Autologous DC vaccination was also attempted as a strategy for therapeutic immunization. A decrease in HIV-1–specific $CD8^+$ T-cell responses associated with a partial control of viral replication occurred in 12 HIV-1–infected patients during autologous DC vaccination.[992]

Autologous RNA-electroporated DCs were evaluated in 10 HIV-1–positive subjects successfully being treated with ART. Autologous monocyte-derived DCs were electroporated with RNA encoding CD40L and HIV antigens (Gag, Vpr, Rev, and Nef) and injected monthly in combination with ART. Mild adverse events included flu-like symptoms, fatigue, and injection-site reactions. No evidence of autoimmunity, changes in viral load, or significant changes in absolute $CD4^+$ and $CD8^+$ T-cell counts were observed.[993,994] This novel concept is being considered for additional trials at this time.

Viral Vectors

HIV-1–infected volunteers who were receiving ART were given a replication-defective Ad5 HIV-1 Gag vaccine in a randomized, blinded therapeutic vaccination study. HIV-1–infected vaccine or placebo recipients underwent analytical treatment interruption for 16 weeks. The vaccine was generally safe and well tolerated, but significant control of viral load was not observed.[995]

The safety and immunogenicity of recombinant MVA and Fowlpox vectors expressing multiple HIV-1 proteins was evaluated in 20 HIV-infected persons with suppressed viral replication on HAART. The vaccines were well tolerated, and increased $CD4^+$ proliferative responses suggested further studies be undertaken to assess viral load.[996]

An interesting observation was made on the effect of therapeutic immunization on the extent of sequence diversity. HIV sequences from chronically infected subjects before and after vaccination with MVA-Nef were assessed, and MVA-Nef reduced Nef sequence variability, in contrast to no changes in Vif or Gag sequence diversity.[997]

In some cases, however, negative effects of viral vector based therapeutic vaccines have been observed, as with ALVAC–HIV-1 vaccine. A multicenter, double-blind, placebo-controlled Phase II clinical trial was conducted in which 65 antiretroviral-treated patients were randomized to receive an HIV-1 recombinant Canarypox vaccine (vCP1452, ALVAC) or placebo, followed by analytical treatment interruption. Patients exposed to vaccine had higher levels of viral replication and more rapid time to treatment resumption. A significant increase in HIV-specific CD4 T cells producing IFN-γ and IL-2 was observed in the vaccine arm compared to the placebo arm following vaccination. In contrast, no difference was observed following vaccination in the phenotype and functional capacity within the CD8 T-cell compartment. These findings suggest that a vaccine-induced transient activation of HIV-specific $CD4^+$ but not $CD8^+$ T cells may have a detrimental effect on HIV outcomes.[998]

NYVAC immunization induced polyfunctional HIV-specific T-cell responses in chronically infected, ART-treated HIV patients and may be further evaluated for therapeutic immunization.[999]

Nucleic Acid Vaccines

DNA vaccines have also been evaluated in the context of therapeutic immunization. A pediatric trial designed to analyze safety and immunogenicity of a therapeutic DNA vaccine was evaluated in 20 HIV-1 vertically infected children in a Phase I trial. Children (6–16 years of age), on stable antiretroviral treatment for at least 6 months with HIV-1 RNA of less than 50 copies/mL and stable CD4 counts (>400 cells/mm^3 or 25%) over 12 months of follow-up, were recruited into the study. The vaccine, a multiclade multigene HIV-DNA vaccine, was well tolerated, and immunogenicity assessments are ongoing.[1000]

A Phase I/II, randomized, placebo-controlled, double-blinded trial was conducted to evaluate the safety and immunogenicity of an HIV-1 DNA vaccine (VRC-HVDNA 009–00-VP) in subjects treated with ART during acute/early HIV-1 infection. Twenty healthy HIV-1–infected subjects who were treated with ART and had HIV-1 RNA of less than 50 copies/mL were randomized to receive either vaccine or placebo. Postvaccination, subjects interrupted antiretroviral treatment, and set-point HIV-1 viral loads and CD4 T-cell counts were determined. No evidence of differences in immunogenicity in subjects receiving vaccine versus placebo, and no significant differences in set-point HIV-1 viral loads or CD4 T-cell counts were detected following treatment.[1001]

Lastly, DermaVir, a plasmid DNA therapeutic vaccine expressing 15 antigens, induced predominantly central memory responses in patients receiving combination ART; studies are continuing with this candidate.[1002]

Summary of Therapeutic Vaccines

Despite several novel approaches being assessed in clinical trials, there is limited evidence for efficacy with therapeutic vaccines against HIV-1 infection. This is likely because of the suppression of key elements of the host immune system conferred by HIV-1 infection. Novel vaccine strategies will soon be entering into clinical trials in HIV-infected subjects, with new and more potent adjuvants, with the aim of eliciting immune responses capable of providing long-term control of infection.

The recent advances in understanding the HIV reservoir, coupled with advances in histone deacetylase inhibitors as potential agents to stimulate the provirus from the reservoir, have led to a reinvigoration of efforts on therapeutic vaccines and antibody based strategies for functional cure.[1003] Several challenges remain however, including development of biomarkers for the reservoir and clinical trials with both histone deacetylase inhibitors and immune interventions.

SUMMARY AND FUTURE DIRECTIONS IN HIV VACCINE DEVELOPMENT

The HIV vaccine field is currently undergoing a renaissance[1004,1005] as a result of three recent advances. First, the demonstration of modest vaccine efficacy in RV-144 has led to clinical research programs focused on correlates of protection, and plans to repeat and expand the observations of the RV-144 efficacy trial. At the time of this writing, plans are being developed for an efficacy trial in South Africa of related immunogens.

Second, a number of new vaccine candidates have recently entered, or will soon be entering clinical trials, which in preclinical studies have outperformed earlier candidates currently in trials, on the basis of either control of infection or in some cases prevention of acquisition of infection in monkeys. The field will also gain knowledge as these candidates progress, and prioritization of the most promising candidates will lead to future efficacy trials.

Finally, the recent identification of broad and potent neutralizing monoclonal antibodies against HIV-1 has led to the identification of new targets for vaccine design, with the aim of eliciting bNAbs. As incremental progress in this field continues, one would expect new and improved candidate vaccines, capable of eliciting such bNAbs, emerging soon.[1006]

Acknowledgments

We thank Sandi Glass and Lisa Gieber (IAVI), for their fabulous editorial and literature compiling assistance.

30 Human Papillomavirus Vaccines

John T. Schiller, Lauri E. Markowitz, Allan Hildesheim, and Douglas R. Lowy

Human papillomavirus (HPV) infections, which are very common, produce epithelial lesions of the nongenital and genital skin and mucous membranes. Although most infections are benign and self-limited, persistent infection by a subset of the more than 150 HPV genotypes (types) can lead to a variety of epithelial malignancies.[1,2] The oncogenic potential of HPVs was shown first in the 1970s by Orth and colleagues for epidermodysplasia verruciformis, a rare condition of widespread nongenital warts that sometimes progress to squamous cell cancer.[3] In the 1980s, zur Hausen and colleagues identified HPV DNA in the majority of cervical cancers,[4] and subsequent epidemiologic studies confirmed that most cases of this cancer can be attributed to the sexual transmission of approximately 12 oncogenic, high-risk HPV types, especially HPV16 and HPV18.[5–7] Cervical cancer is the third leading cause of cancer in women, with an estimated 530,000 new cases and 275,000 deaths annually worldwide, numbers that are predicted to continue increasing over time.[8,9] More than 80% of the cases and deaths occur in the developing world.[10]

The causal link between HPV infection and cervical cancer established the public health importance of this group of viruses. In addition, it is now recognized that infection by HPV16 and HPV18, and infrequently other high-risk types, accounts for a substantial percentage of other anogenital and oropharyngeal cancers (Fig. 30.1).[10] Although cytologic screening is an effective approach to cervical cancer prevention in some developed countries, it has traditionally been too difficult and costly to implement in most developing countries.[11,12] No effective screening strategies have been defined for the other HPV-associated cancers.

The availability of vaccines designed to prevent disease caused by the most oncogenic HPV types, HPV16 and HPV18, in the first-generation vaccines and, more recently, by other oncogenic types, is therefore a significant step toward control of these endemic and potentially lethal infections. As detailed below, the vaccines are effective in preventing new infections and dysplasia, but do not appear to alter the natural history of prevalent infection by HPV16 or HPV18.[13,14] As women and men are at very high risk of developing HPV infection soon after initiating sexual activity, HPV vaccination would have the greatest impact if given before they become sexually active.[11,15]

Most of the attention in HPV vaccines has focused on cervical cancer prevention because of the high incidence of this disease and its strong association with HPV infection. While the incidence of cervical cancer remains high in many developing countries, its incidence has been decreasing in the developed world as a result of effective cervical cancer screening programs.[10] However, the incidences of HPV-associated anal cancer and, especially, HPV-associated oropharyngeal cancer have been increasing in many developed countries.[16] HPV vaccination should also have the potential to reduce the incidences of these HPV-associated cancers, as they also appear to be predominantly sexually transmitted.[17]

The prices of the current commercial HPV vaccines are relatively high and do not target some of the high-risk HPV types. Efforts are therefore underway to develop second-generation vaccines that can prevent infection by a broader range of high-risk HPVs and/or reduce the cost of vaccination.[18] Candidate therapeutic vaccines are also under study, as preexisting persistent infections remain very common, and the preventive vaccines are not effective against them.

CLINICAL DESCRIPTION

Genital HPV infection may be subclinical or produce benign lesions such as external genital or anal warts (condylomas), and flat cervical condylomas or low-grade dysplasias of the cervix, anus, vulva, vagina, or penis.[19] Most infections are self-limited, with the majority of low-grade cervical lesions and infections clearing in 6 to 12 months.[20] In some patients, however, HPV infection persists. If caused by a high-risk HPV type, persistent infection may be associated with increased dysplasia that can eventually progress to invasive cancer. Women who are immunosuppressed, as occurs with HIV infection, are at increased risk of persistent cervical infection and malignant progression to cancer.[21] Increased risk for persistent infection and, especially, anal cancer is also seen in HIV-positive men. There is a good correlation between HPV genotype and clinical phenotype (Table 30.1).

Cervical cancer tends to strike relatively young women.[7] In many developed countries, there is a steady rise in incidence from the late-20s to the mid-40s, after which age the rates tend to remain relatively constant. Most cervical cancers occur at the junction between squamous epithelium of the exocervix and the columnar epithelium of the endocervix, called the transition zone. They arise from premalignant neoplastic lesions that most often present first as mild dysplastic lesions that progress to high-grade dysplasias and carcinoma in situ before becoming malignant (Fig. 30.2). Most high-grade dysplasias may arise from infection of a distinct population of transition zone epithelial cells that have maintained embryologic characteristics.[22] In the cervix, mild cellular abnormalities are termed low-grade squamous intraepithelial lesions (LSILs) by cytology, while on biopsy they are referred to as cervical intraepithelial neoplasia grade 1 (CIN1).[23] More significant cellular abnormalities, referred to as high-grade squamous intraepithelial lesion (HSIL) on cytology and CIN2/3 on biopsy, may be present within a low-grade cervical lesion as early as 12 months after primary infection.[24] It was recently suggested that the CIN1–3 terminology be replaced with a two-tier LSIL or HSIL histologic designation, but this review retains the former convention because it is used in most of the cited literature.[25] The entire process from infection to invasive cancer usually takes 1 to 3 decades.[20]

HPV infections by so-called low-risk (nononcogenic) HPV types are not generally associated with malignant potential. Approximately 90% of anogenital warts are caused by low-risk types HPV6 and HPV11.[26] As with infection by high-risk types, the majority of lesions are self-limited, although some warts may persist for several years, and persistence is more common in patients with impaired cell-mediated immunity. Nononcogenic HPVs can also cause recurrent respiratory papillomatosis (RRP) a rare condition characterized by recurrent papillomas in the upper respiratory tract. Based on age of onset, RRP is classified as juvenile-onset recurrent respiratory papillomatosis (JORRP) or adult onset. RRP occurs less commonly than

genital warts but is caused by the same HPV types.[27] The condition is more likely to develop in infants and young children, where the papillomas may cause hoarseness and substantial morbidity because of partial airway obstruction and their recalcitrance to treatment. JORRP is believed to arise mainly by transmission from a mother with genital HPV infection to her child during labor.

The natural history of infection with high-risk HPVs at anogenital sites other than the cervix and in the oropharynx is less-well understood, although premalignant lesions of the anal verge, termed *anal intraepithelial neoplasia 3 (AIN3)*, and of the vulva (VIN3) and vagina (VaIN3) are well recognized and have some potential for malignant transformation.[28,29] The risk of malignant transformation of high-grade anogenital lesions at anogenital sites other than the cervix is not as clearly defined as in the cervix, although the lower incidence of HPV-associated carcinomas at these sites suggests the risk may be lower.

HPV-positive oropharyngeal cancer is believed to arise following long-term persistent infection at this site.[17,30] Consistent with this hypothesis, seropositivity for HPV16-specific antibodies was associated with an increased risk of oropharyngeal cancer even when the antibodies were detected more than 10 years prior to cancer development.[31] The tumors, which are squamous cell carcinomas that often involve the tonsillar area, frequently arise in patients who lack of history of tobacco use. By contrast, cigarette smoking and alcohol abuse are important risk factors for HPV-negative oropharyngeal cancers. Premalignant stages for the HPV-associated infections have not been well defined, and there is no approved screening test for at-risk individuals.

HPV16 and HPV18 are associated with approximately 70% of cervical cancer in all regions of the world. The two are found in an even greater percentage of the HPV-associated vulvar/vaginal, anal, and oropharyngeal cancers worldwide.

VIROLOGY

Papillomavirus (PV) virions are composed of nonenveloped icosahedral capsids approximately 55 nm in diameter that contain a double-stranded circular DNA genome of approximately 8 kb (Fig. 30.3).[2] PVs are found in many vertebrate species and replicate in the nuclei of stratified squamous epithelia. They are highly species-specific and are named according to the host species they infect: HPV for human PV, BPV for bovine PV, CRPV for cottontail rabbit (Shope) PV, etc. PVs are

EV, epidermodysplasia verruciformis; HPV, human papillomavirus.

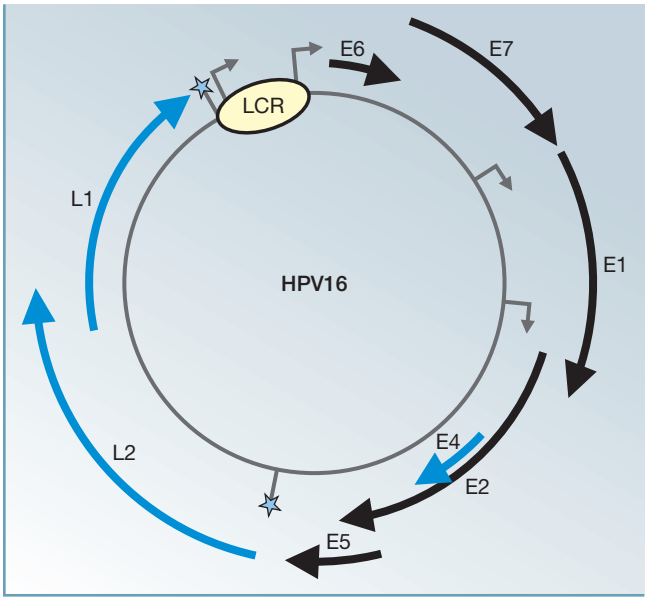

Figure 30.3. Schematic of the 7.9-kb double-stranded DNA genome of human papillomavirus type 16 (HPV16). *Large arrows* indicate open reading frames (ORFs; protein coding regions) and direction of transcription. *Black arrows*, ORFs expressed in the lower epithelial layers; *blue arrows*, ORFs expressed only in the upper epithelial layers; *gray arrows*, transcription start sites; *blue stars*, polyadenylation sites. LCR, long control region.

classified phylogenetically into genera (alpha, beta, gamma, etc), species (1, 2, 3, etc.), types, subtypes, and variants.[32] They are classified according to the comparative homology of their L1 open reading frame, which encodes the major capsid protein and is the most conserved PV open reading frame.[33] PVs tend to have similar phylogenetic relationships when homologies between other regions of the genome are compared, as these viruses appear to have arisen primarily via point mutations scattered throughout the genome, rather than by recombination between PVs. Most of the more than 150 HPV types belong to the alpha, beta, gamma, or mu genera. The alpha HPVs include the high-risk (α5, α6, α7, α9, and α11) and low-risk (such as α10 HPV6 and HPV11) HPVs that cause genital infections, as well as most of the HPVs that cause nongenital common warts (Fig. 30.4). In many people, the beta HPVs may be asymptomatic commensal agents, although they cause lesions in patients with epidermodysplasia verruciformis. The gamma and mu HPVs tend to be asymptomatic or cause foot warts (see Table 30.1).[2] Some of these genera also include animal PVs.

PVs encode two structural (L) proteins, the major (L1) capsid protein and the minor (L2) capsid protein (Fig. 30.5). They are designated major and minor, respectively, because the capsid contains more molecules of L1 than L2. L1 monomers spontaneously form pentamers that can self-assemble to form virus-like particles (VLPs) that, as in authentic virions, have 72 pentameric capsomers and possess the conformation-dependent immunodominant neutralization epitopes, which are predominantly type-specific.[34] The commercialized preventive HPV vaccines discussed later in the chapter are composed of L1 VLPs from several HPV types. In virions, up to 72 L2 molecules are found beneath the axial lumen of the L1 capsomeres.[35] L2 has several functions required for efficient infection.[36] Its aminoterminus contains cryptic epitopes that are broadly cross-neutralizing.[37]

PVs also encode several nonstructural (E) proteins present in infected cells but not the mature virion (see Fig. 30.3). E1 binds the viral origin of DNA replication and possesses a helicase function, whereas E2 is a transcription and replication regulator that binds to E2 binding sites present in several locations in the viral genome.[38] E4 can disrupt the keratin intermediate filament network.[39] E5, E6, and E7 are the main viral oncogenes.[40] E5 from high-risk HPVs appears to contribute to oncogenesis through an interaction with epidermal growth factor receptor.[41] E6 and E7 from high-risk HPVs encode multifunctional oncoproteins.[42] Their best-known biochemical activities are the ability of E6 to inactivate the p53 tumor-suppressor protein by inducing its ubiquitin-dependent degradation,[43] and of E7 to inactivate the retinoblastoma protein tumor suppressor.[44] The viral genome also has a region, the long control region, which does not contain open reading frames but instead includes the viral origin of replication and numerous cis-regulatory elements (see Fig. 30.3).

PVs have a complex life cycle that is adapted to the processes of epithelial wounding and differentiation (Fig. 30.6).[2] In stratified squamous epithelia, cell proliferation is limited to basal cells, with suprabasal cells becoming more differentiated and eventually being sloughed into the environment. Consequently, to induce the long-term infection characteristic of PVs it is necessary to infect and chronically parasitize basal epithelial cells. Evidence from a mouse genital tract PV challenge model suggests that PVs initiate their life cycle by binding to the basement membrane that separates the dermis and epithelium, after exposure of the basement membrane by microtrauma.[45] The cryptic cross-neutralization epitope(s) on L2 become exposed while the virion is still on the basement membrane, where it remains until it transfers to the basal keratinocyte.[46]

The viral life cycle in the keratinocyte can be divided into three phases: viral genome maintenance, production of virion components, and virion assembly (see Fig. 30.6).[47,48] The maintenance phase takes place in the basal cells, which maintain the viral genome as a low copy number episome. E1, E2, E6, and E7 all contribute to this phase. The second phase, which includes viral genome amplification and expression of the capsid proteins, takes place in suprabasal layers. Virion

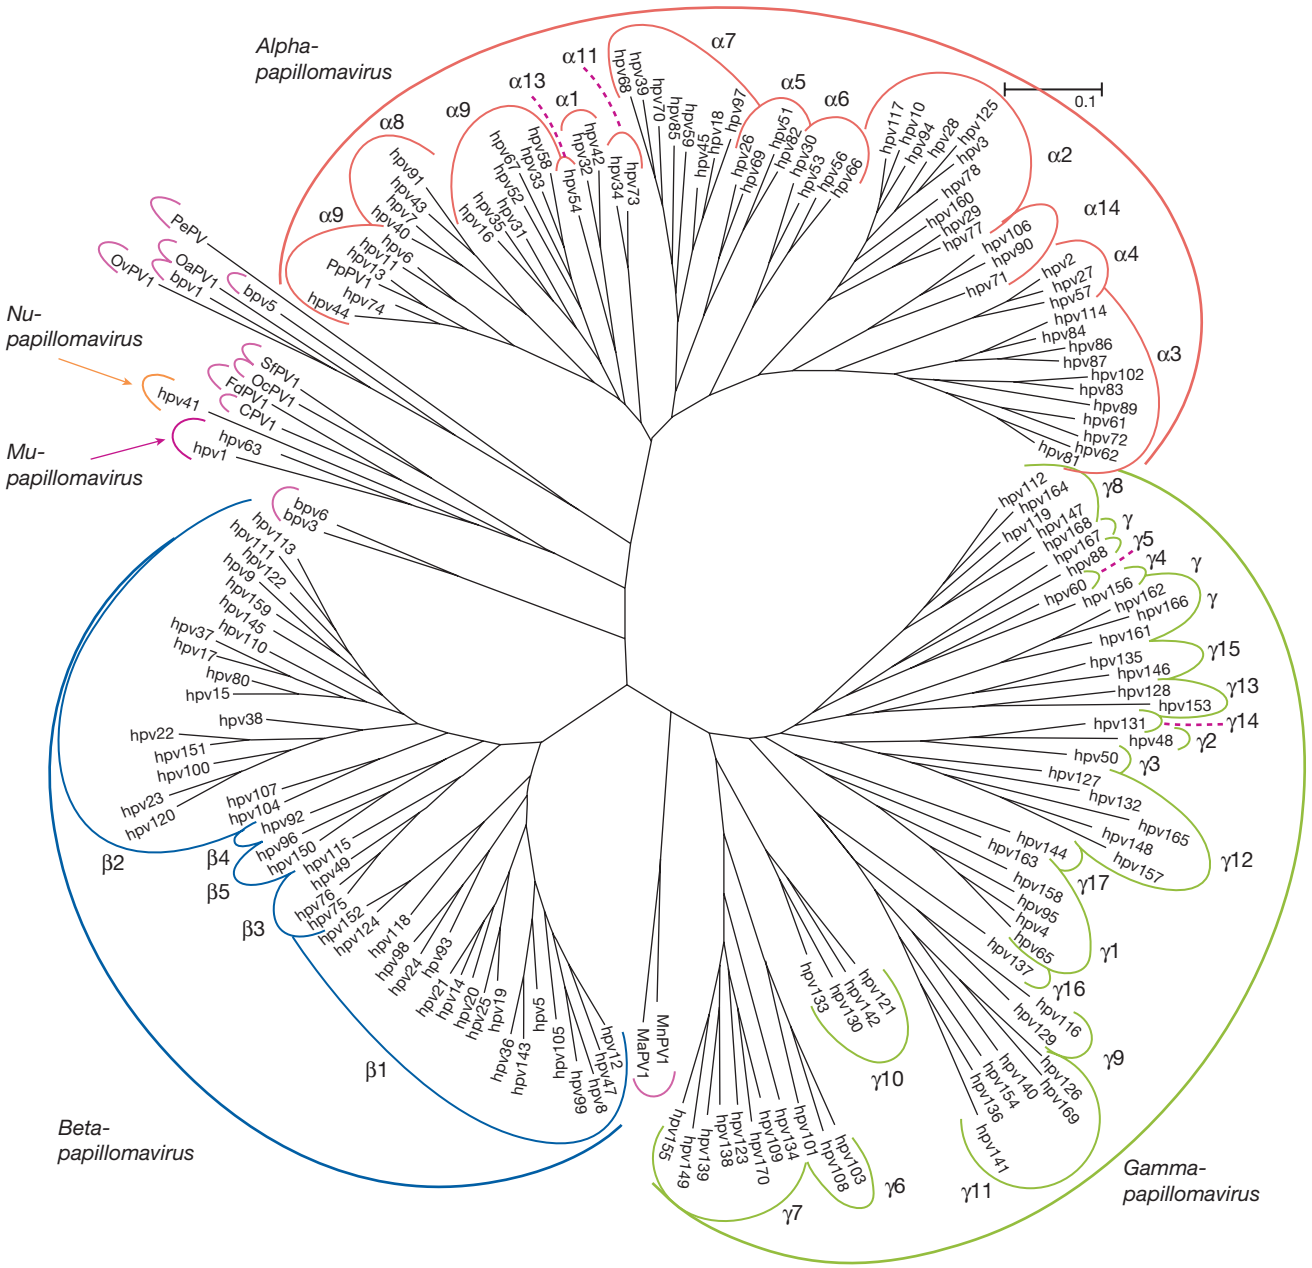

Figure 30.4. Taxonomy of papillomaviruses. The major clades are divided into subclades according to sequence homology within the L1 gene. In general, closely related genotypes produce similar pathology and share some immunoreactivity. *(From de Villiers EM. Cross-roads in the classification of papillomaviruses.* Virology. *2013;445[1–2]:2–10.)*

assembly occurs even closer to the upper epithelial cell layers and leads to eventual shedding of virus.

PATHOGENESIS

The pathogenesis of genital infection in women has been examined in greatest detail.[20,23,40] As noted earlier, genital HPV infection is sexually transmitted and is often acquired soon after sexual initiation. If infected with a low-risk HPV type, such as 6 or 11, the patient may develop genital warts, which do not have malignant potential. If the infection is with a high-risk HPV type, such as 16 or 18, the acute infection may be accompanied by a period of low-grade cytological abnormalities. Most of these infections clear spontaneously, but HPV becomes persistent in a small percentage of cases, and the virus is not cleared from the cervical transformation zone. It is these cases that are at risk of progression to high-grade dysplasia and, in some, to invasive cancer.

The long interval between infection and cancer suggests that although viral infection may be necessary for cancer to develop, it is not sufficient. Other changes in the cell presumably collaborate with the viral genes to produce cancer. The major genetic and environmental determinants of risk of persistence are, with the exception of immunocompetence, not well documented. Cigarette smoking, use of oral contraceptives, high parity, and early age of sexual intercourse all seem to add slightly to the risk of persistent HPV infection and cancer.[49]

Neoplastic changes in cervical epithelium can now be understood in light of the HPV infections that cause them

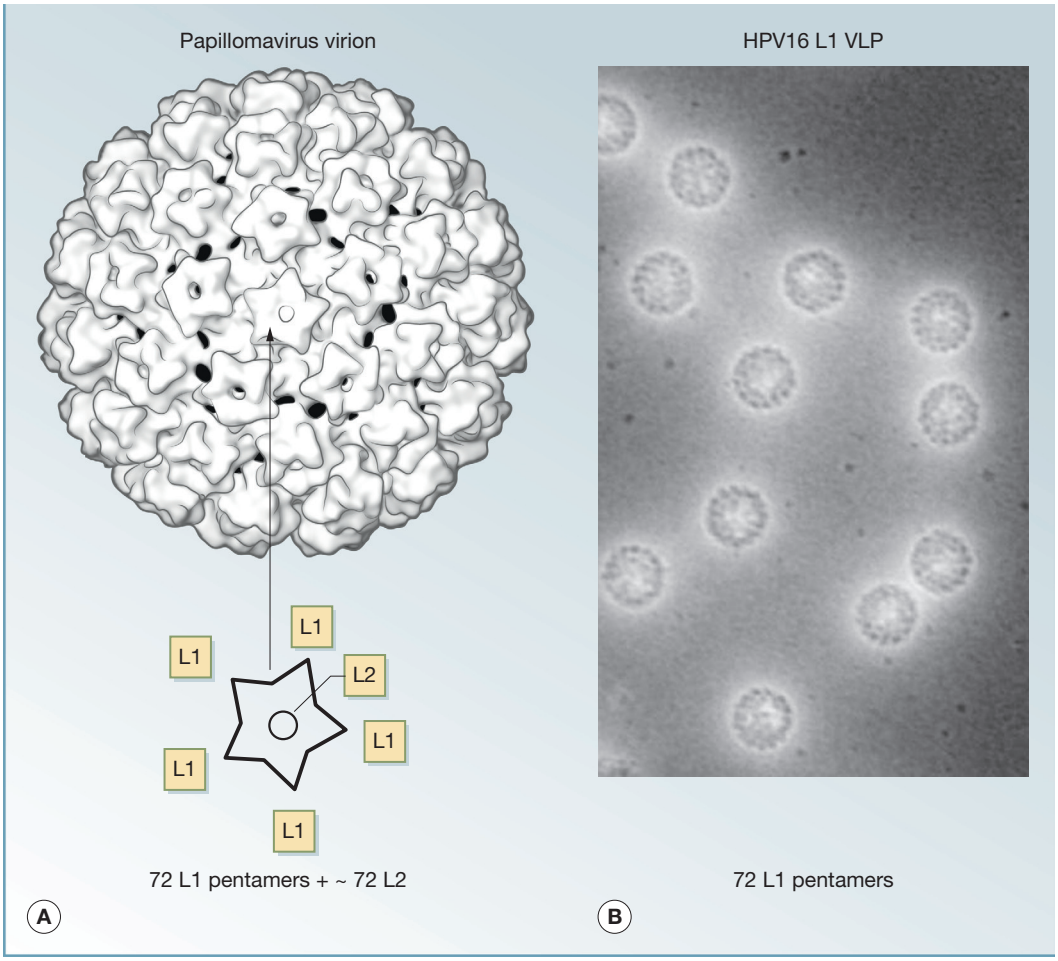

Figure 30.5. A, *Top*, Computer-generated three-dimensional image of a papillomavirus virion; *bottom*, schematic of an L1 pentamer with the location of L2 indicated by the arrow. **B,** Electron photomicrograph of negatively stained HPV16 L1 virus-like particles (VLPs) purified from L1 recombinant baculovirus infected insect cells.

(see Fig. 30.2). The low-grade cervical dysplasias identified in Papanicolaou (Pap) screening tests are simply productive HPV infections. In contrast, high-grade dysplasias and cancers do not produce virions because they do not undergo normal squamous differentiation. Consequently, the L1 and L2 proteins are expressed at low or undetectable levels. The viral genome remains episomal in most high-grade lesions, but is integrated into the host genome in a substantial percentage of invasive cancers.[50] For reasons that are not understood, the frequency of viral DNA integration varies with the HPV type. Integrated viral DNA is found in almost all cancers that contain HPV18 or the closely related HPV45, in about two-thirds of HPV16-positive cancers, and in a minority of cancers that contain HPV31 or HPV33. When the viral DNA is integrated, part of the viral genome is usually deleted, but the E6 and E7 genes are preferentially retained and expressed. Methylation of viral genes, particularly L1, is often associated with progression.[51,52]

E6 and E7, which encode the main viral oncoproteins, function together to destabilize the host genome, leading to aneuploidy and contributing to oncogenic progression. E6 and E7 seem to be required for maintenance of the tumorigenic phenotype. In cervical cancer cell lines, their inhibition leads to apoptosis. There is some evidence that E5 also plays a role in carcinogenesis, especially in tumors where the viral DNA remains episomal.[53] Destabilization of the host genome is associated with a variety of genetic and epigenetic changes in the genome of the host cell that presumably contribute to carcinogenic progression by collaborating with the viral oncogenes.

Among the high-risk HPV types, their relative oncogenicity varies.[54,55] HPV16 is the most oncogenic, in that a higher proportion of HPV16 infections persist and induce high-grade cervical dysplasia or worse when compared with other HPV types, and infections with this HPV type also tend to progress faster than those caused by other types. The next most oncogenic appear to be HPV18, HPV31, and HPV33. The molecular basis for these differences is unclear.

The immune response to HPV infection is incompletely understood.[56] HPVs have clearly evolved multiple mechanisms to evade both innate and adaptive immune responses. For instance, activities of E6 and E7 impair interferon and proinflammatory responses, interfere with antigen presentation, and dysregulate local antigen presenting cells, thereby inhibiting cell-mediated immune responses.[57,58] The development of neutralizing antibodies, which is often delayed for months after initial infection, probably helps prevent reinfection, but is not thought to contribute to clearance.[59,60] As noted earlier, defective cell-mediated immunity is associated with an increased risk of persistent HPV infection and progression to invasive cancer. This observation implies that the host T-cell responses mediate clearance of infection and that infections persist because of an ineffective induction of a host immune response to the infection, or ineffective trafficking of the induced T cells into the infected epithelium.[61] However,

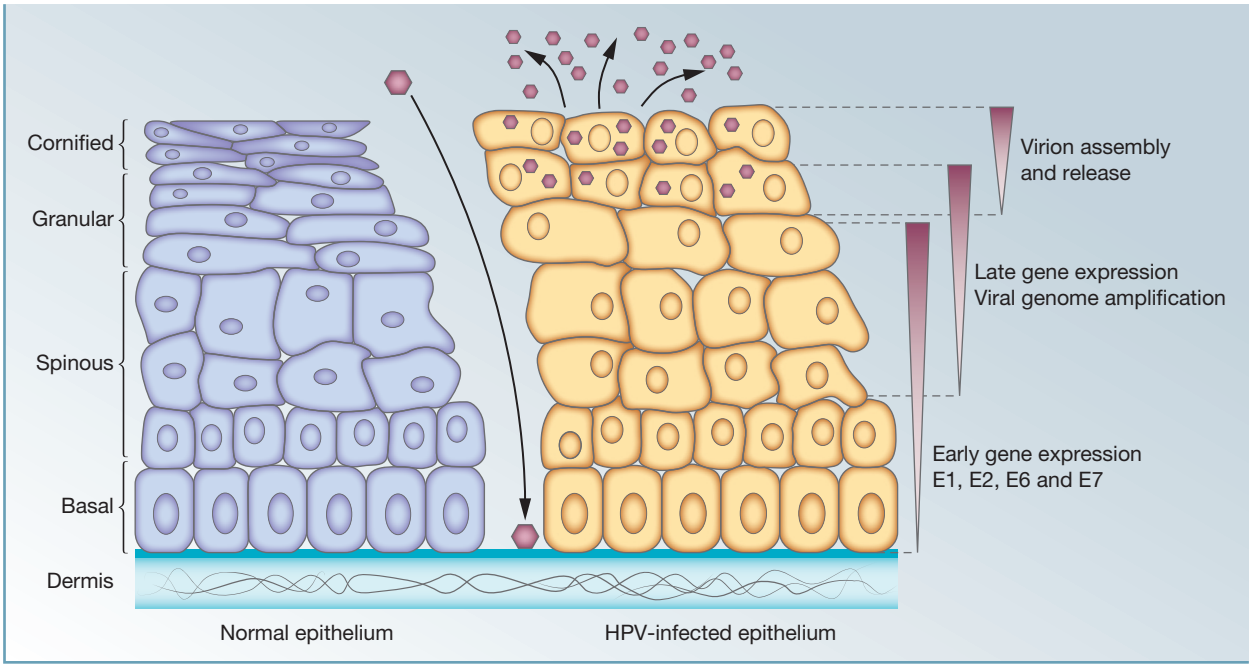

Figure 30.6. Human papillomavirus (HPV) life cycle. Uninfected stratified squamous epithelium is shown on the left and infected epithelium on the right. Binding of the basement membrane (shown in *blue*) at sites of trauma initiates infection of basal keratinocytes, resulting in the establishment of the viral genome as an autonomous replicon in the nucleus. Subsequent events in the viral life cycle are indicated on the far right. *(From Moody CA, Laimins LA. Human papillomavirus oncoproteins: pathways to transformation.* Nat Rev Cancer. *2010;10[8]:550–560.)*

the principal effector mechanisms and target antigens involved in immune-mediate regression of benign PV lesions are not well understood.

EPIDEMIOLOGY AND TRANSMISSION

The epidemiology of infection with genital HPVs has been examined in greatest detail with large-scale epidemiologic studies of cervical infection.[15,23,62,63] Genital HPV infection is spread through sexual contact. It is estimated that more than 80% of sexually active men and women in the United States will acquire at least one genital HPV infection during their lifetime, of which one-half of the infections will be a high-risk type.[64] Women are at especially high risk of becoming infected soon after initiating sexual activity, with more than 40% becoming infected during the first 2 years. The risk of infection increases with the number of sexual partners, and with the number of sexual partners of a current partner. However, infection is so common that even a first sexual relationship conveys substantial risk.[65]

It is difficult to directly compare the prevalence of cervical HPV infection in international studies because of differences in collection procedures and HPV DNA test procedures, and the paucity of population-based studies. However, in almost all studies, point prevalence peaks at an early age (<25 years) and declines thereafter. In middle-aged women (35–50 years), prevalences tend to be in the range of 15% to 20% globally. Prevalences plateau or decrease in older women in most studies, but there are notable exceptions, particularly in some Central and South American counties, where a second peak is seen in women older than age 40 years and in some countries in sub-Saharan Africa, where there appears to be no decline in women in their 30s.[66]

Most HPV infections are subclinical, with no evident abnormality on inspection, but these individuals are able to transmit infection. Simultaneous infection with more than one HPV type is common. Most infections are self-limited, with about half clearing in 6 to 12 months and approximately 90% clearing within a few years.[67,68] The rate of acquisition decreases once women reach their mid-20s. Consequently, the point prevalence of HPV infection tends to be higher among younger sexually active women, and decreases progressively once women reach their mid-20s. The percentage of seemingly cleared infections, as defined by loss of HPV DNA detection by sensitive polymerase chain reaction (PCR)-based methods, that are retained in a latent state and the cancer risk associated with reactivation from latency are uncertain.[69] Male circumcision is associated with a lower risk of HPV transmission and cervical cancer.[70,71] The regular use of condoms may reduce the risk of transmission,[72] but HPV infection can occur beyond the area covered by condoms.

Genital HPV infection in males has been examined less extensively.[73–75] The sexually associated risk factors for acquisition of HPV infection in females appear to be similar in males. Men who have sex with men (MSM) have a high prevalence of HPV infection and HPV-related disease.[76–78] Among heterosexual males, infection may be even more likely to be asymptomatic than in females. Recent data suggest that the rate of HPV infection in men may be stable throughout their lives, in contrast to the decrease in women as they get older.[73]

Although cervical/vaginal infection has been most studied, anal infection in women also occurs commonly. Genital HPV infection, HIV infection, and a history of receptive anal intercourse are associated with an increased risk of anal infection and neoplastic disease.[79] Among men, MSM have the highest prevalence of anal HPV infection and disease, particularly those who are HIV-positive.[80] However, most cases of anal cancer occur in women, many of whom lack a history of receptive anal intercourse.

Oral HPV infection is detected less commonly than genital infection.[81] However, most oral infections appear to be transmitted by sexual contact, with increased risk being associated

with the number lifetime oral or vaginal sex partners, and recent oral sex partners and open-mouthed kissing.[82] High numbers of lifetime vaginal sex partners and oral sex partners are also associated with an increased risk of HPV-positive oropharyngeal cancer.[83] JORRP is associated with transmission of low-risk HPVs, especially HPV6 and HPV11, from the birth canal of infected mothers to infants during delivery.[27]

DIAGNOSIS

Genital HPV infection is usually diagnosed by detection of the viral DNA genome.[84] For research purposes, PCR assays are generally used. They employ consensus or degenerate primer sets corresponding to conserved regions of the genome, followed by specific type determination using blot hybridization technologies. Clinical tests (discussed below) are mostly based on a signal amplification technology designated "hybrid capture" that involves detection of HPV DNA/RNA hybridization products by a monoclonal antibody specific to the hybrids. More recently, other HPV nucleic acid–based assays have been clinically validated and commercialized.[85] The value of serologic assays in detection of HPV infection has been evaluated. L1 VLP-based enzyme-linked immunosorbent assays (ELISAs) and in vitro neutralization assays (discussed below) are type-specific, but relatively insensitive, measures of HPV infection. Only about 50% of women with genital tract infections detected by PCR-based assays are seropositive to the corresponding types and seroconversion takes more than 6 months on average.[86] Serological responses to the nonstructural proteins are seldom detected during cervical infection except in invasive cancer patients, where antibodies to E6 and E7 can often be detected.[31,87]

The diagnosis of genital or nongenital warts usually relies on the clinical appearance. For HPV-associated dysplasia and cancer, diagnosis is by cytology and histologic confirmation. For anogenital cancers, the demonstration of HPV DNA in the tumor does not usually have major implications for clinical management or prognosis. However, in oropharyngeal cancers, HPV-positive tumors tend to respond better than HPV-negative tumors to most treatments and to have a better prognosis.[88]

The success of repeated Pap smears in identifying the majority of women with precancerous lesions of the cervix, coupled with the ability to eradicate these lesions, has led to an emphasis on the routine use of cervical cancer screening to prevent cervical cancer before it occurs.[15,89] High-grade premalignant lesions determined cytologically and confirmed by biopsy can be eradicated by local destruction, which is generally greater than 95% successful at eliminating the lesion and the risk of subsequent cancer. Although a single Pap smear has limited sensitivity (~50%) for detecting HSIL, the specificity is high, and repeated cytologic examinations increase the probability of detecting high-grade lesions. Given the generally long interval between the development of premalignant lesion and progression to invasive cancer, a Pap smear program can offer a high probability that most cervical cancers will be avoided if there is a good call/recall system to ensure that women at risk are screened at regular intervals. However, broadly based cervical cytologic screening programs are not available to most of the developing world.

To increase the sensitivity of a single screening test, the use of cervical swabs for HPV detection has been evaluated as an adjunct to, or as replacement for, cervical cytology. Assay of HPV nucleic acids can be automated and is less operator-dependent. Because acute infection with high-risk HPVs is common, specificity of a positive test result for HPV DNA for premalignant change is overall lower compared with cytologic analysis. However, the specificity of DNA testing is highly age-dependent and is lowest in younger women because they are more likely to have a recent infection that will clear. Results of prospective trials have shown that HPV testing is substantially more sensitive than cytology, with acceptable specificity in women in their late 20s or older.[90] In 2014, one HPV test was approved by the U.S. Food and Drug Administration (FDA) for primary cervical cancer screening.[91] Given that Pap smear screening is more sensitive for HPV16 than for other HPV types, HPV-based screening is likely to have even greater utility than Pap-based screening in HPV-vaccinated populations.[92] A clinical trial carried out in rural India demonstrated the ability of a single HPV DNA test to reduce the risk of death from cervical cancer by approximately half.[93] It is interesting to note that no reduction in mortality was seen in the groups screened once by cytology or by visual inspection of the cervix with acetic acid. An alternative use of HPV DNA testing is for triage of abnormal cytologic changes of uncertain significance, where an HPV-negative result is associated with the same low risk of a future HSIL as a women who is cytologically negative, and where an HPV-positive result has a similar positive predictive value as a low-grade cytological abnormality.[90]

PROPHYLACTIC VACCINES

Preclinical Development

The identification of a virus as the primary cause of a substantial number of human cancers provides an exceptional opportunity for cancer prevention through vaccination. However, certain aspects of PV biology and its relationship to cervical cancer created challenges to the development of effective vaccines. Pioneering work in the 1980s demonstrated that cattle could be protected against BPV infection by immunization with inactivated purified BPV virions[94]; similar observations were subsequently made using canine oral PV-induced oral lesions in beagle dogs.[95] In the beagle dogs, neutralizing antibody was shown to be necessary and sufficient for protection against viral challenge, demonstrating that vaccines to protect against PV infection would likely be conventional, working by induction of neutralizing antibody, and hence would require presentation of conformational "neutralizing" epitopes to provide protection. Prophylactic vaccines based on live attenuated or inactivated virions have proven to be very successful for other viruses, such as polio and measles. This strategy could not be adopted for HPV vaccines for two reasons. First, difficulties in propagating the viruses preclude large-scale production.[96] Second, the viral genomes contain oncogenes.[42] The possibility of carcinogenesis induced by a live or inactivated HPV vaccine would be considered too great for a vaccine designed for use in healthy young people, the vast majority of whom are not destined to acquire cervical cancer in the absence of vaccination. Therefore, the design of prophylactic HPV vaccines has centered on subunit approaches.

The current commercial prophylactic HPV vaccines are based on VLPs, which self-assemble spontaneously from pentamers of the L1 major capsid protein (see Fig. 30.5). PV VLPs can be produced in a variety of cells,[34,97–101] and procedures for production of clinical grade VLPs were first developed using L1-recombinant baculovirus-infected insect cells and *Saccharomyces cerevisiae* (Table 30.2).[102,103] Because the VLPs are produced from a single virion protein, they are noninfectious and nononcogenic. The VLPs are purified by column chromatography and purification involves dissociation into pentamers followed by reassembly into VLPs. This process increases structural regularity, stability, and immunogenicity, and also permits removal of nucleic acids that are encapsidated during intracellular assembly.[103,104] These VLPs are not only morphologically similar to authentic virus, but critically, they also induce high titers of virion neutralizing antibodies after

low-dose parenteral vaccination.[34,105,106] In contrast to VLPs, neither denatured monomeric L1 nor L1 peptides induce neutralizing antibodies (reviewed in ref. 107).

Studies in rabbits, dogs, and cattle demonstrated excellent protection from experimental challenge with high-dose homologous virus after VLP vaccination.[108–110] Strong protection from experimental challenge with high-dose virus was seen in the rabbit model even 1 year after vaccination.[111] Protection could be passively transferred via serum, indicating that neutralizing antibodies are sufficient to confer protection. Although certainly encouraging, the relevance of these results for human vaccine development was limited by the fact that protection mediated by HPV VLP vaccination could not be directly assessed in preclinical animal models because HPVs do not productively infect animals. Also, none of the animal challenge models involved genital infection or venereal transmission, the route by which the HPV infections that cause cervical cancer are acquired. However, it was demonstrated that mice or rabbits vaccinated with HPV VLPs produce high titers of antibodies that prevented infection of cultured cells or human skin chips in a mouse xenograft model.[105,106,112–114] Unfortunately, the neutralizing activity of the VLP antibodies was predominantly genotype-specific. This observation implied that if an HPV vaccine were to confer protection in people, and if neutralizing antibodies accounted for most of the protection, the protection was likely to be predominantly genotype-specific.

The seven high-risk HPV types included in Merck's nonavalent vaccine Gardasil-9 are indicated in red. *(Modified from data on 8977 cases worldwide as reported in de Sanjose S, Quint WG, Alemany L, et al. Human papillomavirus genotype attribution in invasive cervical cancer: a retrospective cross-sectional worldwide study.* Lancet Oncol. *2010;11[11]:1048–1056.)*

CURRENT VACCINES

Formulation

The preclinical trials outlined above induced two companies, GlaxoSmithKline and Merck, to undertake commercial development HPV VLP vaccines.[103] Even though both companies based their vaccines on self-assembled L1 particles, the vaccines differed in several respects (see Table 30.2). The GlaxoSmithKline vaccine, Cervarix, is bivalent, composed of the VLPs of HPV types 16 and 18, which together cause approximately 70% of cervical cancers worldwide (Fig. 30.7). It is produced in L1 recombinant baculovirus-infected insect cells and employs the proprietary adjuvant AS04, composed of aluminum hydroxide plus 3-deacylated monophosphoryl lipid A (MPL, a detoxified form of lipopolysaccharide, that is a Toll-like receptor 4 agonist). The original Merck vaccine, Gardasil, is quadrivalent and is produced in the yeast *Saccharomyces cerevisiae*. It also contains the L1 VLPs of oncogenic types 16 and 18, as well as L1 VLPs of types 6 and 11, which cause approximately 90% of genital warts but are considered nononcogenic. Recently Gardasil-9, an expanded version of Gardasil containing L1 VLPs of five additional oncogenic types—31, 33, 45, 52, and 58—was licensed. This vaccine has

the potential to protect against approximately 90% of cervical cancer worldwide (Fig. 30.7).[115] The Merck vaccines contain a simple aluminum salt adjuvant (aluminum hydroxyphosphate sulfate). None of the vaccines contain a preservative. The vaccines are delivered by intramuscular injection in three doses over 6 months, although the timing of the second dose differs (see Table 30.2). Before initiating Phase III trials, promising safety, immunogenicity, and preliminary efficacy results were obtained with monovalent HPV16 and HPV11 vaccines and subsequently with the bivalent and quadrivalent vaccine formulations in Phase I/II trials.[102,116–120]

Phase III Trial Design

Phase III efficacy trials of cervical neoplasia were independently initiated by Merck and GlaxoSmithKline.[121–123] There was considerable discussion concerning the appropriate end points before the Phase III efficacy trials of Gardasil and Cervarix were undertaken. Cervical cancer was universally rejected as an end point because women in trials with active follow-up would need to receive generally effective ablative therapy of their premalignant lesions before they progressed to cervical cancer. Advisory panels to the World Health Organization (WHO) and national regulators (e.g., the U.S. FDA and the European Medicines Agency [EMA]) considered protection against a combination of CIN2 or worse (CIN2+) and cervical adenocarcinoma in situ (AIS) caused by incident infection of the vaccine-targeted types to be a reasonable end point for obtaining an indication for cervical cancer prevention.[124] Formally, cervical cancer was also included in the combined end point, but, as expected, no incident cases were seen in the trials. This surrogate end point for cancer was acceptable because the relation of cervical HPV infection to CIN and cervical cancer was so well established in natural history studies.[5] Also, CIN2+ usually triggers ablative therapy. Prevention of external genital lesions was also a primary end point in one of the Gardasil trials (Table 30.3).[122]

With a CIN2+ end point in mind, the efficacy trials had a similar design (see Table 30.3). The randomized trials each involved several thousand young women (age range: 15–26 years) followed over approximately 4 years. The controls received a simple aluminum salts adjuvant (Gardasil) or a licensed hepatitis A vaccine (Cervarix). Clinical end points were based on colposcopy-directed biopsy and histologic determination of CIN/AIS by an expert panel. Type-specific cervical HPV infection was determined by sensitive PCR-based assays. Because the main object of the trials was prevention of disease from incident infection, the number of lifetime sexual partners was limited to no more than four or six so as to limit the enrollment of women with prevalent infection (see Table 30.3). The Merck and GlaxoSmithKline trials involved multiple trial sites around the world.

An independent trial of Cervarix, the Costa Rica vaccine trial (CVT), was undertaken by the U.S. National Cancer Institute in cooperation with the Costa Rican government. It was community based and centered in the province of Guanacaste.[125] Persistent type-specific HPV infection and high-grade CIN were used as primary end points in the Costa Rican trial. Persistent infection is a more desirable end point than incident infection because persistent, but not transient, infection is on the causal pathway to cancer. Also, detection of HPV DNA at least twice is more likely to distinguish true infections from transient contaminations. Persistence was operationally defined as detection of the same HPV type DNA in consecutive cervical samples taken approximately 6 or 12 months apart.

Because Gardasil and Cervarix were licensed and widely recommended prior to the initiation of the Phase III trial of Gardasil-9, it was considered unethical to employ a placebo control in an efficacy trial of this second generation vaccine. Therefore the participants were randomized to receive either Gardasil-9 or Gardasil, as an active comparator. The primary disease end point was high-grade cervical, vulvar, or vaginal dysplasia associated with a combination of the five oncogenic types (31, 33, 45, 52, and 58) not included in Gardasil. In addition, noninferiority of the antibody responses to the four VLP types common to the two vaccines was considered a critical criterion.

TABLE 30.3 Outline of Phase III Vaccine Efficacy Trials in Young Women

Characteristic	PATRICIA	FUTURE I	FUTURE II	Costa Rica	V503
Vaccine	Cervarix	Gardasil	Gardasil	Cervarix	Gardasil-9
Control	Hepatitis A vaccine	225 μg aluminum hydroxyphosphate sulfate	225 μg aluminum hydroxyphosphate sulfate	Hepatitis A vaccine	Gardasil
No. of participants	18,644	5455	12,167	7466	14,215
Mean age (y) (range)	20 (15–25)	20 (16–24)	20 (15–26)	21 (18–25)	22 (16–26)
Lifetime no. of sex partners	≤6	≤4	≤4	Unrestricted	≤4
Screening frequency (months)	12	6	12	12	6
Mean duration of follow-up (months)	35[a]	42[b]	42[b]	48	54
Primary efficacy end point	HPV16/18 CIN2+	HPV6/11/16/18 CIN1+ and external genital lesions	HPV16/18 CIN2+	Persistent HPV16/18 infection	HPV 31, 33, 45, 52, or 58 CIN2+,VIN2+, VaIN2+

[a]Interim analysis of 48-month trial.
[b]For combined FUTURE I/II analyses.
CIN, cervical intraepithelial neoplasia; CIN1+, CIN grade 1 or worse; CIN2+, CIN grade 2 or worse; FUTURE, Formulation of Bosentan in Pulmonary Arterial Hypertension; PATRICIA, Papilloma Trial Against Cancer in Young Adults; VaIN+, vaginal intraepithelial neoplasia grade 2 or worse; VIN2+, vulvar intraepithelial neoplasia grade 2 or worse.

Immunogenicity

For reasons outlined below, immunogenicity assessment in the VLP clinical trials has focused on antibody responses. Because the vaccines are administered via intramuscular injection, most analyses have been on serum titers. It has been difficult to compare immunogenicity results of Gardasil and Cervarix because of substantial differences between Merck's and GlaxoSmithKline's main serologic assays.[126,127] GlaxoSmithKline predominantly used a VLP ELISA, which is sensitive but does not distinguish neutralizing from nonneutralizing VLP-binding antibodies.[128] Merck predominantly used a Luminex-based assay involving competition for binding of a type-specific neutralizing monoclonal antibody to the VLPs (chemiluminescent assay [cLIA]).[129] The monoclonal antibodies were specifically chosen because they do not cross-react with VLPs of other types, so the cLIA is exceptionally type specific. However, the cLIA may only measure a subset of potentially neutralizing antibodies in the sera, because VLP-induced multivalent antibodies are known to bind to multiple distinct sites on the VLPs.[130,131]

Despite the assay differences, it is clear that both vaccines induce robust antibody responses in young women, with virtually 100% seroconversion against the HPV types in each vaccine. Geometric mean titers (GMTs) increased after each dose, peaking 1 month after the third dose. There was then a rather steep 1- to 2-log drop in titers over the next 2 years followed by a distinct stabilization in titers (Fig. 30.8). Plateau titers are generally well above those seen after natural infection.[132] Similar responses were observed in adolescent girls and boys (i.e., those younger than 16 years of age), although their serum titers were higher than those 16 years of age or older.[133–137]

An interesting head-to-head immunogenicity trial comparing Cervarix and Gardasil was conducted in women ages 18 to 45 years.[138] Using an in vitro neutralization assay based on pseudovirions transferring a marker gene,[113] Cervarix was found to induce 24-month GMT titers that were, depending on age group, 2.4- to 5.8-fold higher against HPV16 and 7.7- to 9.4-fold higher against HPV18.[139] VLP ELISA titers were similarly higher for Cervarix. GMTs continued to be higher for Cervarix in sera taken at 60 months.[140] Although higher neutralizing titers would, in principle, seem desirable, it remains to be determined whether they will translate into longer-term protection against vaccine-targeted or -related types.

There has been some concern expressed over the finding that Gardasil-induced antibody responses to HPV18 VLPs fell below the level of detection in a substantial minority of women (35%) by 4 years. However, most of these women were shown to maintain detectable VLP antibody responses in a less epitope-restricted bind assay and also an in vitro neutralization assay, suggesting that their immunodominant responses to HPV18 VLPs may be to epitopes that do not overlap those of the competing monoclonal antibodies.[141,142] There is no indication that protection to HPV18 is preferentially waning in Gardasil-vaccinated women.[143]

The immunogenicity of fewer than three doses of Cervarix was evaluated in a post hoc analysis of the CVT. HPV16 and HPV18 antibody responses, as measured by VLP ELISA and in vitro neutralization assays, were noninferior for young women receiving two doses 6 months apart, compared with those who received the proscribed three doses during the 6-month period. Surprisingly, all subjects who received only a single dose seroconverted and maintained a durable response through the 4 years of follow-up. In another unexpected result, GMT titers in single-dose recipients plateaued at levels that were only fourfold lower than those of women receiving three doses and ninefold higher than observed following natural infection (Fig. 30.9).[143a]

In young women, Gardasil-9 was judged to be noninferior to Gardasil in the induction of L1 antibodies to the four VLP types included in both vaccines.[144] The antibody responses in type-specific cLIA assays developed to the five addition types were also robust. These results indicate that increasing the valency, and also dosage of HPV6, HPV16, and HPV18, of the vaccine did not lead to excessive antigen competition among the VLP types. Similar results were reported in an

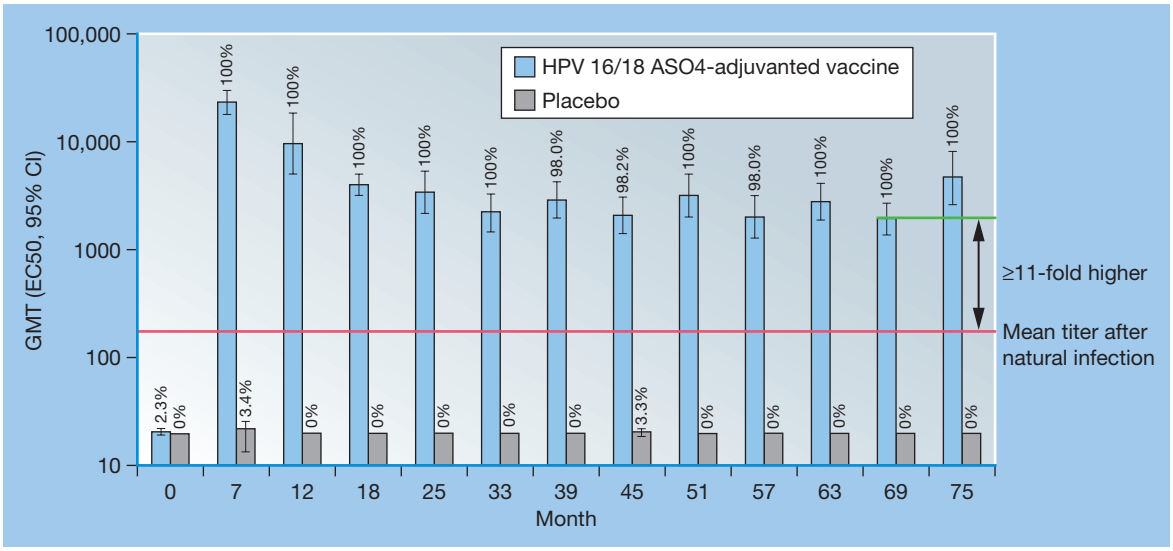

Figure 30.8. Durability of Cervarix-induced human papillomavirus type 16 (HPV16) neutralizing antibodies as measured in an in vitro pseudovirion-based assay. Percent seropositive is shown above the bars. The *red line* indicates the geometric mean titer (GMT) of unvaccinated seropositive women who cleared a natural HPV16 infection. The *green line* indicates the lowest GMT recorded in vaccinated women. Month 7 was 1 month after the third vaccine dose. CI, confidence interval; EC50, median effective concentration. *(From Romanowski B, de Borba PC, Naud PS, et al. Sustained efficacy and immunogenicity of the human papillomavirus (HPV)-16/18 AS04-adjuvanted vaccine: analysis of a randomised placebo-controlled trial up to 6.4 years.* Lancet. *2009;374[9706]:1975–1985.)*

immunogenicity trial comparing Gardasil in 9- to 15-year-old girls.[145]

Efficacy in Women

The primary efficacy analyses involved the Per Protocol (PP) cohorts, which are also called According To Protocol (ATP).

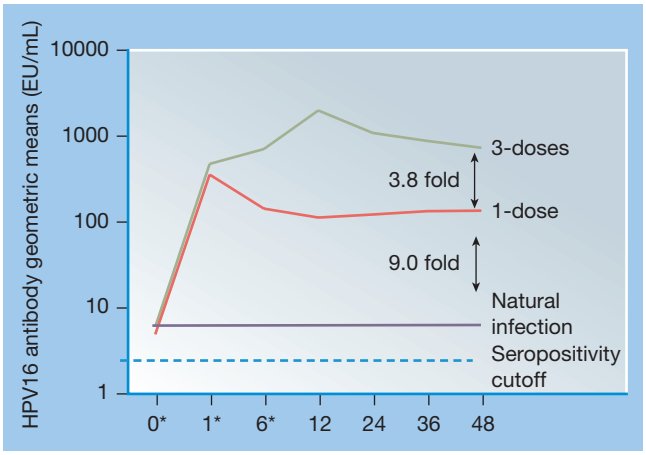

Figure 30.9. Stabilization of antibody responses to human papillomavirus type 16 (HPV16) after a single dose of Cervarix. Geometric mean virus-like particle enzyme-linked immunosorbent assay titers using sera for one- and three-dose Cervarix recipients in the Costa Rica Vaccine Trial are shown. The *x*-axis depicts number of months since first vaccination. Asterisks indicate times of vaccination in three-dose recipients. EU/mL, enzyme-linked immunosorbent assay unit per milliliter. *(Data from Safaeian M, Porras C, Pan Y, Kreimer A, et al. Durable antibody responses following one dose of the bivalent human papillomavirus L1 virus-like particle vaccine in the Costa Rica Vaccine Trial.* Cancer Prev Res (Phila)*. 2013;6[11]:1242–1250.)*

The PP/ATP cohorts included young women who were cervical cytology–negative, cervicovaginal HPV DNA and VLP antibody-negative (at least for the types in the vaccine) throughout the period of vaccination, and received all three doses within prescribed time limits. At the other end of the spectrum are the Total Vaccinated (TVC) or Intention To Treat (ITT) cohorts, which included all randomized women who receive at least one dose of vaccine, regardless of HPV or disease status at enrollment. TVC/ITT analyses best estimate the impact of the vaccine in vaccination programs in this age group, although the limitation on the number of sexual partners (see Table 30.3) limits generalizations to some extent. HPV-naïve or TVC-naïve cohorts included women receiving at least one dose and who, at baseline, were cervical HPV DNA–negative and serologically negative for vaccine types, as well as cervical DNA-negative for nonvaccine genital types. These cohorts were examined because they best approximate the primary target of prophylactic HPV vaccines, adolescent girls before they become sexually active. Adolescent girls were not enrolled in the efficacy trials, primarily because it would take too long to accrue a sufficient number of infections/lesions.

End-of-study results for the Merck Gardasil trials and GlaxoSmithKline and National Cancer Institute CVT trials of Cervarix have been published.[146–150] For all the trials, high efficacy in the PP/ATP analyses was reported. Remarkably, efficacy against vaccine type CIN2+ approached or equaled 100% for both vaccines (Table 30.4). Because simultaneous infection with multiple types was common in the enrolled women, it was often difficult to unambiguously assign lesion causality to a specific type. Assignment methods involved favoring persistent over newly detected types (GlaxoSmithKline) and PCR-based evaluation of HPV DNA in biopsy sections (Merck). Vaccine efficacy against CIN1 and persistent infection was also high for vaccine-targeted types in PP/ATP and TVC-/HPV-naïve analyses. Even transient infection was infrequently detected by sensitive PCR-based methods in vaccinees, suggesting that most of them had acquired sterilizing immunity.

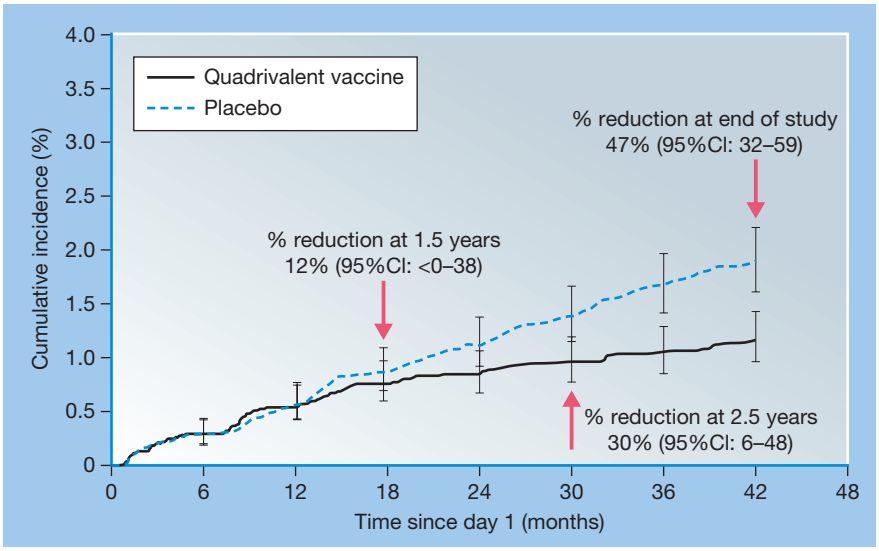

Figure 30.10. Kaplan-Meier time-to-event curve (estimates and 95% confidence intervals [CIs] at 6-month intervals) for cervical intraepithelial neoplasia 3 or adenocarcinoma in situ related to human papillomaviruses (HPV) 6, HPV11, HPV16, and/or HPV18 in the combined Intention To Treat cohorts of the FUTURE (Formulation of Bosentan in Pulmonary Arterial Hypertension) I/II trials of Gardasil (quadrivalent vaccine). *(From Munoz N, Kjaer SK, Sigurdsson K, et al. Impact of human papillomavirus (HPV)-6/11/16/18 vaccine on all HPV-associated genital diseases in young women.* J Natl Cancer Inst. *2010;102[5]:325–339.)*

As expected, the calculated vaccine efficacy in the TVC/ITT cohorts was considerably lower (see Table 30.4). Many of the CIN cases in these types of cohorts are expected to arise from prevalent, rather than incident, infection in trials of relatively short duration, and rates of prevalent infection were similar in vaccinees and controls because the trials randomized subjects. It is important to note that in these types of trials vaccine efficacy is not an absolute outcome, rather it is a time-dependent variable. Efficacy increases with time since vaccination, as disease from prevalent infection is gradually cleared in both arms and disease from incident infection is preferentially prevented in the vaccine arm. This phenomenon is most clearly seen in time-to-event curves (Fig. 30.10).[151] As a corollary, a vaccine that is equally effective at reducing the rate of CIN in two cohorts could exhibit different vaccine efficacies in this analysis if the cohorts differ in the extent of prevalent infection at enrollment. Therefore, reduction in disease rate may be a relevant measure of the potential population impact of an HPV prophylactic vaccine, in addition to the more widely reported efficacy values (see Table 30.4). These considerations are especially important for TVC/ITT analyses, as they usually include many women with prevalent infection. However, they may also be relevant to PP/ATP analyses, as at least a small proportion of women in the PP/ATP cohorts are expected have occult HPV infection at enrollment that will manifest itself during the course of the trial. This situation likely explains why "breakthrough infections" in vaccinees were more often detected toward the beginning of the follow-up phase rather than later in the trials.[143,150]

In the CVT trial, the efficacy of Cervarix for protection against 6 months of persistent cervical HPV16/18 infection after 4 years was 93.6% (95% confidence interval [CI] 88.0–96.9) in the ATP analysis and 52.3% (95% CI 44.3–59.3) in ITT.[150] However, efficacy in the ITT analysis was highly age-dependent, falling from 68.9% (95% CI 53.1, 79.9) in 18 to 19 year olds to 21.8% (95% CI −16.9, 47.9) in 24- to 25-year-olds. This trend reflects the combined effects in the cohort of an increase in prevalent infections with age and a decrease in attack rates.

Vaccine efficacy against nonvaccine types was examined for both vaccines. Efficacy was overall low against infection by nonvaccine oncogenic types (Table 30.5). There was evidence for partial protection against infection by some specific types closely related to the vaccine types. In both PATRICIA (Papilloma Trial Against Cancer in Young Adults) and CVT, Cervarix demonstrated protection against HPV31 and HPV33, two types that are closely related to HPV16, and also protection against HPV45, a type closely related to HPV18.[150,152] For Gardasil, relatively few women were evaluated for cross-type protection, and significant protection was only observed for HPV31 and HPV33. Interestingly, there was no trend for protection against HPV45. Neither vaccine protected against HPV52 or HPV58. Therefore the two vaccines are considered type-restricted with regard to protection against infection, as they provide a high degree of protection against vaccine types and partial protection against a limited number of additional oncogenic types.

Given the type-restricted protection from infection, CIN3+ efficacy irrespective of the type of HPV DNA in the lesion was notably high for Cervarix in the PATRICIA TVC-naïve cohort (91.4% [95% CI 65.5–99.0]).[152] Protection from CIN3+ irrespective of type was more modest in the HPV-naïve cohorts of the Gardasil trials (43% [95% CI 13.0–63.2]).[153] The reasons for these differences are unclear, but could include differences between the vaccines or differences between the trials in study methodology such as inclusion criteria, laboratory assays, and/or study population.[154]

Protection from cervical infection was evaluated in CVT subjects who for various reasons received fewer than the intended three doses. Unexpectedly, protection from HPV16/18 infection after 4 years was as high in women who received two vaccine doses, or even a single dose, as in women receiving the full course of three injections.[155] Similar findings were recently reported in a post hoc analysis of the GlaxoSmithKline's PATRICIA trial (Table 30.6 provides a combined analysis).[156] Interestingly, partial protection from HPV31/33/45 was detected in subjects receiving two doses at a 6-month interval but not in subjects receiving a single dose or two doses

TABLE 30.5 Vaccine Efficacy Against Incident Infection by Nonvaccine Oncogenic Types That Persists at Least 6 Months

	Cervarix: PATRICIA-ATP	Cervarix: CVT-ATP	Gardasil: HPV-Naïve
HPV31	78.7 (7.2–85.2)	64.7 (42.6–78.9)	46.2 (15.3–66.4)

[a]Combined CVT (Costa Rica vaccine trial) and PATRICIA (Papilloma Trial Against Cancer in Young Adults) Total Vaccine Cohort-naïve.[156]

at a 1-month interval. The programmatic implications of these results must be interpreted with caution because the subjects were not formally randomized by number of doses and the long-term durability of the protection after fewer than three doses needs to be assessed.

In 2010, a randomized trial of two and three doses of Gardasil was suspended by the Indian government, leaving many young women with fewer than the intended three doses.[157] At 18 months after vaccination, the GMT VLP antibody titers in girls (ages 10–18 years) receiving one dose or two doses 1 month apart were inferior to the titers in the girls receive three doses, whereas the titers in the girls receiving two doses 6 months apart were noninferior. The frequency of HPV6/11/16/18 incident infection was similar irrespective of number of doses received.[157a] Continued follow-up of the project participants should provide additional data on the relative efficacy of one, two, and three doses of Gardasil, although lack of randomization by dose will be a concern.

In the CVT, protection from anal and oral HPV16/18 infection was evaluated at the exit visit 4 years after initial vaccination. In a restricted cohort that was negative for cervical HPV16/18 DNA and HPV16/18 serum antibodies at entry, the efficacy against anal infection was 83.6% (95% CI 66.7–92.8), compared with 87.9% (95% CI 77.4–94.0) efficacy against cervical infection in the same cohort.[158] HPV16/18 DNA detection was much lower in the oral than cervical or anal specimens, just 0.5%. Nevertheless, in a similar analysis of oral HPV16/18, vaccine efficacy in the restricted cohort against oral infection at the exit visit was 91.7% (95% CI 52.3%–99.6%).[159] Although the analyses were limited by the inability to assess oral and anal infections at entry, it appears that Cervarix affords similar protection against oral and anal HPV16/18 infections as it does against cervical infection.

Gardasil contains HPV6 and HPV11, which are associated with 90% of genital warts, so this vaccine was also evaluated for protection against external genital lesions.[122] End-of-study efficacy for the HPV-naïve cohort was greater than 95% for genital warts and vulvar/vaginal intraepithelial neoplasia grades 1 to 3 (VIN1–3 and VaIN1–3, respectively) (Table 30.7). Efficacy was also relatively high in the ITT analyses, more than 75%, perhaps reflecting a relatively rapid appearance of external genital lesions after incident infection.[153,160]

Unfortunately, there is no evidence that the HPV VLP vaccines act therapeutically.[161] In the Costa Rican trial, Cervarix did not influence the rate of clearance of cervical HPV infections present at the time of vaccination.[14] Neither Gardasil nor Cervarix prevented progression of infection to CIN2/3 among young women who were HPV DNA–positive at the time of vaccination.[121,148] These findings underscore the importance of vaccination before exposure to the viruses, that is, before sexual debut. However, there is evidence, at least for Gardasil, that vaccination can prevent new HPV-associated genital disease in women who were previously treated for an HPV-induced neoplasia.[162] This activity is presumably the result of prevention of new infections, not inhibition of outgrowth of preexisting infections.

Gardasil was evaluated in an efficacy trial of mid-adult women ages 24 to 45 years.[151,163] Unlike the trials in young women, there was no restriction on the lifetime number of sexual partners. In the PP analysis, efficacy was 90.5% (95% CI 73.7, 97.5) for a combined primary end point of incident vaccine type–related persistent infection, CIN1+, and external genital lesions. Protection against HPV16/18–related end

points was 83.1% (95% CI 50.6, 95.8). Vaccine efficacy was similar in 24- to 34-year-old and 35- to 45-year-old women. In ITT analyses, the efficacy against all vaccine types was 30.9% (11.1, 46.5), but was not significant for HPV16/18-specific end points, 22.6% (−2.9, 61.7).[151] The low efficacy in the ITT analyses reflects the relatively high rates of prevalent infection/disease in the older women together with the relatively low rate of new infections, compared with younger women. These limitations were presumably influential in the FDA's decision to not approve Gardasil for mid-adult women. High efficacy against CIN1+ was also recently reported in an interim analysis of the ATP cohort of a Cervarix trial in mid-adult women.[164]

The results of the pivotal Phase III trial of Gardasil-9 were recently published.[144] In comparison to the control group vaccinated with Gardasil, the young women vaccinated with Gardasil-9 exhibited a 97% reduction in combined high-grade cervical, vulvar, and vaginal disease related to the five types—HPV31, HPV33, HPV45, HPV52, and HPV58—uniquely targeted by Gardasil-9 (Table 30.8). Similarly, the efficacy of the vaccine against infection by these types was 96%. As expected, the number of HPV6/11/16/18–associated events was low, and not significantly different, for the two vaccines. These efficacy results, coupled with the noninferior antibody responses to the shared types, led to the recent regulatory approval of Gardasil-9 by the FDA and EMA.

TABLE 30.7 Phase III Vaccine Efficacy of Gardasil Against External Genital Lesion by Vaccine-Specific Types

	No. Women: Control/ Vaccine	Placebo Rate	Vaccine Rate	Efficacy (95% CI)

Data from Munoz N, Kjaer SK, Sigurdsson K, et al. Impact of human papillomavirus (HPV)-6/11/16/18 vaccine on all HPV-associated genital diseases in young women. J Natl Cancer Inst. *2010; 102(5):325–339; and Kjaer SK, Sigurdsson K, Iversen OE, et al. A pooled analysis of continued prophylactic efficacy of quadrivalent human papillomavirus (types 6/11/16/18) vaccine against high-grade cervical and external genital lesions.* Cancer Prev Res (Phila). *2009;2(10):868–878.*

Efficacy in Men

Only one efficacy study in men has been conducted. The end-of-study results of a trial of Gardasil in 4065 young men (ages 16–26 years) have been published.[165,166] The combined primary clinical end point was vaccine type–related external genital lesions, that is, genital warts; penile, perianal, or perineal intraepithelial neoplasia; or cancers at these sites. Most events were HPV6/11–related genital warts. Observed efficacy was 90.4% (95% CI 69.2, 98.1) for PP and 65.5% (95% CI 45.8, 78.6) for ITT. A relatively high efficacy of 60.2% (95% CI 40.8, 73.8) was observed in the ITT cohort against external genital lesions, irrespective of HPV type, which is consistent with the high proportion of external genital lesions in men that are caused by one of the vaccine-targeted types.

The subset of MSM in the above study were concurrently enrolled in a study of anal infection and associated AIN. PP efficacy against HPV6/11/16/18–related AIN of any grade and AIN2+ was 77.5% (95% CI 39.6, 93.3) and 74.9 (95% CI 8.8, 95.4), respectively.[166] The relatively wide confidence intervals reflect the small trial size (300 per arm) and relatively short follow-up (3 years). PP efficacy against persistent anal infection by the vaccine types was 94.9% (95% CI 80.4, 99.4).

Safety Evaluations in the Clinical Trials

The safety data compiled in the Phase III and other clinical trials established that both vaccines, although they were highly immunogenic, were well tolerated in both females and males.[122,135,148,165,166] Common side effects attributable to the vaccine included short-term local pain, swelling, and erythema at the injection site, low-grade fever, and headache. As would be expected from such large trials, several serious adverse events were recorded; however, no pattern attributable to the vaccine was discerned for any of them. An evaluation of Cervarix did not identify any increased risk of miscarriage in pregnancies that occurred during the vaccination period or

afterward.[167] In head-to-head comparisons, Cervarix and Gardasil-9 were both somewhat more likely to be associated with injection site adverse events than Gardasil, but these minor differences did influence completion rates of the three-dose vaccination schedule.[138,144]

IMMUNOGENICITY BRIDGING TRIALS

Immunobridging studies were conducted to extend vaccine licensure to groups for which there are no efficacy data, in particular adolescent girls and boys. All licensed vaccines proved to be safe and highly immunogenic in 9- to 15-year-olds, generating two- to threefold higher GMTs to each of the types in the vaccines than they did in the 16- to 26-year-old women enrolled in the efficacy trials.[133–136] These findings led to regulatory approval for vaccination of adolescent girls, and, in some countries, adolescent boys. Similarly, a safety/immunogenicity bridging trial of Gardasil-9 demonstrated noninferior antibody responses in 9- to 15-year-old girls and boys in comparison to 16- to 26-year-old women. Seroconversion was greater than 99% for all nine types, and GMTs were two- to threefold higher in the adolescents than in the young women.[168]

Among adults, GMTs decreased with increasing age at vaccination for all the HPV vaccines. A safety/immunogenicity study of Cervarix in middle-age women reported high rates of seroconversion but somewhat lower VLP antibody titers that than those detected in young women.[169] Similar trends were seen in the Gardasil trial of middle-age women.[151] In a head-to-head comparison of Cervarix and Gardasil in 18- to 45-year-old women, serum neutralizing titers against HPV16 and HPV18 were 2.0- to 12.8-fold higher for Cervarix at 48 months, but the clinical significance of this difference is unknown.[170]

A 0-1-12–month dosing schedule for Cervarix was found to be noninferior in eliciting VLP-binding antibodies compared with the standard 0-1-6–month dosing schedule.[171] Similarly, delaying the second, third, or both doses of Gardasil did not reduce the antibody responses to the vaccines. In fact, delaying the third dose significantly increased responses. Taken together with the results of several additional studies (reviewed in reference 172) the findings indicate that extending the vaccination period over at least a year is not detrimental.

Both vaccines have been evaluated for compatibility with other vaccines administered to adolescents.[173] Coadministration of either Cervarix or Gardasil with a diphtheria-tetanus-acellular pertussis–inactivated polio vaccine in opposite arms of adolescents was safe and generated antibody responses to each of the antigens that were noninferior to the responses to the two vaccines administered separately.[174,175] Coadministration of Gardasil with a meningococcal polysaccharide vaccine (Menactra) was also judged safe and noninferior to separate administration.[176] Gardasil was also safe and immunogenic when coadministered with a hepatitis B vaccine.[177] Similarly, the antibody responses to Cervarix were judged non-inferior when co-administered with GlaxoSmithKline's hepatitis B virus and hepatitis A virus vaccines.[178]

Gardasil has been evaluated in HIV-infected children ages 7 to 12 years and in HIV-infected adult males.[179–182] The safety profile was similar to that of the placebo controls and/or that of vaccinees in other trials. Vaccination did not alter CD4 counts or plasma HIV RNA levels. Seroconversion was greater than 95% for all four antigens. However, GMTs in the HIV-infected children were 30% to 50% lower than age-similar historic controls. Cervarix has been evaluated in HIV-infected women ages 18 to 25 years. All seroconverted, but GMTs were lower than in HIV-uninfected women in the trial.[183] In a direct comparison of Gardasil and Cervarix in HIV-positive men and women, neutralizing titers against HPV18 were higher for Cervarix, whereas titers against HPV16 were similar for the two vaccines.[184]

Two- and three-dose regimens of Gardasil were compared for the induction of neutralizing antibodies. A two-dose regimen (0 and 6 months) in Canadian adolescent girls (ages 9–13 years) was noninferior to the standard three-dose regimen in young women (ages 16–26 years), both in the induction of peak titers at 7 months and plateau titers at 36 months.[185,186] Similarly, the antibody responses to HPV16 and HPV18 in girls ages 9 to 14 years who were receiving two doses of Cervarix at 0 and 6 months were noninferior to the responses induced in young women ages 15 to 25 years who received the vaccine at 0, 1, and 6 months, both at the 7-month peak and the plateau phase at month 48 and month 60.[187,188] These findings have led to a WHO Strategic Advisory Group of Experts (SAGE) recommendation that two doses of Cervarix or Gardasil be administered at least 6 months apart to girls who start the vaccination series younger than 15 years of age, but that the standard three-dose schedules be retained for older recipients. A similar recommendation was recently made by the EMA. The potential risks of adopting this recommendation, in the absence of data on the durability of protection from disease end points, were recently reviewed.[172]

A recently reported trial compared the immune response to Gardasil-9 in young men and young women 16 to 26 years of age. The antibody responses at month 7 were noninferior for all nine types in heterosexual men compared with women. GMTs were numerically lower for MSM, but seroconversion rates were greater than 99% for all types. These findings were used to support the bridging of the efficacy of Gardasil-9 in young women to young men.[189] GMTs to HPV31/33/45/52/58 in Gardasil-9 were robust, but lower, in young women previously vaccinated with Gardasil than in subjects who had not previously been vaccinated, presumably because of "orginal antigenic sin."[190]

MECHANISM OF PROTECTION

An immune correlate of protection has not yet been established in the efficacy trials, at least in part because of the remarkably small number of vaccine failures to date. Given the low failure rate, it is quite possible that many of the "breakthrough infections" actually represent the emergence or reactivation of prevalent infection rather than being true incident infection. To date, "breakthrough" infections have not correlated with antibody titer.[143] Nevertheless, there are several reasons to believe that neutralizing antibodies are the primary, if not the exclusive, immune effectors for the VLP vaccines. First, neutralizing antibodies are thought to be the principal effectors of many other prophylactic viral vaccines.[191,192] Second, passive transfer of sera from a VLP vaccinee can protect against experimental virus challenge in animal models.[108,110,193] Third, the type-restriction of protection afforded by the vaccines largely mimics the type-restricted in vitro neutralizing activity of serum antibodies from animals and people immunized with VLP vaccines.[106,113,194] It is very unlikely that antibody-dependent cellular cytotoxicity plays a role in protection, because HPV virions are naked icosahedrons that assemble in the nucleus.[96] Consequently, L1 is not displayed on the cell surface, in contrast to the virion spike proteins of many enveloped viruses. It is unclear whether memory B-cell responses play a role in protection, as the superficial exposure to virions from an infected partner may be insufficient to trigger an anamnestic response. It is fortunate that long-lived plasmid cells that maintain stable serum antibody levels indefinitely are apparently generated after HPV VLP vaccination.

There are also several reasons to suspect that cell-mediated immunity may not be directly involved in protection after VLP vaccination, even though HPV VLP vaccines generate robust T-cell responses to L1.[195–197] First, L1 is not detectably expressed in the basal epithelial cells in which the infection is thought to be maintained (see Fig. 30.6).[96] Second, there is no indication, in either animal models or clinical trials, that VLP vaccination induces regression of established infections.[14,108,121] Third, Gardasil induces a predominantly T-helper cell type 2 response, and Cervarix induces a predominantly T-helper cell type 1 response because of the differences in adjuvant in the two vaccines.[198,199] Nevertheless, both vaccines are highly protective against HPV infection and disease.

If antibodies are indeed the primary effectors of protection, it raises the question of how they get to the site of infection. The HPV infections involved in cervical carcinogenesis are largely confined to the epithelia of the genital tract and do not arise via systemic spread.[96] Therefore, only antibodies in the genital tract mucosa would be mediators of protection from the infections that cause cervical cancer. Both Gardasil and Cervarix are delivered by intramuscular injection, and this route of immunization does not induce appreciable amounts of secretory immunoglobulin (Ig) A, which is usually the predominant type of antibody on mucosal surfaces. Fortunately, cervical mucus secretions in women also contain large amounts IgG, much of which is apparently transudated from the serum via the neonatal Fc receptor.[200,201] In a clinical trial comparing serum and mucosal antibodies after intramuscular vaccination of women with HPV16 VLPs, the titers of VLP-specific IgG in cervical secretions were generally found to be about one-tenth those in the serum.[202] However, in women with normal menstrual cycles, both total and vaccine-specific IgG dropped an additional 10-fold during ovulation.

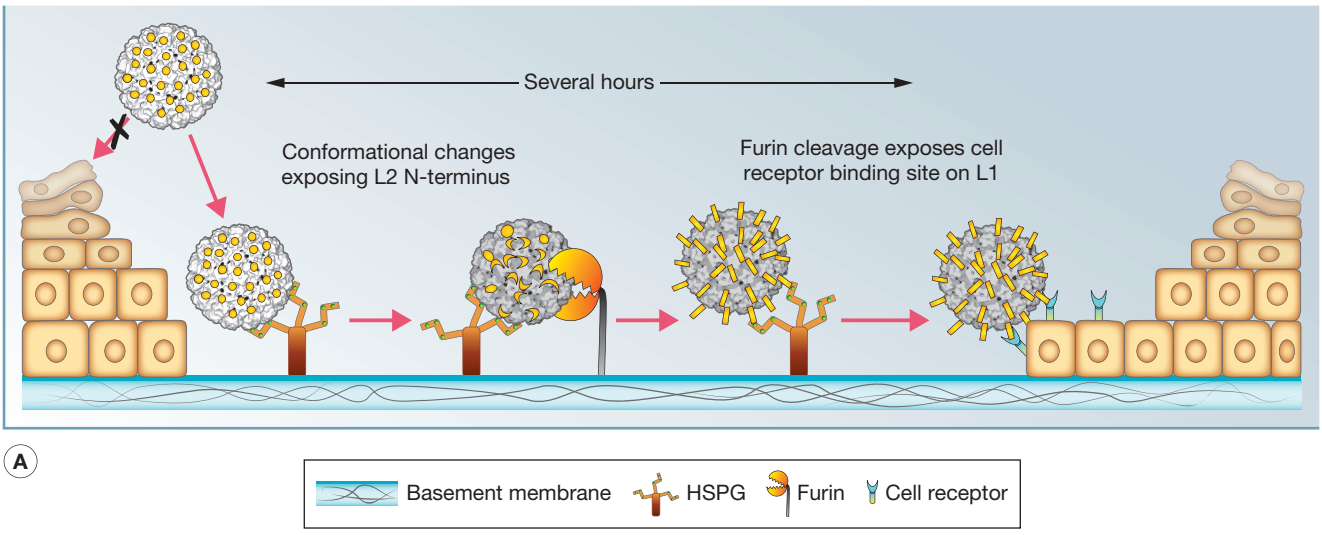
It is also likely that protection is mediated by the direct exudation of serum antibodies at sites of trauma that are believed to be the primary entry point for infection of basal keratinocytes.[45] That Gardasil is very effective in both men and women at preventing external genital warts, which often arise in epidermis that is not bathed in mucosal secretions,[122,165] suggests that the vaccine is able to protect exclusively via the latter mechanism. Exudation-dependent protection would be advantageous because levels of protecting antibodies would not be expected to vary across the menstrual cycle.

