLA-A*0201–positive patients with HMB-45–, NYESO-1–, and/or MART-1–positive resected tumors received nivolumab (1 mg/kg, 3 mg/kg, or 10 mg/kg IV) with a multipeptide vaccine (gp100, MART-1, and NYESO-1 with Montanide ISA 51 VG) every 2 weeks for 12 doses followed by nivolumab maintenance every 12 weeks for eight doses. Thirty-three patients were enrolled. Nivolumab with vaccine was well tolerated as adjuvant therapy and demonstrated immunologic activity with improved survival in patients with high-risk resected melanoma. More specifically, the estimated median relapse-free survival was 47.1 months. Increases of tetramer-specific CD8+ T-cell populations were observed with treatment. These results could support future randomized trials.

Another trial evaluates a *Listeria*-based vaccine (ADXS31–142) alone and in combination with pembrolizumab (MK-3475) in patients with prostate cancer (NCT02325557). ADS31–142 is aimed to elicit an immune response against PSA. Part A will be dose-determining of ADXS31–142 monotherapy and part B will be dose-determining of ADXS31–142 and pembrolizumab (MK-3475) in combination.

As this field is expanding rapidly, combining checkpoint inhibitors with new-generation vaccines that can generate potent and broad tumor-specific immune responses should be an increasingly effective strategy.

Vaccines and Cellular Therapy

Among the promising immunotherapies, cell therapies represent one of the most exciting opportunities as they are applicable to advanced cancer. The last decade witnessed a considerable progress in discovery and development of methods to regenerate the immune repertoire in patients with advanced cancer. Adoptive T-cell therapy has shown striking tumor regressions in the clinic. The major types of cell therapies include (a) tumor-infiltrating lymphocytes (TILs) retrieved from tumor lesions and expanded ex vivo, outside the confinement of an immune-inhibiting environment; (b) TCR-engineered T cells; and (c) chimeric antigen receptor–engineered T cells, respectively, that integrate a novel receptor specificity onto an existing T-cell repertoire.[240,241]

Whichever methodology is used for T-cell repertoire regeneration/reshaping (TILs) or reengineering (chimeric antigen receptors and TCRs), an incoming T-cell product still faces a considerably hostile environment within the tumor environment. There is reduced or lack of antigen expressed by professional APCs otherwise needed to effectively stimulate the cells toward achieving optimal in vivo activation, expansion, differentiation, and migration to tumor sites. In addition, there is a generally immunosuppressive environment as a result of preexisting immune-inhibiting cells such as Tregs and MDSCs. The infused T cells must compete with endogenous T cells for vital growth factors such as IL-15 and IL-7. And, finally, as discussed above, the infused cells still are modulated by a plethora of immune-inhibiting mechanisms that act in concert within the tumor environment per se, including those reactively deployed by immunologically active T cells as part of natural immune homeostasis such as PD-1–PDL1 axis. While reactivation of adoptively transferred T cells is not expected to overcome all these barriers, it would render the cells more numerous and potent through increasing their capability to mediate tumor cell killing.

Thus it is very compelling to consider an integrative approach through which methods to regenerate, reshape, or

reengineer the T-cell repertoire are accompanied by cognate vaccines designed to fully tap into the potential of adoptive therapy in patients with advanced cancers (Fig. 13.5). Under one possible scenario, tumor specimen analysis for TAA expression could lead to selection of one or multiple common target antigens to be pursued through adoptive transfer of cognate TCR-engineered T cells, followed by vaccination leading to effective in vivo stimulation of the adoptively transferred T cells. Such vaccination might be done with a live microbial vector (pox virus vector, attenuated *Listeria*, etc) expressing the antigen of interest, with DCs adequately expanded and differentiated ex vivo, pulsed or genetically engineered to present the cognate epitope(s), or with adjuvanted recombinant proteins.

Another scenario is represented by truly individualized approaches, especially when generic cancer target antigen expression is modest or lacking. Advances in gene sequencing (exome analysis, RNA sequencing) afford rapid sequencing of tumor material. Through bioinformatics tools, one can predict, prioritize and select sequences that encompass putatively immunogenic epitopes and use them to assemble minigenes[242,243] that could be effectively integrated into a given vaccine platform such as DC or live virus–based vaccines. The area of neoantigen based vaccination is rapidly evolving based on progress in understanding the true nature and specificity of TILs and the potential for using tumor-specific and patient-specific epitopes as vaccines. Recent studies raise the possibility that the "mutanome," the totality of nonsynonymous tumor-specific mutations, comprise a large percentage of potentially or actually immunogenic epitopes, especially recognizable by CD4+ T cells.[244] Surprisingly, elements of the MHC class II–restricted mutanome were potently immunogenic and protective against tumor, deploying epitope-spreading mechanisms. These were paralleled by coinduction of MHC class I–restricted immunity, resulting in a broad-based T-cell response against the tumor. While this analysis is more advanced in preclinical models, it raises the intriguing possibility that the mutanome is shaping the immune response away from MHC class I–restricted epitopes and that sequencing coupled with bioinformatics approach and a feasible vaccine platform, such as an RNA-based technology, could pave the way toward an individualized vaccination strategy in cancer.

As identification of neoantigens in each patient is now possible owing to exome sequencing or related approaches, construction of patient-specific vaccines is becoming feasible, and has a higher chance of working when combined with PD-1 blockade and/or T-cell therapy. This approach is now

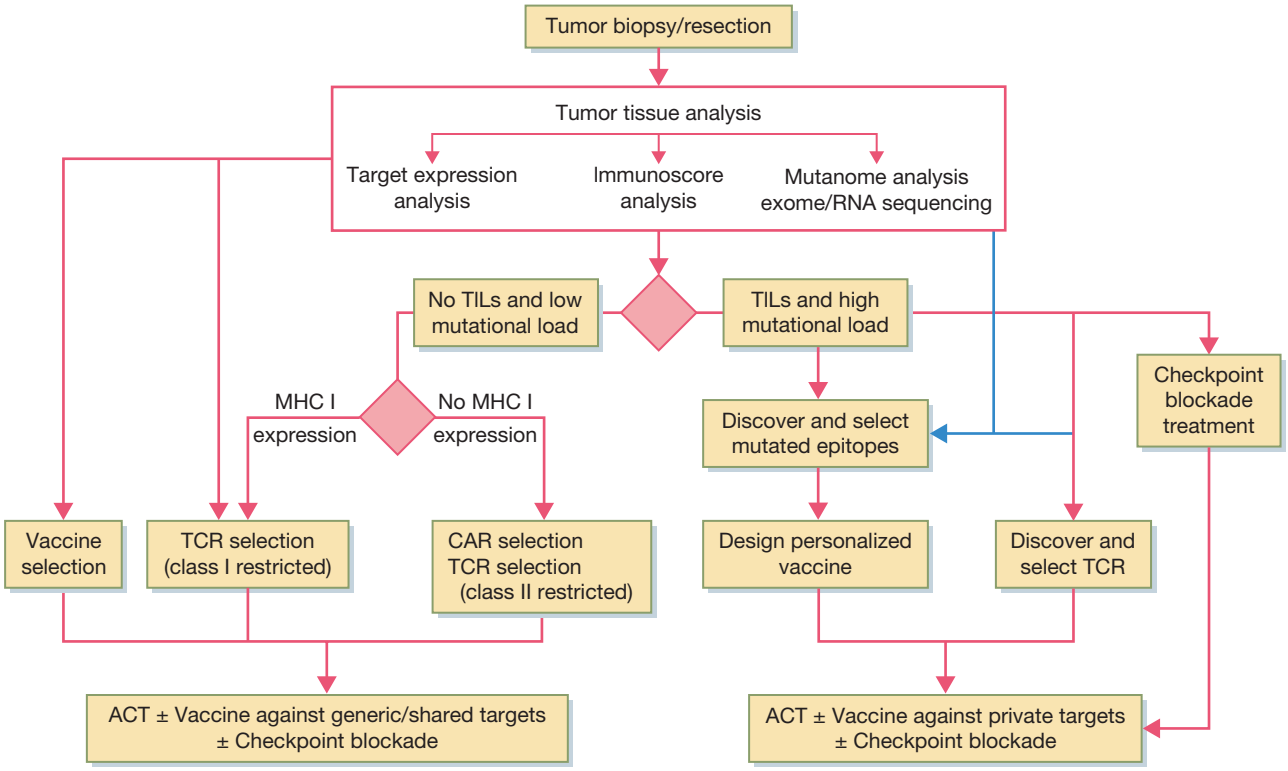

Figure 13.5. An integrative perspective combining vaccination with other therapeutic modalities to achieve durable control of cancer. Novel techniques can be applied to tumor tissue to define the mutanome (the totality of nonsynonymous mutations) by exome sequencing or RNA sequencing, in conjunction with the immunoscore represented by the degree of tumor infiltration with T cells, evaluated by immunohistochemistry. Tumors with high mutational load, which are quite frequently associated with increased TIL infiltrates, would be prime candidates for checkpoint blockade therapy such as CTLA-4 and PD-1 binding antibodies. This category of tumors is also conducive to discovering patient and tumor specific epitopes, cognate TCRs, and/or TILs, resulting in a tool box of highly individualized medicine that could be used as backup or in conjunction with checkpoint blockade to achieve a more durable control of disease. In contrast, tumors with low mutational load would be candidates for immunotherapies directed against generic antigens, prioritized based on tumor antigen expression analysis. Such immunotherapies could comprise TCR or CAR-engineered T cells, as well as vaccines against such generic targets, which could be used in conjunction or separately. ACT, adoptive T-cell therapy; CAR, chimeric antigen receptor; MHC, major histocompatibility; TCR, T-cell receptor; TIL, tumor-infiltrating lymphocyte.

pursued by novel companies such as Neon Therapeutics. Thus, two novel investigator-sponsored clinical studies, in melanoma and glioma, are testing patient-specific neoantigens in the form of peptides, adjuvanted with the TLR agonist, stabilized polyI:C (clinical trials NCT01970358; NCT02287428).

Similarly, another novel company BioNTech AG is advancing an approach based on mRNA-expressing neoantigens directly injected into lymph nodes. They have begun enrolment in RNA-based individualized vaccine trial for melanoma, glioblastoma (http://www.gapvac.eu/), pediatric acute lymphoblastic leukemia, hepatocellular carcinoma (http://www.hepavac.eu/), and triple-negative breast tumor (http://merit-consortium.eu/) patients.[245] Trials integrating all these therapeutic modalities—T-cell transfer, vaccination, and checkpoint blockade—are still awaited.

An interesting perspective tapping into the endogenous TAAs is afforded by the concept of "in situ" vaccination, demonstrated by the licensure of a herpes virus–based immune intervention (T-VEC) with the capability to effectively mobilize the systemic immunity against remote tumor lesions.[151] An optimization of this mechanism through use of potent and targeted immune modulatory compounds or approaches, could obviate the need to use conventional vaccines that engage tumor-specific epitopes.

Irrespectively of the generic or individualized nature of this approach, preclinical results to date strongly support the concept of integrating adoptive T-cell therapy with vaccination.[238,246,247] Individualized or generic vaccines could be used in conjunction with adoptive T-cell therapy with TILs or TCR-engineered T cells directed against one of the TIL cognate epitopes discovered through systematic evaluation of the intratumoral immune repertoire. In addition to substantially increasing the antitumoral response, vaccination could obviate the need to use preconditioning, a strategy that enables the expansion of adoptively transferred T cells' expansion by lymphodepleting the endogenous lymphocytes.

Finally, within this T-cell therapy/vaccination integrative paradigm, one could position vaccination in a variety of ways, either just before or shortly after adoptive T-cell therapy to elicit T-cell activation and expansion, or at various intervals after T-cell therapy (weeks, months, or even longer) to increase the persistence and prolong activity of residual antitumor T cells.

However, although more tools necessary to harness the immune system to fight cancer are becoming available, a number of significant challenges remain. We need to carefully combine cancer vaccines with new immune modulatory tools in well-thought-out strategies to generate specific functional T-cell responses. These combination therapies will need to be carefully optimized in early phase clinical trials. The field needs to continue to develop and validate immunologic biomarkers and use these to optimize new combination approaches. In addition, we must use the experience obtained during the last decade with vaccine trials and carefully select patient populations with the greatest likelihood of success, including patients in early stage adjuvant clinical trials for evaluation of vaccines alone, or combinatorial approaches for later stage disease.

14 Cholera Vaccines

John D. Clemens, Sachin N. Desai, Firdausi Qadri, GB Nair, and Jan Holmgren

HISTORY OF DISEASE

Cholera is a rapidly dehydrating, watery diarrheal disease caused by intestinal infection with the bacterium *Vibrio cholerae* serogroups O1 and O139. Cholera has probably existed on the Indian subcontinent for thousands of years. Ancient manuscripts describe the physical symptoms of what we now recognize as cholera gravis: rapid-onset vomiting, abdominal pain, explosive diarrhea, dehydration, and death. Cholera is one of the dreaded epidemic and pandemic diseases that have had the power to alter history. The disease has the unusual ability to rapidly infect large numbers of people, to spread internationally, and to kill a high proportion of those affected. Before the development of effective rehydration therapy with intravenous and oral fluids, cholera epidemics were associated with case-fatality rates that exceeded 40% and led to tens of thousands of deaths. John Snow is credited with understanding the importance of water as a key vehicle for the spread of the disease,[1] but it was not until the early 1880s that Robert Koch isolated and defined the causative agent from the fecal specimen of a patient with the disease.[2,3]

WHY THE DISEASE IS IMPORTANT

Cholera has been thought to exist on the Indian subcontinent since antiquity. From 1817 to 1923, six pandemics occurred worldwide. Earlier pandemics are known or presumed to have been caused by classical *V.* cholerae O1, while the seventh pandemic is ascribed to the El Tor biotype, which has replaced the classical biotype.[4] Disease caused by *V. cholerae* O1 or O139 continues to be a serious threat to human health, particularly in the developing countries of Asia, Africa, and, recently, the Caribbean. Although formerly it was a major problem in South and Central America, relatively few cases have been reported in this region since 1998.[5] Since the beginning of the seventh pandemic, cholera has become endemic in many parts of Africa, as well as in Haiti, causing large, recurrent, and deadly epidemics. In addition to the threat posed to residents of these regions, the disease is also a risk to travelers to these areas. Indeed, the cases of cholera reported to occur in developed countries are almost always acquired during foreign travel.[6,7]

CLINICAL DESCRIPTION AND COMPLICATIONS

Severe cholera, or cholera gravis, is characterized by acute diarrhea and, usually, vomiting, which lead rapidly (within 4 to 18 hours) to moderate or profound dehydration. Typically, a previously healthy person is suddenly stricken with watery diarrhea and copious vomiting. Ten or more voluminous stools may be passed within a few hours, at first liquid in consistency and then becoming like rice water. The complications from cholera arise from the loss of fluid volume and electrolytes, especially sodium, potassium, and bicarbonate, in the stool and vomitus. These losses can result in hypovolemia, metabolic acidosis, and potassium deficiency.[8] Secondary complications may arise from the hypovolemia or from inadequate or inappropriate fluid and electrolyte replacement. Such complications can include renal failure, hypokalemia, arterial occlusions (especially in the elderly), pulmonary edema, and, in pregnant women, premature delivery or abortion. Most patients experience a decrease in blood glucose levels during treatment, but some young children experience profound hypoglycemia and seizures.[9]

Not all patients with *V. cholerae* infections experience the severe cholera gravis syndrome. In fact, most infected people are asymptomatic or have only mild diarrhea. Past studies have estimated the case-to-infection ratio (number of symptomatic cases per number of people infected) to range from 1 in 3, to 1 in 100, depending on the geographic region, biotype, phase of epidemic, and size of inoculum.[10] The nature of the epidemic appears to affect the case-to-infection ratio, because explosive epidemics tend to have more severe cases, probably because higher inoculum sizes result from the large number of infected persons whose stools contaminate drinking water sources.

BACTERIOLOGY

Formerly, epidemic cholera was caused only by toxigenic strains of *V. cholerae* serogroup O1. However, in 1992, another serogroup, O139, emerged as a cause of epidemic cholera in Asia, with a clinical syndrome and epidemiologic spread identical to infections caused by serogroup O1.[11–13] This new O139 strain was derived from the El Tor biotype of O1 strains and was characterized by the presence of a capsule and a modified lipopolysaccharide (LPS).[14] Thus, there are two serogroups of *V. cholerae* that can cause epidemic cholera, O1 and O139. The new serogroup is especially important for vaccine development because immunity to serogroup O1 *Vibrio* does not confer immunity to serogroup O139.[15] Since its first recognition in Bangladesh and India, *V. cholerae* O139 has spread to other countries in Asia but not outside this region. The incidence of cholera caused by O139 strains waned after 1992, but in 2002 there was a resurgence of this serogroup in Bangladesh.[16] In the Indian subcontinent, the serogroup continues to be isolated, though rather uncommonly, with variations in the proportion of cases caused by this strain depending on the season and location.[17]

There are other serogroups of *V. cholerae* that can cause sporadic cases of diarrhea, or may cause local or systemic infections, but they do not cause epidemic disease. These are called non-O1–non-O139 *V. cholerae* (formerly called nonagglutinating [NAG] vibrios because they did not agglutinate with the O1 antiserum). Some strains of O1 or O139 *V. cholerae*, especially those found in the environment, do not produce cholera toxin. These also do not cause epidemic disease. Thus the epidemic strains always belong to either O1 or O139 serogroups and also produce cholera toxin. The serogroup O1 *V. cholerae* is subdivided into two serotypes based on specific antigens in the O antigen: Ogawa and Inaba. *V. cholerae* O1 is also divided into two biotypes based on biochemical reactions and other phenotypic features: classical and El Tor. More recently, genetic markers for the classical and El Tor strains have been identified. Classical strains, which appear to cause more severe disease than El Tor strains, have largely disappeared in recent years, with the last case detected in Bangladesh in the mid-1990s. The current seventh pandemic strain is an El Tor biotype, and it includes both Ogawa and Inaba serotypes.

Variants of El Tor strains that share phenotypic characteristics of both El Tor and classical biotypes were originally described in Bangladesh,[18] and they are termed *hybrid biotype strains*. Newer molecular markers have also revealed the emergence of cholera strains with phenotypic characteristics that classify them as El Tor, but that elaborate classical-type enterotoxin. These new strains, termed *El Tor variants,* have been found to have displaced typical El Tor cholera in Bangladesh since 2002. Subsequently, they have been found in Kolkata, India, and in Beira, Mozambique, where they have also displaced typical El Tor cholera, and elsewhere in Asia, in Africa, and most recently in Haiti.[19–23] It has been asserted that variant El Tor strains, like classical biotype strains, are associated with more severe disease than that caused by the earlier El Tor strains.[24]

Phage typing was formerly used to further classify strains, but molecular methods are now used.[25] Multilocus enzyme electrophoresis can distinguish between classical and El Tor strains[26] and has grouped the toxigenic El Tor biotype strains into four major clonal groups, or electrophoretic types (ETs), representing broad geographic areas. These include the Australian clone (ET1), the U.S. Gulf Coast clone (ET2), the seventh pandemic clone (ET3), and the Latin American clone (ET4).[27] In addition, a standardized ribotyping scheme for *V. cholerae* O1 and for O139 can distinguish seven different ribotypes.[28,29] It has also been proposed that the biotyping of El Tor be refined to account for the newly emergent hybrid biotype and El Tor variant strains.[30] Recently, using advanced genomic sequencing, it has been possible to study in detail the molecular evolution and global spread of cholera in at least three distinct waves during the current seventh pandemic.[31] Although invaluable for molecular epidemiology, these methods and improved classifications are not necessary in the clinical laboratory.

PATHOGENESIS AS IT RELATES TO PREVENTION

Crucial steps in the pathogenesis of cholera include colonization of the small intestinal mucosa and the elaboration of the enterotoxin (cholera toxin [CT]) (Fig. 14.1). Colonization depends on production of pilus structures such as the toxin-coregulated pilus (TCP).[32] Bacterial motility allows the bacteria to penetrate the mucous lining of the mucosa and come into close association with the epithelium. Colonization of the small intestine depends on three critical virulence factors: TCP, hemagglutinin/protease, and the bacterium's single flagellum.[33–35] Lee and colleagues presented a thorough discussion of the temporal expression of the virulence factors of *V. cholerae* and their role in pathogenesis.[36]

If the bacteria colonize the mucosa in sufficient numbers, they are able to secrete quantities of CT close to the mucosa and thereby cause disease. CT, a protein with a molecular weight of 84,000, has a subunit structure consisting of a central active subunit (A subunit) and a surrounding pentameric binding subunit (B subunit).[37,38] The A subunit is responsible for the physiologic and toxic activity of the toxin, and the B subunit for the characteristic tight binding of toxin to GM_1 ganglioside receptors on the intestinal epithelial cell surface.[39] The CT genes *(ctxAB)* are carried on a lysogenic filamentous phage of *V. cholerae,* called CTXPhi. CTXPhi can transfer between toxigenic and nontoxigenic strains of *V. cholerae*. CTXPhi integrates into the bacterial chromosome and forms stable lysogens.[40] After attachment to the surface of the cells via the B subunit, the A subunit (or, more specifically, its released A1 polypeptide) of CT stimulates the enzyme adenylate cyclase, which initiates a cascade of biochemical events that lead to hypersecretion of chloride and bicarbonate with concomitant water loss following the resulting ionic gradient, far in excess of the absorptive capacity of the gut.[41] The excess fluid is thus passed out as diarrheal fluid.

In cholera, the activity of CT is limited to the intestinal mucosa because CT is not systemically absorbed. Antibacterial and antitoxic intestinal secretory antibodies, primarily secretory immunoglobulin (Ig) A, act synergistically to prevent colonization by cholera vibrios and binding of CT, thereby preventing disease.[42] The predominant antigen inducing protective antibacterial immunity is LPS.[43] The data are contradictory about whether immune responses to TCP contribute to protective immunity.[44–46] Protection against CT is directed toward its B subunit, not only protecting against cholera but also cross-protecting against diarrhea caused by heat-labile toxin (LT) producing enterotoxigenic *Escherichia coli* (ETEC).[47]

MODES OF TRANSMISSION

Transmission occurs through consumption of contaminated water or food and is often the result of combined contamination. Contamination may be fecal or from a natural marine reservoir of the organism. Contaminated water, for example, is often used to rinse fresh food, and thus the food becomes contaminated, serving as the vehicle of transmission. Contaminated food, if kept at room temperature, supports the growth of *V. cholerae* and may lead to common-source outbreaks.[48,49]

DIAGNOSIS

The diagnosis of cholera can be suspected clinically but is confirmed by culturing the organism from a fecal culture. *V. cholerae* is preserved well in routine fecal transport media, although Cary-Blair medium is preferred. Primary bacteriologic plates should include selective media such as thiosulfate-citrate-bile salts-sucrose or taurocholate-tellurite-gelatin agar.[50,51] Bacteriologic confirmation of initial cases in a region is essential because of the epidemic implications, but during major epidemics, laboratory confirmation is not needed except on a sample basis. Rapid immunologic diagnostic tests, using immunochromatographic dipsticks, have been developed for both O1 and O139 *V. cholerae* strains.[52,53] These tests have acceptable sensitivity, but have suffered from poor specificity, although specificity of these tests appears to increase after a 6-hour enrichment period of samples in alkaline peptide water. These tests have found greatest application as point of care diagnostics, especially in epidemic contexts where sensitivity and speed are greatly valued. Newer molecular methods, such as polymerase chain reaction (PCR) are increasingly being developed, but still are not practical for most situations where a reliable cholera diagnostic test result is needed quickly.

Clinical management of the individual case does not depend on laboratory confirmation because treatment is aimed at rehydration and only secondarily toward eradicating the bacteria. Acute and convalescent sera can be tested for vibriocidal or agglutinating antibodies to confirm the diagnosis of cholera caused by serogroup O1; a fourfold rise in titer is diagnostic of recent cholera infection.[54] A similar assay is possible for serogroup O139, but it is more difficult because the capsule found on this strain makes it less sensitive to complement-mediated killing, and the assay is performed in only a few research laboratories. The O139 vibriocidal assay generally uses as the target strain a mutant strain lacking the capsule. Antitoxin antibodies are also stimulated during infection and can be measured; however, this measurement is not completely specific because other vibrios, as well as ETEC, can produce an immunologically similar cholera-like toxin and stimulate antitoxin responses. In general, acute and convalescent sera are not needed to diagnose an individual patient; however, the measurement of serum titers can be helpful during epidemiologic evaluations.

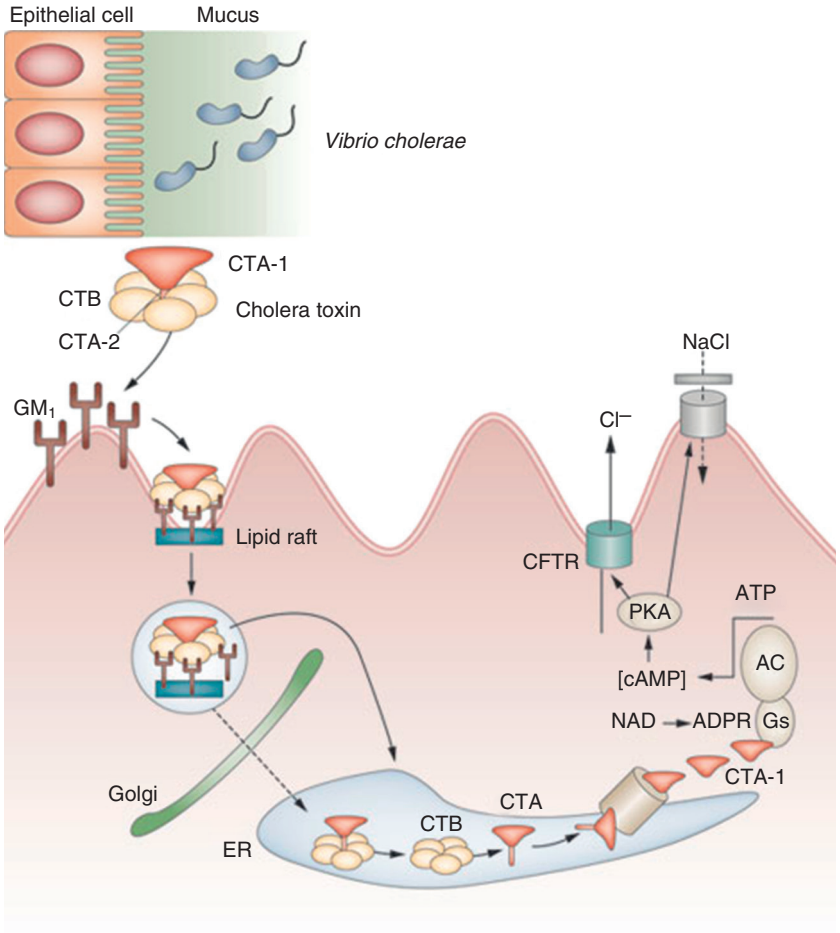

Figure 14.1. Cholera pathogenesis and cholera toxin action. After ingestion, *Vibrio cholerae* colonizes the small intestine and secretes cholera toxin, which has a doughnut-like structure with a central enzymatic toxic active A (A1+A2) subunit associated with pentameric B subunits (B5). After binding to GM_1 ganglioside receptors, mainly localized in lipid rafts on the cell surface, the toxin is endocytosed and travels to the ER via a retrograde pathway which—dependent on cell type—may or may not involve passage through the Golgi. In the ER, the A subunit dissociates from the B subunits and through translocation via the ER degradosome pathway, A1 can reach the cytosol where it can rapidly refold. It binds to ADP-ribosylates Gs, stimulating the AC complex to produce increased cellular levels of cAMP, leading to activation of PKA, phosphorylation of the major chloride channel, CFTR, and secretion of chloride (Cl^-) and water. Cholera toxin-induced chloride (and bicarbonate) secretion is especially pronounced from intestinal crypt cells, while in villus cells the increased cAMP levels instead mainly inhibits the normal uptake of NaCl and water.[14] AC, adenylate cyclase; ADP, adenosine diphosphate; ADPR, ADP ribose; ATP, adenosine triphosphate (ATP); cAMP, cyclic adenosine monophosphate; CTA, cholera toxin A; CTB, cholera toxin B; CFTR, cystic fibrosis transmembrane conductance regulator; ER, endoplasmic reticulum; Gs, guanosine triphosphate (GTP)-binding protein, Gs; NAD, nicotinamide adenine dinucleotide; PKA, protein kinase A. *(From Clemens J, Shin S, Sur D, et al. New-generation vaccines against cholera.* Nat Rev Gastroenterol Hepatol. *2011;8:701–710.)*

CASE MANAGEMENT

Appropriate case management of diarrhea using intravenous and oral rehydration solutions has reduced deaths from diarrhea by approximately 3 million per year over the last 20 years.[55] Oral rehydration salt solution should be considered as the first treatment for cholera, although intravenous fluids with a polyelectrolyte solution (e.g., Ringer lactate) are needed in cases of severe dehydration or shock.[56] The most important elements of therapy are the rapid replacement of fluids to correct the dehydration, base administration to correct the acidosis, and provision of potassium to correct the potassium deficiency. With proper treatment, no patient should die of cholera, but if treatment is delayed, given too slowly, or inappropriately, case-fatality rates exceed 5%, even today.

In severe cholera cases, an effective antibiotic can be used to reduce the volume of diarrhea and the length of time the organism is excreted in the stool. Doxycycline or tetracycline is the antibiotic of choice for sensitive strains, but resistance to this class of drug may occur.[56] Unlike many other enteric organisms, the predominant strains often lose their resistance, so antibiotic resistance is a characteristic that varies from time to time and from place to place.[57,58] Thus, one must monitor antibiotic resistance during cholera epidemics and choose another antibiotic when necessary. Other clinically effective antibiotics include ciprofloxacin, cotrimoxazole, erythromycin, azithromycin, chloramphenicol, and furazolidone.

EPIDEMIOLOGY

Incidence

Endemic cholera denotes the repeated occurrence of cholera in a population over time, without the need for exogenous reintroduction of the pathogen. Practically speaking, the World Health Organization (WHO) defines a cholera-endemic

population as one that has experienced cholera in at least 3 of the past 5 years.[59] In such populations, cholera incidence may still vary considerably from year to year. For example, in Matlab, Bangladesh, the annual incidence of treated cholera episodes varied from 0.2 cases to 5.1 cases per 1000 population over a 15-year period.[60] In cholera-endemic populations, the incidence of cholera is typically greatest in children younger than 5 years, presumably because of lower levels of preexisting natural immunity to cholera in this young age group, reflecting fewer past exposures to cholera vibrios.[61] It had been thought that infants and young toddlers were at low risk in these populations because of the protective effects of breastfeeding,[62,63] but recent studies in Kolkata, India, and in North Jakarta, Indonesia, have shown a very high incidence in this age group.[64]

In contrast to endemic cholera, the term *epidemic cholera* refers to cholera that requires exogenous introduction of cholera vibrios into a population and is not recurrent in time and place. In such populations, which are typically immunologically naïve to cholera because of a lack of past exposures, incidence rates of cholera are usually age independent, and the clinical spectrum of cholera illnesses tends to be more severe. This is well illustrated by the recent outbreak of cholera in Haiti, where high rates have been observed in adults and case-fatality rates have been high. Although useful conceptually, the terms *endemic cholera* and *epidemic cholera* represent two ends of the epidemiologic spectrum, and, in practice, large outbreaks termed epidemics may occur in populations with endemic cholera.

Risk Groups

Cases of cholera occur in both children and adults. In addition to the consumption of specific high-risk foods, other risk factors for cholera include low socioeconomic status, which correlates with the use of impure water, poor sanitation, and poverty. Resettlement camps of internally or externally displaced persons or refugees also pose a key risk for cholera, with approximately 75% of such camps in Africa having an outbreak at some point.[65] Similarly, populations are commonly at risk for cholera outbreaks following natural disasters, as illustrated by the recent major cholera epidemic in Haiti following a severe earthquake and a hurricane in close succession.[66]

Beyond these environmental risk factors, several host factors influence susceptibility to cholera, including being non-breastfed for infants and young toddlers and gastric hypochlorhydria.[62,63,67–70] The protection infants receive from breastfeeding may result from antibodies in the breast milk, but it may also result from less exposure to contaminated food and liquids. Individuals of blood type O are more likely to develop severe illness, although this increased risk appears to apply to El Tor but not to classical cholera.[71–76] A study in Mozambique implicated HIV coinfection as a risk factor for cholera, raising the possibility of the convergence of the ongoing pandemics of these two infections.[77]

Whether or not pregnancy is a risk factor for cholera is not clear, but cholera in pregnancy has been linked with high rates of abortions, stillbirths, premature childbirths, and maternal deaths.[78] Fetal loss rates from cholera cases reaching up to 50% have been reported, for which the degree of dehydration and hypovolemia are the strongest factors associated with fetal loss.[79]

Reservoirs of Infection

Although *V. cholerae* is generally thought to be spread by the fecal–oral route, it can also persist in environmental waters without continued contamination with human feces. During epidemics, environmental waters may become heavily contaminated with *V. cholerae* from infected human feces, and this contamination further spreads the epidemic. Once the surface waters become contaminated, an environmental reservoir may maintain the bacterium without further fecal contamination if appropriate conditions of salinity and temperature exist, as illustrated by the persistent environmental reservoir for *V. cholerae* O1 off the coast of Louisiana in the Gulf of Mexico.[80] As demonstrated in the United States, the environmental reservoir can lead to additional sporadic primary cases from contaminated seafood, but, if sanitation is adequate, secondary cases do not occur. If sanitation is poor, the sporadic cases may be followed by additional secondary cases and may lead to another epidemic through amplification of the inoculum and further contamination of the waters.

In the environment, the *Vibrio* organisms associate with certain plankton (known as copepods), chitinous shelled animals (e.g., crabs), and vegetation.[81–86] These associations appear to be crucial for the long-term survival of *Vibrio* organisms, and they may also enhance horizontal gene transmission among vibrios.[87] Importantly, chitin induces natural competence in *V. cholerae,* enabling bacterial uptake of extracellular DNA from the environment, thereby facilitating genetic transformation.[88] Furthermore, the association with chitinous shells increases the risk of transmission via consumption of crabs, shrimp, and other shellfish, many of which are eaten only partially cooked. In some cultures, raw fish may also become a vehicle of transmission. Unfortunately, even if the fish are caught in uncontaminated waters, they may become contaminated when washed in harbor water as the catch is brought to market, and cooked food may become recontaminated in the kitchen with utensils exposed to uncooked food.

Significance as a Public Health Problem

A recent analysis of the annual global disease burden of cholera estimated that there are approximately 2.8 million cholera cases and 91,500 cholera deaths in endemic countries, and 87,000 cases and 2500 deaths in cholera epidemics.[89] Approximately half of the deaths occur in Africa. More than 1 million cases occurred in Latin America during the first 3 years of the explosive 1991 epidemic, causing approximately 9000 deaths. However, the number of reported cases greatly diminished after 1998, and the last reported cholera death occurred in 2001.[5,90]

Cholera is often underreported to WHO. For example, the actual rates of cholera in Bangladesh, which does not report cholera to WHO, have generally exceeded two per 1000 population annually, suggesting that approximately 300,000 cases occur in this country alone.[91] Bearing in mind these limitations in reporting, the worldwide occurrence of massive and prolonged outbreaks seems to be increasing. Since 2005, such outbreaks, each with a total of more than 10,000 cases, were reported in Afghanistan, Angola, Ethiopia, Haiti, Iraq, Guinea Bissau, Kenya, Nigeria, Somalia, South Africa, South Sudan, and Zimbabwe.[92] The outbreak in Haiti, which began in October 2010, has been responsible as of this writing for approximately 730,000 reported cases and 9000 deaths.[93]

In addition to the endemic and epidemic cases occurring in developing countries, sporadic cases occur along the U.S. Gulf Coast and are often associated with undercooked shellfish, especially crabs.[94] After the U.S. Gulf Coast hurricanes of 2005, two cases of toxigenic *V. cholerae* infection that occurred in a Louisiana couple were attributed to consumption of undercooked or contaminated seafood.[95] Most other cases in the United States and other developed countries arise as a consequence of travel to endemic areas.[96]

PASSIVE IMMUNIZATION

Passive immunization against cholera, although theoretically possible, is not used and would not be practical as a public health tool.

ACTIVE IMMUNIZATION

History of Vaccine Development

The development of vaccines against cholera dates to shortly after the discovery of the bacterial etiology of cholera by Robert Koch in the late 19th century. In the late 20th century, a modern vaccine against cholera was one of the first to exploit the new tools of molecular biology. Yet despite these efforts, cholera remains an important public health problem in much of the world. Until recently, vaccines against cholera have generally not been used to control endemic or epidemic disease. This is in part because interest in using limited resources to improve water quality and sanitation is greater than in using resources to vaccinate populations.[97]

Preparations of parenteral killed whole-cell cholera vaccine were produced shortly after Koch's discovery. In 1884 in Spain, Ferran produced a killed bacterial vaccine and inoculated thousands of people in an area experiencing an epidemic at the time. Of those inoculated, 1.3% came down with cholera, compared with 7.7% of those who were not vaccinated.[98]

Shortly after Ferran, Haffkine began working on a cholera vaccine. His work was stimulated by the cholera epidemics in his native Russia; however, unable to return to his homeland, he went to India, where he began giving vaccines to large numbers of persons living in the Delhi and Kolkata areas. He became convinced of the success of his vaccine in 1894 when none of the 116 immunized persons in a Calcutta slum developed cholera, whereas nine cases were reported among the 84 unimmunized.[100] The popularity of the vaccine grew during the early part of the 1900s as the cholera problem continued and no effective therapy existed. Notable is the account of Russell, who carried out large-scale trials of parenteral cholera vaccines in the 1920s.[101] When vaccine efficacy was assessed in a trial in which more than 8000 persons received two doses and 17,000 received one dose of the parenteral vaccine, and 25,000 persons were not immunized, the vaccines were associated with a protective efficacy of approximately 80% during a 3-month follow-up period. Similarly, in further studies involving up to 3 million persons in uncontrolled trials in India, the injectable vaccine appeared to show excellent efficacy. As well, there were numerous anecdotal reports concerning the effectiveness of the parenteral vaccine.

A killed oral cholera vaccine (OCV) was also tested by Russell in the 1920s in India. In retrospect, this was an especially interesting vaccine because of developments in the 1980s with another killed OCV (described later). The first oral vaccine, termed *Bezredka's bilivaccine* because it was developed at the Pasteur Institute by Bezredka and contained ox bile in addition to killed *V. cholerae* O1, was tested in India along with the parenteral vaccine described earlier. The oral vaccine provided protection that was approximately equal (82%) to that of the injectable vaccine and appeared to be highly protective against cholera-related deaths. Possibly because of the bile, the vaccine also caused diarrhea in some persons, and thus it was not acceptable to potential recipients who feared that the vaccine teams were in fact spreading cholera. Unfortunately, this apparent success with an OCV was not pursued for more than 50 years.

Because of the apparent efficacy of vaccines from these early but poorly designed studies, the panic that accompanied cholera epidemics, and the lack of consistently effective treatment, the parenteral vaccines became widely used. For expatriates, such as colonists living in areas that were endemic for cholera, this was probably wise at the time, especially in the absence of safe water and refrigeration. The requirement to receive booster doses every 6 months was not a serious constraint for these expatriates, because cholera was an ever-present risk, and the vaccine probably prevented many cases during this early colonial period. With the accompanying panic stimulated by cholera epidemics, many countries began requiring proof of vaccination for travelers crossing international boundaries, in the mistaken belief that vaccination would prevent the international traveler from spreading the bacterium between countries.

The parenteral killed whole-cell cholera vaccine ultimately fell from favor for several reasons. First, during the 1960s, several controlled studies from East Pakistan (now Bangladesh), India, the Philippines, and Indonesia showed that the vaccine had only limited efficacy (approximately 50%) and that protection was brief in duration.[100,101] Some vaccine preparations were associated with higher efficacy, but these tended to be associated with higher rates of side effects. Side effects were similar to those of killed whole-cell typhoid vaccines, although perhaps somewhat less severe.[101] More important, however, was that the injectable vaccine had to be given frequently (every 6 to 12 months) to maintain clinically significant protection. Resources for intensive vaccination programs were not available in areas endemic for cholera and, if mobilized, would have taken resources from other more effective interventions. Killed parenteral whole-cell vaccines are no longer recommended by the WHO, and the manufacture and sale of these vaccines in the United States have been discontinued.

Despite the demise of conventional, parenterally administered killed whole-cell cholera vaccines, interest in cholera vaccines continued, but it shifted to the development of orally administered vaccines. The oral approach was motivated by several observations. Persons who have been infected with *V. cholerae* develop a protective immune response. This conclusion is based on both volunteers who were challenged 5 years after an original experimental challenge with virulent *V. cholerae* O1 and on analysis of cohorts from endemic areas of Bangladesh.[102,103] There is some evidence that classical strains may induce a more solid immunity than El Tor strains, although this is confounded by differences in serotype in which Inaba appears to better immunize than Ogawa.[103] Also, with the recognition that immune protection against cholera is the result of intestinal secretory antibacterial and antitoxic antibodies came the observation that oral administration of antigens is the most efficient method of eliciting this mucosal immunity.[104–106] In addition to this biological rationale, oral vaccines also have the major advantages of being easy to administer, not requiring physicians or nurses, and being free of the risk of needle-borne infections. Today's licensed OCVs consist either of killed organisms and antigens, or of live, genetically attenuated strains.

Immunization With Modern, Licensed Oral Vaccines

In recent years, three oral vaccines, two killed and one live, have been developed and licensed in various countries (Table 14.1). A killed vaccine known as Dukoral consists of *V. cholerae* O1 killed whole cells combined with the B subunit of CT (CTB); another vaccine consisting only of killed whole cells, but of both the O1 and O139 serogroups, goes by the trade names Shanchol in India, mORCVAX in Vietnam, and Euvichol in Korea. The live vaccine, formerly produced as Orochol (also known as Mutacol in the Americas) and recently

TABLE 14.1 Comparison of Killed WC-rCTB Vaccine, Live CVD103-HgR Vaccine, and Reformulated Killed WC-Only Licensed Vaccines

Characteristic	WC-rCTB	CVD103-HgR	Reformulated WC-Only
Commercial name	Dukoral	Vaxchora (formerly produced as Orochol and Mutacol)	Vietnam: mORCVAX India: Shanchol Korea: Euvichol
Vaccine type/composition	Killed whole cells of *Vibrio cholerae* O1 (Inaba and Ogawa, classical and El Tor) plus recombinant cholera toxin B subunit (monovalent)	Live attenuated *V. cholerae* O1 classical Inaba strain 596B (monovalent)	Killed whole cells of *V. cholerae* O1 (Inaba and Ogawa, classical and El Tor) and O139 (bivalent)
Regimen	2 doses given 7 to 14 days apart (3 doses for children 2 to 5 y)	1 dose	2 doses given at least 14 days apart
Age range for vaccination	≥2 y	18–64 y	Vietnam: ≥2 y India and Korea: ≥1 y
Duration of protection	2 y (6 mo for children 2 to 5 y)	3 mo (established only in North American volunteers)	At least 5 y
Booster dose requirements	Every 2 y (every 6 mo for children 2 to 5 y)	Unknown	Every 3 to 5 y
Requirement for oral buffer	Yes	Yes	No
Storage temperature	2° to 8°C	–25° to –15°C	2° to 8°C
Shelf life	3 y	18 mo	2 y
International acceptance	WHO prequalified	Not prequalified by WHO	WHO prequalified
Price to the public sector per dose	Will depend on production volume (2008 negotiated price to WHO: ~$5.25/dose for small quantity of 250,000 doses)	Vaccine price not currently available	Vietnam: ~$0.75/dose India: $1.85 per dose Korea: Unknown

WC, whole cell; WC-rCTB, whole cell–recombinant cholera toxin B.
Modified from Abramson JS, Chair; Ad-hoc Cholera Vaccine Working Group. Background Paper on the Integration of Oral Cholera Vaccines into Global Cholera Control Programmes. Presented to the WHO Strategic Advisory Group of Experts (SAGE) in October 2009. Final draft available at: http://www.who.int/immunization/sage/1_Background_Paper_Cholera_Vaccines_FINALdraft_13_oct_v2.pdf.

licensed as Vaxchora, is derived from a strain of *V. cholerae* O1 from which the active moiety of the CT gene *ctxA* is deleted. These are summarized in the following paragraphs.

Killed Whole-Cell Vaccine Plus Cholera Toxin B Subunit

Constituents of the Vaccine. This vaccine contains a mixture of recombinant CTB plus killed strains of *V. cholerae* O1 representing both serotypes (Inaba and Ogawa) and both biotypes (El Tor and classical). Two of the strains are heat-killed (classical Inaba strain Cairo 48 and classical Ogawa strain Cairo 50) to better express the LPS antigens, and two are formalin killed (El Tor Inaba strain Phil 6973 and classical Ogawa strain Cairo 50) to better preserve the protein antigens. The CTB is produced by a genetically engineered *V. cholerae* strain that hyperproduces this antigen. The vaccine is free of the cholera toxin A (CTA) subunit and its toxicity. The recombinant CTB retains its ability to bind to the GM_1 ganglioside of the cell membrane. Because the heat-LT of *E. coli* cross-reacts with CT, this antigen provides cross-protection against diarrhea caused by LT-ETEC.[47] As a killed vaccine, whole cell–recombinant cholera toxin B (WC-rCTB) has no potential for genetic reversion to virulence. CTB is sensitive to stomach acid, so the vaccine is given with a buffer. The protective whole-cell antigens, and especially LPS, are not acid sensitive.

The vaccine is prepared as a liquid formulation, and it comes as a whitish, 3-mL suspension in a single-dose glass vial. Each dose of the vaccine consists of a total dose of 10^{11} killed bacteria with 1 mg of recombinant CTB. The vaccine vial comes with a sachet of buffer consisting of sodium hydrogen carbonate, citric acid, sodium carbonate, saccharin, sodium citrate, and raspberry flavor. The buffer is supplied as white effervescent granules and is to be dissolved in a glass of water, to which the vaccine is added and then taken by mouth.

Manufacture of the Vaccine. Batches of *V. cholerae* 01 strains are grown in large fermenters. The harvested bacteria are then killed with either formalin or heat, and the different batches are combined to make a mixture of the batches in equal concentrations of bacteria. All fermentation, harvesting, and mixing, and all transfers between these steps are performed in a closed, steam-sterilizable system to facilitate processing and to eliminate the risk of contamination. The CTB is prepared from a strain of *V. cholerae* O1 that is genetically engineered to produce this antigen, but it lacks the genes for producing cholera A subunit. After fermentation, CTB is purified and then added to the whole-cell vaccine.

Producer. WC-rCTB (Dukoral) is produced by SBL Vaccin AB (now owned by Vaneva) and is packaged in a two-dose package with two unit-dose vials of vaccine and two sachets with buffer. WC-rCTB is registered in more than 60 countries, but it remains experimental in the United States. It has been prequalified by WHO for purchase by United Nations agencies.

Dosage and Route. For adults, the vaccine is given as two oral doses, coadministered with liquid oral buffer, with an interval of 1 to 2 weeks. Children 2 to 6 years of age should receive three doses with an interval of 1 to 2 weeks between doses. For persons at continued risk for cholera, booster doses should be given every 6 months to children 6 years and younger, and every 2 years to older persons.

Availability in Combinations. The vaccine is not available in combination with any other vaccine.

Vaccine Stability. The vaccine should be kept refrigerated (2° to 8°C), and it should not be frozen.

Immunogenicity and Immune Correlates of Protection. Vaccination with WC-rCTB stimulates the development of both vibriocidal and antitoxin antibodies in the serum, and it also stimulates IgA intestinal antibodies.[105,106] Titers of serum vibriocidal antibodies are lower and less frequent with the killed oral vaccine than with the live oral vaccine (*vide infra*), but the local intestinal immune response is comparable to that seen with naturally occurring cholera.[105] Rises in serum IgG and IgA antitoxin titers as measured by enzyme-linked immunosorbent assay (ELISA) are seen in most vaccinees. CTB stimulates interferon-γ in mucosal tissues after immunization, although it is not known if this relates to protection.[106,107]

As noted earlier, immune protection appears to be mostly attributable to local intestinal IgA antibody against the bacterial cells, although antibody to the toxin also contributes to protection.[104,105,108] Neither a serologic correlate nor a serological surrogate of protection exists. The most commonly used measure of immune responses to cholera vaccines is the serum vibriocidal antibody titer. Seroepidemiologic studies done in Bangladesh demonstrated that titers of these antibodies rise with age, as expected with the cumulative exposure to cholera in this setting. Also, the risk of cholera was shown to be inversely related to the height of serum vibriocidal titers in this setting.[109,110]

However, serum vibriocidal antibodies are not surrogates or correlates of protection, as illustrated by the observation that the previously used whole-cell injectable vaccines stimulated high vibriocidal titers, but these titers did not correlate with long-lasting protection.[100] Moreover, the serum vibriocidal responses to oral whole cell–recombinant B subunit (WC-rBS) are short-lived, lasting only several months, with clinical protection persisting far beyond.[106] Although serum vibriocidal antibodies are not suitable as an immunologic surrogate or correlate of protection, their measurement is nevertheless useful for comparing serologic responses among killed oral vaccines, or among these vaccines when coadministered with different buffers.

After immunization with WC-rCTB, there is a serum vibriocidal response, but it is low in magnitude. WC-rCTB vaccine has typically elicited approximately twofold rises in serum anti-Ogawa and anti-Inaba vibriocidal antibodies in cholera-endemic populations, but higher-fold responses in cholera-naïve populations.[111,112] Little information is available on serum vibriocidal antibody responses to WC-rCTB vaccine in persons infected with HIV, although there is a suggestion that intestinal secretory responses are relatively well preserved except in patients with advanced HIV infections.[113]

Excretion and Transmissibility. As a killed vaccine, WC-rCTB is neither excreted nor transmissible.

Duration of Immunity and Protection. The efficacy of whole cell–cholera toxin B subunit (WC-CTB; in which the B subunit was produced by chemical extraction rather than the currently used recombinant technology) was established in a large field trial in Bangladesh in 1985 (Table 14.2).[114–116] The study enrolled 89,596 persons ages 2 to 15 years and women older than age 15 years; participants were randomized to receive three doses, at 6-week intervals, of one of three preparations: the WC-CTB, a WC-only vaccine with the same cellular constituents as WC-CTB but without CTB, and a killed *E. coli* placebo. Of these, 62,285 persons took all three scheduled doses. In this trial, overall protection by WC-CTB was 85% during the first 4 to 6 months of follow-up, 62% during the first year, 57% during the second year, and negligible thereafter. Vaccination protected adults and children older than 5 years for 3 years, and younger children for approximately 6 months. The efficacy of two doses was similar to that for the complete three-dose regimen, and cross-protection against LT-ETEC diarrhea was conferred to WC-CTB vaccinees.[46] However, efficacy was lower against El Tor cholera than against classical cholera.[116]

The efficacy of WC-rCTB was confirmed in a study in the Peruvian military in which 1426 subjects were randomized to receive two doses of vaccine or placebo 1 to 2 weeks apart.[117] After vaccination, of the 16 cases of cholera detected, 14 occurred in the placebo group (protective efficacy of 86%). In another study in Peru performed over a 2-year period, surveillance was carried out using both active (household) and passive (hospital) surveillance. During the first year, after two doses of vaccine there were few hospital cases and nearly all cases were mild, being detected through active surveillance. During this first year there was no evidence of protection, although methodological issues may have explained an apparent lack of efficacy.[118] A booster dose was given a year after the first immunizations, and during the subsequent year the cholera epidemic was more severe, with most cases being detected in the hospital. During this second year, the vaccine did show high-grade protection.[119]

TABLE 14.2 Protection by Oral B Subunit, Killed Whole Cell (WC-CTB), and Killed Whole Cell–Only (WC) Vaccines in the 1985 Bangladesh Field Trial[a,b]

	Protective Efficacy by Age Group					
	WC-CTB			WC		
Follow-up Period	All Ages	2–5 Years	>5 Years	All Ages	2–5 Years	>5 Years
4 to 6 months	85% (62%)[c]	100%	76%	58% (14%)	35%	71%
First year	62% (50%)	31%	78%	53% (38%)	31%	67%
Second year	57% (42%)	24%	61%	57% (42%)	24%	73%
Third year	17% (–15%)	2%	40%	43% (19%)	2%	62%

[a]Overall 3-year cumulative 3-year protective efficacy of each vaccine was approximately 50%.
[b]Three doses were given at ≥6-week intervals.
[c]Lower boundary of 95% confidence interval for probable error.
From Clemens J, Sack D, Harris J, et al. Field trial of oral cholera vaccines in Bangladesh: results from three-year follow-up. Lancet. *1990;335:270–273.*

Mass vaccination with WC-rCTB was feasible and effective in preventing cholera in Beira, Mozambique, in a population with a high prevalence of HIV infection.[120] In this port city, all healthy, nonpregnant residents of an impoverished neighborhood were invited to receive WC-rCTB vaccine before the anticipated annual cholera outbreak. More than 14,000 persons (57% of the targeted population) received at least one dose of a two-dose regimen. Surveillance for diarrhea was maintained for 1 year after vaccination. In a case-control study, vaccination provided 78% protection against cholera in the year after vaccination and 89% protection against cholera with severe dehydration. Interestingly, all cholera strains isolated during surveillance in this study were El Tor variants that produce classical biotype CT.[120]

Postexposure Prophylaxis. There is no indication for postexposure vaccine prophylaxis.

Safety. WC-rCTB has been well tolerated and is considered safe in persons age 2 years and older.[111,121] Gastrointestinal side effects may occur, but at a rate similar to that observed among placebo recipients. A small, controlled observational study suggested that WC-rCTB inadvertently administered to pregnant women was not associated with adverse pregnancy outcomes.[122] Small studies have found no safety concerns when the vaccine is administered to HIV-infected adults, although a transient increase in HIV viremia after vaccination was noted in one study.[123,124] More than 10 million doses have been administered since licensure, and no important safety concerns have been raised during postlicensure surveillance.

Indications. WC-rCTB is indicated for persons age 2 years and older who are at risk for cholera. The WHO recommends that the vaccine be used in areas where cholera is endemic, and that it be considered for use in areas at risk for cholera outbreaks (preemptive vaccination), as well as in those experiencing such outbreaks (reactive vaccination).[59]

Contraindications and Precautions. The only absolute contraindication to receiving WC-rCTB vaccine is hypersensitivity to a constituent of the vaccine or its excipients. Administration to pregnant or lactating women is guided by assessment of medical risk and benefit.

Reformulated Killed Whole Cell–Only Bivalent Vaccine

The large-scale field trial of killed OCVs in Bangladesh demonstrated that a three-dose regimen of an O1 serogroup vaccine consisting only of killed whole cells without CTB conferred approximately 50% protection that was sustained during 3 years of follow-up.[116] Because this vaccine does not require coadministration with oral buffer and is simple and inexpensive to produce, in the 1980s the Vietnamese government, with assistance from Sweden, embarked on a program to produce an oral killed WC-only vaccine for use in its health programs.[125] A monovalent (O1) WC-only vaccine was licensed as a two-dose vaccine in Vietnam as ORCVAX in 1997. This vaccine was subsequently made bivalent (O1 and O139).[126] Between 1998 and 2009, more than 20 million doses were administered in Vietnamese programs.