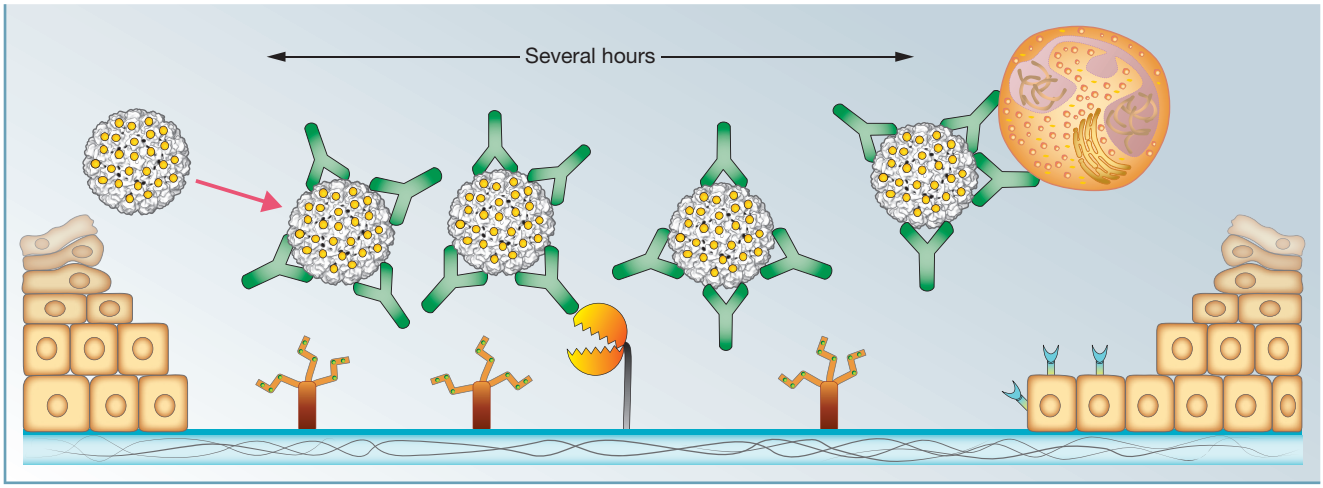
As noted earlier, studies of HPV infection in a mouse cervicovaginal challenge model indicate that a required initial step in infection is binding the acellular basement membrane that separates the dermis from the epithelium,[46] thus explaining the requirement for trauma or permeabilization of the epithelium for infection (see Fig. 30.10). Virion binding to the basement membrane is prevented by high levels of L1 VLP antibodies, either induced by vaccination or passively transferred from vaccinated to naïve animals.[193] Lower levels of VLP antibodies, which are nevertheless sufficient to prevent genital infection, permit basement membrane binding but prevent transfer of the virion to the keratinocytes (Fig. 30.11). The series of conformational changes on the basement membrane needed to expose the keratinocyte-specific receptor-binding site on L1 takes several hours.[46] This extended period provides an exceptionally long time for neutralizing antibodies to bind the capsid, which may help explain the remarkable prophylactic efficacy of HPV VLP vaccines. Levels of passively transferred VLP antibodies that are approximately 100-fold lower than the level that can be detected in an in vitro neutralization assay are able to protect mice from cervicovaginal challenge, suggesting that there exists a potent mechanism of infection inhibition in vivo that is not measured in the in vitro neutralization assays.[203]

DURATION OF PROTECTION

As expected for a relatively recently licensed vaccine, the duration of protection afforded by the VLP vaccines is unknown. There are several reasons to be optimistic about continued protection from these vaccines. First, solid protection against CIN2+ in follow up of randomized trials has been observed for up to 9.4 years with Cervarix,[204–206] for 7 years with Gardasil, and up to 9.5 years for Merck's HPV16 VLP vaccine.[207] Gardasil vaccination of adolescent boys and girls also appears to protect from infection after initiation of sexual activity for up to 8 years.[137]

Antibody titers for the licensed vaccines largely plateaued after 2 years, both in young adults and adolescents (see





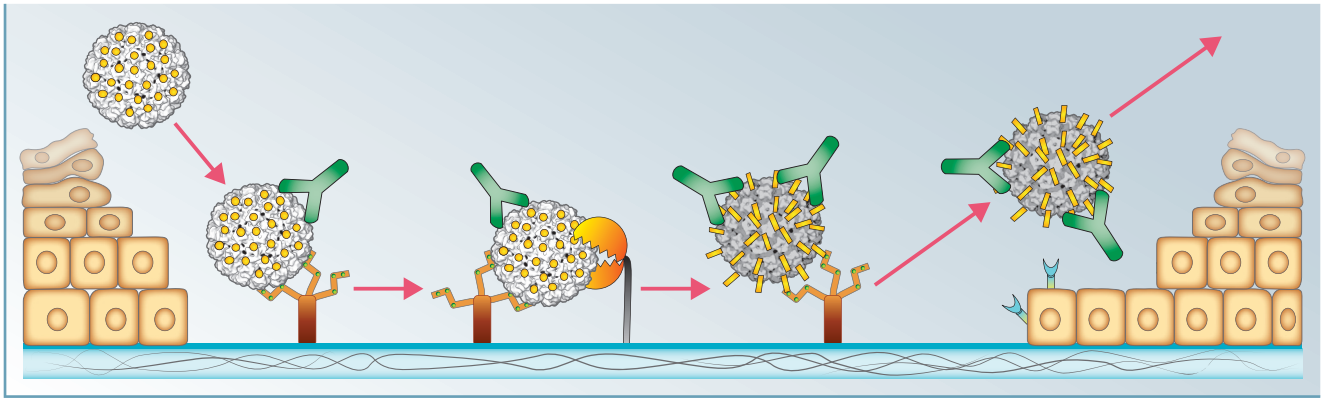


Figure 30.11. Model of in vivo cervicovaginal human papillomavirus infection and the mechanisms of infection inhibition by L1 virus-like particle (VLP) and L2 vaccine-induced antibodies. L1 virion surfaces are depicted in *gray* and L2 virion surface-exposed segments are depicted in *yellow*. **A,** Virions can associate with the keratinocyte surface only after binding basement membrane heparan sulfate proteoglycans (HSPGs) and undergoing a conformational change that result in furin cleavage of L2.

B

C

D

Figure 30.11, cont'd B, High levels of L1 VLP antibodies (shown in *blue*) prevent infection by blocking association with basement membrane HSPGs. **C,** Low levels of L1 VLP antibodies (shown in *green*) prevent infection by blocking transfer from basement membrane HSPGs to the keratinocyte surface receptors. **D,** N-terminal L2 neutralizing antibodies (shown in *blue*) also prevent infection by blocking transfer from basement membrane HSPGs to the keratinocyte surface receptors.

Fig. 30.8).[132,137,141] For instance, cLIA titers 9 years after Gardasil vaccination remained at 70% to 93% of their year 4 values for the four types in the vaccine.[208] There were similar findings for Gardasil-9.[144] This stabilization is reminiscent of the very slowly decaying antibody titers induced by live attenuated virus vaccines such as MMR (measles, mumps, rubella) and vaccinia.[209] It is possible that polymeric B-cell receptor engagement with the closely spaced repetitive neutralizing epitopes on the VLP surface might, together with the adjuvant, send exceptionally strong activating and survival

signals to B cells, signals that rival those induced by live virus infection.[210]

Second, the GMT plateau titers are generally higher than GMT titers seen after natural infection (see Fig. 30.9).[132,141] There is growing evidence that virion antibody responses to natural infection protect from reinfection.[60,211] As noted above, it is difficult to distinguish new infection from reactivation of latent infection, and individuals with low titers in serologic assays might be false-positives, given the relatively arbitrary nature of positive/negative cut points. The fact that HPV genotypes have clearly evolved to be distinct serotypes argues strongly that virion antibodies induced by infection play an inhibitory role in the natural history of the virus.

Third, the titers of passively transferred serum needed to protect against mouse cervicovaginal challenge with high dose HPV virus are at least 500-fold lower than the plateau levels achieved after VLP vaccination.[193] However, because titers of cross-neutralizing antibodies are at least 1 or 2 logs lower than type-specific titers,[194,212] it is possible that protection against nonvaccine types will be of shorter duration.

INDICATIONS

Young Women

Cervarix and Gardasil are licensed in most countries worldwide. Licensure has been based on efficacy and safety data from the pivotal efficacy trials and bridging immunogenicity and safety data in younger age groups discussed above. In 2006, Gardasil was approved by the FDA and by the EMA for prevention of HPV6/11/16/18–related external genital lesions, CIN, AIS, and cervical cancer in females 9 to 26 years of age. Cervarix was approved by the EMA in 2007 and by FDA in 2009 for prevention of HPV16/18–related CIN, AIS, and cervical cancer in females ages 9 to 25 years of age.[213] The latter approval is noteworthy in that it is the first FDA-approved vaccine that contains a specific Toll-like receptor ligand. Gardasil-9 was licensed by the FDA in December 2014 and has the same indications in females as the quadrivalent HPV vaccine.[214]

Young Males

Gardasil and Gardasil-9 are licensed for use in males in the United States. Data on Gardasil efficacy in males were not available in 2006 at the time of first licensure of the vaccine in females in the United States and other countries. In 2009, based on safety data and clinical trial results showing an efficacy of 89% for protection against HPV vaccine-type–related genital warts,[165] Gardasil was licensed by FDA for use in males ages 9 through 26 years for prevention of genital warts.[215] Data from the substudy in MSM, demonstrating efficacy for prevention of anal precancer lesions,[166] convinced the FDA to extend the indication for the quadrivalent vaccine to include prevention of HPV16- and HPV18-related AIN and anal cancers in males and females, ages 9 to 26 years in 2010.[216] Extension of the indication to females was based on the argument that anal HPV infection and associated AIN are biologically indistinguishable in men and women. In December 2014, Gardasil-9 was licensed by FDA in males based on immunobridging data and has indications for prevention of the same outcomes in males as does the quadrivalent HPV vaccine.[214]

Older Women

HPV vaccines are not licensed for women older than 26 years of age in the United States; however, they are so licensed in other countries.[217] Gardasil and Cervarix are effective at preventing incident infection and disease from the vaccine types in clinical trials of among women ages 24 to 45 years.[151,163,164] However efficacy in the ITT analyses was low, because of the relatively high rate of prevalent infection and relatively low rate of new infection in this age group, compared with younger women. In Europe and some other countries, Gardasil and Cervarix have an indication for use in girls and women starting at age 9 years.[217,218]

RECOMMENDATIONS

Target Groups

Recommendations for HPV vaccination vary by country, but the target group for routine vaccination is generally preadolescent females. The U.S. Advisory Committee on Immunization Practices (ACIP) recommended HPV vaccination routinely for girls at age 11 or 12 years in 2006 and for boys in 2011. The vaccination schedule can be started at age 9 years.[219,220] The target age group of 11 or 12 years was selected to target vaccination prior to sexual initiation. This age also allows HPV vaccine to be incorporated into the adolescent vaccination schedule in the United States. Other vaccines are recommended for children age 11 or 12 years, including meningococcal conjugate vaccine and tetanus-diphtheria-acellular pertussis vaccine (Tdap). ACIP also recommends HPV vaccination of girls and women ages 13 through 26 years and of boys and men ages 13 through 21 years who have not been previously vaccinated or who have not completed the full vaccination series. Vaccination of MSM and of immunocompromised men is recommended through age 26 years. Although ideally the vaccine should be administered before potential exposure to HPV through sexual contact, sexually active people who have not been infected with the HPV vaccine types would receive benefit from vaccination. Prevaccination assessments (such as Pap testing and screening for HPV DNA or HPV antibody) to establish the appropriateness of HPV vaccination are not recommended at any age.

HPV vaccines can be administered to people who are immunosuppressed as a result of disease or medications. While studies have found the vaccines to be well tolerated and immunogenic in HIV-infected persons, some found that GMTs were lower among HIV-infected persons compared with those uninfected.[179–183] It is unclear if there will be differences in HPV vaccine efficacy between immunocompromised and immunocompetent persons; ongoing studies are evaluating HPV vaccine efficacy and long-term protection in these populations.

Dosing Schedule

In the United States, HPV vaccines were recommended to be administered in a three-dose schedule in all targeted age groups until 2016, with the second dose administered 1 to 2 months after the first dose and the third 6 months after the first. In 2016, based on immunogenicity studies showing noninferior antibody response after two doses administered 6 to 12 months apart in 9- to 14 year-olds compared with three doses in young women in the age group in which efficacy was demonstrated,[214] ACIP changed its recommendation.[220a] A two-dose schedule is now recommended for persons who initiate vaccination at ages 9 through 14 years. The second dose is administered 6 to 12 months after the first dose. A three-dose schedule is recommended if the vaccination series is initiated at age 15 years or older and for most persons with immunocompromising conditions.[220a] If the vaccine schedule is interrupted, the vaccine series does not need to be restarted.[219] The number of recommended doses is based on age at administration of the first dose. In 2014, WHO had changed its

earlier recommendation for a three-dose schedule[221] and recommended a two-dose HPV vaccination schedule for adolescent girls if the vaccination series is initiated before age 15 years. A three-dose schedule is recommended for those age 15 years.[222]

PRECAUTIONS AND CONTRAINDICATIONS

Hypersensitivity or Allergy to Vaccine Components

Because Gardasil and Gardasil-9 are a recombinant vaccines produced in *S. cerevisiae* (baker's yeast) they are contraindicated for persons with a history of immediate hypersensitivity to yeast or to any vaccine component. Cervarix is contraindicated for persons with a history of immediate hypersensitivity to any vaccine component. The prefilled syringes of bivalent HPV vaccine should not be used in persons with anaphylactic latex allergy because syringes have latex in the rubber stopper. Cervarix single-dose vials contain no latex.

Vaccination During Pregnancy

HPV vaccines are not recommended for use in pregnant women. However, the vaccines have not been causally associated with adverse outcomes of pregnancy or adverse events in the developing fetus.[167,223,224] Initiation of the vaccine series should be delayed until after completion of the pregnancy. If a woman is found to be pregnant after initiating the vaccination series, the remainder of the three-dose regimen should be delayed until after completion of the pregnancy. The pregnancy registries for bivalent and quadrivalent vaccines have been closed with concurrence from FDA[220]; a new registry has been established to collect data on exposure to Gardasil-9 vaccines during pregnancy.

SYNCOPE AFTER VACCINATION

Vaccine Safety

Prelicensure trials for Gardasil included more than 20,000 females ages 9 to 26 years; the Cervarix trials included more than 30,000 females age 10 years and older; and the Gardasil-9 trials included more than 15,000 persons ages 9 to 26 years.[220,225] The most common injection site reaction was pain. There were no differences in serious adverse events, new onset autoimmune and chronic diseases or deaths between vaccine and control groups for any of the vaccines. Substantial data from postlicensure safety monitoring of bivalent and quadrivalent vaccines are available[223,226–234] Data from passive systems are available from several countries, but have limitations, including reporting of events occurring coincidentally after vaccination and incomplete reporting.

The most commonly reported adverse events after vaccination (AEFIs) have been injection-site reactions, dizziness, and headache.[223,226,234] Pain was modestly increased in young females receiving Gardasil after receiving concomitantly administered vaccines.[235]

One of the most common adverse events during the first few years after introduction of the quadrivalent HPV vaccine reported in the Vaccine Adverse Events Reporting System (VAERS) was syncope, with a rate of 8.2 per 100,000 doses distributed.[226] It has also been noted in the passive reporting systems in the United Kingdom and the Netherlands where Cervarix was introduced.[223] Syncope is a well-described preventable adverse event following an injection, particularly in adolescents.[236] Most syncopal episodes occur immediately or within 15 minutes of vaccine administration. To avoid serious injury related to a syncopal episode, recipients should sit or lie down for up to 15 minutes after receiving an injectable vaccine.

Active postlicensure safety evaluations have evaluated specific adverse events and provide the ability to investigate possible associations between vaccination and AEFIs. In the United States, an evaluation by the Vaccine Safety Datalink of approximately 600,000 doses of quadrivalent HPV vaccine administered to girls and women showed no statistically significant increased risk of the prespecified end points (Guillain-Barré syndrome, stroke, venous thromboembolism, appendicitis, seizures, syncope, allergic reactions, and anaphylaxis).[228] A study conducted as part of a manufacturer postlicensure commitment to the FDA included a general safety assessment and an assessment of autoimmune disorders among approximately 189,000 females receiving at least one dose of the quadrivalent vaccine. Same-day syncope and skin infections in the 2 weeks after vaccination were identified as having a likely association with vaccination.[230] Rates of autoimmune disorders were also evaluated; the study identified no autoimmune safety concerns in women who received quadrivalent HPV vaccine.[227] Safety data using national registries are available from Demark and Sweden. In one study, more than 997,000 girls were evaluated, of whom 296,826 had received quadrivalent vaccine.[237] There was no consistent evidence supporting causal associations between exposure to quadrivalent vaccine and conditions evaluated. Further studies using the registries evaluated venous thromboembolism among 1.6 million girls and women[232] and multiple sclerosis or other demyelinating diseases among almost 4 million girls and women[233] and did not find any association with quadrivalent vaccination. A nested case-control study conducted in a managed care organization in the United States also found no association between quadrivalent HPV vaccine and demyelinating disease,[231] and a case-control study conducted in France found none with autoimmune disorders.[229] Available safety data were reviewed by the Institute of Medicine in 2011[238] and by the WHO's Global Advisory Committee on Vaccine Safety (GACVS) at multiple meetings.

Despite the large amount of safety data available, concerns about HPV vaccine safety remain because of anecdotal reports or events temporally associated with vaccination. Antivaccine groups have capitalized on hesitancy and the debate about HPV vaccine in some countries, and have been active in advancing misconceptions about HPV vaccinations.[240] Some countries have seen dramatic declines in vaccination as a result of safety concerns. In 2013, Japan suspended its recommendation for HPV vaccination because of reports of complex regional pain syndrome following vaccination, while investigating further reported adverse events.[240,241] Although a review concluded that there was no evidence to suggest a causal association with HPV vaccine, the recommendation for HPV vaccine was not reinstated. In France, concerns about adverse events, potentially based on unfounded concerns related to other vaccines, has impacted its HPV vaccine uptake, which is one of the lowest in Western Europe.[242]

CERVICAL CANCER SCREENING AMONG VACCINATED FEMALES

Cervical cancer screening is still recommended for vaccinated women to prevent cancers caused by other oncogenic types.[220,243,244] Furthermore, females who were sexually active before vaccination could have been infected with a vaccine type HPV before vaccination. In the United States, cervical cancer screening recommendations have not changed for females who receive HPV vaccine. The introduction of Gardasil-9 will likely require a reassessment of screening

recommendations, particularly in countries with high vaccine coverage.[244a]

High coverage of Gardasil or Cervarix is expected to eliminate, or at least significantly reduce, the incidence of precancerous and cancerous lesions associated with HPV types 16 and 18 and possibly some related types. Coverage with Gardasil-9 would further reduce lesions caused by other types. Elimination of HPV16/18-related lesions in the population will result in lower positive predictive values for both cytology- and HPV-based tests.[245,246] Establishing different guidelines for vaccinated individuals in the United States will be challenging given the low vaccine coverage in 11- and 12-year-old female cohorts, and the incomplete protection in females recommended for catch-up vaccination but who may be vaccinated after exposure to HPV types in the vaccines. Future screening guidelines will have to consider vaccination coverage in the population and the effects on test performance.

PUBLIC HEALTH CONSIDERATIONS

Vaccine Introduction and Cost Effectiveness

Through 2014, HPV vaccines had been introduced in more than 60 countries worldwide.[247] While all country HPV vaccination programs target young adolescent girls, specific target age groups differ, as do catch-up vaccination recommendations.[248,249] Two countries have included males in their national vaccination programs—the United States in 2011 and Australia in 2013.[250] Some provinces in Canada have also introduced HPV vaccine for males.[251] Austria has recommended HPV vaccine for males since 2011 but without funding.

In 2009, when WHO issued recommendations for HPV vaccination, guidance stated that HPV vaccine be included in national immunization programs provided that prevention of cervical cancer or other HPV-related diseases, or both, constitutes a public health priority; vaccine introduction is programmatically feasible; sustainable financing can be secured and the cost-effectiveness of vaccination strategies in the country or region is considered.[221] The recommended primary target age group is a single year age cohort between 9 and 13 years. WHO also stated that HPV vaccine introduction should not divert resources from effective cervical cancer screening programs and that the vaccine should be introduced as part of a coordinated strategy to prevent cervical cancer and other HPV-related disease.

Various issues have been considered in the decision-making process for vaccination introduction, including cost-effectiveness. HPV vaccine modeling is complex because of the natural history of HPV infection and gaps in our understanding of type-specific transmission and progression rates, as well as assumptions about sexual behaviors that are included in the modeling. Multiple different models have been developed to evaluate cost effectiveness[252,253]; most models have found that adding bivalent or quadrivalent HPV vaccination of preadolescent girls to a cervical cancer screening program is cost-effective in developed countries, with estimates ranging from approximately $3000 to $45,000 per quality-adjusted life-year.[254–262] Cost-effectiveness of vaccinating older age groups varies across models, and all models show decreasing cost-effectiveness with increasing age at vaccination because more females would have already been exposed to vaccine HPV types and attack rates are generally lower in older women.[252] Models have found that the nine-valent vaccine would be cost saving compared with a quadrivalent HPV vaccination program provided the difference in price between the two vaccines does not exceed $13.[263]

For vaccine to be affordable and cost-effective in low resource settings, one economic analysis found that the cost per vaccinated girl would need to be less than $10 to $25.[219] Countries that have not introduced cervical cancer screening need to consider the cost-effectiveness of vaccine introduction and cervical cancer screening and the operational challenges of each of these prevention strategies.

The cost-effectiveness of adding males to a female only vaccination program depends on the coverage among females and cost of vaccine.[253] Early cost effectiveness analyses only considered prevention of cervical cancers.[252] With the addition of other HPV-associated cancers to the models, vaccination of males appears more cost-effective, particularly in countries where the rate of HPV-associated oropharyngeal cancer (a predominately male disease) is increasing. However, including males in a vaccination program may not be cost effective if there is high coverage in females.[252,264] When considering vaccination priorities, it is important to note that transmission models of HPV infection suggest that high vaccine coverage of one gender should be sufficient to prevent disease in women and heterosexual men.[265] The overall medical and economic importance of cervical cancer makes vaccination of females prior to their becoming sexually active the highest priority. Models have also examined targeted vaccination of MSM, who have high rates of anal cancer and who would probably have little benefit from a female vaccination program. Vaccination of this population in the United States appears cost effective through the licensed age range, even accounting for previous exposure to HPV.[266]

United States

HPV vaccine was introduced in 2006 for girls and women and in 2011 for boys and men. The target age group is 11 to 12 years, and vaccine is being delivered by primary care providers in both the public and private sectors. Coverage with HPV vaccine in the United States is lower than that for other vaccines recommended for adolescents. Coverage with at least one dose of HPV vaccine among 13- to 17-year-old girls increased from 25.0% in 2007 to 62.8% and among 13- to 17-year-old boys from 8.0% in 2011 to 49.8% in 2015. In 2015, coverage with three doses for girls and boys was 41.9% and 28.1%, respectively. There are wide variations in coverage by state, with vaccine initiation among girls ranging from a low of 47.7% to a high of 87.9% in 2015.[267] A provider recommendation is strongly associated with receipt of HPV vaccine but physician surveys have suggested that some providers delay strongly recommending HPV vaccine until older adolescence, and many parents of unvaccinated girls report no provider recommendation.[268] Multifaceted interventions with clinicians and other immunization stakeholders are ongoing to increase awareness, to encourage strong provider recommendations, and to prevent missed opportunities to improve HPV vaccination coverage.

Australia

In Australia, a publicly funded program started in 2007 using Gardasil for a school-based vaccination. The target age group is 12 to 13 years. From 2007 through 2009, there was also a catch-up program for girls 12 to 17 years of age delivered through schools and for women up to 26 years of age through community providers. Since 2009, the continuing school program routinely vaccinates girls in the first year of high school (12 to 13 years of age); boys of the same age were included in the routine HPV immunization program in 2013.[269,270] Through the school-based vaccination program in Australia more than 70% of girls in the targeted age groups have received three doses of HPV vaccine.[226] Australia was the first country to report an early positive impact of the HPV vaccination program.[271]

Canada

In Canada, while national recommendations are for vaccination through publicly funded programs to girls in at least one of grades 4 to 8 (approximately ages 9 to 13 years); target age group and other aspects of the vaccination program vary by province.[272] In 2009, Quebec implemented a two-dose schedule, with the doses administered 6 months apart for 9- to 10-year-olds with an option to give the third dose 5 years later. Quebec changed to a two-dose schedule with Gardasil for girls vaccinated in grade 4, keeping a three-dose schedule in older age groups. British Columbia changed from a three-dose schedule to an extended three-dose schedule for girls in grade 6 (approximately 11 to 12 years of age) in 2010 and then to a two-dose schedule for the same age group in 2014.[273] Several provinces have introduced HPV vaccine for males.

European Countries

As of 2015, most countries in Europe had introduced HPV vaccination, including 16 with organized programs with efforts in place to systematically offer vaccine to targeted age groups; 11 additional countries have less organized vaccination efforts.[248] Recommendations currently target adolescent girls and some provide for catch-up to varying degrees for older age groups. Among 16 countries with organized programs, 46% have school-based vaccination delivery, 20% have physician- or health center–based delivery, and others have mixed delivery systems. Countries in Europe without school-based programs have generally achieved lower vaccine coverage to date. In the United Kingdom, HPV vaccine was included in the routine immunization program in 2008, using Cervarix delivered through a school-based vaccination program. The age group targeted was 12- to 13-year-old females. There was a catch-up program for females through age 17 years. After the first year of the program, 80.1% of females 12 to 13 years of age who were eligible to receive the HPV vaccine routinely had completed the three-dose series. The United Kingdom changed to the quadrivalent vaccine in their national program in 2012 and in 2014 to a two-dose schedule.[274] Denmark is one of the few countries to achieve high coverage rates in a largely clinic-based vaccination program, with greater than 80% three-dose vaccination rates in 12-year-old girls.[275]

Middle- and Low-Resource Countries

The first middle-income countries to introduce vaccine (2008) into national immunization programs were Panama and Mexico.[249] By mid-2014, 18 countries in Central and South America offered the HPV vaccine through public immunization programs.[276] The first country in Africa to introduce HPV vaccination nationwide was Rwanda.[277] Vaccine was obtained through an industry donation in 2011. Using a school-based program, 93% three-dose coverage was achieved among girls in grade 6. Bhutan introduced vaccine through a donation program in 2010 and also delivered vaccination through schools[278]; coverage was 99% in the target age group in the initial year of the vaccination program.

Gavi, the Vaccine Alliance, prioritized HPV vaccine in 2009 and in 2012 made HPV vaccines available to Gavi-eligible countries.[279] There are two pathways for countries to apply for HPV vaccines: (a) national introduction if there is demonstrated ability to deliver a multidose series to at least 50% of the target vaccination or (b) demonstration projects if countries cannot meet this requirement.[280] In the first 2 years of HPV vaccine Gavi funding, no country introduced a national program. Most countries with demonstration projects chose to implement vaccination through school-based programs. This strategy means that girls who do not attend are less likely to receive vaccine, a challenge that needs to be addressed going forward.[281]

EPIDEMIOLOGIC IMPACT OF VACCINATION

Evidence of population level HPV vaccine impact on HPV-associated disease and infection became available within a few years of vaccination introduction.[282,283] HPV type-specific prevalence,[270,284–288] genital warts,[275,289] and cervical lesions[271,290–293] are among the early and intermediate HPV-associated outcomes being monitored. Data on vaccine impact on HPV-associated cancers will not be available for many more years. Monitoring impact of HPV vaccination is challenging in countries without national registries for vaccine and early HPV-associated outcomes. WHO has stated that monitoring HPV-associated disease or infection is not a prerequisite to vaccine introduction.[294]

Australia was the first country to observe an impact from quadrivalent vaccine introduction. An ecologic evaluation showed a sharp decrease in new genital warts in young women seeking care at a clinic for treatment of sexually transmitted diseases within 2 years after vaccine introduction.[289] Within 5 years of vaccine introduction, the proportion of women younger than age 21 years and 21 to 30 years diagnosed with genital warts decreased by 93% and 73% (Fig. 30.12).[295] A substantial decrease was observed for heterosexual men, suggesting impact from herd immunity. Declines in genital warts among targeted age groups have also been observed in other countries using Gardasil, including the United States and Belgium, where lower coverage has been achieved.[282,296,297]

Declines in vaccine-type HPV prevalence between the prevaccine and vaccine era have been reported from both England and Scotland, where high coverage was achieved using the bivalent vaccine. In England, HPV16/18 prevalence decreased from 19.1% to 6.5% among the vaccine-eligible 16- to 18-year-olds while no decrease was observed in 22- to 24-year-olds, an age group not targeted for vaccination.[286] In Scotland, a decrease was observed in HPV16/18 prevalence from 28.8% to 16.7% among 20- to 21-year-old females attending cervical cancer screening between 2009 and 2012.[284] Data also suggested some cross-protection against types 31, 33, and 45. In the United States, analysis of data from the National Health and Nutrition Examination Survey (NHANES), a nationally representative survey, found a 56% decrease in population prevalence of vaccine-type HPV in self-collected cervical–vaginal samples from females 14 to 19 years of age in the 4 years postvaccine introduction, but no decreases were observed in older age groups.[285]

Although some countries with cervical cancer screening and vaccine registries have demonstrated declines in precancerous lesions (Fig. 30.13),[271,290,293] monitoring of cervical precancers is challenging in the United States. Not only is there incomplete reporting of adolescent vaccination to state-based immunization registries and lack of national cervical cancer screening registries, but most importantly, cervical cancer screening practices have been changing.[298,299] Over the past decade, the recommended age for initiating cervical cancer screening has been raised to 21 years, HPV-based screening has been increasingly used, and screening intervals have been increased. Nevertheless, data show a decrease in the percentage of precancer lesions caused by HPV16/18 among vaccinated women and suggest some population impact of vaccination on precancers while at the same time highlighting challenges in examining the ecologic effect of HPV vaccination on incidence trends during a time of concurrent changes to screening recommendations.[300,301]

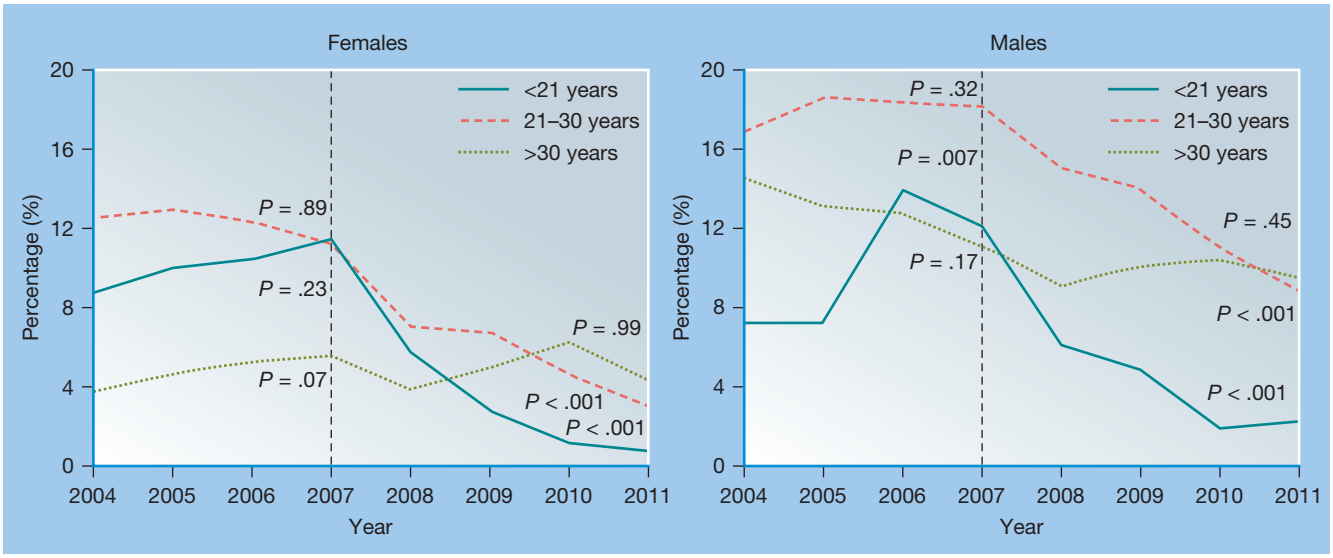

Figure 30.12. Decline in genital treatments of genital warts in young Australians after initiation of Gardasil immunization program. Vertical dashed line indicates the year that the program was initiated.[295]

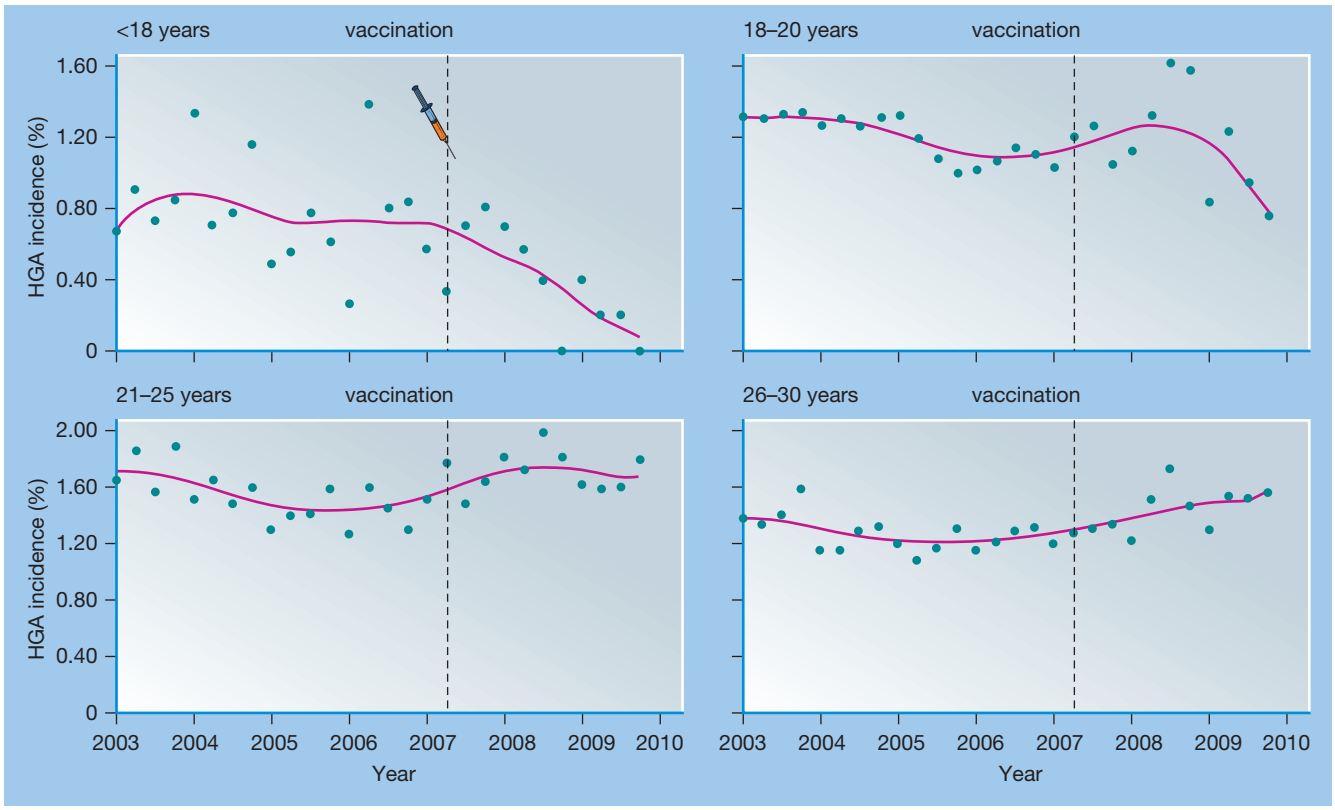

Figure 30.13. Reduction in cervical intraepithelial neoplasia grade 2+ in Australia after the initiation of Gardasil vaccination. HGA, high-grade cervical abnormalities. *(From Brotherton JM, Fridman M, May CL, et al. Early effect of the HPV vaccination programme on cervical abnormalities in Victoria, Australia: an ecological study.* Lancet. *2011;377[9783]:2085–2092.)*

Postlicensure evaluations of vaccine effectiveness for prevention of prevalent infection, genital warts, and cervical lesions have been conducted in a variety of settings.[285,302–305] The highest effectiveness has been observed among those vaccinated at youngest age. For example, Leval and colleagues found effectiveness against genital warts in Sweden of 93% among those vaccinated before age 14 years compared with only 48% among those vaccinated at age 18 to 22 years.[303] Some effectiveness studies have found protection against non–vaccine-targeted, but related, HPV types (i.e., cross-protection).[270,282,284] Other studies have examined effectiveness by number of vaccine doses.[306] The possibility of confounding because of prevalent infection disproportionally affecting vaccinees receiving fewer than three doses has been raised.[307,308]

Long-term monitoring of duration of protection will also be important because vaccination is given in adolescence but

protection is needed for the many years during which exposure may occur. Both vaccine manufacturers are conducting long-term follow-up in the Nordic countries to determine duration of protection[309,310] and further postlicensure effectiveness studies will be important.

SECOND-GENERATION PROPHYLACTIC VACCINES

A number of second-generation prophylactic vaccines, in addition to Gardasil-9, have been generated and evaluated to varying degrees.[18,311] They seek to address some limitations of the current vaccines, including type-restriction, relatively high cost of production and implementation, and the lack of therapeutic activity.

To generate a vaccine with a lower cost of production, Xiamen Innovax Biotech has generated HPV VLPs in *Escherichia coli*, using patented L1 mutants. Results of Phase I and Phase II safety/immunization trials of a bivalent HPV16/18 vaccine, trademarked "Cecolin," were recently reported.[312–314] Encouragingly, consistent induction of high titers of neutralizing antibodies for both types was observed 1 month after the last intramuscular injection at 0, 1, and 6 months. A formulation of 40 μg HPV16 and 20 μg HPV18 VLPs in aluminum hydroxide adjuvant was selected for further development.[314] A Phase III efficacy trial is now underway in China (ClinicalTrials.gov NCT01735006). Several companies have undertaken programs to produce VLPs in yeast species that may produce higher yields than *S. cerevisiae* including Serum Institute of India in *Hansenula polymorpha*, and Indian Immunologicals, Instituto Butantan, and Shanghai Zerun in *Pichia pastoris*. However, only Shanghai Zerun has announced the initiation of a Phase I trial (NCT01548118).

The only other second-generation vaccine approach for which a clinical trial has been published is an academic trial involving the upper respiratory tract delivery of purified VLPs in young women.[315] In a small pilot study, the VLP antibody responses in one-half of the women receiving two aerosolized 50-μg aqueous doses without adjuvant, delivered via a cold ultrasound nebulizer, were similar to the responses in women receiving two 50-μg doses by intramuscular injection. All the women receiving 250 μg to the respiratory tract responded well. Thus, the VLPs appear to be quite immunogenic by the upper respiratory route, which can generate secretory IgA in the female genital tract in addition to serum IgG.[200] However, improvement in formulation or delivery mechanics may be needed to make aerosol delivery of HPV VLPs a practical alternative to injection, and commercial interest in this approach has been limited.

Numerous preclinical studies of more novel approaches for second generation L1 vaccines have been published but only a few appear to be moving toward clinical evaluation, often with academic/commercial sector partnerships.[316,317] Two vaccine candidates are designed to add HPV infection prevention to existing live microbial vaccines. Zydus Cadila has generated an HPV16 L1 recombinant of the Moraten-Berna vaccine strain of measles virus. Vaccination of transgenic mice expressing the human measles virus receptor induced similar levels of measles virus antibodies as the parental vaccine strain, and titers of HPV16-neutralizing antibodies that were comparable to those induced after injection of purified VLPs.[318] If protection from measles is not compromised in humans, the recombinant vaccine might be able to add protection from HPV infection to MMR vaccination programs, which have been widely implemented, even in low-resource settings, potentially at no additional cost. Indian Immunologicals is developing a live HPV16 L1 recombinant *Salmonella typhi* vaccine based on the attenuated strain Ty21a. Encouraging immunogenicity results were obtained in a mouse model.[319] This vaccine holds promise for low-cost production and efficient delivery via the oral route.

Pentameric subunits of L1 can induce neutralizing antibodies, although they had lower intrinsic immunogenicity than VLPs in preclinical studies.[320,321] Pentamers can be readily produced in *E. coli*, raising the possibility of low-cost production.[322] In one variation, a peptide of the E7 oncoprotein was genetically fused to L1 to increase the therapeutic potential of the pentamer-based vaccine.[323] This type L1–E7 fusion protein is expected to undergo clinical testing by BioSidus in the near future.[316]

Vaccines based on the L2 minor capsid protein are also under development. Early studies with animal PVs demonstrated protection from type-specific challenge in rabbits and cattle with L2 protein vaccines.[324,325] The L2 protein contains cryptic neutralizing epitopes that induce appreciable antibody responses only when L2 is taken out of its normal context in the virion or VLP.[326] In contrast to L1, short L2 peptides retain the ability to induce neutralizing antibodies.[327] Antibodies to some L2 epitopes are remarkably broadly cross-neutralizing against an array of mucosal and cutaneous types.[37] In cervicovaginal tissue, these N-terminal L2 peptides are exposed only after basement binding induces a conformational change in the capsid that permit removal of the dozen N-terminal amino acids by the cellular protease furin (see Fig. 30.11).[46] Unlike cryptic neutralizing epitopes of some other viruses, they are exposed for hours prior to internalization of the capsid by the cell.[46] L2 vaccines can protect against cervicovaginal challenge by heterologous types in rabbit cutaneous and oral models and mouse cutaneous and cervicovaginal challenge models, indicating that broad cross-neutralization is not an in vitro artifact.[193,328–330] In the mouse genital model, L2 antibodies permit basement membrane binding but prevent transfer of the capsids to keratinocytes (see Fig. 30.10).[193] Therefore, their in vivo activity is superficially similar to that of low levels of L1 neutralizing antibodies.

Type-specific neutralizing titers induced by L2 vaccines in standard in vitro neutralization assays are generally much lower than the titers induced by L1 VLP vaccines.[326] However, these assays appear to underestimate the potency of L2 vaccines, as L2 vaccinated mice with undetectable serum levels of in vitro neutralizing antibodies are often fully protected from cervicovaginal challenge with the same type. The likely explanation for this discrepancy is that the primary attachment factor, heparan sulfate proteoglycans, and the internalization receptor are topologically separated in vivo.[331] The former is on the basement membrane and the latter on the keratinocyte. In the in vitro assays, both are on the cultured cell membrane, reducing the time that the L2 cross-neutralizing epitopes on the intermediate form of the capsid are exposed to antibodies before the secondary receptor can be engaged.[332] These insights into the mechanism of HPV infection led to the development of an in vitro neutralization assay that better mimics in vivo infection and is 100- to 10,000-fold more sensitive at detecting L2-specific neutralizing antibodies in the sera of L2-vaccinated mice.[333]

Multimeric fusion proteins containing the corresponding L2 peptide of five to eight diverse HPV types can be generated in *E. coli* and appear to be exceptionally potent at inducing cross-neutralizing antibodies.[334,335] These vaccines hold the promise of broad protection against mucosal and cutaneous HPV infections by an inexpensive monovalent vaccine. Other attractive L2 vaccine strategies include fusion to immunogenic proteins (e.g., thioredoxin or flagellin)[328,336] or display on virion surfaces (e.g., adenoassociated virus-2 or bacteriophages).[337,338]

There is an emerging consensus among most experts in the field, based on the results of previous vaccine efficacy trials and current understanding of HPV infection, that the demonstration of efficacy against high-grade dysplasia should not be required for licensure of second-generation HPV prophylactic vaccines.[339] Immunological noninferiority in an in vitro neutralization assay would be sufficient for licensure of alternative dosing schedules or route of administration for the licensed vaccines and for new vaccines that are essentially biosimilars of the current ones. A virologic end point (e.g., protection from an infection that persists for at least 6 months) was recommended as the primary efficacy end point for more novel vaccine candidates. Postlicensure surveillance could be used to confirm the effectiveness of the new vaccines. The recommended changes in primary end points would allow for smaller size and shorter duration of the pivotal trials for licensure and thereby help stimulate continued and more rapid vaccine development.

THERAPEUTIC VACCINES

Disease Targets

HPV-induced proliferative diseases are attractive targets for immunotherapeutic interventions. Two viral oncoproteins, E6 and E7, are continuously expressed from initial infection to malignant carcinoma (albeit at low levels initially), and the virus is apparently unable to evade immune responses by downregulation or loss of these proteins.[42] Because E6 and E7 are non–self-antigens, they may be less subject to mechanisms of immune tolerance than cell-derived tumor antigens.

The stage of HPV-induced neoplasia that should be targeted by therapeutic vaccines has been debated. The most important public health goal is clearly to prevent HPV-induced cancer deaths, which could be accomplished either by successfully treating the cancers or by eliminating the precancerous lesions/infections before they become malignant. Targeting premalignant disease could be considered immunoprophylaxis from the point of view of cancer, but will be considered immunotherapy herein because it involves the elimination of preexisting viral infection.

Cancers will almost certainly be the most difficult stage of the HPV-induced disease spectrum for which to develop an effective immunotherapy. Several of the initial clinical trials of HPV-targeted immunotherapies were safety and immunogenicity studies in cervical cancer patients.[340,341] Clinical responses were not observed, and T-cell responses to vaccination were not always detected. These results are consistent with the limited success, until recently, of immunotherapy against other solid tumors. However, the recent advances in our understanding of the immunology of the tumor microenvironment coupled with developments in adoptive T-cell therapies, combination immunotherapies (particularly involving checkpoint inhibitors such as CTLA-4, PD-1, and PD-L1 monoclonal antibodies), and combination of chemotherapy or radiation therapy with immunotherapy has led to increasing success in treatment of with other solid tumors, notably melanoma.[342–344] Given that HPV-associated cancers harbor viral tumor-restricted antigens to target, it is likely that these conceptual and practical advances will be translated into improved treatments of HPV-associated cancer in the near future. A promising example is the complete response of two of nine patients with metastatic cervical cancer after infusion of ex vivo amplified E6 and E7 reactive T cells.[345]

Most academic and commercial interest is currently focused on the treatment of premalignant HPV-induced neoplasia. In addition to its greater potential for success, the far greater incidence of cervical premalignant disease than cancer also makes it a more attractive commercial target. For example, there are approximately 10,000 cervical cancer cases annually in the United States, compared with an estimated 300,000 high-grade cervical dysplasias, 2,000,000 low-grade dysplasias, and 10,000,000 subclinical infections. However, unless they were used in mass immunization campaigns, therapeutic vaccines targeting premalignant disease are likely to have little impact in developing countries, where more than 80% of cervical cancers occur[8,346] because few women in these countries have access to the screening programs that would identify the premalignant lesions for treatment.

Several aspects of premalignant cervical neoplasias make them attractive candidates for therapeutic vaccines. First, cervical cancer arises from well-defined precursor lesions that normally take many years to progress.[20] Thus, there is a relatively long window of opportunity to intervene in the treatment of premalignant disease. Second, the precursor lesions are routinely identified in screening programs, providing a ready pool of candidates for vaccine trials and eventually for licensed vaccines. Third, effective treatment exists for cervical dysplasias, so women in clinical trials who fail to clear their infection after vaccination should not be placed at undo risk of progressing to cancer.

Most of the recent therapeutic HPV vaccine trials have targeted the intermediate stages of cervical disease, CIN2 and CIN3. Unlike lower-grade lesions, CIN3 is universally considered a premalignant condition that should be treated. However, the overall effectiveness (>90%) and tolerability of current ablative treatments makes the bar for alternative treatments rather high. In addition, the availability of an effective alternative treatment has hampered compliance in some vaccines trials targeting high-grade dysplasias.[347] Decisions regarding whether to treat or follow CIN2 can be difficult, especially in young women.[348] Hence, it would be useful to have a nonablative management alternative. Many clinical trials have included both CIN2 and CIN3 patients. This mixture can complicate the interpretation of results, as the end point encompasses a rather broad biological spectrum of HPV disease, from relatively recently acquired infections with somewhat greater dedifferentiation than normal to longstanding carcinoma in situ.[63] Better responses might be expected among the more recently acquired lesions. Both CIN2 and CIN3 may regress spontaneously, making it difficult to interpret uncontrolled trials.

With the move toward HPV DNA–based primary screening for cervical cancer, there will be an increasing number of women diagnosed with persistent oncogenic HPV infection without clinical lesions.[15] Although these women are at a substantially elevated risk of developing premalignant lesions and ultimately cancer, there are currently no reasonable treatment options for them. A well-tolerated and effective therapeutic vaccine against persistent oncogenic HPV infection would likely have a large future market.

In addition to cervical dysplasias, HPV-induced vulvar, vaginal, and anal dysplastic lesions provide similar opportunities for therapeutic vaccination.[74] They may be less common and not as routinely identified, but in many cases are more difficult to treat by current ablative methods. A substantial number of oral cancers, particularly those of the tonsils and oropharynx, contain HPV DNA, especially type 16, and also express E6 and E7.[349] However, the precursor lesions for these cancers have not been unambiguously identified. Consequently, immunotherapy of HPV-associated oral lesions would currently be limited to cancers.

Genital warts are an attractive target for therapeutic intervention because of their high incidence, considerable morbidity, and frequent recurrence following conventional treatments.[350] There is also the possibility for long-term

follow-up in vaccination studies without alternative intervention in wart patients, in contrast to CIN2/3 patients, where nonresponders receive conventional ablative therapy after no more than 6 months to prevent progression to cancer.

Animal Models

The current animal models for investigating immunotherapeutic approaches against genital HPV infection are limited and have several deficits. HPVs do not cause hyperproliferative diseases in animals, and none of the animal PVs used in established models induce anogenital neoplasia in immune competent animals. Most studies of HPV therapeutic vaccines have used mouse-transplantable tumors expressing the HPV oncogenes. Subcutaneous injection of TC-1 cells, which express HPV16 E6 and E7 in a H-2Db background, is the most commonly used model.[351] A similar murine line that presents E6/E7 peptides in the context of human HLA-A.2 and forms tumors in A.2 transgenic mice has also been used.[352] Protection from tumor challenge and induction of tumor regression is primarily CD8 cytotoxic T-lymphocyte–mediated in these models. These rapidly growing subcutaneous tumors are biologically quite different from the slow growing in situ epithelial tumors that are the clinical targets of most HPV vaccine studies, and it is currently uncertain whether CD8 or other cell-mediated responses are primarily responsible for regression of the latter.[353] In addition, the models appear to have rather low stringency, as several therapeutic vaccination strategies that have proven to be successful in these models have not generated encouraging result in clinical trials.[354,355]

A orthotopic mouse model involving implantation of TC-1–derived tumor cells into the vaginal epithelium may provide a more biological relevant setting for evaluation of HPV therapeutic vaccines.[356] Alternatively, induction of effective immune responses to in situ HPV gene-expressing lesions has been studied in a skin transplantation model, involving grafting onto syngeneic mice the skin of mice transgenic for an HPV16 E7 gene expressed from a basal keratinocyte-specific promoter. The grafts are not spontaneously rejected in immune-competent recipients or in recipients vaccinated with some therapeutic vaccine candidates that lead to rejection of transplantable tumors. Several treatment regimens have induced graft rejection in this model, with overcoming the local immunosuppressive microenvironment a central component to many of them (see reference 357 for a review).

Preclinical studies of therapeutic wart vaccines have primarily employed either CRPV infection of domestic rabbits or canine oral PV (COPV) infection of dogs. The COPV model is attractive because it involves a mucosal infection. However, it can be difficult to study immunotherapies in this model because of the rapid rate of spontaneous regression.[358,359] In contrast, CRPV-induced lesions of the epidermis tend to persist, and most immunotherapeutic approaches have not consistently induced regression of established CRPV warts.[360–362] The principal lessons from these studies are that E2 appears to be the most effective target for immunotherapy and that inclusion of more viral protein targets increases the frequency of regression.

Clinical Trials

Many different strategies have been tested clinically to induce T-cell responses and regression of HPV-induced neoplasia, including peptides, fusion proteins, naked DNA, viral vectors, and dendritic cell–based approaches (see references 354, 355, 357, and 363 for reviews). Several Phase I/II studies in CIN2/3 patients have been published to date. In general, they detected antigen-specific T-cell responses in most vaccinees, but most lacked a placebo control arm and/or sufficient size to critically evaluate clinical responses. However, some encouraging results have been obtained in several relatively larger and/or placebo-controlled trials.

Zycos (then MGI Pharma, now Eisai) conducted a placebo-controlled trial in CIN2/3 patients using a DNA-based vaccine composed of HPV16 and HPV18 E6 and E7 epitopes encapsidated in biodegradable polymer microparticles. A significant clinical response was detected, but only in the subset of 43 women younger than 25 years of age, in whom 70% of lesions regressed, compared with 23% of controls.[365]

An attenuated modified vaccinia Ankara (MVA) expressing mutated HPV16 E6 and E7 and interleukin-12 was developed by Transgene. A clinical response, defined as no CIN2/3 at 6 months, was observed in 10 of 21 (48%) HPV16-positive CIN2/3 patients receiving three doses of the vaccine.[366] The expected rate of spontaneous regression of HPV16 related CIN2/3 is approximately 20%. Eight of the 10 clinical responders were HPV16 DNA–negative at the end of the study.

Stressgen (then Nventa, now Akela) tested a mycobacterial heat shock protein 65–HPV16 E7 fusion protein in several uncontrolled Phase I/II trials.[367–369] The bacterial heat shock polypeptide was included as a molecular adjuvant to activate dendritic cell induction of innate immune responses. Some evidence of efficacy was obtained. For example, 6 months after 58 CIN2/3 patients received three injections, 13 (22%) had a complete pathological response (CIN1 or less), 32 (55%) had partial responses (lesion regression >50%), and 11 (19%) had stable disease.[368] There was no difference in the rate of regression in women infected with HPV16 compared with those infected by other types.

Medigene sponsored a placebo-controlled trial of an HPV16 chimeric VLP in which a portion of HPV16 E7 was fused to L1, thus creating a vaccine with both prophylactic and therapeutic potential. Regression rates in HPV16 DNA–positive CIN2/3 patients at 6 months after intramuscular injection without adjuvant was 39% and 25% in chimeric VLP and placebo vaccines, respectively, a nonsignificant difference.[370] E7 T-cell responses were modest and did not correlate with regression.

Another, quite distinct, MVA-based vaccine has also been investigated. It involves injection of an MVA recombinant expressing bovine PV type 1 E2 directly into the uterus of CIN patients.[371,372] All the vaccines discussed above involve intramuscular or subcutaneous injection of E6/E7-based vaccines. By contrast, this vaccine in theory would function primarily through (a) induction of E6/E7 immune responses that would indirectly result from E2-mediated apoptosis of the HPV E6/E7 expressing tumor cells (E2 inhibits transcription of the viral oncogenes) and (b) the MVA vector inducing a proinflammatory environment at the tumor site. Clinical regression was often observed over 14 weeks in a large, single-arm Phase III study involving 1176 women and 180 men with HPV-induced intraepithelial lesion. Complete regression was seen in 95% and 73% of previously untreated low-grade and high-grade dysplasias in women, respectively, and in 100% of previously untreated urethral and anal condyloma in men.[373] While these results are certainly encouraging, the role of E2 in inducing the responses remains unclear, as the parental MVA was not evaluated. It is also unclear whether the presumably vaccine-induced regression primarily involves tumor antigen-specific or antigen-independent responses.

High-grade VIN is a chronic disorder with a low spontaneous regression rate that often recurs after ablative therapy and is, therefore, an attractive target for HPV-directed immunotherapy. Complete regression of VIN3 was observed, after a 12-month follow-up, in nine of 19 (47%) HPV16-positive

VIN3 patients treated with three or four doses of a mixture of HPV16 E6 and E7 long peptides (25–35 amino acids) in incomplete Freund adjuvant.[374] While there was no control arm in the trial, the response rate was considerably higher than the expected spontaneous regression rate of 2% in VIN3 patients. Interestingly, complete clinical responses correlated with small lesion size, systemic E6/E7-specific interferon-γ–associated CD4 and CD8 T-cell responses and lower numbers of CD25(+)/Foxp3(+) T-regulatory cells in the lesions.[375]

Another trial in VIN2/3 patients involved activation of local innate immune responses, via an 8-week course of topical imiquimod (a Toll-like receptor 7 ligand), followed by induction of systemic HPV immunity by three intramuscular injections of an HPV16 E6/E7/L2 fusion protein vaccine (delivered without adjuvant).[376] Complete regression was observed in 12 or 19 (63%) of patients after 12 months of follow up. As in the previous study, regression correlated directly with antigen specific T-cell responses and inversely with the levels of T-regulatory cells. However, the role of the vaccine component of this combined therapy remains uncertain, because a similar rate of VIN2/3 regression was seen in a study involving 16 weeks of topical imiquimod treatment without vaccination.[377]

Several uncontrolled Phase I studies suggested that therapeutic vaccines might promote regression of anogenital warts. However, in the one large placebo-controlled trial reported to date, therapeutic vaccination with an HPV6 L2-E7 fusion proteins plus GlaxoSmithKline's AS02 adjuvant (monophosphoryl Lipid A and QS21 in an oil-in-water emulsion) failed to increase the efficacy of conventional therapy in a study of 320 patients infected with HPV6 or HPV11.[378]

WHY THERAPEUTIC HUMAN PAPILLOMAVIRUS VACCINES HAVE HAD MODEST SUCCESS

Several factors may have contributed to the limited success thus far of therapeutic HPV vaccines. First, except for the E2 recombinant MVA vaccine, systemic immune responses have been generated and monitored in the trials (with one notable recent exception[379]), whereas local mucosal or epidermal cell-mediated immunity responses are likely to be critical for clearing HPV infected lesions.[353] There is evidence that T cells generated in response to systemic exposure to an antigen do not efficiently migrate into mucosal epithelium, particularly in the absences of local proinflammatory signals.[380–382] The generation of a higher density of T cells in mucosal/epidermal tissues might be needed to produce more effective therapeutic HPV vaccines. This goal might be achieved by local induction of immunity[382] or recruitment of systemic immune responses by topical application of immune response modifiers (e.g., Toll-like receptor agonists or chemokines) after vaccination.[383,384] Second, persistent HPV infection can result in immune tolerance and/or active suppression to the viral antigens because of the activity of the viral oncogenes and long-term exposure of the immune system to low doses of the antigen in a noninflammatory epithelial setting.[58] The transition from normal epithelium to CIN and eventually cancer is associated with a decrease in interferon-γ and increases in interleukin-10, Foxp3+ T cells, indoleamine 2,3-dioxygenase (IDO)+ cells, and macrophages—all indicative of the evolution of a suppressive microenvirionment.[363] The inverse correlation between the number of lesional T-regulatory cell and clinical response supports the importance of altering the local immune environment for vaccine effectiveness. Third, cervical cancers and high-grade dysplasias are genetically unstable, and therefore often evolve to evade immune induction and recognition. The majority of cervical cancer and many CIN3 lesions have defects in major histocompatibility complex class I presentation, often through downregulation of specific class I alleles or defects in processing peptides for class I presentation.[385,386] The failure to detect a significant clinical response in older women in the Zycos trial cited above may have been a result of the longer mean duration of infection in older women and, therefore, the greater probability that immune tolerance/suppression to E6/E7 and/or evolution of immune evasion by the lesions had occurred.

Despite the limited success of therapeutic HPV vaccines to date, there are several reasons to be optimistic about future developments. Our increasing knowledge of the molecular mechanisms involved in the induction and suppression of cell-mediated immunity responses and their targeting to specific tissues should contribute to the rational design of future vaccines. In addition, the apparent continuing interest in academia and industry in these vaccines and the number of therapeutic clinical trials being conducted bodes well for future breakthroughs, particularly with respect to therapy of persistent infection and low-grade disease.

31 Inactivated Influenza Vaccines

Joseph S. Bresee, Alicia M. Fry, Suryaprakash Sambhara, and Nancy J. Cox

HISTORY AND IMPORTANCE

History of the Disease and Vaccines

Influenza is a leading cause of morbidity and mortality worldwide, occurring in annual epidemics and in occasional global pandemics. Five global pandemics of influenza have been well-described, the first beginning in 1889, with subsequent pandemics occurring in 1918, 1957, 1968, and 2009.[1] Each of these pandemics was associated with high attack rates and substantial disease impact. However, influenza pandemics and epidemics have likely occurred for millennia, with early mentions of what might have been epidemics by the 12th century and a pandemic of influenza in the 16th century.[2–4] Isolation of the influenza A virus in 1933[5] rapidly led to the identification of influenza viruses as the cause of epidemics and pandemics of respiratory disease. While the severity and timing of influenza activity was found to vary from year to year, the identification of the influenza virus as the cause of seasonal epidemics (and past pandemics) led quickly to the development, testing, and first use of influenza vaccines in the 1930s and 1940s.[6–9]

Early influenza vaccines were developed for and used primarily in military populations. In 1960, following the 1957–58 pandemic, the U.S. Public Health Service first recommended seasonal influenza vaccines be given to nonmilitary persons who were known to have a high risk of influenza complications.[10] From the beginning, influenza vaccination programs were based on principles that remain relevant for modern vaccine programs. First, for the most part, the strategy of targeting high-risk groups for immunization against influenza became the standard paradigm for influenza vaccination programs and policies globally. With the notable exception of the United States' decision to expand influenza vaccine policy to recommend annual vaccination for all persons older than 6 months of age (i.e., "universal vaccination"),[11] national influenza programs generally target specific persons who are at elevated risk of severe or complicated disease based on age, underlying disease, or pregnancy status.[12,13] Second, until 2003 when the first live attenuated vaccine was approved,[14] influenza vaccines have been produced from inactivated, purified influenza viruses grown in embryonated eggs inoculated with influenza viruses, and administered intramuscularly. Although approaches to influenza immunization have expanded to include additional modes of delivery (e.g., mucosal delivery of live attenuated vaccines, intradermal injection) and approaches (e.g., recombinant protein vaccines),[15] the majority of influenza vaccines given worldwide remain inactivated injected vaccines.[16] Third, because of continual genetic and antigenic changes in influenza viruses, influenza vaccines are continually updated with contemporary strains, and vaccine programs must target recipients annually to ensure protection against current strains. The requirement for annual vaccine development and production and for annual immunization campaigns makes influenza vaccines unique and challenging.

Why the Disease Is Important

Seasonal influenza epidemics are associated with substantial disease burden each year worldwide in persons of all ages. Each year, an estimated 5% to 15% of persons have influenza, although significant variability in rates of illness occur from year to year.[17] Most infections lead to self-limited disease that does not result in healthcare visits; however, severe complications resulting in hospitalization and deaths may occur, particularly in persons with certain underlying health conditions and among young children and the elderly.[18–23] Each year in the United States, for instance, influenza is estimated to be associated with thousands to tens of thousands of deaths,[24,25] and hundreds of thousands of hospitalizations.[22,26,27] As a result, influenza-associated illnesses are a substantial cause of lost work and school time, overwhelmed hospitals and regional medical care systems, and a large economic burden to health systems and families.[28–31] Few other infectious diseases have adversely affected the health and economies of global populations as consistently and extensively as influenza.

Because of the importance of influenza in terms of global disease burden, vaccination against seasonal influenza viruses has been long promoted as the optimal method of influenza prevention. However, the capacity of influenza A and B viruses to undergo continual antigenic change in their two surface antigens, the hemagglutinin (HA) and neuraminidase (NA), complicates vaccination against the disease. This type of antigenic change, which is known as *antigenic drift*, results from the accumulation of point mutations in the RNA genes encoding H and N proteins and leads to the emergence of new variant influenza strains (Fig. 31.1).[32] As the antibody prevalence to older variants increases in the population, the circulation of the older, previously dominant variants is suppressed, allowing new antigenic variants to become predominant. When antibody prevalence to the new variant increases within a population, yet another antigenic variant emerges and the cycle continues. This ongoing process of antigenic drift ensures a continually renewed pool of susceptible hosts and the repetitive occurrence of epidemics. The occurrence of antigenic drift requires robust global surveillance systems that can monitor for the emergence of new strains, and careful review of these data contribute to semiannual updates to influenza vaccine formulations.[33–39]

Finally, the importance of influenza lies also in its capacity to cause global pandemics. Influenza pandemics are the result of "antigenic shift," when an influenza A virus with an H or an H-N combination that has never or not recently infected humans gains the ability to infect, cause disease, and transmit efficiently among humans (see Fig. 31.1).[32] In this case, the population immunity to the new subtype is sufficiently low to facilitate person-to-person transmission and increase severity of illness among those infected. As a result, pandemics are generally associated with higher rates of illness and death compared with seasonal influenza.[40] Four pandemics have occurred in the past century: 1918 (when a new H1N1 emerged), 1957 (H2N2), 1968 (H3N2), and 2009 (H1N1).

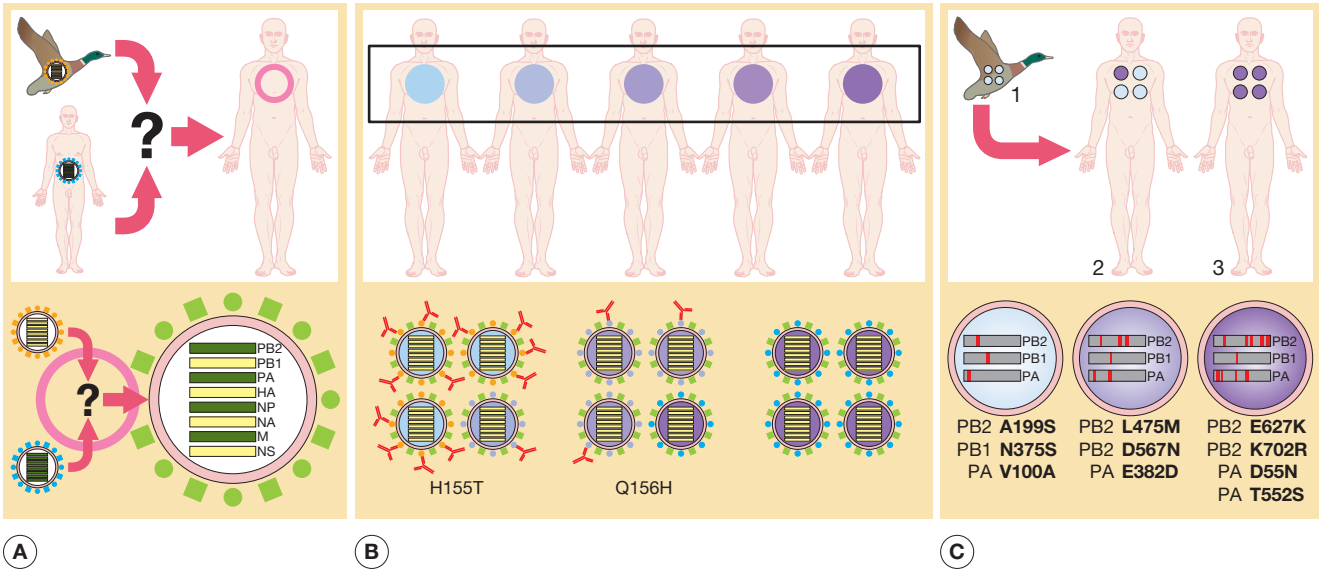

Figure 31.1. Classical mechanisms of influenza A virus variation. A, Antigenic shift, representing what is thought to have occurred in the 1957 pandemic, in which a human H1N1 virus reassorted with an avian H2N2 virus. **B,** Antigenic drift, the process by which circulating influenza viruses in the human population mutate under pressure from antibody to hemagglutinin. **C,** Changes shown experimentally to be associated with adaptation of influenza viruses to mammals or to affect receptor binding or virulence. *(From Doherty PC, Turner SJ, Webby RG, et al. Influenza and the challenge for immunology.* Nat Immunol. *2006;7:449–455.)*

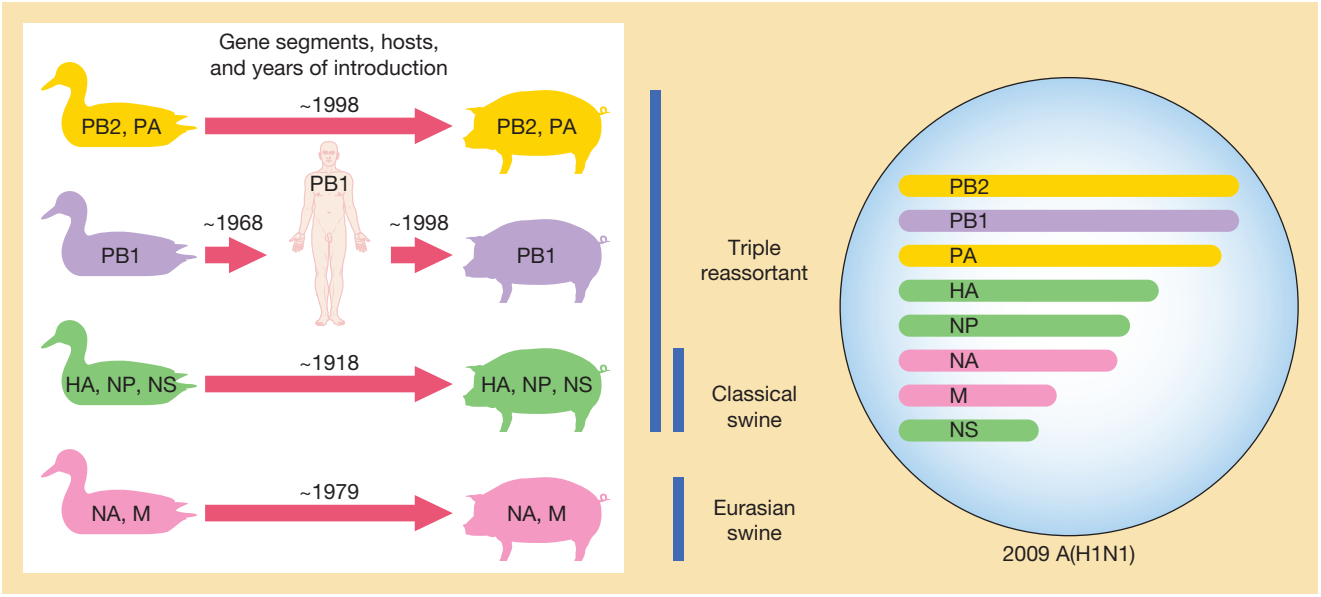

Figure 31.2. Host and lineage origins for the gene segments of the 2009 A(H1N1) virus. Color of gene segments in the circle indicates most recent and prior originating hosts. Genes: HA, hemagglutinin; M, matrix; NA, neuraminidase; NP, nucleoprotein; NS, nonstructural; PA, polymerase acidic; PB1, polymerase basic 1; PB2, polymerase basic 2. *(From Garten RJ, Davis CT, Russell CA, et al. Antigenic and genetic characteristics of swine-origin 2009 A[H1N1].* Science. *2009;395:197–201.)*

Pandemics, such as the "Spanish flu" pandemic of 1918, can be catastrophic.[41,42] However, as demonstrated during the 2009 (H1N1) pandemic, an H subtype that is sufficiently antigenically different from those in currently circulating strains can be enough to cause a pandemic; that is, a new subtype is not necessary if a large segment of the population lacks immunity to the new virus (Fig. 31.2).[43] Pandemic influenza viruses are always influenza A viruses because of the presence of a large reservoir of influenza viruses in animal populations, particularly in avian and swine populations, to which humans have no immunity. The continued circulation and evolution of animal influenza viruses present a constant threat that one of these viruses will acquire the potential to cause a pandemic.[44] The emergence of highly pathogenic avian influenza A(H5N1) viruses in Asia in 1997 with their rapid spread and capacity to cause severe human illnesses,[25,26] led to intensive global and national efforts to prepare for pandemic influenza.[45] Even though influenza B viruses do not pose a pandemic threat, continued antigenic "drift" among these viruses also occurs, with resulting substantial interpandemic disease burden.[46] Since 1997, substantial investments have been made in expanding global surveillance for new emergent

viruses, creating more robust pandemic response plans, proactive pandemic vaccine and antiviral development and stockpiling, and in forming more coordinated international partnerships.[37,39,47–50] These efforts produced real benefits during the 2009 response, but there is a recognition that continued work is required for more effective responses to future pandemics.

Although the quality, availability, and use of inactivated influenza vaccine have increased substantially, influenza vaccines are underused in most countries, and influenza remains a poorly controlled infectious disease.

BACKGROUND

Clinical Description

Influenza is characterized by respiratory symptoms, such as cough and sore throat, along with constitutional symptoms, such as fever, headache, myalgias, chills, fatigue, and anorexia.[19,23,37,38,51–54] In uncomplicated influenza cases, signs and symptoms have abrupt onset and generally persist for approximately 7 days, but resolve with nonspecific therapies. The presence of cough and fever are the best predictors of influenza illness in adults and children during periods of influenza circulation.[54–57] Fever usually ranges between 38°C and 40°C, but may be higher, and usually lasts for 3 to 5 days.[52] Cough is usually unproductive of sputum, but rhinorrhea is common. Substernal tenderness and photophobia occur less frequently. Gastrointestinal symptoms, such as vomiting, diarrhea, and abdominal pain, are less common, but more likely to occur in children. Rash has occasionally been described with influenza B infections.[58] Young infants may present only with unexplained fever or sepsis-like syndrome, without prominent respiratory symptoms. Because fevers are often higher in children; influenza can present as febrile seizures in this age group.[19] Fever may be absent in the elderly, while the presenting signs may include anorexia, lassitude, or confusion.[59,60] Illness typically improves within a week, but cough and malaise may persist for 2 or more weeks. A minority of patients may experience fatigue for months.[61]

Asymptomatic influenza infections are likely common, and may account for greater than 30% of all influenza infections,[62–67] although estimates have varied considerably depending on methods used to confirm influenza infection and study design.[68] Asymptomatically infected persons can shed detectable influenza virus and may transmit influenza to others.[69]

Complications of Influenza

Although any influenza illness can result in severe disease and complications, the risk of complications from influenza is elevated in persons with certain underlying health conditions,[18] young children, and elderly persons compared with healthy nonelderly adults.[22,24,70–76] In addition, pregnant women have had higher rates of hospitalizations associated with seasonal influenza,[77] especially those with underlying health conditions.[77,78] Even though increased mortality caused by seasonal influenza among pregnant women has not been consistently observed, increased complications and risk of death in this population has been documented during pandemics.[79–82] During the 2009 pandemic, pregnant women accounted for 6% to 10% of all patients who required hospitalization or died.[80,81,83,84] In addition, risk factors for severe disease highlighted during the 2009 pandemic included morbid obesity[85–87] and aboriginal ethnic or racial origin (e.g., American Indian, Alaskan Native, First Nation peoples, Australian aboriginal peoples).[88–90] Although risk factors for complications are well known, severe influenza complications and deaths can also occur each season among persons who have no known risk factors.[72,91–93]

The most common serious complications of influenza include exacerbation of underlying chronic pulmonary and cardiopulmonary diseases.[22,73] Increased hospitalizations and clinic visits associated with influenza have been reported among persons with chronic obstructive pulmonary disease,[59,94] asthma,[76,92,95–97] and congestive heart failure.[98,99] In addition, some persons with other chronic diseases also have higher rates of disease complications during influenza illnesses. Children with underlying neurologic diseases have increased risks of hospitalization and deaths, likely because of preexisting difficulties handling respiratory secretions or restrictive lung disease.[100] Exacerbations of diabetes,[98–101] renal diseases,[98,99] and hemoglobinopathies[100,102] have also been reported. Persons with immunocompromising conditions, including cancer, hematopoietic and solid-organ transplant recipients, and HIV have a higher risk of severe or prolonged disease and chronic viral shedding associated with influenza.[99,100,103–108]

In addition to exacerbations of underlying respiratory conditions, influenza can cause lower respiratory tract disease as a result of primary viral pneumonia or from secondary bacterial pneumonias. Influenza has been associated with approximately 10% of hospitalized lower respiratory infections in studies from developed and developing countries that have been conducted for at least 1 full year, with higher proportions observed during periods of influenza circulation.[19,27,31,109–111] Primary viral pneumonia can range from mild disease with radiographic evidence of pneumonia to severe disease with respiratory failure.[52] Primary viral pneumonia and pneumonitis can occur during any influenza infection, but is more commonly observed during pandemics, such as in 2009, where severe cases with shock and respiratory failure were reported.[30,96,112–115] Primary viral pneumonias are also reported among infections with novel influenza A viruses, such as avian influenza A(H5N1).[26] Influenza cases can lead to pneumonias due to secondary bacterial infection, most commonly associated with *Streptococcus pneumoniae and Staphylococcus aureus*.[76,113,114,116–120] Bacterial pathogens have been detected in approximately 20% to 40% of pediatric influenza-associated deaths.[117,118]

More common respiratory tract complications of influenza include otitis media and laryngotracheobronchitis in children and bronchitis in adults. While less common, influenza is associated with nonrespiratory complications that affect almost all other organ systems.[23,121] Neurologic complications include febrile seizures in children, encephalitis/encephalopathy, aseptic meningitis, transverse myelitis, and Guillain-Barré syndrome.[122,123] Reye syndrome, an encephalopathy with hepatic inflammation, associated with influenza has been reported primarily in children associated with salicylate ingestion,[124–127] but the incidence of Reye syndrome has decreased dramatically in the United States after warnings were issued in the 1980s regarding the use of aspirin to treat children.[125,126,127a] Myocarditis and pericarditis were reported in association with influenza, especially with influenza B infections in children. Myositis with rhabdomyolysis and myoglobinuria has been reported, but is uncommon.[128,129] Influenza can present as sepsis-like syndromes in infants and has been associated with hematologic abnormalities, including lymphopenia and disseminated intravascular coagulation.[23]

Virology

Taxonomy and Nomenclature

Influenza viruses, together with Thogoto-like viruses, form the family *Orthomyxoviridae*.[125] Influenza viruses are further

divided into three genera, *influenzavirus A*, *influenzavirus B*, and *influenzavirus C*, based on antigenic differences in two major structural proteins, the nucleoprotein (NP) and the matrix protein (M). Influenza A viruses are further classified into subtypes according to the properties of their major membrane glycoproteins, HA and NA (see Fig. 31.1).[125] Eighteen HA subtypes and 11 NA subtypes have been identified among influenza A viruses.[130] The nomenclature of human influenza viruses includes the type of isolate, the geographic location where it was isolated, the year of isolation, a laboratory identification number, and, for influenza A viruses, the subtype of the HA and NA (e.g., A/Panama/2007/99 [H3N2]). For animal influenza viruses, the type of animal from which the sample was obtained is also included (e.g., A/chicken/Hong Kong/220/1997 [H5N1]).[125]

Natural Hosts

Influenza A viruses naturally infect humans. Influenza A viruses of the H1N1, H3N2, and (rarely) H1N2 subtypes are currently circulating among humans whereas H2N2 viruses circulated among humans in the mid-1900s. However, 16 of the 18 influenza A HA subtypes and 9 of the 11 NA subtypes have been isolated from wild aquatic birds, which serve as a natural reservoir and a source of novel genes for pandemic influenza viruses. Influenza A viruses also infect poultry, pigs, horses, dogs, and occasionally sea mammals.[125] Interspecies transmission of influenza A viruses has occurred and can result in severe illness, as demonstrated by the transmission of influenza A(H5N1) viruses from poultry to humans.[131–134] In 2009, a novel influenza A(H1N1) virus was the cause of a worldwide pandemic. This virus possessed a unique combination of gene segments, including genes that originated from swine, avian, and human influenza viruses that were established in pigs in North America and Europe (see Fig. 31.2).[43] Widespread circulation of the 2009 H1N1 virus occurred in humans before infections in swine were documented, and humans infected with the 2009 H1N1 virus can infect swine.[135] The highly pathogenic influenza A(H5N1) virus also causes illness and death in many different animal species not previously known to be infected with influenza A viruses, such as cats.[136] Recently, two new subtypes of influenza were identified in bats (H17N10 and H18N11); neither of these subtypes have been detected in wild birds.[137–139] Although influenza B virus infection of seals has been documented,[140] humans are the primary host for influenza B viruses. Influenza C viruses infect only humans and pigs and cause sporadic cases or localized outbreaks of mild upper respiratory tract infection.

Virus Structure

Influenza viruses are enveloped and contain segmented RNA-negative sense genomes (Fig. 31.3).[125] Segmentation of the viral RNA allows exchange of genes (i.e., genetic reassortment) among influenza viruses of the same type (see below). The segmented RNA genome is associated with NP and three viral polymerase proteins (PB1, PB2, and PA) within helical nucleocapsids that are surrounded by the matrix protein and the virus envelope derived from the host cell membrane. The spherical, often pleomorphic 80- to 120-nm virus particles have a surface layer of spike-like projections, 10 to 14 nm long, consisting of HA and NA proteins. HA is the major antigen against which the host's protective antibody response is directed and is responsible for attachment of influenza viruses to oligosaccharide-containing terminal sialic acids on the cell surface during early stages of infection (Fig. 31.4). HA of avian influenza viruses preferentially bind sialic acid (SA) residues attached by $\alpha_{2,3}$ linkage to galactose ($\alpha_{2,3}$Gal) while

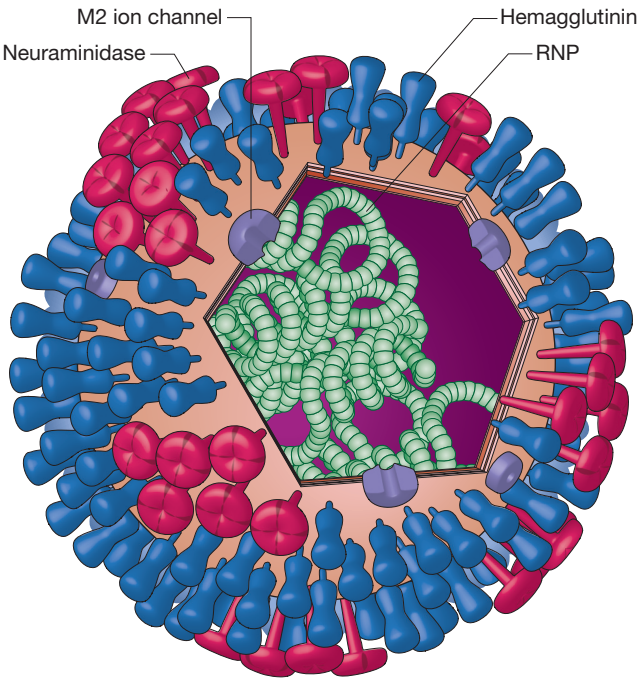

Figure 31.3. Schematic of the influenza A virus depicting some of the key components of virus structure. Hemagglutinin (HA) and neuraminidase (NA) are the two most important surface glycoproteins for host immune response. Protective antibodies that are formed after exposure to influenza viruses (by natural infection or vaccination) are mainly directed at the HA. NA inhibitor medications (oseltamivir and zanamivir), which can treat or prevent infection, block the function of neuraminidase. M2 ion channels control flow of substances into the viral core. Adamantane medications (amantadine and rimantadine) can inhibit M2 ion channel function of influenza A viruses, but are not currently recommended for use because of high levels of resistance among circulating influenza A viruses. RNPs are ribonucleoproteins, which consist of viral genetic material joined with nucleoproteins.

human viruses bind predominantly to those having $\alpha_{2,6}$Gal; however, swine viruses tend to bind both $\alpha_{2,3}$Gal and $\alpha_{2,6}$Gal providing the molecular basis for the observations that pigs serve as a mixing vessel for both avian and human viruses thus facilitating the generation of new influenza viruses.[141] Furthermore, the distribution of SA residues in the respiratory tract varies among the birds, humans, and pigs. While SA $\alpha_{2,6}$Gal is expressed predominantly in the trachea in humans, $\alpha_{2,3}$Gal is expressed on nonciliated cuboidal cells in the region between the bronchioles and alveoli, as well as on alveolar cells, indicating the reasons as to why humans are infected sporadically with avian influenza viruses. Furthermore, the distribution of $\alpha_{2,3}$Gal SA in the lower respiratory tract of humans limits human-to-human transmission of avian influenza viruses via aerosols.[142] In addition, the presence of multiple basic amino acids at the cleavage site in avian HAs and its cleavage by endoprotease furin is attributed to their pathogenicity in susceptible species.[143] Because furin is widely distributed in the body in various tissues and organ systems, avian influenza viruses containing polybasic amino acids are able to infect a wide range of cell types leading to severe disease. The HA is a homotrimeric transmembrane protein consisting of a globular head (HA1) and membrane-anchoring α-helical chain stem (HA2). The error-prone nature of RNA polymerase coupled with immune selection pressure leads to hypervariability in the globular head region. Phylogenetic differences of the HA led to grouping influenza viruses into Group 1 or 2. While H1,

H2, H5, H6, H8, H9, H11, H12, H13, H16, H17, and H18 HAs are placed in Group 1, HAs H3, H4, H7, H10, H14, and H15 are placed in Group 2.[144] While the immunodominant immune response consists of strain-specific antibodies directed against the globular head (HA1), broadly neutralizing antibodies directed to the highly conserved conformational stem (HA2) region can be induced (see "'Universal Vaccines" later). These broadly neutralizing antibodies neutralize many strains within Group 1 or Group 2 influenza viruses.[145] NA is less abundant on the viral surface and facilitates release of mature virus from infected cells. It is homotetrameric protein with a mushroom head and is anchored with a short stem. Similar to HA, nine NA types of influenza viruses are grouped into two groups. Group 1 contains the N1, N4, N5, and N8 subtypes, and Group 2 consists of N2, N3, N6, N7, and N9 subtypes.[146] NA types 10 and 11 are genetically distinct from other NAs. Antibody to NA is believed to restrict virus spread and reduce severity of the influenza infection. By definition, the HA and NA of different subtypes are serologically distinct.[125] Although some serological cross-reactivity may exist among HA or NA of the same influenza subtype but from different species, the extent of cross-protection afforded by such responses is not well understood. During the 2009 H1N1 pandemic, most studies showed that persons who had previously been vaccinated against or likely to have been infected with circulating seasonal influenza A(H1N1) strains appeared to have no significant protection against severe cases with the novel H1N1 virus; some studies performed in Canada suggested that previous vaccination with seasonal influenza vaccines might have increased risk for symptomatic infection with the 2009 H1N1 virus.[147–152]

The influenza A virus envelope also contains matrix (M1) and transmembrane (M2) proteins. M1 protein is located inside the viral membrane and is thought to add rigidity to the lipid bilayer, whereas the M2 protein functions as a pH-activated ion channel.[125] A nonstructural gene encodes two proteins: the multifunctional NS1 which is found only in virus-infected cells and nuclear export protein (NEP), also known as NS2, which is a minor virion component involved in nuclear export of the nucleocapsids containing viral RNA.[125]

Pathogenesis as It Relates to Prevention

Infection and viral replication of seasonal influenza viruses occur primarily in the columnar epithelial cells of the respiratory tract,[153,154] but viral replication can occur throughout the respiratory tract. After infection, epithelial cells become vacuolated, lose cilia, and become necrotic. Regeneration of epithelium takes approximately 3 to 4 weeks, during which time pulmonary abnormalities can persist. Influenza viruses are rarely isolated outside of the respiratory tract, even though infection can result in signs and symptoms referent to several other organ systems and is associated with pronounced constitutional manifestations. Viremia is rarely observed with seasonal influenza virus infections,[155–159] although it has been detected more frequently in human infections with avian influenza A(H5N1) viruses.[160]

Consequently, influenza viruses are spread through exposure to respiratory secretions containing virus from an infected person. The most likely modes of transmission are through large or small droplet aerosols produced by the coughing, or perhaps sneezing, of infectious individuals. The relative contribution of large droplet versus aerosol transmission is not completely clear, but influenza viruses have been detected in large and small droplets, and recent data indicate that aerosol transmission of fine droplets are a significant source of transmission.[161,162] Transmission of virus by direct contact with infected respiratory secretions can also occur, including transmission through fomites.[163] No evidence for transmission through bloodborne or sexual routes has been described.