In 2004, the International Vaccine Institute in Korea, in cooperation with the Vietnamese producer VaBiotech, made several major modifications to the bivalent ORCVAX to bring the vaccine into compliance with WHO standards for inactivated OCV, including replacing a high CT-producing O1 strain with two alternative O1 strains, doubling the LPS content of the vaccine, development of a production process compliant with current good manufacturing practices (GMP), and introduction of improved quality control and lot release assays.[127] After successful Phase II trials of this vaccine in Vietnam and India, and a large-scale Phase III trial in India, this reformulated WC-only vaccine was licensed in 2009 by Shantha Biotechnics as Shanchol in India (and later licensed as mORCVAX in Vietnam and as Euvichol in Korea).

Constituents of the Vaccine. Each dose of the reformulated WC-only vaccine contains 600 (arbitrary) ELISA units of LPS of formalin-killed *V. cholerae* O1 El Tor Inaba (strain Phil 6973); 300 ELISA units of LPS of heat-killed *V. cholerae* O1 classical Ogawa (strain Cairo 50); 300 ELISA units of LPS of formalin-killed *V. cholerae* O1 classical Ogawa (strain Cairo 50); 300 ELISA units of LPS of heat-killed *V. cholerae* O1 classical Ogawa (strain Cairo 48); and 600 ELISA units of LPS of formalin-killed *V. cholerae* O139 (strain 4260B). Each batch of the vaccine is verified to have no detectable CT by a GM_1 ganglioside ELISA with a lower limit of detection of 1 ng/mL. The vaccine is prepared as a liquid formulation and comes as a whitish, 1.5-mL suspension. Shanchol is available in single-dose vials, mORCVAX is available in five-dose vials, and Euvichol in single-dose vials. As a killed vaccine, this vaccine has no potential for genetic reversion to virulence. The WC antigens, and especially LPS, are not acid sensitive, and thus the vaccine does not need to be coadministered with buffer.

Manufacture of the Vaccine. *V. cholerae* serogroups O1 and O139 are grown in large fermenters. The cultures are harvested and the bacterial cells inactivated with either formalin or heat. The cells are then concentrated and washed to form monovalent bulks. The final vaccine is then formulated by mixing each of the required monovalent bulks to their final specified concentration of LPS antigen in phosphate-buffered saline; thimerosal is added as a preservative. All processes are performed under aseptic conditions in compliance with GMP requirements to ensure a product that meets stringent quality standards.

Producers and Trade Names. The vaccine is licensed in India as Shanchol by Shantha Biotechnics (Hyderabad), in Vietnam as mORCVAX by VaBiotech (Hanoi), and in Korea as Euvichol by Eubiologics (Seoul).

Dosage and Route. The vaccine is given as two oral doses, with a 2-week interdose interval, to all persons age 1 year and older. The label does not specify the timing of booster doses, although clinical trial data show protection for at least 5 years after the primary regimen.

Availability in Combinations. The vaccine is not available in combination with any other vaccine.

Vaccine Stability. The vaccine should be kept refrigerated (2° to 8°C), and it should not be frozen. It has a shelf life of 2 years.

Immunogenicity and Immune Correlates of Protection. As for WC-rBS vaccine measurement of serum vibriocidal antibodies forms the basis of evaluating the immunogenicity of this oral killed whole cell–only vaccine, although, as noted earlier, these antibodies are not immunologic surrogates or correlates of vaccine protection. Because the vaccine is bivalent, measurement of anti-O139, as well as anti-O1 antibodies, is done. However, in contrast to serum anti-O1 vibriocidal antibodies, which have been found in the field to correlate with the risk of cholera in endemic populations, there is currently no assay for measuring serum anti-O139 vibriocidal antibodies that has been shown to correlate with the risk of O139 cholera.[128]

In cholera-endemic settings, serum anti-O1 vibriocidal responses to a two-dose regimen of the reformulated WC-only vaccine were more robust than those earlier seen for WC-rCTB vaccine. In Kolkata, India, during a large-scale field trial among children and adults, geometric mean rises in serum anti-O1 vibriocidal antibodies after a two-dose regimen were approximately sixfold, as opposed to the approximately twofold rises seen in a large-scale field trial of a three-dose regimen of WC-CTB in Bangladesh.[114] Serum anti-O139 vibriocidal antibody responses to the reformulated WC-only vaccine are much lower, generally twofold or lower.[129] As for WC-rCTB vaccine, serum anti-O1 vibriocidal responses to the reformulated WC-only vaccine are higher in populations that are naïve with respect to past cholera exposure than in cholera-endemic populations. A recent study in Haiti showed that HIV-infected individuals developed somewhat lower but still appreciable serum vibriocidal antibody responses, compared with those in HIV-uninfected individuals, and that, among HIV-infected persons, the magnitude of these responses varied inversely with CD4 lymphocyte counts.[130]

With no rise in seroconversion rates following the second dose of Shanchol relative to those after a first dose in cholera-endemic populations,[131] efforts to evaluate the efficacy of a single-dose regimen are in progress, as a single-dose regimen would be of great value in controlling cholera epidemics. Questioning the value of such a regimen for persons without preexisting immunity to cholera, however, are studies in humans given Dukoral, showing that intestinal IgA antibacterial and antitoxin antibody responses increase after the second dose of vaccine, relative to those after a first dose, when given to unprimed individuals.[132] As well, a rising serum vibriocidal antibody response to a second dose of Shanchol was observed in evaluations in Haiti and Ethiopia.[133,134]

Excretion and Transmissibility. As a killed vaccine, WC-only is neither excreted nor transmissible.

Duration of Immunity and Protection. The safety and efficacy of a two-dose regimen of the reformulated WC-only vaccine was studied in a large-scale, randomized, placebo-controlled trial that enrolled 69,328 persons ages 1 year and older in the urban slums of Kolkata, India (Table 14.3).[135] No adverse effects occurred more frequently in vaccinees than in placebo recipients. During surveillance, only El Tor cholera was detected, and all isolates were El Tor variants that produced classical biotype CT. The vaccine exhibited a 5-year cumulative efficacy of 65%, with a lower efficacy noted in children ages 1 to 5 years old (42%). While serum vibriocidal antibody titers waned after 1 year,[136] cumulative efficacy was maintained for at least 5 years in the overall trial population, and currently no formal recommendations on a boosting regimen exist. Serum vibriocidal antibody responses to a two-dose booster regimen dose 5 years after the primary doses among participants in the original Phase III field trial were shown to be comparable to those observed after a primary series.[137] Also, similar immune responses have been demonstrated for a standard two-dose regimen with a 2-week interdose interval and a two-dose regimen given with a 4-week interval in Kolkata, suggesting the possibility for increased flexibility of the dose schedule when offered as part of a targeted vaccination program.[138] As no O139 serogroup cholera cases were detected in the Kolkata efficacy trial, vaccine efficacy against O139 cholera was not evaluable. Serum anti-O1 vibriocidal antibody levels declined markedly at 1 year of follow-up in this field trial, despite clinical protection against cholera that persisted for at least 5 years.

TABLE 14.3 Protective Efficacy of the Reformulated Bivalent Killed Whole Cell–Only Oral Cholera Vaccine (Shanchol) in the Kolkata Field Trial[a]

Follow-Up Period	Protective Efficacy by Age Group[b]			
	All Ages	1–5 Years	5–15 Years	≥15 Years
Year 1	45% (–19%, 74%)[c]	17%	81%	66%
Year 2	76% (47%, 89%)	81%	92%	62%
Year 3	66% (40%, 81%)	37%	89%	64%
Year 4	58% (29%, 75%)	48%	89%	86%
Year 5	80% (40%, 93%)	–10%	89%	86%

[a]Two doses given at 2- to 6-week intervals.
[b]Overall cumulative 5-year protective efficacy was 65%.
[c]95% confidence interval for probable error in parentheses.
From Bhattacharya SK, Sur D, Ali M, et al. 5-Year efficacy of a bivalent killed whole-cell oral cholera vaccine in Kolkata, India: a cluster-randomised, double-blind, placebo-controlled trial. Lancet Infect Dis. *2013;13:1050–1056.*

Postexposure Prophylaxis. There is no indication for postexposure vaccine prophylaxis.

Safety. Adverse events occurred with no greater frequency in recipients of the reformulated WC-only vaccine and placebo in the Phase II trials done in Vietnam and India, and in the large Phase III trial conducted in India.[129,135,139] The vaccine is considered safe in persons age 1 year and older. There are no specific data demonstrating safety in pregnancy and lactation, nor for HIV-infected persons, although it is not expected that the safety profile of this vaccine in these groups would differ from WC-rCTB vaccine.[130]

Indications. The vaccine is indicated for persons age 1 year and older who are at risk for cholera. The 2010 WHO recommendation for cholera vaccines, outlined earlier, also applies to this vaccine.[59]

Contraindications and Precautions. The only absolute contraindication to receiving reformulated WC-only vaccine is hypersensitivity to a constituent of the vaccine or its excipients. Administration to pregnant women may be considered after careful evaluation of the benefits and risks.

Live Oral Vaccine (CVD103-HgR)

Live attenuated oral vaccines have been considered attractive because of the possibility that one dose might be sufficient to induce a maximal immune response. Attempts have been made to develop such vaccines by creating genetically attenuated mutants that do not produce cholera holotoxin and are not virulent. If CTB is expressed, such a mutant may stimulate antibacterial and anti-CTB immunity in a manner similar to that of natural infection but without the symptoms associated with naturally acquired *V. cholerae* infection. CVD103-HgR is one such live attenuated strain.[140,141] The strain, derived from classical Inaba strain 569B, has been engineered to express CTB but not the enzymatically active A subunit, and it carries mercury resistance to serve as a marker of the vaccine strain. CVD103-HgR is safe when given in dosages up to 5×10^9 per dose. The safety profile of this vaccine is probably partly the result of the relatively poor colonization of the human intestine. Because the vaccine strain is live, the viability of the bacteria must be preserved while it is in storage, requiring maintenance of a cold chain, and the bacteria must be

protected from stomach acid, which is accomplished by coadministering the vaccine with a buffer.

Constituents of the Vaccine. CVD103-HgR, sold under the trade name Vaxchora, is presented as two packets. One contains the bacterial lyophilate mixed with excipients including sucrose, lactose, sodium dichloride, ascorbic acid, and casein hydrolysate, and the other contains a neutralized sodium bicarbonate buffer (2.16–2.41 g of sodium bicarbonate, ascorbic acid, and lactose). The vaccine is reconstituted by mixing the contents of both in 100 mL of purified water. Each dose of vaccine contains 4×10^8 to 2×10^9 colony-forming units (CFU) of CVD103-HgR.

Manufacture of the Vaccine. Vaxchora is produced by fermentation and harvesting by tangential flow filtration to preserve cell appendages. The bacterial concentrates are mixed with stabilizers, lyophilized, freeze-dried, and then milled into a fine powder and stored at −25° to −15°C.

Producers and Trade Names. Berna Biotech (Berne, Switzerland), and later Crucell, licensed and commercialized CVD103-HgR under the trade names Orochol (10^8 CFU per dose) for use in developed countries and Orochol E (10^9 CFU per dose) for use in developing countries. The vaccine is registered in multiple countries, but production was suspended in 2004. Recently, the U.S. manufacturer PAXVAX recommercialized this vaccine and licensed it in the United States under the trade name Vaxchora.

Dosage and Route. Vaxchora is given as a single oral dose along with a buffer salt to neutralize stomach acid. The effective dosage of live organisms for persons not living in cholera-affected countries is 4×10^8 to 2×10^9.

Availability in Combinations. The vaccine is not available in combination with any other vaccine.

Vaccine Stability. Vaxchora contains freeze-dried live bacteria; a cold chain (−25° to −15°C) is needed to preserve the vaccine's potency up to the point of reconstitution. The vaccine is administered within 15 minutes after reconstitution.

Immunogenicity and Immune Correlates of Protection. After vaccination with this live oral vaccine, the serum vibriocidal antibody response is the best measure of successful stimulation of antibacterial immunity, although, as noted earlier, serum vibriocidal antibodies are not an immune correlate or surrogate of vaccine protection. High titers of serum vibriocidal antibodies, as well as anti-LPS antibodies, are stimulated in most vaccinees given CVD103-HgR. Intestinal IgA antibodies are also produced against the LPS antigen. People who have not been previously exposed to cholera (naïve volunteers) respond well (fourfold or greater rise in vibriocidal antibody titers) to a dosage of 10^8 organisms, whereas volunteers from endemic areas require a higher dosage of 10^9 organisms to stimulate an equivalent response.[141–146] Serum antitoxin responses are seen, but the rises in titer are less consistent and of lower magnitude than for the antibodies directed against the bacterial cell wall antigens.[142] Serum vibriocidal responses have been noted to be lower in HIV-seropositive patients than in HIV-seronegative patients.[147] Prelicensure trials of Vaxchora have demonstrated a similar safety and immunogenicity profile to previously licensed versions of CVD103-HgR.[148,149]

Excretion and Transmissibility. In nonendemic populations, a minority of recipients of CVD103-HgR excrete the vaccine organism in feces.[150] Excretion is less common in persons residing in cholera-endemic settings.[151] A study in urban Indonesia showed that children who received CVD103-HgR did not transmit the vaccine organism to their siblings.[152]

Duration of Immunity and Protection. In a double-blind, placebo-controlled challenge study of efficacy done in the United States, 134 volunteers received a single oral dose of Vaxchora or placebo.[143] The vaccine was well tolerated. Ten days and 3 months later, subgroups of volunteers underwent challenge with virulent, frozen *V. cholerae* N16961, an O1 El Tor strain that was developed as a standard challenge strain and has been completely sequenced.[153,154] Efficacy against moderate to severe diarrhea was 90% at 10 days and 80% at 3 months. Other cholera challenge studies with earlier versions of CVD103-HgR demonstrated that protection begins as early as 8 days after vaccination and lasts for at least 6 months.[146]

In a randomized, placebo-controlled Phase III trial in Indonesia, among approximately 67,000 persons who received a single dose of Orochol or placebo, vaccine efficacy was 14%, a disparity with earlier North American volunteer challenge study results that remains to be convincingly explained.[155] Orochol E was also given in a mass immunization program during an outbreak of cholera in Pohnpei Island, Micronesia; a retrospective cohort study found that the vaccine conferred 79% protection.[156] In view of the observational design of this latter study and the disparity with the findings of the randomized, double-blind Indonesia trial, these findings require further confirmation.

Postexposure Prophylaxis. There is no indication for postexposure vaccine prophylaxis.

Safety. CVD103-HgR in its different license formulations has been well tolerated and is recognized as safe in persons aged 2 years and older. Monitored side effects, including abdominal pain, diarrhea, nausea, vomiting, fever, headache, and rash, were not notable different in vaccinees than in placebo recipients in prelicensure trials.[141,143–146,157,158] A small study by Perry and coworkers indicated that CVD103-HgR is safe in HIV-positive patients, although the subjects in this study were not severely immunodeficient.[147] Data are not available to address safety in pregnancy.

Indications. Based on data from North American volunteer challenge studies, Vaxchora is indicated in travelers ages 18 to 64 years visiting countries with active cholera transmission. Vaxchora has not been used in populations with endemic cholera.

Contraindications. The package insert for Vaxchora lists as contraindications: a history of severe allergic reactions to any ingredient of the product or to previous receipt of any cholera vaccine and receipt of oral or systemic antibiotics in the previous 14 days. Vaxchora should be given at least 10 days before beginning antimalarial prophylaxis with chloroquine.[142]

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Setting

For the public health use of modern cholera vaccines in developing countries, it is important to distinguish between endemic and epidemic cholera. For the control of epidemic cholera, selective vaccination of populations at a definably high risk of an epidemic, or reactive vaccination shortly after

the onset of the epidemic, can be considered.[159] Because populations experiencing epidemic cholera often have limited background natural immunity to cholera, vaccines must be effective in immunologically naïve persons, and they should target all age groups, as the risk of epidemic cholera tends to be age independent.[159]

For endemic cholera, vaccines should be able to immunize in the face of the background natural immunity to cholera that develops in recurrently exposed populations. Vaccination may target preschool and school-age children rather than adults in view of the higher risk of cholera in younger age groups in endemic settings. Long-term protection is more critical than early onset of protection after initiation of dosing for vaccines against endemic cholera. In contrast, early onset of protection after the first dose of vaccine would be of greater importance for vaccines used reactively in epidemic situations, and duration of protection would be of lesser importance.[153]

Vaccine Impact

Several studies of the preventive impact of OCVs under realistic public health conditions have been conducted. In a reactive vaccination program launched to control a large epidemic of cholera in Guinea, Shanchol vaccine, the vaccine currently stockpiled by WHO *(vide infra)* demonstrated 86% protection over 6 months against cholera.[160] When administered in programs to control stable, endemic cholera, Shanchol was demonstrated to confer 69% protection in rural India[161] and 53% protection in urban Bangladesh.[162,163]

Vaccine herd protection, protection of nonvaccinees and enhanced protection of vaccinees as a consequence of their proximity to neighboring vaccinees, can greatly augment the protective performance of vaccines given to populations. Data generated in field efficacy trials in Bangladesh with WC-rCTB and WC-only vaccines and in India with WC-only vaccine demonstrated vaccine herd protection.[164,165] This effect was attributed to a vaccine-induced reduction in transmission of cholera vibrios among the targeted population. In addition, in one trial killed OCVs afforded protection to unimmunized children of immunized mothers, most likely because of interruption of transmission from mother to child.[166] One mechanism for these observations is that these killed OCVs may reduce the load of fecally shed cholera vibrios from infected persons.[167]

An implication of these findings on vaccine herd protection is that killed OCVs may exert a major effect in the control of cholera, even in areas of modest coverage. Mathematical models based on the Bangladesh analyses suggest that the occurrence of cholera in a hyperendemic area of rural Bangladesh could be nearly extinguished at levels of vaccine coverage of approximately 60% with a vaccine having the features of the killed WC-only OCV Shanchol (Fig. 14.2).[168]

Nonetheless, vaccination should be considered as only one of several interventions to prevent cholera. Also critical are

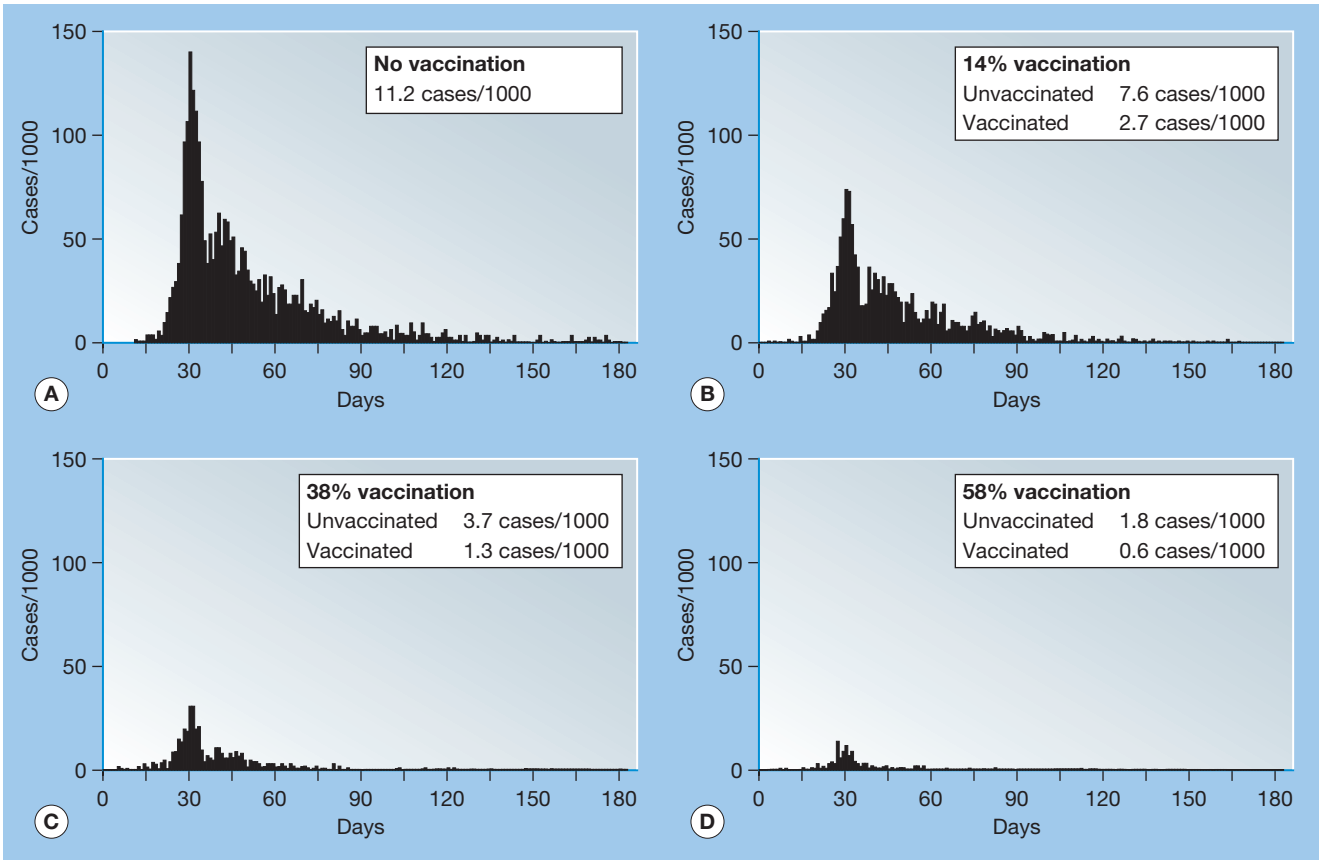

Figure 14.2. Simulated number of cholera cases per 1000 over a 180-day period in the study population in Matlab, Bangladesh, for a single stochastic realization. Mathematical modeling analyses suggest that the occurrence of cholera in a hyperendemic area of rural Bangladesh may be nearly extinguished at levels of vaccine coverage of approximately 60%. **A,** No vaccination; **B,** 14% vaccination coverage of women and children; **C,** 38% vaccination coverage; **D,** 58% vaccination coverage. *(From Longini Jr IM, Nizam A, Ali M, et al. Controlling endemic cholera with oral vaccines.* PLoS Med. *2007;4:e336.)*

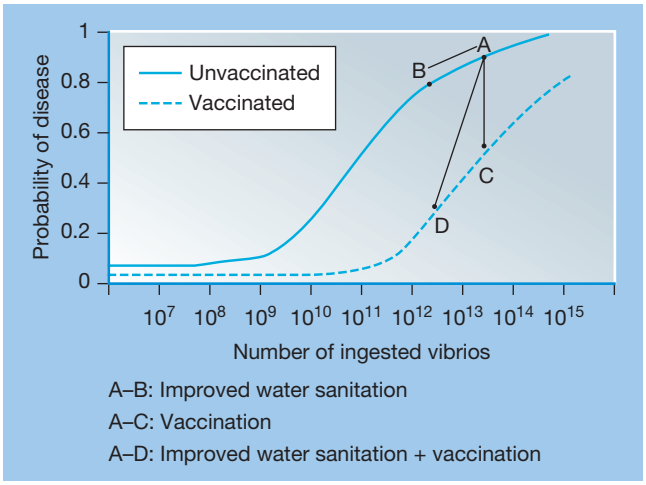

Figure 14.3. Hypothetical impact of oral cholera vaccine complemented by improvements in water quality, hygiene, and sanitation (WASH) on the risk of cholera. Graphic illustration showing relationship of ingested inoculum of cholera organisms to the probability of diarrhea after ingestion. The top curve corresponds to an unvaccinated individual and the bottom curve to a vaccinated individual. The top curve roughly describes the lower risk of symptomatic cholera after WASH interventions, which act to decrease the frequency and/or dose of ingestion of cholera vibrios (movement from state A to state B). The bottom curve reflects the same for vaccinated individuals (movement from state C to state D). The effect of oral cholera vaccines (OCVs) should be to decrease the probability of becoming ill at any (or at least most) ingested doses (movement from state A to state C). Because of these relationships the combined effects of WASH interventions and OCVs should produce a greater preventive effect than either intervention alone (movement from state A to state D). *(From Clemens J, Holmgren J. When, how, and where can oral cholera vaccines be used to interrupt cholera outbreaks?* Curr Top Microbiol Immunol. *2014;379:231–258.)*

complementary control measures to improve water quality, sanitation, and hygiene. There is a theoretical basis to consider these measures as synergistic with vaccination in preventing cholera (Fig. 14.3).

Feasibility and Cost Effectiveness

Logistical feasibility and programmatic acceptability must be considered in decisions regarding the public health use of OCVs. When given in campaigns, two-dose regimens of killed OCVs have been feasibly delivered in endemic settings in Bangladesh, India, Vietnam, and Mozambique.[162,163,169–171] Also, two-dose regimens of WC-rCTB vaccine have been feasibly delivered in refugee camps and during complex emergencies in Uganda and Indonesia.[156,159,172] Because WC-only vaccine is less expensive and does not require the coadministration of buffer, vaccine can be delivered in a faster and less cumbersome manner, as demonstrated in recent preventive and reactive campaigns in Bangladesh, India, Haiti, South Sudan, and Guinea.[66,162,173] The live OCV CVD103-HgR was feasibly delivered in a reactive vaccine effort to contain a cholera epidemic in Micronesia.[156] A published cost-effectiveness analysis of the use of OCVs, which accounted for both the direct and herd vaccine protective effects of Shanchol and used local data from the field on cholera incidence and costs, found the vaccine to be very cost-effective or cost-effective by WHO standards in Kolkata, India; Beira, Mozambique; Matlab, Bangladesh; and Jakarta, Indonesia, depending on the age group targeted.[174] In addition, a recent systematic investment analysis found the vaccine to be very cost-effective in more than 30 countries projected to be early OCV adopters.[175]

Travelers

The rationale for recommending cholera vaccine for travelers and military personnel is similar to that for several other travelers' vaccines—prevention of an unlikely but potentially severe illness. Because OCVs are safe and easily administered, many travelers are likely to welcome the vaccines, especially versions that are also capable of preventing some cases of ETEC diarrhea.[47,121] The Canadian Committee to Advise on Tropical Medicine and Travel has indicated that vaccination with the killed WC-rCTB vaccine, Dukoral, for traveler's diarrhea is of limited value but may be of use for selected, short-term, high-risk travelers older than age 2 years.[176] The U.S. Advisory Committee on Immunization Practices recommends the live oral cholera vaccine, Vaxchora, for adults aged 18 to 64 years traveling to areas with active cholera transmission.

World Health Organization Oral Cholera Vaccine Stockpile

The WHO issued a revised recommendation in 2010 stating that OCVs should be used in areas where cholera is endemic, and should be considered for use in areas at risk for cholera outbreaks (preemptive vaccination), as well as in those experiencing such outbreaks (reactive vaccination).[59] Currently, only Vietnam uses an OCV, produced locally, given in the past in response to epidemics of cholera.[177] Until recently, safe and effective OCVs have failed to be embraced as public health tools for developing countries. Reasons included vaccine expense, moderate levels of vaccine protection, the logistic challenges associated with storage and administration, as well as concerns that vaccine delivery might interfere with other cholera control efforts. In 2011, the 64th World Health Assembly called for an integrated comprehensive strategy, recommending the use of OCV "where appropriate, in conjunction with other recommended prevention and control methods."[178] In 2013, a 2-million dose OCV stockpile was created by WHO as a tool to help control cholera epidemics. Later in the year, the Gavi alliance announced the decision to invest U.S. $115 million over 5 years to fund and expand the stockpile to 20 million doses by 2018 with hopes of breaking the current cycle of low vaccine demand leading to low vaccine supply. The stockpile, which must deploy a WHO prequalified OCV, currently deploys Shanchol because of its relatively low cost and its ease of administration. At the time of this writing, approximately 3.5 million doses of the stockpiled vaccine Shanchol have been used in outbreaks in the African, South East Asian, and Western Pacific regions, and Haiti.[179] Reported levels of protective effectiveness of the vaccine in these settings have ranged from 63% to 87%.[160,180]

FUTURE VACCINES

New Killed Whole Cell–Only Cholera Vaccines

As noted earlier, current killed whole cell–based vaccines consist of a combination of several different inactivated *V. cholerae* strains, some killed by heat, others by formalin. Fermentation of several strains for each vaccine dose is a source of the cost of this vaccine. To circumvent this manufacturing hurdle, workers at the University of Goteborg have genetically engineered an El Tor strain that expresses both Inaba and Ogawa antigens. This Hikojima-like strain is formalin-inactivated, and induces promising serum anti-LPS and vibriocidal antibody

responses in mice.[181] If safe and protective in humans, this single strain vaccine would enable much-less-expensive manufacturing and substantial reductions in vaccine cost.

Live Oral Vaccines Against O1 Serogroup Cholera

Several live oral attenuated vaccine strains against O1 serogroup cholera are under development. Among these is Peru 15, derived by genetically attenuating an O1 El Tor Inaba strain isolated in Peru in 1991. The attenuating mutations include deletion of the entire CT cassette, including flanking recombination sites, and inactivation of the *recA* gene by inserting the coding region for CTB under control of a heat-shock promoter, thereby making the vaccine incapable of incorporating homologous DNA by *recA*-mediated recombination. The strain is also motility deficient. The vaccine was proven safe and highly efficacious in a challenge study of U.S. volunteers, where five of 12 placebo recipients (42%) and none of 24 vaccinees (0%) had moderate or severe diarrhea.[182,183] Placebo-controlled trials conducted among Bangladeshi adults, children, and infants found a single-dose (10^8 CFU) regimen to be safe and immunogenic.[184,185] Cuban investigators have developed *V. cholerae* O1 vaccine strain 638, attenuated by deletion of the CTXPhi prophage and inactivation of the hemagglutinin/protease coding sequences *(hapA)* in an El Tor Ogawa strain. This vaccine was well tolerated in healthy Cuban volunteers, and, in a randomized, double-blind, placebo-controlled trial, strain 638 conferred 100% protective efficacy in a small group of Cuban volunteers who underwent experimental challenge with El Tor *V. cholerae* 01 a month after vaccination.[186] Large-scale production of this vaccine strain has been initiated.[187]

Chinese investigators have constructed a vaccine candidate, designated IEM 108, that consists of an El Tor Ogawa strain naturally deficient in CTXPhi and that contains a *ctxB* gene and an *rstR* gene; the latter precludes acquisition of CTXPhi by the vaccine.[188] Genes *ctxB* and *rstR* are stably maintained by a balanced lethal system based on the gene *thyA*. This strain was immunogenic in rabbits and conferred full protection against wild-type challenges in rabbits.[189]

Investigators in India have developed a vaccine candidate from a clinical nontoxigenic strain of El Tor biotype *V. cholerae* O1, serotype Inaba, which is devoid of the CTX prophage. Through a series of genetic manipulations, *ctxB*, which encodes CTB, was introduced into a cryptic hemolysin locus of the strain. A gene for ampicillin resistance was also introduced as a marker. The resulting strain, termed VA1.3, was found to be safe and immunogenic as a single dose of 10^9 CFU in adult volunteers in India.[190] It has been reformulated and subsequently renamed as VA 1.4.

Live Oral Vaccines Against O139 Serogroup Cholera

Two live oral vaccines against O139 cholera have been tested in volunteers. One O139 vaccine strain, named Bengal 15, has genetic mutations similar to Peru 15, but was produced from a strain of the O139 serogroup. Early trials of freshly harvested vaccine organisms found the vaccine to be safe and efficacious in small numbers of U.S. volunteers.[191] CVD112, another live attenuated strain against O139 cholera, has also been shown to be safe and efficacious in U.S. volunteers.[192] Building on the success of O1 vaccine strain 638, Cuban investigators have constructed an analogous vaccine candidate with an O139 strain. The prototype strain includes a spontaneous deletion in CTXPhi and deletions in *hapA* and *thyA*.[193] This vaccine candidate will undergo clinical studies.

Parenteral Vaccines

A detoxified LPS-protein conjugate vaccine for cholera for parenteral use has been developed and tested in Phase I human studies. This vaccine consists of *V. cholerae* O1 Inaba LPS bound to CT. In volunteers, this vaccine stimulated serum vibriocidal antibodies that persisted longer than those elicited by a killed whole-cell parenteral vaccine, and it stimulated anti-CT antibodies.[194] Other groups have used this strategy to develop a parenteral conjugate vaccine against either O1 or O139 cholera, coupling the *V. cholerae* LPS plus core to tetanus toxoid or a diphtheria toxin mutant. After multiple doses in mice, these vaccine candidates elicited anticapsular polysaccharide and anti-LPS antibodies with vibriocidal activity and were protective in the neonatal mouse model of cholera infection.[195–197]

15 Combination Vaccines

Michael D. Decker, Kathryn M. Edwards, and Barbara J. Howe

The combining of multiple antigens into a single vaccine is not a new concept; combination vaccines have long been a bedrock of immunization programs. Since the early 1990s, we have transitioned from a world in which DTP (diphtheria, tetanus, pertussis) and MMR (measles, mumps, rubella) represented essentially the only combination vaccines in use to one in which even developing countries are routinely using modern combination vaccines providing protection against DTP, hepatitis B, *Haemophilus influenzae* type b, polio, pneumococcus, and various meningococcal serogroups. The field of combination vaccines has matured to the point where a large number of combination vaccines are available with relatively few in development. These efforts, undertaken by many manufacturers and research groups worldwide, have been driven by the recognition that the continual increase in the number of effective childhood vaccines posed substantial economic and logistic difficulties. Providing these vaccines as separate injections requires multiple needlesticks, leading to distressed parents, providers, and vaccinees. Scheduling additional vaccination visits to reduce the number of injections per visit increases costs, burdens staff, and jeopardizes the entire immunization program by increasing the likelihood of missed vaccinations. The shipping, handling, storage, and accountability of a plethora of vaccines are burdensome and expensive and increase the possibility of error. These issues have stimulated continuing efforts to provide new combination vaccines. However, the development and evaluation of combination vaccines can pose numerous issues, as discussed further in this chapter and reviewed elsewhere.[1,2]

The combination vaccines in common use before the 1990s included diphtheria and tetanus toxoids, available alone (DT or Td) or combined with whole-cell (DTwP) pertussis vaccine; inactivated (IPV) or live oral (OPV) trivalent poliovirus vaccine; and measles and rubella vaccine, available alone (MR) or with mumps vaccine (MMR).

The first combination vaccine licensed in the United States was trivalent influenza vaccine, approved in November 1945, and the second was a hexavalent polysaccharide pneumococcal vaccine licensed in 1947.[3] Although developed in 1943, DTwP was not licensed until March 1948. IPV was licensed in 1955. Although the individual OPV serotypes were licensed from 1961 to 1962, efforts to overcome interference seen with simultaneous administration of three attenuated live polioviruses delayed the licensure of trivalent OPV until June 1963. MMR and MR were licensed in April 1971, and quadrivalent polysaccharide meningococcal vaccine in 1978. Only brief mention is made in this chapter of these traditional combination vaccines, which are discussed in their respective chapters.

Most modern pediatric combination vaccines begin with a DTwP or DT/acellular pertussis (DTaP) vaccine and add such antigens as IPV, conjugate *H. influenzae* type b (Hib) and hepatitis B (HepB). As development efforts for the DTaP-based combinations have matured, some manufacturers have turned their efforts toward developing so-called second-shot or companion combinations designed to be given in coordination with a DTaP-based combination, incorporating, for example, conjugate meningococcal antigens. A third developmental stream has been directed toward combination vaccines targeted principally at travelers, typically based on HepB or hepatitis A (HepA) components.

Our focus in this chapter is on the most relevant current combination vaccines, which merge products such as IPV, HepB, Hib, or meningococcal vaccines with each other or with one or more of the aforementioned traditional combination vaccines. Readers interested in combination vaccines of historical interest (e.g., yellow fever/smallpox) or combinations based on components no longer available (e.g., Acel-Imune, PRP-D [polyribosylribitol phosphate-diphtheria toxoid conjugate]) are referred to the 2003 edition of this text.[4]

TERMINOLOGY

The vaccine industry has undergone dramatic consolidation during the past 20 years; long-established companies and new biotechnology startups have been acquired or merged. These changes render nomenclature problematic. For vaccines currently marketed, we will use the name of the current manufacturer, even when describing studies conducted by a predecessor company. For products not presently marketed, we will use the name of the company that produced them, even if that company now is owned or operated under a successor name. To further assist readers, Table 44.6 lists most current major vaccine manufacturers, along with the names of predecessor, component, or acquired companies.

As Box 15.1 shows, the use in this chapter of a virgule to coordinate the names of two vaccines (e.g., DTwP/IPV) indicates a combination of the two vaccines; a plus sign (e.g., DTwP + IPV) indicates concurrent but separate administration. When discussing a specific combination vaccine, the use of a single virgule indicates that the vaccine is supplied with the component following the virgule premixed with the component preceding the virgule; the use of a double virgule (e.g., DTaP//Hib) indicates that the component following the double virgule is reconstituted using the liquid components that precede the double virgule.

Because so many different combination vaccines are available within some classes (e.g., DTaP/Hib) and simple, unambiguous generic names do not exist for the various products, trade names are used whenever possible to refer to specific combination vaccines.

Table 15.1 outlines the current status of the newer combination vaccines, and Table 15.2 provides further details concerning those that are available.

PRINCIPLES OF COMBINED VACCINES

Simultaneous Vaccines

A combination vaccine consists of two or more separate immunogens that have been physically combined in a single preparation. This concept differs from that of simultaneous vaccines, which, although administered concurrently, are physically separate (i.e., injected at separate sites or given by

Text continued on p. 204

BOX 15.1 Key to Typography

Symbol	Meaning
Plus sign (+)	The vaccines linked by the plus sign are administered at separate sites during a single vaccination session. Example: **DTaP** + **Hib**, two separate vaccines given separately but at the same visit.
Single virgule (/)	The vaccines linked by a single virgule are premixed from the manufacturer and are administered in a single injection. Example: **DTaP/Hib**; the two vaccines are shipped by the manufacturer mixed together in a single container.
Double virgule (//)	The liquid vaccine(s) preceding the double virgule are used to reconstitute the dry vaccine following the double virgule. Example: **DTaP//Hib**; the manufacturer ships together a container of liquid DTaP and a container of powdered Hib, with the DTaP used to reconstitute the Hib and the resulting mixture administered as a single injection.

DTaP, diphtheria, tetanus toxoids, and acellular pertussis; Hib, *Haemophilus influenzae* type b.

PhtD/PD/dPly				GSK

Note: While this text was in press, Merck and Sanofi Pasteur announced that their European joint venture, SPMSD, was being dissolved; in the future, products marketed by SPMSD would instead be marketed by their respective manufacturers.

aP, acellular pertussis vaccine (infant formulation); ap, acellular pertussis vaccine (adolescent/adult formulation); D, diphtheria toxoid vaccine (infant formulation); d, diphtheria toxoid vaccine (adolescent/adult formulation); GSK, GlaxoSmithKline; HepA, hepatitis A vaccine; HepB, hepatitis B vaccine; Hib, conjugate *Haemophilus influenzae* type b vaccine; IPV, enhanced inactivated trivalent poliovirus vaccine; J&J, Johnson and Johnson; MCM, Merck Connaught Merieux (joint venture of Merck and Sanofi Pasteur); MMRV, measles, mumps, rubella, and varicella vaccine; Mn, meningococcal conjugate vaccine (included serotypes are shown by following letter[s], e.g., MnC, MnCY); PhtD/PD/dPly, pneumococcal histidine triad protein D, nontypeable *H. influenzae*, and detoxified pneumolysin; SII, Serum Institute of India; SP, Sanofi Pasteur; SPMSD, Sanofi Pasteur MSD; SSI, Statens Seruminstitut; T, tetanus toxoid vaccine; wP, whole-cell pertussis vaccine. See Table 44.6 for information on prior names of pharmaceutical companies.

[a]Products combining only multiple serotypes of a single pathogen are excluded, as are DT (diphtheria and tetanus toxoids–pediatric), Td (diphtheria and tetanus toxoids–adult), DTP (diphtheria, tetanus, pertussis), DTaP (diphtheria, tetanus toxoids, and acellular pertussis), Tdap (tetanus, diphtheria, and pertussis), OPV (oral polio vaccine), IPV (inactivated polio vaccine), and MMR (measles, mumps, rubella). Only those manufacturers who distribute their products internationally are listed; other manufacturers may produce some products (e.g., DTP/IPV) for local or regional use. Some products represent components derived from, or joint efforts of, more than one manufacturer; in such cases, their principal distributor is shown.

[b]No discrimination is made between products distributed in combined form and those distributed in separate containers, for combination at the time of use.

TABLE 15.2 Combination Vaccines Currently Available in Canada, European Union, or United States[a] *(Continued)*

Combination	Trade Name	Source	Each 0.5-mL Dose (After Reconstitution, if Applicable) Is Formulated to Contain (See Listing by Country, Below, for Specific Information Regarding Composition)
	Infanrix IPV	GSK	At least 30 IU DT, at least 40 IU TT, 25 μg PT, 25 μg FHA, 8 μg PRN, poliomyelitis vaccine types 1 (Mahoney, 40D), 2 (MEF-1, 8D), and 3 (Saukett, 32D); 0.5 mg $Al(OH)_3$, 2.5 mg 2-PE
DTaP/IPV/Hib	*Pediacel*	SP	20 μg PT, 20 μg FHA, 3 μg PRN, 5 μg FIM types 2 and 3, 15 Lf DT, 5 Lf TT, poliomyelitis vaccine types 1 (Mahoney, 40D), 2 (MEF-1, 8D) and 3 (Saukett, 32D), 10 μg PRP conjugated to 20 μg TT, 0.6% ± 0.1% (v/v) 2-PE, 1.5 mg $AlPO_4$; trace streptomycin, polymyxin B, and neomycin may be present
	Infanrix IPV Hib	GSK	25 Lf (30 IU) DT, 10 Lf (40 IU) TT, 25 μg PT, 25 μg FHA, 8 μg PRN, 40 D of type 1 poliovirus, 8 D type 2 poliovirus, 32 D type 3 poliovirus, 10 μg of adsorbed purified PRP covalently bound to 20–40 μg TT per 0.5 mL dose; aluminum adjuvant (as aluminum salts), residual formaldehyde, polysorbate (Tween) 20 and 80, M199, glycine, neomycin sulfate, and polymyxin B sulfate
DTaP/IPV/HepB/Hib	*Infanrix hexa*	GSK	25 Lf (30 IU) DT, 10 Lf (40 IU) TT, 25 μg PT, 25 μg FHA, 8 μg PRN, 10 μg HBsAg, 40 D of type 1 poliovirus, 8 D type 2 poliovirus, 32 D type 3 poliovirus, 10 μg of adsorbed purified PRP covalently bound to 20–40 μg TT per 0.5 mL dose; aluminum adjuvant (as aluminum salts), residual formaldehyde, polysorbate (Tween) 20 and 80, M199, glycine, neomycin sulfate, and polymyxin B sulfate
Tdap/IPV	*Boostrix Polio*	GSK	Not less than 2.5 Lf, or 2 IU of DT; not less than 5 Lf (20 IU) of TT; 8 μg of PT, 8 μg of FHA, 2.5 μg of pertactin (69 kDa outer membrane protein), 40 DU of type 1 poliovirus, 8 DU type 2 polio virus, and 32 DU type 3 polio virus; aluminum adjuvant (as aluminum salts), sodium chloride, water for injection, and medium 199. Formaldehyde, neomycin, and polymyxin are present as traces
HepA/Typhoid	*Vivaxim*	SP	A **1-mL dose** contains 25 μg of the Vi polysaccharide of *Salmonella typhi* and 160 antigen units of inactivated HA viral antigen
HepB/HepA	*Twinrix Junior*	GSK	Not less than 360 EU inactivated HepA virus and 10 μg recombinant HBsAg protein; 0.025 mg $Al(OH)_3$, 0.2 mg $AlPO_4$, 2.5 mg 2-PE
	Twinrix Adult	GSK	A **1-mL dose** contains not less than 720 EU inactivated HA virus and 20 μg recombinant HBsAg protein; 0.05 mg $Al(OH)_3$, 0.4 mg $AlPO_4$, 5.0 mg 2-PE
MMRV	*Priorix Tetra*	GSK	$\geq 10^{3.0}$ $CCID_{50}$ live attenuated measles virus (Schwarz strain); $\geq 10^{4.4}$ $CCID_{50}$ live attenuated mumps virus (RIT 4385 strain, derived from Jeryl Lynn strain); $\geq 10^{3.0}$ $CCID_{50}$ live, attenuated rubella virus (Wistar RA 27/3 strain); $\geq 10^{3.3}$ PFU live attenuated varicella virus (OKA strain); amino acids, lactose, mannitol, sorbitol, neomycin sulfate residue, water for injection
	ProQuad (refrigerated version)	Merck	≥3.00 $\log_{10}$ $TCID_{50}$ of measles virus; 4.30 $\log_{10}$ $TCID_{50}$ of mumps virus; 3.00 $\log_{10}$ $TCID_{50}$ of rubella virus; ≥3.99 $\log_{10}$ PFU of Oka/Merck varicella virus, 20 mg sucrose, 11 mg hydrolyzed gelatin, 2.5 mg urea; 2.3 mg NaCl, 16 mg sorbitol, 0.38 mg monosodium L-glutamate, 0.14 mg sodium phosphate, 0.25 mg human albumin, 0.13 mg sodium bicarbonate, 94 μg potassium phosphate, 58 μg of potassium chloride; residual components of MRC-5 cells including DNA and protein; 5 μg neomycin, bovine serum albumin (0.5 μg), and other buffer and media ingredients
EUROPEAN UNION			
Td/IPV	*Revaxis*	SPMSD	At least 2 IU DT, 20 IU TT, and poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU) and 3 (Saukett, 32 DU); $Al(OH)_3$, 2-PE
DTwP/Hib	*QuattVaxem*	Novartis	At least 30 IU DT, 60 IU TT, 2 IU wP, 10 μg PRP conjugated to 25 μg CRM_{197}, 1.36 mg $AlPO_4$, 0.05 mg thimerosal
DTaP/IPV	*DiTeKiPol*	SSI	At least 30 IU (25 Lf) DT, at least 40 IU (7 Lf) TT, 40 μg PT, and at least 60% of the following poliovirus amounts: type 1 (Brunhilde), 40 DU; type 2 (MEF-1), 8 DU; type 3 (Saukett), 32 DU; 1 mg aluminum (as hydroxide), 0.3 mg sodium dihydrogen phosphate dihydrate, <25 μg formaldehyde, <0.2 μg neomycin, trace phenolsulfonphthalein
	Infanrix IPV, Infanrix Tetra	GSK	At least 30 IU DT, at least 40 IU TT, 25 μg PT, 25 μg FHA, 8 μg PRN, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU), and 3 (Saukett, 32 DU); 0.5 mg $Al(OH)_3$, 2.5 mg 2-PE

TABLE 15.2 Combination Vaccines Currently Available in Canada, European Union, or United States[a] *(Continued)*

Combination	Trade Name	Source	Each 0.5-mL Dose (After Reconstitution, if Applicable) Is Formulated to Contain (See Listing by Country, Below, for Specific Information Regarding Composition)
	Tetravac	SPMSD	At least 30 IU DT, at least 40 IU TT, 25 μg PT, 25 μg FHA, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU), and 3 (Saukett, 32 DU); 0.3 mg $Al(OH)_3$, 2.5 μL 2-PE, 12.5 μg formaldehyde
Tdap/IPV	*Boostrix IPV* *Boostrix Polio*	GSK	2 Lf DT, 5 Lf TT, 8 μg PT, 8 μg FHA, 2.5 μg PRN, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU) and 3 (Saukett, 32 DU), 0.6% ± 0.1% (v/v) 2-PE, 0.39 mg Al (as $Al(OH)_3$ and $AlPO_4$), trace formaldehyde, polymyxin B and neomycin
	Repevax	SPMSD	2 Lf DT, 5 Lf TT, 2.5 μg PT, 5 μg FHA, 3 μg PRN, 5 μg FIM types 2 and 3, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU) and 3 (Saukett, 32 DU), 0.6% ± 0.1% (v/v) 2-PE, 1.5 mg $AlPO_4$, trace polymyxin B and neomycin
DTaP/Hib	*Infanrix Hib*	GSK	At least 30 IU DT, at least 40 IU TT, 25 μg PT, 25 μg FHA, 8 μg PRN, and 10 μg PRP conjugated to TT; 0.5 mg $Al(OH)_3$, 2.5 mg 2-PE
DTaP/IPV/Hib	*DiTeKiPol/Act-Hib*	SSI	At least 30 IU (25 Lf) DT, at least 40 IU (7 Lf) TT, 40 μg PT, at least 60% of the following poliovirus amounts: type 1 (Brunhilde), 40 DU; type 2 (MEF-1), 8 DU; type 3 (Saukett), 32 DU, and 10 μg *Haemophilus influenzae* type b polysaccharide conjugated to TT; 1 mg aluminum (as hydroxide), 0.3 mg sodium dihydrogen phosphate dihydrate, <25 μg formaldehyde, <0.2 μg neomycin, trace phenolsulfonphthalein, trometamol
	Infanrix IPV Hib, *Infanrix Quinta*	GSK	At least 30 IU DT, at least 40 IU TT, 25 μg PT, 25 μg FHA, 8 μg PRN, poliomyelitis vaccine types 1 (Mahoney, 40D), 2 (MEF-1, 8D), and 3 (Saukett, 32D), and 10 μg PRP conjugated to TT; 0.5 mg $Al(OH)_3$, 2.5 mg 2-PE
	Pediacel	SPMSD	20 μg PT, 20 μg FHA, 3 μg PRN, 5 μg FIM types 2 and 3, 15 Lf DT, 5 Lf TT, poliomyelitis vaccine types 1 (Mahoney, 40D), 2 (MEF-1, 8D) and 3 (Saukett, 32D), 10 μg PRP conjugated to 20 μg TT, 0.6% ± 0.1% (v/v) 2-PE, 1.5 mg $AlPO_4$; trace streptomycin, polymyxin B, and neomycin may be present
	Pentavac, *Pentaxim*	SPMSD	At least 30 IU DT, at least 40 IU TT, 25 μg PT, 25 μg FHA, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU), and 3 (Saukett, 32 DU), and 10 μg *H. influenzae* type b polysaccharide conjugated to TT; 0.3 mg $Al(OH)_3$, 2.5 μL 2-PE, 12.5 μg formaldehyde
DTaP/IPV/HepB	*Infanrix Penta*	GSK	At least 30 IU DT, at least 40 IU TT, 25 μg PT, 25 μg FHA, 8 μg PRN, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU), and 3 (Saukett, 32 DU), and 10 μg recombinant HBsAg protein; 0.5 mg $Al(OH)_3$, 0.2 mg $AlPO_4$, 2.5 mg 2-PE
DTaP/IPV/HepB//Hib	*Infanrix hexa*	GSK	At least 30 IU DT, at least 40 IU TT, 25 μg PT, 25 μg FHA, 8 μg PRN, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU), and 3 (Saukett, 32 DU), 10 μg recombinant HBsAg protein, and 10 μg PRP conjugated to TT; 0.5 mg $Al(OH)_3$, 0.32 mg $AlPO_4$, 2.5 mg 2-PE
	Hexyon, Hexaxim, *Hexacima*	SPMSD	Pertussis (FHA 25 μg; PT 25 μg), DT >20 IU, TT ≥40 IU, *H. influenzae* type b polysaccharide 12 μg conjugated to tetanus protein 22–36 μg, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU), and 3 (Saukett, 32 DU), 10 μg recombinant hepatitis B antigen, 0.6 mg Al^{3+} as hydrated aluminum hydroxide, Disodium hydrogen phosphate, dihydrogen potassium phosphate, trometamol, saccharose, essential amino acids including L-phenylalanine, and traces of glutaraldehyde, formaldehyde, neomycin, streptomycin, and polymyxin B which are used during the manufacturing process
HepB/HepA	*Twinrix pediatric*	GSK	Not less than 360 EU inactivated HA virus and 10 μg recombinant HBsAg protein; 0.025 mg $Al(OH)_3$, 0.2 mg $AlPO_4$, 2.5 mg 2-PE
	Ambirix (2-dose pediatric series)	GSK	A **1-mL dose** contains not less than 720 EU inactivated HA virus and 20 μg recombinant HBsAg protein; 0.05 mg $Al(OH)_3$, 0.4 mg $AlPO_4$, 5.0 mg 2-PE
	Twinrix adult	GSK	A **1-mL dose** contains not less than 720 EU inactivated HA virus and 20 μg recombinant HBsAg protein; 0.05 mg $Al(OH)_3$, 0.4 mg $AlPO_4$, 5.0 mg 2-PE
HepA/Typhoid	*Hepatyrix*	GSK	A **1-mL dose** contains 25 μg of the Vi polysaccharide of *Salmonella typhi* and not less than 1440 ELISA units of inactivated HA viral antigen; 0.5 mg $Al(OH)_3$, 5.0 mg 2-PE

TABLE 15.2 Combination Vaccines Currently Available in Canada, European Union, or United States[a] *(Continued)*

Combination	Trade Name	Source	Each 0.5-mL Dose (After Reconstitution, if Applicable) Is Formulated to Contain (See Listing by Country, Below, for Specific Information Regarding Composition)
	ViATIM, Vivaxim, Tyavax	SP	A **1-mL dose** contains 25 μg of the Vi polysaccharide of *S. typhi* and 160 antigen units of inactivated HA viral antigen
MnC/Hib	*Menitorix*	GSK	5 μg *Neisseria meningitidis* serogroup C (strain C11) polysaccharide conjugated to 5 μg TT; 5 μg PRP conjugated to 12.5 μg TT
MMRV	*Priorix Tetra*	GSK	$\geq 10^{3.0}$ $CCID_{50}$ live attenuated measles virus (Schwarz strain); $\geq 10^{4.4}$ $CCID_{50}$ live attenuated mumps virus (RIT 4385 strain, derived from Jeryl Lynn strain); $\geq 10^{3.0}$ $CCID_{50}$ live, attenuated rubella virus (Wistar RA 27/3 strain); $\geq 10^{3.3}$ PFU live attenuated varicella virus (OKA strain); amino acids, lactose, mannitol, sorbitol, neomycin sulfate residue, water for injection
	ProQuad (Refrigerated version)	SPMSD	≥3.00 $\log_{10}$ $TCID_{50}$ of measles virus; 4.30 $\log_{10}$ $TCID_{50}$ of mumps virus; 3.00 $\log_{10}$ $TCID_{50}$ of rubella virus; ≥3.99 $\log_{10}$ PFU of Oka/Merck varicella virus, 20 mg sucrose, 11 mg hydrolyzed gelatin, 2.5 mg urea; 2.3 mg NaCl, 16 mg sorbitol, 0.38 mg monosodium L-glutamate, 0.14 mg sodium phosphate, 0.25 mg human albumin, 0.13 mg sodium bicarbonate, 94 μg potassium phosphate, 58 μg of potassium chloride; residual components of MRC-5 cells including DNA and protein; 5 μg neomycin, bovine serum albumin (0.5 μg), and other buffer and media ingredients
UNITED STATES			
DTaP/IPV	*Kinrix*	GSK	25 Lf DT, 10 Lf TT, 25 μg PT, 25 μg FHA, 8 μg PRN, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU), and 3 (Saukett, 32 DU), ≤0.6 mg aluminum, ≤100 μg formaldehyde, ≤100 μg polysorbate 80, ≤0.05 ng neomycin, ≤0.01 ng polymyxin B
	Quadracel	SP	15 Lf DT, 5 Lf TT, 20 μg PT, 20 μg FHA, 3 μg PRN, 5 μg FIM, 40 DU type 1 (Mahoney), 8 DU type 2 (MEF-1), 32 DU type 3 (Saukett), 1.5 mg aluminum phosphate (0.33 mg aluminum) as the adjuvant, polysorbate 80 (approximately 10 ppm by calculation), ≤5 μg residual formaldehyde, <50 ng residual glutaraldehyde, ≤50 ng residual bovine serum albumin, 3.3 mg (0.6% v/v) 2-phenoxyethanol (not as a preservative), <4 pg of neomycin, and <4 pg polymyxin B sulfate
DTaP/IPV/HepB	*Pediarix*	GSK	25 Lf DT, 10 Lf TT, 25 μg PT, 25 μg FHA, 8 μg PRN, poliomyelitis vaccine types 1 (Mahoney, 40 DU), 2 (MEF-1, 8 DU), and 3 (Saukett, 32 DU), and 10 μg of recombinant HBsAg protein; 0.5 mg $Al(OH)_3$, 0.2 mg $AlPO_4$, 2.5 mg 2-phenoxyethanol
DTaP/IPV//Hib	*Pentacel*	SP	15 Lf DT, 5 Lf TT, 20 μg PT, 20 μg FHA, 3 μg PRN, 5 μg FIM, 40 DU type 1 (Mahoney), 8 DU type 2 (MEF-1), 32 DU type 3 (Saukett), 10 μg PRP conjugated to 24 μg TT, 1.5 mg aluminum phosphate (0.33 mg aluminum), polysorbate 80 (approximately 10 ppm by calculation), ≤5 μg residual formaldehyde, <50 ng residual glutaraldehyde, ≤50 ng residual bovine serum albumin, 3.3 mg (0.6% v/v) 2-phenoxyethanol (not as a preservative), <4 pg of neomycin, and <4 pg polymyxin B sulfate
DTaP/IPV/HepB/Hib	*TBD*	SP	15 Lf DT, 5 Lf TT, 20 μg PT, 20 μg FHA, 3 μg PRN, 5 μg FIM, 29 DU type 1 (Mahoney), 7 DU Type 2 (MEF-1), 26 DU Type 3 (Saukett), 3 μg PRP covalently bound to 50 μg OMPC, 10 μg of recombinant HBsAg protein, aluminum salts as adjuvant (a total of 319 μg aluminum), ≤100 μg residual formaldehyde, ≤50 ng residual glutaraldehyde, ≤50 ng residual bovine serum albumin, <5 ng of neomycin, <200 ng streptomycin sulfate, <25 ng polymyxin B sulfate, ≤0.125 μg ammonium thiocyanate, and ≤0.1 μg yeast protein (maximum 1% relative to HBsAg protein)
HepB/HepA	*Twinrix*	GSK	A **1-mL dose** contains not less than 720 EU of inactivated HA virus and 20 μg of recombinant HBsAg protein, 0.45 mg aluminum (as hydroxide and phosphate), 5 mg 2-PE, and trace thimerosal (<1 μg mercury), formalin (not more than 0.1 mg), MRC-5 proteins (not more than 2.5 μg), amino acids, yeast proteins, neomycin, and polysorbate 20