The incubation period for influenza is commonly 2 days, but ranges from 1 to 4 days.[164] Virus can be detected in the upper airway for up to a day before symptoms and approximately 3 to 5 days after illness in adults. The peak of viral shedding, 1 to 3 days following illness onset,[165–167] likely coincides with the period during which most transmission occurs. Children may shed virus for up to 2 weeks, and have higher virus titers in their upper airway,[168] which is one factor that promotes transmission in school settings. Severely immunocompromised persons can shed virus for months.[169–171]

The transmissibility or reproductive number (Ro) for influenza is estimated to be approximately 1.5 to 2, and the serial interval (the interval between the onset of symptoms in a case patient and the onset of symptoms in the contacts who were infected by that patient) is usually estimated to be 2 to 3 days.[172–176] However, given the typical short incubation period for influenza, influenza outbreaks may be explosive, especially in highly susceptible populations as can occur in a pandemic.[172,177–179]

Diagnosis

Infections by other pathogens, including respiratory syncytial virus (RSV), adenovirus, parainfluenza virus, rhinovirus, numerous other respiratory viruses, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae,* and *Legionella pneumophila*, can result in individual illnesses similar to influenza. Nonetheless, certain epidemiological features of influenza outbreaks and epidemics can greatly aid in the clinical diagnosis of influenza. For example, communitywide or institutional outbreaks of febrile respiratory illness cases during winter and spring months are characteristic of influenza, although RSV also can exhibit a similar epidemiological pattern. In most instances, individual cases of influenza are difficult to identify reliably

by clinical examination and routine laboratory findings alone, and the appropriate use of influenza diagnostic tests is helpful. Such tests include virus isolation (culture) and identification, direct detection of influenza virus in clinical specimens, rapid point of care tests, molecular methods, and serological tests.

Isolation of influenza viruses in cell culture or eggs followed by hemagglutination inhibition (HI) testing to identify the virus was the "gold standard" for influenza diagnosis, but has been largely replaced by reverse-transcriptase polymerase chain reaction (RT-PCR). Isolation of influenza viruses remains critical for identifying viruses for use in influenza vaccines. The sensitivity of viral culture depends on when in the course of illness the specimen is collected and its quality.[180] Results usually are not available for at least 3 days, although some rapid culture methods allows virus to be detected within 18 to 24 hours.[181] While state health department laboratories and some hospital laboratories can type and subtype viral isolates, further antigenic characterization generally is conducted in specialized laboratories.

A variety of sensitive and specific radioimmunoassays, fluoroimmunoassays, and enzyme immunoassays can detect viral antigens in clinical samples. Although these assays can produce a result within a few hours, they are often less sensitive than standard virus isolation and they require specialized laboratory equipment and reagents.[180]

There are many commercially available "point-of-care" tests for rapid diagnosis of influenza. Tests may use immunoassays that detect influenza viral proteins or may detect viral NA activity in specimens. Some tests detect influenza A and influenza B viruses but do not distinguish between them, while others detect only influenza A viruses, or detect and distinguish between influenza A and influenza B. In general, these diagnostic tests are useful for determining rapidly if influenza is the cause of outbreaks in institutions or other settings and for documenting circulation of influenza viruses in populations of patients. These tests generally have a sensitivity of 20% to 100% and a specificity of 52% to 100%, with sensitivity estimates in the higher range derived from reports from manufacturers.[182–184] During the 2009 H1N1 pandemic, sensitivity of point-of-care tests was 11% to 70%, and negative test results were viewed as providing insufficient information to help in making treatment or infection control decisions.[185–187] These tests are also not sensitive for detecting avian influenza virus infections in humans.[188] Collection of additional specimens for viral isolation or RT-PCR testing is strongly recommended to confirm rapid antigen test results for human influenza infections. However, for persons suspected of having H5N1 avian influenza infection, viral isolation should not be done except in laboratory facilities under Biosafety Level 3 enhancements. Influenza H5N1-specific RT-PCR testing conducted under Biosafety Level 2 conditions is the preferred method for diagnosis of human infection with H5N1. In the United States, all state public health laboratories, several local public health laboratories, and the Centers for Disease Control and Prevention (CDC) are able to perform influenza H5N1 RT-PCR testing, and are the recommended sites for initial diagnosis.[189]

Molecular methods are now commonly used to diagnose influenza virus infections and have supplanted virus culture as the "gold standard" for virus detection. Methods using RT-PCR are more rapid and sensitive than virus culture.[180] A new molecular approach uses DNA microarrays containing nucleic acid probes to type and subtype influenza viruses.[190,191]

Influenza virus infections can also be detected by measuring increases in influenza-specific antibody between acute and convalescent serum samples.[192] Techniques for measuring antibody against influenza in sera include HI, virus neutralization, enzyme immunoassay, and complement fixation. In general, these tests are little used outside of a research setting, and may underestimate infections among recently vaccinated individuals.[193]

Drugs Active Against Influenza Viruses

Two classes of prescription medications, adamantanes and NA (NA) inhibitors, have been approved in the United States for use against influenza virus infections. The adamantane derivatives, amantadine hydrochloride and rimantadine hydrochloride, inhibit viral replication by blocking the proton channel formed by the M2 protein of influenza A viruses. The channel activity is necessary for viral particle uncoating during early and late stages of viral replication.[194] A single substitution at one of five residues (26, 27, 30, 31, 34) of the M2 protein is associated with resistance to all adamantane derivatives.[195,196] Widespread emergence and now predominance of adamantine resistance among human influenza A(H3N2) and influenza A(H1N1) viruses and among animal influenza viruses have severely limited the usefulness of these medications for influenza treatment or prophylaxis.[197–200]

The NA inhibitors, zanamivir, oseltamivir, peramivir, and laninamivir inhibit the NA of both influenza A and influenza B viruses. Blocking the active site of the NA results in viral aggregation at the host cell surfaces and fewer viruses released from infected cells.[201–204] Resistance to NA inhibitors can occur from substitutions in the active site of the NA or its proximity that reduce drug binding affinity.[205,206] Cross-resistance to multiple NA inhibitors can occur with single-residue substitutions, often with varying degrees of resistance.[206–208] In addition, multiple NA substitutions that result in resistance to multiple NA inhibitors have been reported.[209–212] In 2008, widespread and unexpected circulation of seasonal influenza A(H1N1) viruses that were resistant to oseltamivir and peramivir because of NA substitution H275Y occurred; however, susceptibility to zanamivir was maintained.[213–215] In 2009, the H275Y containing influenza A(H1N1) viruses were replaced by influenza A(H1N1)pdm09 viruses that were susceptible to all NA inhibitors. Currently, it is rare to find NA inhibitors resistance in circulating human or animal influenza viruses.[211,212] Although not common, NA inhibitors resistance can also occur during or after drug use.[209,210,212,216,217]

EPIDEMIOLOGY

Seasonality

Influenza occurs in seasonal peaks in much of the world. In temperate climates, influenza activity typically occurs during the late autumn and winter months—between October and April in Northern hemisphere temperate countries, and between May and September in Southern hemisphere tropical countries.[218] Although in tropical climates influenza transmission occurs year-round, one or two annual peaks can often be discerned in many countries.[219–225] In large countries, differences in seasonal occurrence of influenza can be observed within the country.[220,226] Despite a vaccine nomenclature indicating "Southern" and "Northern" hemisphere formulations, as data from subtropical and tropical countries accumulate, it is clear that seasonal peaks of influenza don't fall neatly into two seasonal patterns—one Northern and one Southern.[218] Data demonstrating a summertime peak in influenza in Central American[12,218] and southeast Asian countries[223] resulted in several countries changing vaccine recommendations to use the Southern hemisphere formulation, despite residing in the Northern hemisphere.

Sporadic cases and institutional outbreaks can occur at any time of the year, including the summer months. Outbreaks

associated with large groups of international travelers suggest that large outbreaks of influenza may begin to occur more frequently during unusual times of the year.[227,228] Within communities, epidemics or outbreaks typically last 6 to 8 weeks or longer. Reasons for the seasonality of influenza are not completely understood and are likely multifactorial and include the role of temperature and humidity on virus survival,[229] and seasonal differences in behavior (indoor crowding in winter months and school attendance).[230–232]

Even in locations where seasonal peaks occur each year, the start, peak, duration, and size of individual seasons vary substantially from year to year and are not predictable. In the United States, approximately 80% of seasons have peaked in January to March during the past 30 years, but peaks in December have been observed in three recent seasons. The timing, size, and impact of epidemics reflect the interplay of several factors, including the extent of the virus' antigenic variation, virulence, and transmissibility; the extent of immunity in the population; and the specific population groups that are affected.

Incidence of Disease

Influenza attack rates vary by season, by geographic location, by setting (e.g., institutional, closed settings versus community settings), by predominant subtype/type, and by age group. In addition, reported attack rates may vary considerably depending on the methods used to document infection (e.g., viral isolation, RNA detection, antibody detection, etc.). In general, virus isolation is considerably less sensitive than RT-PCR or serologic assays for documenting infection; however, not all persons with infections documented by culture will have documented seroconversion and vice versa. However, approximately 30% to 50% of persons with serologic evidence of infection after an influenza season are either asymptomatically infected or have very mild illness.[66,233] Similar rates of mild or asymptomatic infections were observed during the 2009 pandemic.[67]

Among community studies, one study of families in Seattle showed annual attack rates of 19% and 20%, respectively, for serologically confirmed influenza A and B infections between 1965 and 1969.[234] In the same study in 1978–79, rates of influenza A(H1N1) infection soon after its reemergence in 1977 were approximately 31% among persons born after 1956.[235] In Michigan, a community study during 1966–71 found infection rates of 17% and 8% using serology for influenza A and influenza B infections, respectively, but rates of only 1.4% and 1.5%, respectively, using[236] virus isolation.[17,236] The attack rates by age group, based on serology for influenza A, were approximately 15% to 24% in children younger than 5 years, approximately 17% to 21% in children 5 to 19 years of age, and approximately 12% to 18% in persons older than 19 years of age. Rates were lower for influenza B infections. In Houston, between 1976 and 1984, estimated attack rates ranged from approximately 36% to 45% in children 5 years of age and younger, from approximately 40% to 48% in children 6 to 17 years of age, and from 21% to 23% in persons 18 years of age and older.[236]

During the 2009 H1N1 pandemic, the attack rate, as measured by fourfold increases in specific antibody titer among other household members after laboratory confirmation of an index household member, was 20%; 13% of contacts were shown to have viral shedding by RT-PCR. Serial cross-sectional seroprevalence data obtained before and after the summer-fall 2009 H1N1 pandemic wave indicated that the overall attack rate was 11%, including 43% in persons 5 to 14 years of age, 16% in persons 15 to 19 years of age, 12% in persons 20 to 29 years of age, and 5% in persons 30 to 59 years of age.[237] Attack rates among institutionalized populations can be much higher. In military and boarding school populations, attack rates up to 87% and 90%, respectively, have been reported. One review of outbreaks in nursing home populations estimated an average attack rate of 43%,[238] although higher rates have also been found.[239] Influenza outbreaks also have been described in hospitals[240–242] and aboard cruise ships.[227,228]

Current Epidemiology as It Relates to Vaccination

Vaccination strategies for influenza have evolved over time to address the improved understanding of risk groups, changing epidemiology of influenza viruses, and to maximize efficacy in specific target populations. Importantly, vaccine strategies have largely focused on targeting specific groups found to be at increased risk of influenza complications. The first U.S. vaccine policy recognized key high-risk groups for which vaccine was recommended.[10,243] These groups, including elderly persons, those with underlying chronic disease, and pregnant women, remain the foundation for most national influenza immunization strategies[12,244] as well as global recommendations.[245] Even so, over time, additional high-risk groups have been added to many national policies as compelling data were produced demonstrating relatively high risk in these groups. A notable example are policies that target young children, who have a higher risk than older children or non-elderly adults of hospitalizations and deaths associated with influenza. During the 2009 pandemic, data indicated that persons with morbid obesity[85,87,246] and persons from indigenous populations[246–248] were at higher risk of hospitalization and were added to targeted high-risk groups. Finally, because the risk of influenza is universal, even while the risk of severe disease varies among populations, vaccination policy in the United States expanded to recommend influenza vaccine for all persons in 2010.[147] This expansion of policy recognized the value of preventing not only severe disease and deaths,[243] but increasingly preventing milder disease and healthcare visits, with associated costs.

Early monovalent vaccines were replaced with multivalent vaccines, acknowledging the cocirculation of influenza A(H3N2), influenza A(H1N1), and influenza B viruses, the need for type or subtype-specific immunization, and the unpredictability of strain prevalence from year to year.[243] More recently, the emergence and cocirculation of two distinct lineages of influenza B with limited cross-reactivity led to the development and approval of quadrivalent vaccines containing antigens representative of each B lineage.[11] Models have estimated a modest public health benefit of including representative viruses of both B lineages[249]; this benefit may be observed to a greater extent in children, who may generate less robust heterotypic antibody responses to influenza B vaccinations, than among adults.[250]

While multivalent vaccines are used globally in seasonal immunization programs, monovalent influenza vaccines have been used for responding to specific influenza threats. Most notably, monovalent vaccines have been prepared and used for each of the recent pandemics.[8,251–255] The most recent example is during the 2009 H1N1 pandemic. In April 2009, the first cases of human infection with a novel influenza A(H1N1) virus were identified,[256] and the virus spread quickly over the next several months to cause disease worldwide.[257] The 2009 H1N1 pandemic strain possessed a unique combination of gene segments including genes that originated from swine, avian and human influenza viruses that had been circulating among in pigs in North America and Europe.[43] Antibodies to contemporary seasonal influenza A(H1N1) viruses at that time engendered by previous infection or vaccination

offered little or no cross-protection against 2009 pandemic H1N1 viruses.[258] As a result, a monovalent vaccine based on one of the original isolates of the virus was produced and found to be effective in preventing disease associated with the virus[255]; vaccination with the multivalent vaccine produced using the seasonal H1N1 strain was found to confer no protection.[149] Similarly, pandemic strain-specific vaccines were produced for pandemic responses in 1957–58 and 1968–69. A monovalent vaccine also was produced to respond to the emergence of the antigenically drifted strain of H1N1 in 1986.[259,260] Finally, a monovalent vaccine was produced and administered in the United States based on the emergence of a novel H1N1 swine origin virus in 1976, based on the fears that the virus was a pandemic threat.[261] The emergence of a drifted H3N2 virus in 2014–15 with resulting low vaccine effectiveness has renewed interest in developing the ability to produce monovalent or multivalent vaccines rapidly to respond to seasonal threats and to respond to pandemic threats with more rapid vaccine production.

Pandemics of Influenza

Pandemics of influenza have occurred unpredictably and relatively infrequently. Influenza pandemics are caused by the appearance and spread in humans of a new influenza A virus bearing either a novel HA or novel HA and NA combination against which the human population has little or no immunity and which cause illness in humans. The other requirement for a pandemic influenza virus is that it readily spreads from person to person.[262] Influenza viruses that have not circulated in humans in recent years are considered "novel" and arise through antigenic shift or through direct transmission of a novel influenza A virus into the human population from animals if the virus is adapted to human hosts.

Antigenic shift among influenza A viruses can occur in at least two ways. In the first mechanism for shift, the simultaneous infection of a host by influenza A viruses of two different subtypes allows corresponding viral genes to be exchanged (or to reassort) between the infecting viruses. For example, infection of a pig simultaneously by both an avian influenza A virus and a human influenza A virus can allow genes from the virus normally in circulation among birds to reassort with genes of the influenza A viruses circulating among humans. The resulting "reassortment" of human and avian influenza genes could produce new influenza viruses containing many different combinations of genes. Some of the new progeny viruses will contain HA or HA-NA genes from the avian influenza viruses. Pigs may serve as "mixing vessels" for genetic reassortment among influenza A viruses because they are susceptible to infection by avian, swine, and human influenza A viruses since respiratory epithelial cells in pigs possess both SA $\alpha_{2,3}$ receptors for which avian viruses have a preference, and SA $\alpha_{2,6}$ receptors, which are preferred by human influenza viruses.[156] Avian species are considered to be the primary reservoir of influenza A viruses because viruses bearing almost all known HA subtypes circulate among wild birds.[44] The viruses that caused the 1957, 1968, and 2009 pandemics showed evidence of genetic reassortment between avian and human influenza viruses.[4,256]

The second mechanism involves direct transmission of avian viruses to humans with subsequent adaptation to the new host. The 1918 pandemic influenza virus is thought to have arisen in this way.[263] Fears of pandemic influenza have arisen because of the emergence of avian viruses, such as H5N1 and H7N9, that have demonstrated the ability to infect and cause severe disease in humans.[264–267] Since the emergence of avian influenza A(H5N1) in 1997 in Hong Kong,[131] more than 600 human infections have been documented, with a case fatality rate of approximately 60%.[134,160] Similarly, avian influenza A(H7N9) viruses emerged in China in 2013, and since have infected more than 500 persons, almost all in China, of whom approximately 37% have died.[268] Swine-origin influenza A viruses have also been occasional causes of illness in humans in the United States, mostly resulting in mild respiratory illnesses.[269,270] Aside from occasional human-to-human spread of these avian and swine-origin viruses, almost all human infections have been by direct transmission from infected poultry or swine to humans[270–272]; none of these viruses have as yet demonstrated the capacity for sustained human-to-human spread. However, the viruses are geographically widespread in poultry and swine populations, with recent H5 containing viruses identified in poultry in the United States that might allow for more efficient human-to-human transmission.[273]

Pandemics are of great public health significance because of their capacity to result in substantial mortality and morbidity. In addition, because pandemics spread quickly, affect entire countries and regions in a short time, and may have more than one wave, they have the capacity to cause disruptions in healthcare delivery and other societal functions. Between the spring of 1918 and the spring of 1919, three waves of "Spanish flu" caused by influenza A(H1N1) viruses swept around the world leading to more than 550,000 deaths in the United States and more than 20 million deaths worldwide.[262] Three subsequent pandemics, beginning in 1957 (the "Asian flu"), in 1968 ("Hong Kong flu"), and in 2009 were associated with the emergence of the influenza A(H2N2) virus, the influenza A(H3N2) virus, and a new H1N1 virus, respectively, but resulted in lower mortality rates compared with the 1918 pandemic.[262] In fact, the most recent pandemic, which was characterized by relatively low attack rates among persons older than 60 years of age, is estimated to have resulted in fewer deaths than many annual seasonal epidemics in the United States.[274,275] However, during pandemics, severe infections were much more common in children and younger adults compared to typical winter influenza seasons, in which more than 90% of deaths and approximately 60% of hospitalizations occur among persons 65 years of age or older.[73,275] During 2009, the first year after the emergence of the virus, an estimated 61 million illnesses, 274,000 hospitalizations, and 12,400 deaths associated with the 2009 H1N1 virus occurred in the United States.[276] During this period, the highest estimated attack rates occurred in children and young adults, the highest estimated hospitalization rates occurred in children younger than 5 years of age, and 90% of estimated deaths occurred in persons younger than 65 years of age. In one estimate, the mean age among persons whose deaths were attributed to the 2009 H1N1 influenza pandemic was 37 years, compared to a mean age of 76 years among deaths attributed to seasonal influenza A(H3N2).[277] Because of the potential for the development of a new pandemic strain with higher case-fatality rates, preparedness planning has been a priority for most countries since the emergence of H5N1 viruses in 1997. Critical to preparedness has been the development of plans for developing monovalent pandemic vaccines, hoping to circumvent the problem that pandemic vaccines may be available only after the pandemic has begun, mitigating their effectiveness.[49] These plans were effective in responding to the H1N1 pandemic in 2009, and while vaccine was delivered relatively late, it was demonstrated to be effective.[49,255,278] Efforts are underway to speed the process for pandemic vaccine development and delivery, including the continual updating of candidate vaccine virus strains, and work toward more broadly reactive vaccines that might increase the value of prepandemic stockpiled vaccines.

Significance as a Public Health Problem

Influenza is a significant public health threat because of relatively high annual attack rates, coupled with the capacity to cause large numbers of severe illnesses requiring medical care. During influenza seasons, an estimated 5% to 15% of the U.S. population can develop influenza,[17,279] but attack rates of 40% to 50% within institutions such as nursing homes are not unusual.[280,281] In communities, influenza cases often appear first among school-age children, among whom attack rates usually are the highest.[62,235,279,282,283] While attack rates among the elderly are generally lower as a result of differences in mixing patterns and preexisting immunity,[284] rates of serious disease during most seasonal influenza epidemics are highest among the elderly, the very young, and those with certain underlying chronic conditions.[22,24] Influenza epidemics are generally associated with increases in physician visits, hospitalizations, and deaths, as well as increases in school and workplace absenteeism.[65,285,286] The World Health Organization has estimated that between 250,000 and 500,000 deaths occur each year as a result of influenza.[245] While this burden has been well-documented in developed countries,[24,26,287] increasing data from middle-income and low-income countries have confirmed that the burden of severe disease is perhaps even higher in these settings, possibly a consequence of higher rates of underlying conditions such as HIV.[110,288,288a] The large numbers of medical care visits generated by influenza can overwhelm medical care systems, requiring hospitals and emergency services to divert patients.[28] As a result, substantial medical care and societal costs are incurred each season.[29] Pandemic influenza has the potential to cause even greater disease burden and stress on medical care systems. For instance, in 2009, one study found that mechanical ventilation was required by 72% of patients admitted to intensive care units (ICUs), and extracorporeal membrane oxygenation was used for 7% in one series.[82] The high attack rates during that pandemic also prompted school and workplace closures in many areas.

Influenza-associated severe disease cases (such as those leading to hospitalization or death) are usually not confirmed using influenza-specific laboratory tests because of low testing rates or because a person presents for care late in the course of illness, when testing may be less sensitive. As a result, influenza-associated mortality and hospitalizations are usually estimated using models. The most commonly employed models estimate "excess" events, where the number of influenza-related deaths or hospitalizations is calculated by subtracting the number of deaths that would be expected in the absence of influenza (i.e., the "baseline") from the total number of deaths that occurred during an influenza epidemic from the same time period.[72,92,289,290]

Using these methods, in the United States during 1976–2007, the estimated annual number of excess deaths resulting from circulatory or respiratory causes and associated with influenza varied from 3300 deaths to 48,000 deaths.[24] Estimates of the number of deaths using a variety of methods have been similar.[291] Increases in the annual estimated number of deaths caused by influenza since the 1970s have been attributed to the disproportionate growth in the population 65 years of age or older, who account for 90% of deaths caused by influenza. For many of these deaths, influenza is the catalyst of complications resulting from other underlying diseases and might not be recognized as an important cofactor.[21,72] The estimated annual number of deaths related to influenza is typically higher in years where influenza A(H3N2) viruses predominate.[24,289] In the United States, the average annual number of hospitalizations during 1979–2001 that were associated with influenza has been estimated at 226,000 (range: 55,000 to 431,000).[22]

Recently, U.S. estimates of hospitalizations (and outpatient visits) have been calculated using a model in which rates of influenza-confirmed hospitalizations collected from hospital-based active surveillance systems are extrapolated to national figures and then used to estimate less-severe outcomes based on known multipliers. Data from 2005–13 have also estimated substantial numbers of cases and healthcare visits associated with influenza, often estimating higher disease burden than models based on calculation of excess events from non-laboratory confirmed outcomes.[26] According to this model, the United States experienced approximately 400,000 hospitalizations, 14.6 million healthcare visits, and 35 million cases of influenza in the 2013–14 season.[27]

PASSIVE IMMUNIZATION

Passive immunization consists of transfer of ready-made antibodies in serum from an immunized or infected and recovered individual to a naïve individual to protect and/or treat against the disease. During the 19th century, either hyperimmune or convalescent homologous or heterologous polyclonal sera were successfully used both prophylactically and therapeutically against several infectious diseases, including, rabies, tetanus, diphtheria, and influenza, before the advent of antibiotics and antivirals.[292] During the 1918 influenza pandemic, convalescent human serum transfer reduced absolute risk for death in patients from 26% to 8%, if administered within 4 days of the onset of symptoms. However, delayed treatment had a reduced effect on the favorable outcomes.[293] After the identification of the causative agent, in their landmark study Francis and Magill demonstrated that transfer of sera from either influenza virus-infected ferrets and mice or virus-immunized rabbits into naïve mice protected the naïve mice against homologous viral challenge, thus setting the stage for a series of animal studies as well as medical intervention strategies against epidemic influenza.[294] Administration of equine hyperimmune serum or human serum in the respiratory tract for influenza prophylaxis in children or adults reduced influenza-related complications during an epidemic. In addition, passive immunization of sera in patients diagnosed with influenza reduced not only the severity but also the duration of disease.[295]

Despite the demonstrated clinical utility of passive immunization for prophylaxis and treatment against influenza from earlier studies, this approach did not receive much attention because of safety issues associated with the use of human convalescent sera and hyperimmune sera generated in heterologous species. However, an impending avian influenza pandemic and technological advances in generating monoclonal antibodies and polyclonal sera using a variety of approaches along with elucidation of the structural details of HA, reinvigorated interest in exploring passive immunization strategies against pandemic and epidemic influenza.[296–302]

Administration of human or humanized monoclonal antibodies or polyclonal sera against HA or conserved extracellular M2e protected animals against lethal challenge and reduced viral replication. These antibodies vary in their ability to confer protection when given 24 to 72 hours prior to and up to 72 hours postchallenge. Furthermore, intranasal administration is more effective and dose sparing when compared to other routes and a cocktail of monoclonal antibodies is superior and prevents the generation of escape mutants rather than using a single monoclonal antibody.[303–314] Antibodies against the highly conserved stem region of the HA protein have been shown to be broadly neutralizing and/or protective across HA

subtypes as well as within the subtype by inhibiting the fusion of virus and through the function of antibody dependent cell-mediated cytotoxicity function, by lysing virus-infected cells via Fc receptor–expressing macrophages and/or natural killer cells. In contrast, antibodies that are specific to the receptor binding site of the globular domain of the HA inhibit a narrow range of virus subtypes.[145,315–317] Apart from these animal studies exploring the potential utility of passive immunization, a recent case report demonstrated the clinical utility of passive immunization by administrating convalescent plasma from a patient recovered from H5N1 infection to an H5N1 infected individual which resulted in reduced viral load by 10-fold within the first 8 hours of administration and to undetectable levels within 32 hours leading to the patient's recovery.[318]

ACTIVE IMMUNIZATION

History of Vaccine Development and Current Non-Live Vaccines

Efforts to develop influenza virus vaccines began soon after influenza A and influenza B viruses were recognized as the etiologic agents of clinical influenza.[5,319–323] The first commercial vaccines were approved for use in the United States in 1945, based on efficacy studies performed in military recruits and college students using whole-virus inactivated influenza vaccines.[324,325] An influenza vaccine was of particular interest to the U.S. military during World War II, in part because of the devastation caused in both military and civilian populations by the 1918–19 influenza pandemic during the late stages of World War I. The ability to grow large quantities of influenza viruses in eggs, elucidation of the physical properties of the viruses, and development of the principles of chemical inactivation made it possible to prepare millions of vaccine doses.[326]

The processes used to make the current commercially available inactivated influenza virus vaccines share certain key features. All the influenza viruses are replicated individually in substrates of animal origin and are harvested in liquid form. The majority of influenza vaccine viruses are replicated in the allantoic cavities of embryonated hens' eggs, but vaccines for commercial use also are now being produced using mammalian cell lines (MDCK [Madin-Darby canine kidney] or Vero).[327–331] For preparation of the monovalent intermediate vaccines, the harvested influenza viruses are inactivated by controlled treatment using either formalin or β-propiolactone, and several purification steps reduce nonviral proteins and other materials introduced during the manufacturing process. The monovalent vaccines are combined to formulate the final multi-valent bulk vaccines, which then are filled into containers.

Although whole-virus vaccines are still in use in some countries and are highly effective, most vaccines manufactured since the 1970s have been subvirion (sometimes referred to as "split") preparations. These vaccines retain the immunogenic properties of the viral proteins but are associated with greatly reduced reactogenicity.[332–335] Subvirion vaccines are prepared by using a solvent (such as ether or a detergent) to dissolve or disrupt the viral lipid envelope. Additional purification steps can be taken to reduce the amounts of viral proteins (predominantly influenza matrix protein and NP), resulting in vaccines referred to as subunit or purified surface antigen preparations. It is also possible to produce purified influenza virus HA and NA vaccines using recombinant DNA technology,[336–339] and one vaccine is currently licensed using this technology.[340,341]

The original inactivated whole-virus influenza vaccines were crude preparations, and the purity of influenza virus vaccines has steadily increased,[328] aided by the introduction of centrifugation and chromatographic steps to reduce residual egg materials. Because dissolution of the lipid envelope allows retention of immunogenicity with reduction in reactogenicity, "splitting" influenza viruses to produce subvirion preparations has become routine. An intact viral membrane is essential for infectivity of enveloped viruses. Therefore, disruption of the viral envelope adds assurance of viral inactivation. Subvirion vaccines were first prepared using ethyl ether and polysorbate 80, but a variety of detergents, including deoxycholate, tri-*N*-butyl phosphate, Triton X-100, Triton N101, and cetyltrimethylammonium bromide, are now used for commercial vaccine preparation.

The development of "high-growth" influenza A viruses suited to maximal replication in eggs has helped increase vaccine production. Since the early 1970s, influenza virus A/Puerto Rico/8/34 (PR8), a strain very well adapted to replication in eggs, has been used to develop influenza A virus reassortants that combine the HA and NA from wild-type viruses with the high growth properties of the PR8 donor virus.[342,343] Influenza A virus reassortants derived from PR8 often are more uniformly spherical than wild-type viruses,[343] which may facilitate recovery of virus during the various process steps. The growth characteristics of reassortants vary because the HA and NA also affect the adaptation and replication capabilities of the viruses in growth substrates. The overall advantage provided by strains that replicate well in eggs has meant that most, if not all, influenza vaccines prepared in eggs over the last 35 years have been prepared using a "high growth" influenza A virus reassortant. An area of continuing investigation is development of reliable high-growth donor strains of influenza B viruses suited to vaccine production.

Vaccine Constituents, Including Antibiotics and Preservatives

Hemagglutinin is the main immunogen in inactivated influenza vaccines (and the only immunogen in the licensed recombinant vaccine[344]), and its level (i.e., potency) is standardized by single radial immunodiffusion (SRID).[345–347] Although inactivated influenza vaccines contain NA, M, and NP in varying amounts, depending on the process methods, their levels are not specifically quantified. Antibody to NA can add to the protective effect of vaccines, as increased levels of anti-HA and NA antibody in serum and secretions correlated with reducing pH1N1 influenza virus infection and illness in healthy young adults during 2009 pandemic.[348] Furthermore, anti-NA and anti-HA antibodies are found to be independent predictors of immunity to influenza infection.[349] The immune responses to other viral proteins (e.g., M2)[350] are being investigated, but their relative contributions to protection appear much less than the effects of antibodies directed against HAs. Therefore, HA content continues to be the primary concern in preparing inactivated vaccines.

The amount of HA, as measured by SRID, has been correlated with the immunogenicity of subvirion and whole-virion inactivated influenza virus vaccines.[333,334,351] To test commercially prepared influenza vaccines, most authorities favor SRID performed with influenza strain-specific antigens and antisera because other methods have correlated less well with immunogenicity. Because SRID requires strain-specific HA antigen and antibodies, using SRID as a necessary step in the regulatory approval process and is time-consuming. Other methods, such as mass spectrometry,[352] enzyme-linked immunoassays,[353] and chromatography,[354] have been investigated to

speed up this process. Accelerating vaccine production timelines is a key goal in pandemic preparedness plans.

Antibiotics are not added to inactivated influenza virus vaccines as active ingredients. Aminoglycoside antibiotics are used in some production schemes to reduce bacterial growth in eggs during processing steps. Antimicrobial agents associated with anaphylactic-type hypersensitivity responses are strongly discouraged for use at any phase of production. Antibiotics that are used in the production process are reduced to trace or undetectable amounts during purification of the viral proteins and dilution of the concentrated vaccine components during formulation of the final multivalent vaccine. Minimal amounts of the detergents or solvents used for virus disruption may remain in the final vaccine preparation, but purification and dilution steps often reduce the amount to the limits of detection.

Thimerosal, an organic mercury-containing compound with broad, highly effective antimicrobial properties, is present in inactivated influenza virus vaccines produced for multidose presentation. Thimerosal is used to reduce bioburden (the total amount of bacteria and fungi) during production of influenza vaccines in eggs and/or as a preservative to prevent growth of bacteria and fungi. Although vaccines in single-dose containers are formulated to contain no thimerosal or in amounts too low to have a preservative effect (such vaccines may be called "preservative free"), multidose containers are designed to be entered several times, which raises the possibility of introduction and growth of bacteria or fungi.[355] Alternative preservatives such as 2-phenoxyethanol and phenol have been used in other vaccines, and are being evaluated as part of a continuing trend to limit the amount of mercury present in vaccines of all kinds, but have not been found to be an ideal replacement for thimerosal.[356,357]

Either formalin or β-propiolactone is used in influenza vaccine to inactivate the viruses. If processed properly, β-propiolactone is chemically degraded to levels below the limits of detection.[358] Although detectable quantities of formaldehyde persist in inactivated vaccines when formalin is used, the steps used for purification also reduce the amount of free formaldehyde, which, if it remains in high concentration, can reduce the potency of vaccines or interfere with SRID measurements of potency.[359–362]

Adjuvants, which are substances that are intended to augment immune responses to vaccine antigens, have been used with seasonal, pandemic, and avian influenza vaccines. One seasonal influenza vaccine containing an oil-in-water adjuvant (MF59) has been approved for use in persons age 65 years and older in the United States.[355,362a] In addition, an avian influenza A(H5N1) vaccine was approved by the U.S. Food and Drug Administration (FDA) in 2012 that contains AS03 as an adjuvant (AS03 is an oil-in-water emulsion).[363] Influenza vaccines that contain AS03 and MF59 as well as other adjuvants (virosomes and aluminum phosphate), are approved for use in some European countries and Canada.[364] Additionally, some governments have stockpiled adjuvants (such as AS03 and MF59) for use with possible pandemic vaccines against avian influenza viruses to augment immune responses when given to a naïve human population. Adjuvanted vaccines are of particular interest for use in populations that may respond less well to unadjuvanted inactivated vaccines, such as elderly persons and young children. They were used widely in many countries during the H1N1 pandemic.[253]

Because most inactivated influenza vaccines are produced with egg-grown viruses, traces of egg proteins are present in final vaccine formulations, generally measured as ovalbumin content.[355] Because cell-culture vaccines also use egg-grown seed strains, they also may contain traces of egg protein, but concentrations are expected to be exceedingly low. Because recombinant antigen vaccines are produced without eggs, they do not contain egg proteins.[365]

Manufacture of Vaccine

The requirements of national authorities for influenza vaccines generally reflect the guidelines published by the World Health Organization (WHO),[366] but may include items that are specific to individual control authorities. To expedite and standardize clinical studies that are intended to support licensure of new influenza vaccines, both the U.S. FDA and the European Medicines Agency (EMA) have developed guidelines for industry.[367–369] Recommendations for the antigenic composition of influenza vaccines are made by WHO semiannually (once for the Northern hemisphere formulation and once for the Southern hemisphere formulation) to ensure that current influenza vaccines are effective against recently circulating strains in both the Northern and Southern hemispheres.[370,371] Data for these decisions are created through WHO's Global Influenza Surveillance Response System (GISRS). GISRS is a network of surveillance systems and laboratories in more than 120 countries that send data to WHO and share specimens and isolates with five WHO Collaborating Laboratories that provide antigenic and genetic characterization of viruses for use in determining optimal vaccine strains.[371,372] The surveillance system monitors for antigenic and genetic changes in circulating influenza viruses. Surveillance has made it clear that antigenic changes occur not only by point mutations (antigenic drift), but also by way of antigenic shift (at irregular and unpredictable intervals). National regulatory authorities then make national recommendations for influenza vaccine composition, generally based on the WHO recommendations.

Influenza vaccine viruses usually are isolates obtained through GISRS. The WHO and various national authorities recommend use of certain strains based primarily on the antigenic characteristics of their HAs and NAs. Except for recombinant protein vaccines, original isolates are passaged in eggs or primary chick kidney cultures to develop reference strains that are distributed to manufacturers to develop seed viruses. Often the original wild-type strains grow relatively poorly in eggs, so considerable effort is expended examining several antigenically similar strains for several qualities needed to maximize virus yield during large-scale production, including their potential for development of high-growth reassortants, their growth characteristics, and their optimal incubation conditions. Because the available production time for multivalent influenza vaccine is limited by the need to distribute vaccine each autumn, the total amount of vaccine that can be produced is limited by the least-productive strain.[370]

Because most influenza surveillance laboratories are not prepared to handle tissue cultures in a way necessary to prevent introduction of extraneous agents, a concern is that the possible introduction and amplification of extraneous agents during subsequent passages could compromise the safety of vaccines.[373] However, replication of influenza viruses in eggs might provide a partial barrier to extraneous agents that might originate in the clinical source material. Interest in producing vaccines in mammalian cell systems stems from concern that the availability of eggs could be reduced by an event requiring destruction of the egg-producing hens (e.g., an outbreak of avian influenza or Newcastle disease virus), and also from concern that the HAs of viruses grown in eggs may exhibit antigenic alterations.[374–377] Therefore, strategies are being developed to directly isolate influenza viruses in mammalian tissue culture to provide suitable starting seed viruses.

Regardless of the growth substrate used, the prevention of the introduction of extraneous agents is paramount. When

using hen eggs, the main concern is the introduction of extraneous agents, such as avian leucosis virus, that originate in the flocks of chickens providing the eggs. However, extraneous agents could be introduced from the original human host to mammalian tissue cultures, from the tissue cultures used by the laboratory recovering the influenza virus, from the cell substrate used for manufacturing, or from materials used to support the growth of the cell substrate.[378–381] For inactivated vaccines produced either in eggs or mammalian tissue cultures, these concerns are reduced provided that the process used to inactivate influenza viruses will inactivate other microorganisms effectively.

After replication of influenza viruses, a number of manufacturing steps are taken to increase the concentration of the active immunizing ingredients of the vaccines (mainly the viral HAs) and to reduce other (mainly nonviral) materials. For inactivated influenza virus vaccines produced using eggs or mammalian tissue cultures, removal and reduction of egg or tissue culture proteins occurs throughout the manufacturing process, beginning with concentration of virus by means of centrifugation through a sucrose gradient or passage of the virus-containing allantoic fluid over a chromatographic column. The resulting fluids may be additionally purified by dialysis or diafiltration, and the concentration of residual egg or cell proteins is reduced further during the final formulation when the HA concentration is adjusted to achieve final target levels.

Disruption of the lipid envelope permits further purification of the viral proteins and, in particular, the HAs and NAs. These proteins form rosette-like structures in which the hydrophilic heads of the proteins are on the exterior and the hydrophobic tail portions of the molecules are buried internally. The disruption process varies in efficiency, so that HA and NA still can be attached to lipid but in pieces smaller than the original virion. Dissolution of the viral envelope and removal of additional viral components results in vaccine products with reduced reactogenicity.[332–335,382–384]

Chemical inactivation steps are used to minimize the microbial load in the raw viral harvest from the growth substrate, and careful handling and use of component reagents and buffers also facilitate inactivated vaccine sterility. However, filtration steps ensure elimination of undesirable microbes. Although the sterile filtration step does not eliminate endotoxins, which may have been formed previously by bacteria in the product, some of the purification steps can help reduce endotoxin levels.[383] Because endotoxins contribute to febrile responses to injected vaccines, the limits for endotoxin levels on finished product are set well below clinically established thresholds for reactions.[384]

A recombinant HA vaccine is available that is produced in a continuous insect cell line in which genes encoding HA proteins for each of the vaccine strains to be included in the vaccine are inserted into a baculovirus vector, which leads to expression of the HA proteins.[341] Purification steps for this vaccine are similar to egg and cell-based vaccines. Because no eggs are used in the production of this vaccine, no traces of egg antigens are present in the final product.

Producers

Several manufacturers produce inactivated influenza vaccines either for global distribution or for national demand. Each manufacturer has a somewhat different, proprietary process, but all the processes result in vaccines standardized to ensure the immunogenicity of the HA. Global supply of inactivated influenza vaccines has increased significantly in the last decade as demand has increased, in part as a byproduct of pandemic preparedness efforts that have highlighted the burden of seasonal influenza and the value of developing seasonal vaccination programs as a foundation for pandemic response.[16,386,387] As an example, annual inactivated influenza vaccine distribution in the United States increased substantially in the last two decades, with the expansion of target groups during that time. In 2014–15, more than 147 million doses were distributed in the United States.[388] WHO estimated that the world's manufacturing capacity increased from 500 million doses of trivalent vaccine in 2006 to 1 billion doses by 2010.[389] While most vaccines are produced by multinational manufacturers, WHO's Global Action Plan has catalyzed growth of manufacturing capacity in Asia, Eastern Europe, Latin America, and Africa, which holds the promise of increasing global supply and lowering vaccine prices in the future.[387] Even so, more than 80% of seasonal influenza vaccine doses produced in 2009–10 originated from seven large manufacturers that are located in the United States, Canada, Australia, Western Europe, Russia, China, and Japan. Sufficient supply during a pandemic and for newly emerging markets will require greater production capacity with likely growth in emerging suppliers.[390] Information on influenza vaccine manufacturers available by country can be obtained from national regulatory agencies.

Preparations Available

All vaccines mentioned in this chapter are inactivated vaccines produced from influenza viruses grown in eggs or cell culture,[355] with one exception (Table 31.1). A vaccine that contains HA protein recombinantly expressed in baculovirus-infected insect cells was licensed in the United States in 2013.[341] Because this vaccine does not have a production step that includes live virus, there is no inactivation step required. This type of vaccine is included in this chapter. While most approved vaccines are manufactured using embryonated eggs, cell culture vaccines are available in the United States and Europe.[364] Development of vaccines produced in cell culture has been promoted in part for pandemic preparedness, both as a tool to meet increased vaccine demand during a pandemic and as a hedge against the possibility that a pandemic strain derived from avian viruses might endanger birds used to produce the eggs for production.[386]

Monovalent, bivalent, trivalent, quadrivalent, and even pentavalent influenza vaccines have been produced. Multivalent vaccines have generally included both influenza A and influenza B virus components. In recent years, monovalent vaccines have been used only in unusual circumstances to provide protection against a circulating strain substantially antigenically different from those used in the seasonal vaccine formulation. Examples include the creation and distribution of a supplemental A/Taiwan/21/86 (H1N1) vaccine in 1986[260,391] and, more recently the development of the monovalent H1N1 pandemic in 2009.[392] Since 1978, most vaccines have been trivalent and have incorporated influenza A(H1N1) and A(H3N2) subtype viruses and an influenza B virus. During the 1990s, influenza B viruses diverged into two antigenically distinct lineages based on the HA.[393] This led to the development of quadrivalent vaccines that incorporate two B strains (one from each lineage)[394]; quadrivalent vaccines have occupied an increasing proportion of the global market since their introduction and likely will continue to become more common.[395]

Inactivated vaccines can be categorized based on their production methods into three types: whole cell (virions), subvirion (or "split virus"), and purified subunit vaccines.[396] Whole-cell vaccines have become less common because of relatively high rates of local reactions and fevers associated with them.[335,382,397] For subvirion vaccine, the viruses are

TABLE 31.1 Approved Influenza Vaccines in the United States, 2016–17 Influenza Season[a]

Trade Name	Manufacturer	Presentation	Age Indications	Route	HA/Antigen/ Dose (μg)

ID, intradermal; IIV3, trivalent inactivated vaccine; IIV4, quadrivalent inactivated vaccine; IM, intramuscular; IN, intranasal; MDV, multidose vial; RIV3, trivalent recombinant vaccine; SD PFS, single-dose prefilled syringe; SDV, single-dose vial.
Modified from Grohskopf LA, Sokolow LZ, Olsen SJ, et al. Prevention and control of influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices, United States, 2015–16 influenza season. MMWR Morb Mortal Wkly Rep. *2015;64:818–825.*

treated with a solvent that disrupts the lipid envelope while retaining the immunogenic potential of the viral proteins. They are less reactogenic compared with whole cell preparations.[332–335,383,384,397] Subunit vaccines are further purified to reduce the amount of non-HA protein, such as structural proteins.[396]

Adjuvants

While most approved inactivated influenza vaccines (IIVs) are nonadjuvanted, some products contain adjuvants designed to improve the immunogenicity of the vaccine, either in terms of magnitude or breadth of immune response.[364,398] The components of influenza viruses themselves (including possibly the lipid envelope) play a role in producing reactions.[384] Because whole-virus preparations already include cellular lipids in the viral envelope, their increased immunogenicity in some studies may relate to an adjuvant effect of the lipid envelope. Adjuvanted products are generally targeted to populations that might respond suboptimally to standard vaccines, such as in the case of pandemic vaccines given to an immunologically naïve population or vaccines targeted to the elderly or very young children.[399] Adjuvanted vaccines have been used or investigated for decades,[400] and a wide variety of adjuvants have been tested.[364,401–416] While most adjuvants have combined a lipid or fatty acid with a bacterial cell wall or bacterial protein, other materials such as chitosan, polyinositol, aluminum, and cytokines also have been tried. Three types of adjuvants have been approved in some countries in seasonal or 2009 H1N1 pandemic vaccines: oil-in-water emulsions, aluminium phosphate, and virosomes.[364] Two proprietary oil-in-water emulsions, AS03 and MF59, are incorporated into licensed vaccines; AS03 is approved for use in a pandemic H1N1 vaccine and an H5N1 vaccine (for pandemic use), while MF59 is contained in seasonal and pandemic vaccines.[328] Two vaccines use immunopotentiating, reconstituted influenza virosomes.[417] One whole-cell vaccine that uses alum is approved in Hungary for seasonal use.[364,418]

Generally, adjuvants improve vaccine responses but may increase reactogenicity. Increased rates of local reactions, including pain at the injection site, tenderness, and erythema, have been noted in some clinical trials.[419] Elderly recipients of an MF59 adjuvanted influenza vaccine developed geometric mean HI antibody titers that were 1.5 to two times higher against each of the three influenza vaccine components than those of recipients of standard subunit vaccine without

adjuvant.[406,420] In addition, fourfold titer rises were also increased, and there was evidence of broader serological protection against drifted strains that circulated 1 and 2 years after vaccination.[406,410,419,421–424] Adjuvanted vaccines were used in many countries during the 2009 H1N1 pandemic,[253,425] and immunogenicity data indicated that adjuvanted 2009 H1N1 vaccines produced high antibody titers after a single dose.[425–431] Studies using experimental vaccines made with influenza A virus subtypes including H5 and H9 have also demonstrated that higher immune responses were obtained with the vaccine containing MF59 or AS03 as an adjuvant.[413,432–435] However, some experiences suggest that responses of the immunologically naïve may not always be improved by incorporation of an adjuvant in influenza vaccines,[436] particularly an aluminum-based adjuvant system.[435,437] Systems other than the classical adjuvant method are being pursued as means to increase the immunogenicity and possibly effectiveness of IIVs. Several systems being explored combine a number of influenza viral proteins (virus-like particles [VLPs], which contain HA in combination with M or NP) or incorporate viral proteins in presentation systems with other agents or compounds to evoke strong cellular and humoral immune responses (such as inducers of innate immune responses).[438–441]

For the virosome vaccines, influenza virus is inactivated, followed by extraction of the HA and NA proteins which are then associated with lecithin to produce a conformation in which the influenza glycoproteins are exposed in a lipid particle. The vaccine produced comparable or modestly higher immune response compared with inactivated vaccines among elderly persons.[403,442,443] A small study in children with cystic fibrosis suggested that the virosome vaccine might be more immunogenic than subunit vaccine after one dose, but the differences were not striking[416]; immune responses were not superior to unadjuvanted vaccine in a small group of elderly subjects. No clinical efficacy studies comparing standard IIVs with adjuvanted vaccines have been published.

Timeline for Influenza Vaccine Production

Production of influenza virus vaccines follows a similar schedule each year, reflecting the need to produce and administer vaccine before each influenza season (Fig. 31.5). The foundation for influenza vaccine production is global influenza virus surveillance that continues throughout the year in both hemispheres. Information from global surveillance is used to inform manufacturers about trends in antigenic changes in influenza viruses, particularly trends that might signify the need to make changes in vaccine composition. Strains showing antigenic changes are examined and when warranted, high-growth reassortant viruses are produced.

Because several months are required for production of annual influenza virus vaccines, the time allotted for collecting and assessing surveillance data to ensure the best possible recommendations for vaccine composition must be balanced against the time needed by manufacturers to produce all components of the vaccine. If recommendations are made too early, significant antigenic changes may be missed. However, if recommendations are made too late, the total vaccine output can be hampered. In addition to collecting and analyzing viral surveillance data, time is needed to allow experience to be gained handling the vaccine candidate strains and to produce the reagents needed to standardize the new vaccine component viruses.

Manufacturing of monovalent vaccine components begins as early as possible and continues until sufficient material is available to produce the manufacturer's final targeted number of doses. The potency of monovalent vaccine components must be known before formulation of the multivalent vaccines can begin. Currently, the potency of monovalent components and trivalent or quadrivalent vaccine is established using SRID.[346,347] This technique requires both a HA-specific antigen and a HA-specific antiserum. The antiserum is produced by immunizing animals with preparations of purified HA and takes at least 3 to 6 weeks.

Once the potency of all three components can be determined, formulation of the trivalent vaccine begins, followed by its filling into containers, labeling, packaging, and distribution. Despite increases in vaccine production and distribution of multimillions of doses, all manufacturing steps must be completed within 6 to 8 months because administration of vaccine typically begins and largely is completed during October to December in the Northern hemisphere and during April to July in the Southern hemisphere. The time needed for production of a monovalent vaccine against a new pandemic strain would require approximately 4 to 6 months from identification of a candidate vaccine virus to the time when the first vaccine doses would be available. During the 2009 H1N1 pandemic, these timelines were shown to be approximately correct. However, widespread availability of the 2009 pandemic H1N1 monovalent vaccine lagged well behind the peak pandemic wave, again illustrating the urgent need to more rapidly identify candidate viruses for vaccine production,

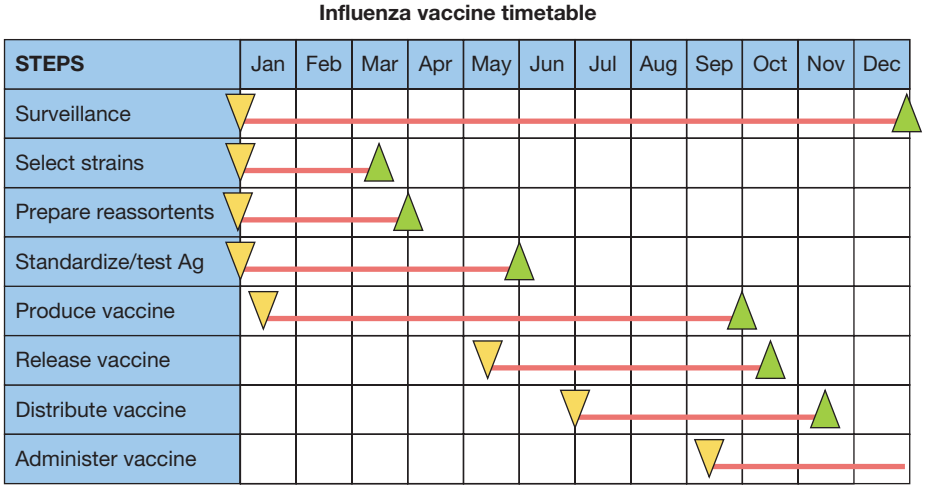

Figure 31.5. Approximate production timetable for influenza vaccines manufactured for the Northern Hemisphere. Southern Hemisphere vaccine production timetable would start in approximately October of each year. Ag, antigen.

develop vaccine virus candidates, and scale up production of a safe and immunogenic vaccine.[390]

Dosage and Route

IIVs have been given by intramuscular, subcutaneous, intradermal, intranasal, and oral routes. Most licensed unadjuvanted IIVs given by intramuscular injection contain 15 µg of each HA antigen per dose (45 µg of total antigen per dose for trivalent vaccines and 60 µg of total antigen per dose for quadrivalent vaccines; based on the SRID content).[355] For children 6 months to 35 months of age, vaccines are produced with 7.5 µg of each HA, which are intended to be provided in a two-dose schedule to ensure adequate immune responses in this naïve population.[355] The IIV dosages are based on extensive clinical studies undertaken when influenza A(H1N1) viruses were reestablished in human populations during the late 1970s.[333,334,382] These studies demonstrated that children and adults who were unexposed to influenza through vaccine or natural infection required two doses of inactivated vaccine to achieve maximal antibody titers, whereas persons with some degree of preexisting immunity needed only a single dose. Subsequent studies conducted with more contemporary vaccines confirmed the need for two doses in previously unvaccinated children younger than 9 years of age to optimize the immune response and vaccine effectiveness.[444–447] The quantity of antigen in each dose is chosen by balancing the desirability of inducing a maximum immune response in an individual (a higher dose increases the probability of achieving a maximum antibody titer) against the desirability of maximizing population coverage (a smaller dose will allow more individuals to be immunized, which might induce some degree of herd immunity) and the desirability of minimizing adverse reactions (a larger dose has a greater probability of causing immediate local and systemic reactions).

Vaccine formulations with higher and lower HA antigen contents are available, often targeted to specific populations. In 2009, a trivalent high-dose vaccine was licensed for use in persons 65 years of age and older. The vaccine contains 60 µg of HA antigen for each vaccine strain, for a total of 180 µg of antigen per dose, based on studies of dose responses in elderly persons that suggested that increased doses of modern subvirion vaccines can increase antibody responses without substantially increasing reactogenicity.[201,448–450] One large clinical trial demonstrated superior efficacy of high-dose vaccine compared with standard-dose vaccine among persons 65 years of age or older.[451,452] In this study, the rate of laboratory-confirmed influenza was 1.9% among persons who received standard-dose vaccine, compared with 1.4% of persons who received the high-dose formulation (a relative efficacy of 24.2%). A similar level of increased relative effectiveness against influenza-associated hospitalizations was observed in a large observational study of national electronic medical claims data[453]; however, a superior effectiveness was only found among persons older than 85 years of age in a large study in a Veterans Administration study.[454] A recombinant antigen vaccine is available that contains 45 µg of total antigen per dose (135 µg of total antigen per dose), and is approved for adults older than 18 years of age based on studies demonstrating comparable immunogenicity and efficacy to standard-dose vaccines.[452,455,456] Lower antigen content is available in intradermally administered preparations (e.g., 9 µg of total antigen per dose) using a prefilled microinjection devices, in which they have been found to provide immune responses comparable to standard dose vaccines, but an increased rate of local reactions.[202,203,457–462] The varying antigen contents of products are designed to produce adequate immune responses and protection (or superior protection in the case of high-dose inactivated vaccine), while minimizing reactogenicity. Although formulations with varying antigen contents are available, most countries do not express a preference for any product over another, as long as the product is appropriate for the person vaccinated (e.g., approved for the age of the person). As vaccine availability increases globally, further studies may be warranted to determine whether vaccine effectiveness can be improved simply by increasing the amount of HA in vaccines given to other specific populations that respond poorly to standard dose vaccine, such as HIV-infected persons.[463]

While IIVs are generally administered using single-use sterile needle and syringes, vaccines have been administered transdermally through jet injector devices, and one such formulation was approved by FDA in 2014.[204,355] The device is a reusable spring-powered device that injects the vaccine through a single-use sterile syringe into the deltoid muscle. In prelicensure evaluation, subjects who were vaccinated using the jet injector had higher rates of injection-site adverse events (tenderness, swelling, pain, and redness), but had noninferior immune responses compared with those vaccinated using needle and syringe.[204]

The intranasal administration of IIV has not been studied as extensively as other routes of delivery. A commercially available nasally administered formulation was withdrawn because of its association with cranial nerve palsies.[442] The ability of oral administration to induce protective antibody responses has been studied for several decades. Recent studies demonstrate adequate immune responses and safety, but this route often requires very large doses or an adjuvant to promote mucosal and systemic immune responses.[464–466]

Vaccine Stability

Vaccine manufacturers in the United States and elsewhere have ongoing programs to assess the stability of all vaccine products. Stability of a product is influenced by the specific formulation of the product, the addition of stabilizing compounds (such as gelatin or polysorbate), the compatibility of the product with the intended container and closure and the preparative treatments needed to reduce adsorption or chemical interaction of the vaccine components with the container, and the vaccine's specific temperature limits. Stability assessment programs usually also examine sterility, pH, and the measurable content of preservatives and other chemical ingredients.

Experience indicates that IIVs are generally sufficiently robust to maintain full potency above the minimum release specifications for more than 1 year, when stored at 4°C to 8. However, the potency of individual influenza virus vaccine components can decline at varying rates. For example, in 1996, the influenza A(H3N2) component (but not the influenza A[H1N1] or influenza B components) in the vaccine from one manufacturer lost potency faster than expected[467]; accelerated potency loss was noted in several vaccine products during the 2009 H1N1 pandemic,[468] and in 2015, vaccine components from two companies fell below potency thresholds before the end of the influenza season.

IMMUNE RESPONSE TO VACCINATION AND CORRELATES OF PROTECTION

Measurement of Antibodies

Influenza vaccination induces primarily antibodies against the major surface glycoproteins, the HA and NA, although in some cases, antibody to the NP and M1 proteins may also be induced owing to the presence of those components in some of the vaccines.[469] While the HI and neutralization tests both

measure levels of strain-specific antibodies, the HI test[180] is most commonly used for measuring the antibody response to human IIVs. In the HI test, antibodies present in an immune serum compete with red blood cells to bind the viral HA. In the absence of antibodies, the viruses agglutinate the red blood cells. Red blood cells from chickens or turkeys are used most often; however, guinea pig or human erythrocytes can be substituted in circumstances where avian red blood cells do not bind well to the influenza viruses in question. The HI assay can be complicated by nonspecific inhibitors of hemagglutination in human and animal serum. The inhibitors can be removed by pretreating serum with receptor-destroying enzyme from *Vibrio cholerae* or with periodate. An HI titer of 40 represents a 50% protection rate against influenza viral infection in a population and is used as a gold standard as a seroprotective titer.[470]

The neutralization test is an alternative method for the detection of strain-specific antibodies to influenza viruses and in some cases may be more sensitive than the HI test and has the added advantage of measuring functional antibody capable of preventing virus infection. Neutralization-enzyme immunoassay tests, or the microneutralization assay, measure neutralizing antibodies in small quantities of serum.[471,472] When detecting serum antibody responses to human influenza strains, titers of neutralizing antibody measured using this method correlate well with titers obtained by HI.[472] The seroprotective HI titer of 1:40 corresponds to an MN titer of approximately 1:160.[473] In addition, neutralizing antibodies may be present when there are low or undetectable levels of HI antibodies. For example, HI antibodies bind to the globular head of the HA. But influenza viruses can also be neutralized with antibodies directed against the HA stem, which would not be detected with an HI assay.[474]

The neutralization or microneutralization assay is preferred when detecting antibody responses to avian influenza viruses, as the traditional HI test using avian RBC is not sufficiently sensitive.[475] A modified HI assay that uses horse RBC, which express a predominance of SA $\alpha_{2,3}$ receptors to which most avian influenza viruses preferentially bind may also be used as an alternate or confirmatory assay for the detection of antibodies against avian influenza virus HA.[476] Finally, enzyme immunoassays are typically performed to measure virus-specific immunoglobulin (Ig) G, IgM, or IgA antibodies in paired pre- and postvaccination serum or respiratory samples. Such immunoassays perform optimally when concentrated and/or purified preparations of viral antigen are used to detect antibodies and may correlate with neutralizing antibodies.[477]

Antibody Responses

The robustness of the serum antibody response to inactivated vaccines is dependent on age and preexisting antibody levels. Thomas Francis noted that individuals exposed sequentially to influenza virus variants with shared epitopes tend to generate antibody responses preferentially to the previously exposed virus and diminished responses to the current strain and termed this phenomenon as "original antigenic sin." [478] Original antigenic sin would potentially have a major negative impact on the immunogenicity of vaccines and vaccine efficacy when the vaccine strains are closely related to previous strains; however, in animal studies administering influenza vaccine with adjuvant overcomes original antigenic sin.[479] In previously primed individuals; the response is predominantly anti-HA IgG, but in young, unprimed children, systemic IgM antibody may be more evident.[480,481] In primed individuals, antibodies that are specific for the vaccine strain or cross-reactive with earlier, antigenically related strains can be detected using the HI assay. Numbers of influenza virus–specific antibody-secreting cells in peripheral blood peak approximately 1 week after vaccination, whereas serum antibody levels peak 2 to 4 weeks after vaccination in healthy, previously primed individuals, but may peak 4 weeks or later in unprimed individuals and the elderly.[480,482–485] The magnitude of antibody-secreting cells responses correlate with serum antibody responses and the expanded B-cell clones use specific immunoglobulin genes.[485] Furthermore, females tend to develop higher antibody titers and vaccine efficacy than males and the molecular basis for these differential responses are not known.[486] In children 9 years of age and younger, and in unprimed individuals, two doses of inactivated vaccine are required to induce an optimal serum antibody response.[444–447,487] IIVs delivered intramuscularly may also induce local influenza virus–specific IgA in oral and respiratory fluids, with responses being more substantial in individuals primed by natural infection.[483] In addition, besides inducing subtype-specific neutralizing antibodies, IIV3 also induces in some individuals broadly neutralizing antibodies that react against the stem region of HA.[311]

Multiple immunogenicity studies conducted with both unadjuvanted and adjuvanted 2009 H1N1 monovalent vaccines demonstrated excellent immunogenicity in healthy persons in all age groups.[427,428,431,488–492] However, adjuvanted but not unadjuvanted 2009 H1N1 vaccine overcame poor responses in individuals who received IIV3 seasonal vaccine earlier.[493] For children younger than 9 years old, immunogenicity of the H1N1 vaccines matched or exceeded what is typically seen with seasonal influenza vaccines. However, higher rates of seroconversion and higher postvaccination antibody levels were achieved in children younger than 11 years old who received either two doses of 15 μg of HA without adjuvant or one dose of 7.5 μg of HA with MF59 adjuvant.[427,491] Increasing the amount of influenza HA per vaccine dose above the currently recommended level of 15 μg generally results in a dose-related increase in serum antibody response, with only modest increases in the occurrence of injection site reactions.[487] In the elderly, increasing dosages of inactivated trivalent vaccine resulted in significantly higher and more frequent serum antibody responses and may offer one approach to enhancing the protective effect of inactivated vaccines in this high-risk population.[448–450] Multiple studies show that increasing the influenza HA fourfold (60 μg per strain) results in significantly higher anti-HA IgG, and one high-dose vaccine has been licensed in the United States for adults 65 years old and older.[11] High-dose vaccine enhanced geometric mean HI titers by 1.8-fold when compared to those from standard vaccine recipients in persons 65 years of age and older with a relative increase in clinical efficacy of 24.2%.[451] Studies are underway to determine whether higher titers predict better vaccine effectiveness. The monovalent 2009 H1N1 vaccines adjuvanted with oil-in-water emulsions or aluminium preparations elicited high HA titers using doses similar to, or two- to fourfold less, than doses used in unadjuvanted vaccines.[426,431,494] In addition, whole virion monovalent 2009 H1N1 vaccines were used in some countries with immunogenicity data demonstrating satisfactory antibody responses after a single dose in older children and adults.[428] In a randomized controlled trial comparing the immunogenicity of a whole virion 2009 H1N1 vaccine (7.5 μg HA) versus an AS03-adjuvanted vaccine (3.8 μg HA), the adjuvanted vaccine was more immunogenic based on antibody responses. On day 21 after one dose of adjuvanted AS03 or whole-virion vaccine, the percentage of persons who developed titers of 1:40 or greater decreased with age for both vaccines, ranging from 94% and 71%, respectively, for those 18 to 44 years of age to 51% and 32%, respectively, for those 65 years of age or older. On day 42 (21 days after the second dose), 100% and 73% of participants 18 to 44 years of age who received adjuvanted versus whole virion vaccine had HI titers of 1:40 or greater, respectively.

However, only 76% and 36% of vacinees who were 65 years of age or older had titers of 1 : 40 or greater to adjuvanted versus whole-virus inactivated vaccines, respectively.[494] Vaccine-induced antibody responses measured by HI or MN have have been found to be similar in pregnant women compared with nonpregnant women, and a recent study has found increased plasmoblasts in vaccinated pregnant women compared with controls.[494a,494b]

Among persons with chronic medical or immunocompromising conditions, serologic response rates are typically lower. IIV3 or pH1N1 vaccine produces adequate antibody concentrations against influenza among vaccinated HIV-infected persons who have no or minimal AIDS-related symptoms, including those who have successfully responded to highly active antiretroviral therapy.[495–499] Among persons who have advanced HIV disease and low $CD4^+$ T-lymphocyte cell counts, IIV3 or pH1N1 vaccine might not induce protective antibody titers[498,500]; a second dose of vaccine does not improve the immune response in these persons.[500–502] A randomized, placebo-controlled trial determined that IIV3 was highly effective in preventing symptomatic, laboratory-confirmed influenza virus infection among HIV-infected persons with a mean of 400 $CD4^+$ T-lymphocyte cells/mm^3; however, a limited number of persons with $CD4^+$ T-lymphocyte cell counts of less than 200 were included in that study.[501] A nonrandomized study of HIV-infected persons determined that influenza vaccination was most effective among persons with greater than 100 $CD4^+$ cells and among those with less than 30,000 viral copies of HIV type 1/mL.[105] Initial studies indicate that the response to 2009 H1N1 antigen is also reduced. For example, a study among HIV-infected persons on highly active antiretroviral therapy who received the 2009 H1N1 monovalent vaccine showed similar poor immunogenicity with an unadjuvanted vaccine,[503] improved immunogenicity with an adjuvanted vaccine (68% with postvaccination HI titers of ≥1 : 40) and excellent immunogenicity after two doses of an adjuvanted vaccine (92% with postvaccination HI titers of ≥1 : 40).[504] Furthermore, a two-dose regimen of adjuvanted pH1N1 vaccine not only induced seroprotective titers that persisted 12 months postvaccination, but also enhanced memory responses to subsequent vaccination with nonadjuvanted seasonal vaccine.[505]

Immunogenicity among persons who received solid-organ transplants, as measured by the proportion who developed seroprotective antibody levels (HI titers ≥40), varies according to transplant type and time since transplantation. Persons with kidney or lung transplants have responses that are similar to or moderately reduced compared to healthy persons; however those with heart or liver transplants respond poorly, especially if vaccination occurs within 4 months after the transplantation procedure.[506–510] Improved humoral immune responses are achieved in patients receiving either a high dose or a booster dose.[511,512] Alternate routes of administration such as intradermal route, booster doses of unadjuvanted or adjuvanted vaccines, or high-dose vaccines may help induce protective immune responses in immunocompromised populations. Furthermore, passive transfer of hyperimmune sera or a cocktail of monoclonal antibodies may help those individuals who do not respond to vaccination.

Cellular Immune Responses

$CD4^+$ and $CD8^+$ T cells also play an important role in immunity to influenza, and in contrast to the strain-specific response of antibodies, tend to be more cross-reactive among subtypes, recognizing more conserved epitopes on the surface proteins and/or internal viral proteins.[223] The ability to recognize a given T-cell epitope is dependent on the HLA (human leukocyte antigen) phenotype of an individual. $CD4^+$ T cells provide help for the antibody response and the induction of $CD8^+$ T cells, whereas $CD8^+$ cytotoxic T lymphocytes (CTLs) have been associated with accelerated clearance of virus and recovery from infection.[224,513] The CTL responses in humans who have received IIVs have not been studied as extensively as the humoral immune response. Immunization of healthy adults with inactivated whole-virus vaccine resulted in enhanced CTL responses in peripheral blood, whereas immunization with subunit vaccine resulted in a poor CTL response, unless the vaccine is formulated to facilitate cytoplasmic delivery of antigens for processing and presentation with class I major histocompatibility complex to induce CD8 T cells.[351,513–515] The duration of the response varied greatly among individuals, persisting for several months to 1 year. In one study, an oil-in-water emulsion adjuvant (AS03) appeared to induce increased numbers of antigen-specific memory B cells compared to unadjuvanted vaccine. Cross-reactive and polyfunctional H5N1-specific CD4 T cells to conserved sequences in HA protein of clade 2 H5N1 HA were identified after a single dose of adjuvanted vaccine and amplified by a second vaccination.[434] CD4 T-cell responses induced by AS03-adjuvanted (3.8 μg HA) 2009 H1N1 vaccine strongly enhanced both antibody and CD4 T-cell responses in adults as well as in older adults.[494,516,517]

The number of influenza virus–specific $CD8^+$ T cells decreases in elderly individuals compared with younger adults.[518–520] Nevertheless, influenza vaccination may transiently enhance CTL responses[514] in this population. There is growing evidence that cell-mediated immune responses may be a component in protecting the elderly from influenza disease.[521,522] In adults 60 years of age and older with congestive heart failure, postvaccination production of granzyme B, a key mediator of cytolysis of virus-infected cells, was significantly lower in subjects with influenza compared with those without laboratory-confirmed influenza.[521] These results suggest that the evaluation of cell-mediated immune responses to vaccination, particularly in older adults, warrants further investigation.

Correlates of Protection

Strain-specific virus-neutralizing antibody directed against the HA is the primary immune mediator of protection against infection and clinical illness, while antibody directed against the NA may reduce the severity of disease through enhancing viral clearance.[523] Based on serological studies of influenza using human serum, an HI titer range of 1 : 32 to 1 : 40 is often referred to as the "protective titer." However, this range of titers represents the level at which approximately 50% of individuals will be protected, and there is no titer value that can guarantee protection from infection.[235,470,524,525] Nevertheless, elevated levels of serum anti-HA antibody generally are correlated with resistance to influenza infection, whereas lower antibody levels are associated with increased risk of illness among persons exposed to influenza viruses,[251,525–527] although elderly individuals with HI titers of greater than or equal to 1 : 40 may still be susceptible to influenza disease.[528] Because of the inherent sensitivity issues with the HI test, given the high degree of sensitivity and correlation of the MN assay with HI test, the MN assay warrants consideration for serological assessment of responses to influenza. Challenge studies using live virus show that protection against influenza is also associated with local neutralizing antibody and secretory IgA found at mucosal surfaces.[481] Although antibodies to NA do not efficiently neutralize influenza infection, they restrict virus release from infected cells, reduce the intensity of infection, and enhance recovery.[529]

EFFICACY AND EFFECTIVENESS

The measurement of influenza vaccine efficacy and effectiveness can be affected by virus and host factors as well as study methodology. Thus, published vaccine efficacy/effectiveness point estimates have varied between studies and comparison of results requires consideration of multiple factors. In years with circulation of viruses that are antigenically drifted from the vaccine virus, vaccine benefit is likely to be lower. However, the degree of antigenic drift from vaccine viruses and proportion of circulating drifted viruses can vary such that during some seasons reported to have circulation of drifted viruses, the overall vaccine effectiveness is still beneficial.[455,530–532] Although multiyear studies are often needed to achieve adequate sample size, the differences in viruses and vaccines from year to year can complicate the interpretation of vaccine efficacy/effectiveness estimates from multiyear studies.

In addition to virus factors, host factors such as age, underlying medical conditions, history of prior infections and prior vaccinations can affect the response to vaccine and vaccine effectiveness.

An important contributing factor to vaccine effectiveness is the level of antigenic match or the antigenic correspondence between the viruses in the vaccines and the circulating influenza viruses during a given influenza season. Influenza vaccines are most effective when the viruses in the vaccines are antigenically indistinguishable from those that are circulating. However, different levels of antigenic divergence between vaccine and circulating viruses have occurred as a result of ongoing antigenic variation of viruses, issues related to egg adaptation and, occasionally, the late emergence of a variant strain that has drifted significantly from the vaccine virus after vaccine recommendations have been made. While the latter occurs only once every 6 to 10 years, it is possible that no benefit from the vaccine may be seen for that particular vaccine component.

The level of antigenic match between vaccine and circulating viruses is measured in the laboratory by using postinfection ferret serum in hemagglutination-inhibition assays and/or neutralization assays. Ferret serum is used for these assays because these serum samples typically have been found to be very sensitive in detecting low levels of antigenic divergence. Importantly, prevaccination and postvaccination human serum are also tested to determine if vaccines have induced good levels of antibody to currently circulating viruses, including any antigenic variants that may have emerged recently. Circulating influenza viruses also undergo genetic sequencing so that the degree of genetic divergence can be ascertained. It must be noted that specific single mutations can confer a greater level of antigenic divergence that multiple individual mutations in other areas of the hemagglutinin.

Young vaccine-naïve children require a second, boosting dose, administered a minimum of 4 weeks apart, for optimal immune response to vaccine.[533–537] Several studies suggest that the time interval between the first and second dose may range from 4 weeks to up to 1 year. Adults older than 65 years of age may have changes in innate immunity that can affect vaccine immunity over time and prior infections could influence susceptibility to infections because of original antigenic sin.[538] In addition, underlying medical conditions, particularly immunosuppression, can affect the ability to respond immunologically to the vaccine.[539,540]

Placebo-controlled randomized clinical trials measure vaccine efficacy with the least bias and offer the strongest evidence for vaccine benefit. In recent years, the number of countries with annual influenza vaccine recommendations for older adults, persons with underlying conditions, pregnant women, and children has increased. Thus, placebo-controlled randomized clinical trials are increasingly difficult to perform, and often impossible for groups recommended for vaccination. When a placebo cannot be used, vaccine effectiveness can be estimated with observational studies; however, biases related to receipt of vaccination need to be appropriately minimized and/or controlled. Recently, the test-negative design has become an increasingly popular study design. In this method, subjects with acute respiratory illness or influenza-like illness are enrolled during a medical encounter and respiratory specimens from all participants are tested with a sensitive diagnostic assay such as RT-PCR; cases are influenza test-positive and controls are test-negative. The test-negative design minimizes selection bias by allowing for the selection of controls with similar healthcare-seeking behaviors as cases. The method has been validated for assumptions common in ambulatory care settings.[541–543]

Finally, the specificity of the outcome measured in the vaccine efficacy/effectiveness study is important. Vaccine efficacy/effectiveness from studies with nonspecific outcomes, such as clinical syndromes (e.g., influenza-like illness or pneumonia), are generally lower than estimates from studies with laboratory confirmed outcomes.[544] For these syndromes, influenza infection accounts for only a proportion of possible causative etiologic agents.[545,546] However, some outcomes are rare or present after detection of influenza viruses is not possible, such as death or cardiovascular events, such that it is not possible to confirm influenza infection. In these situations studies with nonspecific outcomes can still be informative.[546,547] However, care must be taken to minimize selection biases that can bias final vaccine efficacy/effectiveness results. For example, older persons who are generally healthier, and less likely to die or be hospitalized, may be more likely to be vaccinated whereas those who are frailer and less healthy are less likely to be vaccinated.[548–551]

Laboratory-confirmed influenza virus infection is generally the most specific outcome for vaccine efficacy/effectiveness studies. Virus isolation and RT-PCR are specific diagnostic assays to detect influenza virus infection; RT-PCR is currently the most sensitive and specific assay that is widely available. Serologic assays to detect influenza infection (i.e., fourfold rise in antibody titers against circulating viruses) were used frequently to detect influenza infections prior to wide availability of RT-PCR. However, if preinfection antibody levels are high (as is common after receipt of IIVs), infection may not be associated with a fourfold rise in antibodies[193,233,552]; a similar phenomenon has been noted with serologic response to vaccination and prior vaccination.[553–555] Thus, some vaccinated persons who are subsequently infected may be misclassified as negative infections (biasing observed vaccine efficacy/effectiveness estimates higher than the true estimate). Limited data suggest that the degree of misclassification may vary and may depend on infecting and vaccine viruses, as well as the type of prior vaccine.[233,552]

Evidence From Randomized Clinical Trials Measuring Vaccine Efficacy Against Laboratory-Confirmed Influenza-Associated Illness

Older Adults

Among older adults, no placebo-controlled randomized clinical trial measuring vaccine efficacy against RT-PCR– or culture-confirmed influenza infection has been published. One randomized clinical trial (participants 60 years of age or older) relied on serology for laboratory confirmation of influenza

infection and reported a vaccine efficacy of 58% (95% confidence interval [CI]: 26% to 77%) for symptomatic serologically confirmed illness.[394] However, it is unknown if infections were missed by serology among vaccinees. Two randomized clinical trials evaluated the superiority of new vaccines meant to boost the immune response in older adults, adjuvanted and high-dose (60-μg) IIVs, compared to standard dose (15-μg) nonadjuvanted inactivated vaccines (Table 31.2).[451,556] However, only the high-dose inactivated vaccine achieved statistically significant higher relative efficacy (22%) compared to standard-dose inactivated vaccine.[451] In a post hoc analysis, the AS03 adjuvanted inactivated vaccine had a relative efficacy of 24% (95% CI: 5.68 to 35.49) against H3N2 virus infections compared to the nonadjuvanted vaccine.[556]

Adults

Among healthy adults younger than 65 years of age, several placebo-controlled trials measuring vaccine efficacy of IIVs (egg-grown and cell grown) and a recombinant trivalent HA protein vaccine against RT-PCR– or culture-confirmed influenza infection have been published (see Table 31.2).

TABLE 31.2 Summary of Selected RCTs Evaluating Vaccine Efficacy (VE) or Relative Efficacy (RE) for Seasonal and Pandemic Inactivated Influenza Vaccines and Recombinant Protein Vaccines Against Symptomatic RT-PCR–Confirmed or Virus Culture-Confirmed Influenza

[a]Pharmaceutical funding.
[b]Funded by a grant from government or foundation.
CI, 95% confidence interval; IIV, inactivated influenza vaccine; LAIV, live attenuated influenza vaccine; LCI, lower confidence interval; MDCK, Madin-Darby canine kidney; NS, nonsignificant (noted only if full CI not reported); RCT, randomized controlled trial; RE, relative efficacy; RT-PCR, reverse-transcription polymerase chain reaction; VE, vaccine efficacy.

Depending on the year, reported point estimates for vaccine efficacy against all influenza viruses (A and B) have varied from significant estimates of 75% during 2004–05 in the United States and 2008 in South Africa to a nonsignificant estimate of 16% during 2005–06 in the United States.[329,455,495,530,531,552,557–560] During 2005–06, low influenza infection attack rates may have contributed to lower and nonsignificant efficacy estimates.[552,557,559] Reports of antigenic drift among circulating viruses compared to vaccine viruses did not consistently correlate with vaccine efficacy estimates.[455,495,530,531]

During 2007–08, vaccine efficacy of a recombinant trivalent HA protein vaccine was 45% compared to placebo among healthy adults.[455] Two placebo-controlled trials measured efficacy of cell-based IIVs, one during 2007–08 and the other during 2008–09, and reported point estimates of 70% to 72%, respectively.[329,560] One cell-based IIV (Flucelvax) is currently licensed in the United States. Clinical trials during 2004–05, 2005–06, and 2007–08 with three arms—IIVs, live attenuated influenza vaccines, and placebo—suggested that live attenuated influenza vaccines may be inferior to IIVs in adults and are discussed in detail in Chapter 32.[530,531,552]

A metaanalysis that included data from placebo-controlled clinical trials of licensed IIVs with outcomes of RT-PCR– or culture-confirmed influenza infection among adults, and published in February 2011, reported a pooled vaccine effectiveness of 59% (95% CI: 51 to 67).[561] Several placebo-controlled randomized clinical trials measuring efficacy of IIVs used serology to confirm influenza infection; efficacy estimates ranged from 47% to 73% (1983–88, and 1997–98) and equal to or greater than 70% (1940; 1985–90).[7,66,233,285] A metaanalysis that included data from randomized clinical trials of IIVs with serologic, RT-PCR, or culture-confirmed influenza infections among adults reported a pooled vaccine effectiveness of 70% (95% CI: 55 to 80) for matched viruses and 55% (95% CI: 42 to 65) for unmatched strains.[562]

Children

Among children, only a few placebo-controlled randomized clinical trials measuring vaccine efficacy of nonadjuvanted IIVs with an outcome of RT-PCR– or culture-confirmed influenza infection have been published (see Table 31.2). During 1986 through 2000, a randomized trial evaluated vaccine efficacy of a trivalent IIV against culture-confirmed influenza A virus vaccine infection and used a monovalent influenza B virus vaccine as the comparison vaccine.[233,563] A vaccine efficacy of 91% during two seasons when A(H1N1) viruses predominated (1986–97 and 1988–89) and an efficacy of 77% during two A(H3N2) seasons (1987–88 and 1989–90) was reported. A separate study enrolled only young children, 6 to 24 months of age, and reported a vaccine efficacy against all influenza A/B viruses of 66% during 1999–2000, and a nonsignificant vaccine efficacy of –7% (CI, 247% to 67%) during the second year, 2000–01.[564] No antigenic drift in circulating viruses compared to vaccine viruses was reported either season, however, the attack rate during the second year was very low. During 2009–10 in Hong Kong, a vaccine efficacy of 66% was reported against influenza B virus infection among children 6 to 17 years of age[565]; no evidence for a reduction in the severity or duration of symptoms among vaccinated children was reported.[566] During 2010–11, the vaccine efficacy of a quadrivalent IIV among children 3 to 8 years of age was 59% against infection with influenza A/B viruses with influenza-like illness symptoms, compared to a control vaccine, and 74% (95% CI: 51.5% to 86.2%) against influenza A/B virus-associated "moderate to severe" infections; moderate to severe infections were defined as any of the following: fever greater than 39°C (53 of 66 [80%] RT-PCR–confirmed illnesses) or physician-confirmed acute otitis media (1.5%), lower respiratory tract illness (18%), or extrapulmonary complications (0%).[567] Several studies of nonadjuvanted IIVs included serologically confirmed influenza infections as an outcome and reported vaccine efficacy of 45% (3–9-year-old daycare attendees, 1996–97), 56% (3–19-year-old children, 1986–87), and 70% (school-age boys, 1972–73).[391,568,569]

Two randomized clinical trials suggested that adjuvanted IIVs may have superior efficacy in young children compared to nonadjuvanted IIVs (see Table 31.2).[488,570] One study compared a MF59 adjuvanted inactivated vaccine to a nonadjuvanted inactivated vaccine among vaccine-naïve children 6 to 71 months of age.[570] During 2008–09, the vaccine efficacy was 86% for the MF59 adjuvanted vaccine and 43% for the nonadjuvanted vaccine, and the relative efficacy of the adjuvanted vaccine compared to the nonadjuvanted was 75%. Among the subset of children 2 to 24 months of age, the relative efficacy of the adjuvanted to nonadjuvanted vaccine was 73% (95% CI: 29 to 90). During the 2009 pandemic, an AS03 adjuvanted monovalent inactivated vaccine was compared to a nonadjuvanted inactivated monovalent vaccine in children 3 to 8 years of age.[571] The adjuvanted vaccine had a relative efficacy of 77% compared to the nonadjuvanted vaccine.

Three randomized clinical trials that compared live attenuated influenza vaccine to nonadjuvanted IIV in young children suggested that live attenuated influenza vaccine had superior efficacy compared to IIV.[572–574] These studies are discussed in detail in Chapter 32.