TABLE 15.2 Combination Vaccines Currently Available in Canada, European Union, or United States[a] *(Continued)*

Combination	Trade Name	Source	Each 0.5-mL Dose (After Reconstitution, if Applicable) Is Formulated to Contain (See Listing by Country, Below, for Specific Information Regarding Composition)
MnCY/Hib	*MenHibrix*	GSK	5 μg of purified *Neisseria meningitidis* C capsular polysaccharide conjugated to approximately 5 μg of tetanus toxoid, 5 μg of purified *N. meningitidis* Y capsular polysaccharide conjugated to approximately 6.5 μg of tetanus toxoid, and 2.5 μg of purified *H. influenzae* b capsular polysaccharide conjugated to approximately 6.25 μg of tetanus toxoid, 96.8 μg of Tris (trometamol)-HCl, 12.6 mg of sucrose, and ≤0.72 μg of residual formaldehyde
MMRV	*ProQuad* (frozen version)	Merck	≥3.00 $\log_{10}$ $TCID_{50}$ of measles virus; 4.30 $\log_{10}$ $TCID_{50}$ of mumps virus; 3.00 $\log_{10}$ $TCID_{50}$ of rubella virus; ≥3.99 $\log_{10}$ PFU of Oka/Merck varicella virus, ≤21 mg sucrose, 11 mg hydrolyzed gelatin, 2.4 mg NaCl, 1.8 mg sorbitol, 0.4 mg monosodium L-glutamate, 0.34 mg sodium phosphate dibasic, 0.31 mg human albumin, 0.17 mg sodium bicarbonate, 72 μg potassium phosphate monobasic, 60 μg of potassium chloride; 36 μg potassium phosphate dibasic; residual components of MRC-5 cells including DNA and protein; <16 μg neomycin; bovine serum albumin (0.5 μg); and other buffer and media ingredients

Note: While this text was in press, Merck and Sanofi Pasteur announced that their European joint venture, SPMSD, was being dissolved; in the future, products marketed by SPMSD would instead be marketed by their respective manufacturers.

aP, acellular pertussis vaccine (infant formulation); ap, acellular pertussis vaccine (adolescent/adult formulation); D, diphtheria toxoid vaccine (infant formulation); d, diphtheria toxoid vaccine (adolescent/adult formulation); DU, D-antigen units; ELISA, enzyme-linked immunosorbent assay; EU, enzyme-linked immunosorbent assay (ELISA) units; FHA, filamentous hemagglutinin; FIM, fimbrial proteins; GSK, GlaxoSmithKline; HBsAg, hepatitis B surface antigen; HepA, hepatitis A vaccine; HepB, hepatitis B vaccine; Hib, conjugate *Haemophilus influenzae* type b vaccine; IPV, enhanced inactivated trivalent poliovirus vaccine; IU, international units; Lf, limit of flocculation; MMRV, measles-mumps-rubella-varicella; PCVn, n-valent pneumococcal conjugate vaccine; PFU, plaque-forming units; ppm, parts per million; PRN, pertactin; PRP, polyribosylribitol phosphate; PT, pertussis toxoid; SP, Sanofi Pasteur; SPMSD, Sanofi Pasteur MSD; SSI, Statens Seruminstitut; T, tetanus toxoid vaccine; TCID50, median tissue culture infective dose; v/v, volume in volume; wP, whole-cell pertussis vaccine. See Table 44.6 for information on prior names of pharmaceutical companies.

[a]Products combining only multiple serotypes of a single pathogen are excluded, as are DT (diphtheria and tetanus toxoids–pediatric), Td (diphtheria and tetanus toxoids–adult), DTP (diphtheria, tetanus, pertussis), DTaP (diphtheria, tetanus toxoids, and acellular pertussis), Tdap (tetanus, diphtheria, and pertussis), OPV (oral polio vaccine), IPV (inactivated polio vaccine), MMR (measles, mumps, rubella), and MMRV (measles-mumps-rubella-varicella). Excludes products that are licensed but not distributed. Only those manufacturers who distribute their products internationally are listed; other manufacturers may produce some products (e.g., DTP/IPV) for local or regional use. No discrimination is made between products distributed in combined form and those distributed in separate containers, for combination at the time of use.

separate routes). Although some studies have shown altered immune responses to various vaccines when they are given concurrently with other vaccines but at separate sites, there is no evidence that the efficacy of any vaccine recommended for routine use in childhood is materially altered by concomitant administration with any other vaccines recommended for administration at the same age.[5] Similarly, adverse events after concomitant administration of multiple vaccines generally are increased only modestly, if at all, compared with events after the administration of the most reactogenic vaccine alone. Thus, we will not review the many studies that have evaluated simultaneous administration, except to the extent that they provide reference data to which results from combined vaccines can be compared.

Combination Vaccines and the Immune System

Antibodies recognize conformationally determined epitopes on protein or polysaccharide antigens. Modification of an antigen's B-cell epitopes during vaccine preparation may reduce the ability of vaccine-induced antibody to bind to the pathogen. Consequently, the techniques used to produce an antigen may have important implications for the immunogenicity (and, presumably, the efficacy) of a vaccine containing that antigen.[6] This principle is illustrated by the results from the Multicenter Acellular Pertussis Trial, which compared 13 acellular pertussis (aP) vaccines and found that levels of antibody to pertussis toxin correlated poorly with the quantity of toxoided pertussis toxin present in the vaccines.[7] For example, one of the acellular vaccines contained a genetically inactivated pertussis toxin produced by recombinant technology. This vaccine produced markedly higher antibody responses per microgram than did the remainder of the evaluated vaccines, whose pertussis toxin components were inactivated chemically rather than genetically.[7]

Carrier-Induced Epitopic Modification

Theories regarding the human immune response and vaccine studies in animals and humans suggest that simultaneous exposure to multiple conjugate antigens might result in enhanced or diminished immune responses.[8–12]

The phenomenon of carrier-induced epitope-specific modification (suppression or enhancement) of the immune response is one in which antibody responses to haptens presented on a carrier are inhibited or augmented by prior immunization with the specific carrier. Studies in animals show that the dose, route, choice of carrier protein, and presence of adjuvant all contribute to determining whether epitopic suppression or enhancement of the immune response occurs. Suppression more frequently occurs when large amounts of carrier protein are used for priming and high anticarrier antibody titers are achieved.[13] Concurrent administration of two conjugate vaccines using the same carrier also may lead to interference. For example, a study among infants given a combination vaccine containing Hib capsular polysaccharide (polyribosylribitol phosphate [PRP]) conjugated to tetanus toxoid (PRP-T) plus a quadrivalent pneumococcal conjugate

vaccine (PCV) conjugated to tetanus or diphtheria toxoid found reduced Hib antibodies among the infants whose vaccine was conjugated to tetanus toxoid rather than diphtheria toxoid.[14] Another study showed markedly reduced antibody responses to tetanus-conjugated serotypes in a PCV11 when administered concomitantly with a DTaP2/IPV//PRP-T combination vaccine.[15]

These data make it clear that the effect of prior or concomitant administration of proteins used in conjugate vaccines is unpredictable and must be evaluated for each vaccine combination, and the data have prompted evaluation of alternative protein carriers (e.g., protein D from nontypeable *H. influenzae*, as used in a PCV; see below and Chapter 46).

Another interesting example of interference was observed in studies of infants randomized to receive aP3 vaccine or HepB vaccine at birth; all subsequently received DTaP3/IPV/HepB//PRP-T vaccine at 2, 4, 6, and 12 to 23 months. Robust pertussis antibody responses were seen in all, but those given aP at birth had substantially lower responses to both HepB and Hib after the primary series and after the toddler booster, as well as lower diphtheria antibody levels preceding and following the booster.[16,17]

Other Issues Affecting Immune Responses

Chemical or physical interactions among the vaccine components being combined can result in an alteration of the immune response to vaccine.[13] Adjuvants such as aluminum hydroxide and aluminum phosphate bind to inactivated vaccines by noncovalent ionic binding. The combination of one vaccine that is generally administered with adjuvant with another vaccine that is not administered with adjuvant may lead to displacement of the adjuvant and reduced immunogenicity of the first vaccine. Furthermore, the adjuvant might combine with the second antigen and thereby alter the immune response to the second vaccine as well.

Buffers, stabilizers, excipients, and similar components included in one vaccine may interfere with the components of another vaccine (e.g., thimerosal can destroy the potency of IPV). Although such vaccines cannot be shipped mixed together in a single vial, distribution of the two vaccines in a dual-chambered syringe circumvents this problem.[18,19]

When combining different live attenuated viral vaccine strains, competition between the viruses is the most frequently observed problem. It can be circumvented by increasing the number of vaccine doses (e.g., live attenuated poliovirus vaccine) or modifying the concentrations of the individual viral strains in the vaccine (e.g., MMR and MMRV [measles-mumps-rubella-varicella]).[20]

The interpretation of antibody responses requires correlation of antibody responses with protection from disease. For discussions of correlates of protection, please refer to Chapter 3 and to earlier editions[20] of the present chapter.

Other Impediments to the Development of Combination Vaccines

Combination vaccines can present difficult issues with respect to investment of the funds necessary for clinical development. Typically, at the moment of commercial introduction of a new combination vaccine, its component vaccines already are available and would continue to be used instead of the combination, should the combination's price exceed the additional amount buyers are willing to pay for the convenience of the combination. Thus, the price of the combination is effectively capped, and its costs of development must be expected to be recoverable within that cap or the combination will not be developed. Moreover, systems that base compensation on the number of separate vaccines administered create perverse incentives to avoid combination vaccines.

Patent and other proprietary issues also complicate the generation of combination vaccines. Vaccine manufacturers cannot market vaccines that contain antigens they do not own or license. The best possible combination vaccine might be one that incorporated components from two or more manufacturers, but, absent agreement between the companies, this combination will not become available. Although the dramatic consolidation in recent years among vaccine manufacturers has eased this problem, as have cross-licensing agreements, it has not fully disappeared.

Combining multiple antigens into one injection requires demonstration in clinical trials that the combination will not materially reduce the safety or immunogenicity of the component vaccines (and, in some instances, that efficacy is retained).[21–23] Two strategies are commonly followed. One strategy involves comparing the new vaccine with a previously approved combination vaccine that differs by lacking only a single component that has been added to the new combination. This approach has generally been followed in the European Union, which has approved a full range of combinations, each adding one further antigen. When this approach is followed, the sponsor might have several predecessor combinations to choose from; for example, either DTaP/IPV + Hib or DTaP/Hib + IPV might serve as the control group for a study of a DTaP/IPV/Hib vaccine. In such cases, one almost always finds that the choice made was the one with the lowest risk of failure (e.g., comparing with DTaP/Hib + IPV rather than DTaP/IPV + Hib avoids the risk of revealing once again a reduced Hib response in the combination as compared with separately administered Hib). In the other approach, the new combination is evaluated against each of its major building blocks given alone. For example, a DTaP/IPV/Hib combination vaccine might be compared with concurrent but separate injections of DTaP, trivalent IPV, and Hib vaccines. This has been the approach in the United States, where separate injections have represented the standard of care. However, in 2015 the U.S. Food and Drug Administration (FDA) approved a DTaP/IPV/Hib/HepB vaccine that was evaluated following the European approach.

Another advantage of a study that incorporates a previously evaluated combination vaccine is that it may allow comparison of the current results with those obtained in other arms of an earlier study. This bridging technique was used in the Swedish aP efficacy trials to compare the results from each trial.[24–26] The methodological risks of this approach can be reduced through coordinated efforts to enhance the comparability of serologic and reaction data gathered for similar vaccines in independent studies.

Multicenter studies allow larger enrollments—and thus more arms—than are possible at a single institution and, with the increasing sample-size demands of regulatory agencies, have become the norm. A multicenter trial that is well designed with standardized protocols can be an effective means of evaluating multiple vaccines or multicomponent products, as was shown by the Multicenter Acellular Pertussis Trial.[7] The Swedish and Italian DTaP efficacy trials, with their coordinated protocols and control vaccines, are other pertinent examples.[24,27]

Licensure of Combination Vaccines

To be licensed, vaccines must be demonstrated to be safe and effective. For example, U.S. law states that a combination

pharmaceutical product may be licensed when "combining of the active ingredients does not decrease the purity, potency, safety, or effectiveness of any of the individual active components" (21 CFR 601.25[d][4]). Most licensing authorities have similar criteria for the evaluation of these parameters.

Evaluating Effectiveness

It is uncommon to require an efficacy trial for a vaccine that combines components previously proven efficacious; instead, demonstration of adequate immunogenicity is required. Commonly, the sponsor licenses combination products by conducting noninferiority trials, which provide statistical assurance that the investigational product is not inferior by more than a predefined margin (e.g., no more than a 10% difference in seroprotection rates) as compared with the standard products. A product that meets noninferiority criteria might be superior or might be equivalent, but is not inferior to the standard (or, at least, no more inferior than the prespecified margin).

In any study of finite size, the results represent a point estimate within a definable confidence interval. For typical outcomes of interest in studies of manageable size (e.g., 300–1,000 participants), the 95% confidence interval can easily span a 10% range (for such measures as seroprotection or fever rates) or a 1.5:1 ratio (for such measures as geometric mean antibody titers [GMTs]). Thus, although it might seem that the noninferiority margin should be set to zero so that the possibility of inferiority is completely excluded, doing so would have the undesirable effect of rejecting new products that are truly equivalent or even superior.

An FDA Guidance Document[28] regarding combination vaccines states that "If antibody concentrations induced by the combination vaccine are lower than those induced by the component vaccines, a 'protective' antibody level might still be attained." Although appropriate, this principle can prove difficult to apply in practice because of uncertainty regarding such factors as the level of circulating antibody necessary to confer protection; the minimum antibody concentration (if any) necessary for protection of a person for whom immune memory has been established; whether there is a minimum seroconversion rate required for population protection; and whether achieving antibody concentrations that substantially exceed the minimum necessary to confer personal protection provides any further benefit (e.g., by suppressing colonization and thereby reducing transmission or by assuring prolonged protection).

In the face of these difficulties, the FDA has generally been unwilling to proceed with licensure of combination products whose immune performances fail statistical noninferiority, pointing out that the option always exists to conduct an efficacy or effectiveness trial of the combination and thereby escape the need for noninferiority with respect to a reference vaccination regimen. Unfortunately, for many antigens of interest (including DTP, Hib, and HepB), it is no longer possible to conduct such efficacy trials: There simply is no place left in the world where the disease in question is sufficiently prevalent, an effective vaccine is not available and recommended, and conduct of a large randomized trial is logistically possible.

Evaluating Safety

As a general rule, systemic adverse events are increased only modestly, if at all, after concurrent administration of multiple vaccines compared with events after the administration of the most reactogenic vaccine alone. Local adverse events often are somewhat more common and more severe at the site of injection of the combination, but this increase usually is offset by the avoidance of adverse events that would have been caused by the eliminated separate injections. So far, no combination vaccine has elicited a new type of reaction not previously seen with its separate components.

Recent years have seen an increase in sample-size requirements for safety testing from licensing authorities in general and from the FDA in particular. In addition, many authorities expect some (or most) of the safety data to be obtained among subjects from their own countries. Both trends slow licensure without necessarily providing commensurate benefits. There is little evidence that populations differ materially in the nature or rates of vaccine-associated adverse events, and large increases in sample size require substantial increases in resources while yielding only small increases in statistical power. These issues particularly impact combination vaccines, which commonly do not provide new antigens but merely a more convenient presentation and whose uptake therefore is sensitive to price, as discussed earlier.

Question of Multiple Antigens and Immune Overload

Despite being repeatedly debunked, the assertion continues to circulate—particularly on the Internet—that the normal infant immune system is capable of becoming "overloaded" and that vaccination with multiple antigens can induce such overload. There is no evidence to support such an assertion and much evidence to refute it.[29–32] Indeed, it may be true that the infant immune system requires fairly intensive challenge to develop normally and that insufficient stimulation leads to an increased risk of autoimmune disorders.[33,34]

A concern that infant immune systems may be overwhelmed by simultaneous exposure to several antigens is difficult to entertain when one considers the thousands of antigens to which a newborn is naturally exposed in the first few months of life. Moreover, although more vaccines are administered today, far fewer antigens are delivered than in the past, when DTwP and vaccinia were used routinely.[30]

The Institute of Medicine reviewed this issue and concluded that the evidence favored rejection of a causal relationship between multiple immunizations and an increased risk of type 1 diabetes or heterologous infections and was inadequate to accept or reject a causal relationship with allergic disease, particularly asthma.[35]

Postmarketing Surveillance

Unexpected events occurring soon after vaccination, especially if severe enough to require medical attention, should always be reported. In the United States, the National Childhood Vaccine Injury Act requires healthcare providers and manufacturers to report serious adverse events after vaccination to the Vaccine Adverse Event Reporting System (VAERS),[36] established to provide a single system for collection and analysis of reports of all adverse events associated with vaccines. Because the VAERS reports can be submitted by any concerned person, whether parent, provider, recipient, or observer; are spontaneous and passively collected; and do not provide the ability to calculate reliable population-based rates, they are useful for generating hypotheses but not for testing them. Increasingly, postmarketing surveillance is being facilitated by the use of large databases linking information sources such as pharmacies, healthcare providers, hospitals, and commercial healthcare organizations.[37–40] Integrated data information systems maintained by some governments for their publicly financed

medical care or hospitalization programs also have been used for this purpose.[41,42]

COMBINATIONS BASED ON DTWP (OR ITS COMPONENTS)

As noted earlier, DTwP was developed in 1943 and licensed in the United States in 1948. Its component antigens had long been available separately: the first pertussis vaccine (see Chapter 44) was licensed to the Massachusetts Public Health Biological Laboratories in 1914; mixtures of diphtheria toxin and antitoxin came into use the same year; alum-precipitated diphtheria toxoid (see Chapter 19) was licensed in 1926; and adsorbed tetanus toxoid (see Chapter 58) was licensed in 1937.[3] Whole-cell pertussis vaccine is a potent adjuvant, and the combining of the three antigens in DTwP actually improved the immunogenicity of the toxoids compared with separate administration.[43,44] Adsorption of the vaccines with aluminum further improved immunogenicity while decreasing the severity of adverse reactions associated with pertussis vaccine.[45,46]

Advances in tissue culture techniques permitted the development of trivalent IPV (see Chapter 48), which underwent extensive field trials in 1954. These trials found 90% efficacy against poliovirus types 2 and 3 but only approximately 70% efficacy against type 1.[47] Investigation revealed that the preservative thimerosal inactivated poliovirus, with greater impact on type 1 than types 2 or 3; in response, other preservatives were substituted. Further improvements in production techniques in the late 1970s led to enhanced-potency IPV, which provides substantially higher immunogenicity.[48–50] There is no evidence of interference between the inactivated vaccine strains themselves, unlike the situation with trivalent OPV (see Chapter 49).

DTwP-based combination vaccines have disappeared from North America and most of Europe, but have become a mainstay of public vaccination programs in other parts of the world. The DTwP-based combinations in international distribution that are most widely used are those from Bio Farma (DTwP/HepB and DTwP/HepB/Hib), GlaxoSmithKline (DTwP/Hib and DTwP/HepB/Hib), Johnson & Johnson (Crucell; DTwP/HepB and DTwP/HepB/Hib), Panacea (DTwP/HepB and DTwP/HepB/Hib), Sanofi Pasteur (DTwP/Hib and DTwP/IPV/Hib), and Serum Institute of India (SII; DTwP/HepB, which can be used to reconstitute SII Hib vaccine). The changes since the last edition in the preceding list and in Tables 15.1 and 15.2 reflect the continued growth of local Asian producers, who now are the principle suppliers of DTwP-based vaccines (particularly the pentavalent DTwP/HepB/Hib vaccines now widely used in Expanded Programme for Immunization [EPI] programs) to the international markets and various donor or World Health Organization (WHO) agencies. At the same time, these new entrants to the global marketplace have faced growing pains; between 2010 and 2012, vaccines from Bharat Biotech, Panacea, and Shantha lost WHO prequalification status for quality issues (DTwP/HepB/Hib vaccines from Panacea and Shantha subsequently regained prequalification status).[51,52]

With the growing likelihood of replacement of OPV with IPV, IPV-containing combination vaccines hold enormous attraction for EPI program countries. Yet, numerous problems remain, including: all currently available combination vaccines containing IPV are DTaP-based, posing issues of per-dose cost and number of doses needed per child; IPV remains the most expensive single component, with a cost to WHO comparable per dose to that of DTwP/HepB/Hib; manufacturing capability of IPV based on wild-type poliovirus has resided only with the European manufacturers; EPI programs require multidose vials, but as noted, thimerosal is incompatible with IPV; and, stability of the Hib component requires either reconstitution just prior to use, or, for most DTwP vaccines, redevelopment using a different aluminum adjuvant.[53] These barriers are being addressed in several ways: SII has acquired from The Netherlands government Bilthoven Biologicals, a manufacturer of IPV and a developer of Sabin-strain IPV (sIPV) vaccines; GlaxoSmithKline and Biological E have formed a joint venture to develop a DTwP/IPV/HepB/Hib vaccine; Shantha, now owned by Sanofi Pasteur, has gained access to their IPV; and sIPVs are increasingly becoming available.[53,54] Still, it is unlikely that DTwP/IPV/HepB/Hib vaccines will soon become available.

In general, combinations of DTwP with IPV, HepB, and/or Hib do not demonstrate meaningful interference among their components and do not result in adverse reactions that materially exceed, in frequency or severity, those seen with the same DTwP vaccine given alone. Summary information regarding the various classes of DTwP combination vaccines is provided subsequently. Readers interested in additional details are referred to earlier editions of this text.

DTwP/IPV, DT/IPV, and Td/IPV

Clinically important interference among the diphtheria, tetanus, whole-cell pertussis (wP), and IPV components has not been commonly demonstrated for currently available combinations incorporating those antigens (Table 15.3).[18,19,55–76] In the studies in which combination recipients showed reduced antibody responses to diphtheria and tetanus, all or nearly all nevertheless achieved seroprotective levels. Similarly, pertussis and poliovirus seroconversion rates and absolute antibody levels remained high, even with combined vaccine; the clinical importance of any reduction in mean antibody levels, for polio or pertussis, is unknown.

DTwP/Hib (With or Without IPV)

Many studies have shown that administering DTwP and Hib in combination results in reduced mean PRP antibody levels compared with giving the same components separately (see Table 15.3). However, even in studies with statistically significant reductions,[18,55,56] antibody levels still were high (albeit not as high as with separate administration) and at least 90% of children (typically, >95%) developed greater than 1 μg/mL of antibody to PRP. Thus, reduced immunogenicity of Hib when given in combination with DTwP is most often of no clinical importance. Gold and colleagues[58] demonstrated reduced levels of Hib, tetanus, and some pertussis antibodies following DTwP/IPV/Hib compared to separate vaccines, but those results may have been specific to that combination.

Surveillance data provide further reassurance that use of the combined DTwP//PRP-T does not reduce efficacy in comparison with DTwP and PRP-T administered separately. In Chile, surveillance for pertussis in matched areas that used DTwP alone or DTwP//PRP-T found no significant difference in the rates of pertussis in the two areas.[77] In the area using DTwP//PRP-T, efficacy against invasive Hib disease was more than 90%. Surveillance in Canada found a continued low rate of invasive Hib disease after the licensure and widespread use of DTwP/PRP-T in that country, with no change in the extremely low rates of vaccine failure.[78,79] Similarly, there was no increase in invasive Hib disease in the United States after the 1993 licensure of DTwP//PRP-T and a similar product, DTwP/HbOC (PRP-*Hib* oligosaccharide conjugate; Tetramune, Wyeth Lederle Vaccines & Pediatrics).[80]

None of the combinations that include DTwP and any conjugate Hib vaccine is associated with materially increased

TABLE 15.3 Studies Comparing Combined or Simultaneous Administration of DTwP/IPV, DTwP/Hib, and DTwP/IPV/Hib Vaccines for Primary Immunization of Infants

AGG, pertussis agglutinins; D, diphtheria toxin; DCS, dual-chamber syringe; DTwP, diphtheria and tetanus toxoids and whole cell pertussis vaccine; DTwPc, DTwP produced by Connaught Laboratories (Canada); DTwPe, DTwP produced by Wellcome Laboratories (England); DTwPf, DTwP produced by Sanofi Pasteur (France); DTwPg, DTwP produced by Chiron Vaccines, Marburg, Germany; DTwPn, DTwP produced by National Public Health Institute of Finland; DTwPs, DTwP produced by Serum Institute of India; DTwPu, DTwP produced by Connaught Laboratories (US); DTwPv, DTwP produced by Wyeth Laboratories; EPI, Expanded Program on Immunization vaccination schedule (6, 10, 14 weeks); EU, enzyme-linked immunosorbent assay (ELISA) units; FHA, filamentous hemagglutinin; IPV, inactivated poliovirus vaccine; Ig, immunoglobulin; OPV, oral poliovirus vaccine; PRP, polyribosylribitol phosphate; PRP-D, PRP-diphtheria toxoid conjugate vaccine; PRP-HbOC, PRP-diphtheria CRM_{197} protein conjugate vaccine; PRP-OMP, PRP-meningococcal outer membrane protein conjugate vaccine; PRP-T_1 (*ActHIB*, AvP) and PRP-T_2 (*Hiberix*, GlaxoSmithKline), PRP-tetanus toxoid protein conjugate vaccine (lyophilized and reconstituted at time of use with diluent or DTwP, unless indicated as DCS); PRP-T_3, PRP-tetanus toxoid protein conjugate vaccine produced by Serum Institute of India; PT, pertussis toxin; T, tetanus toxin.