A cluster-randomized trial in children ages 6 months to 15 years from Hutterite communities in Canada reported a combined direct (vaccine efficacy against RT-PCR–confirmed infection in enrolled children) and indirect (efficacy against RT-PCR–confirmed infection in nonvaccinated community members in clusters with vaccinated versus unvaccinated children) estimate of 59% (95% CI: 5 to 82) for trivalent IIV during 2008–09; a hepatitis A vaccine was the comparison vaccine.[575]

Evidence From Observational Studies Measuring Vaccine Effectiveness Against Laboratory-Confirmed Influenza-Associated Illness

Observational studies are often the only option to measure vaccine effectiveness against more-severe, less-common influenza outcomes, such as hospitalizations. Many observational studies have assessed vaccine effectiveness to prevent RT-PCR–confirmed or culture-confirmed influenza-associated hospitalizations in adults, a few are summarized here. A 3-year study in Tennessee using a test-negative design (e.g., hospitalized patients who tested negative for influenza were the controls and those who tested positive were cases) during 2006–07 through 2008–09, reported a vaccine effectiveness of 61% (95% CI: 18 to 83) among adults 50 years of age and older.[576] The same group of researchers added two additional seasons to this analysis, including 2006–12 (excluding 2009–10) and reported a vaccine efficacy of 58% (95% CI: 8% to 81%) for persons 65 years of age or older for the five seasons combined.[577] During the 2010–11 season, with a high proportion of A(H1N1)pdm09 viruses, a Spanish cohort study reported a significant vaccine effectiveness of 58% (95% CI: 16 to 79) among hospitalized adults 60 years of age and older or persons with chronic conditions.[578] Results were similar when data were analyzed with a test-negative design and from a separate Spanish study using a test-negative design.[579] In Australia during the 2010 season, a vaccine effectiveness of 49% (95% CI: 13% to 70%) against H1N1pdm09 infection-associated with hospitalization was reported; a test-negative design was

used but testing was clinician-directed.[580] In contrast, during 2012–13, two European Hospital Networks reported vaccine effectiveness against influenza A/B virus infection-associated hospitalization of 33% (95% CI: 11 to 49) and 21% (95% CI: −25 to 50); influenza A(H3N2), influenza A(H1N1)pdm09, and influenza B viruses cocirculated.[581,582] Mid-season, interim results from Canadian studies enrolling hospitalized adults and using a test-negative design during the 2014–15 influenza season, a season with a high proportion of circulating drifted A(H3N2) viruses, failed to find effectiveness against hospitalizations associated with A(H3N2) infection.[583,584] A cohort study in Spain reported a relative vaccine effectiveness of 33% (95% CI: 15% to 48%) among adults 65 years of age and older for intradermal inactivated trivalent vaccine compared to virosomal inactivated trivalent vaccine against influenza-associated hospitalizations during 2011–12.[585]

Few observational studies have reported vaccine effectiveness estimates against RT-PCR– or culture-confirmed influenza-associated hospitalizations in children. One study, enrolled severely ill children admitted to pediatric ICUs in the United States during 2010–11 and 2011–12. They reported a vaccine effectiveness of 74% (95% CI: 19 to 91) using a test-negative design method and 82% (95% CI: 23 to 96) using controls selected from similar clinics as cases.[586] A study from Hong Kong during 2009–13 among children 6 months to 17 years of age reported a vaccine effectiveness against hospitalizations associated with influenza A/B virus infections of 62% (95% CI: 43 to 74).[587] The estimated vaccine effectiveness estimates against hospitalizations associated with A(H3N2) virus infections was 37% (95% CI: −25 to 68), with A(H1N1)pdm09 virus infection was 72% (95% CI: 39 to 87), and with influenza B virus infections was 69% (95% CI: 42 to 83). During 2010–12 in the United States, among persons of all ages, a vaccine effectiveness of 57% (95% CI: 32% to 73%) against RT-PCR–confirmed influenza-associated community-acquired pneumonia hospitalizations was reported; age group–specific estimates were not significant.[588]

During the 2009 pandemic, several studies attempted to measure vaccine effectiveness of the monovalent pandemic vaccine against A(H1N1)pdm09 virus infection-associated hospitalizations. Infection attack rates had already started to decline rapidly when vaccine became available in 2009 and many studies identified a small number of vaccinated cases; therefore, it is possible that residual confounding related to calendar time and/or sparse data bias may exist.[589] A U.S. case-control study enrolling RT-PCR–confirmed hospitalized cases 6 months of age and older, and comparing to community controls, reported a vaccine effectiveness of 50% (95% CI: 13 to 71) for nonadjuvanted monovalent pandemic vaccine.[590] A U.S. study comparing hospitalized children 6 months to 9 years of age with RT-PCR–confirmed A(H1N1)pdm09 infection to matched controls from an immunization registry reported a vaccine effectiveness of 82% (95% CI: 0 to 100) for a single dose of nonadjuvanted inactivated or live attenuated monovalent vaccine.[591] Among hospitalized children in Canada 6 months to 9 years of age, an estimated vaccine effectiveness of 85% (95% CI: 61 to 94) was reported against RT-PCR–confirmed infections for a single dose of an AS03 adjuvanted monovalent inactivated pandemic vaccine.[592]

Since 2003, many observational studies using the test-negative design have reported vaccine effectiveness estimates against RT-PCR– or culture-confirmed influenza-associated medically attended illness; most studies enrolled participants from ambulatory care settings, while some recent studies have reported effectiveness against hospitalizations.[593–605,605a] Several networks in Australia, Canada, Europe, New Zealand, the United Kingdom, and the United States collect data from many partners/sites to report annual vaccine efficacy estimates, and often report mid-season interim estimates to inform communication efforts during the season, and may inform vaccine strain selection.[606–612] Increasingly, influenza A subtype–specific and influenza B lineage–specific vaccine effectiveness estimates have been published, allowing more direct comparison with individual vaccine components. Annual vaccine effectiveness estimates from different geographic locations and both Northern and Southern hemisphere regions have highlighted the importance of vaccine virus characteristics, such as substitutions induced during culture in eggs and antigenic and genetic drift of circulating viruses away from the vaccine strain on vaccine effectiveness estimates.[250,609–611,613–616] In addition, annual vaccine efficacy estimates have reported effect modification of prior season vaccination on current season vaccine effectiveness; the effect on current season vaccine effectiveness varies across seasons and studies.[250,595,613,617,618] Conflicting evidence on the effect of prior vaccination on current season vaccine efficacy was also reported from limited randomized trials.[66,619] Finally, networks capable of collecting annual data have allowed the comparison of vaccine effectiveness for live attenuated influenza vaccines and IIVs in children by season and by subtypes, including effectiveness against illness associated with A(H1N1)pdm09 viruses that were not circulating during randomized clinical trials comparing these vaccines.[595,596,620]

During 2010–11 through 2013–14, reported vaccine effectiveness estimates against medically attended influenza A(H1N1)pdm09 infections have ranged from 80% (95% CI: 52 to 92) in Canada during 2011–12 to 48% (95% CI: 16 to 67) in Europe during 2013–14; neither vaccine viruses nor circulating viruses had had significant antigenic changes since 2009.[593,596,598,605,613,614,618,623–626] During these seasons, vaccine effectiveness estimates against medically attended A(H3N2) virus infections have ranged from nonsignificant estimates of 13% (95% CI: −20 to 36) in Australia during 2011 to 51% (95% CI: 10 to 73) in Canada during 2011–12.[250,593,595,596,603,613,614,616,618,623,627–629] Several studies have reported influenza B lineage–specific vaccine efficacy estimates. In North America, vaccine effectiveness against B Victoria lineage during 2011–12, when it was included in the trivalent vaccine, was 52% (95% CI: 8 to 75) and 71% (95% CI: 40 to 86); vaccine effectiveness against the less frequent, nonvaccine B Yamagata lineage was reported as 66% (95% CI: 58 to 73) and 27% (95% CI: −21 to 56).[595,618] During the subsequent season, 2012–13, when a B Yamagata virus was included in the trivalent vaccine, vaccine effectiveness estimates against B Yamagata and B Victoria virus infections were similar: 51% (95% CI: 36 to 63) to 75% (95% CI: 29 to 91), respectively.[250,613]

A metaanalysis used test-negative design observational studies with vaccine effectiveness estimates for adults 60 years of age and older against RT-PCR–confirmed influenza infection. They reported a significant vaccine effectiveness during epidemic seasons or regional outbreaks when the vaccine viruses matched circulating viruses (52% [95% CI: 41 to 61]; 58% [95% CI: 30 to 70], respectively) and when a mismatch was reported (36% [95% CI: 22 to 48]; 43% [95% CI: 21 to 59], respectively).[630]

Vaccine Efficacy and Effectiveness Against Laboratory-Confirmed Influenza for Pregnant Women and Their Infants

A randomized controlled trial conducted in South Africa reported a vaccine efficacy of 50% against RT-PCR–confirmed influenza A/B infection among HIV-negative pregnant women vaccinated during the third trimester during 2011 and 2012

(see Table 31.2).[631] Vaccine efficacy among HIV-infected pregnant women (under medical care) was 58%. An observational study in the United States during 2010–11 and 2011–12, using a test-negative design, reported a vaccine effectiveness against influenza A/B infection of 44% (95% CI: 5 to 67) among pregnant women.[632]

Infants younger than age 6 months are not recommended for vaccination, although some studies suggest that immune responses among infants are relatively good.[633,634] Passive transfer of antiinfluenza antibodies to neonates after maternal vaccination during pregnancy has been documented.[631,635,636] The South African study that measured vaccine efficacy among women vaccinated during pregnancy also measured efficacy of maternal vaccination on influenza infection among infants until 24 weeks postpartum. A vaccine efficacy of 49% was reported for infants of HIV-negative women (see Table 31.2)[631]; the study was unable to assess vaccine efficacy among infants of HIV-infected women.[636a] A randomized controlled trial conducted in Bangladesh that provided influenza or pneumococcal vaccination to pregnant women during the third trimester reported that infants born to influenza-vaccinated women had a 63% (95% CI: 5 to 85) reduction in rapid influenza diagnostic test–confirmed influenza illness during the first 6 months of life[637]; a laboratory-confirmed influenza outcome was not used for pregnant women. A large randomized controlled trial among of inactivated influenza vaccine among pregnant women in Mali found that vaccine efficacy against laboratory-confirmed influenza illness in infants during during the first 6 months of life was 33.1% (CI: 3.7 to 53.9). In this study, VE was highest in the first 4 months of life (67.9% [CI: 35.1–85.3]).[637a] Similarly, in the South African trial, protection of the infant was found only in the first 8 weeks following delivery.[637a]

Several studies have been conducted to estimate the effect of maternal immunization on birth outcomes, such as the risk of prematurity or the risk of being small for gestational age. A randomized trial in Bangladesh found that babies born to mothers vaccinated during pregnancy with IIV3 were significantly less likely to be born small for gestational age and had a mean birth weight 200 g higher than babies born to unvaccinated mothers.[638] Some observational studies in developed and developing countries found a lower risk of prematurity or low birth weight in babies born to vaccinated mothers, but the effect has not been consistently demonstrated.[638–643a] A recent randomized trial in South Africa found maternal immunization had no effect on infant birth weight.[631]

Duration of Immunity and Protection

Inactivated vaccine induces a rapid systemic and local immune response in healthy young adults.[217] It has been shown that up to 90% of normal subjects develop serum HI titers of 1 : 40 or greater within 2 weeks of vaccination and that second doses provide little or no further increase in titers. Peak serum antibody levels develop within 4 to 6 weeks after vaccination[219] and then antibody levels wane by as much as a 50% within 6 months.[333]

Elderly subjects generally respond less well to influenza vaccines than young healthy adults, and those with chronic debilitating medical conditions generally respond less well than healthy subjects of similar age. Up to 50% of elderly vaccinees may fail to respond to IIV with a fourfold increase in HI antibodies.[311] In addition, antibody responses in the elderly may be somewhat delayed compared to those in younger individuals.[644] Although some studies have noted that antibody responses return toward the baseline more rapidly than in young adults,[645,646] the relevance of these observations to prevention of influenza illness is uncertain.[647]

The duration of protection from illness after influenza vaccination has been studied during several clinical trials. In 1968, a group of schoolchildren was vaccinated with the A/Hong Kong/68 vaccine and was observed over three successive influenza epidemics caused by the A/Hong Kong/68 virus. Three years after vaccination, the vaccine was still 67% effective in preventing influenza.[282] In randomized trials conducted among healthy college students, immunization with trivalent inactivated vaccine before the 1982–83 epidemic provided 92 and 100% efficacy against influenza H3N2 and H1N1 infection–related illnesses, respectively, during the first year, and a 68% reduction against H1N1 infections during the second year without revaccination.[648] Because elderly persons who have received repeated influenza vaccinations develop lower peak HI titers, and these antibody levels return to baseline faster than in young healthy adults receiving influenza vaccine for the first time, immunity may be of shorter duration in this target group than in the young adults studied above.

Several observational studies of influenza vaccine effectiveness have reported decreased vaccine protection within a single season, particularly against influenza A(H3N2) and older adults.[648a–648e] However, this effect has not been observed consistently across age groups and seasons, and the observed decline in protection could be attributable to other factors, such as increased circulation of antigenically drifted variants over the course of the influenza season. Finally, differences in methods used to measure intraseasonal changes in vaccine effectiveness could contribute to inconsistencies. The inconsistent evidence for intraseason waning of influenza vaccine protection makes drawing conclusions difficult, and further evaluation of this effect in larger studies and different seasons is needed.

Although protection may persist for longer than a year after vaccination in young healthy adults, annual immunization with inactivated vaccine is recommended because one or more vaccine antigens usually are updated each year and because reductions in serum antibody levels have been well documented during the year after immunization. In particular, annual immunization of those 65 years of age and older close to the influenza season will help maximize antibody levels and protection in this important target group.

In contrast to the relatively short-lived antibody response to vaccination, immunity to HA can persist for decades after natural infection. During 1977 and 1978, influenza A(H1N1) viruses similar to those circulating in 1950 reappeared and spread throughout the world. Individuals born before 1950 were not affected, indicating that substantial immunity remained after more than 20 years. In addition, studies of the immunogenicity of vaccines against the H1N1 virus found high rates of preexisting immunity among those born before 1957.[261] In contrast, disease occurred in individuals younger than 20 years of age, regardless of previous infection by influenza A(H3N2) viruses, and antibody studies confirmed that these persons were much more likely to require two doses of H1N1-containing vaccine to demonstrate an immune response as would be expected with an immune naïve population showing that intersubtypic immunity in humans is weak. The ability of natural infection to engender long-lasting immunity was dramatically demonstrated during the 2009 influenza A(H1N1) pandemic, where approximately one-third of adults older than 60 years of age had cross-reacting antibodies to the pandemic strain, presumably based on exposures to antigenically similar strains 50 or more years previously.[258] In addition, the surprisingly low burden of severe illness in older populations worldwide suggested that unmeasured partial or full immunity after natural infection was retained in an even larger proportion of older persons.[649,650]

Effectiveness of Vaccination for Decreasing Transmission to Contacts

Influenza vaccination has been shown in certain settings, such as nursing homes and schools, to provide indirect benefits to contacts who remain unvaccinated,[251,568,651,652] a finding that is consistent with models of vaccine-induced herd immunity. Furthermore, mass immunization among those who are most likely to acquire and transmit influenza (usually school-age children) might reduce the overall occurrence of influenza in the community, including in unvaccinated persons.[251,653] The community-level protective effect of vaccinating children was shown during the 1968 pandemic where vaccination of greater than 5% of schoolchildren in a community resulted in lower illness rates among all age groups compared to another unvaccinated community.[251,654] Several recent studies have evaluated the benefits of vaccinating school-age children with influenza vaccine. Overall, studies reported decreases in influenza-related illness in the children, and a modest benefit to adults, either in the household or in the community.[286,575,653,655] However, community impact of childhood vaccination on morbidity and mortality outside of the household effect is difficult to quantify and more studies are needed to assess the costs and benefits to children and the larger communities of school-based or universal vaccination programs.[656] (For further discussion, see Chapter 75.) Community-level, multiyear ecologic studies have also shown population-level impact. A retrospective ecologic study suggested that high rates of vaccination of schoolchildren in Japan had reduced excess mortality rates among older adults and that discontinuation of this vaccination program led to increases in excess mortality rates among elderly Japanese.[657] This study remains controversial because aging of the population and other variables might not have been adequately controlled.[658,659] The largest study to examine the community effects of increasing overall vaccine coverage was an ecologic study that described the experience in Ontario, Canada, which is the only province to implement a universal influenza vaccination program beginning in 2000. On the basis of models developed from administrative and viral surveillance data, influenza-related mortality, hospitalizations, Emergency Department use, and physicians' office visits decreased substantially more in Ontario after program introduction than in other provinces, with the largest reductions observed in younger age groups.[660] In addition, influenza-associated antibiotic prescriptions were substantially reduced compared with other provinces.[661]

Decreasing transmission of influenza from caregivers and household contacts might reduce influenza-like illness and complications among persons at high risk. Observational studies have demonstrated that vaccination of healthcare personnel in a nursing home facility is associated with decreased deaths among patients.[240,662] More recently, controlled trials have shown decreases in mortality and influenza-like illness in facilities where higher vaccine coverage levels among staff were achieved.[663,664] A comprehensive review concluded that vaccination of healthcare personnel in settings in which patients also were vaccinated provided significant reductions in deaths among elderly patients from all causes and deaths from pneumonia.[665]

Safety

Common Adverse Events

Among children and adults, local inflammatory reactions resulting in soreness or erythema at the injection site is the most frequently reported adverse event following vaccination with an IIV. Among adults in placebo-controlled studies, soreness at the vaccination site was most common and reported among 10% to 64% of subjects; soreness generally lasted less than 2 days.[432] These symptoms were mild and rarely interfered with usual daily activities. A review of Vaccine Adverse Event Reporting System (VAERS) data among adults in the United States found the most commonly reported adverse events during this period were injection-site reactions, pain, fever, myalgias, and headache.[666] This review did not identify any new safety concerns. Placebo-controlled trials have found that receipt of trivalent inactivated vaccines are not associated with higher rates for systemic symptoms, such as fever, malaise, myalgia, or headache, compared with placebo injections in older adults and healthy young adults.[333,382,432]

Among children, fever, myalgia, arthralgia, and headache are noted in less than 15% of vaccinees, most often in very young children and among those exposed to influenza virus vaccines or to one of the antigens in the vaccine for the first time.[333,335,351,383,667,668] In a study of 791 healthy children 1 through 15 years of age, postvaccination fever was noted among 12% of those 1 through 5 years of age, 5% among those 6 through 10 years of age, and 5% among those 11 through 15 years of age. However, such systemic side effects have not been observed in more recent randomized trials of inactivated vaccines where the only differences between placebo and vaccine groups have been sore arm and redness at the injection site.[667] In young children, whole-virus influenza vaccines and larger vaccine doses appear to produce more systemic reactions, including fever, than subvirion vaccines.[335,382] Data have not demonstrated significant increases in local or systemic adverse events among recipients of quadrivalent vaccines compared with trivalent vaccines (nor among recipients of monovalent vaccines, such as the 2009 unadjuvanted pandemic H1N1 vaccine[488,489,669]). Large postlicensure studies in the United States among children enrolled in health maintenance organizations strongly support the safety of IIVs. Among approximately 250,000 children included in one study, there was no increase in vaccine-associated medically attended events during the 2 weeks postvaccination compared with the 2 weeks before vaccination and days 15 to 28 following vaccination.[670] A study among approximately 45,000 children 6 to 23 months of age found no statistically significant association of vaccination with any medical events other than a small increase in gastritis and duodenitis (typically self-limited nausea and vomiting). However, statistically significant decreases in upper respiratory illness, asthma, and otitis media were also observed.[671] A subsequent Vaccine Safety Datalink study of 66,283 children 24 through 59 months of age noted diagnoses of fever, gastrointestinal tract symptoms, and gastrointestinal disorders to be significantly associated with IIV (incidence risk ratios of 1.71, 1.18, and 7.70, respectively, compared with time before vaccination and after a postvaccination risk period). No evidence of serious medically attended adverse events was noted in this study.[672]

Regarding higher-dose vaccines, recipients of IIV containing 180 μg of HA antigen had higher rates of injection-site reactions and fever after vaccination compared with those who received standard-dose vaccines (45 μg); however, these reactions were typically mild and transient. In a large trial, 915 (36%) of 2572 persons who received high-dose vaccine reported injection-site pain compared with 306 (24%) of those who received standard-dose vaccine; similarly, 1.1% of high-dose recipients reported moderate to severe fever compared with 0.3% of standard-dose IIV.[449] No differences in rates of serious adverse events were noted between high-dose and standard-dose vaccine recipients in a second randomized controlled trial.[673] Intradermally administered IIVs are associated with higher rates of injection-site reactions compared with intramuscularly administered influenza vaccines among

nonelderly adults, including erythema, induration, swelling, and pruritus; however, rates of injection-site pain were not significantly different nor were rates of systemic symptoms, such as headache, myalgia, or fever.[674]

Adjuvanted inactivated vaccines may be associated with higher rates of local reactions. For instance, among recipients of vaccine containing MF59 there were more local reactions (soreness was six times more frequent and erythema two times more frequent after the first dose of vaccine containing MF59 compared to vaccine without MF59 in one study of the elderly[194]) as well as more systemic reactions such as malaise or myalgia.[422,424] Even so, safety monitoring during the 2009 H1N1 pandemic among countries that used vaccines that included oil-in-water emulsions as adjuvants, generally found that adverse events were rare and typically nonserious, consisting mostly of local reactions, fever, and/or malaise.[675,676] The notable exception was the association of narcolepsy with an AS03-adjuvanted monovalent pandemic vaccine (see below).

Serious Adverse Events

Influenza immunizations can be associated with serious adverse events, although they are uncommon. Two reviews of national data have found that rates of serious adverse events reported following vaccination (not necessarily attributed to influenza vaccination) were 3.4 reports per million in the United States,[666] and less than 1 per million in South Korea.[677] The most common serious adverse event reported in both reviews was Guillain-Barré syndrome (GBS). GBS was first associated with receipt of IIV during the 1976 swine (H1N1) influenza vaccine campaign, when one additional case of GBS was estimated for every 100,000 persons vaccinated[678] (above an estimated annual incidence of 10 to 20 cases per 1 million adults).[679] Most commonly GBS cases are associated with antecedent gastrointestinal or respiratory illness, including influenza infection.[679–683] Studies conducted since the 1976–77 influenza vaccine campaign have failed to detect a significant risk associated with seasonal influenza vaccine in many years[684–686]; however a small but significantly increased risk of GBS among vaccinees has been detected in some studies.[687,688] As a result, the estimated risk for GBS has been approximated as one additional case of GBS per 1 million persons vaccinated.[689] Similar rates were estimated for those who received the H1N1 pandemic vaccine in 2009.[690–692] Most vaccine-associated cases will occur in the second week following vaccination. While a small risk of vaccine-associated GBS has been appreciated, one study has estimated that the risk of GBS associated with influenza infection to be substantially higher, perhaps indicating that the vaccine provides a net reduction of GBS risk among those vaccinated.[683] Because persons with a history of GBS are at higher risk for subsequent cases, influenza vaccination is usually not recommended for persons with a previous history of influenza vaccine–associated GBS, and providers should consider the risks and benefits of vaccinating persons with GBS from any cause. Even so, an 11-year, large, population-based study found no cases of GBS among 107 persons vaccinated who had had a previous case of GBS, including two with previous vaccine-associated cases.[693]

In 2010, a high rate of febrile seizures (nine cases per 100 children vaccinated) was observed among young children who had received a southern hemisphere IIV product.[694,695] Febrile seizures had not previously been associated with IIV.[670–672] After safety signals were observed for febrile seizures from surveillance among U.S. children receiving IIV during the 2010–11 influenza season,[696,697] an increased risk of less than one case per 1000 children vaccinated was detected from further studies in 2010–11 and 2011–12.[697,698] The increased risk was among children 6 months through 4 years of age within 1 day of vaccination; no risk was observed for children older than 4 years of age. The risk was higher when children received concomitant pneumococcal conjugate vaccine (PCV13) (i.e., when the two vaccines are given at the same healthcare visit) and peaked at approximately 16 months of age. No increased risk was observed in the 2012–13 influenza season. It was determined by the CDC's Advisory Committee on Immunization Practices that the benefits of influenza vaccine were greater than the risk of febrile seizures, and no change in policy was recommended.[699]

Other neurologic diseases have been reported following inactivated influenza vaccination, including optic neuritis, transverse myelitis, Bell palsy, multiple sclerosis, and tics. However, a causal association between receipt of vaccine and these diseases has not been established.[666,677] Narcolepsy has been associated with an adjuvanted monovalent pandemic H1N1 vaccine that was used in 2009–10. Following pandemic vaccination programs conducted in late 2009 and 2010, cases of narcolepsy among recipients of a monovalent AS03-adjuvanted H1N1 vaccine were reported, with the risk greatest among children.[700] Epidemiologic studies conducted in several European countries where this vaccine was used revealed a consistent and strong association with receipt of the vaccine.[700–704] The attributable risk was estimated to be between one in 57,500 and 52,000 vaccine recipients in the United Kingdom,[701] and one in 16,000 in Finland.[702] A similar vaccine using AS03 adjuvant produced in Canada was possibly associated with a much lower risk of approximately one extra case of narcolepsy per 1 million vaccinees; although the association in this study could not rule out that the association was confounded by H1N1 seasonality.[705] No association has been noted with other unadjuvanted H1N1 vaccines, nor with pandemic vaccines that used the oil-in-water adjuvant MF59.[706,707] No association has been noted between seasonal influenza vaccines and narcolepsy. Although the mechanism for the risk is not fully known, some data indicate that autoantibodies to hypocretin or human brain ganglioside proteins may play a role in genetically predisposed hosts.[708–710] A recent study found that antibodies developed against the influenza NP in the vaccine associated with narcolepsy cross-react with hypocretin, and that the NP content in the vaccine was higher than that in other adjuvanted pandemic vaccines, possibly explaining the association with a specific product.[708]

Oculorespiratory syndrome (ORS), an uncommon, acute, self-limited reaction to IIV, was first reported during the 2000–01 influenza season in Canada.[711] Affected patients reported red eyes, cough, wheeze, chest tightness, difficulty breathing, sore throat, or facial swelling[712] that began between 2 and 24 hours after receiving vaccine and resolved within 48 hours. In the initial outbreak, ORS was associated with a particular vaccine preparation,[712] and following manufacturing changes in this vaccine, the rates of ORS reports declined substantially.[713] However, other clusters since this episode have been reported.[714,715] Studies suggest that the reaction is not IgE mediated,[716] although symptoms reported have some similarities with immediate hypersensitivity reactions. The risk for ORS recurrence with subsequent vaccination appears to be low,[717,718] but guidance on revaccinating persons with suspected ORS are available.[698]

Special Populations

Pregnant Women. Inactivated vaccines have been found to be comparably safe among pregnant women compared with healthy adults; no special safety concerns have been identified.[78,719,720] No differences in local or mild systemic adverse events or pregnancy outcomes have been noted in this population.[721] Reviews of studies pertaining to seasonal and

monovalent 2009(H1N1) have demonstrated no evidence of harm to the fetus from receipt of IIVs in pregnancy; however, data on safety of influenza vaccination on the fetus when given in the first trimester is somewhat limited.[640,719,720,722–727] A case-control study conducted in healthcare organizations detected no significant increase in the risk of pregnancy loss in the 4 weeks following seasonal influenza vaccination.[728] Similarly, although no increased risk of fetal death was associated with vaccination of pregnant women with pandemic H1N1 vaccine in Norway, researchers did note an association with pandemic 2009(H1N1) infection and fetal loss.[729] Between 2000 and 2003, 20 adverse events among women who received IIV3 were reported to VAERS during a period when an estimated 2 million pregnant women were vaccinated; these included nine injection-site reactions, eight systemic reactions (e.g., fever, headache, and myalgia), and three miscarriages.[730]

Immunocompromised Persons. Available data on the safety of IIV among HIV-infected persons demonstrate no evidence of a clinically significant impact on HIV infection or immunosuppression.[698] While early studies suggested transient increases in replication of HIV-1 in the plasma or peripheral blood mononuclear cells of HIV-infected persons following vaccination,[731–733] more recent studies with superior designs have not documented a significant increase in HIV replication,[734–737] change in $CD4^+$ T-lymphocyte cell counts, or progression of HIV disease after IIV receipt among HIV-infected persons compared with unvaccinated HIV-infected persons.[498,738] Data are limited regarding the safety of IIV among persons with other immunocompromising conditions. IIV vaccination did not affect allograft function or cause rejection episodes in small numbers of recipients of kidney transplants,[508,739] heart transplants,[506] or liver transplants.[510,740] Reports of corneal graft rejection after IIV have been made, but a causal association is not clear.[741–743]

Indications for Vaccine

Influenza vaccination is indicated for anyone 6 months of age or older who wishes to reduce the risk of influenza and its complications.[355] In most countries, national policies focus recommendations on either persons at elevated risk of severe influenza or complications should they become infected, or persons who are at risk of transmitting influenza to high-risk persons in the workplace or at home (Table 31.3).[12,245,744,744a] Policies that target high-risk groups focus on persons at each end of the age range (frequently children younger than 5 years of age and persons older than 60 or 65 years of age), those with specific underlying diseases found to increase the risk of complications, either from influenza or from the underlying diseases, and pregnant women. In addition, many countries recommend vaccines for healthcare workers to prevent transmission from infected workers to patients in their care with high-risk conditions. Although the magnitude of this risk has been difficult to measure, healthcare worker–to–patient infections have been documented.[745–747] In 2012, WHO's Strategic Advisory Group of Experts (SAGE) issued recommendations for influenza that focused on five target groups: children younger than 5 years of age (especially those younger than 2 years of age), elderly persons, persons with underlying diseases, pregnant women, and healthcare workers.[245] In these recommendations, WHO recommended pregnant women be vaccinated as the highest priority, given the finding that they are at high risk of complications and hospitalization, the finding that the vaccine is safe, data indicating that vaccination may also protect their young infant from influenza (an age during which vaccine is not approved for administration), and the finding that vaccination of pregnant women may be programmatically feasible in many countries compared with some of the other target groups. This recommendation has catalyzed influenza vaccine policy development and vaccine uptake in middle- and low-income countries.[12,748]

TABLE 31.3 Groups at Risk for Severe Influenza or Complications From Influenza Infection

- Children <5 y (especially children <2 y)
- Adults aged ≥65 y
- People who have medical conditions including:
  - Asthma
  - Neurological and neurodevelopmental conditions (including disorders of the brain, spinal cord, peripheral nerve, and muscle such as cerebral palsy, epilepsy [seizure disorders], stroke, intellectual disability [mental retardation], moderate to severe developmental delay, muscular dystrophy, or spinal cord injury)
  - Chronic lung disease (such as chronic obstructive pulmonary disease [COPD] and cystic fibrosis)
  - Heart disease (such as congenital heart disease, congestive heart failure, and coronary artery disease)
  - Blood disorders (such as sickle cell disease)
  - Endocrine disorders (such as diabetes mellitus)
  - Kidney disorders
  - Liver disorders
  - Metabolic disorders (such as inherited metabolic disorders and mitochondrial disorders)
  - Immunocompromising condition resulting from disease or medication (such as people with HIV or AIDS, or cancer, or those on chronic steroids)
  - People <19 y who are receiving long-term aspirin therapy
- People who are morbidly obese
- Residents of long-term care facilities
- Indigenous populations
- Pregnant women

Modified from Centers for Disease Control and Prevention (CDC). Influenza (Flu): People at High Risk of Developing Flu-Related Complications. Available at: http://www.cdc.gov/flu/about/disease/high_risk.htm.

The United States adopted a "universal" vaccination recommendation in 2010,[147] in which all persons older than 6 months of age are recommended to receive annual influenza vaccination.[355] This strategy, which has not been adopted by other countries, was the result of steady expansion of recommendations for target groups, especially between 2000 and 2009, by which time, an estimated 84% of persons in the country were in at least one recommended target group. The universal recommendations recognized that all persons are at risk for influenza and even serious disease, and that a universal recommendation may simplify messages regarding who should be vaccinated, resulting in higher vaccine coverage in high risk groups.[11]

Contraindications and Precautions

IIVs should not be given to persons known to have an anaphylactic hypersensitivity to eggs or egg antigens or to influenza vaccine until they are evaluated by a physician. In addition to egg antigens, it is possible (as with any vaccine) that other components may be sensitizing. Information about vaccine components is located in package inserts from each manufacturer. The contraindication to vaccines among those with anaphylaxis to egg antigens extends to cell-grown vaccines that are produced using egg-grown seed strains.[355] However, recombinant influenza vaccine may be given to persons with known egg allergies since no eggs are used in their production.[355]

Severe allergic reactions to IIVs are rare. While other components of influenza vaccines may be associated with allergic reactions, most attention has been on egg allergies, as most inactivated vaccines use embryonated eggs in production. Many manufacturers measure and report ovalbumin content in their products; those that do provide ovalbumin content report maximum amounts that are equal to or less than 1 μg/0.5 mL dose.[18] While a threshold below which a vaccine would not expected to cause reactions is unknown, vaccines containing as much as 0.7 μg of ovalbumin per 0.5 mL have been tolerated in children.[749,750] A large study that followed 4172 patients with egg allergies found no cases of anaphylaxis associated with influenza vaccination.[751] Although those with a history of anaphylaxis to eggs should not receive influenza vaccine, most persons with egg allergies can safely receive influenza vaccines, if specific safety measures are followed.[355] The CDC recommends that persons with a history of hives associated with egg allergy should receive any licensed vaccine. Persons with more-severe reactions to eggs (e.g., angioedema, respiratory distress, light-headedness, or recurrent emesis) and those who have required epinephrine or another emergency medical intervention, especially if within minutes to hours after egg exposure, are at higher risk of serious systemic or anaphylactic reaction upon reexposure to egg proteins. As a result, this group can also receive any licensed vaccine, but the vaccine should be administered in an inpatient or outpatient medical setting, and be supervised by a health care provider who is able to recognize and manage severe allergic conditions.

The risk-to-benefit ratio of vaccination needs to be assessed carefully for other types of allergic reactions. For example, allergic reactions to thimerosal are characterized by a delayed-type hypersensitivity that most often results in a local inflamed or indurated lesion similar to that seen with positive reactions to tuberculin skin tests used to document infection with tuberculosis.[752] Even though the reaction may progress to vesiculation or ulceration, the reaction is not life threatening and can be managed with application of topical steroids. Current "preservative-free" influenza vaccines may contain trace amounts of thimerosal, but influenza vaccines containing no thimerosal are now available in many countries.

Vial stoppers or syringe plungers used for influenza vaccine can contain latex in the rubber composition, and concerns have been raised about reports of allergic reactions to latex rubber.[753] The contact surfaces of the rubber-containing parts are treated (usually with silicone) to reduce the possible introduction of latex rubber antigens into the vaccine. Nonetheless, latex antigens might still enter influenza vaccine by way of repeated needle insertions through the stoppers of multidose containers, because a needle puncture could entrain small bits of the stopper. In recognition of these concerns, some manufacturers use alternate elastomeric products that do not contain latex, and others are making changes. The risk of exposure and sensitization to latex in vaccines is very low, and this risk needs to be weighed against the potential benefit of vaccine.[754] Information regarding the latex content of container components can be found in the package insert written specifically for each vaccine.

Precautions for vaccination with influenza vaccination include moderate or severe acute illness with or without fever[755] and GBS within 6 weeks following a previous dose of influenza vaccine.

OTHER DIRECTIONS FOR INFLUENZA VIRUS VACCINES

IIVs are very safe and moderately efficacious. However, developing influenza vaccines that provide broader protection against heterotypic strains and more durable protection would substantially improve influenza prevention programs.

Live attenuated (cold-adapted) influenza vaccines are described in detail in Chapter 32. These vaccines were developed to elicit an immune response, including production of secretory IgA antibodies in the mucosal tissues of the respiratory tract that would be similar to the response that develops after natural infection while minimizing the symptoms associated with viral replication. Live attenuated influenza vaccines (LAIVs) have been used extensively in countries of the former Soviet Union since the 1980s. Use of LAIV in the United States has increased gradually since licensure in 2004, and has been particularly useful in immunization programs that focus on providing vaccination in schools and other mass vaccination settings.[11] Recently additional countries have approved the use of LAIVs and incorporated them into their immunization portfolios. Additionally, manufacturers in China, India, and Thailand have developed or are developing LAIVs, which should further expand their use.[387]

The use of mammalian cells to replicate influenza viruses for use in inactivated vaccine might provide several advantages, including the potential availability of a product for use by those who are allergic to eggs or egg proteins. Antigenic selection of viruses more adapted to avian cells often occurs when human influenza viruses are passaged in eggs but not when the same viruses are passaged solely in mammalian tissue culture. Therefore, it is also possible that human influenza viruses replicated only in mammalian tissue cultures will produce vaccines that are antigenically more similar to circulating viruses, increase production yield, and increase vaccine effectiveness.[328,331,375,377] Unlike other vaccines, influenza vaccine generally must be available for administration within 9 to 12 months after identification of a new vaccine virus, so that there is little time for investigating (and documenting) whether the seed virus is free of extraneous agents. The time pressure associated with the production and distribution of influenza vaccine, combined with the lack of field facilities that can maintain tissue cultures under conditions to prevent the introduction of extraneous agents are currently obstacles to using tissue culture isolates in influenza vaccine production. Because antigenic changes occurring in eggs appear to be irreversible, influenza vaccines produced in tissue cultures using seed viruses originally recovered in eggs are not expected to improve vaccine effectiveness. An infrastructure capable of supporting use of influenza viruses passaged only in mammalian tissue cultures is required to realize the full theoretical benefits. Thus far, clinical studies demonstrate that the immunogenicity and effectiveness of cell culture–derived vaccines can equal that of egg-derived vaccines and meet FDA immunogenicity criteria for licensure.[329,756,757] However, there remains uncertainty about whether cell culture–derived vaccines can substantially shorten production time, necessitate changes in potency testing and other licensure requirements, or present an unforeseen risk for vaccine contamination.[328,373]

High-growth influenza virus reassortants play a central role in facilitating the production of large quantities of influenza vaccine. However, it has not always been possible to produce high-growth reassortants with the desired characteristics using classical reassorting procedures, because these procedures rely on coinfection of two different viruses followed by selection of viral clones with specific genotypic and phenotypic traits. Reverse genetics methods provide a powerful tool to improve the ability to produce reassortants with the desired properties.[758,759] Recent reverse genetic systems relying only on transfection of cells with all genes needed to make a complete virus are now available, so that influenza A and influenza B reassortant viruses can be tailored specifically to growth substrates

such as eggs and mammalian tissue cultures. Reassortant viruses using reverse genetics techniques have been necessary for producing influenza A(H5N1) vaccine virus candidates, and these techniques are currently being used in the production of LAIVs.

Other strategies for producing influenza vaccine have taken advantage of recent advances allowing rapid sequencing of influenza virus genes as well as adjuvants and formulation that can deliver antigens for CD8 T-cell induction. For example, vectors containing influenza HA or NA genes have been used to infect tissue cultures in which the viral protein of interest (HA or NA) is produced in massive amount and can be purified for use as a vaccine. Clinical trials of purified HA or NA vaccines produced by using a baculovirus vector have demonstrated that such preparations can be standardized to produce immunogenic vaccines with reactogenicity profiles similar to the profiles of vaccines produced by viral replication.[337–339] Clinical studies demonstrated that baculovirus vector vaccines produce a similar immunogenicity profile as subvirion vaccines in adults,[340,760] and was approved by the FDA for adults 18 through 49 years of age.[761] The immunogenicity of Flublok was significantly lower compared to standard preparations in young children, although the immunogenicity and seroconversion and seroprotection rates were not inferior to egg-derived split vaccine in those 65 years of age and older.[452,762]

Noninfectious VLPs, consisting of key antigens such as HA and NA expressed in recombinant viral vectors and contained within particles expressed in insect or plant cell cultures that resemble wild-type viruses, have been shown to be immunogenic in animal and Phase I and Phase II clinical studies.[328,763–771] In healthy adults, pH1N1 VLPs without an adjuvant met all primary and secondary end points and showed seroconversion in 62.2% and 70.3% of participants, respectively, on day 21 and day 42. However, VLPs with Alhydrogel adjuvant showed seroconversion rates of 25.6% and 51.2% on days 21 and 42, respectively, and the reasons for the suppression could be because of altered HA antigen structure postadsorption or poor stability of HA with Alhydrogel.[772] Similarly, 2009pH1N1 VLP vaccine without an adjuvant induced seroconversion in 79% and 85% of recipients on days 14 and 36 postvaccination, respectively.[773] While these data suggest that VLPs vaccines may not require adjuvants to enhance their immunogenicity, results from a recent study with H7N9 VLPs indicate the requirement for an adjuvant as seroconversion rates of 64.9% and 80.6% were achieved with 5 μg of antigen together with 30 or 60 units of immunostimulating complex (ISCOM) Matrix on day 35 when compared to 9.5% seroconversion rate achieved with 45 μg of antigen alone in healthy adults.[774] Results from a Phase II dose-ranging clinical study assessing safety and immunogenicity of a quadrivalent VLP seasonal vaccine as compared to a standard IIV3 are awaited.

DNA vaccines, which are based on plasmids grown in bacteria containing the relevant viral gene(s), also have been investigated. Unlike the mammalian DNA, bacterial DNA contains unmethylated cytosine phosphate guanine (CpG) motifs which are known to stimulate the mammalian innate immune system via Toll-like receptor (TLR) 9. In animal models, DNA vaccines can stimulate both humoral and cellular immune mechanisms.[775] Although DNA vaccines could be relatively easy and inexpensive to produce and have been shown to have protective effects in animal models[775,776] and one small clinical study, progress has been slow on DNA vaccines for humans, in part because the immune response in humans has been relatively poor.[777,778] Specific CpG motifs in plasmid DNA have differential effects on the immune response, but additional work is needed to identify optimal motifs for immunogenic and protective effects in humans.[779–782] In a double-blind, randomized, placebo-controlled Phase Ib clinical trial, healthy adult subjects received 4 μg of trivalent influenza DNA vaccine and 2 μg of trivalent influenza DNA vaccine plus DNA-encoded heat labile toxin from *Escherichia coli* or placebo by epidermal route with a device. The subjects were then challenged on day 56 postvaccination with a H3N2 virus and were monitored for virus shedding by quantitative polymerase chain reaction (qPCR). The vaccine efficacy for the 4-μg dose was 41% and 53% for any illness with or without fever and upper respiratory tract infection, respectively.[778] In a double-blind, placebo-controlled Phase I study, healthy adults received two intramuscular injections of Vaxfectin-adjuvanted H5 HA or H5HA,NP and M plasmid DNA vaccine or placebo 21 days apart, either with a needle or with a needle-free device. No consistent enhancement with a needle-free device was observed. Seroconversion occurred in 47% to 67% of subjects reaching HI titers equal to or greater than 40. H5-specific T-cell responses were also detected in 75% to 100% of vaccine recipients.[783] Although these data are encouraging, improvements in plasmid vector design for enhanced expression in vivo, as well as efficient delivery methods with formulations, will take DNA vaccine strategies forward.

Replication-incompetent and replication-competent human and nonhuman adenoviral vectors have been investigated as an egg-independent strategy for seasonal and pandemic influenza in preclinical and Phase I/II clinical studies.[439,784–791] Adenovirus-vectored HIV, cancer, and Ebola vaccines have shown excellent safety profiles in human clinical trials.[786,792–794] This approach either alone or as a prime-boost strategy offers several advantages as they can be grown to very high titers in vaccine-certified cell lines, can be delivered by parenteral, mucosal or transdermal routes, and overcome poor immunogenicity of antigens.[439,785,793] In addition, HA and NA from multiple strains can be delivered with a single vector to generate a broader immune response against multiple strains.[795] Unlike the conventional split or recombinant protein antigens, adenovirus-vectored vaccines induce effective humoral and cellular immune responses against the antigens of interest. Hence, adenovirus-vectored influenza vaccines containing conserved internal proteins or epitopes is a potential approach for developing universal influenza vaccines. Preexisting adenovirus-vector immunity can be overcome by alternate delivery routes or use of nonhuman adenovirus-vectors.[790,793] A recent Phase I clinical study with a replication competent adenovirus-vectored vaccine delivered orally primed vaccinees for a subsequent boost with a H5N1 vaccine; this prime-boost approach induced broadly cross-reactive humoral and cellular immune responses against other clades.[786,796]

"Universal" Vaccines

The diversity of influenza virus subtypes and the time pressures for production of vaccines based on HA content have prompted a renewed effort to develop vaccines with broad protective effects by way of innate and adaptive immune responses against the conserved influenza viral proteins. Approaches to develop universal influenza vaccines primarily concentrated on determining the conserved proteins/epitopes of influenza that are accessible to immune recognition so that humoral and/or cellular immune response can confer protection against severe disease and death.

Universal influenza vaccines in development include those targeting the influenza NP, M1, and HA proteins.[145,328,797] The ectodomain of M2 (M2e) is very highly conserved among influenza A strains. It has been shown that passive transfer of monoclonal antibody against M2 reduced viral replication

against challenge in mice but did not prevent infection.[798] In subsequent preclinical studies, mice immunized with M2e with hepatitis B core protein as a particle or synthetic peptides or VLPs with or without adjuvant induced antibody responses against M2e and protected mice against death, but not from infection and illness in virus-challenge models.[799–802] Because M2e is expressed in very low amounts on the surface of viral particles but is abundantly expressed in virus-infected cells, M2e vaccines may not be able to prevent infection, but could aid in reducing morbidity as well as assist in viral clearance via antibody-dependent cell-mediated cytotoxicity (ADCC) or complement-mediated death mechanisms. Indeed, a requirement for Fc receptors and alveolar macrophages for M2e antibody-mediated protection has been reported.[803] In a Phase I clinical trial, participants received two doses, on days 0 and 28, of 0.3, 1.0, and 3 μg of recombinant fusion protein consisting of four tandem copies of M2e attached to flagellin, a TLR5 ligand that is known to function as an adjuvant. All these doses were found to be safe and well tolerated, although the 10 μg dose of candidate vaccine tested originally was found to be reactogenic. After one dose, the seroconversion rates (fourfold increase) ranged from 63% to 72% in subjects who received 0.1 or 1 μg of antigen, which increased to 75% and 100% after two doses, respectively.[804] However, it is not clear if the antibody levels induced are protective.

Influenza NP protein is well conserved and NP-specific CD8 T-cell responses cannot prevent virus infection, but do aid in viral clearance and death.[805] In a number of preclinical studies, NP– DNA vaccine, Adeno-NP, or modified vaccinia virus (MVA)-NP generated NP-specific CD8 T-cell responses that conferred protection against challenge with heterosubtypic viruses.[806–814] In a series of Phase I clinical trials both in healthy adults and older adults, MVA-based influenza vaccine candidates expressing the internal proteins NP+M1 were shown to be safe and well tolerated and to induce/recall potent CD8 T-cell responses.[815,816] When challenged with A/Wisconsin/67/2005 virus, 2 of 11 vaccinees and 5 of 11 control subjects developed influenza symptoms and virus shedding; however, the symptoms were moderate and of shorter duration in vaccinees when compared to the control subjects.[817] Furthermore, in both preclinical and Phase I clinical studies, coadministration of MVA-NP+M1 with seasonal influenza vaccine enhanced antibody responses to the seasonal vaccine and enhanced CD8 T-cell responses.[818,819] In a preclinical study, mice were immunized with an MVA-vector expressing NP, an internal protein that is well conserved among influenza A viruses, the stem region of HA, matrix proteins 1 and 2, the viral polymerase basic protein 1, or the HA stem fused to a quadrivalent matrix protein 2 extracellular domain. When challenged with a lethal dose of H5N1, H7N1, or H9N2 viruses, only MVA-NP conferred significant protection, which correlated with the induction of CD4 and CD8 T-cell responses. Other conserved proteins did not provide substantial protection when administered alone.[820]

Synthetic recombinant peptide vaccines[821–823] consisting of conserved sequences from HA, NP, and M1, which were delivered with adjuvants such as flagellin, as monomers or multimers, induced cross-reactive antibody and T-cell responses and conferred protection against heterosubtypic challenge in animal models.[821–826] In a Phase I clinical study, 60 subjects received either 250 or 500 μg of synthetic recombinant vaccine containing conserved linear epitopes from the HA, NP, and M1 proteins of influenza type A and influenza type B strains twice at 21-day intervals with or without Montanide, a mineral oil–based adjuvant. The vaccine was well tolerated and sera from vaccinees lysed MDCK cells infected with several strains of influenza viruses in the presence of rabbit complement, indicating that the sera from vaccinees bound to the viral antigens expressed on the infected MDCK cells that were subsequently lysed through complement-mediated death. Furthermore, vaccine-specific T-cell proliferative responses and cytokine secretion was observed in peripheral blood mononuclear cells from vaccinees.[827] In a subsequent randomized, placebo-controlled study, the priming ability of this vaccine in the induction of immune response to IIV3 was evaluated in 120 older-adult participants. Priming with synthetic recombinant vaccine with or without alum resulted in enhanced seroconversion for all three IIV3 strains as well as for strains not contained in the IIV3, compared to priming with placebo. In addition, synthetic recombinant vaccine induced significant levels of T-cell responses that were further augmented following incubation in vitro with IIV3.[828] These findings suggest that this vaccine candidate has the potential to be used as a standalone universal influenza vaccine as well as together with IIV3 to broaden immune responses against several influenza viruses of different HA types in addition to the three strains contained in the vaccine, as the vaccine candidate contains conserved common linear influenza epitopes of both A and B viruses.

Unlike the globular head domain (mainly HA1) of HA which is subject to antigenic drift, the stalk domain, consisting of a part of HA1 and all of HA2 is highly conserved. Furthermore, antibodies with specificity against this region have shown crossreactivity against several heterologous HAs.[145,311,474,829] Passive transfer of these antibodies conferred protection against lethal challenge in animal models.[311,830] These antibodies may function by preventing membrane fusion and through ADCC activity and complement-mediated lysis. Hence, this region has attracted attention for developing a universal influenza vaccine. Indeed, mice immunized twice with plasmid DNA expressing headless stalk and subsequently boosted with VLPs containing recombinant stalk domain conferred protection against death in a lethal challenge model. However, the mice did exhibit morbidity, suggesting that antistalk antibodies may not prevent infection, but reduce disease severity.[831] Antistalk antibodies are rarely found in humans and are not generally induced by vaccination.[832] However, antistalk antibodies are found in humans who were vaccinated with 2009pH1N1 or H5N1 vaccine, suggesting that a unique head-and-stalk combination generates antistalk antibodies that are broadly cross-reactive.[833,834] This observation was confirmed in animal studies in which mice were immunized sequentially with unique heads from H9, H6, and H1, but the same stalk from Group 1 HA resulting in stalk-specific antibody responses, which conferred protection against challenge with H5N1 virus that belongs to Group 1 HA.[835] A human clinical trial with influenza vaccines that have chimeric HA from H5 and H8 with the same stalk is currently planned using a prime-boost immunization regimen.[836]

Pandemic Vaccines and Novel Influenza A Vaccines

In addition to annual seasonal influenza vaccine development and production to address the risk of antigenically drifted seasonal viruses, a public health imperative exists to prepare vaccination strategies to address the emergence of novel influenza A viruses with pandemic potential.[837–839] Pandemic vaccine preparedness faces several challenges. First, the inherent unpredictability of influenza viruses together with the need to elicit subtype specific immunity through vaccination, makes creation of inactivated pandemic vaccines in advance of a pandemic risky. While vaccine stockpiles have been proposed and created by several governments that are meant to speed delivery of vaccine to key target groups early in a pandemic, continued evolution of avian and swine influenza A

viruses that pose the greatest threat, make stockpiled vaccine potentially less useful, as the risk of mismatch between vaccine and circulating strains grows over time.[50,840] For instance, stockpiled vaccines prepared using Clade 1, 2.1, 2.2, and 2.3 avian influenza A(H5N1) viruses early following their emergence, are increasingly antigenically different from contemporary H5N1 viruses.[386] This challenge has been addressed both by continual risk assessment and updating of vaccine strains using contemporary strains and by planning for the use of adjuvants to enhance immune responses to potentially heterotypic exposures. A second challenge is the production time required to produce adequate doses of vaccines to meet the rapid spread of pandemic viruses. Because inactivated vaccines require several months to produce, they might have limited utility to prevent illness during the initial wave of disease in many countries. This was evident during the 2009 influenza A(H1N1) pandemic, during which a safe and effective vaccine was rapidly developed, and hundreds of millions of vaccine doses were manufactured and administered within 8 months of the identification of the first human infections with the novel H1N1 virus.[255,390] Even so, most countries experienced the peak of their pandemic wave before the vaccine was widely available. Prepandemic stockpiles of vaccines are one solution to a rapid vaccine response. In addition, streamlining current inactivated vaccine production steps, preparedness plans that accelerate policy, regulatory and distribution hurdles, and new vaccine technologies (e.g., recombinant antigen vaccines) are active areas of work and collaboration between public health and industry partners. Finally, effectively immunizing humans who are immunologically naïve to novel strains requires either higher doses of vaccine, more than one dose, or adjuvants to generate protective immune responses. This challenge has highlighted the need for greater production capacity to meet higher dosing needs and global needs, the value of adjuvant development and approvals, and potentially new vaccine approaches.[386,839]

Finally, the manufacture of vaccines from pathogenic avian influenza viruses by traditional methods is not feasible for safety reasons as well as technical issues. Strategies adopted to overcome these include the use of reverse genetic systems to generate modified recombinant strains,[841] the use of baculovirus-expressed HA or related nonpathogenic avian influenza strains and the use of adjuvants to enhance immunogenicity.[328] Following the emergence of highly pathogenic avian influenza H5N1 viruses in humans in 1997, two vaccine strategies were developed to overcome these limitations. One approach was to use a "surrogate" apathogenic H5 vaccine strain that was antigenically related but not identical to the highly pathogenic avian influenza H5N1 strain, overcoming the need to grow and purify a vaccine under high containment conditions. A surface-antigen vaccine based on the apathogenic A/duck/Singapore/97 (H5N3) virus, which possessed an HA that was antigenically similar to A/Hong Kong/156/97 (H5N1), was administered with or without MF59 adjuvant in two doses of 7.5, 15, or 30 μg of H5 HA given 3 weeks apart.[413] Although both vaccines were well tolerated, the nonadjuvanted vaccine was poorly immunogenic, with only 36% of persons demonstrating a fourfold rise in antibodies after two 30-μg doses of vaccine. Individuals who received the H5N3 vaccine formulated with MF59 adjuvant achieved significantly higher antibody responses with a majority of individuals showing seroconversion to the vaccine strain. Follow-up revaccination 16 months later, using the same vaccine formulation substantially boosted antibody titers in those receiving the adjuvanted, but not the nonadjuvanted, vaccine.[842] Boosting with the adjuvanted 1997 H5N3 vaccine, but not the nonadjuvanted vaccine, also induced cross-reactive antibodies against H5N1 strains isolated from humans in 2004.[843] These results suggested that the use of adjuvants may not only be beneficial for dose-sparing of vaccine, but also for enhancing the cross-reactivity of the antibody response. Another approach relied on production of a baculovirus-expressed purified H5 HA protein based on the HA gene cloned from the prototype H5N1 strain, thus overcoming the need to grow large quantities of virus in eggs. Previous clinical trials had determined that responses to doses of 15 to 45 μg of recombinant H1 and H3 antigens in primed populations were similar to those induced by licensed inactivated vaccines.[844] However, in an unprimed population, even the highest dose (two doses of 90 μg) of the baculovirus-expressed recombinant H5 vaccine elicited seroconversion in only 52% of subjects as measured by a microneutralization assay.[845]

When H5N1 viruses reemerged in humans in 2003–04, a surrogate low pathogenicity H5 subtype virus that was antigenically closely matched with the circulating H5N1 strains was not identified. Therefore, seed viruses for the production of experimental H5N1 vaccines were generated from human H5N1 isolates using the plasmid rescue system, also known as reverse genetics technology.[846] This process had first been used to generate reassortant vaccine candidates based on the HA and NA genes from H5N1 strains isolated from humans in 1997 and either the internal protein genes of the A/Ann Arbor/6/60 *ca* vaccine donor virus[847] or PR8, the high-growth donor for inactivated vaccines.[848] In this process, the H5 HA gene is genetically modified to remove the multibasic amino acid motif associated with pathogenicity for chickens, such that the resulting reassortant vaccine strain is avirulent for experimentally infected chickens, and is attenuated in mammalian species.[849] Neither of the 1997 H5N1 reassortant vaccine candidates was evaluated in humans. A plasmid rescue-derived subvirion vaccine based on A/Vietnam/1203/2004 (H5N1) virus was evaluated in 450 healthy adults receiving two doses of 7.5, 15, 45, or 90 μg of antigen. The frequency of serum antibody response was highest among subjects receiving two doses of 90 μg; 54% of individuals receiving this vaccine dose achieved neutralizing antibody titers of 1 : 40 or greater and did not suffer severe side effects.[48] In another study, an inactivated split vaccine based on A/Vietnam/1194/2004 (H5N1) and administered in two doses of 7.5, 15, and 30 μg, with or without aluminum hydroxide adjuvant, was evaluated in 300 healthy adults. The adjuvanted 30-μg formulation was safe and induced the highest rate of response (67%) after two vaccinations (compared with 52% among persons who received the 30 μg dose without adjuvant).[437]

In a study of a lipid-based adjuvanted H5N1 vaccine, using a recombinant reverse-genetics engineered seed virus, 400 adults 18 to 60 years of age were randomized to receive two doses of either 3.8, 7.5, 15, or 30 μg antigen vaccine with or without the adjuvant. The immune response was substantially higher in the group who received the adjuvant even at the lowest antigen dose; 66% and 86% of those who received the adjuvanted 3.8-μg dose vaccine seroconverted after one and two doses compared with 14% and 22%, respectively, among those who received the nonadjuvanted 3.8-μg dose, and 57% and 65% among those who received the nonadjuvanted 30-μg dose vaccine. However, reactogenicity (arm soreness and redness, fatigue, and headache) were significantly more common in those receiving the adjuvanted vaccine.[850] In clinical studies, humoral responses against the adjuvanted 3.8-μg dose vaccine fulfilled licensure criteria for immunogenicity for influenza vaccines for adults and 3- through 8-year-old children,[851,852] and the 1.9-μg dose was immunogenic in 6- to 23-month-old children.[429] Studies using aluminium or MF59 adjuvanted vaccines have also demonstrated potential for dose sparing and broad immune responses that include antibodies that might provide better cross-protection against heterotypic

viruses compared to unadjuvanted vaccines.[853,854] Adjuvanted vaccines also appear to promote broad and persistent cross-clade immunity, which could make them candidates for a prepandemic vaccine.[855] Taken together, these studies confirmed previous findings suggesting that very high doses of unadjuvanted H5 vaccine are needed to elicit antibody responses in a majority of subjects, and that addition of an adjuvant may allow for some level of dose-sparing, cross-protection against other subtypes, and possibly a reduction in the number of doses required. In addition, persons primed with the adjuvanted vaccine exhibited much better response to a heterologous antigen (different H5N1 clade) when boosted 14 months later.[856] An MF59-adjuvanted H5N1 Clade 1 vaccine used to provide a booster dose to persons who had received an H5N3 Clade 0 vaccine 6 years earlier was able to elicit a substantial increase in antibody levels to both H5N1 Clade 1 and Clade 2.2 antigens. The booster response was higher among subjects who had been primed with the adjuvanted H5N3 vaccine.[857] A recent study found that persons previously vaccinated with a Clade 1 strain who were then boosted with a Clade 2 strain had higher HI antibody titers against the Clade 2 virus than subjects who received two doses of the Clade 2 strain vaccine.[857a]

Currently, two H5N1 vaccines are approved by the FDA. Both were prepared under contracts with the U.S. Department of Health and Human Services for stockpiling in advance of a pandemic. One is an unadjuvanted inactivated vaccine based on a Clade 1 H5N1 virus (A/Vietnam/1203/2004) and is two 90-μg doses 28 days apart.[858] The vaccine elicited both a fourfold or greater rise in antibodies and an HI titer of greater than 1:40 in 43% of recipients compared with 0% among placebo recipients.[858] The second, approved in November 2013, contains 3.75 μg of the HA of the influenza virus strain A/Indonesia/05/2005 (H5N1) and the AS03A adjuvant (11.86 μg tocopherol).[859] The vaccine is given intramuscularly in two doses 21 days apart and approved for persons 18 years of age and older who are at increased risk of exposure to the influenza A virus H5N1 subtype contained in the vaccine. In an immunogenicity study of this vaccine, 92% of subjects had an HI titer of greater than 1:40 and 87% had a fourfold or greater rise in antibodies against the vaccine strain 21 days postvaccination.[860] At 6 months postvaccination, 62% of the subjects had titers of at least 1:40. These results were similar to antibody responses found in nonplacebo controlled trials.[851,861,862] Heterologous responses (to currently circulating strains and strains in vaccine development) vary greatly.[860] The safety data from these studies demonstrated no severe adverse events; the studies were too small to yield data on uncommon disorders such as narcolepsy.[851,860–862] In addition, 29 vaccine candidate viruses have been developed and four more are in development, highlighting the great diversity and continuing evolution of these viruses.[863] Neither approved vaccine is currently recommended for interpandemic use, either to prevent H5-associated disease among exposed persons (e.g., laboratory workers) or as a priming dose for future exposure to similar pandemic viruses. Data on vaccine efficacy are not available for either vaccine. In 2013, WHO's SAGE Working Group on Influenza Vaccines and Immunizations developed global recommendations for use of licensed H5N1 vaccine during interpandemic periods. In these recommendations, vaccine is strongly recommended for laboratory workers involved in certain high-risk activities, such as large-scale production with virus. Vaccine is also recommended for first responders and healthcare workers managing patients, but not recommended for persons who may only potentially come into contact with infectious animals, workers in areas where the virus is enzootic, or the general population.[840]

In addition to H5N1 vaccines, substantial work has focused on H7N9 vaccines following the emergence of this virus as a human threat in 2014 in China. Immunogenicity studies of inactivated vaccines and VLP vaccines with and without adjuvant have been conducted. Like previous avian influenza vaccines, the studies have demonstrated that unadjuvanted vaccines are poorly immunogenic and that two doses are required to maximize immune responses. In a U.S. study, most subjects had a significant immune response, with better immune responses among those that received vaccine with AS04 adjuvant than with MF59.[864] The responses were not dose-dependent and 86% of subjects that received two 3.75-μg doses had a fourfold rise in antibodies against the vaccine strain measured by HI. Similar findings were observed in another multicenter trial in the United States, in which MF59-adjuvanted vaccines generated seroconversion in 59% of participants.[865] Finally, a recent study of a H7N9 VLP vaccine candidate using ISCOMATRIX adjuvant observed seroconversion in more than 60% of subjects, but, again, poor immune responses in the absence of adjuvant.[774]

Avian influenza H9 and other H7 subtypes have also caused disease in humans, as have swine viruses (especially H3N2 variant viruses), leading to vaccine development for several of these strains.[432,866–869] In addition, the 2009 H1N1 pandemic demonstrated that the appearance of antigenic variants of HA subtypes that currently circulate in humans, or subtypes that circulated before a substantial fraction of the current population was born, can cause a pandemic. For example, because H2N2 viruses circulated in humans from 1957 until 1968, individuals born after this time lack immunity to the H2 subtype and are therefore a susceptible population for reintroduction of the H2 subtype.[870] Because of the continually changing and emerging group of zoonotic influenza viruses and the accompanying potential risk to humans, an iterative process to assess the risk associated with novel influenza viruses has been established among global partners, that results in updated candidate vaccine development and vaccine trials.[871] In addition, rapid models to understand the possible impact of novel influenza A vaccines have been developed that will aid in decision making regarding investments and policy.[872] Vaccines will continue to be a central part of global pandemic plans.

PUBLIC HEALTH CONSIDERATIONS

Global Vaccination Efforts

Substantial progress has been made in the past decade toward expansion of the use of seasonal influenza vaccines worldwide. Several factors have contributed to this progress. First, the emergence of avian influenza A(H5N1) viruses in Asia and their westward expansion provided the impetus among countries to develop plans for pandemic vaccine use. These plans have been facilitated by WHO's Global Action Plan for Influenza Vaccines (GAP).[387] The GAP strategic plan was based on the principle that pandemic vaccination implementation must be founded on a robust national seasonal vaccination program. Second, the 2009 pandemic was both an illustration of the progress in national program development and the work still to be done in most countries. Finally, the updating of the WHO SAGE recommendation in 2012 served as a catalyzing force for low-income and middle-income countries.[245] This is evidenced in the Americas, which has observed an expansion of vaccination programs.[12] While fewer low-income countries outside the Americas have begun vaccination, the example of Lao People's Democratic Republic (Laos) in introducing vaccine as a collaboration with the Partnership for Influenza

Vaccine Introduction has provided a possible pathway for other low-income countries.[748]

Further expansion of vaccine use globally will require lower cost or subsidized vaccines, greater data on the value of vaccines in low-income settings, information on the optimal timing of vaccination in tropical and subtropical countries,[872a] data on vaccine performance in some key populations (such as immunocompromised persons), compelling data on cost effectiveness, and methods to overcome programmatic challenges in targeting noninfant populations. New vaccines that need not be given each year and which might elicit more broadly reactive immune responses, will expedite willingness of many countries to expand vaccination.

Vaccination Coverage Levels

Worldwide

Although WHO has recommended influenza vaccination for high-risk groups and healthcare workers in all countries,[245] national programs for influenza vaccination are primarily in place in high-income and middle-income countries. WHO has urged member states with influenza vaccination policies to increase vaccination coverage of all people who are at high risk, setting goals in 2003 that were not reached, including vaccination coverage of elderly people of at least 50% by 2006 and 75% by 2010.[873] Few countries have achieved these goals. Even so, expansion of vaccine target groups and increases in vaccine coverage levels have been made in many countries in the past decade. In Latin America, national influenza immunization programs were present in 35 countries in the region in 2008, compared with 13 countries in 2004.[12] In addition, these countries expanded vaccination to cover pregnant women and children as well as the traditional target groups of the elderly and healthcare workers. Finally, the region used enhanced surveillance data to switch several Central American countries from the Northern hemisphere formulation to Southern hemisphere formulation to better fit the seasonality of influenza in the region. Growth in policies and target groups have also been reported in the Asian Pacific region, although less so among the low-income countries in the region.[16,244]

As countries expand policies for use of seasonal vaccines, global production has increased as well, as have the number of manufacturers who make or plan to make vaccine. Growth of vaccine production capacity was estimated to have increased from 876 million doses of trivalent influenza vaccine in 2009 to 1.42 billion doses in 2011; although substantially fewer (1.029 billion) were produced that year.[874] An industry survey estimated that doses of vaccine distributed increased by 87% between 2004 and 2011.[16] In this study, only 3.7% of doses were distributed in the WHO regions representing many of the low-income countries in Africa, South Asia, and the Middle East. However, a follow-up study demonstrated a slowing expansion of vaccine distribution. Between 2008 and 2013, a 12% increase in doses distributed was observed; during this period, however, a 32.5% decrease in doses distributed was observed in Europe.[875] Nearly all the world's vaccine production capacity is contained in the Western Europe, Western Pacific, and North American WHO regions, but the WHO GAP program might expand production in other regions.[389,390]

Vaccination programs capable of delivering annual influenza vaccination to a broad range of the population could potentially serve as a resilient and sustainable platform for delivering vaccines or other medical assistance, and monitoring outcomes for other urgently required public health interventions. Seasonal vaccination programs have also been promoted as a tool for pandemic preparedness.

United States

In the 2015–16 influenza season, overall vaccine coverage in the United States was estimated to be 46%; 42% among adults and 59% among children 6 months to 18 years of age.[876] Rates of vaccination in the United States have steadily risen in the last decade, particularly among children. Between 2004 and 2012, vaccination rates among children rose from 16% to 47%, with the expansion of vaccination recommendations from young children to all children during this time.[877] Rates are highest among children 6 to 23 months of age, among whom 75% are vaccinated.[876] No gender differences in vaccination rates have been observed in children, but rates remain lower among socioeconomically disadvantaged populations.[876,878]

Among adults, rates are highest among persons 65 years of age and older. Between 1989 and 1999, vaccination rates in this group rose from approximately 33% to 66% and have remained stable except for a small decrease noted during the 2015–16 season.[11] In the 2015–16 influenza season, 63% of this group was vaccinated, compared with 36% of 18- to 64-year-olds.[876] Among nonelderly adults, persons with at least one high-risk condition are more likely to be vaccinated (46%) than those without a high-risk condition (34%), a trend seen in previous years as well.[879] Like children, racial differences in influenza vaccination rates remain.

Vaccination of specific risk groups have made some gains in recent years. Among pregnant women, rates increased from 11% in 2001 to 38% to 50% in 2011, in large part because of the recognition of risk of severe outcomes during the 2009 pandemic.[880] The most recent estimate in this group from the 2014–15 influenza season was 50%[881]; few gains have been made since the pandemic year. Increases in vaccination rates in healthcare workers have been observed in recent years, in some part because of greater access to vaccination in the workplace and to workplace requirements in some healthcare settings. In 2014–15, 77% of healthcare workers were vaccinated, with highest rates among physicians, nurses, and pharmacists.[882]

Efforts to increase vaccine uptake in the United States have included efforts to ensure that persons coming into clinics during influenza season receive an offer of vaccine, use of client reminder/recall systems,[883,884] and expanding access in pharmacies, workplaces, and schools.[885] In addition, communicating the impact of influenza vaccination on reduction of severe disease risk and overall number of hospitalizations may help put the value of influenza vaccine in context.[26]

Disease Control Strategies

In contrast to control efforts for some diseases, the primary goal of influenza vaccination programs is to reduce the number of serious complications, including deaths, resulting from influenza infections. In most countries, the primary focus of prevention strategies has been to vaccinate those at highest risk for complications as well as their close contacts, reflecting knowledge that influenza exerts a disproportionately severe impact on the elderly, those with chronic medical conditions, and the very young. Even in the United States, where all persons 6 months of age and older are recommended to receive vaccine, one rationale for universal recommendations was that it would be simpler to communicate than a risk-based policy, thereby increasing vaccine coverage among vulnerable populations. In addition, until recently there were practical limitations (e.g., vaccine supply and program infrastructure) on trying to vaccinate entire populations annually. As part of pandemic preparedness and also in response to the 2009 H1N1 pandemic, these barriers have been reduced, with

large-scale investments in vaccine development, manufacture, and, to a lesser extent, immunization programs. However, there is increased interest in achieving these goals both through vaccination of persons at risk and by reducing community transmission through increased overall vaccine coverage among all persons. In addition, the identification of newly recognized risk factors for illness (e.g., morbid obesity, aboriginal persons such as Native Americans) and a growing appreciation of the burden of illness among healthy older children and younger adults has led to a recommendation to vaccinate all persons in the United States, and incrementally expanding recommendations in many other countries.

The recommendation to vaccinate persons 6 months of age or older annually in the United States in 2011 has led to some gains in vaccine coverage, and resulting reduction in disease outcomes.[27] Other governments have attempted annual vaccination of large portions of the population, including the Japanese vaccination programs conducted between 1962 and 1987 that focused on immunizing children,[657] and more recent efforts in Ontario, Canada to provide universal influenza vaccination to its population.[660] Although it might be assumed that high vaccine coverage within communities would lead to reduced community transmission and reductions in severe influenza-related outcomes, no large prospective study has yet convincingly demonstrated that vaccinating entire populations, or epidemiologically important subpopulations such as school-age children, will provide significant protection against influenza-related complications (e.g., death or hospitalization) for other groups. Showing significant reductions in influenza-related complications has been difficult because of the yearly variability of influenza epidemiology, the infrequent use of specific laboratory testing that could serve as the source of reliable surveillance data, the need to study a large population to capture enough severe outcomes, and the relatively low coverage achieved in areas where universal vaccination has been recommended.

Eradication or Elimination, If Feasible

Influenza cannot be considered an eradicable disease for several reasons. Most important, avian species are the natural host to influenza A viruses, and certain other animal species, particularly swine, also can support the circulation of some influenza A virus subtypes. Eradicating circulation of influenza A viruses among all animal species capable of hosting them is impossible. Furthermore, the ability of influenza viruses to rapidly change their antigenicity, the need to update vaccines frequently, and the level of effectiveness of influenza vaccine are insurmountable practical barriers to ever administering enough vaccine quickly enough to eliminate influenza virus circulation among human populations.

32 Influenza Vaccine—Live

Catherine J. Luke, Seema S. Lakdawala, and Kanta Subbarao

Influenza viruses cause recurrent and widespread disease in humans. Vaccination is the most effective means of preventing influenza infection. The use of inactivated influenza virus vaccine (IIV) in humans has been the subject of numerous studies, with an emphasis on providing an effective vaccine with minimal reactogenicity. An alternative approach to influenza immunization using live attenuated virus administered by nasal spray has been successful. This chapter reviews the research that led to the licensing of the live attenuated influenza vaccine (LAIV) in the United States, and the clinical experience with LAIV since licensure. In this chapter, inactivated influenza vaccines are generally referred to as IIV or in specific instances as trivalent inactivated vaccine (TIV). More extensive background information on influenza can be found in Chapter 31 on inactivated influenza vaccines.

WHY THE DISEASE IS IMPORTANT

Influenza viruses are the most common cause of lower respiratory tract infections. The number of cases of influenza that occur varies depending on the susceptibility of the population to the virus and the infectiousness of the virus during an outbreak. In addition, influenza seasons vary in length and severity. In the United States, an estimated average of 36,000 deaths were associated with influenza epidemics between 1990 and 1999, and approximately 226,000 hospitalizations between 1979 and 2001[1,2]; approximately 90% of the deaths attributed to influenza occurred among persons age 65 years or older.[3,4] In 2010, the Centers for Disease Control and Prevention (CDC) released revised estimates for influenza-associated deaths from 1976 to 2007 that ranged from approximately 3000 to 49,000 per year.[4] Influenza type A infection occurs most frequently and is responsible for the greatest amount of morbidity and mortality. Although influenza B does not cause pandemics, it is responsible for regional epidemics that are generally less severe than influenza A epidemics.

Influenza incidence rates vary with the nature of the epidemic virus strains and the population affected. Rates calculated from surveillance of persons with upper respiratory illness suggest that influenza is responsible for roughly 10% to 20% of all respiratory illnesses per epidemic year,[5,6] with rates for influenza A being somewhat higher than those for influenza B. Most studies have found infection rates in preschool- and school-age children to be much higher than in adults, particularly during influenza B epidemics.[5–8] Consequently, families with school-age or younger children suffer disproportionately from influenza.[7,9] These findings support the ideas that influenza infects persons with the lowest prior immunity and that children are a common source of influenza in the community.

INFLUENZA

Influenza viruses are spread from person to person primarily via coughs and sneezes of infected persons. The incubation period for influenza is 1 to 4 days, with an average of 2 days.[10] Adults and children are typically infectious from the day before symptoms appear, until approximately 5 days after illness onset. Children can be infectious for a longer period, and very young children can shed virus for up to 6 days before symptom onset. Severely immunocompromised persons can shed virus for weeks.

Uncomplicated influenza illness is characterized by the abrupt onset of systemic and respiratory signs and symptoms (e.g., fever, myalgia, headache, severe malaise, nonproductive cough, sore throat, and rhinitis). Respiratory illness caused by influenza is difficult to distinguish from illness caused by other respiratory pathogens on the basis of symptoms alone. Sensitivity and predictive value of clinical definitions can vary, depending on the degree of cocirculation of other respiratory pathogens and the level of influenza activity.

Influenza illness typically resolves after a few days, although cough and malaise can persist for more than 2 weeks. Influenza can exacerbate underlying medical conditions (e.g., pulmonary or cardiac disease); lead to primary influenza viral pneumonia, or to secondary bacterial pneumonia; or occur as a coinfection with other viral or bacterial pathogens. Influenza infection is also associated with encephalopathy, transverse myelitis, Reye syndrome, myositis, myocarditis, and pericarditis.

Multiple mechanisms provide resistance to influenza in humans.[11,12] Acquired immunity to influenza is mediated by serum antibodies, antibodies at mucosal surfaces, and influenza-specific T cells. Antibody alone is sufficient for protection, and T cells play a role in recovery. Innate immune responses, such as production of interferon or other antiviral factors by macrophages, may also contribute to resistance to influenza infection. Immunity after natural infection provides long-lived protection against influenza virus infection and disease in the absence of antigenic shift or drift. This effect was illustrated during the 1977 influenza season, when H1N1 viruses reemerged after a 20-year absence. Epidemiologic surveys revealed that, compared with persons born after 1955, persons born before 1955 had a lower influenza attack rate in 1977. It is presumed that prior exposure to H1N1 strains in the 1950s conferred immunity to the nearly identical strains that appeared in 1977. In 2009, when the swine-origin H1N1 pandemic influenza virus (H1N1pdm09) emerged, older adults who had prior exposure to antigenically related H1N1 influenza viruses were found to have cross-reactive antibodies to the pandemic virus,[13] and disease was not as severe in this age group as in younger adults.[14,15] The H1N1pdm09 strain has replaced previously circulating seasonal H1N1 viruses, so in this chapter, H1N1 viruses isolated after 2009 are referred to as H1N1pdm09. Immunity acquired by natural infection can also provide some protection against influenza strains that have undergone antigenic drift.

VIROLOGY

Because of the complexity of the subject, it is beyond the scope of this chapter to address all aspects of influenza virology. For a comprehensive review of the biology of influenza viruses, the reader is directed to other texts.[16,17]

Orthomyxoviruses have segmented, single-stranded, negative-sense RNA genomes. Influenza A and B viruses have

TABLE 32.1 Products of Influenza A and B Virus Genes

RNA	Gene Products	Functions
1	PB2	Viral polymerase component, binds to cellular 5′ host premessenger RNA cap
2	PB1	Viral polymerase component with RNA transcription and replication activities
	PB1-F2	Viral protein produced by overlapping reading frame with proapoptotic functions
3	PA	Viral polymerase component with RNA and DNA endonuclease activity
4	HA	Virion surface attachment and fusion glycoprotein; major antigenic target
5	NP	Major component of ribonucleoprotein and type-specific antigen
6	NA	Virion surface glycoprotein with sialic acid cleavage activity, major antigenic target
	NB	Glycoprotein membrane ion channel found only in type B influenza
7	M1	Membrane matrix protein and type-specific antigen
	M2	Nonglycosylated membrane ion channel, found only in type A influenza
8	NS1	Viral nonstructural protein that modulates cellular host responses
	NS2/NEP	Nonstructural protein involved in nuclear export of viral RNA

eight RNA segments that encode at least 10 proteins (Table 32.1): hemagglutinin (HA), neuraminidase (NA), three polymerase proteins (PA, PB1, and PB2), nucleoprotein (NP), nonstructural protein 1 (NS1), nuclear export protein (NEP), and matrix proteins (M1 and M2 in influenza A; M1 and BM2 in influenza B). A second open reading frame in the PB1 gene encodes the PB1-F2 protein. The protective antibody response is directed at the two major surface glycoproteins, HA and NA. Influenza A viruses exhibit both antigenic drift[18] and antigenic shift,[19] whereas influenza B viruses show only antigenic drift.[20] Antigenic drift is caused by point mutations in the HA and NA genes that are driven by immune pressure and the infidelity inherent in the replication of RNA genomes. Although not subject to antigenic change, other genes also undergo mutational drift.[20] The rate of drift can vary among genes and viral subtypes.[21–24] Antigenic shift, however, requires complete replacement of one or both of the surface glycoprotein genes and is a consequence of the segmented genome of influenza viruses. During mixed infections, gene segments from two parent viruses can reassort to generate a virus with a novel gene constellation.[25,26] New antigenic changes, occurring by either mechanism, allow the virus to overcome existing immunity in previously infected hosts.

PATHOGENESIS AS IT RELATES TO PREVENTION

The pathology caused by influenza virus has been reviewed extensively.[27–30] Epithelial cells in the upper airway are most likely the primary site of infection.[31] Bronchitis and tracheitis are common,[32] and there may be some lung involvement.[33] Otitis media is common in children. Viremia has been reported only sporadically[34,35] amid numerous negative reports.[36–38] Influenza B demonstrates pathology similar to that of type A and is common in children. Influenza in humans is usually restricted to infection primarily of the upper respiratory tract and trachea, although, during severe influenza, lung lesions may occur.[39] The amount of virus present probably determines the extent and severity of symptoms.[40,41]

The most precise diagnosis of influenza is obtained by reverse transcriptase–polymerase chain reaction (RT-PCR) or by virus isolation in embryonated eggs or in cell cultures of nasopharyngeal or tracheal aspirates. Serologic diagnosis can be made by demonstrating four-fold rises in hemagglutination-inhibiting (HAI) antibodies.

LIVE ATTENUATED VACCINES

The segmented genome of orthomyxoviruses that permits genetic reassortment has been employed to generate vaccine strains containing the genes for the HA and NA of newly emergent wild-type (wt) viruses, while retaining other genes from attenuated strains. Attenuated master donor strains must be shown to not cause significant illness in humans and to reproducibly pass the property of attenuation on to reassortants through genes other than the HA and NA. Approaches to developing live attenuated vaccines for influenza include host-range mutants[42–48] temperature-sensitive (ts) mutants,[49] cold-adapted (ca) mutants,[50] NS1 deletion mutants,[51] M2 cytoplasmic tail mutants,[52] replication-deficient viruses,[53] and codon pair deoptimized influenza viruses,[54] but this chapter will focus on the cold-adapted LAIV that is licensed for prevention of seasonal influenza in the United States and several other countries (see below).

HISTORY AND DEVELOPMENT OF COLD-ADAPTED INTRANASAL LIVE ATTENUATED VACCINE

The ca A/Ann Arbor/6/60 (H2N2) (A/AA ca) and ca B/Ann Arbor/1/66 (B/AA ca) viruses that are the backbones of the LAIV licensed in the United States were developed at the University of Michigan.[50,55–57] The A/AA ca virus was derived in primary chick kidney (PCK) cells from a virus originally isolated from an ill child. This virus was grown at successively lower temperatures in PCK cells followed by seven serial plaque-to-plaque purifications. This virus had the following three properties: ts, which implies that the vaccine virus replication was reduced at the higher temperature (39°C); ca, which implies that the virus grew well at a reduced temperature (25°C) compared with permissive temperature (33°C); and att, which implies attenuated behavior in ferrets. The B/AA ca vaccine donor strain was developed in the same manner, although it took fewer intermediate passages to achieve the final ca variant for type B virus than for type A.[56] The wt B/AA/1/66 influenza virus was restricted for growth at 36°C at the time of isolation, and therefore the ts phenotype is defined by a reduction in replication titer at 37°C compared with the achievable titer at 25°C or 33°C.[55,56] Changes in the nucleotide sequence for all eight genes of the attenuated A/AA ca virus, compared with the nucleotide sequence of its wt counterpart, have been identified. Four major loci at base positions 1195 and 1766 of the PB1 gene, 821 of the PB2 gene, and 146 of the NP gene were identified as determinants of the ts phenotype by reverse genetics. Position 2005 of the PB1 gene was also found to contribute to the ts phenotype.[58,59] The ts, attenuation (att), and ca phenotypes of the B/AA ca donor strain are also conferred by multiple genes: PA and NP for ts; PA, NP, and M for att; and PA, NP, and PB2 for ca.[60–62] The concept underlying the use of ts viruses as live attenuated respiratory virus vaccines is that the vaccine virus will replicate in the

cooler upper respiratory tract and induce immunity but will be restricted in replication and will therefore be attenuated in the warmer, core body temperature of the lower respiratory tract.

The reassortant vaccine viruses included in LAIV were previously generated by classical reassortment, achieved by coinfection with vaccine donor viruses and wt influenza viruses, but they are now derived using plasmid-based reverse genetics as discussed later (Fig. 32.1). The resulting recombinant reassortant virus contains six internal gene segments of the vaccine strain combined with the two antigen-encoding gene segments, HA and NA, and it is referred to as a 6:2 reassortant. Numerous reassortants have been made using the A/AA ca virus and B/AA ca donor viruses, and, in all cases, attenuation, antigenicity, and genetic stability have remained unaltered and consistent.[56,57,63,64] Influenza A and B ca donor strains were also developed for a LAIV in Russia. The current Russian influenza A donor strain, A/Leningrad/134/47/57, contains changes in at least one of the polymerase genes as well as in the HA, NA, NP, and M genes.[65,66]

REVERSE GENETICS

The influenza virus genome comprises eight negative-sense virion (v) RNA segments that cannot function as messenger RNAs (mRNAs) to produce proteins; to initiate replication of the viral genome, viral polymerase proteins carried in with the virion must transcribe mRNAs from the viral gene segments to produce mRNAs. Several systems have been developed that allow recombinant influenza viruses to be produced entirely from cloned plasmid DNAs.[67–69] Hoffman and colleagues further refined these techniques and developed an eight-plasmid system.[68] In this method, each viral complementary (c) DNA is inserted into a dual-promoter bidirectional plasmid

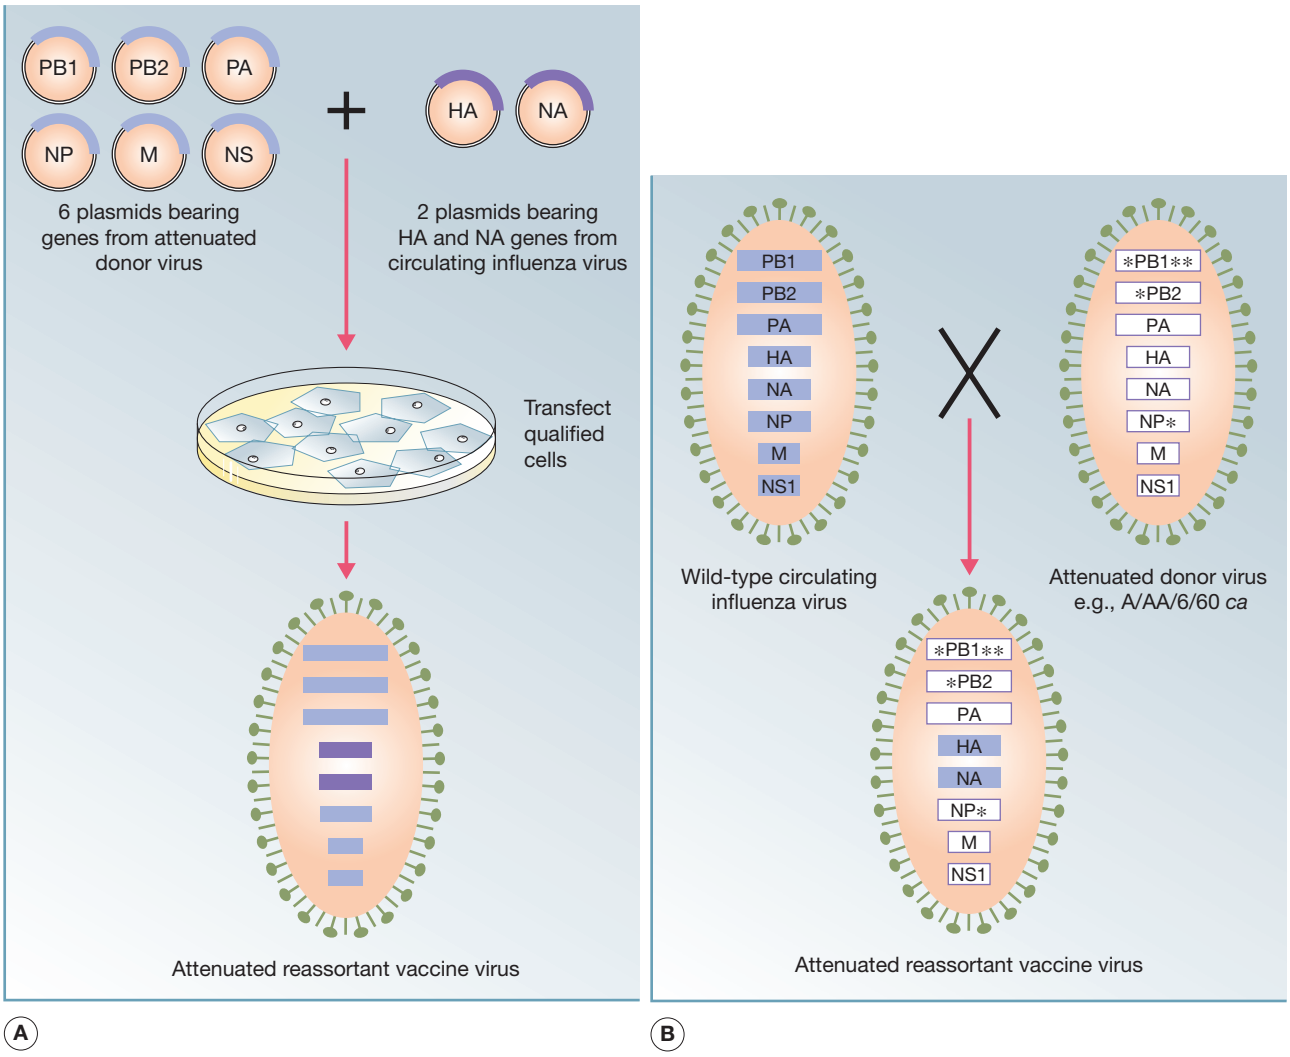

Figure 32.1. A, The eight-plasmid reverse-genetics system to generate recombinant live attenuated influenza vaccines. Six plasmids encoding the internal protein genes of the attenuated donor virus (three polymerase proteins [PA, PB1, and PB2], nucleoprotein [NP], nonstructural protein [NS], and matrix protein [M]) are mixed with two plasmids encoding the hemagglutinin (HA) and neuraminidase (NA) genes of the circulating influenza virus. Qualified cells are transfected with the plasmids, and the attenuated reassortant virus is isolated. **B,** Generation of live attenuated influenza vaccine viruses with the six internal protein genes from the attenuated donor viruses (the five major attenuating mutations for the A/AA cold-adapted [ca] donor virus are indicated by an asterisk), and the HA and NA genes from the circulating influenza virus by classical reassortment. The 6:2 reassortants generated by this method are selected in the presence of antiserum specific for the HA and NA of the attenuated donor virus. *(Modified from Luke CJ, Subbarao K. Vaccines for pandemic influenza.* Emerg Infect Dis. *2006;12:66–72.)*

where the viral gene is flanked by RNA polymerase I (pol I) and RNA polymerase II (pol II) promoters. Thus, eight negative-sense viral RNAs and positive-sense mRNAs are generated from the eight plasmids.

This system is now used routinely to generate the seed virus for seasonal LAIV in the United States. The HA and NA gene segments of the predicted epidemic strain are cotransfected into a cell with plasmid DNAs encoding the other six gene segments of the vaccine donor strain such as A/AA ca (see Fig. 32.1A). The resulting recombinant virus contains six internal gene segments of the vaccine strain, combined with the two gene segments encoding the surface glycoproteins, HA and NA. Another application of reverse genetics is exemplified by the construction of live attenuated pandemic vaccine viruses by plasmid rescue.[70,71] Virulence determinants, such as the polybasic cleavage signal between the HA1 and HA2 subunits of the H5 HA, can be modified or removed by recombinant DNA techniques.[72] Plasmid rescue techniques have advanced basic research on influenza virus as well as vaccine development.

CHARACTERISTICS AND FORMULATIONS OF LIVE ATTENUATED INFLUENZA VACCINE

LAIVs based on the A/AA ca and B/AA ca master donor strains were first licensed in the United States in 2003[73] as a trivalent vaccine. The need for a quadrivalent seasonal influenza vaccine to provide coverage against the two lineages of influenza B that circulate in the human population was a matter of debate for several years. The influenza B epidemic strain was difficult to predict, and there was often a mismatch between the vaccine strain and the circulating influenza B virus. For example, between 2001 and 2010, the influenza B component of the vaccine was of the correct lineage five out of the 10 influenza seasons.[74] Studies by the CDC determined that production of quadrivalent seasonal influenza vaccines would be possible, and would have added benefit in protection against influenza B disease.[75] The clinical trials conducted with the trivalent formulation of LAIV also supported licensure of a quadrivalent LAIV (Q/LAIV), because both vaccines were manufactured using the same process, the dose of each of the component strains is the same, and both formulations are administered by the same route, in the same diluent. In addition to the clinical experience with trivalent LAIV, bridging noninferiority clinical trials were conducted in support of licensure of Q/LAIV.[76,77] Q/LAIV had a similar safety profile to the trivalent LAIV in adults and children and was shown to be noninferior to trivalent LAIV in terms of immunogenicity (see "Noninferiority Studies to Support Licensure of Quadrivalent LAIV" below). In early 2012, Q/LAIV was approved by the U.S. Food and Drug Administration (FDA). Q/LAIV, marketed in the United States as FluMist Quadrivalent, was available for the first time in the 2013–14 influenza season, and contains two influenza B components, so that viruses representative of both the B/Victoria and B/Yamagata lineages are included. Q/LAIV contains $10^{6.5}$ to $10^{7.5}$ focus forming units (FFU) of the four component viruses and is administered in the same manner and volume as the trivalent LAIV. Q/LAIV has replaced trivalent LAIV. Q/LAIV is manufactured and marketed by MedImmune in the United States. It is also licensed in Canada, the United Kingdom, Austria, Finland, Germany, Norway, Spain, Sweden, and Israel. In Canada, Q/LAIV is marketed as FluMist Quadrivalent; elsewhere it is marketed under the trade name Fluenz Tetra.

LAIV is sprayed into the nose using a simple syringe-like device that delivers a 0.1-mL volume of a large-particle aerosol into each nostril for a total volume of 0.2 mL (Fig. 32.2). Vaccination of children requires minimal cooperation. The device is easy to use, and the vaccine is readily accepted and preferable to many over a parenteral injection by needle and syringe. Studies demonstrated self-administration of LAIV was successful, and may be an option for situations where mass immunization is necessary.[78,79]

Figure 32.2. Transilluminated illustration of large-particle aerosol generated for intranasal administration. The tip of the applicator is inserted into the anterior nares, and the plunger is depressed to administer the live attenuated vaccine to a nostril. Removing the flange on the plunger allows a second spray to be administered into the other nostril.

The component influenza virus strains in LAIV are updated each year as recommended by national health authorities. Monovalent bulk vaccine is produced for each reassortant 6 : 2 vaccine strain in specific pathogen–free hen's eggs. The allantoic fluids are clarified by centrifugation and stabilized by the addition of stabilizing buffer: each 0.2-mL dose contains 0.188 mg/dose monosodium glutamate, 2.00 mg/dose hydrolyzed porcine gelatin, 2.42 mg/dose arginine, 13.68 mg/dose sucrose, 2.26 mg/dose dibasic potassium phosphate, and 0.96 mg/dose monobasic potassium phosphate. Each dose contains residual amounts of ovalbumin (<0.24 μg/dose) and may also contain residual amounts of gentamicin sulfate (<0.015 μg/mL) and ethylenediaminetetraacetic acid (EDTA) (<0.37 μg/dose). It is free of preservatives; however, because the vaccine is produced in specific pathogen-free hen's eggs, it should not be administered to persons with egg allergies. Monovalent bulk preparations of each of the four strains in the formulation are combined along with the stabilizing buffer to achieve a titer of $10^{6.5}$ to $10^{7.5}$ FFU/dose and filled into the sprayer device. FluMist Quadrivalent is a refrigerator-stable (i.e., 2 °C to 8 °C) formulation of Q/LAIV. The shelf life of Q/LAIV is 18 weeks.

Genetic and Phenotypic Stability of Live Attenuated Influenza Vaccine

LAIV strains are genetically and phenotypically stable during the vaccine manufacturing process and after replication in humans.

Stability During Vaccine Manufacture

The low-fidelity RNA-dependent RNA polymerase of influenza viruses results in an estimated error rate of 10^{-4} to 10^{-5} misincorporations per nucleotide position per genome replication.[80] Because the manufacturing process of LAIV requires sequential amplification of virus seeds in embryonated hen's eggs, it is possible that mutations that alter the biological properties of the vaccine virus could accumulate, possibly resulting in loss of attenuation or change in antigenicity.

Analysis of the genetic sequence of monovalent ca LAIV revealed a high level of genetic homogeneity in vaccine viruses at several stages of the manufacturing process.[81] A total of six nucleotide changes resulting in amino acid substitutions were identified in the internal protein genes of four influenza A and five influenza B vaccine viruses compared with their respective ca donor viruses, and these changes were generally found to occur in the manufacturing steps upstream of amplification in eggs—that is, during reassortment and clonal isolation. None of the changes occurred at positions that confer the ts and att phenotypes of the cold-adapted viruses.[58–60,62] A total of 14 nucleotide changes were observed in the HA and NA genes of the four influenza A and five influenza B vaccine viruses compared with their respective wt parent viruses (one to two changes per virus for six of the viruses), but the antigenic properties of the HA were not affected.

Genotypic and Phenotypic Stability After Replication in Humans

During the early evaluation of LAIV, the stability of the ts and ca phenotypes were monitored as surrogates for genetic stability. As sequencing technology advanced and the genetic bases for the phenotypes of the LAIV donor virus were determined, genetic stability and phenotypic stability were evaluated in virus isolates from vaccine recipients. The ts and ca phenotypes of several monovalent AA ca-based LAIV were found to be stable after replication in humans.[82] In one study, an AA ca reassortant virus was recovered that had partially lost its ts phenotype after replication in children, but the virus retained the att phenotype in ferrets.[83]

Genetic stability of the trivalent ca influenza virus vaccine, containing ca influenza A H1N1, H3N2, and ca influenza B reassortant viruses, was reported by Cha and colleagues.[84] Virus isolates from nasal and throat swab specimens obtained from 17 children after vaccination were subtyped by multiplex RT-PCR and genotyped. All viruses detected during the 2-week postvaccination period were vaccine viruses, and all maintained the 6:2 reassortant genotype, as well as the ca and ts phenotypes.

Two studies of the genetic and phenotypic stability of trivalent LAIV in children were undertaken in a daycare setting. In one study of children younger than 3 years, it was found that the ts and ca phenotypes were preserved in all recovered viruses tested ($n = 135$).[85] One placebo recipient in this study became infected with an influenza B virus that was a component of the LAIV. This virus retained the ts, ca, and att phenotypes of the vaccine strain and had the same genetic sequence as the influenza B vaccine virus isolated from a vaccine recipient in the same playgroup. In another study, Buonagurio and colleagues[86] examined 56 independent isolates obtained from children after vaccination. Between one and seven nucleotide changes per virus were observed in 80% of isolates compared with the vaccine viruses, but none resulted in changes in the ts, ca, and att phenotypes.

Safety of Live Attenuated Influenza Vaccine

In the United States, LAIV is approved for use in healthy adults and children from 2 to 49 years of age who do not have a history of egg allergies or asthma. Numerous studies have been performed before and after licensure to evaluate the safety of LAIV vaccine in both children and adults. These studies assessed the risk of fever, runny nose and congestion, cough, bronchitis, headache, fatigue, vomiting, and serious adverse events (SAEs) that resulted in hospitalization. LAIV is generally well tolerated in adults, and only runny nose and congestion have been observed at a greater frequency in LAIV recipients than in trivalent inactivated influenza vaccine (TIV) or placebo recipients.[87] Children had a significant increase in runny nose, congestion, and fever after one dose of LAIV, but these symptoms did not occur as often following the second dose.[88–95]

Some studies also reported an increased rate in children vaccinated with LAIV compared with placebo, of SAEs such as wheezing, upper respiratory tract infections, and increased hospitalization, that are likely to have resulted from vaccination.[88,90,91] Although the rates of some of these events were not statistically different between vaccinated children and placebo recipients, a post hoc analysis of one study determined that the reported SAEs occurred exclusively in children younger than 24 months of age.[88] The vaccine is known to be safe in 2- to 17-year-old children, and is not licensed for use in children younger than 2 years of age.[96]

Postlicensure analyses of all adverse events (AEs) reported to the U.S. Vaccine Adverse Event Reporting System (VAERS) during the 2003–04 and the 2004–05 influenza seasons[97] and for the seasons from 2005 to 2013[98,99] have been reported for trivalent LAIV. In the first two postlicensure seasons, approximately 2,500,000 persons received trivalent LAIV, and VAERS received 460 AE reports.[97] No fatalities were reported. There were seven reports of possible anaphylaxis, two reports of Guillain-Barré syndrome (GBS), one report of Bell palsy, and eight reports of asthma exacerbation among persons with a prior history of asthma. Events in persons for whom the vaccine was not indicated accounted for 73 reports (16%). Between 2005 and 2013, approximately 50 million doses of trivalent LAIV were distributed for use in adults and children.[98] Separate reviews of reports to VAERS were conducted for adults[99] and children.[98] Available safety data were limited, particularly for adults. Over eight influenza seasons, 1207 events were reported to VAERS for adults of the approved age range of 18 to 49 years, of which 8.9% were serious. Nine deaths were reported. Deaths and nonfatal SAEs were only reported in the U.S. Department of Defense population, which includes military personnel and Department of Defense beneficiaries treated at military clinics or hospitals. The most common categories of reported serious nonfatal events were neurological (39%), cardiovascular (14%), or other noninfectious conditions (19%). A higher rate of GBS and cardiovascular events were reported in the Department of Defense versus the civilian population. This finding is the subject of further investigation. The most commonly reported AEs were not serious in nature: headache, fever, and nausea. There were 207 reports of the administration of expired vaccine, 155 reports of administration of vaccine to adults 50 years of age and older, and some reports of inadvertent administration to pregnant women, none of which resulted in a SAE. Over the seven influenza seasons between 2005 and 2012, there were 2619 AE reports to VAERS associated with administration of trivalent LAIV in children, of which 7.5% were serious, and there were five deaths.[98] Four of the five deaths were children with chronic underlying conditions. An increase in reported events was observed from 2005 to 2011, mainly attributable to an increase in reports of nonserious AEs. SAE reports for 2- to 4-year-old children peaked in the 2007–08 influenza season at 25% (15 of 60 vaccinees); this was the first influenza season following approval for use of LAIV in this age group. The two most frequently reported categories of nonfatal SAEs were neurologic (29.2%) and respiratory events (22.4%). The most frequent neurologic diagnoses were seizures and GBS, and the most frequent respiratory diagnoses were pneumonia and asthma or reactive airway disease. The most commonly reported vaccine administration error was administration of expired vaccine, which was not associated with AEs. For both pediatric and adult populations, the reviews of reports

to VAERS for trivalent LAIV were reassuringly consistent with prelicensure safety analyses and postlicensure safety data from the first two influenza seasons after FDA approval. Because VAERS is a passive surveillance system it is not possible to assess the reports for causal associations between vaccines and AEs.[98,99]

A similar analysis was conducted for Q/LAIV for the first influenza season following licensure, 2013–14,[100] when approximately 12.7 million doses of Q/LAIV were distributed in the United States. VAERS received 779 AE reports for individuals in the approved age range of 2 to 49 years, 95% of which were nonserious. In children, the most commonly reported AE was administration of expired vaccine (42%), followed by fever (13%) and cough (8%). In general, the safety profile of Q/LAIV was similar to that of trivalent LAIV. The most commonly reported AEs in adults were headache (18%), administration of expired vaccine (15%), and exposure during pregnancy (12%). One death, resulting from complications of brain tumors, was reported in children, and no deaths were reported for adults. Neurologic conditions were the most commonly reported nonfatal serious events in both children and adults. Two cases of GBS were reported in children, and none in adults; disproportional reporting of this AE compared to other vaccines was not observed. There were 100 reports of Q/LAIV being administered to individuals outside of the approved age range; 28 children younger than the age of 2 years and 72 adults older than the age of 49 years received Q/LAIV. Seventy-five percent of these children and 87.5% of the adults did not experience AEs. There were 49 reports where the age of the vaccinee was unknown. As was the case with the postlicensure VAERS reporting for the trivalent LAIV, the most commonly reported vaccine administration error was administration of expired vaccine. Administration of expired vaccine may be related to the change in LAIV formulation from frozen to refrigerator-stable in 2007 that resulted in a shorter shelf life of the vaccine, or to the relatively shorter shelf life for LAIV compared to IIV.[101] This error would be expected to result in lack of protection afforded by the vaccine, rather than adverse reactions to it. The administration of expired vaccine, administration to individuals outside the approved age group, and administration to individuals in whom LAIV is contraindicated (e.g., pregnant women) underscore the need for continued education and training of healthcare workers. In summary, none of the postlicensure reviews of events reported to VAERS for trivalent or quadrivalent LAIV identified any unexpected serious risks when the vaccine was used as approved.

TRANSMISSION OF LIVE ATTENUATED INFLUENZA VACCINE

LAIV strains replicate in the nasopharynx of the recipient and are shed in the respiratory secretions. Data in the published literature failed to detect transmission of vaccine viruses derived from the passaged cold-adapted master donor viruses in multiple age groups and settings.[63,83,85,102–109] In an evaluation of direct transmissibility in a daycare setting in children 8 to 36 months of age, 80% of the 98 FluMist recipients shed one or more vaccine strains, with a mean shedding duration of 7.6 days. One possible transmission event was observed among the 99 placebo recipients and was confirmed by phenotype and genotype analysis. The safety profile for this child after transmission was similar to that for the other children in the study who received vaccine or placebo; the child was not ill and did not experience an SAE.[85] An open-label, single-arm, multicenter Phase II study reported by Mallory and colleagues[110] demonstrated that at least one component of seasonal LAIV was shed by 79% of children between 6 and 59 months of age. In this study, virus shedding was most frequently seen in children 6 to 23 months of age, and it occurred mostly on postvaccination days 1 through 11, with shedding beyond day 11 detected almost exclusively in the younger age group. Peak titers of vaccine virus were detected on postvaccination day 2, and mean peak titers were generally less than 10^3 $TCID_{50}$ (median tissue culture infective dose)/mL.

In the year after initial FDA approval, the clinical use of LAIV was restricted in some institutions because of a theoretical concern that live attenuated virus might transmit from vaccinated hospital employees to unvaccinated patient contacts. After several years of experience, this concern proved to be unfounded, and person-to-person transmission of LAIV has not been a problem. Izurieta and colleagues[97] summarized vaccine AE reporting regarding LAIV, and no instances of recognized transmission were identified. In the one case in which transmission was suspected, and in which viral isolates were obtained, it turned out that a wt influenza virus, not vaccine virus, was involved in the transmission. The Advisory Committee on Immunization Practices (ACIP) to the CDC modified its initial recommendation to reflect the practicalities of vaccine usage in hospitals. The only concern that remains now is a theoretical one. Employees who are vaccinated should not have contact within 7 days with immunosuppressed patients who are in reverse isolation (such as bone marrow transplant recipients). All other situations are considered acceptable for using LAIV.

Immunogenicity of Live Attenuated Influenza Vaccine

Replication of LAIV in the upper respiratory tract induces both antibody and cellular immune responses. This section addresses the induction of these immune responses in healthy adults and children.

Antibody Responses

Serum antibody titers are the most common immune response measured in vaccine studies, in part because antibody alone is sufficient to protect from influenza virus infection. Serum HAI antibody titers induced by IIV are generally accepted as a correlate of protection.[111] Influenza-specific antibody titers measured by HAI assays serve as a surrogate for virus-neutralization assays. The enzyme-linked immunosorbent assay (ELISA) detects binding antibodies that may be broadly cross-reactive[112] while HAI and neutralization assays detect more strain-specific and functional antibody.

Numerous studies have found that seroconversion following vaccination with LAIV occurs more frequently in immunologically naïve individuals. Because adults are immunologically primed by repeated prior exposure to influenza strains that have circulated in recent years, seroconversion rates in adults vaccinated with LAIV are often not significantly higher than in placebo recipients.[87,113,114] This observation correlates with reduced shedding of vaccine virus after vaccination with LAIV in adults compared with young children.[113] In influenza-naïve children, LAIV elicits a robust serum antibody response in both HAI and neutralization assays.[89,92,115–118] Lee and colleagues[116] and Belshe and associates[89] compared serum antibody responses after LAIV in 1- to 5-year-old seronegative children by neutralization assay or HAI, and they reported seroconversion rates of 58% and 16% against H1N1, 100% and 92% against H3N2, and 100% and 88% against influenza B, respectively, after a single dose of the trivalent LAIV vaccine. Administration of a second dose of LAIV 28 to 60 days later improved the seroconversion rate against the H1N1 virus in these studies to 77% and 61%, respectively.

The influenza virus HA is a homotrimer with a globular head, bearing the receptor binding pocket and five antibody binding sites, and a relatively conserved stem region. The majority of antibody produced against the HA is directed at the globular head, where antigenic changes in the protein occur. There is renewed interest in conserved epitopes in the HA stem region to induce broadly cross-reactive antibodies that neutralize influenza A viruses from different subtypes.[119–126] These cross-reactive HA stem antibodies have been detected using sensitive new technologies including phage display libraries and immortalization of memory B cells from humans after natural influenza virus infection or after receipt of TIV. It is likely that LAIV also induces stem antibodies, but the proportion of the serum anti-HA antibody response that is directed to the stem is not known. The presentation of a stem epitope in a vaccine may have potential as a universal influenza virus vaccine.[127,128]

Serum antibody responses in healthy adults after LAIV vaccination are known to be low in comparison to those elicited by TIV, but production of mucosal antibodies and circulating antibody-secreting cells have been described in a higher percentage of LAIV recipients.[129–131] Clements and colleagues[132] found that the titer of influenza-specific immunoglobulin (Ig) A in the nasal wash of adults vaccinated with monovalent LAIV against H1N1 or H3N2 viruses was higher than in those vaccinated with TIV (83% for LAIV vs 38% for TIV). Interestingly, however, the reverse was true for influenza-specific IgG titers in nasal wash specimens: 94% of persons vaccinated with TIV had an increase in IgG titer, compared with 59% of LAIV recipients. Although it is still unclear how the presence of mucosal antibodies mediates protection, levels of IgA in nasal wash specimens correlated with protection on challenge with wt influenza virus.[132] In contrast to the case in children, mucosal IgA in adults vaccinated with LAIV declined 6 months after vaccination.[129] In a study of 79 adults who received LAIV, twofold or greater rises in IgA antibody titer in nasal wash specimens were seen in 33% of subjects, compared to 9% with fourfold rises in serum antibody titer.[133] It has been demonstrated that adults vaccinated with LAIV had a more prominent vaccine-specific IgA plasmablast response compared to subjects who received IIV.[134] In a small study in children who received LAIV or TIV followed by LAIV, levels of mucosal IgA measured by kinetic ELISA or Luminex were marginally higher in children following the first dose of LAIV, but this was not statistically significant.[135] Ambrose and colleagues reported significantly higher vaccine-specific nasal IgA antibody in a subset of children who received LAIV compared to placebo in three prospective, 2-year randomized clinical trials.[136] Although mucosal IgA responses are elicited by LAIV, their precise role in vaccine efficacy remains to be elucidated. Newer studies suggest that circulating memory B cells are also an important measure of vaccine-induced immunity in adults[130,131,134] and children.[137,138] B-cell and antibody responses, particularly plasmablast responses, to LAIV and TIV were compared in young adults.[134] Six to 8 days postvaccination, the titers of plasmablast-derived polyclonal antibodies were significantly higher in TIV recipients, but higher levels of cross-reactive plasmablast-derived polyclonal antibodies that bound heterologous strains from the previous year's influenza vaccine were observed in LAIV recipients. In children, LAIV resulted in a significant increase in naïve, memory, and transitional B cells in peripheral blood 30 days after vaccination,[137] whereas TIV elicited an increase in plasmablasts 7 days after vaccination.

The majority of the antibodies measured in studies of LAIV were against the influenza virus HA protein. There is evidence that anti-NA antibodies may be important in limiting the severity of influenza in humans.[139] The immune response elicited against the NA after vaccination with LAIV has not been extensively studied. In recent years, there has been a renewed interest in studying the contribution of antibody to the NA in influenza vaccine–mediated protection. Improved assays to measure NA inhibiting (NAI) antibodies in sera are being employed in this effort.[140,141] The levels of serum NAI antibodies in a recent study comparing the relative efficacy of TIV and LAIV were correlated with protection in individuals who had measurable HAI responses.[142] Responses were observed by HAI and NAI assays in 77%, and 37% of recipients of IIV, respectively, and in 21%, and 6% of LAIV recipients. Higher NAI titers in recipients of IIV were associated with a lower frequency of vaccine failure.

Cellular Responses

In contrast to the antibody response that is directed at the surface glycoproteins of the virus, the main targets of the cellular immune response to influenza are the conserved internal proteins of the virus. Although cell-mediated immunity plays an important role in clearance of influenza virus during natural infection, it is unclear to what extent vaccine-induced, cell-mediated immunity contributes to protection against disease, because the rate of influenza virus replication is very rapid, and the recall of memory T cells likely occurs after the peak of viral replication.[143] However, it is anticipated that a robust T-cell response induced by vaccination would protect against complications or severe disease. Because LAIV replicates in host cells, it induces $CD4^+$ and $CD8^+$ T-cell immunity. However, assays for the assessment of cellular immune responses to LAIV in clinical trials have lagged behind antibody assays and have primarily focused on the induction of T-helper cell type 1 (Th1)-mediated immunity by enumeration of interferon gamma (IFNγ)-producing T cells and natural killer cells by flow cytometry, ELISA, and enzyme-linked immunosorbent spot (ELISPOT) assay. Significant increases in $IFN\gamma^+$, $CD4^+$, and $CD8^+$ T cells after LAIV have been observed in both children and adults.[137,138,144–147]

In summary, immune responses to LAIV are more frequently detected in influenza-naïve subjects, making the responses in children more robust than in adults. It is important to note that although humoral and cellular immune responses to LAIV can be measured, an immune correlate of protection for LAIV has not yet been identified (see "Immune Correlates of Protection for Live Attenuated Influenza Vaccine" later).

Innate Immune Responses

As the pathways by which the innate immune system senses and responds to pathogens are being unraveled, it is becoming clear that the innate immune response plays a very important role in determining the adaptive immune response to pathogens and vaccines. The application of systems biology to the field of vaccinology promises to bring a new understanding of this interplay.[148–150] One study that compared the whole genome transcriptional profile of peripheral blood mononuclear cells collected from children vaccinated with TIV or LAIV found differences in the early immune responses elicited by the two vaccines.[151] Increased expression of IFN response genes was observed in mucosal RNA samples from adults vaccinated with LAIV.[133] In children, both LAIV and TIV induced overexpression of IFN response genes, but this occurred early (day 1 postvaccination) in all age groups for TIV, and only on day 7 postvaccination in children younger than 5 years of age for LAIV recipients.[137] These data suggest that early induction of IFN response genes may be important for the development of antibody responses.

Efficacy and Effectiveness of Live Attenuated Influenza Vaccine

Vaccine efficacy data were initially obtained from double-blind, placebo-controlled clinical trials in adults that measured the ability of the vaccine to protect persons from infection with a homologous wt virus. To prove that influenza vaccines are efficacious against natural infection, it is necessary to vaccinate a population before an influenza epidemic and compare the infection rates in vaccinated subjects with a group given a placebo. Case definitions of influenza vary according to study and may include culture-positive infection, fourfold rise in antibody titer during the influenza epidemic, or clinical observations of influenza-like illness (ILI). Specific point estimates of vaccine efficacy are ideally obtained by RT-PCR–positive or culture-positive identification of cases, thereby eliminating clinical syndromes caused by other viruses.[152] Efficacy field trials with culture-positive end points are often conducted in young children[89,153] because attack rates of influenza in children are high and they shed high quantities of virus for several days, making virus detection a sensitive and specific case-finding method. Efficacy trials in adults are more commonly conducted using clinical end points such as febrile respiratory illness. Influenza is the most common cause of febrile respiratory illness in adults, and virus isolation to identify influenza infection is difficult because adults may shed virus in low quantity and for a brief duration. Serologic diagnosis of a fourfold antibody rise in paired sera obtained before and after an epidemic is also often used in adults, with case definition being any subject with a fourfold antibody rise in response to the epidemic virus. However, subjects with vaccine-induced antibody may not produce sufficient antibody during the subsequent natural infection to result in a detectable fourfold antibody increase. Therefore, this definition has inherent bias, unlike the clinical end point for adult studies or the virus isolation end point for pediatric efficacy trials. Also, it is difficult to directly compare efficacy rates obtained from challenge studies with rates from field trials because challenge studies are typically conducted in small numbers of subjects who are seronegative for the challenge virus, whereas field trials are typically much larger and include subjects with a variable history of previous exposure to influenza.

Vaccine effectiveness and vaccine efficacy can be confused. In this chapter, *vaccine efficacy* means the specific reduction in attack rates of laboratory-confirmed influenza, and it is represented mathematically as $(1\text{-Rv/Rp}) \times 100\%$, where Rv is attack rate in vaccinees, and Rp is attack rate in placebo recipients.

Vaccine effectiveness refers to the reduction in clinical and socioeconomic events that can be expected to be associated with influenza but could also be caused by other agents. End points such as ILI, medically attended acute respiratory illness (MAARI), acute respiratory illness with cough, febrile acute respiratory illness, days of work missed by caretakers, and days absent from daycare have been used to determine vaccine effectiveness.

In this section, we describe the efficacy of LAIV against culture-confirmed influenza in healthy adults and children as determined from double-blind, placebo-controlled challenge studies and field trials. Studies with end points other than laboratory-confirmed diagnosis were used to determine vaccine effectiveness.

Efficacy in Adults

Several challenge studies, summarized in Table 32.2,[103,114,154–157] have been conducted in adults. Many studies of monovalent LAIV vaccines found that LAIV significantly reduced the number of persons presenting with clinical signs of respiratory illness after challenge. However, vaccination did not dramatically reduce the frequency of persons shedding challenge virus (Table 32.2).[114,154–157] Reduction in mean titer and duration of shedding varied by influenza type and subtype,[103,114,156] with a statistically significant effect on H3N2 virus shedding. A challenge study that compared the efficacy of trivalent LAIV to placebo in adults found that LAIV was 85% efficacious against culture-confirmed infection and respiratory illness after experimental challenge with wild-type influenza virus.[114]

Two randomized, double-blind, placebo-controlled, multiyear studies assessed the efficacy of LAIV and TIV in protection against naturally occurring influenza (see "Efficacy of Live Attenuated Influenza Vaccine Compared with Trivalent Inactivated Influenza Vaccine," later); both studies used culture-confirmed influenza as the primary end point.[87,158–160] In years when the circulating strain was well matched to the vaccine strain, the efficacy of LAIV was 90% (95% confidence interval [CI], 72–96%) for H1N1 in 1988–89, 56% (95% CI, 1–81%) for H3N2 in 1989–90, 43% (95% CI, 15–70%) for H3N2 in 2005–06, and 36% (95% CI, 0–59%) for H3N2 and B in 2007–08.[87,158,159] It is important to note that the study done during the seasons from 1988 to 1990 included persons 1 to 65 years of age, whereas the later studies included only adults 18 to 49 years of age.

Efficacy in Children

Given the risk of severe illness associated with influenza infection in young children, challenge studies with wt virus cannot be conducted in this population. Therefore, efficacy in children is assessed either by evaluating replication of an attenuated vaccine virus as a surrogate for challenge with a wt virus (see Table 32.3),[154] or by following vaccinated children through natural exposure to influenza virus over the course of an influenza season. Efficacy was assessed by challenge with an attenuated H1N1 vaccine virus in a placebo-controlled study in healthy children. More placebo recipients shed virus than LAIV-vaccinated children, demonstrating a vaccine efficacy of 83% (95% CI, 60–93%).[154]

Several studies measured the efficacy of LAIV in children against naturally acquired culture-confirmed illness as the primary end point; children younger than 2 years of age were included in most of these studies.[88,89,91,93,94,161,162] Table 32.3 summarizes the efficacy rates of LAIV from comparable studies in large cohorts of children and those that have undergone post hoc analysis to include data only from children 2 years of age or older. These studies found efficacy rates between 70% and 94% against antigenically similar strains.[163,164] Even more striking are the Kaplan-Meier curves for the time to the first culture-confirmed influenza illness in children given one or two doses of LAIV (Fig. 32.3).[91,164] The data from these studies demonstrate that LAIV is efficacious in young children and that even a single dose can protect seronegative children from disease.

Efficacy Against Antigenic Drift Variants

Because antigenic drift is a constant process that can occur after vaccines are manufactured, efficacy of influenza vaccines against antigenic drift variants is a desirable property. This is usually assessed in large, community-based, randomized, controlled studies that span a period during which an antigenic variant virus emerges. Interestingly, many of the efficacy studies extended over 2 or more years and included a season in which the predominant circulating influenza virus was antigenically distinct from the vaccine strain (Table 32.4). The efficacy of LAIV against drifted strains was higher in children than in adults, just as it is against antigenically similar

TABLE 32.2 Efficacy of LAIV in Protection From Experimental Challenge With Wild-Type Influenza Virus

Study	Population[a]	Vaccine Virus, Dose	Time to Challenge	Challenge Virus, Dose	No. of LAIV Recipients			No. of Placebo Recipients		
					Total	Infection[b]	Illness[c]	Total	Infection[b]	Illness[c]

strains. The cross-protection conferred by LAIV against antigenic drift variants may result from the breadth of the immune response elicited by LAIV vaccination (see "Immunogenicity of Live Attenuated Influenza Vaccine," earlier), which includes immunity to conserved viral proteins such as the M and NP proteins. In young adults who received LAIV, a higher level of NP-specific plasmablasts were observed compared to recipients of TIV, and the cross-reactive plasmablast response to heterologous influenza strains from the previous year's vaccine was also of greater magnitude in LAIV vaccinees.[134] However, LAIV was not effective against an H3N2 drift-variant in the 2014–15 influenza season, suggesting that the breadth of cross-protection conferred by LAIV is influenced by the extent of antigenic change.[165–167]

Effectiveness of Live Attenuated Influenza Vaccine

Table 32.5 summarizes key effectiveness results following a single dose of LAIV or placebo in healthy working adults. Vaccine significantly reduced the number of severe febrile illnesses and days of febrile upper respiratory tract illnesses among healthy, working adults. Vaccine also led to lower rates of work absenteeism, healthcare provider visits, and the use of prescription antibiotics and nonprescription medications. These benefits were observed during a season in which the predominant circulating influenza virus strain, A/Sydney/5/97 (H3N2), was not well matched to the A/Wuhan/359/95 strain contained in the vaccine.[78] In contrast, a similar effectiveness study of the TIV in similar age adults conducted in the same influenza season demonstrated no protection compared to placebo recipients.[168]

The frequencies of influenza-associated otitis media (OM) and MAARI have been used to measure the effectiveness of LAIV vaccination in children. Both were reduced in each year in three multiyear multicenter trials.[94,169,170] Belshe and colleagues concluded that LAIV was 98% effective in reducing OM during the 1996–97 season, based on one case of OM in the vaccine group and 20 cases in the placebo group, and

94% effective during the 1997–98 season during which an antigenic drift variant circulated, based on two cases in the vaccine group and 17 cases in the placebo group.[169] Gaglani and colleagues demonstrated a more modest impact (20% direct effectiveness [95% CI, 14–25%]) of LAIV on MAARI in children 1.5 to 18 years of age during the 2000–01 season.[170] Reduction in influenza-associated OM and MAARI associated with influenza also led to an increase in LAIV effectiveness as measured in time a caretaker takes off work, days missed from daycare, and incidence of outpatient or emergency department visits. Vesikari and colleagues measured the effectiveness of LAIV on socioeconomic end points during two influenza seasons.[94] LAIV was effective during a mild influenza epidemic in the first season, but a significant impact was also seen during the second season that was associated with a high attack rate in placebo recipients, with reductions in the need for a guardian to take time off work, the number of days of work lost, and days of daycare missed.[94] During the second season (2001–02), there was an unmatched influenza B component in the vaccine, demonstrating that LAIV was not only efficacious but also effective during a drift season in children.

The relative effectiveness of LAIV versus IIV against MAARI has been evaluated since 2010 in studies conducted by the U.S. Influenza Vaccine Effectiveness Network, using a test-negative study design, where influenza cases are defined as patients with MAARI confirmed to be influenza by RT-PCR. Patients with similar illnesses who do not have RT-PCR–confirmed influenza infection serve as control subjects. The test-negative design controls for factors associated with illness severity and propensity to seek care when ill.[171] In the 2011–12 influenza season the point estimates of vaccine effectiveness for children 9 to 17 years of age were similar for LAIV and IIV (adjusted vaccine efficacy [VE] of 60% [95% CI, −15 to 86] for LAIV vs 61% [95% CI, 28–79] for IIV), whereas LAIV was more effective than IIV in children 2 to 8 years of age (adjusted VE 61% [95% CI, 16–82] vs 40% [95% CI, 6–62]).[172] In the 2012–13 influenza season, LAIV was not significantly more effective than IIV in children 2 to 17 years of age against influenza A H3N2 (adjusted VE for LAIV 46% [95% CI, 13–66] vs IIV 36% [95% CI, 15–51]) or influenza B/Yamagata (adjusted VE for LAIV 53% [95% CI, 20–73] vs IIV 68% [95% CI, 54–77]).[173] In the 2013–14 influenza season—the first in which the Q/LAIV formulation was used—the predominant circulating strain was H1N1pdm09. Significant VE was demonstrated for IIV but not for Q/LAIV.[174] In fully vaccinated children 2 to 17 years of age, Q/LAIV was not effective against any influenza (adjusted VE 17% [95% CI, −39 to 15]), whereas IIV was effective in this age group (adjusted VE 60% [95% CI, 36–74]). Vaccine effectiveness was not demonstrated for Q/LAIV against H1N1pdm09 in 2- to 17-year-olds (adjusted VE 18% [95% CI, −38 to 51], or in any age-stratified model, but was demonstrated for IIV (adjusted VE 58% [95% CI, 50–65]). Similar effectiveness estimates were reported for the 2013–14 influenza season in postmarketing studies conducted by the manufacturer[175]: Q/LAIV did not show significant effectiveness against H1N1pdm09 (adjusted VE 13% [95% CI, −5 to 51]), but was effective against the influenza B/Yamagata virus circulating that season (adjusted VE 82% [95% CI, 12–96]). In this study, IIV was effective against both H1N1pdm09 (adjusted VE 74% [95% CI, 50–86]) and the B/Yamagata strain (adjusted VE 70% [95% CI, 18–89]). The postmarketing studies conducted by the manufacturer employ a test-negative study design similar to that of the U.S. Influenza Vaccine Effectiveness Network studies. In the 2014–15 influenza season, an H3N2 antigenic drift variant emerged shortly after the selection of the Northern Hemisphere vaccine strains, resulting in a mismatched vaccine. Estimates for vaccine effectiveness for influenza vaccines for the United States for 2014–15 were 19%.[165,166] An interim analysis of effectiveness indicated that neither Q/LAIV nor IIV provided significant protection in children 2 through 17 years of age; LAIV did not offer greater protection than IIV during this season.[167,176] Further analysis of data from the U.S. Influenza Vaccine Effectiveness Network from the 2010–11 to 2013–14 influenza seasons[177] found that the odds of influenza were similar for LAIV and IIV recipients during the first three seasons studied. In 2010–11 and 2013–14, the odds of influenza illness caused by H1N1pdm09 were significantly greater among LAIV recipients compared to IIV recipients 2 to 8 years of age.

Interim VE estimates reported by the CDC from the U.S. Influenza Vaccine Effectiveness Network for the 2015–16 influenza season have heightened concerns that Q/LAIV is not effective against H1N1pdm09,[178,179] although data from the manufacturer are not in agreement with these findings.[180] The effectiveness of LAIV against H1N1pdm09 strains since the emergence of the swine-origin pandemic H1N1 influenza virus in 2009 is discussed in detail below under "LAIV Against the 2009 Pandemic H1N1 Virus."

Relative effectiveness of LAIV and IIV in adults has not been reported in the U.S. Influenza Vaccine Effectiveness Network studies as data on LAIV in adults are sparse.

Retrospective effectiveness studies comparing LAIV to TIV were conducted in the U.S. military, in new recruits undergoing training as well as other military personnel (nonrecruits)[181,182] who receive annual influenza vaccination. The analyses relied on administrative records, and in most cases, effectiveness against culture-confirmed influenza illness could not be determined. A retrospective cohort analysis among military service members over the 2005–06 and 2006–07 influenza seasons demonstrated that TIV was slightly more effective than LAIV against ILI for nonrecruits over both seasons. However, in Army and Air Force recruits, significantly greater effectiveness against ILI was observed with LAIV.[181] A separate retrospective cohort analysis of effectiveness of LAIV and TIV[182] examined the incidence of healthcare encounters among U.S. military active-duty nonrecruits over three influenza seasons. Data from more than 1 million persons per year were analyzed and a statistically significant reduction in the incidence of healthcare encounters resulting in a primary diagnostic code consistent with pneumonia or influenza in recipients of TIV compared with no vaccine was reported. A consistent effect of LAIV vaccination was observed in only one season, and this effect was less than TIV in both total and propensity-matched cohorts. Both vaccines were comparable in effectiveness among vaccine-naïve service members. The relative effectiveness of LAIV and TIV in military personnel for the influenza seasons between 2006 and 2009 was similar: no differences in the rates of ILI, influenza, or pneumonia were observed.[183] In the 2010–11 influenza season, overall vaccine effectiveness was found to be low against clinically apparent, laboratory-confirmed influenza, although protection was marginally better with TIV.[184] Vaccine effectiveness was not observed against H1N1pdm09 virus infection. In another study of military personnel this was attributed to antigenic drift in the circulating H1N1pdm09 strain and decreased serologic response to H1N1pdm09 in vaccinees.[185] Although it is difficult to determine the role of antibody in effectiveness of LAIV in adults as serum antibody responses do not correlate with protection, these findings are consistent with the other reports of low effectiveness of LAIV against H1N1pdm09 in the 2010–11 season.

In summary, the relative effectiveness of LAIV and TIV vary in specific populations, and vaccination with LAIV appears to be more effective in children and military recruits than in adults.

Noninferiority Studies to Support Licensure of Quadrivalent Live Attenuated Influenza Vaccine. The strategy to obtain marketing approval for Q/LAIV from the FDA was based on the following similarities between the trivalent and proposed quadrivalent formulations: the vaccine components are based on the same attenuated ca master donor strains, manufactured using an identical process, all excipients in the vaccine are the same, they are given at the same dose in the same volume by the same delivery method, and are in the same refrigerator-stable formulation. Therefore, the body of clinical data that supported licensure of trivalent LAIV was relevant to Q/LAIV.[186] A bridging strategy was used, where two large clinical studies were designed to demonstrate that Q/LAIV was noninferior to trivalent LAIV in safety and immunogenicity in adults[77] and children.[76]

A randomized, double-blind, active-controlled clinical trial was conducted in 1800 healthy adults 18 to 49 years of age.[77] Subjects were randomized 4:1:1 to receive Q/LAIV ($n = 1200$), trivalent LAIV with the influenza B/Yamagata strain ($n = 300$), or trivalent LAIV with the B/Victoria strain ($n = 300$). The primary end point for the study was the comparison of postvaccination strain-specific geometric mean HAI titers, where the criterion for noninferiority was met if the upper bound of the two-sided 95% CI for the ratio of the geometric mean of the HAI titer for trivalent LAIV to Q/LAIV was 1.5 or less for all strains included in the vaccine. Although HAI antibody responses are not frequently observed in adults following administration of LAIV, and do not correlate with efficacy, they have served as an end point for other bridging studies including the transition from frozen to refrigerator stable formulation, assessment of consistency between lots of vaccine, and studies that examined the effect of concomitant administration of other live virus vaccines with LAIV. In addition to the primary immunogenicity end point, solicited symptoms and AEs were compared between groups. Q/LAIV met the criterion for immunologic noninferiority in adults, and solicited symptoms and AEs were similar for trivalent LAIV and Q/LAIV, an observation that was confirmed in analyses of postmarketing surveillance AE reporting data.[100]

A similar study was conducted in children 2 to 17 years of age.[76] Subjects were randomized 3:1:1 to receive Q/LAIV ($n = 1385$), trivalent LAIV with the influenza B/Yamagata strain ($n = 300$), or trivalent LAIV with the influenza B/Victoria strain. Children 2 to 8 years of age received two doses, and those 9 to 17 years of age received a single dose of LAIV. The immunologic noninferiority criterion was the same as for the adult study. Q/LAIV met the immunologic noninferiority criterion, although it was noted that the immunogenicity of the H3N2 and H1N1 vaccine components were lower than expected. The safety of Q/LAIV in children was comparable to that of trivalent LAIV, although a small but statistically significant increase in fever was noted in 2 to 8 year olds following the first dose of Q/LAIV. Q/LAIV was approved by the FDA in 2012 and was used for the first time in the 2013–14 influenza season.

Duration of Immunity Induced by Live Attenuated Influenza Vaccine

Longer-term persistence of immunity may emerge as a characteristic of the host response induced by LAIV. When the persistence of serum and nasal antibodies induced by TIV or LAIV in seronegative children were compared, LAIV recipients had significantly higher and more sustained levels of both serum and nasal antibodies measured by HAI and ELISA.[187,188] Prolonged humoral immunity may provide protection against antigenic drift variants that emerge. B-cell and T-cell immune responses in children vaccinated with LAIV were sustained for at least 1 year after vaccination.[138] The decline in HAI and NAI antibody responses over an 18-month period following vaccination with either IIV or LAIV was measured in the sera of adults who had participated in a placebo-controlled efficacy trial in Michigan between 2004 and 2007.[87] Although a greater proportion of IIV recipients than LAIV recipients had an HAI titer of 1:32 or greater and an NAI titer of 1:40 or greater 1 month after vaccination, the decline in antibody titers in both groups was slow; HAI and NAI antibody titers decreased twofold in approximately 600 days.[189] Community-based studies have found protection from illness up to 12 months after vaccination.[190] The durability of direct effectiveness against MAARI was assessed in children who were vaccinated with a single dose of LAIV during the 1999–2000 season and then were given placebo in the 2000–01 season; the direct effectiveness against MAARI of a single dose of LAIV administered a year prior to surveillance compared to unvaccinated children for both seasons was 22% (95% CI, 11%–32%).[170] Recent studies with investigational pandemic LAIV (pLAIV) have demonstrated long-term immunological

memory: individuals who received H5N1 or H7N7 pLAIV had a rapid, robust antibody response to a corresponding IIV administered years later[191,192] (see "Live Attenuated Influenza Vaccine Against Other Influenza Viruses of Pandemic Potential" below).

As with IIV, there is some concern that repeated annual vaccination may result in decreased effectiveness of LAIV. Data from systematic clinical trials conducted over several seasons that are specifically designed to address this question are not available. In a 5-year study comparing the efficacy of IIV and LAIV against influenza A,[158] a consistent decrease in efficacy was not observed. However, the authors noted that seroconversion rates were higher in the first year of the study compared to subsequent years. The same observation was made in another study in which HAI and NAI antibody titers were compared over 18 months following vaccination with either IIV or LAIV in adults[189]: recipients of both types of vaccine had significantly lower HAI titers in the second year of the study, although rates of antibody persistence did not differ between the two groups. Analysis of antibody and B-cell responses to influenza vaccination with either IIV or LAIV suggest that the type of vaccine received in the previous season can influence immune responses[193]; receipt of IIV in the previous season was associated with lower HAI antibody responses to IIV or LAIV in the subsequent season, and lower B-cell effector responses to IIV but not LAIV. In a study conducted by the U.S. Influenza Vaccine Effectiveness Network overall influenza vaccine effectiveness in the 2011–12 season appeared to be negatively affected by vaccination in the prior influenza season,[172] but this analysis did not take vaccine type into account, so it is not possible to determine whether the effect was similar for IIV and LAIV. Vaccination in the previous and current influenza seasons was reported to result in lower influenza vaccine effectiveness in households[194,195] and the community,[194] but, again, analyses were not stratified by vaccine type. Further studies to determine the effect of prior season vaccination on the effectiveness of LAIV are warranted, but relatively few adults receive LAIV compared to IIV.

IMMUNE CORRELATES OF PROTECTION FOR LIVE ATTENUATED INFLUENZA VACCINE

A serum HAI antibody titer of 1:40 (or 1:32) was established as the 50% protective titer against influenza infection in healthy adults who were experimentally challenged with an influenza virus.[111] It is widely accepted that this correlates with protective immunity induced by inactivated influenza vaccines[196] and this benchmark forms the basis of the licensing criteria for inactivated influenza vaccines in the United States and in Europe.[197] In addition, Ohmit and colleagues found that postvaccination HAI titers elicited by TIV or LAIV were not fully predictive of protection against influenza infection,[198] and the applicability of this correlate of immunity in children has been questioned.[199]

Intranasally administered LAIV elicits mucosal and cell-mediated immunity in addition to serum antibody.[146] The contribution of the different arms of the immune system to LAIV-induced protection has been evaluated in mice and ferrets.[200–202] In mice, both cellular and humoral immunity contribute to LAIV-mediated protection and their relative contribution to viral clearance depends on the location and replication of the vaccine virus. Optimal protection against wild-type virus challenge in mice requires the development of neutralizing antibody; the magnitude of the humoral response and access of antibodies to the respiratory tract are equally important determinants of protection.[202] However, the relevance of the findings from the mouse model for the human experience are not clear because LAIVs replicate in the lower respiratory tract of mice but not in the lower respiratory tract of humans. In ferrets, $CD4^+$ and $CD8^+$ T-cell responses correlated with protection from challenge virus replication in the upper respiratory tract.[200]

In humans, the protective antibody response to influenza viruses is primarily directed at the HA and NA glycoproteins. Both serum IgG and mucosal IgG and IgA antibodies independently contribute to this resistance,[102,132,142] with serum IgG antibodies providing protection primarily to the lower respiratory tract and IgA antibodies providing protection primarily to the upper respiratory tract (reviewed in reference 82). The contribution of T cells to protection from influenza virus infection in humans was evaluated in a challenge study and two recent prospective studies in the United Kingdom. In the challenge study with an H1N1 virus, the presence of preexisting cross-reactive influenza-specific $CD4^+$ T cells correlated with protection from severe illness and decreased shedding.[203] In a cohort study, Sridhar and colleagues found that in the absence of cross-reactive neutralizing antibodies, $CD8^+$ T cells specific to conserved viral epitopes correlated with cross-protection against symptomatic influenza illness during the 2009 pandemic.[204] Individuals who developed less-severe illness had higher frequencies of preexisting T cells to conserved CD8 epitopes.[204] In a separate study of a population cohort of 1414 unvaccinated individuals from 2006 to 2010, Hayward and colleagues found that preexisting cross-reactive T-cell responses to NP were independently associated with decreased odds of nasal viral shedding in those infected with seasonal or pandemic influenza. The presence of baseline influenza A NP-specific T cells correlated with less symptomatic, polymerase chain reaction (PCR)-positive influenza A infection (overall adjusted odds ratio, 0.27; 95% CI, 0.11–0.68; $P = .005$, during pandemic [$P = .047$] and seasonal [$P = .049$] periods). Protection was independent of baseline antibodies. Taken together, the data from these studies indicate that preexisting T-cell immunity independent of baseline antibodies protects against symptoms and viral shedding associated with influenza.

IIVs induce higher titers of serum HAI and NAI antibodies than LAIV in primed individuals, but LAIV is more efficient in inducing mucosal IgA antibody responses.[132,142] In human challenge studies and in field studies, LAIV was highly efficacious even in persons with modest serum HAI responses[73,114,158] and either serum antibody or nasal wash IgA was a predictor of protection.[154] The induction of influenza-specific T cells by LAIVs has been demonstrated in children.[132,145,146] In a large field study of seasonal LAIV administered to young children, more than 100 spot-forming cells per 10^6 peripheral blood mononuclear cells in an IFNγ ELISPOT assay was associated with protection against culture-confirmed influenza illness.[162]

In addition, it has been shown that LAIVs alter the expression of IFN-related genes, whereas IIVs do not, suggesting that the innate immune response plays an important role in protection mediated by LAIVs.[149] A robust Type I (IFNγ) interferon response was observed when peripheral blood mononuclear cells from LAIV recipients were cultured with LAIV.[147] A comparison of genome-wide transcript profiles in whole blood from young children 7 days following vaccination with LAIV or TIV revealed that LAIV induced higher expression of Type I IFN and interferon-stimulated genes than TIV.[151] In summary, our understanding of LAIV-induced immunity will be enhanced as assays that permit evaluation of cellular and innate immune responses are incorporated into clinical studies designed to explore immune correlates of protection for LAIV and biomarkers of early responses to LAIV.

EFFICACY OF LIVE ATTENUATED INFLUENZA VACCINE COMPARED WITH TRIVALENT INACTIVATED INFLUENZA VACCINE

Comparison of the efficacy of LAIV relative to TIV may provide useful data to inform public health policy decisions on the recommendations for influenza vaccination in different populations. Although LAIV and TIV were compared in several clinical trials,[205] definitive conclusions regarding relative efficacy cannot be drawn from studies that were not randomized controlled studies or when efficacy was not measured as reduction in culture-confirmed ILI.

Relative Efficacies of Live Attenuated Influenza Vaccine and Trivalent Inactivated Influenza Vaccine in Children

Between 1985 and 1990, randomized controlled clinical trials of a single dose of bivalent influenza A LAIV compared with inactivated vaccine or placebo were conducted at Vanderbilt University.[158] In 2001, Neuzil and colleagues reanalyzed the data from subjects who were younger than 16 years of age at the time of the study.[206] Efficacy was based on protection from culture-positive or serologically confirmed influenza illness. In general, the frequency of culture-positive influenza illness was too low to assess the rates of disease or VE by age group, and the attack rates for the different subtypes differed.

During the seasons when H1N1 influenza viruses circulated, the inactivated vaccine and LAIV had very similar efficacies against culture-positive ILI. Although the efficacies of inactivated vaccine and LAIV were also similar for the H3N2 years, at 77% and 68%, respectively, the CIs were extremely wide. There was a low rate of influenza illness and a high rate of seroconversion in placebo recipients; the latter affected the assessment of VE by serology.

LAIV was reported to be more efficacious than TIV in infants and young children in a large international multicenter study.[88] A statistically significant reduction in the number of cases of culture-confirmed influenza illness was observed for both H1N1 and H3N2 viruses compared with TIV. A significant reduction in the number of cases of influenza B was not observed with either vaccine. Statistically significant reductions in culture-confirmed lower respiratory tract illness and influenza-associated OM were also observed in recipients of LAIV. However, the absolute efficacy of either vaccine could not be determined from this study because a placebo group was not included.

The efficacy of LAIV versus TIV has also been studied in children at high risk for severe influenza disease. Fleming and colleagues compared the efficacy of LAIV and TIV in adolescents and children with asthma.[207] Children between the ages of 6 and 17 years with a clinical diagnosis of asthma received a single dose of either TIV or the refrigerator-stable formulation of LAIV. The primary end point of the study was efficacy as determined by the incidence of culture-confirmed influenza illness caused by a community-acquired virus that was antigenically similar to the vaccine and only relative efficacies were reported. Overall, LAIV was found to be 34.7% more efficacious than TIV. There was a trend toward greater efficacy of LAIV against influenza A H1N1 and influenza B, but there was no difference between the two vaccines against influenza A H3N2. Influenza B was the predominant strain during the influenza season of this study, and LAIV had an overall 31.9% greater efficacy than TIV against all influenza viruses. There was no difference between the two vaccines for the pharmacoeconomic end points such as use of prescribed medications or antibiotics, incidence of unscheduled healthcare provider visits, incidence of hospitalizations, and number of days of absence from school or work.

The efficacy of two doses of LAIV or TIV in young children with a history of recurrent respiratory tract infection was reported by Ashkenazi and colleagues.[208] In this randomized, open-label trial, there were 52.7% fewer cases of culture-confirmed influenza caused by influenza viruses that antigenically matched the vaccine in children who received LAIV. Greater relative efficacy was observed for LAIV against influenza A H1N1 and influenza B, but not against influenza A H3N2. LAIV recipients also had a slight reduction in the number of visits to healthcare providers for respiratory tract illness and in absences from school, kindergarten, or daycare.

In summary, although some studies had design limitations, LAIV has been reported to be more efficacious than TIV in children, and several metaanalyses have reached the same general conclusion.[205,209,210] Post hoc analyses of the studies just described have also been conducted to address the relative efficacy of LAIV compared with TIV in children by age group,[161] as a function of length of time after vaccination,[211] and against influenza-associated OM.[212] The relative efficacy of LAIV compared to TIV in three studies conducted in children did not vary by age group,[161] suggesting that prior influenza infection or vaccination may not result in reduction of efficacy of LAIV. Relative efficacy of LAIV versus TIV against matched strains was greater at more than 4 to 8 months postvaccination compared to 0 to 4 months postvaccination (range, 49–89% vs 25–60%) in three large randomized clinical trials in children,[211] and greater protection against influenza-associated OM was observed in LAIV recipients in two TIV-controlled clinical trials,[212] an effect that was most evident in children 2 years of age and older. The interpretation of these studies is limited because most of the studies did not include a placebo arm.

Relative Efficacies of Live Attenuated Influenza Vaccine and Trivalent Inactivated Influenza Vaccine in Adults

Few comparative studies of LAIV and TIV have been reported in adults, and most of these studies measured vaccine effectiveness against symptomatic influenza. Table 32.6 summarizes the estimated relative efficacies of LAIV and TIV in these studies. In the multiyear placebo-controlled study conducted at Vanderbilt University,[158] efficacies of LAIV and TIV in adults against culture-confirmed influenza A did not significantly differ among study years. Both vaccines were efficacious in preventing seroconversion, and TIV was more efficacious than LAIV in the years when H3N2 viruses circulated.

The most comprehensive comparative efficacy studies of LAIV and TIV in adults were part of a multiyear study conducted at the University of Michigan comparing the efficacies of TIV and LAIV relative to placebo.[87,159,160] The primary end point was laboratory-confirmed symptomatic influenza, determined by virus isolation or serology. In the first year of the study, 2004–05, an influenza A H3N2 antigenic drift variant and two lineages of influenza B were the predominant circulating viruses, permitting determination of VE against antigenically mismatched strains.[160] Although the data suggested greater efficacy with TIV, a significant advantage of TIV over LAIV in terms of relative efficacy could not be demonstrated because there were too few laboratory-confirmed illnesses. LAIV prevented influenza illness, but the absolute efficacy was not significant. These findings contrast with previous studies in adults and children, where LAIV was highly efficacious against an H3N2 antigenic drift variant.[78,153] In the subsequent year (2005–06), influenza activity was relatively low. Efficacy

TABLE 32.6 Relative Efficacy of LAIV Versus TIV in Adults

Study Design	End Point	Estimated Efficacy Against Indicated End Point		Reference
		LAIV	TIV	
Multiyear, double-blind, randomized, placebo-controlled	Culture-confirmed influenza A H1N1, any study year	85% (95% CI, 70–92%)	76% (95% CI, 58–87%)	158
	Culture-confirmed influenza A H3N2, any study year	74% (95% CI, 52–86%)	58% (95% CI, 29–75%)	
	Culture-confirmed influenza A for years when H3N2 was circulating	32% (95% CI, 17–44%)	73% (95% CI, 65–79%)	
Double-blind, randomized, placebo-controlled	Culture-confirmed influenza, any virus	57% (95% CI, –3–82%)	77% (95% CI, 37–92%)	160
	Culture-confirmed influenza A	74% (95% CI, –12 to 95%)	74% (95% CI, –11 to 95%)	
	Culture-confirmed influenza B	40% (95% CI, –103 to 87%)	80% (95% CI, 8–97%)	
	Symptomatic influenza confirmed by culture or RT-PCR	48% (95% CI, –7 to 74%)	75% (95% CI, 42–90%)	
	Symptomatic influenza confirmed by culture or serology	30% (95% CI, –57 to 67%)	67% (95% CI, 16–87%)	
Double-blind, randomized, placebo-controlled	Symptomatic influenza confirmed by culture or serology	43% (95% CI, –15 to 71%)	54% (95% CI, 4–77%)	87
Double-blind, randomized, placebo-controlled	Culture-confirmed influenza, any virus	36% (95% CI, 0 to 59%)	68% (95% CI, 46–81%)	159
	Culture-confirmed influenza A H3N2	29% (95% CI, –14 to 55%)	72% (95% CI, 49–84%)	

CI, confidence interval; LAIV, live attenuated influenza vaccine; RT-PCR, reverse-transcription polymerase chain reaction; TIV, trivalent inactivated influenza vaccine.

of TIV was demonstrated when serologic evidence of influenza infection was included, but efficacy of LAIV was not statistically greater than placebo.[87] Laboratory-confirmed influenza rates in the third year of the study were higher, so a more comprehensive analysis of absolute and relative efficacy was possible.[159] The data demonstrated greater efficacy of TIV than LAIV against culture-confirmed influenza A (see Table 32.6). Efficacy of either vaccine against influenza B could not be determined because there were too few isolates of influenza B. The Michigan study underscores the difficulties in conclusively demonstrating the efficacy of influenza vaccines in well-controlled clinical trials. The unpredictable attack rate, the types of influenza virus circulating from season to season, and the antigenic variability of influenza viruses are all factors that must be considered.

A challenge study designed to demonstrate efficacy of LAIV and TIV in humans was reported by Treanor and colleagues.[114] Subjects were randomized to receive LAIV, TIV, or placebo, and 28 days later they were challenged with antigenically matched wild-type influenza virus. No significant difference was observed between LAIV and TIV in efficacy against laboratory- confirmed influenza illness, demonstrated by isolation of virus or seroconversion. However, vaccination with TIV resulted in a statistically significant reduction in shedding of challenge virus and infection rate. Interpretation of this study was limited by the small numbers of subjects, and lower-than-expected infectivity of the challenge virus in the placebo group.

Live Attenuated Influenza Vaccine in High-Risk Populations

Populations at highest risk for severe disease associated with influenza infection include very young children, persons with asthma or cystic fibrosis (CF), those suffering from an immunodeficiency, and adults older than 65 years of age. LAIV is currently licensed in children 2 years of age or older, based on several studies in large cohorts of children. Although the vaccine was well tolerated in most children, there was a significant increase in the risk of reactive airways disease in children 18 to 35 months of age.[90] Another large cohort study comparing LAIV to TIV found a significant increase in the rates of hospitalization for any cause in 6- to 11-month-olds in the first 180 days after vaccination.[88] However, LAIV was more effective than TIV in the young children in this study; the LAIV vaccine group had 54.9% fewer culture-confirmed influenza infections than TIV ($P < .001$). Although LAIV may be effective in children younger than 2 years of age it is not recommended by the ACIP or by the American Academy of Pediatrics because of concerns associated with reactive airways disease and hospitalization.

LAIV is not currently licensed for use in persons with asthma in the United States. Because children with asthma are at particularly high risk for severe influenza illness, further studies have been undertaken to examine the safety of LAIV in adolescents with asthma. In a study comparing placebo with LAIV in 9- to 17-year-old children with moderate to severe asthma,[213] mild exacerbations of asthma were recorded in two of 24 LAIV recipients and zero of 24 placebo recipients. A more recent open-label study compared TIV with LAIV in more than 2000 asthmatic children 6 to 17 years of age.[207] Participants with severe disease and recipients of immunosuppressive therapy were excluded. Although runny nose and nasal congestion were more common after LAIV, there were no significant differences between the two groups with regard to wheezing, peak expiratory flow rate, asthma exacerbations, asthma symptom scores, or nighttime awakening scores, indicating that LAIV is safe and effective in asthmatic children.[207,214] The efficacy of LAIV in preventing influenza in asthmatic children was 34.7% (95% CI, 3.9–56.0%) higher than TIV. Additionally, the rate of emergency department visits or hospitalizations within 42 days was equivalent after vaccination with LAIV or TIV in children 2 to 5 years of age with asthma or recurrent wheezing.[215]

Severe morbidity in association with influenza infection has been found in patients with CF,[216] and vaccination with TIV is recommended for all patients with CF and their families. In a 3-year study in patients with CF and their families, both LAIV and TIV were effective.[217]

Concerns about the inadvertent exposure of immunodeficient patients to a live vaccine have prompted small studies of the safety and immunogenicity of LAIV in persons infected with HIV and those with cancer. In one study of noninfected adults and HIV-infected adults with $CD4^+$ counts greater than

200 cells/mm^3, LAIV resulted in similar rates of runny nose and other minor symptoms in HIV-infected and noninfected persons. Among HIV-infected persons, no difference in HIV viral load and CD4$^+$ levels were seen up to 6 months after vaccination between the vaccinated group and placebo recipients.[218] Additional studies to assess the immunogenicity of LAIV and shedding of vaccine virus have been conducted in a small number of children who were immunocompromised because of HIV infection or cancer.[219–222] None of these studies reported any SAEs or ILI. Additionally, HIV-infected children produced anti-influenza neutralizing antibodies and increased salivary IgG antibodies following receipt of LAIV.[222] These studies suggest that exposure to LAIV does not pose a risk to HIV-infected persons and that LAIV vaccine may be useful to protect HIV-infected persons against influenza infection.

Persons 65 years of age and older are one of the highest-risk groups for serious illness and death from epidemic influenza.[223] Although LAIV is approved only for healthy persons between 2 and 49 years of age, these vaccines have been evaluated in healthy adults 50 years of age and older, and in those with chronic cardiopulmonary conditions or diabetes mellitus. Table 32.7 summarizes these studies.[224–231] In most of these studies, LAIV was administered simultaneously with TIV and LAIV was safe and well tolerated. Coadministration of TIV and LAIV was reported to enhance local HA-specific IgA antibody responses.[225,229,230,232] However, the efficacy of the combination of the two vaccines compared with TIV alone remains equivocal. A recent study by Forrest and colleagues designed to determine the relative efficacy of LAIV versus TIV in persons 60 years of age and older[233] was inconclusive because of the low incidence of influenza in both vaccine groups.

TABLE 32.7 Safety and Efficacy of Live Attenuated Cold Adapted Influenza Vaccines in Individuals Aged ≥50 Years

Vaccine	Study Population and Age Range	Safety	Efficacy/Effectiveness		Reference
			Measure	% Efficacy (95% CI)	
Monovalent A/H1N1 LAIV alone or with TIV	Ambulatory elderly, 65–83 y	Very rare reports of rhinitis (LAIV) and pharyngitis (LAIV + TIV)	N/A	ND	230
Bivalent A LAIV (H1N1 and H3N2) alone or with TIV	Healthy elderly, 60–90 y	Very rare reports of low-grade fever with rhinitis and local reactions (LAIV + TIV)	N/A	ND	229
Trivalent LAIV with TIV	Elderly nursing home residents, mean age 84.1 y	No significant symptoms reported	Lab-documented influenza A Outbreak-associated respiratory illness Outbreak-associated ILI	60.6% (18–82%) 56.8% (23–76%) 65% (17–86%)	231
Bivalent A LAIV (H1N1 and H3N2) with TIV	Chronically ill elderly, ≥60 y	Vaccines well tolerated	N/A	ND	227
Trivalent LAIV with TIV	Chronically ill elderly with cardiovascular or pulmonary conditions, or diabetes mellitus, 65–75 y	Sore throat, runny nose more frequent with LAIV	N/A	ND	228
Trivalent LAIV with TIV	Adults with chronic obstructive pulmonary disease, ≥50 y	Significant increase in runny nose, shortness of breath, chills, headache and itchiness at injection site with LAIV + TIV	Lab-documented influenza-caused illness: • Any influenza virus • H3N2 influenza A • Influenza B • Possible advantage in reducing respiratory consequences of influenza infection as measured by pulmonary function and symptoms at the end of the study	Not statistically significant: 16% (–22 to 43%) 26% (–17 to 53%) 5% (–113 to 48%)	225, 226
Trivalent LAIV alone	Community-dwelling ambulatory adults, ≥60 y	Cough, sore throat, runny nose/nasal congestion, headache, myalgia, tiredness, loss of appetite more frequent with LAIV. Single report of bronchopneumonia and single report of asthma with LAIV	Culture-confirmed influenza, any vaccine strain Culture-confirmed influenza, any strain Culture-confirmed influenza A H3N2 Efficacy in subjects ≥70 y against influenza A H3N2 Efficacy in subjects 60–69 y against influenza A H3N2 Efficacy against influenza B	42.3% (21.6–57.8%) 41.6% (20.9–57.1%) 52.5% (32.1–67.2%) 65.7% (37.3–82.2%) 41.8% (8.3–63.7%) Not efficacious	224

Community Protection Afforded by Live Attenuated Influenza Vaccine

Indirect protection of unvaccinated individuals within a community that is afforded by the immunity of immunized members of the community has been demonstrated for infectious diseases of viral and bacterial etiology, and it is widely accepted that this phenomenon occurs with influenza.[234] Although influenza vaccine policy in the United States has been focused on the immunization of persons 65 years of age and older and vaccination rates increased from 31% to 67% between 1989 and 1997, influenza epidemics still cause widespread morbidity and mortality in this age group.[234–236]

Several lines of evidence suggest that widespread immunization of otherwise healthy populations may interrupt transmission of influenza and thereby indirectly protect those in high-risk groups. For example, vaccination of healthcare workers was associated with reduced morbidity and mortality from influenza among nursing home residents,[237–241] and healthcare workers now constitute a priority group for influenza vaccination in the United States.[223]

Widespread vaccination of schoolchildren has also been proposed as a measure to reduce the burden of influenza in the community, because children are important vectors for the spread of influenza. The ability to modify the course of an influenza outbreak by vaccination of schoolchildren has been demonstrated in several studies. A vaccination rate of 86% with a monovalent inactivated vaccine in schoolchildren in Tecumseh, Michigan, resulted in a threefold reduction in the excess attack rate for the community from influenza compared with a neighboring community in which schoolchildren were not vaccinated.[242] A clear difference was observed in the rates of school absenteeism between the communities, and there was evidence that protection was not limited to children of school age. In Japan, vaccination of schoolchildren was mandatory between 1977 and 1987. In 1987, the laws were relaxed, and parents could decide whether or not their children received vaccine. In 1994, vaccination rates fell to low levels amid doubts about the effectiveness of the vaccine. In an analysis of all-cause mortality and death attributed to influenza and of vaccination rates from Japan and from the United States between 1949 and 1998, Reichert and colleagues found that excess mortality rates, predominantly in older persons, dropped significantly in Japan with initiation of the program to vaccinate schoolchildren, from rates three to four times those in the United States to rates similar to those in the United States.[243] Excess mortality rates in Japan increased with discontinuation of the vaccination program for schoolchildren.

From a practical standpoint, LAIV could be an extremely effective method to achieve community protection if high vaccination rates with an efficacious vaccine are achieved in schoolchildren and influenza transmission to other segments of the community is interrupted. Large numbers of children could be vaccinated in a short period, and intranasal administration is preferred over injection of inactivated vaccine. There is evidence from several studies that this is an effective approach. A study conducted in the 1990s demonstrated that vaccination of schoolchildren with either inactivated or Russian LAIV resulted in significant protection. In schools where children received LAIV, vaccination rates and illness among staff and unvaccinated children were inversely correlated, suggesting reduction of transmission as a result of vaccination. Such a correlation was not seen in the schools where children received inactivated vaccine or in schools where children received placebo.[244]

There are several studies in a community in central Texas that report both direct and indirect protection against ILI afforded by vaccination of children. In these studies, age-specific rates of MAARI during the influenza season in intervention communities, where children received LAIV, were compared with rates in comparison communities, where children did not receive vaccine. Vaccination of approximately 20% to 25% of children, 1.5 to 18 years of age, in intervention communities resulted in indirect protection of 8% to 18% against MAARI in adults older than 35 years of age. This small effect may translate into a substantial effect at the population level. Moreover, the size of this effect may be diluted from use of clinical rather than laboratory end points.[245] In another study, significant protection against laboratory-confirmed influenza illness and pneumonia and influenza events was observed in the children who received LAIV, but not in those who received TIV. Indirect effectiveness against MAARI was observed in 5- to 11-year-old children and in 35- to 44-year-old adults.[246] In a third study,[247] when schoolchildren were vaccinated with LAIV against antigenically mismatched influenza viruses, significant indirect protection from influenza was observed in all age groups, except those 12 to 17 years of age. Combined virologic surveillance and MAARI visit data suggested that a single dose of LAIV provided better protection against influenza than TIV.

King and colleagues reported a small pilot study followed by a larger, multistate, school-based immunization intervention study using LAIV.[248,249] In the pilot study,[248] significant (45% to 70%) relative reductions in fever or respiratory illness–related outcomes including physician visits by adults, physician visits by children, prescription or other medicines purchased by household members, and family schooldays and workdays missed, were observed for intervention ("target") school households compared with control school households. In the larger trial, intervention school households reported significantly fewer ILI-related doctor or clinic visits for children; fewer episodes of fever plus cough or sore throat in children and adults; lower ILI-related prescription, over-the-counter, and herbal medication use for ILI; lower absenteeism rates for elementary and high-school students; and fewer missed workdays for adults caring for their own ILI or for others during the peak influenza week. Relative reductions across these outcomes ranged from 25% to 40%, again confirming indirect as well as direct benefit. Limitations of this study included the lack of placebo groups and the use of questionnaires for reporting of ILI.

A cluster, randomized, blinded trial was undertaken over three influenza seasons from 2012–15 in 52 Hutterite communities in Canada to determine whether vaccinating children and adolescents with trivalent LAIV would provide better community protection than IIV.[250] Influenza virus infection occurred at a rate of 5.3% (295 of 5560 person-years) in the LAIV group compared to 5.2% (304 of 5810 person-years) in the IIV group. The hazard ratio comparing LAIV with IIV for influenza A or B virus was 1.03 (95% CI, 0.85–1.24). The authors concluded that immunizing children with LAIV does not provide better community protection against influenza than IIV.

In summary, a large body of data demonstrates the effectiveness of vaccination of schoolchildren for the control of influenza in communities, from both direct and indirect effects of immunization. Both LAIV and TIV are highly efficacious against influenza in children, and a mechanism to explain how LAIV could afford better indirect protection is not clear. The data from these studies support the widespread vaccination of schoolchildren as a means of reducing morbidity and mortality in other high-risk members of communities.

Heterosubtypic Immunity

Immunity elicited by infection with an influenza A virus that provides protection against infection by a virus from another HA or NA subtype is referred to as heterosubtypic immunity. This phenomenon was first proposed after the 1957 pandemic, when adults may have had some protection against the pandemic H2N2 strain as a result of previous influenza infection with an H1N1 virus.[251,252] Heterosubtypic immunity has been reported in animal models,[253–256] but evidence of the phenomenon occurring in humans is weak. Given that vaccination with LAIV is known to elicit a broad range of immune responses against conserved influenza virus proteins (see "Immunogenicity of Live Attenuated Influenza Vaccine" earlier), it is possible that LAIV may confer heterosubtypic immunity. One study was designed to address the impact of heterosubtypic immunity induced by LAIV in children.[257] Children with preexisting HAI titers against either H1N1 or H3N2 viruses were challenged with a monovalent LAIV of the other subtype, and the ability of prior immunity to restrict the replication of the vaccine virus was sought as evidence of heterosubtypic immunity. Regardless of prior seropositivity, infection rates were equivalent, suggesting that LAIV did not induce heterosubtypic immunity. Larger population-based studies are underway to determine whether robust heterosubtypic immunity exists in humans.

Interference Between Strains

Infection with closely related viruses can lead to a predominance of one strain over another if replication of one virus interferes with the replication of the other strain. This phenomenon is of concern in the context of a multivalent live virus vaccine, because it can lead to variable efficacy of different components. Only a few studies have examined whether interference exists between influenza strains in the trivalent LAIV. Interference is most accurately assessed in subjects in whom a robust serum antibody response occurs; therefore, young seronegative children are the ideal subjects for such studies (see "Antibody Responses" earlier). Although there is insufficient evidence to conclude that interference between LAIV vaccine strains exists, the seroconversion rate in children against the H1N1 strain after the first dose was lower than for H3N2 and B strains, and this was rescued by administration of $10^{7.0}$ $TCID_{50}$ of each vaccine strain, which is approximately the dose in the licensed vaccine, or by administration of a second dose of vaccine.[89,116]

The question of interference between the component strains of LAIV came to the fore again when the Q/LAIV was being developed. A review of nonclinical studies in animal models and clinical trials in which interference between strains had been examined concluded that there is no clinically significant evidence of interference between component strains of LAIV.[258] However, it was recently proposed that interference between the component strains of LAIV may be a contributing factor to the observed reduced effectiveness of LAIV in recent seasons, particularly against the 2009 pandemic H1N1-like viruses.[178] It is possible that the change to the Q/LAIV formulation is associated with lower effectiveness of the H1N1 strain. It is important to note that in the immunogenicity bridging studies in humans to support licensure of Q/LAIV,[76,77] as well as the animal studies on interference reviewed by Bandell and colleagues,[258] the H1N1 components of LAIV were pre-2009 seasonal H1N1 viruses. Interference could compound other factors that were proposed to account for reduced vaccine effectiveness, such as thermostability of the HA[259] or increasing population immunity by repeated annual vaccination.

LIVE ATTENUATED VACCINES AGAINST PANDEMIC INFLUENZA

Experience with LAIV against seasonal influenza suggests that live vaccines may be an effective vaccination strategy for pandemic influenza. Potential advantages of LAIV include induction of humoral and cellular immunity, protection after a single dose, broad cross-protection against antigenic drift variants, high yield, and efficient manufacturing using infrastructure that is already in place for seasonal LAIV. To minimize the risk of the introduction of novel HA and NA genes into the environment, LAIV would not be used for vaccination against a novel pandemic influenza virus until the virus was known to be spreading in the human population.

Live Attenuated Influenza Vaccine Against the 2009 Pandemic H1N1 Virus

In response to the emergence of the H1N1pdm09 in 2009, a monovalent LAIV was rapidly produced by MedImmune.[70,260] The HA and NA genes of the vaccine virus were derived from the A/California/7/2009 (H1N1) influenza virus.[70] In randomized, double-blind, placebo-controlled clinical trials in healthy children (2 to 17 years old) and adults (18 to 49 years old), the monovalent H1N1pdm09 LAIV was found to have a safety profile similar to that of seasonal LAIV. As has been observed with seasonal LAIV, seroconversion rates (defined as a fourfold or greater rise in serum HAI titer) were modest. In children, seroconversion was observed in 11.1% and 32.0% of vaccine recipients by study day 29 (post–dose 1) and study day 57 (post–dose 2), respectively, compared with 6.3% and 14.5% in placebo recipients, regardless of baseline serostatus. In adults, seroconversion rates were 6.1% and 14.9% by study days 29 and 57, respectively, compared with 0% and 5.6% in the placebo group.[260]

In a study of H1N1pdm09 influenza vaccine effectiveness from four communities in the United States, it was reported that 21% of 1057 vaccine recipients received the live vaccine.[171] Effectiveness of the live vaccine, for those between 2 and 49 years old, was demonstrated only if vaccination more than 7 days prior to illness onset was considered, and the adjusted effectiveness estimate was 61% (95% CI, 12–82%). As recommended by the World Health Organization, the ca A/California/07/2009 (H1N1) was included in the subsequent seasonal trivalent LAIVs, and in the Q/LAIV for the 2013–14 season.

Table 32.8 summarizes vaccine effectiveness data for LAIV against A/California/07/2009-like H1N1pdm09 influenza. Low or no significant VE against H1N1pdm09 influenza was reported in the United States for the 2013–14 influenza season.[174,175,261] This was thought to be related to the thermal instability of the HA, resulting from the presence of the particular amino acid residue, E47, in the stalk region of A/California/07/2009-like H1N1pdm09 viruses.[259] Accordingly, the A/California/07/2009-like H1N1pdm09 component of Q/LAIV was replaced with a virus that did not have this residue in the HA stalk, A/Bolivia/559/2013 (H1N1). Despite this change in strain, the U.S. Influenza Vaccine Effectiveness Network reported no effectiveness of Q/LAIV against H1N1pdm09 in children and adolescents in an interim analysis of the 2015–16 influenza season, when H1N1pdm09 was the predominant circulating strain,[179] whereas IIV was found to be effective. However, data from a postmarketing study (ICICLE [Influenza Clinical Investigation for Children]) conducted by the manufacturer reported a point estimate for adjusted VE of LAIV of 50%,[180] which contrasted with a VE of −21% reported by the U.S. Vaccine Influenza Vaccine Effectiveness Network.[179] It should be noted that the adjusted VE point

TABLE 32.8 Effectiveness of LAIV Against H1N1 Influenza Since 2009

Season	LAIV	Study Description	Age Group (Years)	No. of Subjects Who Received LAIV Among		No. of Subjects Who Received IIV Among		Adjusted VE Estimate (95% CI)		Reference

estimates for IIV against H1N1pdm09 were similar and the Q/LAIV was less effective than IIV in both analyses. The point estimates for VE against any influenza for LAIV also differed greatly between the two studies (46% [95% CI, 7–69] in the ICICLE study versus 3% in the U.S. Influenza Vaccine Effectiveness Network study). Although it is widely acknowledged that observational studies have several limitations, the reported studies used a test-negative study design and were conducted in similar numbers of subjects. As of the time of writing, there is no clear explanation for the discordance in the findings with respect to effectiveness of Q/LAIV from the various studies conducted to date. This question notwithstanding, findings from the U.S. Influenza Vaccine Effectiveness Network interim analysis for the 2015–16 influenza season further fueled concerns that the H1N1pdm09 component of LAIV is particularly problematic, which led to the recommendation from the ACIP that Q/LAIV not be used for the 2016–17 influenza season (see "Indications for the Use of Live Attenuated Influenza Vaccine to Prevent Influenza" below). Notably, in a report published after the ACIP recommendation, trivalent LAIV and IIV were shown to be similarly effective in preventing RT-PCR–confirmed H1N1 influenza in the 2013–14 season in a cluster randomized trial in Hutterite communities in Canada, with a hazard ratio of 1.09 (95% CI, 0.34–3.49), although vaccine effectiveness was not assessed because the study did not include a placebo group.[250]

Live Attenuated Influenza Vaccine Against Other Influenza Viruses of Pandemic Potential

Although pLAIVs against other influenza viruses with pandemic potential have not been licensed, potential pLAIVs on the A/AA ca and Len/17 ca virus backbones are being evaluated.[71,262] Reassortant A/AA ca vaccine viruses against H9N2, H5N1, H7N3, H7N7, H6N1, and H2N2 subtypes of influenza were generated and evaluated in preclinical studies and in clinical trials.[191,263–267] In Phase I clinical trials in healthy adults, the A/AA ca pLAIV viruses were found to be safe, but were highly restricted in replication and were variably immunogenic.[191,263–267] Despite the absence of robust detectable antibody responses to the primary vaccination with pLAIV, subjects who received either H5N1 or H7N7 pLAIV exhibited rapid and robust antibody responses when they received a single dose of inactivated subvirion vaccine (ISV) of the same subtype years after they had received pLAIV.[191,192] Table 32.9 summarizes these findings. In the case of H5N1, subjects received ISV almost 5 years after receipt of H5N1 pLAIV, and the antibody responses to ISV in pLAIV-primed individuals occurred at higher frequency, were of higher titer, and higher affinity than in unprimed subjects.[192] In addition, the antibody in H5N1 pLAIV-primed subjects cross-reacted with several antigenically divergent viruses of other H5N1 clades. Similar observations were seen in subjects primed with H7N7 pLAIV who received an H7N7 ISV approximately 2 years later[191,268]: sera from primed subjects was of higher titer and cross-reacted with antigenically distinct H7 influenza viruses, including the recently emerged H7N9 influenza virus.[191,269] These findings suggest that receipt of pLAIV results in a long-lasting B-cell memory response. The observations have significant implications for pandemic preparedness, and studies evaluating the optimal interval between priming and boosting, as well as the order in which the LAIV and ISV are administered are underway. Clinical studies with pLAIV will be highly informative for determining the correlates of protection for LAIV.

In response to the emergence of H7N9 avian influenza in China in 2013, a candidate H7N9 LAIV was generated, bearing the HA and NA of the A/Anhui/1/2013 (H7N9) virus. This candidate vaccine was immunogenic and efficacious in ferrets[270] and is currently being evaluated in Phase I clinical trials. Pandemic LAIV based on the Russian Len/17 ca donor strain are also in development.[262] Several other approaches to the development of live attenuated vaccines for pandemic influenza are being pursued. An H5N1 vaccine based on an NS1 deletion mutant[271,272] was tested in a Phase I clinical trial in Europe. Shedding of the vaccine virus was not observed in any of the subjects, and it was found to be safe and immunogenic.[273] Cytoplasmic tail mutants of M2[52,274] and Newcastle disease virus–vectored vaccines[275] are also being explored, but they are still in the preclinical stage of evaluation.