[a]A ratio <1 indicates that mean antibody levels were lower with the combined vaccine than with separate injections; a ratio >1, that levels were higher with combined than separate injections. A blank cell indicates that the comparison was not possible or is not available.

[b]Difference significant at $P \leq .05$.

[c]*P*-value not available. However, the rate of seroconversion (AGG ≥320) was significantly lower ($P < .05$) in the combined group (79%, vs 92%).

[d]Agglutinin titers were not determined. However, ratios for antibody to pertactin and fimbrial antigens were 0.55 ($P < .05$) and 0.74, respectively.

[e]Combined vaccine group was compared to UK historical controls, who received the same PRP-T on the same schedule, but a different DTwP.

[f]Serologic assays were performed only for the DTwP/PRP-HbOC group (PRP, 8.20 μg/mL; D, 0.92 IU/mL; T, 7.52 units/mL; AGG, 110.1/dilution), and were said to be "comparable to values reported…in other series."

[g]Pertactin, 0.56.

[h]Pertussis IgG.

adverse reactions compared with DTwP alone. Typically, injection site reactions were slightly greater with the combinations than with the DTwP alone, but they were less than the aggregate of local reactions seen when separate vaccines were given at separate injection sites.

DTwP/HepB (With or Without Hib)

A number of studies[81–107] have evaluated combination vaccines that incorporate DTwP, HepB, and Hib components (Table 15.4). In general, the addition of HepB to DTwP resulted in significantly increased mean HepB antibody levels and unchanged DTwP responses; the further addition of Hib to the combination resulted in no consistent changes in antibody responses.

DTwP/HepB with or without Hib has been introduced in an increasing number of countries, many of them developing countries that use the Expanded Programme on Immunization (EPI) 6–10–14-week schedule for their public vaccination program.

Crucell (now Johnson & Johnson) and Novartis (now GlaxoSmithKline) developed a fully liquid DTwP/HepB/Hib vaccine (Quinvaxem) containing 10 µg PRP-CRM_{197} and 10 µg HepB surface antigen.[96] A lot-consistency study demonstrated 1-month postimmunization GMTs of 7.9 µg/mL for Hib and 108 mIU/mL for HepB; 91% of subjects had HepB titers of 10 mIU/mL or more.[103] Kanra and colleagues[104] compared this combination with separately administered DTwP/Hib (QuattVaxem) and HepB (Hepavax-Gene) vaccines from the same manufacturer and found comparable adverse event and seroconversion/seroprotection rates in the two groups. Compared with separate injections, the combination elicited GMTs that were significantly higher for HepB and significantly lower (but still protective) for Hib, tetanus, and pertussis. Suarez and colleagues[91] evaluated use of the pentavalent combination versus separate DTwP and Hib vaccines to boost toddlers primed with DTwP/HepB//Hib vaccine and found no material differences in antibody responses for the two groups. A safety study involving 3000 Guatemalan infants found Quinvaxem to be associated with lower rates of healthcare visits and no increase in serious adverse events (SAEs) or hospitalizations,[105] and another study has shown Quinvaxem to be interchangeable in the primary series with a European DTwP/HepB//Hib (Tritanrix HB + Hib).[106]

GlaxoSmithKline has evaluated a DTwP/HepB/Hib vaccine containing reduced quantities of PRP-T (2.5 vs 10 µg PRP) and thimerosal (6 vs 25 µg/dose). Studies in India,[108] Latin America,[109] and the Philippines[110] compared the new vaccine with standard-formulation DTwP/HepB/PRP-T vaccine. The Philippine study showed no reduction in Hib responses after the primary series or booster dose; the other two studies showed that Hib seroprotection rates following the reduced-potency combinations were high, but mean antibody levels were about half those seen with the full-strength formulation.

Shantha Biotechnics has developed a fully liquid DTwP/HepB/Hib vaccine (Shan5), for which it reports D, T, P, HepB, and Hib seroconversion rates of 99.4%, 99.4%, 89.9%, 97.8%, and 98.3% respectively.[107] Sharma and colleagues evaluated SII's DTwP/HepB/Hib vaccine, Pentavac, and Panacea Biotec's similar Easyfive combination given to Indian infants at 6, 10, and 14 weeks.[94] Adverse reactions were similar, except that Pentavac was associated with significantly less injection-site pain and hindrance of limb movement; antibody responses did not differ after the primary series or following a dose of DTwP/Hib vaccine at 15 to 18 months.[94,95] Clinical trial data for other DTwP/HepB or DTwP/HepB/Hib vaccines from Asian manufacturers are generally not available in the indexed literature.

COMBINATIONS BASED ON ACELLULAR PERTUSSIS VACCINE

Overview

The development of numerous effective aP vaccines (see Chapter 44) and their licensure in combination with diphtheria and tetanus toxoids (DTaP) quickly stimulated efforts to combine DTaP with other routine vaccines of infancy, such as Hib, IPV, and HepB. Building on the experience with DTwP combination vaccines, efforts turned first to evaluating combinations of DTaP and conjugate Hib vaccines, in light of their similar schedules, universal use in developed countries, and lack of orally administered alternatives. However, it was soon found that combining DTaP with Hib tended to reduce, often markedly, the Hib antibody response. This discovery slowed development of combinations based on DTaP/Hib and stimulated development of alternative combinations such as DTaP/IPV, DTaP/HepB, and DTaP/IPV/HepB. It also prompted research into the clinical relevance of the reduced response, which has resulted in Hib-containing pentavalent (e.g., DTaP/IPV/Hib) and hexavalent (e.g., DTaP/IPV/HepB/Hib) combinations becoming accepted in Europe and some other jurisdictions despite reduced Hib responses. In contrast, attention in North America initially focused on DTaP/IPV/HepB and on DTaP/Hib-based combinations built on the Canadian-manufactured DTaP5 (see Chapter 44 for details of nomenclature), which does not interfere materially with Hib responses. More recently, a European DTaP/IPV/HepB/Hib vaccine (Infanrix hexa) has become widely used in Canada.

The DTaP-based combinations most widely available worldwide are produced by Sanofi Pasteur and GlaxoSmithKline. GlaxoSmithKline markets a full range of Infanrix (DTaP3)-based combinations, including the only currently available hexavalent and various pentavalent and quadrivalent combinations. Sanofi Pasteur markets products based on the French DTaP2 (e.g., Tetravac, TETRAXIM) in Europe and elsewhere and products based on the Canadian DTaP5 (e.g., Quadracel, Pentacel, Pediacel) in the Western Hemisphere, Asia, and elsewhere.

Adding IPV to DTaP, Tdap, or DTaP/Hib

Overview

The incorporation of IPV into DTaP, DTaP/Hib, or Tdap (adolescent-adult formulation tetanus, diphtheria, and acellular pertussis vaccine) has no consistent effect on antibody responses to the included components, with few comparisons achieving statistical significance. Surveillance in Sweden conducted over many years showed continued reductions in pertussis incidence among the Swedish population, concomitant with the transition from DTaP to DTaP/IPV and DTaP/IPV/Hib.[111] Multiple manufacturers are developing IPVs based on Sabin strains; early data do not suggest important differences in immunogenicity or safety between IPV and sIPV or between DTaP/IPV and DTaP/sIPV.[54,112,113]

The Studies

Although Tables 15.5 through 15.9 attempt to separate data regarding DTaP/IPV, DTaP/Hib, DTaP/HepB, DTaP/HepB/Hib, and DTaP/IPV/Hib combinations, in fact, most of the relevant studies have evaluated several of these combinations simultaneously. In the few that have looked only at DTaP/IPV, pertussis responses tend to be maintained or enhanced with the combination[114–124] and poliovirus responses varied inconsistently; few of these variations achieved statistical significance.

TABLE 15.5 Antibody to PRP Among 120 Infants Given DTaP at 2 Months; Then DTaP, IPV, and Conjugate Hib Vaccine, Separately or Together, at 4 and 6 Months[114,115]

	Hib Primary Series GMC (μg/mL)	
Vaccines Given at 4 and 6 Mo	**6 mo (No.)**	**7 mo (No.)**
DTaP3, IPV, and PRP-T_2, all separate	0.19 (30)	3.94 (30)
DTaP3 and IPV mixed, PRP-T_2 separate	0.18 (28)	3.10 (30)
DTaP3 and PRP-T_2 mixed, IPV separate	0.10 (29)	0.38 (30)
DTaP3, IPV, and PRP-T_2 all mixed	0.09 (27)	0.56 (30)

DTaP3, diphtheria and tetanus toxoids and acellular pertussis vaccine (*Infanrix*, GlaxoSmithKline); GMC, geometric mean concentration of antibody; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus vaccine; No., number of subjects providing serum samples for assay; PRP, polyribosylribitol phosphate; PRP-T_2, PRP-tetanus toxoid protein conjugate vaccine (*Hiberix*, GlaxoSmithKline).

A number of key issues were illustrated by one of the first published studies comparing combined versus separate administration of DTaP, IPV, and Hib. Finnish infants were immunized at 2 months with DTaP3 and then at 4 and 6 months with DTaP3, IPV, and PRP-T all administered separately, all combined, only the DTaP3 and IPV combined, or only the DTaP3 and PRP-T combined.[114] As shown in Table 15.5,[114,120] PRP antibody responses were markedly reduced among infants receiving PRP-T in combination (whether or not IPV was included in the combination), but not if the PRP-T was given separately (whether or not the IPV was given separately). Pertussis responses varied little (Table 15.6); poliovirus responses were reduced with the combination. The extent to which any of these results was attributable to the nontraditional schedule, which included only two Hib doses, is unclear. In a follow-up study, available participants were boosted with DTaP3 and PRP-T at 24 months of age. Vaccines were given separately to children who had been primed with separate vaccines; children who had been primed with combination vaccines were randomized to be given a booster with separate or combined vaccines.[120] Despite the large difference in PRP antibody levels at 7 months of age, there was little difference in levels before the booster dose at 24 months of age (not unexpectedly, given the logarithmic decay in antibody). After receiving a booster dose, responses were strong but about twice as high among children primed with separate vaccines, suggesting a persistent deficit related to the initial difference in priming. The groups primed with combined vaccine had roughly equal responses to the booster dose, whether they were given combined or separate vaccines as booster doses.

Table 15.6 presents representative results from the many studies of the DTaP/IPV vaccines marketed as Tetravac, Infanrix-IPV, Quadracel, TETRAXIM, or KINRIX. In general, the combinations are noninferior with respect to seroprotection/seroconversion rates, produce mean antibody levels that do not meaningfully differ from those of the separately administered components, and can be given concomitantly with other vaccines routinely recommended for age.[116–131]

The aP component of Baxter's Certiva (a DTaP1 with a pertussis component that consists solely of pertussis toxin; see Chapter 44) has been combined with DT and IPV from Statens Seruminstitut (SSI) as DiTeKiPol.[132–134] A comparison of this DTaP1/IPV at 3, 5, and 12 months of age versus DT/IPV at 5, 6, and 15 months plus wP at 5 weeks, 9 weeks, and 10 months found that the combination achieved protective antibody levels for diphtheria, tetanus, and the polio serotypes. Adverse reactions were similar for the DTaP1/IPV and DT/IPV groups.

Although it is generally true that vaccines given simultaneously at separate injection sites do not interfere with each other, such interactions are occasionally noted. Among subjects given DTaP2//PRP-T (TriHIBit) along with IPV, sequential IPV-IPV-OPV, or OPV at 2, 4, and 6 months, Rennels and colleagues[135] found that the PRP GMTs (1.2, 1.3, and 3.1 μg/mL, respectively) and the proportions achieving PRP antibody responses of 1.0 μg/mL or greater (54%, 55%, and 79%, respectively) were reduced by coadministration of IPV. In contrast, Daum and colleagues[136] found that PRP antibody responses to the same DTaP2/PRP-T combination did not significantly differ among groups also receiving OPV or IPV at 2 and 4 months (GMTs, 4.0 vs 3.4 μg/mL; proportions ≥1.0 μg/mL, 77% vs 74%). This contradiction remains unexplained.

TdaP1/IPV (DiTekiPol Booster, SSI), Tdap3/IPV (Boostrix-IPV, GlaxoSmithKline) and Tdap5/IPV combination vaccines (Repevax, Sanofi Pasteur MSD) have been licensed for use as a booster among previously primed persons (the lower limit of licensure age varies by regulatory authority, from 3 to 10 years). Studies of Tdap3/IPV and Tdap5/IPV show that these two combinations produce antibody responses and reaction rates similar to those of separate vaccines.[128–130,137–149] When administered at age 4 to 6 years, diphtheria and pertussis antibody responses and adverse event rates are somewhat lower than with DTaP or DTaP/IPV.[130,148,149] Repeat boosting 5 or 10 years after a Tdap3 or Tdap5 administration produced good antibody responses, with unremarkable safety results.[142–144] Zimmerman and colleagues randomized adults ≥60 years of age to receive Tdap5/IPV and influenza vaccine either concomitantly or 1 month apart; immune responses did not materially differ.[145] Similarly, immune responses did not materially differ among adolescents given simultaneous or separate Tdap5/IPV and quadrivalent human papillomavirus vaccine.[146]

Theeten and colleagues[147] evaluated three doses of Tdap3, one dose of Tdap/IPV followed by two doses of Tdap3, and three doses of Td, administered on a 0–1–6-month schedule to adults age 40 years or older with no known T or d vaccination for at least 20 years. Rates of adverse reactions and immune responses to the T and d components did not differ among the groups; pertussis and polio immune responses were as expected.[147]

Adding HepB to DTaP or to DTaP/IPV

Overview

Combining HepB with DTaP or with DTaP/IPV generally produces somewhat higher DTaP and polio antibody responses than are achieved with the same components given separately on the same schedule. However, combination vaccine schedules do not provide the extended time between the second and third doses that is required for optimal HepB responses, resulting in lower HepB antibody responses.

Studies

Table 15.7 summarizes studies comparing the performance of the GlaxoSmithKline DTaP3/HepB vaccine with the separately administered components and also comparing various administration schedules.[150–155] The combination vaccine showed immune responses similar to those of separate vaccines given on the same schedule.

A comparison of combined vaccine at ages 2, 4, and 6 months versus a currently recommended schedule in

the United States—HepB at birth and 1 and 6 months of age and DTaP3 at 2, 4, and 6 months of age—found significantly higher antibody responses for combined vaccine for every component except HepB, which was significantly lower.[153] However, the mean HepB antibody with combined vaccine was nevertheless high (1052 mIU/mL), and 99% of subjects had levels ≥10 mIU/mL, the level considered protective. Antibody responses to concomitantly given Hib and OPV did not differ between the two groups.

Table 15.7 also reveals a clear-cut correlation between dosing interval and HepB response of the combination. Progressively compressing the schedule from 2–4–6 to 3–4.5–6 to 3–4–5 months leads to progressively reduced HepB responses, whether given separately or in combination; in each case, results are somewhat higher with the combination. An Italian study[152] that evaluated a 3–5–11 schedule recorded higher HepB responses following the third dose, again suggesting that increasing the dosing interval is associated with an enhanced immune response.

GlaxoSmithKline's DTaP3/IPV/HepB combination vaccine (Infanrix Penta; Pediarix) has been evaluated in a variety of schedules and compared with its components given separately, with DTwP-based combinations, and as a control vaccine in studies of the GlaxoSmithKline hexavalent combination (see later text in this chapter).

In a randomized U.S. study, the response rates following DTaP3/IPV/HepB vaccine at 2, 4, and 6 months of age were shown to be noninferior (indeed, often superior) to U.S.-licensed DTaP3, HepB, OPV, and IPV vaccines administered separately on the same schedule.[155] Another randomized U.S. study comparing DTaP3/IPV/HepB plus Hib and PCV7 versus separate concomitant vaccines given at 2, 4, and 6 months found antibody responses in the combined-vaccine group to equal or exceed those in the separate-vaccine group.[156] This study also addressed the concern that PCV7 (Prevnar) vaccine might alter the immunogenicity of coadministered DTaP vaccines. A separate arm of the study administered the PCV7 2 weeks after dose of DTaP3/IPV/HepB, rather than concurrently; antibody responses in the group given DTaP3/IPV/HepB concurrently with PCV7 equalled or exceeded those in the group receiving DTaP3/IPV/HepB and PCV7 2 weeks apart, except that D titers were significantly higher in the latter group. However, point estimates for D seroprotection rates were slightly higher in the simultaneous-vaccine group, and statistical noninferiority was met.[156] The question of possible interference of PCV with DTaP3/IPV/HepB responses was further addressed by a study in which infants given DTaP3/IPV/HepB plus PRP-T received either PCV7 or PCV13 concomitantly; noninferiority criteria were met for all antigens.[157]

In a study in Moldova, 320 infants given a birth dose of HepB were randomized to receive either DTaP3/IPV/HepB + Hib or DTwP/IPV/Hib + HepB at 6, 10, and 14 weeks of age.[158] After the primary series, both groups showed equivalently high seroprotection rates and mean antibody levels. The HepB seroprotection rate in the DTaP3/IPV/HepB + Hib group was greater than 98.6% immediately before the third dose (14 weeks of age) compared with 88.7% in the DTwP/IPV/Hib + HepB group. An Estonian study administered either DTaP3/IPV/HepB or DTaP3/HepB + IPV at 3, 4.5, 6, and 15 to 27 months and found most antibody responses to be higher (some significantly so) in the combined-vaccine group

following the third and the fourth doses.[159] Adverse reactions following DTaP3/IPV/HepB are generally similar to those following the separate vaccines except for an increase in rates of fever following the first dose, which has been demonstrated in the German[160] and U.S.[161] licensing studies and in postmarketing evaluations.[162,163] The U.S. study found significantly higher rates of fever of any intensity and fever higher than 39°C after dose 1 in the combination vaccine group.[161]

Another U.S. study evaluated DTaP3/IPV/HepB versus DTaP3 or DTaP5 given separately and found fever of 38.3°C or higher to occur significantly more often with the combination than with the separate DTaP3 after all three doses (4.2% vs 2.7%, 8.8% vs 4.9%, and 5.7% vs 4.7% for doses 1–3, respectively).[162] Compared with the DTaP5, fever was significantly more common after doses 1 and 2 (4.2% vs 2.1% and 8.8% vs 6.5%) but not after dose 3 (5.7% vs 5.6%).[162]

The U.S. licensure study also collected data on unplanned visits to seek medical care following immunization; medical attention was sought for fever within 4 days following first vaccination by 1.2% of DTaP/IPV/HepB recipients versus none of the separate vaccine recipients.[161] Thompson and colleagues[163] evaluated the effect of changing from separately administered vaccines to DTaP3/IPV/HepB and found that 6- to 10-week-old infants receiving DTaP3/IPV/HepB were more likely to visit the emergency department and receive tests within 3 days of vaccination, compared with infants who received separate DTaP, IPV, and HepB/Hib. The DTaP3/IPV/HepB recipients had a sevenfold increased risk of receiving a full sepsis workup and a threefold increased risk of receiving antibiotics within 7 days of vaccination. However, a large safety study conducted following U.S. licensure of Pediarix did not identify any safety signals.[164] In particular, there was no difference in the incidence of medically attended fever events in the 4-day period after any dose of vaccine, nor in the incidence of all seizures or febrile seizures, between the DTaP3/IPV/HepB recipients and matched historical controls.

Several studies have evaluated coadministration of DTaP3/IPV/HepB with various Hib vaccines (PRP-OMP, PRP-HbOC, and two PRP-Ts [GlaxoSmithKline and Sanofi Pasteur]) and found no interference.[155,165] Five different booster options for children primed with the pentavalent vaccine have been investigated, with all regimens resulting in high rates of seroprotection or seropositivity and marked increases in GMTs or antibody concentrations.[166–168]

Safety data, based on more than 20,000 doses, show the low rates of minor local reactions typical of aP-based vaccines, with somewhat lower rates among combination recipients for most reactions.[169] Again, a rectal temperature of 38°C or greater was more common in subjects who received DTaP3/HepB/IPV and Hib concomitantly than in subjects who received DTaP3 and Hib concomitantly. The incidence of temperature greater than 39.5°C, although higher with the combination, nevertheless was low in the DTaP3/HepB/IPV + Hib vaccine group (1.4%) and the control group (0.8%). A similar pattern of adverse reactions was found in the booster phase of the same study.[170]

Adding Hib to DTaP or to DTaP/IPV

Overview

Numerous studies[108–110,117,118,126,148,155,171–243] have evaluated various DTaP/Hib and DTaP/IPV/Hib combinations and have produced remarkably consistent results (comparisons of immune responses are shown in Table 15.8 for quadrivalent combinations and Table 15.9[244–252] for pentavalent and hexavalent combinations). Adverse events following primary and booster immunization generally are similar to those seen with the separate vaccines; a modest increase in rates of low-grade fever or minor local reactions is not uncommon and is offset by the absence of local reactions at sites spared injection because a combination was used. All combinations are highly immunogenic when used to boost previously primed children. When used for primary immunization, responses to the components other than Hib have been generally similar to those obtained with separate administration. The combination vaccines (other than those containing the weaker immunogen PRP-D) also stimulate good Hib responses, with GMTs typically in the range of 2 to 5 μg/mL, but these responses almost always are substantially lower than the high responses obtained with PRP-T or HbOC when given separately.[253–255] The clinical relevance of this reduction in Hib immunogenicity, which impeded licensure of these combinations in some jurisdictions, particularly including the United States, was discussed in detail in prior editions of this textbook.[20,256–273]

Studies

DTaP1. The SSI DTaP1/IPV combination (DiTeKiPol) has been marketed with ActHIB for reconstitution as a DTaP1/IPV//PRP-T combination (DiTeKiPol-ActHIB). A study compared DiTeKiPol and ActHIB given combined or separately at 3, 5, and 12 months. Following the second and the third injections, Hib GMTs were lower with the combination, but the proportions achieving levels of 1.0 μg/mL or higher were equal (27% after the second and 92% after the third injection; see Table 15.9).[186] A large-scale safety study using Danish national datasets found that the DTaP1/IPV/HepB combination was associated with a small but significant increase in risk of febrile seizure on the day of the first or second vaccination (3 and 5 months), but no increase in the risk of subsequent epilepsy.[211]

DTaP2. TriHIBit, the combination created by using Tripedia (no longer available) to reconstitute PRP-T (ActHIB), was used in the United States as a booster in children 15 to 18 months old and produced Hib antibody levels comparable to those seen with the separate vaccines.[172] When used for primary immunization of infants, however, mean PRP antibody levels were significantly lower with the combined vaccine (4.3 μg/mL) than with the separate vaccines (7.0 μg/mL).[176,178] The magnitude of reduction in PRP antibody associated with giving a TriHIBit rather than separate Tripedia + PRP-T depended on the number of times the vaccines were administered in combination. Moreover, administration of separate vaccines for the third dose of the primary series did not overcome the reduced immune response associated with prior use of the combination, showing once again the persistent effect of the initial priming experience.[224]

DTaP2//Hib or DTaP2/IPV//Hib[209] vaccines produced by Sanofi Pasteur using their French two-component aP vaccine (Triavax; see Chapter 44) have been evaluated in evaluated in British,[223] Belgian,[177] and Turkish[177,210] infants, among others (see Table 15.8).[208] The British infants developed low levels of antibody to PRP (mean: 0.48 μg/mL) after primary immunization at 2, 3, and 4 months of age,[223] but developed higher levels (mean: 36.8 μg/mL) after a booster dose of PRP-T at 13 months of age.[223] Although the Belgian and Turkish infants (immunized at 3, 4, and 5 months of age) had markedly higher mean PRP antibody levels than the British infants after primary immunization with combined vaccine, responses nevertheless were substantially lower than with separate vaccines.[177]

Lagos and colleagues[117,118] randomized infants to five study groups: DTaP2/IPV//PRP-T; DTaP2/IPV + PRP-T; DTaP2/IPV;

aP, acellular pertussis vaccine; D, diphtheria toxin; DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; FHA, filamentous hemagglutinin; FIM, fimbriae; GMC, geometric mean concentration of antibody; HbOC, PRP-diphtheria CRM_{197} protein conjugate vaccine; IPV, inactivated poliovirus vaccine; OPV, oral poliovirus vaccine; PRN, pertactin; PRP, polyribosylribitol phosphate; PRP-D, PRP-diphtheria toxoid conjugate vaccine; PRP-T, PRP-tetanus toxoid protein conjugate vaccine; PT, pertussis toxin; T, tetanus toxin.

[a]A ratio <1 indicates that mean antibody levels were lower with the combined vaccine than with separate injections; a ratio >1 indicates levels were higher with combined than separate injections. A blank cell indicates that the comparison was not possible or is not available.

[b]aP2f = French 2-component aP (e.g., *Triavax* or similar); aP2u = *Tripedia*; aP3 = *Infanrix*; aP4 = *ACEL-IMUNE* or similar Takeda-type aP vaccine; aP5 = *Tripacel* or equivalent 5-component aP vaccine (see Chapter 44 for details of vaccines). PRP-T_1 = *ActHib* (Sanofi Pasteur); PRP-T_2 = *Hiberix* (GlaxoSmithKline).

[c]Difference significant at $P \leq .05$.

DTaP2 + IPV; or DTaP2 + OPV. These vaccines were given at 2, 4, and 6 months of age. In addition, the latter three groups received PRP-T at 3, 5, and 7 months of age. All groups had poliovirus seroconversion rates of 99% or 100%, with higher antibody levels among the groups receiving IPV in combination than in the groups receiving separate IPV or OPV (see Tables 15.6 and 15.9). Responses to pertussis toxin, filamentous hemagglutinin (FHA), and PRP were robust in all groups but were superior in infants receiving separate injections. At age 7 months, PRP antibody levels were markedly higher in the study groups given PRP-T separately at 3 and 5 months of age, even though they had only received two doses of Hib vaccine by that time whereas the other groups had received three doses. It is not known whether this result was caused by age, carrier priming, or immunologic interference. When a booster dose of DTaP2//PRP-T was given at 12 months, all groups had strong PRP antibody responses (mean levels: 48.6–95.2 μg/mL), but significantly higher antibody levels were seen in the groups primed at 3, 5, and 7 months of age.[117,118]

Philippine,[212] Indian,[213] and South African[214] studies of DTaP2/IPV//Hib (Pentaxim; Pentavac) vaccine given on the EPI schedule (6–10–14 weeks) found antibody responses to be similar to those previously reported, whether HepB vaccine was given at 0–6–14 weeks or 6–10–14 weeks. A fourth dose of DTaP2/IPV//Hib given at 18 to 19 months following primary vaccination at 6–10–14 weeks among Indian or South African children resulted in strong antibody responses to all antigens.[215,216] Antibody to PRP rose from 0.35 to 47.1 μg/mL among the South African toddlers and from 1.75 to 70.6 μg/mL among the Indian toddlers. Pentaxim was also evaluated in Thailand, as a fourth-dose booster following a primary series of a DTaP2/IPV/HepB//Hib combination (Hexavac; see later in this chapter) and as a primary series given at 2, 4, and 6 months of age.[217,218] Antibody responses again were similar to those previously reported, except that Hib antibody responses were substantially higher than those seen in the Philippine or Indian studies, probably owing to the difference in schedules. Following boosting at 18 to 19 months, antibody to PRP rose from 1.21 to 61.2 μg/mL.[219] A Chinese study evaluated Pentaxim given at 2, 3, and 4 months or at 3, 4, and 5 months versus separately administered DTaP (Wuhan Institute), IPV, and Hib (both supplied by Sanofi Pasteur) vaccines.[189] The combination vaccine was noninferior to the separate vaccines for all seroprotection and seroconversion rates; PRP GMTs were high for all groups, but significantly lower with the combination.

As noted earlier, combination vaccines—once exclusively produced by European and North American suppliers—increasingly are being developed by Asian and Latin American manufacturers. Most such efforts to date have involved

aP, acellular pertussis vaccine; D, diphtheria toxin; DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; EPI, Expanded Program on Immunization vaccination schedule (6, 10, 14 weeks); FHA, filamentous hemagglutinin; FIM, fimbriae; GMC, geometric mean concentration of antibody; HepB, hepatitis B; IPV, inactivated poliovirus vaccine; HbOC, PRP-diphtheria CRM_{197} protein conjugate Hib vaccine; OMP, outer membrane protein; OPV, oral poliovirus vaccine; PCVn, n-valent pneumococcal conjugate vaccine; PRN, pertactin; PRP, polyribosylribitol phosphate; PRP-T, PRP-tetanus toxoid protein conjugate vaccine; PT, pertussis toxin; T, tetanus toxin.

[a]A ratio <1 indicates that mean antibody levels were lower with the combined vaccine than with separate injections; a ratio >1 indicates that levels were higher with combined than separate injections. A blank cell indicates that the comparison was not possible or is not available.

[b]ap1 = Monocomponent aP containing PT only (*Certiva* or equivalent); aP2 = French 2-component aP (e.g., *Triavax* or similar); aP3 = *Infanrix*; aP4 = *ACEL-IMUNE* or similar Takeda-type aP vaccine; aP5 = *Tripacel* or equivalent 5-component aP vaccine, aP2c = aP2 manufactured by Wuhan Institute of Biological Products (see Chapter 44 for details of vaccines). PRP-T_1 = *ActHib* (Sanofi Pasteur); PRP-T_2 = *Hiberix* (GlaxoSmithKline).

[c]DTaP5/IPV/PRP-T combined, fully liquid, in vial.

[d]Difference significant at $P \leq .05$.

[e]DTaP and IPV were given at 2, 4, and 6 months; PRP-T was given at 3, 5, and 7 months. Polio antibody levels estimated from figures.

[f]Both groups also received PCV7.

[g]Both groups also received PCV13 and RotaTeq. Separate HepB given at birth in both groups and at 2 and 6 months in Group 2.

[h]Estimated from figure.

[i]Finland, Germany, and Belgium

[j]Both groups also received MMRV (measles-mumps-rubella-varicella).

combinations based on DTwP, but new DTaP-based combinations have begun emerging from China. Li and colleagues reported a study of 720 infants randomized 2:1 to receive a DTaP/Hib vaccine (produced by Minhai Biotechnology) or DTaP (produced by Chengdu Institute of Biological Products) + a Hib-TT (produced by Lanzhou Institute of Biological Products). Although details are not provided, it seems that both pertussis vaccines are of DTaP2 design, containing pertussis toxin (PT) and FHA. Subjects were vaccinated at 3, 4, 5, and 18 months of age. PRP antibody responses did not differ between the groups; pertussis responses were modestly higher and tetanus-diphtheria (TD) responses modestly lower in the combined-vaccine group following dose 3; there were no material differences following the booster dose.[220]

DTaP3. Schmitt[179] and Schmitt and colleagues[180] used Infanrix (GlaxoSmithKline) to reconstitute two similar PRP-T vaccines, ActHIB (Sanofi Pasteur) and Hiberix (GlaxoSmithKline). PRP antibody levels and seroconversion rates with the two Hib vaccines were reasonably comparable, but were higher with separate than combined vaccine. The combined and the separate vaccines produced high levels of antibody to the DTaP3 components; all antibody levels were slightly lower with the combined vaccine.[179,180] Available subjects were given a booster at 18 to 19 months of age with Hiberix, ActHIB, or Hiberix vaccine mixed with Infanrix. PRP antibody levels after the booster dose were high: 24 to 40 μg/mL for children boosted with the Infanrix//Hiberix combination and 85 to 137 μg/mL for children primed and boosted with the separately administered Hib vaccines.[180] Assessment of T-lymphocyte proliferative responses and cytokine production after priming and before and after the booster dose found no differences between combined and separate vaccines.[229,230]

A study comparing GlaxoSmithKline's DTaP3/IPV and PRP-T, given combined or separately at 2, 4, and 6 months of age, found antibody levels to be similar with combined vaccine or separate administration for diphtheria toxoid, the three pertussis antigens, and the three poliovirus types.[233] Anti–tetanus toxoid titer was higher with the combined vaccine, whereas the mean PRP antibody response was reduced by half with the combined product. PRP antibody levels no longer differed between the two groups before and 1 month after the booster dose given at 18 months of age. Following the fourth dose, all children in both groups had antibody levels more than 1 μg/mL; GMTs were 32.9 and 47.8 μg/mL for the combined and separate groups, respectively.

To further evaluate the question of priming by PRP-T given in combination with DTaP3, a study was conducted in Israel in which children vaccinated with DTaP3/IPV//PRP-T at 2, 4, and 6 months were boosted at 10 or 12 months with unconjugated PRP antigen.[234] The plain PRP elicited an increase in antibody titers within 7 to 10 days, achieving levels higher than the levels reported in several trials conducted in unprimed children vaccinated with the unconjugated vaccine at the same age. These findings demonstrate priming of the PRP response.

DTaP5. In addition to the previously discussed DTaP5/IPV (Quadracel), other combination vaccines based on the Canadian five-component aP vaccine, such as DTaP5//Hib (Actacel), DTaP5/IPV//Hib (Pentacel),[235] and DTaP5/IPV/Hib (Pediacel)[236] have been evaluated in various locales. In a comparative trial in Taiwan of the DTaP5//Hib combination versus the separate components, 95% of combination recipients achieved at least 1 μg/mL of antibody to PRP. Geometric mean pertussis and Hib antibody levels did not differ between combined and separate administration (see Table 15.8).[182] Another comparative trial examined vaccination at 2, 4, 6, and 18 months of age with (a) DTaP5/IPV used to reconstitute lyophilized PRP-T (Pentacel), (b) fully liquid DTaP5/IPV/PRP-T (Pediacel), or (c) DTaP5/IPV and PRP-T given separately.[184,185,201] All three groups responded well after primary and booster immunization (see Table 15.8). The liquid and lyophilized combinations performed similarly[184]; antibody responses with the liquid combination did not differ significantly from those of the separate vaccines for any antigen.[184,185,201] Halperin and colleagues[243] compared DTaP3/IPV//Hib and DTaP5/IPV//Hib as fourth doses among Canadian children and found significantly higher PRP antibody levels (29 vs 19 μg/mL) in children boosted with DTaP5/IPV//Hib. Guerra and colleagues[207] reported a comparison of Pentacel with separate Daptacel, IPOL, and ActHIB given at 2, 4, and 6 months of age; at 15 months, children received either Pentacel or Daptacel plus ActHIB. Rates of adverse reactions following Pentacel were similar or lower than following separate vaccines. Antibody responses did not materially differ between the two groups. Chatterjee and colleagues reported results of a comparison of Pentacel versus Daptacel + IPOL + ActHIB given at 2, 4, 6, and 15 months of age, along with the usual concomitant vaccines.[126] Seroprotection rates and PRP antibody levels did not materially differ between the groups. Rates of adverse reactions were somewhat lower with the combination than with the separate vaccines. Large postlicensure safety studies of Pentacel have not identified any safety signals.[274,275]

Lin and colleagues[203] compared Pediacel with Quadracel + PRP-T and found both regimens highly immunogenic. PRP antibody levels of 1.0 μg/mL or higher were achieved in 97% and 99%, respectively; GMTs were very high, at 11.4 and 21.7 μg/mL, respectively. Responses to other contained or concomitant antigens were excellent and similar between the two groups, and adverse reaction rates did not materially differ. One year later, 93% of Pediacel recipients had PRP antibody levels of 0.15 μg/mL or higher.[204] Following a booster dose of Pediacel, geometric mean antibody concentrations (GMCs) rose to 60 and 62 μg/mL in the combined and separate vaccine groups, respectively.

Grimprel and colleagues[241] reported a comparison of Pediacel with Infanrix/IPV//Hib given at 2, 3, 4, and 12 to 18 months of age along with PCV7. Most antibody levels were similar between the two groups. As would be expected from their formulations, FIM (fimbrial) responses were higher in the Pediacel group and PRN (pertactin) responses were higher in the Infanrix/IPV//Hib group. Hib responses were significantly higher in the Pediacel group following the third dose (1.38 vs 0.59 μg/mL) and the fourth dose (32.4 vs 19.3 μg/mL). Berner and colleagues randomized German toddlers ages 11 to 18 months who were previously primed with 3 doses of a hexavalent vaccine, to receive Pediacel or Infanrix hexa as boosters; both groups received concomitant PCV7.[205] There were no material differences in rates of adverse reactions nor in seroprotection or booster antibody response rates, except that FHA responses were lower, and FIM responses higher, in the Pediacel group. Both groups had strong anti-PRP antibody responses. Vesikari and colleagues compared Pediacel with Infanrix-IPV-Hib given at 3, 5, and 12 months of age.[206] Post–dose 2 seroprotection rates did not differ between the two groups. Post–dose 3, significantly higher D and lower PRP antibody responses were found in the Pediacel group. Polio GMCs were also lower in the Pediacel group, but seroprotection rates were 99% to 100%. Pertussis antibody levels differed as would be expected based on the respective formulations. Langley and colleagues randomized Canadian infants to receive Pediacel at 2 and 4 months and Infanrix at 6 months (PPI) or Infanrix at 2 months and Pediacel at 4 and 6 months (IPP). Adverse events were similar in the two groups; significantly higher responses to PT and FIM and a significantly lower response to FHA were seen in the IPP group.[242]

It has long been speculated that the less-pronounced Hib interference seen with the DTaP5-based combinations might relate to the fact that they alone use aluminum phosphate rather than aluminum hydroxide as adjuvant. Mawas and colleagues[276] found that rat Hib antibody responses were reduced with DTaP3/PRP-T compared with PRP-T alone, but were not reduced with DTaP5/IPV//PRP-T. The investigators next evaluated the administration of unadjuvanted Hib; Hib adsorbed onto aluminum hydroxide or aluminum phosphate; DTaP3; PRP-T combined with DTaP3; and PRP-T combined with the individual unadjuvanted components of DTaP3. The addition of PRP-T to DTaP did not affect DTaP responses. The combined administration of pertussis toxoid and PRP-T enhanced Hib responses, compared with their coadministration, whereas combining PRP-T with tetanus toxoid or FHA suppressed Hib responses. Finally, they found that adsorption of PRP-T onto aluminum phosphate reduced responses twofold, whereas adsorption onto aluminum hydroxide reduced responses 5- to 11-fold.[277]

Although it has been suggested that PCV7 might alter the immunogenicity of coadministered DTaP vaccines, several studies have shown no material differences in antibody responses between groups who received PCV7 concomitantly with, or 1 month separate from, each dose of Pentacel.[278–280] Reaction rates tended to be higher in the groups receiving concomitant PCV7, particularly for fever.[280]

Halperin and colleagues[243] compared Pentacel and DTaP3/IPV/Hib as fourth-dose boosters among toddlers primed with three doses of Pentacel. Local reactions were more common with Pentacel, whereas systemic reactions were generally similar for the two groups. There were no differences in seroresponse or seroprotection rates. As would be expected given their respective formulations, mean Hib and FIM titers were higher and PT, FHA, and PRN titers lower in the Pentacel group. The Canadian National Advisory Committee on Immunizations concluded that these two combination vaccines, as well as Pediacel, could be used interchangeably at the fourth (toddler) and fifth (preschool) doses to boost properly primed children.[281]

Effect of Age, Schedule, and Prematurity. Various studies suggest that immunization at an earlier age is associated with reduced antibody responses to Hib when given in combination with DTaP. In a French study in which PRP-T was administered at 2, 3, and 4 months of age, combined with or separately from DTaP2/IPV, PRP antibody levels were 1.95 μg/mL with the combined vaccine and 5.18 μg/mL with separate vaccines (see Table 15.9).[187,188] Another French study compared administration of DTaP2/IPV//PRP-T at ages 2, 3, and 4 months or 2, 4, and 6 months and found higher mean antibody levels for all antigens in the group immunized later.[188,225,226] Responses to PRP differed significantly, for the proportions exceeding 1 μg/mL (70% vs 89%) and for mean antibody levels (1.7 vs 4.7 μg/mL).[188] However, when given a booster at 15 months of age, both groups responded equally well to all antigens (PRP antibody levels were 36.8 and 31.8 μg/mL for 2–3–4 and 2–4–6 months, respectively).[188,226] Similar results have been obtained among Swedish children immunized at ages 3, 5, and 12 months or 2, 4, 6, and 13 months. Not surprisingly, antibody levels were higher after primary immunization with the 2–4–6 schedule than with the 3–5 schedule, although there was no significant difference in the proportion who achieved defined protective levels or had fourfold rises in antibody titer.[227] Following booster immunization at 12 or 13 months of age, antibody levels were virtually identical in the two groups.

Premature birth also has been shown to accentuate the reduction in antibody responses to Hib when given in combination with DTaP. A study comparing antibody responses to DTaP3//PRP-T in infants born at less than 32 weeks' gestation and full-term infants found markedly reduced Hib GMTs (0.27 vs 0.81 μg/mL) and proportions achieving 1 μg/mL (21% vs 46%) among the premature infants.[228] Both groups of children responded well to a fourth dose administered in the first year of life.[282] In contrast, another study by the same investigators found that premature infants given DTaP5/IPV/Hib (Pediacel) + meningococcal serogroup C conjugate vaccine showed substantially higher Hib GMCs than had been seen with the DTaP3//Hib combination (1.21 vs 0.27 μg/mL).[283]

Omeñaca and colleagues[284] compared responses to DTaP3/HepB/IPV/Hib (Infanrix hexa) among 94 preterm and 92 full-term infants and found that tetanus and pertussis responses were similar in the two groups. Responses to the other antigens were lower in the preterm infants, but seroprotection rates nonetheless were still 100% for polio and only moderately reduced for HepB and PRP (Hib). The vaccine was well tolerated in both groups. This study population was followed through booster vaccination in the second and fifth years of life.[285–287] At age 18 to 20 months, prior to receiving the fourth dose, antibody levels were essentially identical in the two groups except for PRP (0.3 vs 0.5 μg/mL). Following the fourth dose, strong antibody responses were seen in both groups; anti-PRP GMCs were now higher in the preterm group (70.9 vs 63.3 μg/mL). DTaP booster at 4 years of age resulted in essentially identical postboost antibody levels in the two groups.[285]

Under close monitoring, Faldella and colleagues[288] gave DTaP/HepB/IPV/Hib (Hexavac) at 7 weeks of age to 45 infants (23 with chronic disease, 22 stable and healthy) born at less than 31 weeks' gestation who were still in the neonatal intensive care unit. Immunization was not associated with variations in cardiac electrical activity or cerebral blood flow, but five (11%) of the 45 infants with chronic disease required medical support for vaccination-related apnea, bradycardia, and/or desaturation.[288] The authors concluded that vaccination of infants with chronic conditions preferably should be conducted before neonatal intensive care unit discharge.

DTaP/HepB/Hib and DTaP/IPV/HepB/Hib Combinations

A number of studies have evaluated GlaxoSmithKline's DTaP3/HepB//PRP-T combination vaccine.[193,194,289–292] As seen with most of the DTaP3//Hib and DTaP3/IPV//Hib combinations previously described, DTaP3//Hib-based combinations typically produce lower PRP antibody levels than are obtained with separate administration of the Hib component. For example, among children randomized at 2, 4, and 6 months of age to receive DTaP3/HepB//PRP-T, DTaP3/HepB + PRP-T, or DTaP3 + HepB + PRP-T, mean PRP antibody levels at 7 months of age were 1.6, 6.3, and 6.2 μg/mL, and the proportions achieving 1 μg/mL were 71%, 92%, and 90%, respectively.[193] No interference was seen in the antibody responses to the other components. Subjects with 7-month PRP antibody less than 1.0 μg/mL were administered a booster dose at 11 to 15 months of age; postboost GMTs ranged from 3 to 5 μg/mL, depending on original study group, indicating that priming was achieved with all regimens.

Pichichero and Passador[194] evaluated the DTaP/HepB//Hib combination versus separately administered vaccines and found antibody responses to be lower in the combined vaccine group for nearly all antigens and substantially lower for Hib (GMC, 1.2 vs 5.5 μg/mL; proportion achieving 1.0 μg/mL or higher, 58% vs 88% for the combined and separate groups, respectively). Children with low antibody responses to primary

immunization had excellent responses when given booster doses.[194] The same PRP results were found in a German study in which infants were immunized at 3, 4, and 5 months of age; mean PRP antibody levels were 1.2 and 5.5 μg/mL, respectively, for DTaP3/HepB//PRP-T and DTaP3/HepB + PRP-T.[289] Zepp and colleagues[290] gave unconjugated PRP to children at 12 months of age who had been immunized at 3, 4, and 5 months of age with DTaP3/HepB//PRP-T. Again, the children developed good antibody responses to PRP promptly after the booster immunization, demonstrating that the combination vaccine had successfully primed the immune system.[290] A consistency study with three lots of DTaP3/HepB mixed with three lots of PRP-T found Hib antibody levels of 0.15 μg/mL or greater in 100% and 1 μg/mL or greater in 85% of subjects; the GMT was 4.05 μg/mL.[291]

Hexavalent (DTaP/HepB/IPV/Hib) vaccines from GlaxoSmithKline and Sanofi Pasteur have been licensed in Europe and elsewhere. The GlaxoSmithKline product (Infanrix hexa) consists of GlaxoSmithKline's liquid DTaP3/HepB/IPV used to reconstitute its lyophilized PRP-T. The Sanofi Pasteur product (Hexavac, now withdrawn; see below) was a fully liquid combination of DTaP, IPV, and Hib components manufactured by Sanofi Pasteur plus HepB antigen manufactured by Merck. Both products have been extensively studied to characterize their immunogenicity, safety, and adaptability to a variety of primary and booster schedules.[166,167,189,190,191,195–198,212–220,293–307] Initial studies of both products showed good immunogenicity for their included antigens, producing seroprotection or seroconversion rates and GMTs similar to those seen with separate injections, except that Hib responses were somewhat lower than seen with separate administration of the Hib component (see Table 15.9). Rates of local and systemic adverse events following administration of the hexavalent combined vaccines are comparable to those seen with other licensed DTaP-based vaccines.

In 2005, reports appeared documenting a reduction in immunogenicity of the HepB component of Hexavac,[308–310] and the European licensing authority suspended its marketing authorization.[311,312] Although the manufacturing issue with the Merck HepB component was eventually resolved, Hexavac was not reintroduced. Subsequent booster studies of children primed with Hexavac or a comparator HepB-containing combination vaccine found little or no difference in postboost antibody responses, indicating that children in the Hexavac group were successfully primed.[313–318]

Studies in which either Hexavac or Infanrix hexa was administered alone or concomitantly with CRM_{197}-conjugated PCV7 found that antibody responses to the hexavalent antigens were not materially altered by coadministration with PCV7.[319–322] Rates of adverse reactions did not differ between study groups, except that low-grade fever (temperature 38–39°C) was more common, both in the infant series and with the toddler booster, in the groups receiving concomitant PCV7.[168,312,323]

Administration of a conjugate meningococcal C vaccine (Meningitec, Pfizer) simultaneously with Infanrix hexa at 2, 4, and 6 months or separately at 3, 5, and 7 months showed no material differences in proportions seroprotected or rates of adverse reactions.[324] A follow-up study at 18 months of age demonstrated superior antibody persistence in the separate vaccines group for diphtheria and meningococcus C.[325] Following a booster dose of DTaP/IPV//PRP-T, the group primed with simultaneous vaccines had significantly higher Hib, tetanus, polio, PT, and FHA titers and a significantly lower diphtheria titer.[325] Studies evaluating concomitant or separate administration of NeisVac-C meningococcal vaccine[326] (Baxter BioScience) or rotavirus vaccine[327] (Rotarix, GlaxoSmithKline) with Infanrix hexa found no material effects on immunogenicity or reactogenicity. A study evaluating administration of Infanrix hexa either simultaneously, one month before, or one month after GlaxoSmithKline investigational ACWY-TT conjugate meningococcal vaccine demonstrated that Infanrix hexa antibody responses did not materially differ for concomitant vs sequential administration.[328]

A number of studies have evaluated antibody persistence following use of Infanrix hexa to prime and boost according to a variety of national schedules. In general, antibody persistence was comparable to that seen with individual vaccines.[329–333] Anti-HBs antibody concentrations of 10 mIU/mL or higher were seen in 85% to 86% of children at 4 to 6 years of age, and 72% to 78% remained above that threshold at 7 to 9 years of age. Nearly all children (96–99%) had seroprotective levels following a challenge dose of vaccine. Seroprotective antibody levels persisted up to 9 years of age in ≥90% of children for diphtheria, Hib, and polio and in 65% of children for tetanus, but in only 38% for PT.[331] Among Scandinavian children vaccinated at 3, 5, and 11 to 12 months with Infanrix hexa or with DTaP/IPV//Hib and evaluated for antibody persistence at age 5 years, most had protective antibody titers for diphtheria, tetanus, Hib, and (in the hexa group) HepB; antibody to PT persisted less well, particularly in the hexa group.[323] Another study population vaccinated with Infanrix hexa or HepB plus DTaP/IPV//Hib at 3, 5, and 11 to 12 months was given HepB vaccine at age 10 to 11 years.[334] Distributions of antibody titers and responses to booster were similar in the two groups. Long-term safety surveillance studies of Infanrix hexa have not identified any safety signals.[335–337]

Sanofi Pasteur has developed a fully liquid hexavalent DTaP2/HepB/IPV/Hib combination vaccine (Hexaxim, Hexacima, or Hexyon, depending on location) that combines a novel HepB component manufactured in Argentina with the DTaP2/IPV/Hib combination Pentaxim.[338] A study in South African infants vaccinated at 6, 10, and 14 weeks of age compared this new hexavalent combination, with or without a dose of HepB vaccine at birth, with separately administered DTwP/Hib, HepB, and OPV vaccines.[244] Hib antibody responses were lower and all other antibody responses were higher in the groups receiving the combination vaccine. As expected, the group receiving a birth dose of HepB vaccine had substantially higher HepB antibody responses. There were no material differences in adverse reactions among the groups. At 15 to 18 months, study participants received the same pertussis-containing combination vaccine given before, along with concomitant vaccines; antibody responses in the hexavalent-combination group equaled or exceeded those in the DTwP/Hib group.[339] Hexaxim was compared to Infanrix hexa among Thai infants vaccinated at 2, 4, and 6 months.[245] Seroprotection rates and GMCs were similar between the two groups except for Hib (proportions with antibody to PRP ≥1.0 μg/mL, 85.2% with Hexaxim vs 71.1% with Infanrix hexa; GMCs, 5.07 vs 2.41 μg/mL), tetanus (100% of both groups achieved ≥0.1 mIU/mL but GMCs were 1.38 mIU/mL for Hexaxim vs 1.83 mIU/mL for Infanrix hexa), and polio (100% achieved seroprotection but GMCs were significantly lower in the Hexaxim group). Argentinean infants were randomized to receive Hexaxim or Pentaxim plus HepB (control group) at 2, 4, and 6 months of age. Postvaccination antibody responses did not materially differ between the two groups. HepB antibody levels were 1148 and 848 mIU/mL in the Hexaxim and control groups respectively.[246] At 18 months, antibody persistence was similar in the two groups except for antibody to HepB, which persisted better in the group originally given Pentaxim plus HepB (99.5% vs 85.5% with antibody 10 mIU/mL).[340] In a study conducted in Peru and Mexico, infants were randomized to receive Hexaxim

or DTwP/HepB//Hib plus OPV.[341] A HepB antibody level ≥10 mIU/mL was achieved by 100% of each group, but HepB GMCs were significantly higher in the group given DTwP/HepB//Hib (3376 vs 1075 mIU/mL). Another study in Mexico randomized infants to receive one of three lots of Hexaxim or Infanrix hexa; there were no material differences in antibody responses between Hexaxim lots or between Hexaxim and Infanrix hexa.[247] GMCs were significantly higher in the Hexaxim group for antibody to PRP and to FHA, and in the Infanrix hexa group for poliovirus antibodies.

COMBINATIONS BASED ON HEPATITIS VACCINE, WITHOUT DTP OR DTAP

HepB/Hib Combinations

Comvax (Merck & Co; also marketed by Sanofi Pasteur MSD in Europe as Procomvax and other trade names) combined HepB vaccine (Recombivax, 5 µg) and PRP-OMP conjugate Hib vaccine (PedvaxHIB, 7.5 µg). Merck discontinued production of this vaccine in 2014; readers interested in further information regarding Comvax are referred to the 2012 edition of this text.[20]

HepB/HepA Combinations

A combination incorporating HepA and HepB antigens (Twinrix; GlaxoSmithKline) is available in the United States, Canada, Europe, and elsewhere. The combined vaccine is available in an adult formulation that contains 720 EU of inactivated HepA antigen and 20 µg of recombinant HepB antigen (Twinrix Adult), in a pediatric formulation that contains half these amounts (Twinrix Pediatric), each given as a three-dose series, and in a pediatric formulation containing the adult dosage but given as a two-dose series (Ambirix).

A comparative trial in adults of Twinrix versus its individual components (Havrix and Engerix-B) given separately at 0, 1, and 6 months found excellent antibody responses, with 100% of combined-vaccine recipients achieving protective levels of both antibodies before the 6-month injection.[342] Another comparative trial[343] confirmed the equivalence of Twinrix and its component vaccines given separately at 0, 1, and 6 months: 99.6% of 264 Twinrix vaccinees developed antibodies against HepA (GMT: 4756 mIU/mL) versus 99.3% of 269 recipients of the monovalent vaccines (GMT: 2948 mIU/mL); for HepB, 95.1% of the Twinrix vaccinees achieved protective titers (GMT: 2099 mIU/mL) versus 92.2% (GMT: 1871 mIU/mL) of the subjects receiving monovalent vaccines. Other studies have provided comparable data.[344,345]

Northdurft and colleagues evaluated an accelerated schedule, developed for persons (e.g., travelers) in need of rapid protection against HepA and B, in which Twinrix is given at 0, 7, and 21 days, with a booster at 1 year, and compared it to HepB given on the same schedule plus HepA given at day 0 and at 1 year (the control group).[346] One week after the third dose, 100% of Twinrix recipients and 99% of controls were positive for anti–HepA antibodies (GMT, 845 mIU/mL vs 512 mIU/mL) and 82% of the Twinrix vaccinees were protected against HepB versus 84% in the control group (GMTs: 65 vs 98 mIU/mL, respectively). At 3 months after the first dose, 100% of Twinrix recipients versus 98% of controls were seroprotected against HepA and 95% of Twinrix recipients versus 91% of controls were seroprotected against HepB. In all studies, Twinrix was well tolerated, with no increased reactogenicity compared with the individual components.