INDICATIONS FOR USE OF LIVE ATTENUATED INFLUENZA VACCINE TO PREVENT INFLUENZA

LAIV is approved for use by the FDA for active immunization to prevent disease caused by influenza A and B viruses in healthy children, adolescents, and adults, between 2 and 49 years of age. In 2014, the ACIP issued a recommendation that when immediately available, LAIV should be used rather than IIV for healthy children 2 to 8 years of age who have no contraindications or precautions.[276] The guidelines also stated that IIV should be used if LAIV was not available, and vaccination should not be delayed if LAIV was not available.

TABLE 32.9 Immunologic Priming by H5 and H7 Pandemic LAIV

pLAIV				Serum HAI Antibody Titer at Indicated Time Point				
							Responders (Day 28 Post-ISV)[a]	
Vaccine	No. of Doses	ISV, Dose	Interval Between pLAIV and ISV	N	Pre-ISV GMT (Range); All Subjects	Post-ISV Day 28 GMT (Range); All Subjects	%	GMT
H5N1 VN04[b]	2	H5N1 VN04, 45 μg	56 mo	11	5[b]	87[c] (5–1280)	73	222
H5N1 HK03[b]	2	H5N1 VN04, 45 μg	54 mo	10	5[d]	29[c] (5–480)	50	146
H7N7 NL03[e]	2	H7N7 NL03, 45 μg	19–24 mo[f]	13	2[d]	181[g] (2–512)	69	234

GMT, geometric mean titer; HAI, hemagglutination-inhibiting; ISV, inactivated subvirion vaccine; LAIV, live attenuated influenza vaccine; pLAIV, pandemic live attenuated influenza vaccine.

This preferential recommendation was based on the available efficacy data comparing LAIV and IIV in children. The age range was based on the existing upper age limit for receipt of two doses of LAIV in naïve children. However, this recommendation was reversed in March 2015 when low effectiveness of LAIV against H1N1 influenza in some previous seasons was reported.[100,176]

In 2016, based on estimates from the U.S. Influenza Vaccine Effectiveness Network of low effectiveness of LAIV against H1N1pdm09 in 2015–16 and data from prior influenza seasons since 2010 that contrast with higher and statistically significant effectiveness of IIV in the same studies, the ACIP recommended against the use of LAIV in the United States for the 2016–17 influenza season. The FDA, however, issued a position statement that the agency continues to find that the benefits of Q/LAIV outweigh potential risks and that no specific regulatory action is warranted at this time.[277] The FDA statement cited the inherent limitations of the observational studies upon which the ACIP recommendation was based, as well as the variability of influenza vaccine effectiveness across seasons. In the United Kingdom, where Q/LAIV is the cornerstone of the childhood influenza vaccination program, Public Health England found no reason to change the current recommendations regarding the use of Q/LAIV.[278,279] Effectiveness data from studies conducted in the United Kingdom and Finland, which demonstrated overall effectiveness of Q/LAIV in 2015–16,[180] informed their decision.

Prior to the ACIP recommendation for 2016–17, the ACIP guidelines for use of LAIV recommended that children 2 to 8 years of age should receive two doses at least 4 weeks apart in their first year of influenza vaccination; children in this age group who received at least two prior doses of influenza vaccine in the past, require only one dose. For persons 9 to 49 years of age, it was recommended that a single dose annually prior to exposure to influenza should be administered. In contrast to IIV, which has been used largely in populations at high risk for death or other complications of influenza, LAIV is currently indicated to prevent influenza in persons without underlying high-risk conditions. Table 32.10 compares and contrasts LAIV and IIV.

The age range up to 49 years was selected for initial clinical use in healthy persons because of the adequacy of safety and efficacy data in that age range. The effectiveness trial in healthy working adults was specifically designed to examine the clinical benefits of LAIV compared with placebo in all persons 18 to 64 years old, but there were limited effectiveness data in the subgroup of 50- to 64-year-olds, a population universally recommended to receive trivalent inactivated vaccine.[78] Post hoc analysis among persons 50 to 64 years of age (641 [14%] of the 4561 adults) did not reveal statistically significant reductions in illness measures (proportion, episodes, or days of illness), but there were significant reductions in illness-associated missed work days and visits to healthcare providers. In a similarly designed effectiveness study in more than 1000 adults 18 to 64 years of age conducted by the CDC, TIV was compared with placebo in the same season; there were no reductions in any illness measures in any age group.[168] In Canada, the upper age limit for LAIV is 59 years.

SPECIAL CONSIDERATIONS AND CONTRAINDICATIONS

The following precautions should be considered before vaccinating with Q/LAIV in the United States:

- Q/LAIV is not indicated for persons younger than 2 years of age.
- Q/LAIV is not indicated for persons 50 years of age and older.
- Q/LAIV is contraindicated for persons with a history of hypersensitivity, especially anaphylaxis, to any component in LAIV, including eggs.
- Q/LAIV is contraindicated for children or adolescents receiving aspirin or other salicylates because of the association of Reye syndrome with wild-type influenza infection.
- Persons with a history of GBS should not receive Q/LAIV.

TABLE 32.10 Comparison of Live Attenuated Influenza Vaccine (LAIV) and Inactivated Influenza Virus Vaccine (IIV)

	LAIV	IIV
Route of administration	Intranasal spray	Intramuscular injection
Type of vaccine	Live virus	Killed virus
Number of included virus strains	4 (2 influenza A, 2 influenza B)	4 (2 influenza A, 2 influenza B) Trivalent formulation is also available (2 influenza A, 1 influenza B)
Vaccine virus strains updated	Annually	Annually
Frequency of administration	Annual	Annual
Can be administered to children and adults at high risk[a] from complications arising from influenza	No	Yes
Can be simultaneously administered with other vaccines	Yes[b]	Yes[c]
If not simultaneously administered, can be administered within 4 weeks of another live vaccine	Yes, but prudent to wait 4 weeks	Yes
If not simultaneously administered, can be administered within weeks of an inactivated vaccine	Yes	Yes

[a]Populations at high risk from complications of influenza infection include persons older than 65 years of age; residents of nursing homes and other chronic-care facilities that house persons with chronic medical conditions; adults and children with chronic disorders of the pulmonary or cardiovascular systems; adults and children with chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression; children and adolescents receiving long-term aspirin therapy (at risk for developing Reye syndrome after wild-type influenza infection); and women who will be in the second or third trimester of pregnancy during influenza season.

[b]No data exist regarding effect on efficacy; LAIV coadministration has been evaluated systematically only in children with measles-mumps-rubella (MMR) II and Varivax vaccines.

[c]Trivalent inactivated influenza vaccine coadministration has been evaluated systematically only in adults with pneumococcal polysaccharide vaccine.

- Pregnant women should not receive Q/LAIV unless clearly needed. This recommendation is based on a theoretical concern: there has been no indication of fetal harm from LAIV in animals studies, and it is not known whether LAIV can cause fetal harm when administered to a pregnant woman, or can affect reproductive capacity.
- Persons with asthma, reactive airways disease, or other chronic disorders of the pulmonary or cardiovascular systems; persons with other underlying medical conditions, including metabolic diseases such as diabetes, renal dysfunction, and hemoglobinopathies; and persons with known or suspected immune deficiency diseases or receiving immunosuppressive therapies should not receive Q/LAIV.

If close contacts of severely immunosuppressed persons (e.g., bone marrow transplant patients while they are in a protected environment) are given Q/LAIV, they should avoid close contact with the immunosuppressed patient for 7 days.

For vaccination of healthy persons 2 to 49 years of age in close contact with members of all other immunocompetent high-risk groups (e.g., persons with heart disease, lung disease, or diabetes), either IIV or Q/LAIV is an acceptable vaccination option.

TIMING OF LIVE ATTENUATED INFLUENZA VACCINE ADMINISTRATION

Vaccination with LAIV can begin as soon as vaccine is available for the season. Children younger than 9 years old receiving LAIV for the first time should begin in October or earlier in the Northern Hemisphere, because they will need a second dose a minimum of 4 weeks after the initial dose. It was observed that different two-dose regimens of TIV alone, LAIV alone, LAIV followed by TIV, or TIV followed by LAIV administered to children 6 to 35 months of age at an interval of 1 month were well tolerated and induced similar levels of HAI antibody.[146] The level of replication of LAIV was compared in children who were vaccinated with LAIV or TIV a month earlier. Children who were previously vaccinated with LAIV had less replication of the subsequent dose of LAIV than children who were vaccinated with TIV a month earlier.[135] Both studies were conducted with a small number of children, but the findings suggest that flexibility in immunization regimens may be an effective approach to vaccination of young children against influenza. The safety and immunogenicity of concurrent administration of LAIV with measles-mumps-rubella II and Varivax vaccines have been evaluated in children 12 to 15 months of age[280]; they were safe and well tolerated, and the immune responses to the relevant viral antigens were similar whether the vaccines were given concurrently or separately. In the absence of specific data indicating lack of interference with other vaccines, it is prudent to follow the ACIP General Recommendations on Immunization. Inactivated vaccines do not interfere with the immune response to other inactivated vaccines or to live vaccines. An inactivated vaccine can be administered either simultaneously or at any time before or after LAIV. A live vaccine not administered on the same day should be administered after a 4-week (or longer) interval when possible.

Administration of Live Attenuated Influenza Vaccine and Influenza Antiviral Use

It is not known whether administering influenza antiviral medications affects the safety or efficacy of LAIV; LAIV should not be administered until 48 hours after cessation of influenza antiviral therapy, and influenza antiviral medications should not be administered for 2 weeks after receipt of LAIV.

CONCLUSIONS

LAIV has the potential to significantly contribute to the control of influenza and influenza-associated illnesses. LAIV has significant advantages in convenience of administration. The observation of high efficacy of LAIV compared with TIV against matched strains and, in some seasons, drifted strains, are compelling reasons to use the vaccine in children. Effectiveness of LAIV in adults has also been demonstrated. However, low effectiveness of LAIV reported in some studies with the quadrivalent vaccine in recent influenza seasons, particularly in the face of significant effectiveness on IIV, is of concern. Efforts to further investigate these findings and identify contributing factors should be undertaken to ensure the continued availability of this important public health measure to protect against influenza infection and illness.

33 Japanese Encephalitis Vaccines

Scott B. Halstead, Susan L. Hills, and Katrin Dubischar

Japanese encephalitis (JE), a mosquito-borne flavivirus infection, is the leading recognized cause of childhood encephalitis in Asia. Despite JE being vaccine preventable, thousands of cases and deaths are reported annually.[1] However, in many locations, the disease is not under systematic surveillance, and official reports undoubtedly underestimate the true number of cases.[2–4] JE virus (JEV) is transmitted throughout most of Asia and parts of the western Pacific, in a region supporting 3.2 billion people—almost 50% of the world's population (Fig. 33.1). Consequently, regional JE-associated morbidity probably exceeds worldwide morbidity from herpes encephalitis.[3,5,6] Because of the near-eradication of poliomyelitis, JE is the leading cause of childhood viral neurologic infection and disability in Asia.[7] The integration of JE vaccine into routine immunization programs in some of the higher-income Asian countries—including Japan, South Korea, Taiwan, and Thailand—has led to its near elimination, with the greatest disease burden now in many of the least-developed countries in Asia (Fig. 33.2).[7] By any standard, JE is a major public health problem. Fortunately, it is controllable by proven effective vaccines.[8]

HISTORY OF DISEASE

Summer-fall encephalitis outbreaks consistent with JE were recorded in Japan as early as 1871, the largest of which, in 1924, led to more than 6000 cases, with more than 60% of them fatal.[9] A filterable agent from human brain tissue was isolated in rabbits that year, and in 1934, Hayashi transmitted the disease experimentally to monkeys.[10] Soon after, the isolation of JE and the related St. Louis encephalitis (SLE) viruses made possible serologic confirmation of encephalitis cases occurring elsewhere in the region, including two cases in Americans acquired in China and Japan in 1934 and 1935.[11] The virus initially was called Japanese B encephalitis (the modifying "B" has since fallen into disuse) to distinguish the disease from von Economo type A encephalitis, which had different clinical and epidemiologic characteristics. The mosquito-borne mode of JE transmission was confirmed with the isolation of JEV from *Culex tritaeniorhynchus* mosquitoes in 1938. Subsequent field studies established the role of aquatic birds and pigs in the viral enzootic cycle. Viruses isolated from human cases in Japan in 1935 and Beijing in 1948 provided the prototype Nakayama, and Beijing and P3 strains, respectively. These strains were widely used in vaccine production for many years.

During the first half of the 20th century, JE was recognized principally in temperate areas of Asia with perennial outbreaks in Japan, Korea, and China.[12] Annual outbreaks of several thousand cases recurred in Japan until 1966. In Korea, 5616 cases and 2729 deaths were recorded in 1949 when JE became a notifiable disease, and epidemics continued every 2 or 3 years, culminating in an unprecedented 6897 cases in 1958.[13] As recently as 1982, 1197 cases were reported in South Korea.[14] JE also had a substantial impact on U.S. servicemen in Korea, including approximately 300 cases recorded in 1950.[15] In China, reporting of JE cases began in 1951, and many provinces recorded outbreaks in the early 1950s.[16,17] Between 1965 and 1975, more than 1 million cases were reported, almost 175,000 in 1971 alone. Until the 1990s, 20,000 to 40,000 cases were recorded annually from China (Fig. 33.3).[16,17] Since widespread use of JE vaccine in Japan from 1967, Taiwan from 1968, and Republic of Korea from 1983, JE epidemics have not occurred in these countries (see Fig. 33.2). While the combination of vaccination with occupational and environmental changes has led to the near elimination of the disease in humans, there have not been corresponding changes in zoonotic circulation of virus (Fig. 33.4). JE vaccine has also played a major role in reducing national JE incidence in China since its wider use in the late 1980s. From 2001 through 2007, fewer than 10,000 cases were reported annually, and since 2008, when JE vaccine was included in the national Expanded Program on Immunization (EPI) and the central government assumed the full cost of JE vaccination in all endemic provinces, fewer than 5000 cases have been reported each year.[17,18]

In Southeast Asia, although sporadic viral encephalitis cases were noted from early in the 20th century, JE was not recognized as a major public health problem until 1969, when an epidemic was reported from the Chiang Mai Valley in northern Thailand.[19] Yearly outbreaks producing thousands of cases and hundreds of deaths followed in the northern region, and JE became recognized as a leading cause of childhood mortality and disability.[20,21] This led to a successful effort to introduce JE vaccine as a routine childhood immunization. Subsequently, in 1974, the first of several epidemics was recorded in an area of Myanmar (Burma) adjacent to the Chiang Mai Valley.[22,23] In Vietnam, epidemics occurred in the late 1960s and during the 1970s, with incidence rates exceeding 18 per 100,000 population in some years.[12,24] After reinstatement of notification in the late 1970s, several thousand JE cases were reported annually. During the 1970s, JE was also recognized as an important cause of encephalitis in the Philippines, Malaysia, and Singapore.[25,26] Subsequently, there has been increased recognition of disease burden from JE throughout Southeast Asia and several countries have introduced JE vaccination programs.

In South Asia, serosurveys in 1952 and serologically confirmed clinical cases in 1955 in India marked the first recognition of disease in the region.[27,28] Outbreaks in India were documented only in southern areas until 1973 when a large outbreak occurred in the Burdwan and Bankura districts of West Bengal.[29] Large JE outbreaks, often involving adults, subsequently were reported from various Indian states. In 1978, Nepal experienced its first JE epidemic in the southern Terai region along the Indian border, with 422 cases and 119 deaths, and large outbreaks continued to regularly occur.[24,30] Although virus was isolated in Sri Lanka in 1968 and endemic transmission had occurred for many decades, the first major outbreak occurred in 1985.[31,32] Elsewhere in South Asia, Bangladesh reported a small outbreak in 1977, but following that the disease was not recognized and no systematic assessments occurred until 2003.[33,34] In the west, JEV has spread as far as the Indus valley in Pakistan.[35] Despite large-scale vaccination programs, JE remains a problem in India, while cases have markedly declined in Nepal and Sri Lanka (Fig. 33.5).

In the western Pacific region, self-limited outbreaks occurred on the islands of Guam in 1947 and Saipan in

1990.[36–38] During the 1990s, southward extension of the geographical range of JEV transmission was noted when cases occurred in northern Australia. JE cases were first reported in the outer Torres Strait Islands in 1995, and a case was detected on Cape York Peninsula on the northern mainland of Australia in 1998.[39,40]

WHY THE DISEASE IS IMPORTANT

JEV is the most common vaccine-preventable cause of encephalitis in Asia. Each year, an estimated 67,900 JE cases occur.[2] Approximately 75% of these cases occur in children younger than 15 years of age, with an annual incidence of 5.4 cases per 100,000 children.[2] There is no antiviral therapy or other therapy available to mitigate the effects of JEV infection, and disease outcome is often severe. The case fatality rate is 20% to 30%, and 30% to 50% of survivors have long-term physical or cognitive sequelae.[41,42] Given its incidence and severity, JE is a major public health problem. JE vaccination has gained wide support from public health authorities with growing recognition of the scope of the problem. However, in many Asian countries, introduction or expansion of vaccination programs is still needed. Additionally, as enzootic transmission of JEV continues even in locations that have achieved good control, high-quality vaccination and surveillance programs must be maintained long term.

BACKGROUND

Clinical Description

The great majority of infections are inapparent, with only one in approximately 250 infections resulting in symptomatic illness in susceptible Asians with higher overt infection rates in non-Asian populations.[43,44] The principal recognized clinical manifestation of illness is encephalitis. Milder clinical manifestations, such as aseptic meningitis and simple febrile illness with headache, can sometimes occur but often escape detection.[15,45–53] Patients occasionally also present with poliomyelitis-like acute flaccid paralysis.[54]

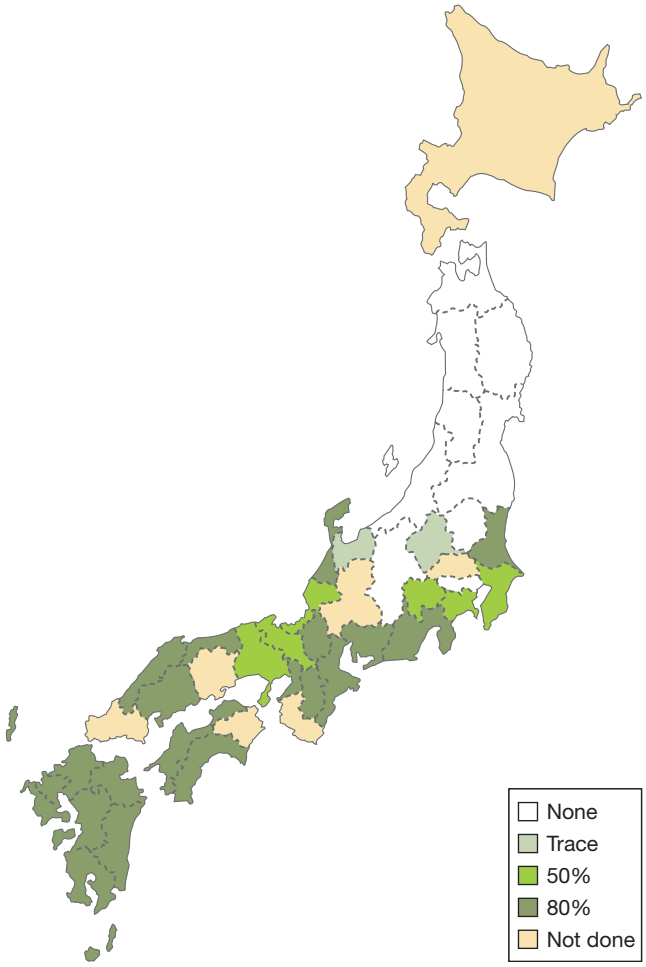

Figure 33.4. Japanese encephalitis seroprevalence in swine by district, Japan, October 1996. The absence of reported human cases belies continued transmission of the virus in its enzootic cycle, as demonstrated by high rates of pig infections. *(From Taniguchi K, Matsunaga Y. National epidemiologic surveillance of vaccine-preventable diseases, Japan, October 1996, with permission.)*

The incubation period is 5 to 15 days. Illness usually begins with abrupt onset of high fever, change in mental status, gastrointestinal symptoms, and headache, followed gradually by disturbances in speech or gait or other motor dysfunction. Irritability, vomiting, and diarrhea or an acute seizure may be the earliest signs of illness in an infant or child. Seizures occur in 55% to 85% of pediatric patients but are less frequent in adults.[53,55–58] A progressive decline in alertness eventually leads to stupor and coma. Patients may become completely unresponsive and require ventilatory assistance (Fig. 33.6). Generalized weakness and changes in muscle tone, especially hypertonia and hyperreflexia, are common, but focal motor deficits indicative of direct brain tissue damage, including paresis, hemiplegia, or tetraplegia; cranial nerve palsies (especially central facial palsy); and abnormal reflexes also may be present (Fig. 33.7). Sensory disturbances are seen less frequently. Central hyperpnea, hypertension, pulmonary edema, and urinary retention may complicate the illness. Although symptoms suggest elevated intracranial pressure in many cases, papilledema and other signs of increased intracranial pressure are rare. Signs of extrapyramidal involvement, including tremor, mask-like facies, rigidity, and choreoathetoid movements, are characteristic of JE, but these signs may be obscured initially by generalized weakness.

The typical clinical course in patients whose main presentation is poliomyelitis-like acute flaccid paralysis is a brief febrile illness followed by rapid onset of flaccid paralysis in one or more limbs, despite a normal level of consciousness.[59] Weakness occurs more frequently in the legs than in the arms and is usually asymmetric. Approximately 30% subsequently develop encephalitis, with a reduced level of consciousness and upper motor neuron signs. At 1 to 2 years later, persistent weakness and marked wasting in the affected limbs can be found. Flaccid paralysis has also been reported in patients with a more characteristic encephalitic presentation of JE.[15,58,60] In patients with flaccid paralysis, electrophysiological studies have confirmed anterior horn cell damage, and magnetic resonance imaging of the spinal cord has shown abnormal signal intensity on T2-weighted images.[59,61]

During an outbreak in Uttar Pradesh, India, a biphasic illness was described in which 2.7% of patients had recurrent symptoms after apparent recovery.[51] This was further described in a retrospective study in India among 62 patients, six of whom had early relapse characterized by progressive neural involvement with anterior horn cell damage.[62] Recurrent neurologic signs and symptoms have been observed as late as 8 to 9 months after recovery.[63] Although JEV has been isolated from peripheral blood mononuclear cells from patients with

recurrent neurologic disease, a rise in antibody titers has not been observed.[63] Recurrent neurologic disease does not necessarily result in poorer outcome.[62,63]

Complications

Reports of case-fatality and disability rates vary greatly. Of the cases, 5% to 30% are fatal.[37,50,52,55,56,64–73] Some deaths occur after a brief prodrome and fulminant course lasting a few days, whereas others occur after a more protracted course with persistent coma. Severity may vary by age. Young children (younger than 10 years of age) are reported to be more likely than adults to die, and, if they survive, they are more likely to have residual or more severe neurologic deficits.[37,55,65] Disability rates vary widely, with study findings showing sequelae in 45% to 65% of patients within the first year and in 30% to 80% of patients up to 10 years later.[37,50,52,55,56,64–73,75] However, differences in rates partly reflect the intensity of the follow-up examination, including type of neurologic sequelae examined and use of formal cognitive and neurologic examinations, completeness of the follow-up examination, and whether calculations were based on the total patient cohort or survivors (Fig. 33.8). The reported rate of long-term, severe neurological disability among survivors reaches as high as 45%.[52,56,65,66]

Figure 33.8. A patient recovering from Japanese encephalitis (JE) in a private clinic in Adoni, India, 2002. Although JE is reportable in India, private clinics do not report into the system, resulting in underreporting.

Principal sequelae fall into three main categories: psychosocial, intellectual, and physical. Deficits can include memory loss, impaired cognition, behavioral disturbances, seizures, motor weakness or paralysis, and abnormalities of tone and coordination. Over time, abnormalities can improve or eventually resolve. However, some sequelae can worsen and new abnormalities can develop. In China, some patients developed additional neurologic signs and symptoms 3 to 17 years after acute infection, including optic nerve degeneration and seizures.[76]

A poor prognosis is associated with a short prodromal interval, deep obtundation at hospital admission, irregular and central hyperpneic respiratory patterns, focal deficits, status epilepticus, the presence of extrapyramidal signs, flexor and extensor posturing, and pathologic reflexes.[52–54,68,77–79] In some locations, more than 25% of JE cases have concurrent neurocysticercosis, which increases the risk for JEV neuroinvasive disease and contributes to higher JE mortality rates.[80–82] There is evidence that preexisting dengue immunity is associated with better outcome of JE, but this is not true of yellow fever (YF) vaccination and is unknown for other cocirculating flaviviruses like West Nile virus.[83–85]

Virology

The JEV is one of more than 70 viruses in the *Flavivirus* genus of the *Flaviviridae* family.[86,87] Morphologically, flaviviruses are spherical, positive, single-stranded RNA, approximately 40 to 50 nm in diameter, with a lipid membrane enclosing an isometric 30-nm–diameter nucleocapsid core.[88] Membrane surface projections are composed of a glycosylated envelope (E) and membrane (M) protein, a mature form of the premembrane (prM) protein. The JE viral RNA, 10,976 bases long, encodes an uninterrupted open reading frame, flanked by 95- and 585-base untranslated regions at the 5′ and 3′ ends, respectively.[89,90] Protein translation at the first encountered AUG codon near the 5′ end yields a polyprotein precursor of 3432 amino acids that is cotranslationally or posttranslationally processed by a virus-specific nonstructural (NS) protease complex, NS2B-NS3, host cell signal peptidase, or an unidentified host cell–specific protease into at least 10 mature viral proteins. The order of proteins encoded in the JEV open reading frame, as with other flaviviruses, is 5′-C-prM-E-NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5-3′.

Flaviviruses replicate in a variety of cultured cells of vertebrate and arthropod origin. Viral entry occurs by receptor-mediated endocytosis, with the formation of coated vesicles, or by direct fusion with endosomal membranes.[91–94] The nucleocapsid is uncoated by acid-dependent fusion of viral and endosomal membranes, releasing genomic RNA into the cytoplasm, where viral replication continues with immediate translation of the uncoated viral genome.[94] The translated polyprotein then is processed and assembled into a virus-specific replication complex.

The hydrophobic carboxyl terminus of the E protein provides a membrane-associated anchor, while an extensive ectodomain, stabilized by disulfide bridging, is folded into three structural and antigenic domains (I, II, and III) that are variably related to determinants representing flaviviral group, subgroup, and virus-specific epitopes and biologic functions.[95] Binding of JE virions to certain cells of the central nervous system (CNS) lineage may be associated with the presence of specific neurotransmitter receptors.[96] Dengue-2 virus selectively binds to cellular heparan sulfates of the glycosaminoglycan family via E protein glycosaminoglycan-binding motifs within the carboxyl terminal and externally accessible regions of domains I and III.[97,98] Similar mechanisms may apply to JEV and other flaviviruses.[99]

Virus-specific and cross-reactive neutralizing epitopes have been mapped to specific regions of the flavivirus E glycoprotein.[100,101] Comprehensive cross-neutralization studies indicate the close antigenic relationship of JEV to SLE, West Nile, Koutango, and Usutu viruses and several flaviviruses found in Australia (e.g., Murray Valley encephalitis, Alfuy, Stratford, and Kokobera viruses) with their classification into a single antigenic complex.[102,103] No serologic cross-reactivity with hepatitis C virus has been observed.[104]

The biochemical, antigenic, and genetic relationships of JEVs isolated from different geographic regions and at various times have been compared by using polyclonal and monoclonal antibodies, two-dimensional gel electrophoresis of T1 ribonuclease-digested virion RNA, and genomic sequencing.[105–107] The molecular phylogeny of JEVs, based on the 240-base nucleotide sequence of viral prM, divides JE isolates into five distinct genotypes (Gs), with a maximum divergence of 21% among the isolates (Table 33.1).[108–114] GIII has been the source of numerous JE epidemics throughout history and was the most frequently isolated genotype throughout most of Asia from 1935 until the 1990s. Three genotypes (I, III, and V) were confirmed to be cocirculating in China in both high- and low-prevalence areas.[115] GIII consisted of two clades (mainland clade and Taiwan clade). Two recent evolutionary studies have examined the genotype displacement of GIII by GI in China.[116,117] Compared to the mainland GIII clade, GI and the Taiwan clade were newly introduced and evolved more rapidly. In recent years, multiple reports have indicated that GI has displaced GIII as the most frequently isolated virus genotype in a number of Asian countries,[118] including Thailand,[119] Korea,[120] Japan,[111] Malaysia,[121] Vietnam,[122] India,[123] and Taiwan.[124] A recent study has reconstructed the spatiotemporal chronology of the emergence of GI throughout Asia and identified genetic determinants underlying the genotype displacement as it unfolded across Asia. A possible explanation of this displacement was the observed increase in vitro multiplicative ability of GI viruses compared to GIII viruses in avian and/or mosquito cells, suggesting an increase in the efficacy of mosquito-avian mosquito transmission cycles in nature.[125]

TABLE 33.1 Japanese Encephalitis Viruses by Genotype and Countries With Early Isolations of Specific Genotypes

Genotype	Country or Region (Year[s] of Isolation)
I	Japan (1935, 1955, 1957, 1959, 1979, 1982) China (1949, 1960) Korea (1982, 1987, 1991, 1994) Okinawa (1968–1992) Taiwan (1972, 1987) Philippines (1977, 1984) Vietnam (1964–1988) Nepal (1985) India (1963, 1970, 1972, 1975, 1978–1980, 1982, 1985) Sri Lanka (1969, 1987)
II	Thailand (1979, 1982–1985, 1992, 1993) Cambodia (1969)
III	Indonesia (1970, 1978, 1979, 1981) Thailand (1983) Malaysia (1970) Sarawak (1968) Australia (1995)
IV	Indonesia (1981)
V	Singapore (1994)

Data from references 108–114, 117, and 125–128.

An antigenic analysis using five virus-specific monoclonal antibodies classified strains into four antigenic types, without correspondence to the aforementioned genotypes.[129]

The JEV isolates from the same region but from different years show a high degree of nucleotide similarity. The 16 Vietnam and 23 Okinawa strains of JEV isolated between 1964 and 1988 and between 1968 and 1992 differed by only 3.2% and 4%, respectively.[108,111] However, viruses could be distinguished chronologically before and after 1986 in Okinawa and before and after 1975 in Vietnam. RNA copying errors and bottlenecking (e.g., survival of a single strain during harsh ecological conditions) seem to be the main mechanisms by which JEV continuously evolves, although novel viral introductions have been documented, indicating the potential for genotypic displacement.[38,112] However, when 92 genomes with complete envelope sequences in the GenBank were analyzed, the level of intergenotypic diversity was less than observed across poliovirus or dengue serotypes. This genetic analysis supports the contention that all known JEV isolates comprise a single serotype from the standpoint of protection.[130] This information is important to the design of JE vaccines.

Pathogenesis as It Relates to Prevention

After an infectious mosquito bite, viral replication occurs locally and in regional lymph nodes. Virions disseminate to secondary sites, where further replication contributes to low-level viremia. Invasion of the CNS probably occurs from the blood by antipodal transport of virions through vascular endothelial cells.[131,132] Infection in the CNS spreads by viral dissemination through the extracellular space or by direct intercellular spread.[133] Sensitized T-helper (Th) cells stimulate an inflammatory response by recruiting macrophages and lymphocytes to the perivascular space, parenchyma, and CNS, where the inflammatory response clears infected neurons, with subsequent formation of glial nodules.[131,134–136] The predominant cell type in the cerebrospinal fluid (CSF) and in the parenchyma is the helper-inducer (CD4) T cell, with B lymphocytes confined chiefly to the perivascular space.[135,137]

Pathologic abnormalities are found chiefly in the CNS; however, inflammatory changes in the myocardium and lung and hyperplasia of reticuloendothelial cells in the spleen, liver, and lymph nodes have been described.[134] Cerebral edema and congested leptomeninges are visible on gross examination of the brain, and "punched-out" necrolytic lesions in the gray matter may be seen.[134,136,138,139] Histopathologic examination discloses a pattern of diffuse microglial proliferation with nodular formation around dead or degenerating neurons, in which viral antigen can be demonstrated by immunohistochemical staining.[131,136] Viral antigen is distributed principally in the thalamus, midbrain, hippocampus, and temporal cortex, but also in Purkinje and granular cells of the cerebellum and in the brainstem reticular formation. Viral antigen also has been demonstrated in well-preserved neurons independent of glial reaction, well after the acute phase of illness, suggesting intracellular viral persistence.[140] Gliomesenchymal nodules are seen in a parallel distribution within the brain and anterior horn of the spinal cord. In patients dying with residual neurologic impairment several years after resolution of the acute illness, scarred rarefied foci are found in a characteristic distribution in the thalamus, substantia nigra, and hippocampus.[140] Virus has also been isolated from peripheral blood mononuclear cells 8 months after initial infection in three (38%) of eight asymptomatic children after cocultivation with primary mouse embryo fibroblasts.[63]

Why only one in several hundred infections in nonimmune residents of endemic areas develops into symptomatic neuroinvasive disease is unclear. It must be concluded that circulating JEV delivered by mosquito subcutaneously has poor capability of reaching the human brain even in genetically susceptible whites.[43] Some rare event or host factor may control the invasion of the CNS. Factors that contribute to neuroinvasion include a somewhat increased risk of encephalitis in children compared with adults, as observed in Guam, and, based on work in laboratory animals, genetic host factors.[36,141–144] Selective pressure for genetic resistance to infection in populations with long exposure to a fatal viral infection may explain the observed higher case-infection ratios in foreigners visiting endemic areas than in resident Asian populations. Innate immunity, such as levels of interferon-α and some genetic factors that affect cellular proteins, may be related to whether clinical illness develops in individual people. Viral replication is dependent on normal cellular proteins, while some host cells have allelic forms of these proteins that may be less supportive of or interfere with viral replication.[145,146] This is an example of the kind of cellular mechanism that may operate to reduce morbidity in Asian compared with non-Asian populations.

Macrophages are important in the nonspecific clearance of virus, and their depletion leads to extended viremia, CNS invasion, and death in experimentally infected mice.[147] However, circulating antibody fulfills a critical role in modulating infection by limiting viremia in the preneuroinvasive phase. Both JEV-specific and heterologous (e.g., dengue) antibodies contribute to protection, and low levels of neutralizing antibody may be sufficient to prevent viremia.[83,148–151] Guinea pigs or mice previously immunized with attenuated JE vaccine but without detectable neutralizing antibodies (<1:4) were protected against intraperitoneal challenge infection, and, their sera passively protected mice.[152] Experimentally infected monkeys immunosuppressed with cyclophosphamide had no measurable antibody response and exhibited increased susceptibility to paralytic encephalitis and a diminished CNS inflammatory reaction.[153] Conversely, passive transfer of JE

monoclonal antibodies after active infection enhanced neurovirulence in intracerebrally challenged mice.[154]

Clinically, high CSF interferon-α levels and low CSF virus-specific immunoglobulin (Ig) M and IgG antibodies have been associated with a fatal outcome, suggesting that delayed or poor local antibody response and uninhibited CNS virus proliferation determine outcome.[155,156] The reactivity of intrathecal and serum antibodies differs in Western blot analyses, but the relationship of these response patterns to outcome is unknown. Recovered patients develop antibodies to structural and NS proteins and exhibit CD4 and CD8 T-cell proliferative responses to JE viral lysate, rather than structural E and prM/M proteins only.[157] In a large clinical study, only 24% of patients developed a T-lymphocyte response to whole virus or viral E protein (structural proteins), and response was not correlated with survival.[158]

Other studies suggest an important role for immunopathology in the pathogenesis of JE. Antibodies to neural antigens (neurofilament and myelin basic protein) were associated with death, suggesting that neural damage resulted in a destructive autoimmune response.[139,159–161] CSF viral immune complex formation also was associated with mortality, further implicating the possibility of autoimmune injury.

Cell-mediated immune mechanisms have been described in athymic nude mice, which, in contrast with normal adult mice, die or develop an extended illness with secondary viremias after peripheral inoculation.[162,163] Antibodies did not appear in nude mice, indicating the functional importance of Th cells. Interestingly, although virus replicated to high titers in brain tissue, histopathologic evidence of encephalitis was absent, indicating that T cells are required in mediating pathologic changes. Mice immunosuppressed with cyclophosphamide and then immunized with live attenuated vaccine, but not inactivated vaccine, are able to resist experimental challenge. Specific JE viral immunity can be transferred passively with spleen cells from immune mice, including animals immunized with live attenuated JE vaccine, but not from animals immunized with inactivated vaccine.[152,164,165] Both Lyt2.2 and L3T4 cells are needed to protect adult mice against intracerebral challenge, and direct intracerebral introduction of the effector cells is required, suggesting the importance of local T-cell enhancement of antibody production in the CNS.

Conditions that compromise the integrity of the blood-brain barrier have been suspected to increase the risk for neuroinvasion and neurodissemination. Several observations suggest that dual infection with another infectious agent, especially *Taenia solium* in neurocysticercosis, is a risk factor.[80,138,166–168] The incidental finding of cysts in a disproportionate number of JE cases at autopsy suggested their potential contribution to a fatal outcome. There are anecdotal observations of dual herpes and JE viral infections in autopsied human JE cases.[168] The mechanisms by which dual infections apparently augment the risk of symptomatic illness are unclear, but increased CNS dissemination of JEV was shown experimentally in mice infected with both JE and herpes.[168] Other physiologic or structural conditions that compromise the integrity of the cerebral vasculature or the blood–brain barrier also may contribute to risk. Atherosclerotic and hypertensive cerebrovascular diseases are suspected risk factors for SLE, and foreign bodies (e.g., ventricular shunts) have predisposed patients to poliovirus neuroinvasion.[169] Experimental disruption of the blood–brain barrier by microwave irradiation was shown to predispose mice to JE viral neuroinvasion.[170,171]

The impact of HIV infection and AIDS on the outcome of JE has not been reported; however, HIV infection seemed to increase the risk for developing overt SLE or West Nile encephalitis after infection.[170,172]

Diagnosis

Although a history of exposure to mosquitoes in a JE endemic area and certain clinical features may suggest JE, there are no pathognomonic features, and laboratory confirmation, usually by serologic tests, is necessary.[173] The JEV occasionally can be recovered from blood in the preneuroinvasive phase (up to 3 to 7 days after infection), but most patients have low or undetectable levels of viremia by the time of clinical presentation with encephalitis.[45,156,174,175] Virus or viral RNA has been recovered from the CSF in 68% of patients when the highly sensitive system of isolation in *Toxorhynchites splendens* mosquitoes was used, and less frequently with other isolation methods or nucleic acid amplification tests.[176–178] However, neither viral isolation nor detection of viral RNA by nucleic acid amplification test is sufficiently sensitive for routine diagnostic purposes. Viral antigen or viral RNA often can be demonstrated in brain tissue when no virus can be isolated from the same specimen and when viral antibodies are undetectable. The JEV produces cytopathic effects in Vero, $LLCMK_2$ (monkey kidney epithelial cells), and PS (porcine kidney cell line) cells, and kills suckling mice inoculated intracerebrally. C6/36 and AP61 mosquito cell lines and *T. splendens*, inoculated intrathoracically, also are sensitive systems for viral isolation. Infection produces no cytopathic effect in C6/36 cells, so inoculated cultures must be examined for viral antigen by immunofluorescent antibody or other techniques. Viral isolates are readily identified by genetic tests or by immunofluorescent techniques using virus-specific monoclonal antibodies or by neutralization.

The most widely used serologic test is the enzyme-linked immunosorbent assay (ELISA) for detection of IgM antibodies.[156,179–184] JEV-specific IgM antibodies are detectable in CSF of most patients by 4 days after symptom onset and in serum by 7 days after onset.[77,156,177,185] For cases diagnosed during well-established outbreaks, a positive JE IgM ELISA result in an acute phase serum sample should be considered diagnostic. However, for an isolated case of encephalitis or for cases in countries where multiple dengue viruses are endemic, laboratory-confirmed JE requires the detection of JE IgM antibodies in the CSF. If acute samples collected within 10 days of illness onset lack detectable IgM, a convalescent sample from the CSF should be collected and tested.[186]

When plaque-reduction neutralization tests (PRNTs) are available, they can be used to measure virus-specific neutralizing antibodies and to discriminate between cross-reacting antibodies in primary flavivirus infections. In most countries in Asia, routine access to PRNTs is likely to be limited except through the World Health Organization (WHO) JE laboratory network.[8] Evidence of a recent JEV infection can be confirmed by a fourfold or greater rise in virus-specific neutralizing antibodies between acute-phase and convalescent-phase serum specimens collected 2 to 3 weeks apart. Hemagglutination inhibition assays can also be used to measure a fourfold or greater rise in antibodies and confirm acute JEV infection. Vaccination history, date of symptom onset, and information regarding other flaviviruses known to circulate in the geographic area that might cross-react in the assay should be considered when interpreting results. In patients who have been infected with another flavivirus in the past (i.e., who have secondary flavivirus infections) or have been immunized with a flaviviral vaccine (e.g., YF or tickborne encephalitis vaccines), cross-reactive antibodies may make it difficult to identify which flavivirus is causing the patient's illness.

The WHO defines a case of acute encephalitis syndrome (AES) as a change in mental status (including symptoms such as confusion, disorientation, coma, or inability to talk) and/or new onset of seizures (excluding simple febrile seizures) after the acute onset of fever (Box 33.1).[186,187] A suspected case

BOX 33.1 World Health Organization–Recommended Case Definition and Laboratory Criteria for Confirmation of JE: Field Tested Version

CLINICAL CASE DEFINITION	A case of acute encephalitis syndrome (AES) is defined as the acute onset of fever and a change in mental status (including symptoms such as confusion, disorientation, coma, or inability to talk) and/or new onset of seizures (excluding simple febrile seizures[a]) in a person of any age, at any time of year. Other early clinical findings may include an increase in irritability, somnolence, or abnormal behavior greater than seen with usual febrile illness.
CASE CLASSIFICATION	
Suspected Case	A case that meets the clinical case definition for AES. Suspected cases should be classified in one of the following four ways:
Laboratory-Confirmed JE	A suspected case that has been laboratory-confirmed as JE.
Probable JE	A suspected case that occurs in close geographic and temporal relationship to a laboratory-confirmed case of JE, in the context of an outbreak.
AES, Other Agent	A suspected case in which diagnostic testing is done and a causative agent other than JE virus is identified.
AES, Unknown	A suspected case in which no diagnostic testing is done, in which testing identified no causative agent, or in which the test results were indeterminate.
LABORATORY CRITERIA FOR CONFIRMATION	Clinical signs of JE are indistinguishable from other causes of AES. Laboratory confirmation is, therefore, essential for accurate diagnosis of JE. Laboratory confirmation of a JE virus infection includes the following: 1. Presence of immunoglobulin (Ig) M antibodies specific to the JE virus in a single sample of cerebrospinal fluid (CSF) or serum,[b] as detected by an IgM-capture enzyme-linked immunosorbent assay (ELISA) specifically for the JE virus.[c] 2. Detection of JE virus antigens in tissue by immunohistochemical studies. 3. Detection of JE virus genome in serum, plasma, blood, CSF,[d] or tissue by reverse transcriptase–polymerase chain reaction or an equally sensitive and specific nucleic acid amplification test. 4. Isolation of the JE virus in serum, plasma, blood, CSF,[d] or tissue. 5. Detection of a fourfold or greater rise in antibodies specific to the JE virus as measured by hemagglutination inhibition or plaque reduction neutralization test in serum samples obtained during the acute and convalescent phases of illness. The two specimens for IgG should be obtained at least 14 days apart. The IgG test should be done in parallel with other confirmatory tests to eliminate the possibility of cross-reactivity, as indicated.[c]

Most JE infections are asymptomatic. Therefore, in areas that are highly endemic for JE, it is possible to have AES resulting from a cause other than JE virus and have JE virus–specific IgM antibody present in serum. To avoid implicating asymptomatic JE as the cause of other AES illnesses, sterile collection and testing of a CSF sample from all persons with AES are recommended when feasible.

Only the first 5 to 10 cases of an outbreak need be confirmed through laboratory testing. During periods of epidemic transmission of JE virus, laboratory confirmation of every case may not be necessary.

[a]A simple febrile seizure is one in a child 6 months to younger than 6 years; the only findings are fever and a single generalized seizure lasting less than 15 minutes, and the child recovers consciousness within 60 minutes of the seizure.

[b]A serum sample should be obtained at admission. Because it may not yet be positive in a JE-infected person, a second serum sample should be obtained at discharge, on the 10th day of illness, or at the time of death and tested for presence of JE virus–specific IgM.

[c]Further confirmatory tests (e.g., for cross-reactivity with other flaviviruses circulating in the geographic area) should be done when there is an ongoing dengue or other Flavivirus outbreak; when vaccination coverage is very high; or in cases in areas where there are no epidemiologic and entomological data supportive of JE transmission.

[d]Detection of virus genome or virus isolation in serum, plasma, or blood is specific for JE diagnosis; however, it is not sensitive because virus levels are usually undetectable in a clinically ill person with JE. Therefore, a negative result by these methods should not be used to rule out JE in a suspected case. Similarly, detection of virus genome or virus isolation in CSF is usually found only in fatal cases and, therefore, is not very sensitive and should not be used for ruling out a diagnosis of JE.

JE, Japanese encephalitis.

Modified from Hills S, Dabbagh A, Jacobson J, et al. Evidence and rationale for the World Health Organization recommended standards for Japanese encephalitis surveillance. BMC Infect Dis. *2009;9:214; and Solomon T, Thao TT, Lewthwaite P, et al. A cohort study to assess the new WHO Japanese encephalitis surveillance standards.* Bull World Health Organ. *2008;86:178–186.*

of JE is one that meets the clinical case definition for AES. Suspected cases are classified into four categories: (a) laboratory-confirmed JE; (b) probable JE; (c) AES, other agent; or (d) AES, unknown (see Box 33.1). A laboratory-confirmed case must meet the WHO laboratory criteria for confirmation of JE as follows: (a) presence of JEV-specific IgM antibody in a single sample of CSF or a serum sample obtained 7 or more days after onset of fever; (b) detection of JEV antigens in tissue by immunohistochemical analysis; (c) detection of the JEV genome in serum, plasma, blood, CSF, or tissue by reverse transcriptase–polymerase chain reaction or an equally sensitive and specific nucleic acid amplification test; (d) isolation of JEV in serum, plasma, blood, CSF, or tissue; or (e) detection of a fourfold or greater rise in JE antibodies as measured by hemagglutination inhibition or PRNT in serum obtained during the acute and convalescent phases of illness. These tests should be performed in parallel with other confirmatory tests to eliminate the possibility of cross-reactivity.[186,187]

Recommended Types of Surveillance

Surveillance for JE should be conducted year-round. Where feasible, surveillance for and reporting of JE should be performed within the context of integrated disease surveillance

and linked synergistically with similar surveillance activities, such as those for acute flaccid paralysis or meningitis.[186,187]

In All Asian Countries

Comprehensive syndromic surveillance for AES with aggregate reporting is recommended. In sentinel hospitals, surveillance should be case-based with specimens obtained for laboratory confirmation. The number of sentinel hospitals can be gradually increased when feasible logistically.

In Asian Countries Where a High Level of Japanese Encephalitis Control Has Been Achieved

Surveillance should be case-based throughout the country and include laboratory confirmation of all suspected cases. Regardless of the type of surveillance, reporting should be weekly or monthly and include "zero reporting" (i.e., no blanks should be left in the reporting forms; a zero should be used when no cases are detected). Outbreak investigations should be initiated if there is a sudden increase in cases or if cases reported are different from historical information in terms of season, geographic area, age group, or case fatality.

Treatment

No specific therapy is available, but supportive treatment can substantially reduce morbidity and mortality. Good nursing care and close attention to managing ventilation, fluids, and nutritional status, and prevention of bed sores and secondary infections, can improve outcome. Mannitol and other modalities to control intracranial pressure often are needed and seizure control is important. Aspiration pneumonia is a particular concern in any patient with a reduced gag reflex. Trihexyphenidyl hydrochloride and central dopamine agonists have been used to treat acute extrapyramidal symptoms.[64] Experimental studies in mice and monkeys suggested the potentially beneficial effect of interferon.[188] In an uncontrolled series of 14 patients treated with recombinant interferon-α, 13 survived.[189,190] However, in a double-blind, placebo-controlled trial with interferon-α2a in 87 Vietnamese children with confirmed JE, it showed no impact on the overall outcome.[191] For many years cortisone has been used to treat JE, but a randomized, placebo-controlled trial of dexamethasone in 40 patients showed no benefit of this treatment.[192] In an Indian trial, 70 patients received oral ribavirin, and 83 received placebo. Early mortality rates did not differ between the groups, and there were no statistically significant differences in secondary outcome measures.[193]

Use of JE antibodies or immunoglobulin preparations is discussed under "Passive Immunization and Cross-Protection" below.

EPIDEMIOLOGY

Incidence and Prevalence Data

In 2010, it was estimated that 67,900 JE cases occur annually, but changes in the intensity of JEV transmission cause fluctuations from year to year.[2] In developed Asian countries (e.g., Japan, Taiwan, and Korea), the incidence of JE has decreased over several decades and currently fewer than 10 to 20 cases are typically reported annually (see Fig. 33.2). Other countries, including Thailand, Nepal, and Sri Lanka, also have reported a substantial decline in cases during the past 1 to 2 decades. The major contributing factor to the decrease in cases has been immunization. However, a number of other factors probably have contributed to the decline, including secular trends toward a higher standard of living, a reduction in land under cultivation, widespread use of agricultural pesticides, and centralized pig production. The impact of economic development and secular factors has been demonstrated most clearly in Singapore, which has no national immunization program. Although JE previously was endemic on the island, only sporadic cases have been detected since 1992 and a serosurvey performed in 1993 demonstrated no antibodies in children younger than 15 years of age, indicating the near-elimination of viral transmission through the indirect effects of modern urban infrastructure, mosquito control, and complete prohibition of pig rearing on the island.[194–196] Banning the rearing of pigs, although possibly effective, is not reproducible in other constituencies.

Although JE incidence is now low in several of the 25 JE-endemic countries, the disease burden is still high in many areas. Almost 34,000 cases are still estimated to occur annually in China, and high incidence rates of 11.1 cases per 100,000 children 15 years of age and younger and 8.2 cases per 100,000 children younger than 10 years of age have recently been documented in Cambodia and Indonesia, respectively.[2,197,198] Surveillance activities also are improving the understanding of the extent of disease burden in countries with previously limited data, such as Bangladesh and the Philippines.[26,34]

In countries where childhood cases have been prevented by immunization with inactivated vaccine, the age distribution of cases has shifted toward adults, particularly to elderly people. In Japan, the previous bimodal age distribution of cases, with peaks in young children and elderly people, shifted toward a predominance of cases in adults (Fig. 33.9).[199–201] This shift does not necessarily mean an increase in the number of cases in older populations, but immunity of the younger populations has allowed the epidemiology of the elderly population to become more predominant. A similar pattern is seen in Korea and Taiwan and has emerged in some municipalities of China.[14,199,202] An analysis of age-specific incidence by decade in an area of Shanghai showed that, since 1961, case rates declined most dramatically in children, reflecting the impact of immunization; however, rates also declined in other age groups, reflecting a similar decrease in risk (Fig. 33.10). The result is that incidence rates are similar in adults and children.

In Taiwan, the loss of inactivated mouse brain vaccine-derived immunity has been inferred from declining JE antibody prevalence rates, from 49% in primary school to 38% in junior high school, 34% in junior college, and 29% in university students.[203] A similar trend also has been seen in Japan, where the induction and maintenance of immunity, presumably by immunization, through the first decade of life is followed by a subsequent decline, reflecting loss of vaccine-induced antibodies. Waning vaccine-induced immunity, age-related host factors, and reduced opportunities for natural exposure and "boosting" infections in an increasingly urban population may contribute to increased risk of acquiring JE in adults, even adults who might have been infected naturally earlier in life.[204] Surveillance to measure the incidence of JE in adults and to detect cases of secondary vaccine failure should be undertaken to determine the need for booster doses after childhood.

JEV has increased in geographic range across Asia in recent decades, and transmission in new areas continues to be documented.[205] Some studies correlate the apparent spread to or amplification of JE in new areas with agricultural development and intensive rice cultivation supported by irrigation schemes.[206] In Sri Lanka, the first recognized large outbreak in 1985 occurred after rerouting a river to a previously arid district for agriculture. Subsequent attempts at vector control failed to prevent an outbreak the following year. Similarly in

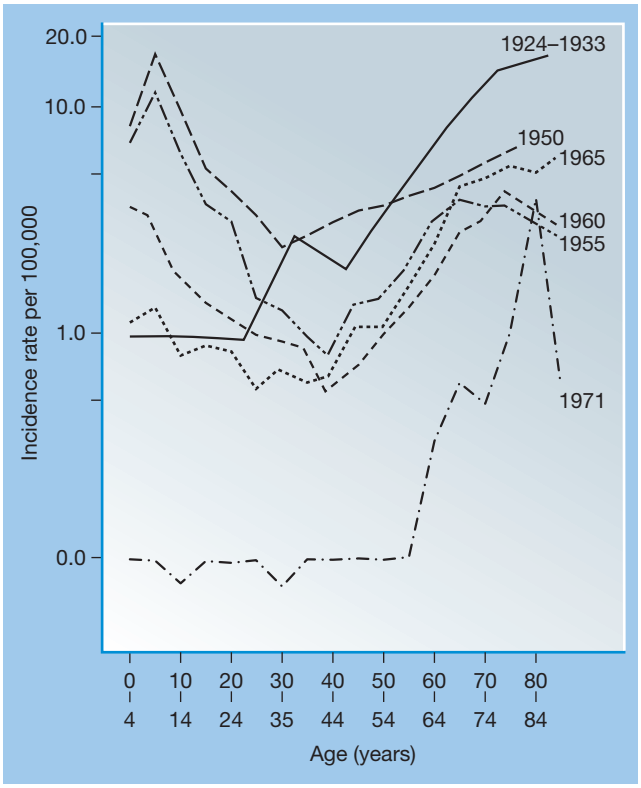

Figure 33.9. Age-specific incidence of Japanese encephalitis (JE) in Japan, 1924–1971. Although JE was most visible as a childhood disease, the age-specific incidence was bimodal, with elevated risk in children and elderly persons. As a result of universal childhood immunization, sporadic cases now occur almost exclusively in elderly persons. The causes of increased risk with advanced age are unknown. *(Modified from Oya A. Epidemiology of Japanese encephalitis, Rinsho to Biseibutsu.* Clin Diagn Microbiol. *1989;16:5–9.)*

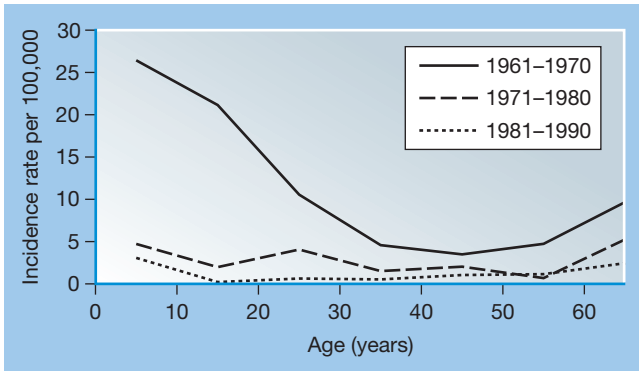

Figure 33.10. Age-specific incidence of Japanese encephalitis, Nanshi District, Shanghai, by decade. *(Data from Z.Y. Xu, personal communication.)*

southern Nepal, hyperendemic transmission of malaria and JE were documented to follow deforestation and development in the Terai. Viremic migratory birds or windblown mosquitoes are other possible mechanisms of JE viral importation over significant distances. Such factors are hypothesized to have led to outbreaks on Saipan and the Torres Strait Islands between New Guinea and northern mainland Australia.[38,40]

JE incidence may fluctuate yearly or regionally, but sustained childhood immunization programs are essential

Figure 33.11. Free pigs being herded out of city streets during the 2005 outbreak in Uttar Pradesh, India.

because JEV is maintained in an enzootic cycle and viral eradication from nature is not possible (Fig. 33.11). This is well illustrated in Japan, where viral surveillance using sentinel pigs and horses continues to document yearly high levels of transmission of JEV (see Fig. 33.4).[207] When the recommendation for JE vaccination was temporarily suspended in 2005 in Japan, vaccination rates in young children declined and two unvaccinated children with JE were reported in 2006 and 2009, before the recommendation for routine childhood vaccination was reinstated.[208]

Modes of Transmission and Reservoirs of Infection

Enzootic Areas in Asia

JE occurs in epidemics or in an endemic pattern or both in virtually every country of Asia (see Fig. 33.1; see also Table 33.14). Officially reported cases significantly underestimate the geographic extent or magnitude of risk because of underreporting (Fig. 33.12). Transmission is seasonal, occurring approximately from May to September in most temperate areas of Asia. Farther south, the transmission season is somewhat longer, extending from March through October (Fig. 33.13). In tropical areas and subtropical areas of Asia transmission can occur year-round and often intensifies following monsoon rains with the possibility of two transmission intervals in a calendar year.[26,197,198]

JE is principally a disease of rural areas in which vector mosquitoes proliferate in close association with birds and pigs, which serve as vertebrate amplifying hosts, with contribution of other species to sustained transmission less well studied (Figs. 33.14 through 33.16).[1,2,45,209,210] Humans and horses may become ill after infection, but such infections contribute minimally to the transmission cycle.[211,212] Experimental observations and field studies indicate that the virus overwinters in infected adult mosquitoes.[210] Vertical infection of mosquitoes may contribute to virus survival.[209] Long-term persistence in tissues and blood of JEV-infected vertebrate hosts, such as bats and reptiles, has been demonstrated. Introduction of the virus by viremic migratory birds or by windblown mosquitoes also may occur.[209,213] Self-limited outbreaks on western Pacific islands—Guam in 1947, Saipan in 1990, and the Australian Torres Strait islands in 1995 and

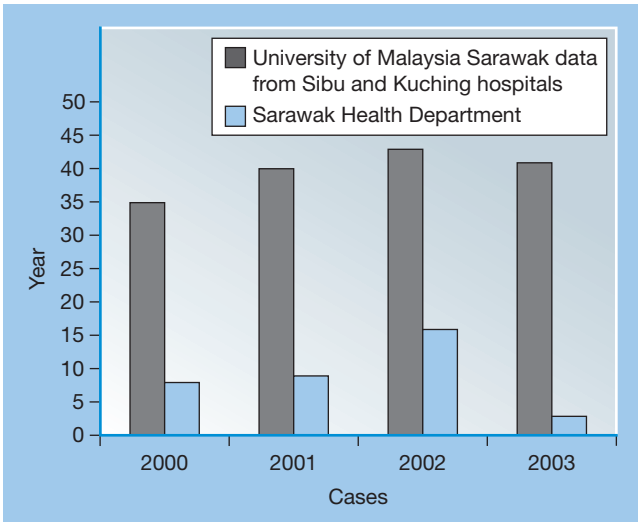

Figure 33.12. Underreporting of Japanese encephalitis (JE) happens for many reasons, including lack of recognition, no diagnostics, political pressure, and poor record keeping. In this example from Malaysia, JE cases are reported to the local ministry office from the hospitals, but the information is not passed to the central level to be recorded. *(Jane Cardosa, PhD, University of Malaysia Sarawak, personal communication.)*

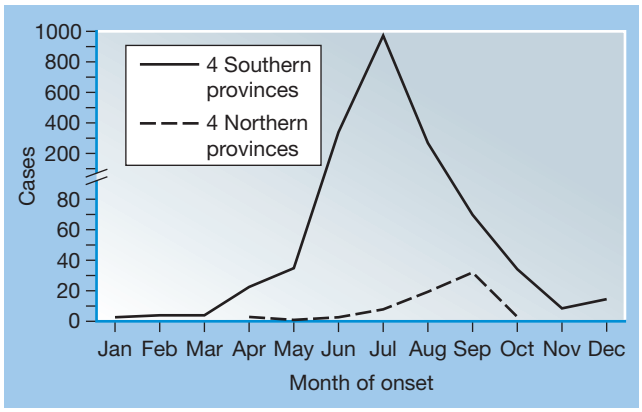

Figure 33.13. Seasonal distribution of Japanese encephalitis cases in four southern and four northern provinces, China, 1993. *(From Yu YX. Japanese encephalitis in China.* Southeast Asian J Trop Med Public Health. *1995;26[Suppl 3]:17–21.)*

1998—were examples of viral introductions possibly by migratory birds or, in the last case, by windblown mosquitoes.[36,38,40,214]

C. tritaeniorhynchus is the principal JEV vector in most areas of Asia, but various other ground pool– and rice paddy–breeding species, including *Culex vishnui*, *Culex pseudovishnui*, *Culex gelidus*, *Culex fuscocephala*, *Culex bitaeniorhynchus*, *Culex infula*, *Culex whitmorei*, and *Culex annulus*, are also important locally.[209,210] The JEV has been identified in 16 different mosquitoes in India and 19 in Indonesia,[45] and JEV has been recovered from *Culex pipiens pallens* and *Culex quinquefasciatus* in urban locations. In addition, *Culex annulirostris* has been identified as a vector in the western Pacific, *Aedes togoi* in sylvatic locations in Siberia, and members of the *Anopheles hyrcanus* group in northeastern India.[112,209,215] Although vector abundance and risk for human infection are associated with rainfall, with the introduction of wet rice cultivation,

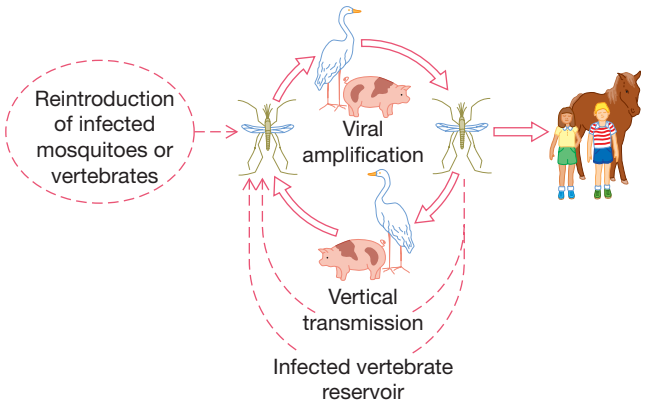

Figure 33.14. Transmission cycle of Japanese encephalitis (JE) virus. The open arrows indicate known portions of the cycle, and the dashed arrows indicate speculative portions. Infections and illnesses in humans and horses are incidental to the transmission cycle. The overwintering mechanism for JE virus is undefined, but experimental field observations suggest a role for vertical transmission in vector mosquitoes.

Figure 33.15. In Indonesia, flooded rice paddies are the principal breeding sites for larval stages of Japanese encephalitis virus mosquito vectors. The disease is transmitted chiefly in rural areas, especially in areas using irrigation schemes, where vector mosquitoes and pigs, the principal vertebrate amplifying host, are abundant near human residences.

Figure 33.16. Rice cultivation in Kurnool District, India, which alone is responsible for almost 46% of the Japanese encephalitis cases in Andhra Pradesh State.

paddy-flooding schedules have come to influence vector bionomics. Single paddies can produce more than 30,000 adult mosquitoes in a day. Collectively, these human-made breeding sites overpower the impact of natural sources. In these circumstances, mosquito abundance fluctuates with periodic rice field flooding and can peak at any time of the year, including the dry season (see Figs. 33.15 and 33.16).[216,217]

In temperate regions, vector mosquitoes emerge in May, and, after several initial rounds of viral amplification, high rates of pig seroconversion are detected. This is followed almost immediately by the onset of human cases, typically in July and August. By virtue of high levels and lengthy periods of viremia after infection and their prevalence as domestic animals, pigs are the key hosts for viral amplification (see Fig. 33.11). Infections in adult pigs are asymptomatic, but gestational infection frequently results in abortions and stillbirths, with significant economic losses. In some locations, enzootic transmission of the virus among aquatic birds has been well established, and, in outbreaks in which pigs are absent birds may serve as amplifying hosts.[218] Other domesticated animals, such as cattle, dogs, sheep, cows, and chickens, and peridomestic rodents may become infected, but these animals fail to develop sufficient viremia to support further viral amplification.[219] JEV mosquito vectors are zoophilic; consequently, cows and certain other animals can reduce risk to humans by diverting vector mosquitoes (zooprophylaxis).[220] Immunization of pigs prevents abortion and stillbirths and also may reduce viral transmission by nullifying the role of pigs as viral amplifiers. Experimental immunization of nearly the entire pig population on one island led to a significant reduction in human cases.[220–222] Unfortunately, this model is expensive and not easily reproducible with the high birth rates in the swine population and impossible in settings where pigs forage freely, a common practice in low-resource areas. Therefore, in rural parts of Asia, immunization of pigs has not been found to be an effective public health measure.[223] In humans, neither the use of permethrin-impregnated or untreated mosquito nets provide statistically significant protection.[224–227]

Other modes of transmission have been documented on rare occasions. In India, JEV was isolated from an aborted fetus, suggesting that intrauterine transmission of JEV can occur.[228,229] Based on experience with similar flaviviruses, blood transfusion and organ transplantation also are considered potential modes of JEV transmission.[230,231] At least 22 laboratory-acquired JEV infections have been reported in the literature.[232] Transmission in the laboratory setting could occur through needle sticks, and theoretically, through mucosal or inhalational accidental exposures.

RISK GROUPS

Residents in Endemic Area

Behavioral and other factors associated with the risk of acquiring JE vary regionally. Rural location, household crowding, religion, ethnicity, exposure to domestic animals, outdoor evening activities, and lack of air conditioning were detected as risk factors in some studies.[9,38,233–236] Risk of JE is highest in children younger than age 15 years, as most adults have acquired natural immunity after childhood infection (Fig. 33.17).[81,237,238] Although risk for acquiring JE is greatest in rural areas, conditions that permit enzootic viral transmission exist within or at the periphery of many Asian cities. JE cases in persons residing in urban area are commonly reported, including from suburban areas of major cities such as Bangkok, Beijing, Shanghai, and Delhi.[238–243] Sporadic reports of cases from Hong Kong and Singapore attest to the possibility of enzootic viral transmission near highly developed urban areas.[196,238] Reports of JE antibodies in feral pigs on a Singapore offshore island and JE reported in horses in Hong Kong strengthen these arguments.[195,244]

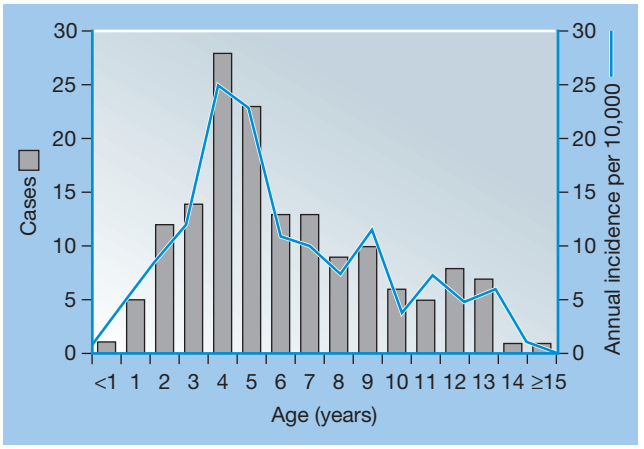

Figure 33.17. Reported Japanese encephalitis cases and age-specific incidence, Nallur Primary Health Centre, South Arcot District, Tamil Nadu, India, 1986–1990. *(Modified from Gajanana A, Thenmozi V, Samuel P, et al. A community-based study of subclinical Flavivirus infections in children in an area of Tamil Nadu, India, where JE is endemic.* Bull World Health Organ. *1995;73:237–244.)*

Previously, areas with high Muslim populations were believed not to be at risk because pig rearing is rare compared with Hindu and Christian populations.[34,245,246] In Indonesia, despite substantial data demonstrating JEV transmission in animal and mosquito populations since the 1970s, the perception that populations in predominantly Muslim areas were not at risk of JE led to a lack of human surveillance and an underappreciation of JE disease. However, a study of patients hospitalized with AES found serologically confirmed cases in all areas of the country, including areas with high Muslim populations.[198,237,245,247] Bangladesh, another predominantly Muslim country, also has demonstrated that JEV is a cause of encephalitis there.[34]

Travelers and Expatriates

Although JE vaccine is used principally in Asia to protect local populations, vaccines also are marketed in developed countries for travelers to Asia, expatriates, and, especially, military personnel (see Table 33.14). For the purposes of this discussion, expatriates are defined as residents through a transmission season. Sporadic cases have been reported in travelers from North America, Europe, Russia, Israel, Australia, and New Zealand, and, paradoxically, in Japanese and Taiwanese tourists to other endemic areas of Asia.[248–252] Data on JE cases among travelers from nonenzootic countries have been published.[251–256] Between 1973 and 2008, there were 55 cases of JE that occurred in citizens of 17 countries, an average of 1.5 published cases per year. The age range of patients was 1 to 91 years with a median of 34 years.[252] Of the 55 patients, 10 (18%) died and 24 (44%) had mild to severe sequelae. Of 37 persons with travel histories, 24 (65%) had spent 1 month or more in JE-endemic areas, and most had factors identified that may have increased infection risk. It is estimated that for every published case there may be an additional case of JE among travelers.[256] U.S. Department of Transportation statistics indicate that 4 million U.S. citizens traveled by air to Asia in 2004; however, this is not the population at risk. Most

travelers have brief itineraries during nonenzootic season, without outdoor or nighttime exposure in at-risk areas. Some may have been immunized.[257] The annual incidence in American travelers can be estimated roughly at less than 1 per 1 million population.

Risk also can be extrapolated from attack rates in unimmunized American, Australian, and British military personnel exposed in Asia. Rates have ranged from 0.05 to 2.1 per 10,000 population per week in soldiers who were exposed intensely under field conditions, in some cases during epidemics (Table 33.2).[43,47,252,256,258–262] These rates are similar to rates among children residing in hyperendemic areas, where annual reported incidence rates typically are in the range of 0.1 to 2 per 10,000 population. By accepting the high estimate and recognizing that transmission is limited to about a 5-month period in most areas, the monthly risk can be estimated as 1 per 50,000 population, or 1 per 200,000 population per week.

The risk for acquiring JE after a single mosquito bite can be estimated by considering the following probabilities of infection and illness:

1. Only bites of vector species are potentially infectious.
2. Even in epidemic circumstances, viral infection rates in vector mosquitoes rarely exceed 3%.
3. If a nonindigenous person is infected, symptomatic neuroinvasive illness may occur at a rate of 1 per 30 to 50 infections.[43]

Further reducing the risk of an infectious bite, *C. tritaeniorhynchus* and other JE vectors are chiefly zoophilic and prefer animal rather than human hosts. They feed chiefly in the evening and during the crepuscular (twilight) periods at dawn and dusk, and, although they may enter houses to feed, they principally are exophilic and seek hosts outdoors. Travelers can reduce risk by wearing mosquito repellent and long-sleeved shirts and trousers, by avoiding outdoor activities in the evening, and staying in screened or air-conditioned rooms.[224,266,267]

Risk for acquiring JE during travel is highly variable and depends on the destination and season of travel and the activities of the traveler (Table 33.3; also see Table 33.14). Travelers who remain in rural areas for extended periods are at greatest risk. Cases have been reported in travelers with brief itineraries staying in resorts or urban locations, but most have had factors identified that put them at risk for mosquito bites and JEV infection.[249–251] For example, in 2010, two JE cases were reported in U.S. citizens who had traveled to Asia for 21 and 10 days, respectively.[268,269] One of them, a child who visited the Philippines, stayed in a screened house in Metro Manila but on four occasions visited coastal and rural destinations, including evening walks on the beach.[268] The second, an adult, stayed in Shanghai, China, but made three trips, each of about 2 days' duration to three outlying areas. During at least one of his side trips, he participated in outdoor activities, including swimming and hiking.

TABLE 33.3 Risk and Protective Factors for Acquiring Japanese Encephalitis During Travel to Asia

Permethrin-treated mosquito nets

PASSIVE IMMUNIZATION AND CROSS-PROTECTION

JE immune plasma and immunoglobulin are not commercially available. Experimental data in mice, goats, and rhesus monkeys indicate a prophylactic and therapeutic potential for polyclonal antibodies or a mixture of JE monoclonal antibodies, although combined use with peripheral and intraspinal or subdural administration was required for maximum effect.[270–273] A small controlled trial in humans suggested a

potential therapeutic benefit of passive immunization with antibodies.[270] More recently, intravenous injection of human immunoglobulin prepared from donors resident in JE-endemic areas was administered in an exploratory double-blinded clinical trial to Nepalese children with JE. The product was administered according to protocol and well-tolerated. The sponsors recommend larger clinical trials.[274] However, experience with prophylaxis of tickborne encephalitis (TBE) using human TBE-specific immunoglobulin indicates that antibody must be administered within a short period after tick exposure to be effective and that late administration (i.e., after 4 days) may worsen outcome.[275] This enhancement phenomenon has been replicated in animal models using JE and Murray Valley encephalitis.[276] Although there are few data, early treatment with interferon-α, perhaps in combination with immune plasma, may prevent illness after a known exposure, such as a laboratory accident, although treatment with interferon-α alone has not been found effective.[45,189–191]

All flaviviruses share many common antigens. Immunity, presumably from antibodies, against some flaviviruses offers low-level protection against disease from different species of flaviviruses. For example, prior dengue infection with one or more types has been found to reduce the incidence and the severity of sequelae from subsequent infections by encephalitis viruses, including SLE and JE. Original observations were made during a virgin soil epidemic of JE on Guam in 1947 to 1948, where much of the population was immune to dengue 1 virus from World War II epidemics.[36,277] Similar observations were made on the incidence of SLE during an outbreak in Florida, where some persons had been infected previously by dengue 2 virus.[278] Further observations on the possible protective effect of prior dengue infection on the incidence of clinical JE have been suggested in prospective studies in Thailand.[55,83,279–281]

ACTIVE IMMUNIZATION

Worldwide, at least eight different types of JE vaccines are produced and used, some in several countries (Table 33.4). For many years, only inactivated JE vaccine produced in mouse brain was available in developed countries.[283] Biken, a Japanese manufacturer, distributed approximately 2 million doses of this product abroad through Sanofi Pasteur for many decades; however, production of this vaccine was discontinued in December 2005, and all remaining stocks expired in early 2011.[284,285] The two vaccines currently most widely available internationally are the live attenuated SA 14-14-2 JE vaccine produced by Chengdu Institute of Biological Products (CDIBP), China and the inactivated Vero cell-derived JE vaccine manufactured by Valneva Scotland Ltd and licensed by Valneva Austria GmbH, Vienna, Austria (formerly Intercell AG). Live attenuated SA 14-14-2 vaccine is in use or licensed in at least 10 countries and was prequalified by the WHO for persons 8 months of age and older in 2013. In the decade through 2011, 145 million doses had been exported to JE-endemic countries and 245 million doses had been used in the domestic Chinese market.[286] Producers of the Vero-based inactivated JE vaccine produced by Valneva Scotland Ltd are listed below. Following technology transfer from Valneva, Biological E produced a similar JE vaccine in India which is distributed under the trade name JEEV. JEEV was WHO prequalified in 2013 for adults 18 to 49 years of age, and in 2014 for children 12 to 36 months of age.[287] A live YF 17D-JE chimeric vaccine (trade name, IMOJEV, IMOJEVMD, and THAIJEV) is manufactured by Sanofi Pasteur and by Government Pharmaceutical Organization–Merieux Biological Products Co. (GPO-MBP), a joint venture between GPO, Thailand and Sanofi Pasteur (Fig. 33.18). It is used or licensed in Australia, Thailand, Brunei Darussalam, Malaysia, Myanmar, and the Philippines.[286,288] It was prequalified for individuals 9 months of age and older in 2014.[287]

Inactivated Mouse Brain–Derived Japanese Encephalitis Vaccine

History of Vaccine Development

Initial Approaches That Were Abandoned. Inactivated mouse brain–derived JE vaccines were produced in Russia and Japan in the 1930s.[289] During World War II, a simple uncentrifuged 10% suspension of infected mouse brain, inactivated with formalin, was produced in the United States as a vaccine for the military. The vaccine was variably immunogenic, and efficacy field trials could not be completed.[265,290–292]

A more stable inactivated chick embryo–derived vaccine, also developed by the U.S. military, had an 80% efficacy in Japanese children when given as a combination of mouse brain and chick embryo–derived vaccines.[293–297] However, the latter vaccine was less immunogenic in adults, and its efficacy in soldiers was never evaluated. Although this vaccine was given to all U.S. soldiers assigned to Asia from 1948 to 1951,

TABLE 33.4 Licensed Japanese Encephalitis Vaccines

Inactivated	Mouse brain	Nakayama, Beijing-1	Korea: Green Cross; Boryung Biopharma; Taiwan: Adimmune Corp; Thailand: Government Pharmaceutical Organization; Vietnam: Vabiotech
	Vero	Beijing-1	Japan: Biken (Research Foundation for Microbial Diseases of Osaka University), Kaketsuken
	Vero	Beijing P-3	China: Beijing Tiantan Biological Products Co; Liaoning Chengda Biotechnology Co
	Vero	SA 14-14-2	United Kingdom: Valneva Scotland Limited; India: Biological E
	Vero	Kolar strain (JEV 821564XY)	India: Bharat Biotech
	Hamster kidney cells	Beijing-1	China: Liaoning Yisheng Biopharma Co.
Live attenuated	Hamster kidney cells	SA 14-14-2	China: Chengdu Institute of Biological Products, Wuhan Institute of Biological Products, Lanzhou Institute of Biological Products
Chimera	Vero	JE SA 14-14-2/yellow fever 17D	Thailand: Government Pharmaceutical Organization-Merieux Biological Products Co.; Sanofi Pasteur

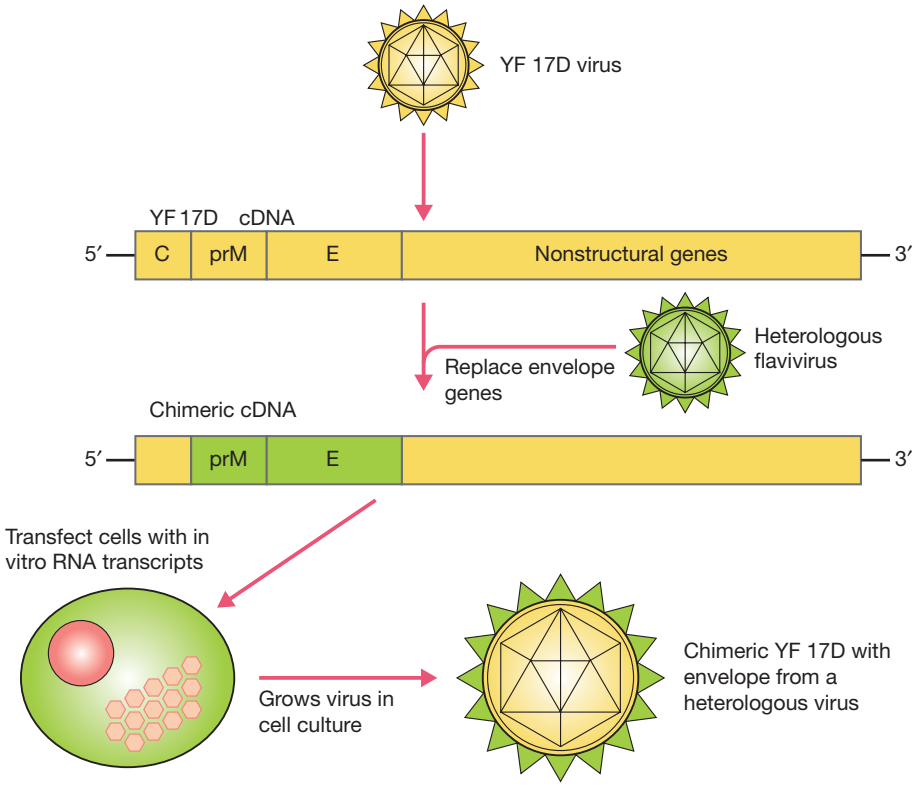

Figure 33.18. Chimeric Japanese encephalitis (JE) vaccine concept. The chimeric JE vaccine results from the insertion of the prM and E structural genes from the SA 14-14-2 virus into the nonstructural genes of yellow fever vaccine 17D (YF 17D). cDNA, complementary DNA. *(Data from Acambis, Inc.)*

its use was discontinued in 1952 after review of available data failed to produce convincing evidence of immunogenicity and efficacy.[258–262]

Description of Current Vaccine and History of Development. Successive refinements of the mouse brain vaccine were introduced by research institutes in Japan, resulting in a highly purified vaccine marketed worldwide but no longer produced by Biken.[298,299] It is not clear whether inactivated mouse brain vaccines currently manufactured in developing countries are subject to the same purification procedures as used for the Biken vaccine. Information regarding constituents and methods of production of the Biken vaccine will be of continuing interest as persons in some countries continue to be immunized with similar vaccines. The use and timing of booster doses of inactivated JE vaccines must be addressed for many decades to come.

Constituents, Including Antibiotics, Preservatives, and Adjuvants

The Nakayama strain of JEV, isolated from the CSF of a patient in 1935 and maintained by continuous mouse brain passage, has been the principal strain used in mouse brain–derived vaccines produced throughout Asia.[283] The strain was chosen because of good propagation characteristics and because it provided protection against several JE viral strains in mice. Cross-immunization studies in mice with strains from diverse areas of Asia indicated that strains of the JaGAr01/Beijing type (e.g., Beijing-1, known as P1 in China and the equivalent P3 strain; see later discussion) confer a broader neutralizing antibody response against various JE viral isolates than does the Nakayama strain.[106,300,301] The Beijing-1 strain grows to higher titer, and the vaccine produces higher heterologous antibody titers in immunized mice than does the Nakayama strain vaccine. Although vaccine produced from either strain meets standardized mouse protection tests for potency, the Beijing-1 vaccine is formulated in half the volume. Biken, the principal Japanese manufacturer of JE vaccine, used the Beijing-1 strain since 1989 in vaccine produced for domestic consumption, whereas the Nakayama strain was used in vaccines distributed internationally.

Manufacture of Vaccine

Mouse brain–derived vaccines are currently produced in Thailand, Vietnam, Taiwan, and South Korea by inoculating 3-week-old mice intracerebrally. When mice show signs of illness, brains are harvested, pooled, and suspended. Vaccine is made using similar sequences of centrifugation, ultrafiltration, protamine sulfate precipitation, and formalin inactivation in the cold, followed by further purification by ultrafiltration, ammonium sulfate precipitation, and continuous zonal centrifugation on sucrose density gradients. National standards in Japan specify minimal immunogenicity and potency in mice (compared with a vaccine standard) and maximal total protein (80 g/mL) and myelin basic protein (MBP) content (2 ng/mL), among other specifications. Bulk vaccine is diluted with medium 199 and phosphate buffer to meet a potency standard.[302,303] Although the quantity of JE E protein is not controlled, in one study, a dose was estimated to contain approximately 50 g. The vaccine is stabilized with gelatin and sodium glutamate and preserved with thimerosal.

Producers

Inactivated JE vaccines are produced by national manufacturers in several Asian countries, as detailed in Table 33.4.

Preparations Available, Including Combinations

Vaccines produced in Vietnam, Taiwan, and Thailand are in liquid form. No combination inactivated vaccines are available. However, in several countries, JE vaccine is frequently coadministered with other vaccines on the immunization schedule. In a study of children 15 months old, simultaneous administration of inactivated JE vaccine with measles-mumps-rubella vaccine did not result in reduced immunogenicity or increased side effects.[304] Under the Thailand EPI, JE vaccine is given concurrently with the fourth doses of diphtheria, tetanus toxoid, and pertussis (DTP) and oral poliovirus vaccines at 18 months of age.[305]

Dosage and Route of Administration

In most areas of Asia, vaccine produced from the Nakayama strain is given subcutaneously in two 0.5-mL doses 1 to 4 weeks apart (1.0 mL for people >3 years), usually beginning at the age of 12 months or older, with a dose at 1 year and one or more additional booster doses as outlined below.[283] In practice, immunization schedules are variable. The Biken package insert recommended an interval of 1 to 2 weeks for primary immunization; however, many immunogenicity studies have used a 4-week interval. Primary vaccination is recommended at 18 months of age in Thailand, at 15 months in Taiwan, and at 12 to 23 months in Korea. With no evidence from efficacy studies, boosters are recommended to be given 1 year later. In Korea, subsequent booster doses were given annually until 15 years of age, but now a revised schedule of giving boosters at 6 and 12 years of age is recommended. In Taiwan, an additional booster is given at school entry (age 5 or 6 years). Beijing-1 strain–derived vaccine is formulated with a higher antigen concentration, and the recommended dose is 0.5 mL (0.25 mL for children <3 years).

The primary series has been administered to infants along with DTP vaccine as early as 2 months of age in clinical trials, but, because JE uncommonly occurs in children younger than 1 year, vaccination is typically recommended starting in children 1 year of age and older.[305] A comparison of administration routes in adults showed that a 0.1-mL intradermal dose given at two sites may be as immunogenic as the standard administration of 1.0 mL subcutaneously, at least when given as a booster.[306]

Vaccine Stability

Lyophilized Biken vaccine was stable at 4°C for at least 1 year and retained more than 90% of its potency after 28 weeks at 22°C. At 37°C, lyophilized vaccine retained 95% of its original potency after 4 weeks.[299]

Inactivated Primary Hamster Kidney Cell–Derived JE Vaccine

Because inactivated primary hamster kidney (PHK) vaccine has been produced exclusively in China and newer vaccines are now in use there, details on history of vaccine development, constituents, production, and administration have been omitted. Readers are referred to earlier versions of this chapter for details.

Inactivated Vero Cell-Derived Japanese Encephalitis Vaccine (SA 14-14-2 Virus Strain)

Description of Current Vaccine and History of Development

The wild-type parental virus, SA-14, was isolated from a pool of *C. pipiens* larvae from Xian, China, following 11 passages in mouse brain. The derivation of the strain SA 14-14-2 was performed through an empirical process of serial passage performed in Beijing, China, in PHK cells and was given the strain designation SA14 clone 14-2 (also designated SA 14-14-2).[307] At the Walter Reed Army Institute of Research (WRAIR), the SA14 clone 14-2 was first adapted to primary dog kidney (PDK) cells and then to Vero cells. Attenuated SA 14-14-2 vaccine strain was initially passaged eight times in certified PDK cells. The PDK cell–passaged virus was then passaged in certified Vero cells and used as the master seed for making the inactivated vaccine.[308] Phase I and Phase II clinical trials were carried out at WRAIR, and the vaccine was then licensed to the Austria-based company Intercell AG (now Valneva Austria GmbH) for further development.[308,309] The vaccine was tested under the name IC51 and in 2009, was licensed for adults in the United States and Europe as IXIARO and in Australia as JESPECT. The vaccine was licensed for pediatric use in 2013.