Several long-term follow-up studies among children, younger adults, and older adults have found excellent antibody persistence.[347,348] Seventeen years following a three-dose Twinrix Adult series given to persons at 17 to 43 years of age, 96 to 100% remained seropositive for antibody to HepA and 88 to 92% had protective anti-HBS concentrations.[348] Those given HepB vaccine boosters because their antibody had dropped below 10 mIU/mL demonstrated strong anamnestic responses.[348]

A two-dose pediatric Twinrix schedule also has been evaluated.[349–353] Children given three doses of the pediatric formulation at 0, 1, and 6 months or two doses of the adult formulation at 0 and 6 months or at 0 and 12 months had equivalent immune responses and adverse reaction profiles. Therefore, the adult formulation of Twinrix can be administered to children and adolescents in a two-dose schedule, with the second dose following the first by 6 to 12 months (in Europe, the product packaged for use in this indication and schedule is called Ambirix).[354] Follow-up of subjects randomized at age 12 to 15 years to receive HepB/HepA vaccine on the two-dose or three-dose schedule showed very high seroprotection levels 10 years later, not differing by schedule.[355] Ten years following a two-dose Ambirix series given to children ages 1 to 11 years, 100% were anti–hepatitis A virus (HAV) positive and 82% had anti-HBs concentrations ≥ 10 mIU/mL. All those with anti-HBS concentrations <10 mIU/mL mounted a vigorous antibody response to a booster dose of HepB vaccine.[356]

HepA/Typhoid Combinations

Vaccines composed of *Salmonella typhi* capsular polysaccharide Vi (Vi vaccine) have proven safe and effective in prevention of typhoid fever. The combination of Vi with HepA offers an attractive option for travelers or others who need protection from both diseases, given that typhoid fever and HepA are among the most common vaccine-preventable diseases in travelers and share overlapping areas of endemicity. Two such vaccines are available, Hepatyrix (GlaxoSmithKline) and Viatim (Sanofi Pasteur; also marketed as Vivaxim). Hepatyrix is provided as a premixed liquid preparation in a single syringe, whereas Viatim is presented in a dual-chambered syringe that mixes the two liquid components at the moment of injection.

The proof of concept for these combinations was obtained in preliminary studies that found similar GMTs when HepA vaccine (Havrix) and typhoid vaccine (Typherix) were administered separately or combined.[357] One month postvaccination, GMTs did not significantly differ between the two groups; seroconversion rates in the two groups were 94–100% for Vi and 98–100% for HepA.[357] A lot-consistency study among 462 persons 15 to 50 years old found that greater than 95% of subjects had seroconverted for anti-Vi antibodies and greater than 86% for HepA antibody by day 14 following Hepatyrix, rising to 96% and 100%, respectively, after 1 month.[358] After a booster dose of Havrix, all vaccinees were seropositive against HepA, with a 7.5-fold increase in GMT. No increase in reactogenicity was seen with the combination vaccines.

Viatim was evaluated in a study that compared separate administration of Typhim Vi typhoid vaccine and Avaxim HepA vaccine with a single injection using the dual-chambered syringe (Typhim Vi in one chamber and Avaxim in the other chamber). Seroconversion rates at 14 days for combined and separate administration were 86.4% and 88.2%, respectively, for Vi and 95.6% and 94.2%, respectively, for HepA; at 28 days, Vi rates were essentially unchanged, but HepA rates had risen to 98.7% and 100%, respectively (because of differing definitions of seroconversion, these rates cannot be directly compared with those cited for Hepatyrix in the preceding paragraph).[359] Three years later, 99% in each group were seroprotected for HepA, and 32% of combined and 36% of separate vaccine recipients were seroprotected against typhoid;

these proportions rose to 67% and 70% following a booster dose. Another study evaluated three lots of Viatim and found that 92.1% of subjects achieved a fourfold or greater rise in Vi antibodies; all previously seronegative subjects seroconverted for HepA.[360]

A direct comparison of Viatim with Hepatyrix found statistically higher Vi and HepA seroconversion rates and GMTs at 14 and 28 days after Viatim, whereas systemic and local reactions (mainly pain at the injection site) were lower after Hepatyrix.[361]

An extemporaneous mixture of Typherix with Twinrix did not differ significantly from separate injections with respect to immunogenicity or adverse reactions, except that the likelihood of injection site pain was higher (77% vs 57%).[362]

COMBINATIONS BASED ON MMR VACCINE

After substantial effort (detailed in the fifth edition of this text), MMRV vaccines are now available from GlaxoSmithKline (Priorix Tetra)[363–367] and Merck (ProQuad).[368,369] The two MMRV vaccines incorporate different measles strains but the same rubella strain (see Chapters 37 and 53), plus each company's derivative of the Jeryl-Lynn mumps strain and the Oka varicella strain (see Chapters 40 and 62). For each MMRV vaccine, multiple clinical trials comparing the combination with separately administered MMR + V vaccines demonstrated that the MMRV combination stimulated immune responses equivalent to those achieved with separate MMR + V (for rubella, GMCs were somewhat lower with MMRV but seroprotection rates were 99–100%).[363–369] However, rates of fever and of febrile convulsions during the period from the fourth to the tenth day following initial vaccination of children 12 to 23 months old were materially higher (in the range of 30–40 per 100,000) with the quadrivalent combinations than with separately administered MMR + V; no similar increase was seen following the second dose.[370–375] Accordingly, Advisory Committee on Immunization Practices (ACIP) recommendations express a preference for use of separate MMR and V for children 12 to 47 months old first receiving these vaccines.[375] MMRV is preferred for the second dose and for persons first immunized at 4 years or older, and is an acceptable first-dose option for younger children with informed parental consent. Further information regarding these combinations can be found in Chapter 62.

COMBINATIONS INCORPORATING MENINGOCOCCAL OR PNEUMOCOCCAL CONJUGATE VACCINES

In the prevaccine era, the three most common causes of bacterial meningitis in children were Hib, meningococcus, and pneumococcus. Effective conjugate vaccines exist for all three agents, and combining these vaccines would offer obvious epidemiological synergies. Unfortunately, efforts to incorporate PCV into such combinations have been stymied by interference among the agents or overtaken by increases in the number of included serotypes in standalone PCV vaccines.

The first successful combination in this class, a combined meningococcal C conjugate (MnC)/Hib vaccine called Menitorix, was licensed by GlaxoSmithKline in Europe for use in infants and toddlers. Clinical trials[376–382] indicated that the MnC/Hib combination, given in association with DTaP3/IPV or DTaP3/IPV/HepB at 2, 3, and 4 or 2, 4, and 6 months, produced Hib antibody levels that exceeded, and meningococcus serogroup C seroprotection rates that were noninferior to, those seen in groups given MnC + Pediacel or MnC + Infanrix hexa. Administration of MnC/Hib as a booster at 12 to 18 months of age was associated with excellent antibody responses, with no interference with MMR responses. Similar results were obtained in preterm and full-term infants.[383] Infants vaccinated at 3, 5, and 11 months with MnC/Hib plus Infanrix penta had significantly higher Hib and HepB responses, and significantly lower meningococcal C responses, than control infants given Infanrix hexa plus MnC.[384] Adult laboratory workers with potential workplace exposure to Hib or meningococcus C who were given a single dose of MnC/Hib had good antibody responses to Hib, meningococcus C, and tetanus.[385] Adverse reaction profiles were unremarkable throughout. Several study populations were followed for up to 5 years; antibodies persisted at least as well in the MnC/Hib recipients as in the separate-vaccine control groups.[386–388]

GlaxoSmithKline has also developed a combined meningococcal serogroups CY (MnCY)/Hib vaccine (licensed as MenHibrix in the United States), in which each polysaccharide antigen is conjugated to tetanus toxoid. Data from clinical trials[377,389–396] indicate that the administration of this combination concomitantly with Infanrix and PCV7 at 2, 4, and 6 months resulted in antibody responses that were equivalent for most antigens to those seen with separate administration of Infanrix, PCV7, and ActHIB. Pertussis and pneumococcal antibody responses were somewhat lower with the combination, but predefined noninferiority end points were met; Hib responses were significantly higher. At ages 12 to 15 months, subjects previously given the combination received it again while subjects previously given ActHIB were randomized to receive ActHIB or the combination.[391] Hib antibody responses were significantly higher in the two groups that received a fourth dose of the same vaccine given in the primary series, as compared with subjects who had received three doses of standalone Hib vaccine followed by one dose of the MnCY/Hib combination. As expected, antibody responses to meningococcal serogroups C and Y were significantly higher with the combination than were antibody responses among a group of children age 3 to 5 years given polysaccharide meningococcal vaccine. Five years after the booster dose, antibody levels remained higher in the group given MnCY/Hib than the group given Hib alone.[397] There were no material differences in safety end points in any study.[398]

An Australian study[394] compared the same MnCY/Hib combination vaccine with Meningitec (an MnC vaccine conjugated to CRM_{197}) plus ActHIB and with ActHIB alone, in each case coadministered with Infanrix penta (Pediarix) and PCV7. At 12 to 15 months of age, participants in the first two groups received MnCY/Hib and participants in the third group received PedvaxHIB. Following the third and the fourth doses, Hib antibody levels were highest in the group given the MnCY/Hib combination and were the lowest in the group given Meningitec. Antibodies to meningococcal serogroup C were significantly higher both before and after the fourth dose in the MnCY/Hib group compared with the MnC group.

Serological follow-up was conducted for up to 5 years following administration of MnCY/Hib vaccine given as a four-dose infant–toddler series[390] or as a single-dose booster to children primed with three doses of Hib vaccine.[391] Antibody levels did not significantly differ between groups with respect to administered antigens; Hib and meningococcal antibody titers were somewhat higher in the group given 4 doses of MnCY/Hib.

COMBINATION VACCINES NO LONGER IN DEVELOPMENT

Wyeth Lederle conducted clinical trials of PCV/Hib, PCV/MnC, and PCV/MnC/Hib combinations.[399–403] In general, these studies found that the combinations produced lower

antibody responses for either the pneumococcal or the Hib components compared with separate vaccines, possibly a result of antigen overload with the carrier protein. It seems unlikely that any such PCV-containing combinations will achieve licensure.

GlaxoSmithKline conducted clinical trials[404,405] of a heptavalent vaccine, reconstituting MnC/Hib with DTaP/IPV/HepB, but development of this vaccine was stopped due to lower MnC responses with the combination than with separate vaccines.[404] A study was reported comparing DTaP/IPV used to reconstitute MnC/Hib versus DTaP/IPV//Hib plus MnC; good antibody responses were reported for the hexavalent combination but this vaccine is no longer in development.[406]

A study of liquid combination full-, half-, or one-third-strength IPV combined with DTwP/HepB, then used to reconstitute Hib so as to provide a hexavalent whole-cell combination vaccine, found postvaccination seroprotection or seropositivity rates that did not differ significantly from those of separately administered DTwP/HepB//Hib plus IPV. However, for every hexavalent formulation, there were one or more antigens for which postvaccination GMCs or GMTs were significantly lower than seen in the separate-vaccine group.[407] This hexavalent combination is no longer in development.

FUTURE COMBINATION VACCINES

Sanofi Pasteur and Merck have developed a fully liquid hexavalent DTaP/IPV/HepB/Hib vaccine composed of DTaP5 and IPV from Sanofi Pasteur plus HepB and PRP-OMP from Merck. Prelicensure studies of the vaccine (referred to during development as V419 or PR5I) have been conducted in North America and Europe. The vaccine, now listed in the EU under the trade name Vaxelis, will be marketed by a Merck-Sanofi joint venture, MCM Vaccines.[407a] Initial studies evaluated alternate formulations that differed in amount of the HepB component and the choice (PRP-OMP vs PRP-T) and amount of the Hib component.[248–252,408–413] Following an initial evaluation of two formulations as a fourth dose in toddlers,[408] Halperin and colleagues[409] evaluated four alternative formulations (12 μg PRP-T, 3 μg PRP-OMP, or 6 μg PRP-OMP, each combined with 10 μg HepB; or 6 μg PRP-OMP combined with 15 μg HepB; in each case, further combined with DTaP5/IPV) given at 2, 3, 4, and 12 to 14 months of age. Diaz-Mitoma and colleagues[410] compared Pentacel plus HepB vaccine with three alternative formulations of the liquid hexavalent combination (12 μg PRP-T, 3 μg PRP-OMP, or 6 μg PRP-OMP, each combined with DTaP5/IPV and 10 μg HepB) given at 2, 4, 6, and 12 to 14 months of age. Based on the foregoing, development of this DTaP5/IPV/HepB/Hib combination vaccine proceeded using a formulation containing 10 μg HepB, manufactured with a modified process, and 3 μg PRP-OMP. A subsequent study compared this DTaP5/IPV/HepB/Hib combination at 2, 4, 6, and 15 months, with PCV7 given concomitantly or 1 month later, to Pentacel plus PCV7 at 2, 4, 6, and 15 months with Engerix-B given concomitantly at 2, 4, and 6 months of age.[248,249] Antibodies to diphtheria were high in all groups, but significantly higher in the groups not receiving concomitant PCV7. Otherwise, the timing of PCV7 administration had no material impact on antibody responses to the hexavalent vaccine, nor did coadministration with the hexavalent vaccine impact pneumococcal antibody responses. Antibody responses to the DTaP, IPV, and HepB components of the hexavalent vaccine equaled or exceeded those seen with the standard-of-care separate vaccines. PRP antibody levels were excellent in all groups, but differed, being substantially higher in the hexavalent group after the primary series and substantially higher in the separate-vaccines group after the booster. Subsequent Phase III studies[250–252,411–413] evaluated safety, immunogenicity, lot consistency, and coadministration with other routine vaccines given to infants and toddlers. Marshall and colleagues compared the hexavalent plus PCV13 and RotaTeq at 2, 4, and 6 months to Pentacel plus PCV13, RotaTeq, and (at 2–6 months) HepB, and found the immune response to the hexavalent to be noninferior to control except for FHA GMCs (but FHA seroresponse rates were noninferior).[250] At 15 months, both groups received Daptacel plus PCV13; the hexavalent group also received PRP-OMP while the control group received PRP-T. Postbooster antibody responses in the group primed with the hexavalent were noninferior to those of the control group.[250] In another U.S. study, Block and colleagues evaluated immunogenicity and safety of three lots of the hexavalent, given with PCV13 and RotaTeq at 2, 4, and 6 months, versus a control group given Pentacel, PCV13, and RotaTeq at 2, 4, and 6 months and HepB at 2 and 6 months; both groups received Pentacel plus PCV13 at 15 months.[251] Following the infant series, all lot-consistency hypotheses were met, as were all immunogenicity noninferiority hypotheses except for GMCs for FHA and for one (6B) of the 13 PCV serotypes (but for each, noninferiority was demonstrated for seroresponse rates). Following the toddler booster, noninferiority was met for all antigens except for PRN GMCs (but noninferiority was met for PRN seroresponse rates). Adverse event rates were similar in the two groups, except that fever was more common in the hexavalent group (47.1%) than in the control group (33.2%). Vesikari and colleagues evaluated the hexavalent vaccine versus Infanrix hexa at 2, 3, 4, and 12 months; each group also received PCV13 and RotaTeq with the infant doses and MMRV with the fourth dose.[252] Immune responses in the investigational group were all noninferior to those of the control group; adverse event rates did not materially differ between the groups. Silfverdal and colleagues evaluated the hexavalent vaccine versus Infanrix hexa at 2, 4, and 11 to 12 months; each group also received PCV13 and either RotaTeq or Rotarix with the infant doses and PCV13 with the third dose.[411] Immune responses in the investigational group were all noninferior to those of the control group, and were superior for anti-PRP following the second dose. Adverse event rates were similar except for fever (6.4%) and somnolence (5.8%), which were higher in the investigational group. Martinón-Torres and colleagues investigated immune responses to a mixed schedule in which Spanish infants given HepB at birth were given the hexavalent plus MnC, PCV13, and RotaTeq at 2 months; Pediacel, MnC, PCV13, and RotaTeq at 4 months; and the hexavalent plus RotaTeq at 6 months.[412] At 7 months of age, 98.9% of subjects were seroprotected (antibody levels ≥10 mIU/mL) against HepB (GMC: 1055 mIU/mL) and 100% against Hib (≥0.15 μg/mL antibody to PRP; GMC: 8.0 μg/mL). The proportion reporting fever was lower following the hexavalent at 2 and 6 months than after the comparator vaccine at 4 months (4.9% and 4.7% vs 6.3%). Finally, Oliver and colleagues evaluated the hexavalent given at 2, 3, and 4 months concomitantly with PCV13 (at 2 and 4 months) and either MnC-TT or MnC-CRM at 3 and 4 months. All children received MnC/Hib at 12 months. In the group given MnC-TT, 100% had serum bactericidal antibody (SBA) titers of 1 : 8 or greater following the first, second, and booster doses; in the group receiving MnC-CRM, the corresponding percentages were 96.4%, 99.1%, and 97.3%. Following three doses of the hexavalent, 97.8% to 100% had ≥0.15 μg/mL of antibody to PRP and 96.3% to 96.8% had ≥10 mIU/ML of antibody to HepB; all subjects were seroprotected against D, T, and the three poliovirus types.[413]

GlaxoSmithKline is exploring the development of vaccines that provide broad-based (i.e., not serogroup-specific) protection against pneumococci, nontypeable *Haemophilus influenzae* (NTHi), or both.[414–416]

In the first study, vaccines composed of pneumococcal histidine triad protein D (PhtD) and/or detoxified pneumolysin (dPly), combined with alum or AS02$_v$ adjuvant system (an oil-in-water emulsion combined with monophosphoryl lipid A and the saponin QS21) and formulated either as free proteins or in an eight-valent PCV, were evaluated in adults 65 to 85 years of age given one dose or two doses 60 days apart.[414] The AS02$_v$ groups had higher rates of solicited local and systemic adverse reactions and better immune responses than the other groups. Another study evaluated a combination vaccine containing PhtD plus NTHi protein D (PD) and dPly (dPly), which we will refer to as HiP. Healthy young adults were randomized to receive two doses 60 days apart of HepB (as a control) or HiP formulated with or without AS03 adjuvant (a tocopherol and squalene-based adjuvant, as used, for example, in GlaxoSmithKline's European Union-licensed pandemic influenza vaccines). Local and systemic adverse events were more common in the AS03 group than the other two groups and increased more with the second dose in the two HiP groups than the HepB group. GMCs were highest and persisted best in the AS03 group.[415] A third study evaluated PhtD vaccines formulated with no adjuvant, alum, or AS02$_v$, administered to young (18–45) or elderly (≥65 years of age) adults. Humoral and cellular responses improved with the AS02$_v$ adjuvant system, such that antibody responses in the elderly AS02$_v$ group were comparable to those in the young-adult groups receiving vaccine formulated with alum or no adjuvant.[416]

Wuxi Biological is developing a MnAC/Hib vaccine to address meningococcal epidemiology in China. Hu and colleagues compared this vaccine to separate administration of Wuxi MnAC plus ActHib among children ages 6 to 23 months or 3 to 5 years.[417] Noninferiority was demonstrated for all safety and seroprotection endpoints; meningococcal GMTs did not differ between the investigational and control groups but PRP antibody levels, although very high in both groups, were significantly higher in the control groups (16.2 vs 20.0 μg/mL in the younger children and 45.2 vs 70.7 μg/mL in the older children). ZhiFei Biotech apparently has received marketing approval in China for a similar vaccine, but no study results are available in the indexed literature.[418]

There are also combination vaccines licensed or under development that incorporate multiple serotypes of a single antigen. Among these potentially important combination vaccines are human papillomavirus vaccines (see Chapter 30); trivalent or quadrivalent influenza vaccines, including those of heightened potency or novel modes of delivery (see Chapters 31 and 32); polyvalent pneumococcal vaccines (see Chapters 46 and 47) and meningococcal vaccines (see Chapter 38), especially the conjugate products that are progressively replacing the older polysaccharide vaccines; polyvalent rotavirus vaccine (see Chapter 52); and quadrivalent dengue vaccines (see Chapter 17). Other targets for combination vaccines include tickborne infections, arboviruses, and additional agents of diarrheal diseases.

PRACTICAL ISSUES IN THE USE OF COMBINATION VACCINES

Choice of Combination Versus Separate Component Vaccines

In its 2011 update of the General Recommendations on Immunization, the ACIP states that "Licensed combination vaccines can be used whenever any components of the combination are indicated and its other components are not contraindicated…. The use of a combination vaccine generally is preferred over separate injections of the equivalent component vaccines."[5] Similarly, the Red Book notes that "Parenteral combination vaccines may be administered instead of their equivalent component vaccines if licensed and indicated for the patient's age….When patients have received the recommended immunizations for some of the components in a combination vaccine, administering the extra antigen(s) in the combination vaccine is permissible if they are not contraindicated and doing so will reduce the number of injections required."[419]

When a combination consists of the same components that the practitioner would have given separately at the same visit, the combination is preferred. In other circumstances (e.g., the combination does not incorporate the same components that the practitioner would have given; the components are the same, but the practitioner would have given one or more on a different schedule; the patient does not need one or more of the components, but receipt is not contraindicated), use of the combination is acceptable but not necessarily preferred.

The risk of failing to deliver an indicated vaccination increases with the number of vaccinations indicated at a given visit.[420] Accordingly, the use of combination vaccines may help ensure timely completion of indicated vaccinations. Investigators from the New York Health Department reported that vaccination timeliness rose from 84% to 93% following introduction of a DTaP/HepB/IPV combination vaccine,[421] and investigators from the Georgia Health Department reported significant improvements in coverage rates and timeliness of vaccination for the antigens included in the combination vaccine.[422] A study in a large U.S. managed care health plan found that use of a DTaP-based combination vaccine did not alter the timeliness of DTaP immunization but significantly improved the timeliness of the other included components.[423] None of these ecological studies, however, controlled for other factors that might explain their observations. For example, in each study, the timeliness of vaccination also improved for components not included in the combination, raising the possibility that improvements in coverage were the result of improvements in administrative, provider, or patient performance unrelated to choice of vaccine. A German study that did control for temporal (e.g., birth cohort) effects evaluated the proportion of children having received one dose, the full primary series, or full immunization by 3, 5, and 15 months of age respectively.[424,425] Comparing hexavalent with separate vaccines, mean age at first immunization improved by 0.5 month for Hib, 0.4 month for polio, and 0.9 month for hepatitis B virus (HBV), and mean age at full immunization improved by 2.2 months for Hib, 3.2 months for polio, and 1.4 months for HBV. A study using data from the 2012 (U.S.) National Immunization Survey found that use of combination vaccines was associated with 60% lower likelihood of an incomplete immunization series among children age 24 months.[426] As might be expected, the use of combination vaccines has also been shown to reduce administration time and associated labor costs.[427]

Administration of Superfluous Antigens

As a variety of vaccines become available that combine different antigens, physicians will increasingly find that the simplest (and even, perhaps, the least expensive) alternative will be use of a combination vaccine that includes an antigen that the patient does not need, having already received that antigen in the recommended quantity and timing. Some antigens are known to be associated with increased adverse effects when administered too frequently (e.g., diphtheria toxoid), but these are few. Fortunately, it has been shown for many vaccine antigens that an extra dose may be given without adverse consequence. In particular, the low reactogenicity of Hib, IPV,

and HepB vaccines makes it unlikely that an extra dose of any of these antigens would cause a problem.

Interchangeability

When multiple combination vaccines are available from several different manufacturers, practitioners will question whether the vaccines can be used interchangeably. This question can be difficult to answer even for monocomponent vaccines, and there is little hope of definitive answers for multicomponent vaccines. Consider, for example, a study performed to evaluate the interchangeability of the three conjugate Hib vaccines indicated for the infant primary series.[428] Of the 27 theoretically possible permutations of three vaccines and three injections, five were evaluated. In a world of multiple, distinct DTaP, DTaP/Hib, DTaP/Hib/IPV (and so on) combination vaccines, there is little likelihood that any particular substitution will have been studied.

The ACIP has recognized certain vaccines as interchangeable within their respective series: Hib, HepB, HepA, rotavirus, and quadrivalent meningococcal conjugate.[5] For the vaccines for which there are no data on the interchangeability of licensed products from various manufacturers (e.g., DTaP[5,429,430] and the newer combination vaccines[5]), the ACIP has recommended that the same product be used throughout the primary series. However, if the identity of the previously used product is unknown or if the product is not available at the time of the child's visit, any licensed product appropriate to the child's immunization status and requirements may be used. As the Centers for Disease Control and Prevention notes, "Unavailability of the vaccine used for earlier doses is not a reason for missing the opportunity to administer a dose of acellular pertussis vaccine for which the child is eligible."[431] Similarly, Canada's National Advisory Committee on Vaccination (NACI) has stated that "Based on expert opinion and using the limited data available to date, NACI recommends that the DTaP-IPV/Hib and DTaP-IPV combination vaccine products currently approved for sale in Canada may be used interchangeably for the 18-month and 4- to 6-year booster, respectively."[281]

In this day of bulk vaccine purchase through competitive bidding by large health maintenance organizations and the government, it is unrealistic to presume that the same vaccine will always be available for each child at the time of each vaccination. The situation is further complicated by the fact that 25% of U.S. children see at least two different healthcare providers for their vaccination series and that the average time for a child to remain in a publicly funded healthcare plan is 10 months. Different practitioners are likely to stock different combination vaccines. Because the need to interchange vaccines will arise often, it is reassuring to know that interchanging one brand of vaccine for another has never been shown to result in performance that is outside the range expected for the vaccines in question.

Ad Hoc Combinations

Providers should not create their own ad hoc combinations by mixing separate vaccines in the same syringe unless there is evidence establishing the stability, safety, and immunogenicity of the resultant combination, as reflected in the package inserts.

PUBLIC HEALTH CONSIDERATIONS

Cost Issues

Whether the combination vaccine purchaser is a government, a health maintenance organization or some other intermediary, or the practitioner and patient, it must be expected that economic factors will influence decisions. It is obvious that premium pricing of the combination or reduced provider reimbursement (as a result of administration of fewer injections) may inhibit use of the combination. Less obvious, but equally important, are the economic benefits that flow from use of a combination, which include savings resulting from simplified vaccine purchase, storage, and handling; reduced costs for labor and supplies; elimination of the need for scheduling several vaccination visits to avoid multiple injections; and, of course, increased patient satisfaction and greater compliance with vaccination recommendations.

Many of the newer vaccines, such as DTaP, conjugate Hib, and complex combinations, are substantially more expensive to produce than DTwP, OPV, and other traditional combination vaccines. Certainly, cost considerations will constrain the use of some of these vaccines in certain parts of the world. DTwP, for example, is produced locally at low cost in many countries, and its replacement with DTaP must be weighed against other healthcare expenditures. However, some other relatively expensive vaccines, such as HepB or Hib, offer such clear benefits that they are being used in many developing countries, and once a country has committed to using (for example) HepB or conjugate Hib vaccine, it is likely that combinations that also provide such antigens as DTP or IPV can be purchased for less than the cost of purchasing, storing, shipping, tracking, and injecting the separate component vaccines.

Tracking of Vaccinations

The increasing variety of alternative vaccines (including those with multiple antigens) that might be used to satisfy childhood vaccination requirements makes it unlikely that a practitioner will be able to deduce the precise vaccination history of a new patient. Although U.S. legislation has mandated since March 1988 that medical records of vaccination should contain the identity of the vaccine manufacturer, the date of administration, and the lot number of the vaccine given, such practitioner-based records typically are not retrievable by others. Immunization registries (also termed immunization information systems) are confidential, population-based, computerized information systems that collect vaccination data about all children within a geographic area. Registries can elucidate uncertain vaccination histories, identify children who are due or late for vaccinations, generate reminder and recall notices to ensure that children are vaccinated appropriately, identify provider sites and geographic areas with low vaccination coverage, and provide denominator information for outbreak investigations. One of the U.S. health objectives for 2020 is to increase to 95% the proportion of children younger than 6 years whose immunization records are included in a fully operational, population-based immunization registry. As of 2009, some 77% of U.S. children younger than 6 years participated in a registry.[432] Efforts should continue to increase the percentage of children participating in registries.

Assisting these efforts are improvements that facilitate the accurate and convenient recording of vaccine information in the medical record. Increasingly, vaccine unit-dose containers are being supplied with machine-readable barcodes and/or peel-off stickers that can be placed in the medical record. Since 2011, the Centers for Disease Control and Prevention (CDC) and the FDA have been moving toward implementation of 2D barcodes, which can contain more information than linear barcodes in a smaller space.[433] Linear barcodes currently contain vaccine product identification information only, whereas 2D barcodes can contain the vaccine product identification information as well as the lot number and

expiration date, offering the potential for a marked improvement in medical record accuracy. Numerous vaccines are now distributed in the United States labeled with 2D barcodes.

In summary, combination vaccines have dramatically altered vaccination practices, particularly among the pediatric population, permitting protection against increasing numbers of diseases without equivalent increases in the number of injections required while maintaining the safety and protection associated with the individual vaccines.[434]