Constituents, Including Antibiotics, Preservatives, and Adjuvants

In contrast with the mouse brain–derived inactivated vaccines, inactivated Vero cell–derived SA 14-14-2 vaccine contains no preservatives, antibiotics or gelatin stabilizers. The vaccine contains aluminum hydroxide at a concentration of 0.1% as an adjuvant. Other excipients are phosphate-buffered saline (PBS) consisting of sodium chloride, potassium dihydrogen phosphate, disodium hydrogen phosphate, and water for injection. From the manufacturing process, inactivated Vero cell–derived SA 14-14-2 vaccine also contains formaldehyde (≤200 ppm), bovine serum albumin (≤100 ng/mL), host cell DNA (≤200 pg/mL), sodium metabisulfite (≤200 ppm), host cell proteins (≤300 ng/6 μg of protein), and protamine sulfate (≤1 μg/mL).

Manufacture of Vaccine

Working viral seed is produced at Valneva Scotland Ltd (Livingston, UK). The JE vaccine production seed is prepared by inoculating Vero cells grown in roller bottles. After virus inoculation and propagation, virus harvests are filtered, pooled, and concentrated. The concentrated virus pool is treated with protamine sulfate to remove Vero cell DNA. The virus pool is then purified by batch centrifugation in a sucrose gradient. The purified material, containing hemagglutinating virus, is inactivated with formaldehyde, which is then neutralized with sodium metabisulfite. Following neutralization, the inactivated virus is sterile filtered through 0.2 μm filters and diluted to a specified antigen content of 12 μg/mL. Finally the preparation is adsorbed to 1.5 mg/mL aluminum hydroxide and dispensed as a 0.5-mL dose per syringe.

Producers

The vaccine is licensed and distributed under the trade name IXIARO in Europe, North America, Hong Kong, Singapore and Israel, while in Australia and New Zealand, the vaccine is licensed and distributed by bioCSL under the trade name JESPECT. Following transfer of the manufacturing technology for IC51, the Indian company Biological E produces

a similar vaccine under the trade name JEEV at its facility in Hyderabad.

Preparations Available, Including Combinations

Inactivated Vero cell–derived SA 14-14-2 vaccine is provided as prefilled syringes containing 0.5 mL of vaccine, corresponding to a single dose for adults and children 3 years of age and older. For children 2 months through 2 years of age, each dose is 0.25 mL, and a marked syringe has been developed to allow administration of the 0.25-mL dose. No combination vaccines are available, but the vaccine can be coadministered with inactivated hepatitis A, rabies, or meningococcal vaccines without detrimental effects on immunogenicity.[310–312] There are no data on coadministration with measles, mumps, rubella (MMR) or other childhood vaccines.

Dosage and Route of Administration

For adults and children 3 years of age and older, the dose is 0.5 mL. Each 0.5-mL dose contains 6 µg of JEV strain SA 14-14-2 viral protein adsorbed on 0.25 mg Al^{3+} (hydrated aluminum hydroxide), corresponding to a potency of 460 ng ED_{50} (median effective dose) or less. For children 2 months through 2 years of age, each dose is 0.25 mL (3 µg of viral protein) (Table 33.5).[313,314] The vaccine is administered intramuscularly. The primary series consists of two doses administered 28 days apart. An accelerated schedule with doses administered 7 days apart provides noninferior seroprotection rates to a standard schedule.[312] If administration of the second dose is delayed, a second dose given up to 11 months after the first dose also provides similar seroprotection rates to the standard 0 and 28 day schedule.[315] Seroconversion rates after a single dose were only 21% to 29% at day 10 and 40% to 43% at day 28, but reach 97% by 7 days after administration of a second dose.[316] Protection before administration of the second dose is therefore uncertain and the full schedule should be completed 7 days before departure to a JEV endemic area. For adults, booster doses of vaccine should be administered before a potential reexposure if 12 months or more have elapsed since initiation of the primary series.[315,317] Six years after a booster dose, 96% of subjects remain seroprotected.[318]

TABLE 33.5 Recommended Immunization Schedule for Vero Cell–Derived Inactivated Japanese Encephalitis Vaccine

Vaccines	Primary[a]	Booster[a]
Adults and children ≥3 y	0.5 mL given on days 0 and 28[b] (conventional schedule) Complete series 1 wk before travel Adults 18–65 y can be vaccinated in a rapid schedule of 0.5 mL given on days 0 and 7[c]	Age ≥18 y: 1–2 y after primary series given in a conventional or rapid schedule, administer 0.5 mL prior to travel to JE endemic countries Age 3–17 y: Need for and timing of a booster dose not determined yet
Children 2 mo to <3 y	0.25 mL given on days 0 and 28	Need for and timing of booster doses not determined yet

[a]All doses given intramuscularly.
[b]IXIARO Summary of Product Characteristics, http://www.ema.europa.eu/docs/en_GB/document_library/EPAR_-_Product_Information/human/000963/WC500037287.pdf
[c]A rapid schedule is not approved in some countries, including the United States.

Existing recommendations for repeated booster suggest that a second booster should be given 10 years after the first booster dose, prior to potential exposure to JEV.[395] Similarly in children, a booster should be administered before potential reexposure if 12 months or more have elapsed since the primary series. Two years after a booster dose, 100% of children remain seroprotected.[395]

Vaccine Stability

The vaccine has an approved shelf life of 18 to 24 months, depending on the local regulatory approval. Immunogenicity of the vaccine is slightly lower toward the end of the shelf life but still induces seroconversion in more than 93% of vaccinees.[319]

Live Attenuated Japanese Encephalitis Vaccine

History of Vaccine Development

Initial Approaches That Were Abandoned. Attenuated JE viral strains have been sought by passaging wild strains serially in various cell culture systems, including PHK, chick embryo, and mouse embryo skin cells.[320–323] Loss of neurovirulence in mice, hamsters, pigs, or any combination of the three initially suggested the possibility of safe use in humans. Attenuation may be correlated with decreased binding to mouse brain cell receptors.[324] In China, the vaccine parent strain, SA 14, was isolated in 1954 from *C. pipiens* larvae collected in Xian (Table 33.6). After isolation and 11 serial passages in weanling mice, the virus was attenuated through 100 passages in PHK cells at 36°C to 37°C. Neurovirulence in monkeys had been lost at this passage level. Further plaque selection and cloning in chick embryo cells and subpassages in mice and hamsters by peripheral and oral infection were performed resulting in a stable nonneurovirulent virus. The resulting SA 14-5-3 strain no longer reverted to an established criterion of neurovirulence after intracerebral passage in suckling mice while remaining potent in mouse immunization-challenge studies.[325–334] The SA 14-5-3 virus did not kill 3-week-old mice by subcutaneous or direct intracerebral inoculation. Direct intrathalamic and intraspinal inoculation of the virus in monkeys resulted in no mortality or morbidity and only minimal CNS inflammation, limited to areas around the injection sites. Histopathologic

TABLE 33.6 Attenuation History of Japanese Encephalitis SA 14-14-2 Virus[307]

	Name
Parental Japanese encephalitis SA14 virus isolated from pool of *Culex pipiens* larvae by 11 passages in mouse brain	SA14
100 serial passages in primary hamster kidney (PHK) cells followed by three plaque purifications	SA 14-12-1-7
Two plaque purifications	SA 14-17-4
One mouse spleen passage (intraperitoneal inoculation) followed by four plaque purifications	SA 14-9
One mouse skin passage (subcutaneous inoculation) followed by one plaque purification	SA 14-9-7
Six hamster spleen passages (oral inoculation) followed by two plaque purifications	SA 14-5-3
Five suckling mice skin passages (subcutaneous inoculation) followed by two plaque purifications	SA 14-14-2
Amplification in PHK or primary dog kidney cells[334]	

changes were characterized by perivascular lymphocytic cuffs and focal mononuclear cell infiltration, with rare direct neuronal degeneration or necrosis.

The SA 14-5-3 vaccine was shown to be safe in humans, and field trials in endemic areas demonstrated seroconversion rates greater than 85%. However, rates of only 61% were obtained in subjects from nonendemic areas.[325] Expanded field trials in southern China involving more than 200,000 immunized children confirmed the vaccine's safety and yielded efficacies ranging from 88% to 96% over 5 years. However, the vaccine's poor immunogenicity in *Flavivirus*-naïve subjects from nonendemic areas suggested that the SA 14-5-3 virus, like previous live JEV candidate vaccines, was overattenuated and did not replicate uniformly in humans. To increase immunogenicity, the SA 14-5-3 virus was serially passaged five times by subcutaneous inoculation of suckling mice, using skin, subcutaneous tissue, and local peripheral lymph nodes as the passage material.[307,326] After plaque selection and cloning twice in PHK cells, the SA 14-14-2 strain was obtained. The SA 14-14-2 virus was equally attenuated but more immunogenic in mice, pigs, and humans, producing seroconversion rates greater than 90% in nonimmune subjects.[329,330] The response to intracerebral inoculation of live attenuated JE vaccines in infant mice is a reliable surrogate for more expensive use of monkeys for this purpose.[307,335]

Description of Current Vaccine and History of Development. The history of vaccine development and the genotypic and phenotypic attributes of SA 14-14-2 vaccine have been described.[307] Workers at the National Institute for the Control of Pharmaceutical and Biological Products (NICPBP) in Beijing managed the attenuation of PHK-passaged JE strain SA 14-14-2 and found it to be safe and immunogenic in animals and humans (see Table 33.6). The vaccine's efficacy was demonstrated in field trials, and the vaccine was licensed in the China in 1988 (for details see the 6th edition of this text). Attenuation of the SA 14-14-2 virus was produced empirically by serial passage in nonneural tissues, and the underlying molecular basis of its neuroattenuation is partially known. The nucleotide sequence of the neurovirulent parent SA 14 virus differs from that of SA 14-14-2 and two other attenuated SA 14-2–derived vaccine viruses in seven amino acid substitutions found in all three attenuated strains. Four were in the envelope protein (E138, E176, E315, and E439), one was in NS protein 2B (NS2B63), one was in NS3 (NS3105), and one was in NS4B (NS4B106).[336–338] These mutations have been shown to be very stable. An amino acid change at E138 in SA 14-14-2 virus was shown to be sufficient for mouse neuroattenuation when introduced into a wild-type JE complementary DNA infectious clone. Nucleotide sequences of structural protein genes revealed that the attenuated and parental viruses differed by eight amino acid mutations in the E protein. Attenuated JEVs also have been obtained by selecting neutralization escape variants. Attenuation was associated with single base changes resulting in single E protein amino acid changes and was linked with altered early virus–cell interactions but not with replication.[339,340]

The reduced neurovirulence of the SA 14-14-2 strain was confirmed in 3-week-old mice and monkeys.[307] Compared with the parent SA-14 strain, which killed weanling mice by subcutaneous or intracerebral inoculation with median lethal doses (LD_{50}) of $10^{5.5}$ and $10^{8.3}$ LD_{50}/mL, respectively, the SA 14-14-2 virus produced no mortality and only minor clinical signs in a few intracerebrally inoculated mice. Combined intrathalamic and intraspinal inoculation of rhesus monkeys produced no clinical illness and only minor inflammatory reactions in the substantia nigra and cervical spinal cord. Mice were more sensitive than monkeys to intracerebral infection, with some animals showing mild neuronal lesions in the cerebral cortex, hippocampus, or basal ganglia.[307] Compared with histopathologic lesions produced by the parent SA-14 virus, the inflammatory reaction and neuronal necrosis seen after SA 14-14-2 virus were significantly less. In 5-week-old mice inoculated intracerebrally with the virus pair, ultrastructural studies showed that the parent virus produced cytopathologic changes in the majority of neurons, particularly in the rough endoplasmic reticulum and Golgi apparatus of the neuronal secretory system, although it could not be confirmed that the vaccine strain replicated at all and neurons appeared normal.[332]

No deaths or histopathologic abnormalities were observed in athymic nude mice after intraperitoneal or subcutaneous inoculation of a viral dose greater than 10^7 median tissue culture infective doses ($TCID_{50}$), and virus could not be recovered from brain tissue.[164] Although cyclophosphamide increases susceptibility of mice (and also of monkeys) to virulent JEV, immunosuppression with cyclophosphamide did not lead to encephalitis in mice inoculated peripherally with the SA 14-14-2 virus.[165] The strain also did not kill intracerebrally inoculated weanling hamsters. Phenotypic characteristics of the vaccine strain (PHK8), such as small plaque, reduced mouse neurovirulence, and genetic properties, were stable through at least 10 additional PHK cell culture passages.[307,333]

No evidence of viremia up to 14 days following SA 14-14-2 JE vaccine administration was found in a study among 19 adults in India previously unexposed to JEV.[341] The SA 14-2-8 strain, closely related to SA 14-14-2, propagated well in *C. tritaeniorhynchus* mosquitoes after intrathoracic inoculation but could not be transmitted. In oral infection trials, only 11% of *C. tritaeniorhynchus* mosquitoes ingesting vaccine became infected compared with 100% with wild-type JE.[342] The virus did not revert to a neurovirulent phenotype after mosquito passage.[342] Intrathoracic inoculation of the SA 14-14-2 strain into vector mosquitoes replicated to titers similar to parental SA-14, but the authors did not test transmissibility of vaccine virus.[343]

Constituents

Several hundred ampules of seed virus, prepared from the sixth passage level of SA 14-14-2 virus, are maintained at the NICPBP, Beijing. Lyophilized seed virus (PHK5) is provided to production institutes, where it is passaged once for the production seed (PHK6). The PHK cells are obtained from 10- to 12-day-old golden Syrian hamsters maintained in colonies at the Chengdu and Wuhan production institutes. Current Chinese pharmacopeia and WHO guidelines specify the use of specific pathogen-free hamsters for the primary cell cultures. A specific pathogen-free hamster colony has been established at the Chengdu facility and is used for all vaccine production.[344] Monolayers are inoculated with diluted virus, and cells are fed with minimal essential medium containing human albumin, gentamicin, and kanamycin. Infected cell culture fluid with an infectious titer of approximately $10^{7.2}$ plaque-forming units (PFU)/mL is harvested at 78 to 96 hours and coarsely filtered, and the resulting liquid vaccine is lyophilized. Gelatin (1%) and sucrose (5%) are added as stabilizers. The major components of the final vaccine are human serum albumin, gelatin, sucrose, lactose, and carbamide. Lyophilized vaccine is reconstituted and diluted with sterile water for injection (single-dose vial) or PBS (five-dose vial).[287,345]

The reconstituted vaccine should be a transparent orange-red or light pink liquid. The PFUs of vaccine is not to be lower than $10^{5.7}$ PFU/mL in the reconstituted vaccine.

Manufacture of Vaccine

Vaccine must meet standards according to the WHO guidelines and Chinese pharmacopeia for absence of neurovirulence in adult mice, stability for reversion to neurovirulence after intracerebral passage in suckling mice, and freedom from adventitious agents, including retroviruses.[346] A highly sensitive product-enhanced reverse-transcriptase assay could not detect any reverse transcriptase activity in finished or bulk vaccine. A cocultivation assay on production cell culture using human cell lines followed by product-enhanced reverse-transcriptase assay allowed an expanded opportunity of detecting cross-species infection of retroviruses into human cells and did not show any reverse transcriptase activity in PHK cells. No evidence was found in SA 14-14-2 vaccine of murine leukemia virus-related viruses.[347]

Producers

Vaccine is produced by three manufacturers in China: CDIBP, Lanzhou Institute of Biological Products, and Wuhan Institute of Biological Products (see Table 33.4). In 1998, 200,000 doses of vaccine from CDIBP were donated to Nepal. In 2001, CDIBP became the first and only manufacturer to officially export vaccine outside of China when it successfully licensed and began exporting vaccine to Nepal. Since that time, CDIBP has additionally licensed vaccine in South Korea (2002), Sri Lanka (2002), India (2006), Thailand (2007), Laos (2008), Democratic People's Republic of Korea (2009), Myanmar (2010), Vietnam (2013), and Malaysia (2013). With local authority approval, children in Cambodia have also been vaccinated, commencing in 2009. CDIBP's vaccine is distributed under the trade names CD.JEVAX or RS.JEV. As of 2015, CDIBP is the only facility to fully comply with all the WHO production standards for the live attenuated vaccine.[287]

Preparations Available, Including Combinations

No combination vaccine is available. However, live attenuated SA 14-14-2 vaccine is commonly coadministered with measles-containing vaccines because their schedules coincide. In a randomized trial in the Philippines in which 8- to 10-month-old children were administered measles and SA 14-14-2 JE vaccines concomitantly or separated by 1 month, measles and JE seroprotection rates were high and comparable in all groups and reactogenicity profiles were similar.[348,349] Safety and immunogenicity of coadministration of measles and SA 14-14-2 JE vaccines were also assessed in a single arm study in Sri Lankan infants 9 months of age, which demonstrated good seroprotection rates and no safety concerns.[350]

Dosage and Route of Administration

Live attenuated SA 14-14-2 vaccine is prequalified by WHO as a single 0.5-mL dose for children 8 months of age and older. The vaccine is frequently administered to children at 8, 9, or 12 months of age to coincide with other routine immunizations, and to provide protection as early as possible while avoiding potential interference from passively acquired maternal antibodies.[349,350] In endemic settings, the need for a booster dose has not been established. In China and India, a two-dose schedule provides a second opportunity for vaccination and aims to ensure high coverage with at least one dose. In other countries, two doses are routinely given (e.g., South Korea, Thailand).

Vaccine Stability

The infectious titer of lyophilized vaccine is not appreciably changed after storage at 37°C for 7 to 10 days, at room temperature for 4 months, or at 2°C to 8°C for at least 1.5 years. After reconstitution with sterile saline or distilled water and storage at 23°C, the vaccine's infectious titer is stable for 2 to 4 hours or 2 hours, respectively.[345] The vaccine should be stored and shipped at 2°C to 8°C, protected from sunlight, and used within 18 months after the titration test is completed. Multidose vials once reconstituted should be used during the immunization session or within 6 hours, whichever comes first.[287]

Phenotypic and genotypic attributes of the SA 14-14-2 vaccine have remained stable over several decades.[307]

Chimeric Vaccines

History of Vaccine Development

The chimeric JE vaccine is constructed from the YF 17D genome that contributes NS genes and the SA 14-14-2 genome that contributes prM and E genes (see Fig. 33.18). The product was invented at St. Louis University; developed by Acambis, Cambridge, Massachusetts; and licensed for global distribution to Sanofi Pasteur, Lyon, France.[351] The chimera is constructed from DNA, transcribed to RNA and electroporated into Vero cells. The resultant infectious clone has the neurovirulence properties of SA 14-14-2 but Vero cell growth characteristics of 17D.[352,353] Attenuation of the chimeric virus was shown to depend on clusters of at least three of the six amino acid changes in the JE E protein.[353] JE-CV has proved to be immunogenic in rhesus monkeys and protects against intracerebral and intranasal challenge with the wild virus strain.[354,355] The chimera has not been shown to be transmitted by mosquito vectors of JE or YF viruses.[356]

A number of preclinical studies have shown that the JE-CV vaccine is safe, immunogenic, and protective in mouse and nonhuman primate models.[335,352–354,357] A clinical trial in adults (18 years of age and older) found that a single dose of IMOJEV generates comparable seroconversion rates (~99%) to those seen after three doses of JE-VAX (~95%), with approximately 94% of the participants seroconverting within 14 days.[358] A low-level, transient viremia was present in the majority of subjects (10/12 naïve and 11/12 YF-immune JE-CV recipients) and was similar in magnitude and duration to the viremia induced by YF 17D. In 100% of JE-CV subjects, including all YF-immune subjects, neutralizing antibodies developed against JE (seroconversion) by 30 days following vaccination; YF-immune subjects responded with higher JE neutralizing antibody titers than did naïve subjects.[359] A 5-year follow-up study found approximately 87% of vaccinees receiving one dose had detectable neutralizing antibodies at both month 6 and 5 years; this percentage increased to approximately 96% with a booster at month 6.[360] This result has been modeled to achieve a predicted 10 years of "protection."[361] In Thailand, the Philippines, and Taiwan, clinical trials in children (12 to 18 years of age or 24 months of age) have shown that single-dose administration elicits seroconversion in approximately 95% of naïve toddlers. In the Thai trial, among 182 flavivirus-naïve children, 96% developed neutralizing antibody titers to 1:10 or greater at 28 days, but 15% of primary responders had titers less than 1:10 at 1 year after single-dose immunization[362–364] There have been no serious safety concerns following administration of this vaccine.[358,360,363] Furthermore, the JE-CV virus is restricted in its ability to infect and replicate in six potential vector mosquito

species following oral feeding of artificial blood meals containing high titers of virus.[356,365] In a multicenter trial in Taiwan, 550 children 12 to 18 months of age were alternately given JE-CV or live-attenuated licensed MMR vaccine at 6-week intervals, or they were administered concomitantly.[366] The immune responses were higher than 95% in all groups and remained high for 12 months after vaccinations in the groups that had sequential administration of vaccines, but decreased slightly in the coadministration group.

Constituents. The vaccine contains Vero cell proteins, mannitol, lactose, glutamic acid, potassium hydroxide, histidine, human serum albumin, sodium chloride, and water for injection. No adjuvant or antimicrobial preservatives are added.

Manufacture of Vaccine. The vaccine is grown in cultured Vero cells.

Producers. The chimeric JE vaccine is manufactured by Sanofi Pasteur and licensed in Australia as IMOJEV. The vaccine is manufactured from furnished seed by the GPO-MBP in Thailand where it is licensed and marketed as THAIJEV.

Preparations Available, Including Combinations. There are no combination vaccines.

Dosage and Route of Administration. One dose (0.5 mL) containing $10^{4.0–5.8}$ PFUs, is administered subcutaneously. It is licensed in Australia for individuals older than the age of 12 months and WHO prequalified for children 9 months of age and older.

Vaccine Stability. Vaccine is stored at 2°C to 8°C and has a shelf life of 2 years.

IMMUNOGENICITY OF JAPANESE ENCEPHALITIS VACCINES

The JE viral strains isolated in different geographic locales or at different times exhibit minor antigenic differences and biologic characteristics such as growth in cell culture and neuroinvasiveness in experimentally infected mice. However, there is no evidence of corresponding differences in human pathogenicity and no evidence that immune responses to one strain, whether as a live viral infection or as a vaccine, does not protect against disease caused by another.[130,367–370] In the modern era, antibodies raised by administration of JE vaccines have been measured by IgM and IgG ELISA, hemagglutination inhibition, complement-fixation, and tissue culture–based neutralization tests of varying formats. A neutralizing antibody titer of 1:10 or greater is accepted as evidence of protection and postvaccination seroconversion.[371] Passively immunized mice that acquire this level of neutralizing antibody are protected against challenge from 10^5 LD_{50} of JEV, a typical dose transmitted by an infectious mosquito bite. Indirect observations from human trials have associated efficacy with this criterion.[372] PRNTs are used most frequently, and procedural differences, such as choice of challenge virus strain, cell systems, addition of exogenous complement, and choice of end points (ranging from 50% to 90% plaque reduction in serum dilution tests), affect test sensitivity.[373] In one assessment, neutralizing antibody titers in three laboratories (the U.S. Centers for Disease Control and Prevention [CDC], Japan's National Institutes of Health, and the Yale Arbovirus Research Unit) were shown to be highly correlated (R. DeFraites, unpublished data, 1998). This same result was not replicated when several laboratories evaluated standard serum samples for a test serum bank being developed by the WHO.[373] An international standard of protective antibody units is in the process of being established.[371]

Inactivated Mouse Brain Vaccine

Antibodies

Among Asian children immunized with two doses of Nakayama strain– or Beijing-1 strain–derived vaccines, neutralizing antibody responses to the respective homologous vaccine strains are in the range of 94% to 99%; responses to strains representing a heterologous antigenic group are lower.[374–377] The proportion of vaccinees retaining detectable neutralizing antibodies and their geometric mean antibody titers (GMTs) declined rapidly in the year after the primary two-dose series, so that only 78% to 89% of Nakayama vaccine recipients and 88% to 100% of Beijing-1 vaccine recipients still had detectable levels before the scheduled 1-year booster. Antibody persistence was greater among Beijing-1 vaccine recipients. After booster immunization (or third vaccine dose), antibody response rates were uniformly high (100%). During the history of the administration of JE vaccines in Asia, additional booster doses have been given empirically, usually with the goal of restoring neutralizing antibody titers to the detectable range and according to the philosophy that more is better, as illustrated in a U.S. study of mouse brain vaccine (Fig. 33.19). However, there are no studies of the efficacy of such booster doses in Asian countries. In fact, the long-term efficacy of two or three doses of killed vaccine has not been measured. There is evidence of sustained protection in adults who do not receive booster doses of JE vaccines in Korea, Japan, and Taiwan. This evidence is compatible with solid protection being provided to immunized persons with very low titers of neutralizing antibodies.

Immunogenicity studies in Asian subjects should be interpreted in the light of the immunologic background of vaccinees. Although some studies have been done in nonendemic areas and in subjects without JE viral antibodies, in other studies, undetected exposures to JE, dengue, and other flaviviruses prevalent in Asia may have resulted in an augmented antibody response after immunization.

Where the influence of previous flaviviral infections was unlikely, vaccinees receiving two doses had lower seroconversion rates and lower GMTs than vaccinees receiving three doses.[378–382] After administration of two doses of inactivated vaccine, neutralizing antibody titers declined to less than 1:8 in 90% of vaccinees at 6 to 12 months following vaccination. A three-dose primary schedule was more immunogenic, resulting in seroconversion rates exceeding 90% and significantly higher neutralizing antibody titers.[378–382] Administration of vaccines at long (days 0, 7, and 30) versus short intervals (days 0, 7, and 14) using three doses resulted in uniform seroconversions in all subjects but significantly higher neutralizing antibody titers in vaccinees immunized over the longer period (30 days). Vaccine prepared from the Beijing-1 strain seems to be more immunogenic, despite its smaller delivered volume, yielding higher seroconversion rates and higher antibody titers to heterologous Nakayama virus.[383–385] Similar but more marked differences were seen in comparative neutralization of field viral strains from Taiwan, paralleling those in experimentally immunized mice.[386] The clinical importance of these differences in strain reactivity in the neutralization test is uncertain. Results of an efficacy trial comparing a monovalent Nakayama strain vaccine with a bivalent vaccine also containing Beijing-1 antigen showed that the two were equally efficacious.[387] Neutralizing activity below the threshold of detection may be protective. B-cell

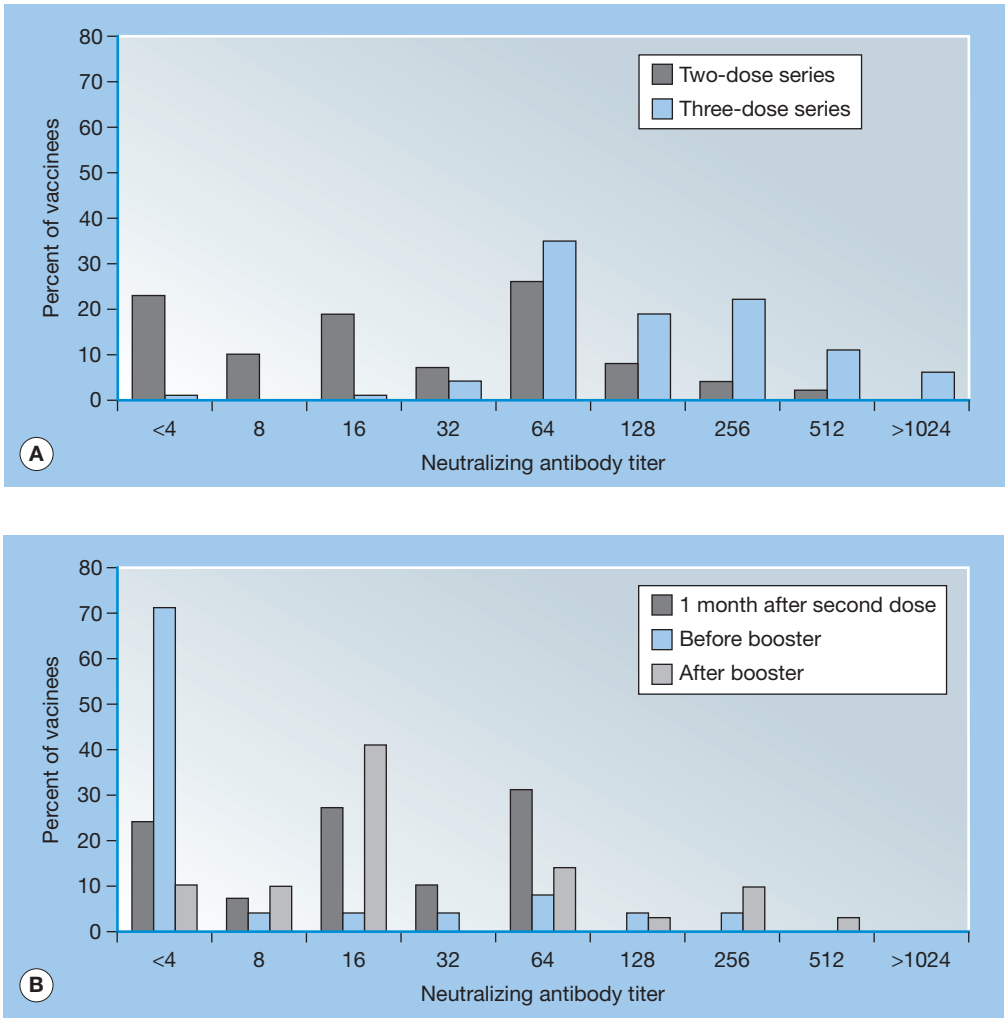

Figure 33.19. A, Antibody response to inactivated mouse brain–derived Japanese encephalitis vaccine in a trial among U.S. citizens. Only 77% of vaccinees who received two doses seroconverted, compared with 99% of vaccinees who received three doses. Geometric mean antibody titers also were higher in the latter group (28 vs 141). **B,** At 6 to 12 months after primary immunization, only 10% of vaccinees who were given two doses retained protective levels of neutralizing antibody. Booster immunization led to a greater than 90% response. *(Modified from Poland JD, Cropp CB, Craven RB, et al. Evaluation of the potency and safety of inactivated Japanese encephalitis vaccine in US inhabitants.* J Infect Dis. *1990;161:878–882.)*

memory, anamnestic antibody responses, and T-cell memory may contribute to protect seronegative vaccinees, but nevertheless provide immunologic help to clear infections on reexposure. Previous exposures to dengue and certain other flaviviruses probably enhance the immune response to JE vaccine.

Cellular Responses

Persons given inactivated vaccine are exposed only to viral structural proteins, and, in contrast to convalescent patients, they do not produce radioprecipitating antibodies to viral NS proteins.[387] Their memory T-cell proliferative responses to a viral-like particle containing only structural proteins also differ from those of recovered patients, with CD4 and CD8 cell responses to viral NS proteins.[157] The implications of these immune response differences are uncertain. While cellular responses have been studied following infection with wild-type JE or immunization with JE vaccines, these have not been correlated with protection or disease outcome.

Correlates of Protection

Neutralizing antibodies measured in a mouse or tissue culture neutralization test have been generally accepted as a correlate for protection. A WHO expert panel determined that a 50% PRNT ($PRNT_{50}$) titer of 10 or greater was acceptable as an immunologic correlate of protection from JE in humans.[371]

In Special Groups, Such as Immunosuppressed Persons

Impaired responses to vaccination were observed in infants with vertically acquired HIV infection when compared with HIV-uninfected infants born to HIV-infected women: five (36%) of 14 HIV-infected children and 18 (67%) of 27 control children developed JE antibodies after immunization (odds ratio [OR], 0.3; $P = .06$); among children with positive titers, the GMT of HIV-infected children also was lower (15.1 vs 23.8; $P = .17$).[388] The response to additional doses beyond the primary two doses was not studied. Immune response in other immunocompromised states has not been studied systematically.[389]

Inactivated Vero Cell Vaccine

Correlates of Protection

Passive immune transfer of human sera with high PRNT titers after immunization with inactivated Vero cell–derived SA 14-14-2 vaccine that resulted in a titer equal to or greater than 1 : 10 in mice protected them from lethal challenge with SA-14 and the non–genotype 3 JE strain KE-093.[390] Groups of 10 female ICR mice (6–7 weeks old) received human antisera in 0.5-mL amounts (intraperitoneal injection) and were then challenged intraperitoneally 17 to 18 hours later with a lethal dose of SA-14 or KE-093 strain. Challenged mice were observed for 20 days, and blood samples were obtained just before challenge and at day 21. Mice with JE neutralizing antibody titers equal to or greater than 1 : 10 before challenge had survival rates of 86% (6/7) and 100% (10/10) after challenge with the KE-093 and SA-14 strains, respectively.[390] Human immune serum samples from clinical trial participants were tested for neutralization of other JEV strains and showed broad neutralizing capacity against a variety of strains (SA-14, Nakayama, Beijing, P-20778).[41,391,392]

Antibodies

Immunogenicity of inactivated Vero cell–derived SA 14-14-2 vaccine served as an indicator of vaccine efficacy in the clinical development of the vaccine. A validated PRNT was applied to determine neutralizing antibody response to vaccinations and the WHO-recommended immunological correlate of protection ($PRNT_{50}$ titer of ≥10) was used. Licensure of inactivated Vero cell–derived SA 14-14-2 vaccine was based on noninferior immunogenicity of the vaccine compared with field-effective, mouse brain–derived JE vaccine (JE-VAX, Biken; distributed by Sanofi Pasteur). Seroconversion rates and GMTs were comparable for both vaccines (Table 33.7).[316,391,393] Inactivated Vero cell–derived SA 14-14-2 vaccine led to 96.4% seroconversion rate (all subjects were seronegative at baseline) at day 56, compared with 93.8% seroconversion rate for JE-VAX. GMTs were 243.6 and 102.0, respectively; however, the $PRNT_{50}$ assay used SA 14-14-2 JEV strain as the challenge virus and use of the homologous strain to the inactivated Vero cell–derived SA 14-14-2 vaccine likely accounted for the higher titer for the Vero cell–derived vaccine.

A study investigating the kinetics of the neutralizing antibody response after vaccination detected a 97.3% seroconversion rate by 7 days after the second dose, suggesting rapid boosting of immunity following the second dose (Fig. 33.20).[316] One study has investigated the response to an accelerated schedule of vaccine. JE vaccine doses were administered on days 0 and 7, and rabies vaccine was also administered on days 0, 3, and 7. The JE seroprotection rate in the accelerated schedule group was noninferior to the rate in the group who received the standard schedule of two doses of JE vaccine on days 0 and 28 (99% vs 100%). The accelerated schedule led to higher GMTs at both 7 and 28 days after the last active immunization and up to 12 months later (Fig. 33.21).[394,395]

The pivotal pediatric clinical trial was conducted in children 2 months to 17 years of age in the Philippines.[393,396] Among children who received two age-appropriate doses, 384 (100%) of 385 were seroprotected at 28 days after the second dose (95% confidence interval [CI], 96–100%). At 6 months, 134 (88%; 95% CI, 82–92%) of 152 children 2 months to 2 years of age and 224 (95%; 95% CI, 91–97%) of 237 children 3 to 17 years of age were seroprotected. Immunogenicity was also investigated in a small cohort of children from nonendemic countries who were traveling to endemic regions. Among 54 children 10 months to 17 years of age (median, 15 years of age), the seroprotection rate was 100% at day 56.[393] In a small trial in India, 22 (96%; 95% CI, 87–100%) of 23 children 1 and 2 years of age were seroprotected at 28 days after receiving two doses.[313] No statistically significant differences were detected in the seroprotection rates between this group receiving two doses and children who received three doses of the inactivated mouse brain–derived JE vaccine (manufactured by Korean Green Cross).

In Special Groups

Immunogenicity of inactivated Vero cell–derived SA 14-14-2 vaccine has not been studied in immunocompromised persons. In 200 elderly persons (65 years of age and older) the

vaccine was less immunogenic compared to younger populations, with a seroconversion rate of 65% and a GMT of 37 at 70 days after the first dose.[393]

Live Attenuated Vaccine, SA 14-14-2

Antibodies

In early studies in China, after a single dose, antibody responses were produced in 85% to 100% of nonimmune 1- to 12-year-old children, with a response gradient that paralleled the viral titers.[307,329,330,397] Lower seroconversion rates were obtained with vaccine dilutions that had infectious titers less than $10^{5.7}$ PFU/mL, which has been established as the minimal standard of vaccine infectivity.

More recent clinical trials with live attenuated SA 14-14-2 vaccine have been conducted in the Philippines, Bangladesh, Thailand, and South Korea. In the Philippines trial, immunogenicity was assessed among children 8 to 10 months of age who were randomly assigned to receive one dose of live attenuated SA 14-14-2 JE vaccine 1 month before, after, or coadministered with measles vaccine.[348,349] JE seroprotection rates in the three groups 28 days postvaccination were 92.1% (81/88), 90.6% (163/180), and 90.5% (201/222), respectively. GMTs were 203, 155, and 139. In a study among Bangladeshi infants 10 to 12 months of age (N = 727 in the

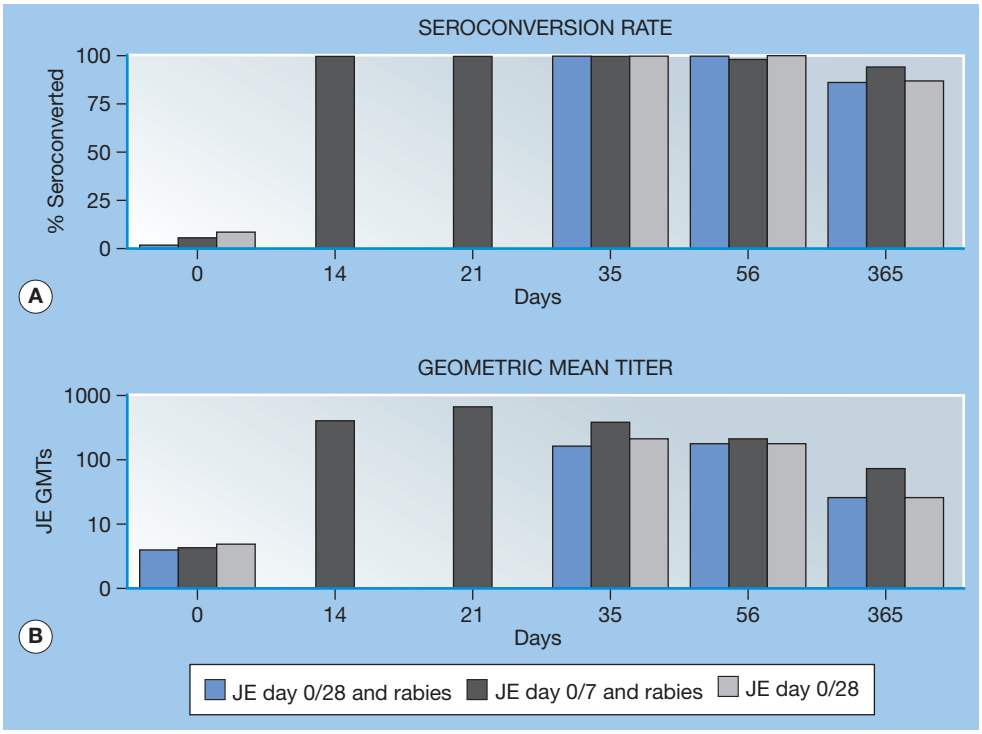

Figure 33.21. Japanese encephalitis (JE) seroconversion rates **(A)** and geometric mean titers **(B)** at intervals up to 365 days following administration of inactivated Vero cell–derived JE vaccine (IXIARO). The Vero cell–derived vaccine was administered in an accelerated days 0, 7 schedule (together with purified chick embryo cell [PCEC] rabies vaccine administered on days 0, 3, and 7) or in one of two comparison regimens of a standard days 0, 28 schedule (together with PCEC rabies vaccine on days 0, 7, and 28) or a days 0, 28 schedule alone. Seroconversion was defined as a $PRNT_{50}$ titer ≥1 : 10. $PRNT_{50}$, 50% plaque-reduction neutralization test. *(Modified from Jelinek T, Burchard GD, Dieckmann S, et al. Short-term immunogenicity and safety of an accelerated pre-exposure prophylaxis regimen with Japanese encephalitis vaccine in combination with a rabies vaccine: a phase III, multicenter, observer-blind study.* J Travel Med. *2015;22:225–231; and IXIARO Summary of Product Characteristics, available at http://www.ema.europa.eu/docs/en_GB/document_library/EPAR_-_Product_Information/human/000963/WC500037287.pdf.)*

per-protocol analysis) randomized to receive one of four different lots of vaccine, seroprotection rates at 28 days ranged from 80.2% to 86.3%, and GMTs ranged from 52.8 to 77.3.[398] When live attenuated SA 14-14-2 JE vaccine was used in the control arm in a JE vaccine study in Thailand among children 9 to 18 months of age, 97.6% (122/125) of participants who received live attenuated SA 14-14-2 JE vaccine had seroconverted by day 28.[364] GMT was 171 when SA 14-14-2 JEV was used in the PRNT assay. In a similar study in South Korea among children 12 to 24 months of age, 99.1% (116/117) seroconverted by day 28 with a GMT of 579 (chimeric virus in the PRNT assay).[399]

Cellular Responses. Induction of cellular immunity was shown by higher levels of protection when cyclophosphamide-suppressed immunized mice were vaccinated with live attenuated SA 14-14-2 vaccine compared to inactivated PHK cell vaccine (see earlier discussion).[328,400]

Correlates of Protection

Although correlates of protection were not well established when earlier studies with the SA 14-14-2 vaccine were conducted, recent studies have used the WHO-recommended $PRNT_{50}$ titer of equal to or greater than 10 as the immunological correlate of protection. This recommendation may not apply to immune responses to attenuated viruses, as measured efficacy rates are higher than measured neutralizing antibody responses. Attenuated vaccine was found to be protective in a challenge model using JE strains from various Asian countries collected over a span of 50 years.[328,370,400]

In Special Groups

There are few data on use of live attenuated SA 14-14-2 vaccine in immunosuppressed patients. A trial in Thailand evaluated patients who had undergone allogenic hematopoietic stem cell transplantation 2 or more years earlier and were off immunosuppressive medications for 6 months or longer.[401] Among 18 patients who were not seroprotected at baseline, nine (50%) had seroconverted by 3 months after one dose, but only six (33%) were still seroprotected at 12 months, seven (39%) seroconverted by 3 months following two doses (all remained seroprotected 12 months later), one (6%) seroconverted by 12 months following two doses, and one (6%) did not develop a seroprotective titer. Although this is a small study, these results suggest a poorer immunologic response is likely in immunosuppressed children than in healthy children. There are no data on the use of vaccine in pregnant or breastfeeding women.

Chimeric Vaccine

Antibodies

A single dose of chimeric JE vaccine given to children 16 to 18 months old raised similar levels of neutralizing antibodies against seven strains of JEV, genotypes I and III, within the margin of measurement error.[402]

Correlates of Protection

One Phase III study enrolled 820 participants across 10 centers (five each in the United States and Australia). Half were randomized to receive chimeric JE vaccine and the other half to receive licensed mouse brain vaccine. Ninety-four percent of participants completed the trial. Incidence of adverse events was acceptable in the chimeric JE vaccine arm and JE neutralizing antibody responses were equivalent or better than to standard licensed mouse brain vaccine through day 60.[358]

Duration of Immunity/Protection

In a long-term follow-up assessment in a randomized control Phase II trial, 97.6% (95% CI, 93.3–98.8) of adults showed seroprotective levels 6 months after a single administration of IMOJEV. At 60 months after vaccination 86% had seroprotective levels, but no data exist for seroprotection after 5 years.

EFFICACY AND EFFECTIVENESS OF VACCINE

Inactivated Mouse Brain Vaccine

Efficacy of the Nakayama vaccine was initially evaluated in two masked, randomized, placebo-(tetanus toxoid–) controlled field trials (Table 33.8). In the first one in 1965 in Taiwan, two doses of the inactivated mouse brain–derived vaccine yielded an 80% efficacy in the first year after immunization.[403–405] A subsequent masked, randomized, placebo-controlled field trial in Thailand compared the efficacies of the monovalent Nakayama vaccine with a specially formulated bivalent vaccine also containing Beijing-1 antigen.[282] Two doses of vaccine or placebo were given 1 week apart to children 1 year of age or older. After 2 years, efficacies of the monovalent and bivalent vaccines were identical at 91%. Reduced attack rates of dengue and dengue hemorrhagic fever were also observed in JE-vaccinated groups, although the differences were not significant.

Two recent case control studies evaluated the effectiveness of the mouse brain–derived inactivated vaccines produced in Thailand and Vietnam. Vaccine effectiveness in Thailand among children 18 months to 5 years of age who had received at least 1 vaccine dose was 97.5%.[390,406] In Vietnamese children, vaccine effectiveness among children aged younger than 15 years of age who were vaccinated with at least three doses was 92.9%.[407]

Experimental studies in monkeys and neutralizing antibody studies in humans suggest that immunization against JE might provide cross-protection against West Nile virus, leading some workers to recommend JE vaccine to protect laboratory workers against West Nile virus.[151,408] A small number of workers at the U.S. CDC laboratory in Fort Collins, Colorado, who had been immunized against JE, nevertheless had mild overt West Nile infections.[409]

Inactivated Vero Cell Vaccine

Direct tests of efficacy and effectiveness of inactivated Vero cell–derived SA 14-14-2 vaccines were not undertaken as there was consensus in a WHO consultation that efficacy studies comparing new with existing JE vaccines would be infeasible owing to prohibitive sample sizes.[371] However, immunogenicity as an indicator of efficacy was demonstrated with noninferior immune responses to Vero cell vaccine when compared to mouse brain–derived vaccine (see Table 33.7).[391]

Live Attenuated Vaccine, SA 14-14-2

Five major efficacy trials of SA 14-14-2 vaccine, completed in China from 1988 to 1999 in 1- to 10-year-old children, consistently demonstrated protection rates of greater than 98%.[410] (See the 6th edition of this text for more details.) Inactivated vaccine was already widely used at the time, so placebo-controlled trials were not ethical. A noninferiority trial was conducted with the inactivated vaccine using immunogenicity end points (unpublished data).

A case-control study performed in 1993 in Sichuan Province, China, in children younger than age 15 years, measured effectiveness of routinely delivered SA 14-14-2 vaccine at 80% (95% CI, 44–93%) for a single dose and 97.5% (95% CI, 86–99.6%) for two doses given at a 1-year interval.[411] The PFU per dose was not available for this trial; after 1996, the method of determining PFU dose was refined and standardized (Y.F. Yao, personal communication, 2004; L.J. Yang, personal communication, 2005). In addition, the study authors noted that program quality was unknown, including maintenance of cold chain and vaccine administration techniques, and these factors could have affected the results. In Nepal in 1999, more than 160,000 children 1 to 15 years of age received a single dose of SA 14-14-2 vaccine ($10^{5.8}$ PFU/0.5 mL) just a few days before the onset of a large JE outbreak and vaccine effectiveness was 99.3%. In a case-control study, no JE cases had a history of vaccination compared with 59% of age- and sex-matched village control subjects.[412] The effectiveness findings for a single dose in preventing JE cases in the next year and 5 years later were 98% and 96%, respectively.[413,414] This study provided evidence that SA 14-14-2 was useful in combating epidemics. Although the vaccine lot used in this field trial was made for export and the vaccine packaged in individual 1-mL syringes, this study clearly demonstrates that under supervised administration, SA 14-14-2 vaccine can be highly protective after just one dose.

TABLE 33.8 Efficacy of Inactivated Mouse Brain–Derived Japanese Encephalitis Vaccine[a]

Country	Study Group	No. at Risk	Case Rate/100,000	Efficacy (95% CI) (%)
Taiwan, 1965[348,350]	Total vaccinated	133,943	4.48	76 (63–90)
	1 Dose	22,194	9.01	50 (26–88)
	2 Doses	111,749	3.58	80 (71–93)

[a]Two doses of Nakayama or bivalent Nakayama/Beijing mouse brain–derived vaccines.
CI, confidence interval.

Following the widespread use of SA 14-14-2 vaccine in India, two case-control studies measured vaccine effectiveness. In one study among children 1 to 15 years of age, effectiveness was 94.5% at 6 months following a mass immunization campaign.[415] In another study, vaccine effectiveness was measured following administration of a single dose of vaccine as part of the routine immunization program. Among children 24 to 54 months of age, vaccine effectiveness was 84% up to 3 years after vaccination.[416] These and other data from China attest to the effectiveness of the SA 14-14-2 vaccine used in a single-dose preventive campaign complemented by routine EPI administration to infants in reducing the public health burden of JE.

Chimeric Vaccine

Efficacy

Because several effective JE vaccines are available, a randomized, controlled efficacy trial would have been logistically very difficult. Consequently, the chimeric vaccine was licensed on the basis of its ability to induce neutralizing antibodies, which is thought to be a reliable correlate of efficacy.

DURATION OF IMMUNITY AND PROTECTION

Inactivated Mouse Brain Vaccine

Studies in Asia to determine the persistence of vaccine-derived immunity are complicated by boosting through cocirculating related flaviviruses such as dengue and West Nile viruses or reexposure to JEV itself, all of which may reinforce and broaden vaccine-derived immunity to JEV.[102,103,148–150] Even with the potential for these reinforcing infections, several studies in Asian and Western subjects (see previous discussion) indicate a progressive decline in antibody levels in the first year after primary immunization with two doses of mouse brain vaccine.[298,380] Cross-sectional serosurveys in Japan and Taiwan (see earlier discussion) demonstrate a rapid decline of antibody levels in childhood. Observations of vaccine efficacy in the Taiwan field trial parallel these results: in the second year after immunization, protective efficacy declined from 80% to 55% (95% CI, 39–75%).[404] In the Thailand field trial of the Nakayama vaccine, efficacy was shown through 2 years of observation. Further follow-up data are not available. A retrospective study on Taiwan estimated the efficacy of a single dose of Nakayama strain inactivated JE vaccine at 86.7%.[417] However, efficacy data on control subjects were simply extrapolated from historical estimates of JE vaccine delivery in Taiwan and not individual vaccination records. Vaccine efficacy for a 30-year period was calculated using the JE attack rate in a single year, 1967, and it is likely that as the population has become more urban and rice cultivation has declined, JE infection rates in human beings would have fallen significantly.

Booster doses after a two-dose primary immunization series in endemic settings are universally recommended. Indeed, JE cases have been observed in children with a history of adequate primary vaccination.[418] Booster doses are followed by significant increases in neutralizing antibody titer and uniform anamnestic responses in subjects who had reverted to seronegative. A small study of vaccinees receiving an Indian-manufactured JE vaccine found that 34 (97%) of 35 retained neutralizing antibodies 3 years after a primary series of three doses and 31 (91%) of 34 retained antibodies at 4.5 years, with GMTs of 71 and 32, respectively. However, the boosting effect of naturally acquired flaviviral infections in these subjects cannot be ruled out.[419] During the history of the administration of JE vaccines in Asia, additional booster doses have been given empirically, usually with the goal of restoring neutralizing antibody titers to the detectable range with the philosophy that more is better (see Fig. 33.19).

Flavivirus-naïve U.S. Army soldiers who received a three-dose primary immunization series retained protective neutralizing antibody titers for at least 1 year (GMT: 76), with antibody titers at 12 months unchanged from those observed at 3 months after immunization (GMT: 78). A booster dose given at 12 months was followed by a significant anamnestic response (GMT: 1117). In a limited number of subjects studied 3 years after the primary series, 16 (94%) of 17 who had neither traveled to Asia nor received a booster dose retained neutralizing antibody titers of greater than 1 : 10, with their GMTs at 6 months and 3 years remaining unchanged.[381] A large study of 293 laboratory workers revealed that more than 50% lost neutralizing antibody titers to below 1 : 10 just over 2 years after immunization. The authors also noted significant lot-to-lot variation in antibody response to vaccination.[420] Although these observations suggest that the first booster immunization is needed no sooner than 2 to 3 years after primary immunization, the interval for subsequent boosters has not been established. Although studies suggest that antibodies quickly wane no matter how many doses of inactivated vaccine are given, if a person with an undetectable level of antibodies is bitten by an infected mosquito, a B-cell memory response likely occurs, raising antibodies to protective levels before JEV invades the CNS.

Inactivated Vero Cell Vaccine

The persistence of antibodies following immunization with inactivated Vero cell–derived SA 14-14-2 vaccine was investigated in three studies among adults from nonendemic areas with varying results. Findings showed that between 58% and 83% of subjects still had neutralizing antibody titers of 1 : 10 or more at 12 to 15 months after the primary immunization (Table 33.9).[315,316,392] Reasons for the differing results are not completely understood, but the studies were carried out in different geographic areas, and a high prevalence of prior TBE vaccination in the trial showing higher antibody persistence might have contributed to this difference.[317]

Booster doses of inactivated Vero cell–derived SA 14-14-2 vaccine are needed in adults to sustain long-lasting titers of neutralizing antibodies 1 : 10 or greater. Based on data on the persistence of antibodies and immunogenicity of booster doses, the CDC's Advisory Committee on Immunization Practices (ACIP) recommends that adults should be given a booster dose if it is more than 12 months after the primary series and there is the potential for JEV exposure.[421] In a booster trial in 198 subjects 18 years of age and older, inactivated Vero cell–derived SA 14-14-2 vaccine was administered at 15 months after primary immunization. The booster dose was highly immunogenic and yielded a GMT of 900 (a 40-fold increase relative to prebooster titer), with 100% of subjects achieving a $PRNT_{50}$ titer of 1 : 10 or more by 28 days after the booster dose. At 1 year postbooster, the GMT was 361 and 98.5% of subjects still had a $PRNT_{50}$ of 1 : 10 or more (see Fig. 33.20B).[317] A follow-up study included 67 (34%) of the original 198 study participants. At a mean of 75.5 months following a booster dose, 64 of the subjects (96%) still had a neutralizing antibody titer equal to or greater than 10 and the GMT was 148.[318] In six subjects 50 years of age and older, the GMT of 52 (95% CI, 10–269) was lower than the GMT of 165 (95% CI, 118–230) in those younger than age 50 years. GMTs were not significantly different in subjects with and without a history of TBE or YF vaccination. Among the 67 participants, 17 (25%) had traveled to a JE-endemic country since the booster dose and the impact on the immune response of possible exposure

TABLE 33.9 Persistence of Neutralizing Antibodies Against Inactivated Vero Cell–Derived SA 14-14-2 Vaccine Following Two-Dose Primary Immunization Schedule

Both seroconversion rate and seroprotection rate are defined as the rate of subjects with $PRNT_{50}$ ≥1 : 10.
PRNT, plaque reduction neutralization test.

to wild JEV is unknown. Modeling of antibody decline following a booster dose suggested an average duration of protection of 14 years (range: 2–25 years) and that an estimated 75% of subjects would be protected for at least 10 years. In another study, vaccine recipients whose titers had dropped to less than 1 : 10 were administered booster doses at 11 months (n = 16) or 23 months (n = 24) after primary immunization. All subjects seroconverted following the booster dose, regardless of the time of booster dose administration.[315] No data are available on immunogenicity of booster doses administered longer than 23 months after primary immunization.

There are limited data on duration of protection in children and in individuals living in endemic areas. In a study in the Philippines, the seroprotection rate in children 2 months of age and older to younger than age 17 years given two doses of vaccine was 90% 3 years after the primary series.[396] Among 23 traveling children from JE-nonendemic countries (mean age: 14.3 years; one child younger than 3 years of age at priming) protection rate was was 91.3% (21/23 subjects) 2 years after the primary series.[422]

The response to a booster dose in children was studied in 150 children in the Philippines 9 months of age and older to younger than 17 years. A booster administered 12 months after the primary series resulted in an approximately 40-fold increase in GMT, with highest GMTs in the youngest children. Two years after the booster, the seroprotection rate was maintained at 100%. Currently existing booster recommendations for children are similiar to adults; that is, a booster should be administered before potential reexposure if 12 months or more have elapsed since the primary series.[395]

Live Attenuated Vaccine, SA 14-14-2

In a case-control study in Nepal, persons given a single dose of SA 14-14-2 vaccine in 1999 were followed up in 2000 and again in 2004. The protective efficacy of JE vaccine 12 to 15 months after administration was 98.5% (95% CI, 90.1–99.2%) and at 5 years was maintained at 96.2% (95% CI, 73.1–99.9%).[413,414] As suggested by long-term experience of up to 11 years of sustained reduction in JE cases in areas where many children received only a single dose of SA 14-14-2 vaccine, efficacy of this and possibly other JE vaccines greatly exceeds the ability to detect circulating neutralizing antibodies.

An immunogenicity study conducted in the Philippines followed children for 3 years after a single dose of live attenuated SA 14-14-2 vaccine.[396,423] In infants vaccinated at 8 months of age, seroprotection rates 1, 2, and 3 years later were 90%, 81%, and 79%, respectively. Among infants vaccinated at 10 months of age, corresponding seroprotection rates were 86%, 81%, and 82%. The 1-year results were consistent with findings from a JE vaccine immunogenicity study conducted in Thailand in which SA 14-14-2 JE vaccine was administered to 125 children 9 to 18 months of age in the study's control arm. At 1 year following vaccination, 87.5% of infants who received a single dose of SA 14-14-2 vaccine still had a seroprotective titer.[364] GMT decreased between 1 and 6 months and then remained stable until month 12.

Chimeric Vaccine

Duration of Immunity/Protection

In a long-term follow-up assessment of a randomized control Phase II trial, 97.6% (95% CI, 93.3–98.8) of individuals showed seroprotective levels 6 months after a single administration of IMOJEV, with projected seroprotection rates estimated to be 86.8% 60 months after vaccination.[360] There are no data for seroprotection after 5 years.

ADVERSE EVENTS

Inactivated Mouse Brain–Derived Japanese Encephalitis Vaccine

Common Adverse Events

Localized Reaction. Local tenderness, redness, or swelling at the injection site occurs in approximately 20% of persons immunized with inactivated mouse brain–derived vaccines. Mild systemic symptoms, chiefly headache, low-grade fever, myalgias, malaise, and gastrointestinal symptoms, are reported by 10% to 30% of vaccinees (Table 33.10).[376,378,379,424–426]

Systemic Hypersensitivity Reactions. Vaccine-related allergic adverse events, not reported previously from Asia, were recognized after 1989 in Australia and several European and

[a]Local tenderness, redness, swelling, itching, and numbness.
[b]Chiefly fever, headache, malaise, rash; also chills, dizziness, myalgia, nausea, vomiting, abdominal pain, diarrhea, sore throat, blurred vision, increased salivation and taste, difficulty concentrating, and emotional instability.

North American countries as the vaccine became used widely for travelers.[263,424–435] Hypersensitivity reactions have consisted principally of generalized urticaria, angioedema, or both, which in a few patients were potentially life threatening. These reactions generally have responded to oral antihistamines or corticosteroids, but recalcitrant cases have required hospitalization and parenteral steroid therapy. A temporally related death was reported in a man with multiple hypersensitivities who also had received plague vaccine.[263] Numerous lots and different manufacturers have been implicated in the hypersensitivity reactions.[429] In retrospect, allergic side effects, including urticaria, angioedema, and moderate dyspnea, were also observed in recipients of the crude mouse brain vaccine administered on Okinawa in 1945.[265]

An important feature of the hypersensitivity reactions is the potential for delayed onset, particularly after a second dose. In a prospective study of 14,249 U.S. Marines, the median interval between immunization and onset was 18 to 24 hours after the first dose, with 74% of reactions occurring within 48 hours.[263,428] Among those experiencing a reaction after the second dose, there was a greater delay, with a median interval of 96 hours and a range of 20 to 336 hours. Reactions have also developed after a second or third dose when earlier doses were given uneventfully. A nested case-control study found an elevated risk with history of various allergic disorders (e.g., urticaria: OR, 11.4 [95% CI, 2.4–62.1]; allergic rhinitis: OR, 9.2 [95% CI, 2.8–23.1]; asthma, rhinitis, or both: OR, 6.5 [95% CI, 2.1–20.8); and any allergy: OR, 5.7 [95% CI, 1.8–18.1]).[263] Another small study also implicated alcohol consumption and receipt of another vaccine 1 to 9 days previously, as opposed to simultaneous administration, as risk factors.[433]

Reported rates of hypersensitivity have varied according to the approach to ascertainment. Prospective and retrospective studies have found risk of an allergic adverse event, usually defined as objective urticaria or angioedema, in the range of 18 to 64 per 10,000 vaccinees.[427,432,433,435,436] A cluster of two deaths resulting from anaphylactic shock in children receiving JE vaccine was reported in Korea in 1994. In a follow-up study to measure the incidence of JE vaccine–related adverse events, one case of anaphylactic shock with syncope and collapse, three cases of generalized urticaria, and three cases of severe erythema were found in 15,487 Korean children immunized between May 15 and June 30, 1995. The rate of 0.03% was lower than that observed in adult travelers, which could reflect biologic differences in reactivity or the sensitivity of surveillance (Y.M. Sohn, unpublished data, 1996).

Reported rates of hypersensitivity reactions during postmarketing surveillance in the United States and Japan in the 1990s were 6.3 and 0.8 events per 100,000 doses, respectively.[437] In a subsequent analysis of reports submitted between 1999 and 2009 to the U.S. Vaccine Adverse Event Reporting System (VAERS), 106 (35.3%) of 300 total events were classified as hypersensitivity reactions for a rate of 8.4 per 100,000 doses distributed.[438]

Although the pathogenesis of the hypersensitivity reactions is not proven, in three Japanese children experiencing systemic reactions, IgE antibodies to gelatin were demonstrated, suggesting that gelatin, which is added as a vaccine stabilizer, may be a provoking antigen.[439] Further analysis of reactions showed two patterns: One was a combination of urticarial rash and wheezing, which was associated with the presence of antigelatin IgE in the serum, and the second was a cardiovascular collapse syndrome, in which antigelatin IgE was absent and was apparently caused by another mechanism.[439] Immunologic studies demonstrated IgE antibodies to human albumin, which is added to the vaccine as a stabilizer and chemically altered by the inactivating agent β-propiolactone.[440] Allergic reactions in recipients of crude mouse brain vaccine in Okinawa were attributed to formalin-altered proteins.

Rare Adverse Events

From the beginning, the vaccine's neural tissue substrate raised concern about the possibility of postvaccination neurologic side effects.[441] The manufacturing process purifies the infected mouse brain suspension extensively, and MBP content is controlled below 2 ng/mL, well below the dose considered to have an encephalitogenic effect in a guinea pig test system. However, measurements of other acute disseminated encephalomyelitis (ADEM)-associated neural proteins (e.g., proteolipid protein, myelin-oligodendrocyte glycoprotein) have not been reported. Experimental immunization of guinea pigs and cynomolgus monkeys with adjuvant and 50 times the normal dose of vaccine did not result in clinical or histopathologic evidence of encephalomyelitis.[442–445]

One case of Guillain-Barré syndrome, temporally related to JE immunization, was reported among approximately 20,000 American soldiers immunized with the vaccine before U.S. licensure. An early prospective study to detect vaccine-associated adverse events in Japan found no neurologic complications occurring within 1 month after vaccination in 38,384 subjects receiving crude or purified vaccine.[441] A countrywide study to detect neurologic complications found 26 temporally related cases (meningitis, seizures, demyelinating disease, polyneuritis) between 1957 and 1966, but rates and comparisons with nonimmunized control subjects were not available.

In 1992, two anecdotally reported cases of temporally related, vaccine-associated ADEM in Japan prompted a survey of 162 Japanese medical institutions to solicit additional cases.[446] Five more cases spanning 22 years were reported, including two with elevated CSF MBP levels.[447] Neither the numerator of cases nor the denominator of vaccinees was defined rigorously, but the authors estimated that ADEM occurred in fewer than 1 in 1 million vaccinees. An unrelated

report described two deaths from anaphylactic shock, and four ADEM cases (two fatal) temporally related to vaccination in Korea in 1994; one, also fatal, was reported in 1996. An additional fatal case of acute encephalopathy occurred in a 15-year-old girl who received her ninth dose of JE vaccine and her third dose of a hantaviral vaccine (also made in mouse brain) at 4 and 2 weeks, respectively, before onset of stupor and seizures (Y.M. Sohn, unpublished data, 2002). In Denmark, after a vaccinee developed ADEM in 1995, a review of the national database disclosed two similar temporally related cases in 1983 and 1989, all in adults.[448] A high rate of temporally related ADEM, one in 50,000 to 75,000 vaccinees, was determined.

In the United States, postmarketing surveillance between 1993 and 1998 detected one case of Guillain-Barré syndrome in a 55-year-old male 17 days after vaccination. He had also received rabies vaccine 5 weeks prior and had gastroenteritis 1 week prior to onset. One febrile seizure was also reported for a reporting rate of 0.2 events per 100,000 doses for all neurological adverse events.[437] Between 1999 and 2009, four neurologic events were reported in temporal association with vaccination for a reporting rate of 0.3 per 100,000 doses distributed; the events included one case each of Bell palsy, generalized weakness, ataxia, and seizure.[438] In Japan, 17 vaccine-related neurologic disorders were reported from April 1996 to October 1998.[437] In 2005, the government of Japan withdrew its recommendation for routine immunization using inactivated mouse brain–derived JE vaccine.[285] Routine immunization was recommended again once Vero cell–derived vaccines were licensed.

Adverse Events in Immunosuppressed Persons

There are few data on the safety and immunogenicity of inactivated JE vaccines in immunocompromised persons. A small study of children with various chronic diseases, including some oncology patients, disclosed no difference in immunogenicity or reactogenicity compared to responses in healthy children.[389] Infants vertically infected with HIV responded less well to the vaccine (see earlier discussion), but no unusual adverse events were recorded.[388]

Adverse Events During Pregnancy

No adverse outcomes of pregnancy have been associated directly with JE vaccine. Currently, the ACIP notes that the safety of JE vaccine in pregnancy is unknown, and because vaccination poses a hypothetical risk to the fetus, routine vaccination during pregnancy is not recommended. However, the ACIP also advises that pregnant women traveling to a JE-endemic area should be vaccinated if the risk of infection is greater than the theoretical risks of immunization.

Spread to Contacts

Spread to contacts is not a risk because the vaccine is inactivated.

Inactivated Vero Cell Vaccine

Common Adverse Events

The adverse event profile of inactivated Vero cell–derived SA 14-14-2 vaccine was characterized in a series of prelicensure clinical trials, comparing the local and systemic safety profiles with alum-containing PBS and with inactivated mouse brain–derived JE vaccine.[391,449]

Localized Reactions. The localized reactions seen after immunization with inactivated Vero cell–derived SA 14-14-2 vaccine are similar to local reactions after other intramuscularly administered, alum-adjuvanted vaccines. In several trials, the major local reactions have been injection site pain and tenderness, which have been reported in 20% to 30% of recipients of vaccine and placebo (Table 33.11). Local redness, swelling, itching, and hardening were less commonly observed.

TABLE 33.11 Injection Site–Solicited Adverse Reactions[a] After Inactivated Vero Cell–Derived SA 14-14-2 Vaccine or Placebo Control[b] in Subjects in the Safety Population With Evaluable Diary Cards

	Incidence					
	After Dose 1 (% of Subjects[c])		After Dose 2 (% of Subjects[c])		After Dose 1 or 2 (% of Subjects[c])	
Adverse reaction	Vero cell JE vaccine (n = 1963[d])	Control (n = 645[d])	Vero cell JE vaccine (n = 1951[d])	Control (n = 638[d])	Vero cell JE vaccine (n = 1963[d])	Control (n = 645[d])
Any Reaction	48.5	47.7	32.6	32.2	55.4	56.2

Pruritus	2.6	3.3	1.6	1.9	3.8	4.5

[a]Injection-site reactions were assessed for 7 days after each dose.
[b]The control was phosphate-buffered saline and aluminum hydroxide.
[c]Denominators used to calculate percentages are based on the number of evaluable diary card entries (defined as documented presence on any day [i.e., entry of "yes"] or absence on all days [i.e., entry of "no"]) for each individual symptom and observation period.
[d]Number of subjects who returned diary cards after each dose.
JE, Japanese encephalitis.
Data from U.S. Food and Drug Administration (FDA) Approved Prescribing Information for IXIARO. Revised August 2015. Available at: http://www.fda.gov/downloads/BiologicsBloodVaccines/Vaccines/ApprovedProducts/UCM142569.pdf; and Tauber E, Kollaritsch H, von Sonnenburg F, et al. Randomized, double-blind, placebo-controlled phase 3 trial of the safety and tolerability of IC51, an inactivated Japanese encephalitis vaccine. J Infect Dis. *2008;198:493–499.*

Most local reactions after immunization with inactivated Vero cell–derived SA 14-14-2 vaccine are transient and mild. The local reactogenicity profile seemed to be more favorable than the mouse brain–derived JE vaccine in terms frequency of severe reactions, with any severe symptom reported in nine (2.1%) of 421 subjects versus 59 (13.8%) of 427 subjects ($P < .0001$), respectively.[391]

Common Systemic Reactions. Headache and myalgia were the most common systemic reactions reported in vaccinated subjects and placebo recipients in clinical trials of inactivated Vero cell–derived SA 14-14-2 vaccine (Table 33.12). Other mostly mild systemic reactions observed in vaccinees were fever, rash, nausea, vomiting, diarrhea, and excessive fatigue. All reactions were seen at similar frequencies in recipients of placebo.

Systemic Hypersensitivity Reactions. Adverse events that generally might be associated with systemic hypersensitivity reactions were analyzed in a metaanalysis of clinical trials that included 3558 subjects receiving inactivated Vero cell–derived SA 14-14-2 vaccine; 657 subjects receiving placebo control (PBS + alum); and 435 subjects receiving a mouse brain–derived inactivated JE vaccine.[450] Total potential hypersensitivity-related adverse events were reported at similar frequencies in recipients of inactivated Vero cell–derived SA 14-14-2 vaccine (3.5%) and a PBS + alum control vaccine (3.7%), but the incidence was significantly higher in the group receiving the mouse brain–derived JE vaccine (5.5%; for difference between inactivated Vero cell–derived SA 14-14-2 vaccine and mouse brain–derived inactivated JE vaccine, $P = .04$). Urticaria was reported in four of 3558 subjects receiving inactivated Vero cell–derived SA 14-14-2 vaccine (two generalized and two localized reactions of mild to moderate severity) and one of 657 subjects receiving PBS + alum vaccination. All cases occurred between 6 and 28 days after administration of the vaccine. All recovered successfully; three subjects received no treatment, one was treated with antihistamines plus a corticosteroid, and one with antihistamines alone (both in the inactivated Vero cell–derived SA 14-14-2 vaccine group). Only the reaction following the PBS + alum vaccination was judged as possibly related to the vaccination by the investigator. Two subjects had no reaction to a second dose of vaccine. Angioedema was not reported in any of the cases.[450]

In an open-label pediatric trial in the Philippines, 195 infants 2 to 11 months of age were randomly assigned to receive the inactivated Vero cell–derived vaccine (N = 131) or

seven-valent pneumococcal conjugate vaccine (N = 64). Another 1674 children 1 to 17 years of age received inactivated Vero cell–derived vaccine (n = 1280) or hepatitis A vaccine (n = 394). The incidences of local, systemic, medically attended, and serious adverse events were similar between children who received JE or the relevant comparison vaccines. The main local reactions were redness in children younger than age 1 year and pain and tenderness in older children. The predominant systemic reaction was fever.[341]

Rare Adverse Events

One evaluation of postmarketing surveillance data reviewed adverse event reports from the first 12 months following licensure of inactivated Vero cell–derived SA 14-14-2 vaccine in Europe, Australia, and the United States. Data analyzed included consumer reports, regulatory authority reports, European pharmacovigilance data, and reports from the VAERS database. Overall, there were 25 adverse drug reactions (ADRs) reported, including 13 from Europe, 6 from the U.S., and 6 from Australia, translating into a reporting rate of 10.1 per 100,000 doses distributed. Four of these ADRs (16%) were serious (reporting rate for serious ADRs: 1.6 per 100,000 doses distributed). The serious ADRs were distinctive plexus neuritis of all extremities, meningism (later downgraded by the local regulatory authority to be a nonserious case), oropharyngeal spasm, and iritis. No cases of anaphylaxis or angioedema were reported.[451]

The second review analyzed adverse events reported to VAERS in the first 3 years postvaccine licensure in the United States from May 2009 to April 2012.[452] Although events occurred in temporal association with vaccination, causality cannot generally be assessed for VAERS reports. All reports were for adults 17 years of age or older as the review period was prior to pediatric licensure, and some reports overlapped those reviewed in the multicountry analysis described above. There were a total of 42 adverse events reported during the 3-year period, equating to a reporting rate of 15.2 adverse events per 100,000 doses distributed. Among these 42 reports, there were 12 hypersensitivity adverse events for a reporting rate of 4.4 per 100,000 doses distributed, and six neurologic adverse events for a reporting rate of 2.2 per 100,000 doses distributed. Among the hypersensitivity events, four occurred within 2 hours (immediate hypersensitivity events) and eight occurred between 2 hours and 10 days (delayed hypersensitivity events) after vaccination. Among the six neurologic events, three were classified as central and three as peripheral neurologic events. Overall, the most commonly reported events were the 12 hypersensitivity events and 10 reports of fever, with three or fewer reports each of musculoskeletal pain, local reactions, nonspecific somatosensory complaints, rash, and syncope. In total, 27 (64%) events occurred after the first dose and 10 (24%) followed a second dose. The inactivated Vero cell–derived vaccine was the only vaccine administered in 17 (40%) of the reports. Five events (12%) were classified as serious as they resulted in hospitalization (n = 4) or "observation for a life-threatening condition," for a reporting rate of 1.8 per 100,000 doses distributed. The five serious adverse events included one case each of immediate hypersensitivity, delayed hypersensitivity, appendicitis, encephalomyelitis, and myopericarditis. Other vaccines, including smallpox and anthrax vaccines were administered at the same time for three of these patients (Table 33.13). Overall, most events were nonserious, no unexpectedly high reporting rates for specific events were identified, and no deaths were reported. Therefore, these postmarketing surveillance data from the first 3 years postlicensure supported the good safety profile documented in prelicensure clinical trials.

Adverse Events in Immunosuppressed Persons

Safety of inactivated Vero cell–derived SA 14-14-2 vaccine has not been studied in immunocompromised persons. Postmarketing data through the first 5 years of marketing did not contain reports on use in immunocompromised persons. Naturally, concerns that the vaccine could cause JE in immunocompromised persons are not applicable to an inactivated vaccine.

Adverse Events During Pregnancy

Inactivated Vero cell–derived SA 14-14-2 vaccine is pregnancy category B (United States). There are limited data from the use of the vaccine in pregnant or breastfeeding women. In a reproductive and prenatal/postnatal toxicity study in animals, no vaccine-related effects were observed on reproduction, fetal weight, survival, and development of the offspring. However, incomplete ossification of parts of the skeleton was observed in the group receiving two doses, but not in the group receiving three doses. As a precautionary measure, use of the vaccine during pregnancy or lactation should be avoided as per European labeling. After reviewing data from 28 women who became pregnant during clinical trials with inactivated Vero cell–derived SA 14-14-2 vaccine, the European regulatory authority concluded that there was currently no evidence for a causal relationship of abnormal pregnancy outcomes with the vaccine (Valneva, on file). Cases in which women are inadvertently vaccinated during pregnancy should be reported to the manufacturer for follow-up of the pregnancy and infant health status. Further data will be generated as part of a vaccine safety surveillance program.

TABLE 33.13 Serious Adverse Events Reported to the U.S. Vaccine Adverse Event Reporting System Following Receipt of IXIARO, May 2009 to April 2012

Event Type	Days Postvaccination	Age (y)	Sex	Primary Symptoms or Condition	Concurrent Vaccines
Immediate hypersensitivity	0	45	M	Dyspnea, sensation of throat closure	MMR, HepA
Delayed hypersensitivity	2	56	M	Dyspnea, cough	None
Appendicitis	5	40	M	Abdominal pain	None
Myopericarditis	11	22	M	Chest pain	Smallpox, Anthrax, Typh
Central neurological	39	20	M	Encephalomyelitis	Smallpox, Typh, HepA/HepB

HepA, hepatitis A vaccine; HepB, hepatitis B vaccine; MMR, measles, mumps, rubella vaccine; Typh, typhoid vaccine.
From Rabe IB, Miller ER, Fischer M, et al. Adverse events following vaccination with an inactivated, Vero cell culture-derived Japanese encephalitis vaccine in the United States, 2009–2012. Vaccine. *2015;33:708–712.*

Spread to Contacts

Spread to contacts is not a risk because the vaccine is inactivated.

Live Attenuated Japanese Encephalitis Vaccine

Common Adverse Events

Safety data are available from clinical trials as well as from postmarketing surveillance following the use of live attenuated SA 14-14-2 JE vaccine in more than 400 million individuals in Asia. In an early safety study in China, of 867 children in whom fever was closely monitored during a 21-day period after immunization, temperatures of 37.6°C or higher were recorded in fewer than 2% of vaccinees, and fever-onset days were distributed throughout the observation interval, mitigating against a vaccine-related febrile illness after a specific incubation period.[453] In the same study, symptoms were recorded from 588,512 other vaccinees; fever was reported in 0.05% of subjects, rash in 0.01%, dizziness in 0.003%, and nausea in 0.003%, but these rates are difficult to interpret in the absence of similar observations in control subjects.

A block-randomized cohort study investigated vaccine safety in 13,266 vaccinated and 12,951 nonvaccinated 1- to 2-year-old children who were followed up prospectively for 30 days. No cases of encephalitis or meningitis were detected in either group, and rates of hospitalization, new onset of seizures, fever lasting more than 3 days, and allergic, respiratory, and gastrointestinal symptoms were similar in the two groups. Based on study findings, a vaccination-related encephalitis risk above 1 in 3400 could be excluded.[454]

In a randomized trial conducted in the Philippines from 2005 to 2006, local reactions were reported in 27 (27%) of 100 children 8 months of age and 27 (12%) of 224 children 10 months of age.[348] The majority of local reactions were mild and transitory. Systemic reactions were reported in 58% and 39% of children, respectively. The most common early systemic reactions were irritability and drowsiness. Fever within 7 days was reported in 24% and 25% of infants in both groups, but no fever was 40°C or higher. No serious adverse events were reported. As there was no placebo group in the trial, the proportion of systemic events attributable to live attenuated SA 14-14-2 JE vaccine could not be determined. In four other recent studies, the proportion of children with local reactions ranged from 1% to 44%.[350,364,398,399] In only one of these studies were any serious adverse events thought to be vaccine related reported; two children in a study in Korea had fevers that were classified as serious as they resulted in hospitalization of the children.[399] In the same study, one child had urticaria considered by investigators to be vaccine-related.

Rare Adverse Events

In national postmarketing surveillance in China during 2009–2012, 6024 adverse events temporally associated with immunization were reported, for a rate of 9.7 events per 100,000 doses distributed. There were 70 events classified as serious including febrile convulsions, thrombocytopenic purpura, and myelitis. Among nine encephalitis cases, one was considered possibly vaccine-related while the others were classified as coincidental illnesses. No other safety signals were identified.[341,455] Following use of the vaccine among more than 9.3 million children 1 to 15 years of age in mass vaccination campaigns in India, 65 serious adverse events were reported. Most were considered to be unrelated to the vaccine. Two clusters of encephalitis-like syndromes were identified. WHO's Global Advisory Committee on Vaccine Safety (GACVS) reviewed available information and considered the events were unlikely related to vaccine. On other occasions, the GACVS has reviewed data on the live attenuated SA 14-14-2 JE vaccine and noted its excellent safety profile.[341,456]

Adverse Events in Immunosuppressed Persons

Although experimental data suggest that JE SA 14-14-2 virus may not be neurotropic in immunosuppressed animals, there are no data on the vaccine's safety in immunocompromised persons, specifically HIV-infected patients. It should not be administered to persons known to be immunosuppressed; instead, inactivated JE vaccine should be used.

Adverse Events During Pregnancy

No observations on the vaccine's safety in pregnant women have been reported. Live attenuated JE vaccine has a theoretical risk in pregnant women. Usage advisories are that pregnant women should not be vaccinated. When JE vaccine must be given to pregnant women or to immunocompromised persons, available inactivated JE vaccine should be used rather than live vaccine.

Spread to Contacts

No spread to contacts has been reported. Transmissibility of vaccine virus by vector mosquitoes is not well studied.

Chimeric Vaccine

Adverse Events

Common postvaccination symptoms include tiredness, malaise, injection-site pain, headache, and myalgia. Less-common postvaccination events include itching at injection site, joint pain, gastrointestinal symptoms, upper respiratory symptoms, rash, and fever.

Rare Adverse Events

A small number of serious adverse events were reported during clinical development of the vaccine, including high-grade fever.[358] No serious hypersensitivity reactions or neurologic adverse events were identified in clinical trials. However, because the vaccine has been used in limited numbers of people, the possibility of rare serious adverse events cannot be excluded. Additional postmarketing safety data collected from larger populations are needed to fully evaluate this issue.

Adverse Events During Pregnancy

Animal studies did not indicate direct or indirect harmful effects with respect to pregnancy, embryo-fetal development, parturition, or postnatal development. However, as with all live attenuated vaccines, pregnancy constitutes a contraindication.

Contraindications

The chimeric JE vaccine should not be administered to anyone with HIV, congenital or acquired immune deficiency, or a history of severe allergic reaction to any component of the vaccine. Vaccination must be postponed in case of febrile or acute disease. Vaccine should not be given to patients on immunosuppressive therapies such as chemotherapy or high doses of systemic corticosteroids given generally for 14 days

or more. IMOJEV must not be administered to pregnant or lactating women.

Adverse Events in Immunosuppressed Persons

None have been reported, but the vaccine should not be administered to this group.

Spread to Contacts

No reports.

INDICATIONS FOR VACCINE (WHO AND WHY)

Endemic Areas

In rural areas of Asia, intense JEV transmission in the enzootic cycle leads to a high risk of exposure at an early age. The risk of infection increases sharply with the waning of the protective effects of maternal immunity and as increasing outdoor activity places young children at risk of bites from infected mosquitoes. In hyperenzootic settings, there may be almost universal seroconversion by the age of 15 years, indicating that by that age everyone has been exposed and had an asymptomatic, mild illness, or clinical disease. The WHO recommends that JE vaccination should be integrated into the national immunization program in all areas where JE is recognized as a public health priority, and notes that even if the number of JE-confirmed cases is low, vaccination should be considered where there is a suitable environment for JEV transmission, such as the presence of animal reservoirs, ecological conditions supportive of transmission, and proximity to other areas with known JEV transmission.[42] For the most part, stepwise implementation of national JE vaccination programs, initially in epidemic foci and in areas with hyperenzootic transmission, has been necessary because of economic considerations.[457,458] The current recommendation is to mount a one-time catch-up campaign to cover all at-risk age groups (typically children <15 years) followed by the introduction of routine immunization through the EPI. Although most JE immunization programs were initiated in limited areas, as surveillance systems improved, programs have expanded to the entire country.[459,460] It is important to note that immunization schedules and boosting may be different in endemic than in nonendemic settings.

Although incidence may vary from year to year and within countries, universal childhood immunization is desirable because, even in economically advanced countries, viral transmission cannot be eliminated and the cumulative risk of acquiring the illness over a lifetime of exposure justifies universal protection. This ongoing risk was confirmed in a Japanese cross-sectional serologic study measuring NS1 antibodies that showed average annual infection rates of 1.8% in west Japan from 2004 to 2008 and 1.3% in Tokyo from 2004 to 2006.[285] When only unvaccinated persons were included, average annual infection rates were 2.6% in both areas.[207,285,461] Indeed, when Japan temporarily withdrew its recommendation for routine childhood immunization in 2005, two reports of JE in unvaccinated children followed in 2006 and 2009.[208] Conditions leading to epidemic transmission are unpredictable, and, at intervals, outbreaks may lead to large numbers of cases, even in urban areas.

Expatriates

With safe and effective new JE vaccines available, vaccination is recommended for all expatriates whose principal residence is in an area where JE is enzootic.[41,253,426,462] Risk of acquiring JE among expatriates is variable and depends principally on the specific location of residence, housing conditions, nature of activities, and the possibility of unanticipated exposure to high-risk areas (see the next section, "Travelers"). Risk varies regionally and within specific countries, and viral transmission can fluctuate from year to year in a given location. Fig. 33.1 and Table 33.14 summarize and extrapolate available data on locations and seasonality of risk by country and

TABLE 33.14 Risk of Japanese Encephalitis by Country, Region, and Season[a]

Country	Affected Areas/ Jurisdictions	Transmission Season	Vaccinating	Comments
Australia	Outer Torres Strait islands	December–May	Targeted populations (outer Torres Strait Islands)	1 Human case reported from north Queensland mainland
Bangladesh	Probably widespread	Cases throughout the year; peak, May–October	No	Sentinel surveillance identified cases in Chittagong, Dhaka, Khulna, Rajshahi, Ranjpur, and Sylhet Divisions
Bhutan	Rare reports	No data	No	Virus transmission likely
Brunei	Rare reports	Presumed year-round transmission	Private market	Virus transmission likely
Cambodia	Enzootic throughout country	Year-round with peak season May–October	Included in the Expanded Programme on Immunization (EPI) (subnational)	Sentinel surveillance identified cases in 15 of 23 provinces
China	Cases in all provinces except Xizang (Tibet), Xinjiang, and Qinghai; rare cases in Hong Kong	Northern China: May–September; southern China: April–October	Included in the EPI in all affected provinces	Vaccine not routinely recommended for travelers to major cities; highest JE rates in Guizhou, Shaanxi, Sichuan, and Yunnan Provinces, and Chongqing City

Continued on following page

TABLE 33.14 Risk of Japanese Encephalitis by Country, Region, and Season[a] *(Continued)*

Country	Affected Areas/ Jurisdictions	Transmission Season	Vaccinating	Comments
India	Cases in all states except Dadra, Daman, Diu, Gujarat, Himachal, Jammu, Kashmir, Lakshadweep, Meghalaya, Nagar Haveli, Orissa, Punjab, Rajastan, and Sikkim	Northern India: July–December; southern India: Goa, May–October; Tamil Nadu: October–January; Karnataka: April–December; Andhra Pradesh: September–December	Included in the EPI in all affected districts	Highest rates reported from West Bengal, Bihar, Karnataka, Kerala, Tamil Nadu, Andhra Pradesh, Assam, Uttar Pradesh, Haryana, and Goa
Indonesia	Presumed to be endemic nationwide	Year-round; peak period with rainy season, November–March	No	Sentinel surveillance has identified cases in Bali, Kalimantan, Java, Nusa Tenggara, Papua, and Sumatra
Japan	Enzootic in all islands, except Hokkaido	June–October, except Ryukyu Islands (Okinawa), April–October	Yes	Vaccine not routinely recommended for travelers to major cities
Korea, North	Presumed to be endemic nationwide	July–October	Vaccine campaigns	
Korea, South	Enzootic throughout country	May–October	Yes	Vaccine not routinely recommended for travelers to major cities
Laos	Enzootic throughout country	June–September	Included in the EPI (subnational)	
Malaysia	Enzootic in peninsular Malaya and Borneo	Year-round transmission	Subnational program	Most human cases reported from Sarawak
Myanmar	Enzootic throughout country	May–October	No	
Nepal	Enzootic in Terai; some cases reported from Kathmandu Valley and other hill and mountain districts	June–October	Included in the EPI (subnational)	Highest rates of disease reported from western Terai districts; vaccine not routinely recommended for those trekking in high-altitude areas
Pakistan	Presumed enzootic in central Pakistan	June–January	No	
Papua New Guinea	Low-level transmission	Year-round	No	
Philippines	Enzootic throughout country	Year-round with peak season July–September	No	
Russia	Enzootic in Far Eastern provinces	July–September	No	
Singapore	Little transmission	Year-round	No	Vaccine not routinely recommended
Sri Lanka	Enzootic throughout country	Scattered cases year-round; peak season follows monsoon rains	Included in the EPI	Highest rates of human disease reported from Anuradhapura, Gampaha, Kurunegala, Plonnaruwa, and Puttalam districts
Taiwan	Enzootic throughout country	May–October	Yes	Vaccine not routinely recommended for travelers to major cities
Thailand	Enzootic throughout country	Cases occur year-round in south; May–October in north	Included in the EPI	
Vietnam	Enzootic throughout country	Year round with peak season May–October, especially in the north	Included in the EPI	Highest disease rates in the northern provinces
Western Pacific	Sporadic introductions	Insufficient data	No	Vaccine not recommended

[a]Assessments based on published reports, reports to the World Health Organization, and personal correspondence. Because virus is transmitted in a zoonotic cycle, reports of human cases in countries with vigorous vaccination programs are not a reliable indicator of risk. For an update, refer to the U.S. Centers for Disease Control and Prevention, Travelers' Health (http://wwwnc.cdc.gov/travel).

region. Patterns of viral transmission may change, and physicians and travelers are cautioned to consult public health officials for current data and trends. The risk may be difficult to assess because JE is poorly reported, accurate data may not be available, and local immunization prevents disease, giving a false sense of security.

Travelers

Administration of a licensed JE vaccine is recommended for select travelers to Asia, but is not recommended as a routine immunization. In the United States, the vaccine is recommended for persons spending 1 month or more in enzootic settings during the transmission season. This includes recurrent travelers or expatriates who will be based in urban areas but who are likely to visit rural areas during a high-risk period for JEV transmission. Vaccine should be considered for short-term (<1 month) travelers if they have an increased risk for JEV exposure, such as spending a substantial amount of time outdoors in rural areas, participating in extensive outdoor activities (e.g., camping, hiking, fishing), or staying in accommodations without air conditioning.[41,462]

JE vaccine is not recommended for short-term travelers whose visit will be restricted to urban areas or time outside of a well-defined transmission season.[463] European recommendations vary by country with some (e.g., Germany and France) having broad recommendations for immunization for travelers with higher risk itineraries regardless of duration of travel, and some having more restrictive recommendations focusing on prolonged travel.[465,466] In many Asian countries, the use of vaccines in endemic areas masks viral activity, making it difficult to determine risk accurately. Travelers and their physicians should weigh individual risk factors and disease risk in the area and season of anticipated travel (see Figs. 33.1 and Tables 33.3 and 33.14). Advanced age and pregnancy may affect risk and outcome of JE. Repellents and other protective measures are recommended regardless, because other vector-borne diseases may be transmitted in the same areas. General precautions are especially important for travelers in whom vaccine is contraindicated, who are unable to complete immunization because of departures on short notice, or who do not choose to be immunized because their visits to high-risk areas are brief or carry an equivocal risk. The recommendations for vaccination may change as data on cost and risk profiles become available for vaccines licensed for use in travelers.

Research Laboratory Workers

There have been at least 22 cases of laboratory-acquired JEV, principally in research settings where infectious JEV was used.[232,467] Infection can be transmitted by percutaneous or mucous membrane exposures and potentially by aerosols, especially from preparations containing high viral concentrations, which occur during viral purification. Immunization presumably protects against percutaneous exposures; however, it is unknown whether vaccine-derived immunity, especially from inactivated vaccine, protects against aerosol infection. Immunization is advised for all research laboratory personnel who potentially may be exposed to field or virulent strains of the virus. Based on a review of data firmly establishing the attenuation of vaccine SA 14-14-2 strain, the U.S. Subcommittee on Arbovirus Laboratory Safety recognizes that immunized workers should be permitted to handle SA 14-14-2 strain under biosafety level 2 conditions, paralleling recommendations for the attenuated vaccine strains of YF, Junin, Rift Valley fever, chikungunya, and Venezuelan equine encephalitis viruses.[468]

CONTRAINDICATIONS AND PRECAUTIONS TO IMMUNIZATION

Mouse brain–derived JE vaccine is contraindicated in people who have had an allergic reaction to the vaccine, to gelatin, or to other rodent-derived products, including previous doses of JE vaccine. As previously noted, hypersensitivity reactions to mouse brain–derived JE vaccine are more common in persons with allergic conditions (e.g., asthma; allergic rhinitis; drug or Hymenoptera venom sensitivity; and food allergy, especially to gelatin-containing foods). If these persons are offered JE vaccine, they should be advised of the potential for vaccine-related angioedema and generalized urticaria. Hypersensitivity to a protein found in mouse urine is common in animal caretakers and certain laboratory workers. It is unknown whether this sensitivity carries a specific risk in recipients of JE vaccine. Anecdotal reports of ADEM occurring in temporal relationship to vaccination suggest that the mouse brain–derived vaccine should not be used in persons who have recovered from ADEM or Guillain-Barré syndrome or who have multiple sclerosis or other demyelinating disorders. Contraindications for inactivated Vero cell–derived vaccine are hypersensitivity to one of the components, for example, protamine sulfate, or allergic reaction to a previous dose of the vaccine or another JE vaccine. Live JE vaccines pose a theoretical risk to the developing fetus but no adverse outcomes of pregnancy have been associated directly with JE vaccine. Travelers and their physicians must balance the theoretical risks of JE vaccine in pregnancy against the potential risks of acquiring JE and the adverse outcome of the disease. The live attenuated SA 14-14-2 and chimeric JE vaccines are not recommended for administration to pregnant women, and are also contraindicated in immunosuppressed persons, those known to have HIV, and individuals with a severe allergy to any of the vaccine components.[287]

A theoretical risk, explored by passive transfer of antibody in animal models, is the antibody-mediated enhancement of JE infection and disease.[276] A similar phenomenon has occurred in humans who contracted respiratory syncytial virus (RSV) infection or measles after their antibody levels had waned below protective thresholds following immunization with inactivated RSV or measles vaccines. A similar phenomenon has been demonstrated in laboratory animals using inactivated versus live attenuated vaccines for JE or Murray Valley encephalitis.[469,470] Antibody-dependent enhancement is also postulated as a pathogenic mechanism in severe dengue infections. Fundamental differences in cellular pathogenesis may preclude this phenomenon from occurring in JE where the brain and not macrophages or pulmonary epithelial cells are major targets of viral infection.[471]

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Effects of Vaccination

JE has a devastating effect on health resources and the affected communities. Epidemics frequently result in pressure from the community to take action to control the disease and provide a safe living environment. Vaccination for JE has been the single most effective and reliable means to control JE in endemic settings. Although a secular trend toward declining JE incidence has been observed with widespread use of JE vaccine, coincident socioeconomic changes also may have contributed to falling disease incidence. It was this same change in socioeconomic status that allowed developed Asian countries to afford vaccine and introduce it. In general, the higher the socioeconomic status of each country, the earlier that universal JE vaccine coverage was introduced. Less-affluent countries

are catching up. For example, in Nepal, a JE immunization program was launched in 2006, and by 2009, mass campaigns had been implemented in 23 districts. Analysis of surveillance data from 2004 to 2009 on laboratory-confirmed JE and clinical AES cases demonstrated that postcampaign, the JE incidence rate of 1.3 per 100,000 population was 72% lower than expected had no campaigns occurred, and an estimated 891 JE cases were prevented. In addition, AES incidence was 58% lower, with an estimated 2787 AES cases prevented, suggesting that three times as many disease cases may have been prevented than indicated by the laboratory-confirmed JE cases alone.[458] Owing to interventions managed by PATH, a not-for-profit organization in Seattle, Washington, with funding from the Bill and Melinda Gates Foundation, SA 14-14-2 JE vaccine is now routinely administered in Sri Lanka and large quantities were imported to combat epidemics in India.[350] In Thailand, a vertical control program based on vector control was implemented from 1970; the program demonstrated no impact on disease. The program was then integrated with an increased focus on outbreak response, again without impact on disease. In 1986, vaccine began to be integrated into the routine immunization system in the highest-risk areas of the country; this had a dramatic impact on disease incidence as immunization was expanded to additional provinces (Fig. 33.22).[21,472]

Observations from China, also reinforce the impact of immunization. The JE incidence rates in Beijing and other areas of China where high immunization rates are maintained have declined dramatically and remained low (Fig. 33.23).[2,16,473] Until recently, vaccine coverage, while high in prosperous regions in China, remained low in many poorer high-risk rural locations. The principal barrier to immunization had been the cost of vaccine to the family because JE vaccine was not subsidized by the government as a routine childhood vaccine. However, in 2008, JE vaccine was expanded into the EPI system in endemic provinces.

Disease Control Strategies

As a zoonotic disease with natural viral reservoirs, JE never can be eradicated. Although its transmission can be modulated by factors mentioned earlier, these approaches alone or in combination cannot be relied on to reduce disease incidence. The only effective strategy is vaccination. Successful control of JE by universal immunization in many Asian countries provides ample proof that expansion of vaccine coverage throughout the continent will lead to the near-elimination of the disease.[474]

Cost-to-Benefit Information

Several studies have demonstrated the economic benefits of JE vaccination with live attenuated SA 14-14-2 and mouse brain-derived inactivated vaccines.[475–478] Factors including vaccine price, disease incidence, number of doses used in the vaccine schedule, and vaccination strategy selected (campaign and/or routine immunization) impact the calculations. In a recent evaluation conducted in Guizhou province, China, investigators modeled use of live attenuated SA 14-14-2 JE vaccine in a two-dose schedule in the routine EPI in a theoretical cohort of 100,000 persons followed from birth to 65 years. The selected strategy would cost about US$435,000 each year and prevent 406 JE cases, 102 deaths, and 122 chronic disabilities. If future cost savings were ignored and only EPI program costs used, the program would cost US$95.50 per disability-adjusted life-year (DALY), less than China's Gross Domestic Product per capita in 2009 of US$3741, making it a cost-effective investment. Taking into account future savings, use of JE vaccine in the EPI for a 100,000-person cohort would lead to savings of US$1,591,975 for the health system and US$11,570,989 from the societal perspective.[18] Other assessments in Cambodia, Indonesia, and India similarly have found that vaccination programs with SA 14-14-2 JE vaccine would be cost-effective, if not cost saving.[477–479]

A partnership was developed between CDIBP and PATH to increase the supply of live attenuated vaccine with pricing well below US$1 per dose for the poorest countries of Asia (Gross National Product [GNP] <US$1000). The availability of this vaccine at a lower price should result in increased access to JE vaccine throughout Asia.

Unlike populations in JE-endemic countries, universal JE vaccination for all travelers is not considered to be cost-effective. Although evaluations have not been done, given the large numbers of travelers to Asia (135.5 million travelers to JE enzootic countries of Asia in 2015), the very low risk for JE for most travelers to Asia (<1 case/million travelers overall), and the high cost of JE vaccine (US$400 to US$500 per two-dose primary series for the inactivated Vero cell–derived

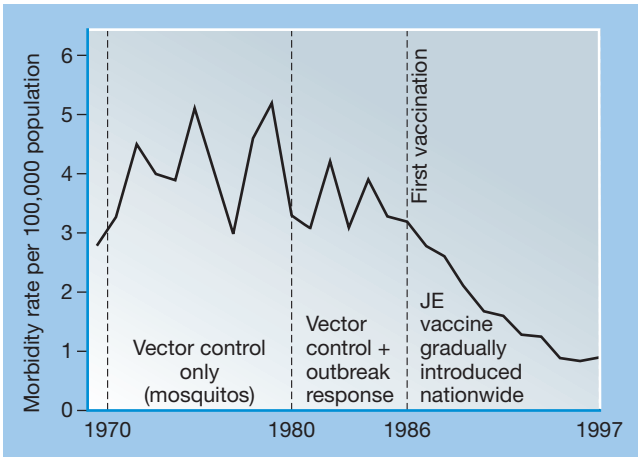

Figure 33.22. In Thailand, Japanese encephalitis (JE) cases failed to respond to control measures directed against vector mosquitoes; attack rates declined only after introduction of JE vaccine.

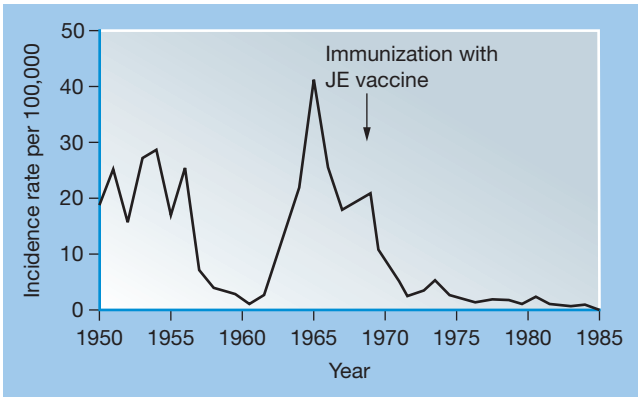

Figure 33.23. Declining incidence of Japanese encephalitis (JE) in Beijing and association with mass immunization, 1950 to 1985. *(Modified from Gu PW, Ding ZF. Inactivated Japanese encephalitis (JE) vaccine made from hamster cell culture (a review).* JE HFRS Bull. *1987;2:15–26.)*

vaccine), universal vaccination of travelers is not cost effective. However, for selected travelers at high risk and for resident expatriates, the equations change significantly.

Eradication or Elimination, If Feasible

Eradication of JEV from nature is not feasible. Elimination of clinical JE in humans is possible through universal vaccine coverage of the at-risk population. Disease control relies on individual protection because there is no herd immunity with JE as there is no human-to-human transmission.

NEW AND FUTURE VACCINES

A number of JE vaccines are in development, some have been licensed, and others are approaching licensure. Vero-based inactivated JE vaccines have been licensed by Biken and Kaketsuken for the Japanese domestic market. As the postlicensure experiences with these vaccines are somewhat limited, they are described in summary form here.

Inactivated Vaccines

Several groups have produced experimental inactivated whole-virion vaccines from infected Vero cell cultures.[480–482] Cell culture medium with high viral infectious titers, harvested continuously from microcarrier cultures, inactivated with formalin, and further concentrated has yielded candidate vaccines meeting mouse protection potency standards established for the inactivated mouse brain vaccine. The vaccine produced by Intercell has been licensed widely in the world. Its properties were described earlier in the chapter.

The Research Foundation for Microbiological Disease of Osaka University, Biken, has produced JEBIK V, a Vero-based vaccine formulated in alum and using the Beijing-1 JE strain. By using a bellows system for feeding Vero cells and batch harvesting, high yields of virus have been obtained.[482] Virus has been grown in serum-free medium using glycine and sorbitol stabilizers in the inactivation process.[483] A 2001 Phase I study of a two-dose regimen showed the vaccine to be well tolerated, with only mild elevations of liver function test results, and immunogenic, with JE-neutralizing antibody seroconversions observed in all seronegative subjects. A two-dose Phase III trial in 110 Flavivirus-susceptible children produced neutralizing antibody in 100% of subjects with no adverse events. A second Phase III open-label trial resulted in high levels of neutralizing antibodies in all children previously immunized with mouse brain vaccine and given one dose of JEBIK V. The vaccine was licensed in Japan in 2009.[484,485] Administration of this vaccine is as follows: for persons 3 years of age or older, 0.5 mL is given intramuscularly; 0.25 mL is given to children younger than 3 years of age. Two doses are given, 1 to 4 weeks apart. A booster dose is given approximately 1 year after the two-dose series. A fourth dose is given to 9- to 13-year-old children (I. Kurane, personal communication, 2010).

The Chemo-Sero-Therapeutic Research Institute, Kaketsuken, one of the Japanese producers of mouse brain–derived JE vaccines has produced a purified, unadjuvanted, Vero cell–derived vaccine (Encevac) formulated without gelatin or thimerosal. Vero cell DNA and protein concentrations are several picograms per dose in the final product. In a Phase I trial, 30 JE-susceptible adults were given three doses of vaccine at 0 and 4 weeks and 6 months with no serious adverse events observed and all subjects developing JE-neutralizing antibodies. Phase II studies involved 200 children 6 to 90 months of age who were given three doses with 100% rate of seroconversion. Mild adverse events were noted in as many as 45% of subjects following administration of the first dose. In 2011, the company obtained a license to market this vaccine in Japan.[485] Similarly, Vero cell–inactivated vaccines are now being produced in China by Beijing Tiantan Biologial Products Co, Ltd. and Liaoning Chengda Biotechnology Co, Ltd., and in India by Bharat Biotech.[486]

A collaborative group in Australia and Japan has grown the Beijing-1 strain of JEV in American Type Culture Collection (ATCC)-derived Vero cells grown in microcarrier cultures without serum.[482,483] When this virus was inactivated with formalin and stabilized with 0.5% glycerin, two doses given 1 week apart raised neutralizing antibodies 1 week later to several genotype I and genotype III JEVs in vaccinated mice. PRNTs were comparable to those titers obtained following two doses of standard mouse brain JE-VAX.[483] This early result was improved by adding delta inulin, a polysaccharide-based adjuvant (ADVAX). Two doses of unadjuvanted and cell culture–based adjuvanted vaccine (JE-ADVAX) were given at 1-week intervals to mice, and neutralizing antibody responses were compared with those obtained following immunization with two doses of comparison vaccines. Neutralizing antibody titers in mice given Vero-based vaccine incorporated with delta inulin were 100-fold higher than in mice given cell culture JE vaccine. Mice given JE-ADVAX were protected against lethal intranasal challenge with JE Nakayama strain, whereas mice vaccinated with cell culture–based or mouse brain–based vaccines were not. JE-neutralizing antibody responses in mice vaccinated with the chimeric JE vaccine and with licensed IXIARO (Jespect) vaccines were comparable to responses observed to JE-ADVAX.[481] A similar immunization regimen in mice provided protection against lethal challenge with West Nile virus with protection attributed to antibodies and could be adoptively transferred by memory B lymphocytes but not T cells.[487]

Vaccinia-Vectored Vaccines

Replication-deficient canary pox (ALVAC) and highly attenuated vaccinia viruses (NYVAC) have been used as vectors for delivering PrM-E or PrM-E-NS1 genes.[488] Several candidate JE vaccines are in various stages of clinical and preclinical development or research.[374,375] Recombinant vaccine candidates engineered by inserting four JE viral genes—prM, E, NS1, and NS2a—into vaccinia (NYVAC) or canarypox (ALVAC) viruses have been extensively evaluated. Both recombinants expressed the encoded JE structural and NS gene products and stimulated JE protective antibodies in mice; two doses of the former also protected rhesus monkeys against lethal viral challenge. In a Phase I human trial, the vaccines were somewhat more reactogenic than mouse brain vaccine but were otherwise safe. Two doses of the NYVAC-JE recombinant were nearly as immunogenic as three doses of inactivated mouse brain JE vaccine, but only in vaccinia-naïve volunteers. JE-neutralizing antibodies were elicited in all five non–vaccinia-immune recipients but in none of the five vaccinia-immune volunteers. Antibody responses were observed in only one of 10 ALVAC-JE vaccinees.[489] Although the NYVAC-JE recombinant virus proved safe and potent in vaccinia-nonimmune subjects, the apparent failure to replicate in vaccinia-immune subjects places some limits on its utility.

Other Genetically Engineered Constructs

Neuroattenuated JEV was produced by introducing defined nucleotide substitutions into the E gene. Virions and virion subunits derived from complementary DNA protected mice from death following challenge.[490,491] The JE viral subunit proteins produced in various expression systems, including

Spodoptera frugiperda, *Escherichia coli*, *Saccharomyces cerevisiae*, and *Drosophila* Schneider 2 cells, have had variable success in eliciting mouse immunogenicity and protective potency, depending on the expressed epitopes and their conformation.[491–495] The identification of peptides mimicking the conformation of viral epitopes may be expedited by screening pentapeptide libraries against monoclonal antibodies with previously defined specificity.[496] A vaccinia–JEV recombinant that releases extracellular particles composed of JE, prM, and E proteins resulted in an apparently more authentic configuration than when presented as simple peptides.[497] When given without adjuvant, extracellular particles induced long-lasting antibody and memory T cells in immunized mice. Immunogenic subviral particles containing JEV E protein also have been produced in other systems, including an alphaviral recombinant virus.[498,499] Novel delivery systems and adjuvants have been explored as a means to improve immunogenicity, to direct the Th1 or Th2 response, or to improve the convenience of immunization (e.g., the inactivated mouse brain vaccine has been microencapsulated in glycolide and lactide polymer microspheres designed to degrade at specific intervals).[500]

A pseudoinfectious JEV (named RepliVAX) has been made by deleting the capsid gene (C). The virus can be propagated in C protein–expressing cells, permitting them to form infectious particles structurally identical to live virus and secreted forms of NS1, but, in normal cells, RepliVAX JE cannot produce infectious particles. This vaccine was shown to protect mice and hamsters from lethal challenge.[501]

Subunit Vaccines

Vaccines expressing JE envelope protein or domain III have been presented to mice in an adenovirus construct or after expression in a baculovirus, J12#26 cells, *E. coli* or *Drosophila* cells, respectively.[502–507]

DNA Vaccines

Another approach being explored is the intramuscular or intracutaneous injection of naked DNA plasmids encoding viral prM and E genes under the control of a cytomegalovirus immediate early promoter. Using JE plasmids, immunized mice were protected against challenge with wild-type viruses.[508–511] In swine, two intramuscular doses produced high antibody titers and high anamnestic responses to challenge with live attenuated virus.[512] Another vaccine in development includes the secretory signal sequence derived from tissue plasminogen activator fused to the full-length or partial JEV envelope protein gene. Cells transfected with the latter construct secreted E protein and produced better protection against intracerebral challenge in mice.[513]

34 Lyme Disease Vaccines

Allen C. Steere

Lyme disease was described as a separate entity in 1976 because of the geographic clustering of children in Lyme, Connecticut, who had been thought to have juvenile rheumatoid arthritis.[1] The rural setting of the case clusters and the identification of an expanding skin lesion, erythema migrans, as a feature of the illness suggested that the disorder was transmitted by an arthropod. It soon became apparent that Lyme disease was a multisystem illness that affected primarily the skin, nervous system, heart, and joints.[2] Epidemiologic studies of patients with erythema migrans implicated certain ixodid ticks as vectors of the disease.[3]

In addition to providing clues about the cause of the illness, the initial expanding skin lesion linked Lyme disease in the United States with certain syndromes in Europe that were described in the early to mid-20th century.[4–6] Lyme disease and these various syndromes were brought together conclusively in 1982, when Burgdorfer and Barbour isolated a previously unrecognized spirochete, now called *Borrelia burgdorferi*, from *Ixodes scapularis* ticks.[7] The spirochete then was recovered from patients with Lyme disease in the United States[8,9] and in patients with erythema migrans, meningopolyneuritis, or acrodermatitis in Europe[10–12]; additionally, the patients' immune responses were linked conclusively with this organism.[8]

Later, *B. burgdorferi sensu lato* (*B. burgdorferi* in the general sense) was divided into three pathogenic groups.[13] To date, all North American strains have belonged to the first group, *B. burgdorferi sensu stricto* (*B. burgdorferi* in the strict sense). Although all three groups have been found in Europe, most isolates there have been group 2 *(Borrelia garinii)* or group 3 *(Borrelia afzelii)* strains; only groups 2 and 3 have been found in Asia.

Lyme disease (or Lyme borreliosis) is now the most common vector-borne disease in the United States and Europe.[14] As efforts to prevent tick bites have been largely ineffective, vaccination is an attractive strategy for prevention of the illness.

CLINICAL DESCRIPTION

Lyme disease occurs in stages, with different manifestations at each stage. In 70% to 80% of patients in the United States, the infection begins with a characteristic expanding skin lesion, erythema migrans (stage 1), which occurs at the site of the tick bite.[15–17] After an incubation period of 3 to 32 days, redness forms around the site and expands slowly (Fig. 34.1).[18] Within days to weeks, *B. burgdorferi* in the United States often disseminates hematogenously (stage 2). During this period, patients often have influenza-like symptoms such as malaise and fatigue, headache, neck pain, arthralgias, myalgias, fever, or regional lymphadenopathy. In addition, secondary annular skin lesions may develop that are similar to initial erythema migrans lesions.

Within weeks, during or shortly after the period of early, disseminated infection, objective signs of acute neuroborreliosis develop in approximately 15% of untreated patients.[19,20] Possible manifestations include lymphocytic meningitis, subtle encephalitis, cranial neuropathy (particularly unilateral or bilateral facial palsy), or motor or sensory radiculoneuritis. During this same period, approximately 5% of untreated patients have acute cardiac involvement, most commonly fluctuating degrees of atrioventricular block.[21,22] Even without treatment, these manifestations of the illness usually resolve within weeks to months. Months after the onset of illness (stage 3), approximately 60% of untreated patients in the northeastern United States begin to have intermittent attacks of oligoarticular arthritis, usually in one or a few large joints at a time, especially the knee.[23] By the time arthritis is present, the infection often seems localized to affected joints, and systemic symptoms are minimal. Synovial tissue in joints shows synovial hypertrophy, vascular proliferation, and a marked infiltration of mononuclear cells.[24,25] However, even in untreated patients, intermittent or persistent Lyme arthritis usually resolves completely within several years.

Months to several years after disease onset, usually after the period of oligoarticular arthritis, up to 5% of untreated patients in the United States experience chronic neurologic manifestations of Lyme disease,[26] primarily a mild encephalopathy[26,27] or an axonal polyneuropathy.[28,29] In patients with encephalopathy, intrathecal antibody production to the spirochete can often be demonstrated by antibody-capture enzyme immunoassay,[30] and in those with polyneuropathy, electromyograms typically show diffuse involvement of both proximal and distal nerve segments.[28,29] The basic outlines of Lyme borreliosis are similar worldwide, but there are regional variations, primarily between the illness found in America and that found in Europe.[31]

A small percentage of patients develop chronic pain, neurocognitive symptoms, or fatigue symptoms in association with or soon after Lyme disease.[31] Compared with Lyme disease, these pain and fatigue syndromes tend to produce more generalized and disabling symptoms, including marked fatigue, headache, diffuse musculoskeletal pain and stiffness in many joints, diffuse dysesthesias, difficulty with concentration, and sleep disturbances. These syndromes, which are sometimes called chronic Lyme disease, are not specific for that infection, and they may be triggered by other infectious or noninfectious conditions. In fact, the majority of patients now diagnosed with chronic Lyme disease lack evidence of past or present *B. burgdorferi* infection.[32]

BACTERIOLOGY

The structure of *Borrelia* species, including *B. burgdorferi*, is similar to that of all spirochetes: a protoplasmic cylinder surrounded by periplasm containing the flagella, which is surrounded, in turn, by an outer membrane (Fig. 34.2).[33] The genome of *B. burgdorferi* is quite small (approximately 1.5 Mb) and consists of a highly unusual linear chromosome of 950 kb as well as nine circular and 12 linear plasmids.[34,35] The remarkable aspect of the *B. burgdorferi* genome is its large number of sequences for predicted or known lipoproteins, including plasmid-encoded outer surface proteins (Osps) A through F. In addition, during early, disseminated infection, a surface-exposed lipoprotein, called VlsE, undergoes extensive antigenic variation.[36] The only known virulence factors of *B. burgdorferi* are surface proteins, which allow the spirochete to attach to a variety of mammalian cells.

Figure 34.2. Scanning electron micrograph of *Borrelia burgdorferi*, the causative agent of Lyme disease. Of the *Borrelia* species, *B. burgdorferi* is the longest (20 to 30 μm) and narrowest (0.2 to 0.3 μm), and has the fewest flagella (7 to 11). *(From Johnson RC, Hyde RW, Rumpel CM. Taxonomy of the Lyme disease spirochetes.* Yale J Biol Med. *1984;57:529–537.)*

PATHOGENESIS

To maintain its complex enzootic cycle, *B. burgdorferi* must adapt to two markedly different environments, the tick and the mammalian host.[37] In the midgut of the tick, the spirochete expresses OspA and OspB.[38] When a blood meal is taken, these two proteins are downregulated and OspC is upregulated as the spirochete traverses to the tick salivary gland and then to the mammalian host. In the salivary gland, OspC binds a tick protein (Salp15 [saliva protein of 15 kDa]), which protects the spirochete from antibody-mediated killing in the host.[39] In addition, some strains of *B. burgdorferi* have complement regulator–acquiring surface proteins that bind complement factor H and factor H–like protein 1, which protect the organism from complement-mediated killing.[40]

After injection into the skin, *B. burgdorferi* usually first multiplies locally in the skin at the site of the tick bite. Several days later, the spirochete begins to spread in the skin, and, within days to weeks, it may disseminate to many sites. A number of mechanisms may aid in dissemination. For example, the sequences of OspC vary considerably among strains, and certain types, particularly OspC type A followed by OspC type I, have a greater inflammatory potential[41] and can more often be detected in blood.[42,43] Spreading through the skin and other tissue matrices may be facilitated by the binding of human plasminogen and its activators to the surface of the spirochete.[44] During dissemination and homing to specific sites, the organism attaches to certain host integrins,[45] matrix glycosaminoglycans,[46] and extracellular matrix proteins.[47] *Borrelia* decorin-binding proteins (Dbps) A and B bind decorin,[48] a glycosaminoglycan on collagen fibrils, which may explain why the organism is commonly aligned with collagen fibrils in the extracellular matrix in the heart, nervous system, or joints.

Both innate and adaptive immune responses, especially macrophage- and antibody-mediated killing, are required for optimal control of the infection and spirochetal eradication.[49–52] The primary role of *B. burgdorferi*–specific T-helper 1 cells is to prime T-cell–dependent B-cell responses to *B. burgdorferi* proteins.[53] Furthermore, *B. burgdorferi* has two immunogenic glycolipids,[54] which induce immunoglobulin (Ig) G antibody responses in some patients with early infection and in almost all patients with Lyme arthritis,[55] a late disease manifestation. The combination of these responses leads to the production of antibodies against many components of the organism, which promote spirochetal killing by opsonization and complement fixation.[49] Despite innate and adaptive immune responses, the organism may sometimes survive in selected niches for several years. In histologic sections, *B. burgdorferi* has been seen only extracellularly[56]; it has not been shown to survive intracellularly for prolonged periods.

DIAGNOSIS

B. burgdorferi can be cultured in a complex liquid medium called Barbour-Stoenner-Kelly medium.[8,9] However, except for acrodermatitis in Europe, a late disease manifestation, positive cultures have been obtained only early in the illness, primarily from skin biopsy specimens of erythema migrans lesions,[57] less often from plasma samples,[58] and only occasionally from cerebrospinal fluid samples in patients with meningitis.[59] Later in the infection, polymerase chain reaction (PCR) testing has been used for the detection of *B. burgdorferi* DNA in joint fluid.[60,61] However, because *B. burgdorferi* DNA at this site is derived from moribund or dead spirochetes, PCR testing of joint fluid is not an accurate indicator of active spirochetal infection.[62] Moreover, PCR testing is not often positive with samples from other sites later in the illness.[63] Thus, the diagnosis of Lyme disease is usually based on recognition of a characteristic clinical picture, exposure in an endemic area, and, except in patients with erythema migrans, a positive antibody response to *B. burgdorferi* by enzyme-linked immunosorbent assay (ELISA) and Western blot,[64] interpreted according to the criteria of the Centers for Disease Control and Prevention (CDC).[65] In Europe, where there is less expansion of the antibody response, no single set of criteria for the interpretation of immunoblots results in high levels of sensitivity and specificity in all countries.[66]

During the first several weeks of infection, when most patients have erythema migrans, serodiagnostic tests are insensitive, and they depend primarily on the detection of an IgM response to the spirochete.[67] However, after 4 to 8 weeks of infection, when most patients in the United States have disseminated infection, the sensitivity and specificity of the IgG response to the spirochete are both very high, in the range of 95% to 99% as determined by the two-test approach of ELISA and Western blot.[67] A positive IgG blot requires reactivity with at least five of the following 10 bands (18, 23, 28, 30, 39, 41, 45, 58, 66, and 93 kDa).[65] In persons who have been ill for longer than 4 to 8 weeks, a positive IgM test alone is likely to represent a false-positive result; therefore, such a response should not be used to support the diagnosis of Lyme disease after the first 2 months of infection. A new serologic test, an IgG ELISA that uses a peptide in the sixth invariant region of the VlsE lipoprotein of *B. burgdorferi*, may be valuable, as this test typically becomes positive before five IgG bands are present on Western blots.[67,68] However, the VlsE test as a standalone test is not quite as specific as standard two-tiered testing.[68a] Another approach is to use two EIAs, such as the whole sonicate EIA followed by the VlsE C6 peptide EIA, which is not quite as sensitive as the VlsE test by itself, but it maintains the specificity of standard two-tiered testing.[68b]

Antibody titers fall slowly after antibiotic treatment, but IgG and even IgM responses may persist at low levels for many years after treatment.[69] Moreover, Western blots, a nonquantitative test, do not change much after treatment. Thus, current serologic tests demonstrate exposure to the spirochete, but they cannot distinguish accurately between past infection and active infection. In addition, *B. burgdorferi* may cause asymptomatic infection. In the SmithKline Beecham Lyme disease vaccine trial in the United States, asymptomatic IgG seroconversion was demonstrated by Western blotting in approximately 10% of persons with Lyme disease.[70] Under these circumstances, positive serologic results for Lyme disease may cause diagnostic confusion.

Alternate approaches for diagnosis, such as determination of a metabolic biosignature, are being researched.[71]

TREATMENT AND PREVENTION WITH ANTIMICROBIALS

Evidence-based treatment recommendations for Lyme disease have been published by the Infectious Diseases Society of America (Box 34.1).[72] For early localized or disseminated infection, doxycycline (100 mg twice daily for 14 to 21 days) is recommended in persons 8 years of age or older, except for pregnant women.[73,74] Amoxicillin (500 mg three times daily), the second-choice alternative, should be used in children or pregnant women.[73,74] In case of allergy or other contraindication to doxycycline or amoxicillin, cefuroxime axetil (500 mg twice daily) is a third-choice alternative.[75] Erythromycin (250 mg four times daily) or its congeners, which are fourth-choice alternatives, are recommended only for patients who are unable to take doxycycline, amoxicillin, or cefuroxime axetil.[74]

For patients with objective neurologic abnormalities, 2- to 4-week courses of IV ceftriaxone (2 g once per day) are given most commonly.[26,76,77] Parenteral therapy with cefotaxime or penicillin G may be a satisfactory alternative. Objective evidence of relapse is rare after a 4-week course of therapy. In patients with high-degree atrioventricular nodal block, IV therapy for at least part of the course and cardiac monitoring are recommended, but insertion of a permanent pacemaker is not necessary.

Either oral or IV regimens are usually effective for the treatment of Lyme arthritis, although some patients require IV therapy for successful treatment of their arthritis.[78,79] However, despite treatment with either oral or IV antibiotic therapy, a small percentage of patients in the United States have persistent proliferative synovitis for months or even several years after 2 or more months of oral antibiotics or 1 or more months of IV antibiotics, or both. This outcome is thought to involve

BOX 34.1 Antibiotic Treatment Regimens for Lyme Disease[a]

EARLY INFECTION (LOCAL OR DISSEMINATED)

Adults

- Doxycycline, 100 mg orally twice daily for 14 to 21 days
- Amoxicillin, 500 mg orally 3 times daily for 14 to 21 days
- Alternatives in case of doxycycline or amoxicillin allergy:
  - Cefuroxime axetil, 500 mg orally twice daily for 14 to 21 days
  - Erythromycin, 250 mg orally 4 times a day for 14 to 21 days

Children (Age ≤8 Years)

- Amoxicillin, 250 mg orally 3 times a day or 50 mg/kg per day in 3 divided doses for 14 to 21 days
- Alternatives in case of penicillin allergy:
  - Cefuroxime axetil, 125 mg orally twice daily or 30 mg/kg per day in 2 divided doses for 14 to 21 days
  - Erythromycin, 250 mg orally 3 times a day or 30 mg/kg per day in 3 divided doses for 14 to 21 days

NEUROLOGIC ABNORMALITIES (EARLY OR LATE)

Adults

- Ceftriaxone 2 g IV once a day for 14 to 28 days
- Cefotaxime, 2 g IV every 8 hours for 14 to 28 days
- Na penicillin G, 20 million U IV in 6 divided doses every 4 hours for 14 to 28 days
- Alternative in case of ceftriaxone or penicillin allergy:
  - Doxycycline, 100 mg orally 3 times a day for 30 days; this regimen may be ineffective for late neuroborreliosis
  - Facial palsy alone: oral regimens may be adequate

Children (Age ≤8 Years)

- Ceftriaxone, 75 to 100 mg/kg per day (maximum: 2 g) IV once a day for 14 to 28 days
- Cefotaxime, 150 mg/kg per day in 3 or 4 divided doses (maximum: 6 g) for 14 to 28 days
- Na penicillin G, 200,000 to 400,000 U/kg per day in 6 divided doses for 14 to 28 days

ARTHRITIS (INTERMITTENT OR CHRONIC)

- Oral regimens listed above for 30 to 60 days or
- IV regimens listed above for 14 to 28 days

CARDIAC ABNORMALITIES

- First-degree atrioventricular block: oral regimens, as for early infection
- High-degree atrioventricular block (P-R interval >0.3 s): IV regimens and cardiac monitoring; once the patient has stabilized, the course may be completed with oral therapy

PREGNANT WOMEN

- Standard therapy for manifestation of the illness; avoid doxycycline

[a]Antibiotic recommendations are based on the guidelines from Wormser GP, Dattwyler RJ, Shapiro ED, et al. The clinical assessment, treatment, and prevention of Lyme disease, human granulocytic anaplasmosis, and babesiosis: clinical practice guidelines by the Infectious Disease Society of America. *Clin Infect Dis*. 2006;43:1089–1134.

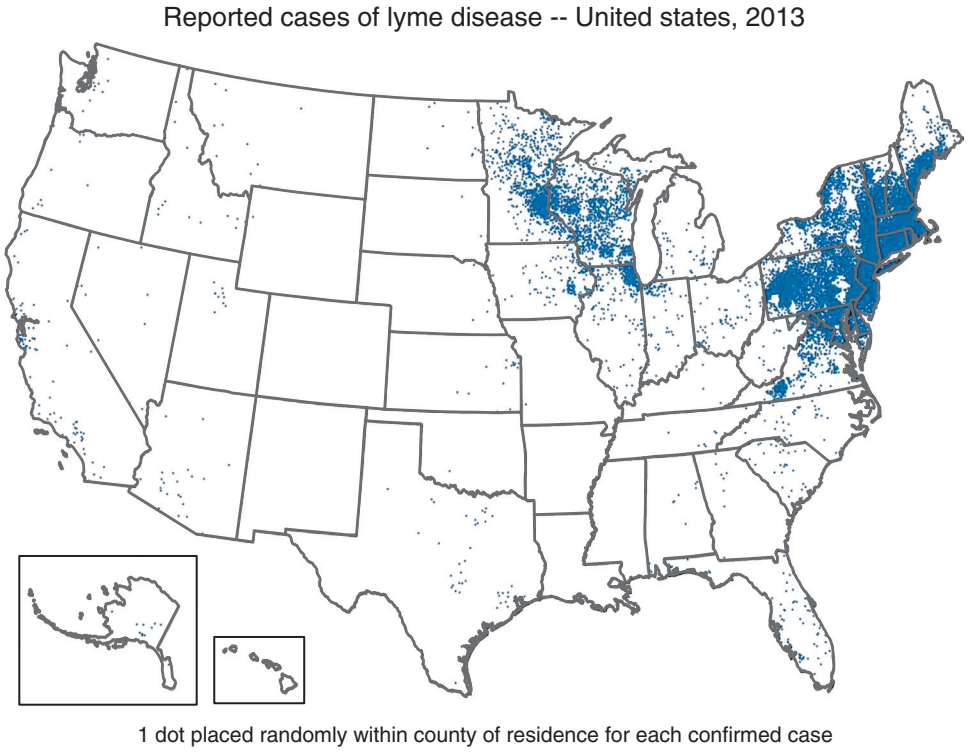

Figure 34.3. Number of cases of Lyme disease in the United States, by county, reported to the Centers for Disease Control and Prevention in 2013. Most of the cases occurred in the northeast and upper midwest. *(From the Centers for Disease Control and Prevention. http://www.cdc.gov/lyme/stats/graphs.html.)*

excessive inflammation,[80] immune dysregulation,[81] and infection-induced autoimmunity.[82,83] Patients who have persistent arthritis despite this treatment may be treated with antiinflammatory agents, disease modifying antirheumatic drugs, or arthroscopic synovectomy.

Should tick bites be treated with antibiotic prophylaxis? In studies, the frequency of Lyme disease after a recognized tick bite has been only approximately 1%,[84] perhaps because at least 24 hours of tick attachment seems to be necessary for transmission to occur.[85] Thus persons should remove an attached tick as soon as possible, and no other treatment is usually necessary. However, if the tick is engorged, indicating a longer duration of attachment, a single 200-mg dose of doxycycline usually prevents Lyme disease when given within 72 hours after the tick bite.[86]

Five double-blind, placebo-controlled trials of additional antibiotic therapy have been conducted in patients who have pain, neurocognitive symptoms, or fatigue symptoms after standard courses of antibiotic therapy for Lyme disease. None of the trials showed sustained benefit from additional oral or IV antibiotic therapy, but they documented the potential for severe adverse reactions, including IV catheter–related infections and antibiotic-associated colitis.[87–89a]

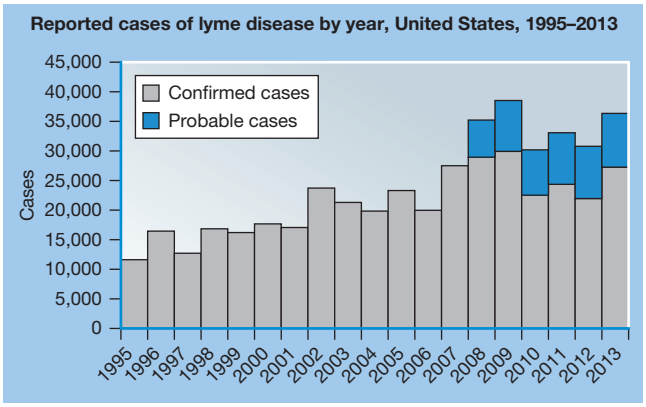

Figure 34.4. Number of cases of Lyme disease in the United States, by year, reported to the Centers for Disease Control and Prevention (CDC) from 1995 through 2013. For the past several years, more than 30,000 cases have been reported annually, but the CDC estimates that the actual number is 10 times higher, or 300,000 cases annually. *(From the Centers for Disease Control and Prevention. http://www.cdc.gov/lyme/stats/graphs.html.)*

EPIDEMIOLOGY

Incidence and Prevalence Data

Lyme disease occurs primarily in three distinct foci in the United States: in the Northeast from Maine to North Carolina, in the Midwest in Wisconsin, Minnesota, and Michigan, and to a lesser degree in the West, primarily in northern California (Fig. 34.3).[14,90] In Europe, the highest reported frequencies of the disease are in middle Europe and Scandinavia, particularly in Germany, Austria, Slovenia, and Sweden.[91] The infection is also found in Russia, China, and Japan.

Since surveillance for Lyme disease was begun in the United States in 1982, the number of cases reported to the CDC has increased dramatically (Fig. 34.4). In recent years, more than 30,000 cases have been reported yearly, accounting for more than 95% of all reported cases of vector-borne illness in the United States.[14] However, the CDC estimates that the actual number of cases is at least 10 times that number, or 300,000 or more cases per year.[92,93] The proliferation of deer, which are

the preferred host of the adult *I. scapularis,* was a major factor in the emergence of epidemic Lyme disease in the northeastern United States during the late 20th century.[49] Moreover, OspC type A and type B strains, which cause 30% to 50% of the infections in the northeastern United States,[42,94,95] have a high transmission frequency among ticks[96]; they may be increasing in frequency in nature, and this may also be an important factor in the intense emergence of Lyme disease in this region.[97,98]

Lyme disease has evolved differently in different geographic locations. In the northeastern and north-central United States, *I. scapularis* ticks are abundant, and a highly efficient cycle of *B. burgdorferi* transmission occurs between immature larval and nymphal *I. scapularis* and white-footed mice.[99] This cycle results in high infection rates in nymphal ticks and a high frequency of human Lyme disease during the late spring and summer months.[14] In the SmithKline Beecham Phase III Lyme disease vaccine trial, the yearly incidence of the disease in participants from hyperendemic areas was greater than 1%, and in some regions the seroprevalence of antibody to *B. burgdorferi* was as high as 5%.[100]

The vector ecology of *B. burgdorferi* is quite different on the West Coast in northern California, where the incidence of Lyme disease is low.[14] There, two intersecting cycles are necessary for disease transmission, one involving the dusky-footed wood rat and *Ixodes spinipalpis* ticks, which do not bite humans, and the other involving *Ixodes pacificus* ticks, which do.[101] Because nymphal *I. pacificus* prefer to feed on lizards, which are not susceptible to *B. burgdorferi* infection, only the relatively few *I. pacificus* nymphs that previously fed on infected wood rats in the larval stage are responsible for spirochetal transmission to humans.

Significance as a Public Health Problem

Even though the occurrence of Lyme disease is highly focal, certain locations, primarily in the northeastern United States, have been greatly affected.[14] Such areas have included suburban locations near Boston, New York, Philadelphia, Baltimore, and Washington, DC, which are some of the most heavily populated parts of the country.[102] In addition, *I. scapularis* ticks continue to spread, and one can anticipate that epidemics of Lyme disease will continue to occur in new locations in the United States. Currently, the major preventive measures are use of protective clothing, tick repellants, and personal inspection after tick exposure, but their efficacy is limited.[103, 104] Thus, vaccination would be an attractive strategy for prevention of the infection.

PASSIVE IMMUNIZATION

Although passively transferred sera from Lyme borreliosis patients to mice protected them from the infection,[105] passive immunization is not an important factor in protective immunity in Lyme disease. The spirochete is transmitted only by tick bite; person-to-person transmission has not been noted. Most patients have symptoms of the infection for months before protective immunity develops.

ACTIVE IMMUNIZATION

History of Vaccine Development

In 1986, Johnson and colleagues reported that Syrian hamsters could be immunized successfully against homologous strains of *B. burgdorferi* using a formalin-inactivated, whole-cell lysate of the spirochete.[106,107] These seminal studies showed that vaccination against Lyme disease was feasible. However, cross-protection among strains was limited. Immunization with European strains did not provide protection against U.S. strains, and immunization with U.S. strains did not provide protection against European strains. Moreover, hamsters inoculated with a Northeast coast strain were not protected from infection with a West coast strain. Subsequently, an inactivated whole-cell vaccine with a proprietary polymer-based adjuvant, called *B. burgdorferi* bacterin (Fort Dodge Laboratories, Fort Dodge, IA) and a bivalent whole-cell killed vaccine (Solway Animal Health, Mendota Heights, MN) were licensed in the United States for use in dogs.[108,109]

In 1990 in the United States, Fikrig and colleagues reported that immunization with a recombinant OspA protein of *B. burgdorferi* protected mice from challenge with several strains of the spirochete.[110] At the same time in Germany, Schaible and colleagues showed that injection of a monoclonal antibody to OspA provided protection in a murine model of the infection.[111] Protection was afforded by the development of high-titered antibody to a conformational antibody epitope, called LA-2, in the C-terminal portion of the protein.[112] Because *B. burgdorferi* expresses OspA primarily in the midgut of the tick, spirochetal killing was accomplished mainly in the tick before transmission to the human host.[113] Immunization with the lipid component of the protein was important in the induction of the primary immune response.[114] In addition to mice, protective immunity to OspA was demonstrated in hamsters,[115] dogs,[116] and monkeys.[117] As with whole-cell lysates, immunization with OspA was highly protective when the challenge isolate was either identical or closely related to the one from which the protein was derived.[118,119] However, protection from more diverse isolates was more limited.[118,120]

At the same time, other approaches to vaccination were studied. In one study, a recombinant bacille Calmette-Guérin vaccine expressing an OspA lipoprotein protected mice against intradermal challenge with *B. burgdorferi*.[121] In addition, antibody responses to other Osps of *B. burgdorferi,* including OspB,[122] OspC,[123] OspF,[124] and DbpA,[125] afforded some degree of protective immunity in animal model systems, but not the complete protection observed with OspA (Table 34.1). In contrast, antibody reactivity with OspE or the flagellar protein of the spirochete did not provide protective immunity.[122]

TABLE 34.1 Protection of Experimental Animals From *Borrelia burgdorferi* Infection[a]

Immunization	Challenge	Protection[b]
B. burgdorferi	*B. burgdorferi*	+++++
OspA	*B. burgdorferi*	+++++
OspB	*B. burgdorferi*	++++
OspC	*B. burgdorferi*	+++
OspE	*B. burgdorferi*	–
OspF	*B. burgdorferi*	+
P35 and P37	*B. burgdorferi*	++++
Flagellin	*B. burgdorferi*	–
P39	*B. burgdorferi*	+
P66	*B. burgdorferi*	+
DbpA	*B. burgdorferi*	++

[a]The data reflect the authors' interpretation of published studies.
[b]The degree of protection is graded on a scale from – to +++++, with – representing no protection and +++++ representing substantial (nearly complete) protection. Intermediate grades reflect mild to moderate protection.
DbpA, decorin-binding protein A; Osp, outer surface protein.

In the early 1990s, two companies, Pasteur Mérieux Connaught (now Sanofi Pasteur) and SmithKline Beecham (now GlaxoSmithKline) began the development of recombinant OspA vaccines for human use.[126,127] The vaccine made by GlaxoSmithKline was a recombinant OspA lipoprotein with adjuvant,[127] whereas the Sanofi Pasteur vaccine was a recombinant OspA lipoprotein without adjuvant.[126] In December 1998, the vaccine made by GlaxoSmithKline, called LYMErix, was licensed and sold commercially until February 2002. Several review articles were written about Lyme disease vaccination.[128–135]

LYMErix Vaccine

LYMErix, produced by GlaxoSmithKline, contained lipidated OspA adsorbed onto aluminum hydroxide adjuvant in phosphate-buffered saline with phenoxyethanol as a preservative (pH 6.5 to 7.1).[100,128] It was produced using recombinant DNA technology. The OspA gene from the ZS7 strain of *B. burgdorferi sensu stricto* was placed in the pOA15 plasmid vector and grown in *Escherichia coli* strain AR58.[100,128] The OspA lipoprotein produced was a single polypeptide chain of 257 amino acids; the lipid moiety was covalently bonded to the N-terminus after translation. The LYMErix preparation was not formulated in combination with other vaccines.

Dosage and Route of Administration

Each 0.5-mL dose of LYMErix contained 30 µg of lipidated OspA with adjuvant, which was administered intramuscularly, usually in the deltoid muscle.[100] For primary immunization, it was recommended that three injections be given: one at the first visit, the second 1 month later, and the third at 12 months. However, equivalent antibody levels could be achieved by giving the third injection at either 2 or 6 months rather than at 12 months.[136,137] The important point was that the third injection should be in April to provide maximum levels of protection during May through July, the questing period for nymphal *I. scapularis* ticks.

Vaccine Stability

The recommendation was to refrigerate LYMErix at 2°C to 8°C. With refrigeration, the vaccine had an expiration date that was 24 months after the date of manufacture. The vaccine was stable at room temperature for up to 4 days. If freezing occurred, the vaccine was to be discarded.

Results of Vaccination

Immunogenicity of the Vaccine

Antibody Responses. Lyme disease vaccine induced an IgG antibody response to OspA, including reactivity with the protective conformational epitope, LA-2, in the C-terminal portion of the protein.[112] Because the mechanism of the vaccine was antibody-mediated killing of the spirochete in the tick,[113] OspA antibody titers were the critical factor in vaccine efficacy. The levels of LA-2–equivalent antibodies were determined in a competitive-inhibition enzyme immunoassay in which a murine monoclonal antibody (also called LA-2) competed for binding with the patient's LA-2–equivalent anti-OspA antibodies.[111,128] An alternative assay was the determination of IgG antibody titers to full-length OspA by indirect ELISA.[138] This assay measured the amount of antibody not only to the protective antibody epitope of OspA but also to other OspA epitopes. For this reason, full-length OspA levels were not as accurate in predicting protection as were LA-2–equivalent antibody levels.

In the immunogenicity portion of the SmithKline Beecham Phase III trial, 95% of the 938 vaccine recipients tested from one site had LA-2–equivalent OspA antibody levels of 100 ng/mL or greater at month 2, 1 month after the second injection (Fig. 34.5).[100] Ten months later, the mean titer had declined markedly. At month 13, 1 month after the third injection, a marked anamnestic response was seen, and 99% had levels of 100 ng/mL or greater. At month 20, the mean titer had again declined. Thus, after three injections, most vaccine recipients developed high levels of LA-2–equivalent OspA antibody, but the antibody levels waned rather rapidly.

In the vaccine study, seven individuals were identified with very low antibody titers after vaccination.[139] The macrophages of these individuals produced less tumor necrosis factor-α and interleukin-6 after OspA stimulation, and had lower expression of Toll-like receptor (TLR)-1 than normal cells. TLR1 and TLR2 are required for lipoprotein recognition, and defects in the TLR1/2 signaling pathway may account in part for hyporesponsiveness to OspA vaccination.

Cellular Immune Responses. In the SmithKline Beecham Phase III trial, T-cell proliferative responses were determined to full-length OspA and to 20 overlapping OspA peptides in 41 vaccine and 44 placebo recipients from one site. Although the strength of the responses was often quite low, reactivity in

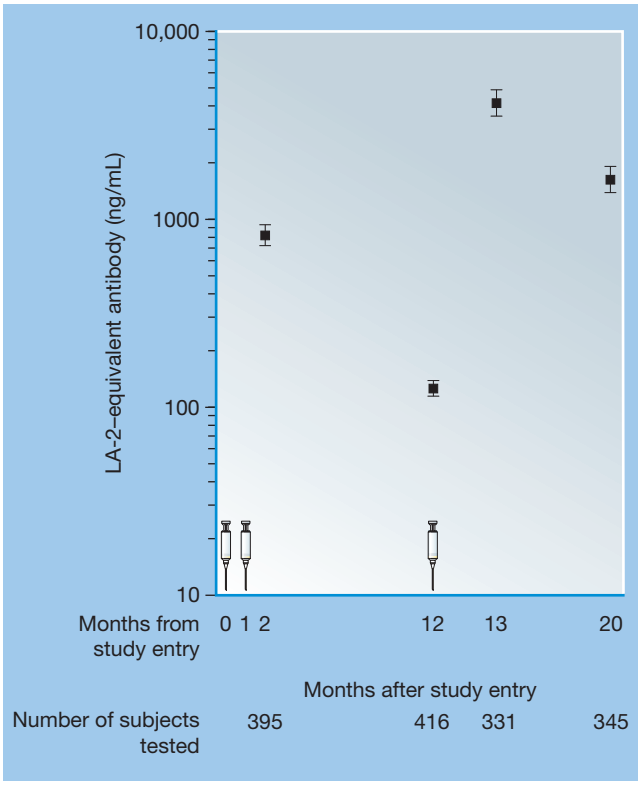

Figure 34.5. Levels of antibody to the protective epitope of OspA (LA-2–equivalent antibody) in vaccine recipients at one study site. At month 2, 1 month after the second injection, the geometric mean antibody titer was 816 ng/mL. Ten months later, the mean titer had declined. At month 13, 1 month after the third injection, a marked anamnestic response was seen, and the mean value was 4127 ng/mL. At month 20, the mean response had again declined, but it was still twice as high as at month 2. The vertical bars indicate 95% confidence intervals. *(From Steere AC, Sikand VK, Meurice F, et al. Vaccination against Lyme disease with recombinant* Borrelia burgdorferi *outer-surface lipoprotein A with adjuvant.* N Engl J Med. *1998;339:209–215. Copyright Massachusetts Medical Society.)*

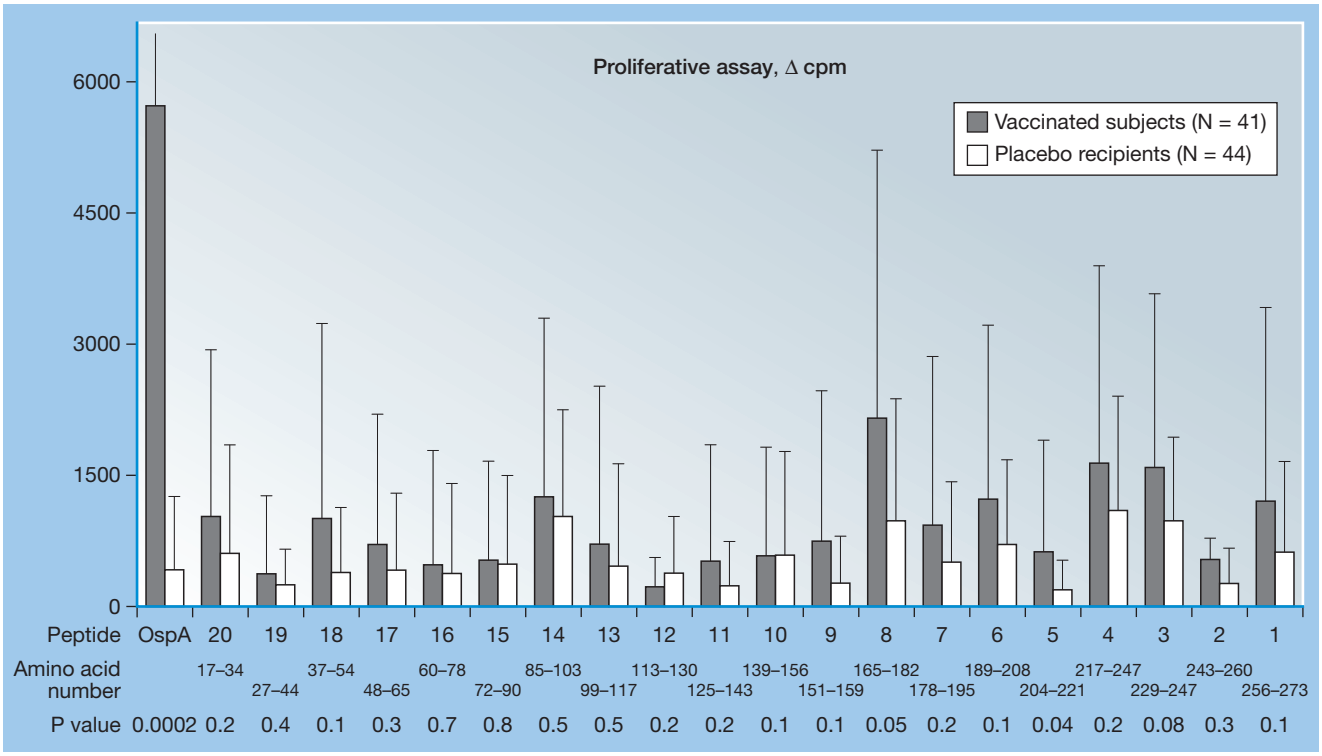

Figure 34.6. T-cell proliferative responses to full-length OspA and to 20 overlapping OspA peptides in 41 vaccine and 44 placebo recipients at one study site. Compared with that in placebo recipients, the responses in vaccine recipients were greater to full-length OspA and to epitopes contained in peptides 18, 14, 8, 4, 3, and 1. Significant differences between vaccine and placebo recipients were in the responses to full-length OspA ($P = .0002$) and peptide 8 ($P = .05$) as determined by *t*-test.

the 41 vaccine recipients was significantly greater to full-length OspA and to peptide 8 than in placebo recipients (Fig. 34.6). This peptide contains the immunodominant T-cell epitope of OspA recognized by individuals with the human leukocyte antigen (HLA)-DRB1*0401 or other related alleles. Although a T-helper–cell response may prime B cells to produce antibody to OspA, at least in some individuals, vaccine-induced cellular immunity was not thought to play a direct role in spirochetal killing.

Correlates of Protection

In animal models, the levels of LA-2–equivalent antibodies, which were directed against the protective antibody epitope of OspA, accurately predicted the probability of becoming infected with *B. burgdorferi*.[116] In the SmithKline Beecham Phase III vaccine trial, the antibody titers were significantly lower in vaccinated subjects with breakthrough cases of Lyme disease than in subjects in two comparison groups ($P < .01$ for each comparison) (Fig. 34.7).[100] Later, these serum samples were used to determine the IgG antibody titers to full-length OspA by indirect ELISA. Titers of 700 to 1400 ELISA units (EL.U.)/mL provided 70% to 95% sensitivity in discriminating between vaccine success and failure.[138] After three injections, 90% of the adults tested and 100% of children attained levels of 1400 EL.U./mL.[140]

Herd Immunity. *B. burgdorferi* survives in a horizontal cycle of transmission between ticks and mice[49]; human infection is a dead end in the spirochetal life cycle. Therefore, herd immunity in human populations does not influence the frequency of infected ticks or the enzootic cycle of infection.

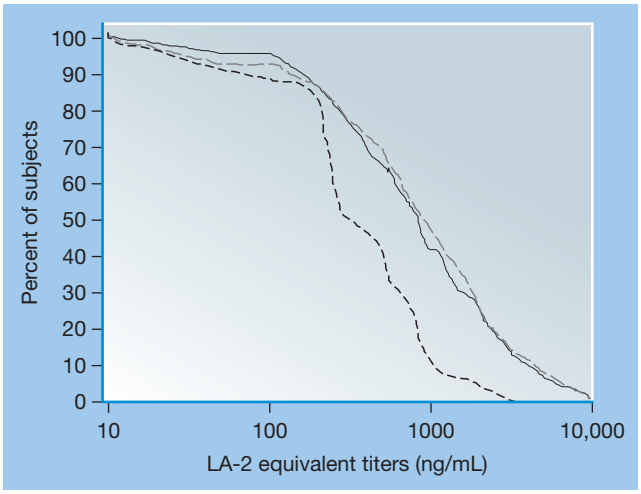

Figure 34.7. Reverse cumulative curve of LA-2–equivalent OspA antibody levels at month 2 in 20 vaccinated subjects with breakthrough cases of definite Lyme disease, in 512 vaccinated subjects evaluated for Lyme disease during year 1 whose diagnosis was not confirmed, and in 395 vaccinated subjects from one study site. At month 2, 1 month after the second injection, the titers were significantly lower in vaccinated subjects with breakthrough cases of Lyme disease than in the other two comparison groups ($P = .01$ for each comparison). *(From Steere AC, Sikand VK, Meurice F, et al. Vaccination against Lyme disease with recombinant* Borrelia burgdorferi *outer-surface lipoprotein A with adjuvant.* N Engl J Med. *1998;339:209–215, Copyright Massachusetts Medical Society.)*

Vaccine Efficacy

The efficacy of recombinant OspA vaccines was determined in two Phase III trials, one sponsored by SmithKline Beecham[100] and the other sponsored by Pasteur Mérieux Connaught.[141] The SmithKline Beecham study involved 10,936 subjects, ages 15 to 70 years, who lived in 10 states endemic for Lyme disease. Participants received an injection of either recombinant *B. burgdorferi* OspA lipoprotein with adjuvant, or placebo, at enrollment and 1 and 12 months later. In cases of suspected Lyme disease, culture of skin lesions, PCR testing, or serologic testing was done, and serologic testing was performed in all study participants 12 and 20 months after study entry to detect asymptomatic infection.

In the first year, after two injections, 22 subjects in the vaccine group and 43 in the placebo group contracted definite Lyme disease ($P = .009$); the point estimate of vaccine efficacy was 49% (95% confidence interval [CI], 15% to 69%).[100] In the second year, after the third injection, 16 vaccine recipients and 66 placebo recipients contracted definite Lyme disease ($P < .001$); the point estimate of vaccine efficacy was 76% (95% CI, 58% to 86%). Except for one participant each year who presented with Lyme arthritis, all definite cases in vaccine recipients had erythema migrans. Moreover, the arthritis case in year 1 most likely acquired the infection in the year before enrollment. During the first year, two subjects in the vaccine group and 13 in the placebo group had asymptomatic IgG seroconversion to *B. burgdorferi* ($P = .004$). In the second year, all 15 subjects with asymptomatic seroconversion were in the placebo group ($P = .001$). Thus, the efficacy of the vaccine in preventing asymptomatic infection was 83% in the first year and 100% in the second year.

In the SmithKline Beecham vaccine trial, the clinical picture of nonspecific systemic symptoms, without erythema migrans, accompanied by IgM or IgG seroconversion to *B. burgdorferi* sonicate was defined as possible Lyme disease.[100] Vaccine efficacy was not demonstrated among the participants who had this clinical picture.[100] However, in a post hoc analysis, in which this clinical picture and IgG seroconversion with the more sensitive and specific VlsE C6 peptide ELISA was redefined as definite Lyme disease, 17% of the 201 patients with definite Lyme disease presented with nonspecific systemic symptoms, without erythema migrans.[16] Among these patients, vaccine efficacy was similar to those with erythema migrans.[142]

In the trial sponsored by Pasteur Mérieux Connaught,[141] 10,305 subjects 18 years of age or older were recruited. The first two injections were administered 1 month apart, and some patients received a booster dose at 12 months. The primary end point was the number of new clinically and serologically confirmed cases of Lyme disease. The efficacy of the vaccine was 68% in the first year and 92% in the second year among the 3475 subjects who received the third injection. Thus, both studies showed that three injections of a recombinant OspA vaccine were quite effective in the prevention of Lyme disease for at least one tick transmission season.

Duration of Immunity and Protection. Although vaccinated subjects usually developed high levels of antibody to the protective epitope of OspA after three injections, the response declined rather rapidly.[100] If the correlate of protection was defined as 1400 EL.U./mL, a level with 95% sensitivity to discriminate between vaccine success and failure,[138] a fourth injection probably would have been needed in most patients the following year. Although long-term immunogenicity studies were not completed, it was anticipated that additional booster injections would have been needed in adults approximately every other year to maintain antibody titers at this level.

Postexposure Prophylaxis and Therapeutic Vaccination

There was no role for postexposure prophylaxis or therapeutic vaccination with recombinant OspA vaccines. Because *B. burgdorferi* downregulates OspA expression during transmission to the human host,[38] an antibody response to this protein does not afford protection once the spirochete is transmitted to the human host. However, in patients with Lyme arthritis in the northeastern United States, OspA seems to be upregulated again, and OspA antibody responses are common.[136a]

Safety

Common Side Effects

During both Phase III clinical trials, pain and tenderness at the vaccination site were the most commonly reported adverse events.[100,141] In the SmithKline Beecham Phase III trial, approximately 24% of vaccine recipients noted pain at the injection site, compared with 7% of placebo recipients ($P < .001$) (Table 34.2).[100] In addition, approximately 3% of vaccine recipients reported systemic symptoms of myalgias, achiness, fever, and chills, a significantly higher percentage than seen in placebo

TABLE 34.2 Percentage of Subjects With Symptoms (Overall Incidence, ≥1%) Classified as Related, Possibly Related, or Unrelated to Vaccination[a]

Symptoms	Vaccine (%)	Placebo (%)	*P* Value
RELATED OR POSSIBLY RELATED TO VACCINATION			
Local (Injection Site)			
Soreness	24.1	7.6	<.001
Redness	1.8	0.5	<.001
Swelling	0.9	0.2	<.001

From Steere AC, Sikand VK, Meurice F, et al. Vaccination against Lyme disease with recombinant Borrelia burgdorferi *outer-surface lipoprotein A with adjuvant.* N Engl J Med. *1998;339:209–215, copyright Massachusetts Medical Society.*

recipients. These reactions usually occurred within 48 hours after vaccination and lasted for a median duration of 3 days. They were usually mild or moderate in severity, and the severity usually did not increase with subsequent injections. At one site, where information was solicited about fever, no patient reported a temperature above 39°C. No hypersensitivity reactions were noted. Eleven percent of participants had a past history of Lyme disease, and 2.3% were seropositive for *B. burgdorferi* at study entry.[100] These individuals were not different from the rest of the subjects in the safety profile of the vaccine.[100]

Similarly, in a study of safety and immunogenicity of LYMErix in 4087 children ages 4 to 18 years, children generally achieved higher LA-2–equivalent antibody titers than adults, and the responses persisted longer, suggesting that the vaccine may be more effective in children than adults.[140] In the vaccine group, 20.4% had local injection-site reactions or systemic symptoms compared with 5.9% of the placebo recipients (P = .001). However, most reactions had a mean duration of only 2 to 3 days and were mild or moderate in severity.

Rare Reactions

In the natural infection, a small percentage of patients with Lyme arthritis have persistent synovitis for months or even several years after 2 to 3 months of treatment with antibiotic therapy, termed antibiotic-refractory Lyme arthritis.[143] Although PCR results for *B. burgdorferi* DNA are usually positive before antibiotic therapy, they are frequently negative after such courses of antibiotics,[60] and both PCR and culture results have been uniformly negative in synovial tissue obtained at synovectomies 12 months or more after the start of antibiotics.[62] These observations suggested that Lyme arthritis may continue after the near or total eradication of *B. burgdorferi* from the joint, perhaps sustained by an infection-induced autoimmune response.[144] This outcome is associated with HLA-DR molecules that bind the $OspA_{163–175}$ epitope of *B. burgdorferi* (DRB1*0101, DRB1*0102, DRB1*0401, DRB1*0402, DRB1*0404, DRB1*0405, and DRB5*0101),[145] and with T-cell recognition of this epitope.[146–149] Human lymphocyte function–associated antigen (LFA)-1$\alpha_{L\ 332–340}$, which has partial sequence homology with $OspA_{163–175}$, was originally proposed as a candidate autoantigen in antibiotic-refractory Lyme arthritis.[147] Subsequently, it was shown that the LFA-1 peptide was not a relevant autoantigen in this illness.[150,151]

Nevertheless, the question arose whether vaccination with recombinant OspA might exacerbate Lyme arthritis or induce autoimmune arthritis in genetically susceptible individuals. In the Phase III vaccine trials, however, vaccination with OspA was not associated with arthritis, neurologic abnormalities, or any other late syndrome 30 days or more after vaccination.[100,141] Although several subjects in the SmithKline Beecham Phase III trial developed inflammatory polyarthritis during the study and three subjects developed Lyme arthritis, these persons were found in both the vaccine and the placebo groups. In the Pasteur Mérieux Connaught trial, subjects with prior Lyme arthritis did not develop arthritis after vaccination.[141] Moreover, in a separate study of 30 patients with previous Lyme disease, those with a previous history of Lyme arthritis did not have a recurrence of arthritis after vaccination.[152] In the pediatric safety and immunogenicity study, one child had transient ankle swelling after dose 2, which resolved and did not recur after dose 3.[140] Nevertheless, because of lingering concerns about the theoretical potential for arthritogenicity, caution was urged with Lyme disease vaccination, particularly in people with arthritis.

As with any vaccine trial, rare side effects may not be recognized in comparisons of vaccine and placebo groups. Thus, the question remained: Might vaccination with OspA induce arthritis but at a frequency below the level of detectability in vaccine trials? In 2001, four patients in a case series were reported to have developed arthritis after OspA vaccination.[153] In one of the patients, *B. burgdorferi* infection was probably acquired before vaccination, but joint swelling became manifest months after vaccination. The arthritis resolved with antibiotic therapy. This phenomenon was observed in three patients in the SmithKline Beecham Phase III trial, two in the vaccine group and one in the placebo group.[100] Three months after the third injection of vaccine, the second patient developed a moderate effusion of a knee, which lasted for several months. The third patient developed swelling of the finger and toe joints within 24 hours after the second injection, and his symptoms improved over the next 5 days. The final patient developed, 24 hours after the second vaccination, synovitis of multiple proximal interphalangeal joints, which lasted approximately 7 weeks.

In 2002, the CDC and the U.S. Food and Drug Administration (FDA) published the reports relating to Lyme disease vaccination from their Vaccine Adverse Event Reporting System (VAERS). From December 1996 through August 2000, during the first 19 months after licensure, approximately 1.4 million doses of LYMErix were distributed, and, during this period, 905 adverse events (0.06%) were reported to the VAERS.[154] The most common reports were of arthralgias (250 reports) or myalgias (195 reports) occurring after the first dose. These frequencies were consistent with the events observed in the clinical trials. In addition, arthritis was reported to have developed in 59 patients, arthrosis in 34 patients, and rheumatoid arthritis in nine patients, usually after the second or third dose.[154] This frequency of arthritis was thought to be below the expected background incidence of arthritis occurring during this time period in an unvaccinated population. An analysis of HLA-DR profiles and OspA immunity in a subgroup of these patients was not suggestive of a vaccine-induced process.[155]

As detailed in a recent review,[156] recent work in a mouse model suggests that OspA in genetically susceptible persons stimulates a particularly strong T-helper cell type 1 response,[157] which may be one of several factors that can set the stage for a putative autoimmune response in affected joints. However, vaccination with OspA did not induce arthritis in this mouse model, and case and control comparisons in human vaccine trials did not show an increased frequency of arthritis among OspA-vaccinated individuals. Thus, a vaccine-induced immune response to OspA does not replicate the sequence of events needed in the natural infection to induce antibiotic-refractory Lyme arthritis.

Immunosuppressed Individuals

Lyme disease vaccines were not tested in immunosuppressed patients, and thus no information is available about the effectiveness of vaccination in such persons.

Spread to Contacts

Because Lyme disease vaccines consisted of only a recombinant OspA protein, there was no risk of spread to contacts.

Indications for Vaccine

Most *B. burgdorferi* infections result from periresidential exposure to infected ticks during property maintenance, recreation, or leisure activities.[103] Thus, persons who live or work in residential areas surrounded by woods or overgrown brush infested with vector ticks are at risk for acquiring Lyme disease. However, cost-effectiveness analyses concluded that

vaccination for Lyme disease was economically attractive only for those who have a seasonal probability of *B. burgdorferi* infection of greater than 1%.[158–160] Although these analyses were performed to inform a public health decision, an individual patient in a lower-risk area who is willing to pay out of pocket could reasonably decide in favor of vaccination.

The CDC's Advisory Committee on Immunization Practices advised that vaccination should be considered by persons 15 to 70 years old who live in or visit high-risk areas and have frequent and prolonged exposure to *I. scapularis* ticks.[161] Vaccination was not recommended for persons with minimal or no exposure to such ticks. However, as vaccination is not currently available, this preventive approach to Lyme disease is not possible at this time.

Contraindications and Precautions

Recombinant OspA vaccines were tested only in normal individuals. Therefore, safety information was not available about vaccine use by patients with other diseases or by pregnant women. Although studies in children were underway, these vaccines were not licensed for use in children at the time of withdrawal of the vaccine.

Nonimmunologic Prevention

Protective measures for the prevention of Lyme disease include the avoidance of tick-infected areas, the use of protective clothing, the use of repellants and acaricides, tick checks, and modifications of landscapes in or near residential areas.[103] However, these methods of prevention have not been shown to lower the incidence of Lyme disease,[133] presumably because people have trouble maintaining these tick prevention efforts throughout the entire tick-transmission season.

Withdrawal of LYMErix

Although the FDA approved LYMErix, the first new recombinant Lyme disease vaccine, in late 1998, the manufacturer voluntarily withdrew its product from the market a little more than 3 years later, in 2002, amid media coverage, fears of vaccine side effects, and declining sales. Several articles have reviewed the factors involved.[162–166] Some of the reasons included the low risk of Lyme disease in most parts of the country, the manufacturer's direct-to-consumer advertising that overstated the risk in these areas, the need for booster injections every or every other year, the relatively high cost of this preventive approach compared with antibiotic treatment of early infection, and the theoretical (although never proven) concern that in rare cases, vaccination might trigger autoimmune arthritis. For all these reasons, the vaccine received a tepid endorsement by the public health community. Most importantly, the Lyme disease advocacy community, which initially supported the vaccine, became critical opponents.[166] For the most part, advocacy groups consisted of patients with other illnesses, particularly pain and fatigue syndromes,[32] but they said that vaccination made their "Lyme disease" worse. Paradoxically, the vaccine's success in scientific studies was seen as threatening their central position that Lyme disease is chronic, protean, and difficult to treat.[166] An additional problem is that the vaccine was not covered by the Vaccine Injury Compensation Program, which made it a target for personal injury lawyers. One law firm filed a class action suit in December 1999, and individual suits began to flood in.[163] In July 2003, GlaxoSmithKline, now the maker of LYMErix, settled the class action suits.[163] The final agreement included over $1 million in legal fees for prosecuting attorneys, but it provided no financial compensation to the vaccine "victims."

FUTURE CONSIDERATIONS

OspA Vaccination for Global Use

The OspA Lyme disease vaccines developed in the 1990s should be considered first-generation vaccines. A goal of future vaccines would be to provide longer-term protection and broader protection against variant strains of *B. burgdorferi*. The development of a Lyme disease vaccine for use in Europe has been more difficult than in the United States because all three pathogenic species of *B. burgdorferi sensu lato* cause the infection there.

Recently, Baxter Healthcare in Vienna, Austria, developed a multivalent OspA Lyme borreliosis vaccine (mv rOspA LB vaccine) containing three recombinant OspA antigens, which was designed to provide protection against almost all *B. burgdorferi sensu lato* strains associated with human disease worldwide. For this development, knowledge of protective OspA epitopes was used to design recombinant OspA molecules combining the protective properties of two OspA antigens in a single molecule. In addition, the sequence of the *B. burgdorferi* epitope ($OspA_{163–175}$) that has partial sequence homology with human LFA-1 was replaced with a corresponding (non-hLFA-1) sequence from a serotype-2 OspA molecule (Fig. 34.8).

In a proof-of-principle studies, a single recombinant OspA containing protective elements from two different OspA serotypes (1 and 2) induced antibody responses that protected mice against infection with either *B. burgdorferi sensu stricto* (serotype-1) or *B. afzelii* (OspA serotype-2),[167,168] as well as *B. garinii, Borrelia spielmanii, Borrelia valaisiana, Borrelia lusitaniae,* and *Borrelia japonica* strains,[169] further indicating that the vaccine had the potential to prevent Lyme disease worldwide.

In Phase I/II clinical trials to evaluate the safety and immunogenicity of the mv rOspA Lyme borreliosis vaccine, with and without adjuvant, the 30-μg adjuvanted formulation showed an excellent tolerability profile and induced the highest antibody titers following a booster dose, 9 to 12 months after the initial immunization.[170] Despite these promising results, Baxter Bioscience terminated their Lyme disease vaccine research program in 2014.

Valneva Austria GmbH has also developed a lipidated OspA vaccine. The vaccine includes three proteins, each containing the C-terminal half of two OspA serotypes linked to form a heterodimer along with a N-terminal lipid moiety.[171] Three immunizations protected mice from spirochetes expressing OspA serotypes 1, 2, and 5.

Other Altered OspA Proteins

Other altered OspA proteins have been developed as vaccine candidates. In one study, the entire 255-amino-acid ectodomain of OspA was inserted into the major B-cell epitope of the hepatitis B virus capsid protein.[172] This fusion protein induced an antibody response to the LA-2–protective epitope similar to that of recombinant lipidated OspA. In another study, a C-terminal fragment of OspA was generated that lacked approximately 45% of the residues from the N-terminus.[173]

Human OspA-Specific Monoclonal Antibody

Another experimental approach is injection of a humanized OspA-specific, borreliacidal monoclonal antibody, rather than injection of an OspA protein, to induce an OspA antibody response.[173a] When passively administered to mice prior to challenge with *B. burgdorferi*–infected ticks, these humanized monoclonal antibodies were capable of preventing

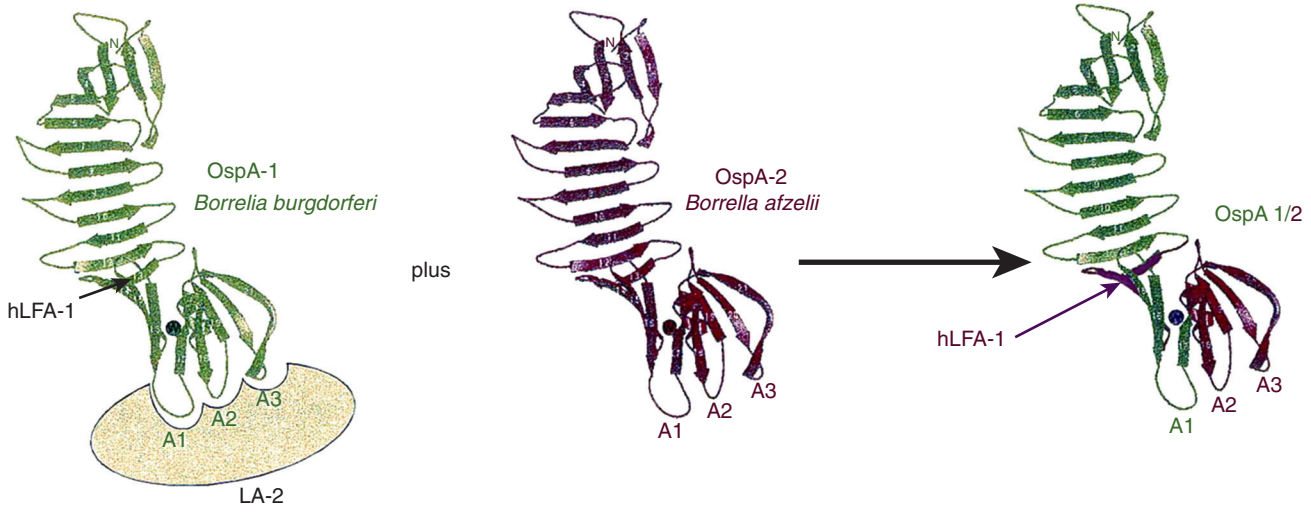

Figure 34.8. Proximal portion of a serotype-1 OspA sequence is fused to the distal portion of a serotype-2 OspA sequence. The resultant composite molecule contains the first of the three surface-exposed loops recognized by protective monoclonal antibody LA-2. The second and third loops recognized LA-2 are replaced by equivalent sequences from the serotype-2 molecule. The hLFA-1 epitope in β-sheet 13 from the serotype-1 sequence was replaced with a 25-amino-acid sequence derived from the serotype-2 sequence.

transmission completely. This approach has not yet been tested in human subjects, but if successful, it would presumably require infusions of OspA antibody each year prior to the tick transmission season.

OspC Vaccine Candidates

In an effort to provide protection against the range of European strains, Baxter Healthcare in Vienna initially researched a multivalent OspC vaccine. A potential advantage of this approach was that *B. burgdorferi sensu lato* strains express OspC on transmission and entry into mammalian hosts.[174] Therefore, anamnestic immune responses in the host could provide protection, rather than depending solely on the maintenance of high levels of circulating OspA antibodies, which kill spirochetes in the tick while it feeds. However, a major disadvantage was the greater variability of OspC compared with OspA. The company developed a 14-valent OspC vaccine, which was given in three 100-µg or 140-µg doses. In Phase I trials, the major problem was vaccine-induced erythema and swelling at the injection site, particularly after the third injection, which occurred in up to half of persons. Consequently, this approach was discontinued. Subsequently, one research group found that combinations of as few as two OspC proteins identified all patients who had OspC antibodies.[175] Another research group developed a tetravalent OspC-based, recombinant, chimeric vaccinogen, with linear epitopes presented by OspC types A, B, K, and D.[176] When mice were vaccinated with this construct, they developed complement-dependent bactericidal antibodies against strains expressing each of the OspC types.

OspA Immunization of Rodent Reservoirs

Another novel approach is being researched in which mouse reservoirs of *B. burgdorferi* are immunized with OspA. In one study, wild white-footed mice *(Peromyscus leucopus)*, the preferred host for nymphal *I. scapularis* ticks, were immunized by subcutaneous injection with either recombinant OspA or a negative control antigen in experimental or control grids.[177] In two large-scale experiments, the authors estimated that approximately 69% of the mouse population was immunized more than once, approximately 55% of all mice in each experimental group seroconverted to OspA, and the nymphal tick infection prevalence declined by approximately 16%. In a 5-year-prospective field trial, oral vaccination of wild white-footed mice with OspA resulted in a reduction of 23% in nymphal infection prevalence at 2 years and a 76% reduction at 5 years.[178] Similarly, another study predicted that a mouse-targeted vaccine would reduce infection prevalence among ticks by 56%.[179] However, the authors warned that other factors, particularly contributions to pathogen maintenance from non-mouse hosts, would preclude elimination of *B. burgdorferi* through mouse vaccination alone. They proposed increasing the impact of wildlife vaccination by the use of concombinant acaricide applications.

Immunization Using Multiple *B. burgdorferi* Proteins

In mice, antibody to OspA gives the best protective response of any single, known *B. burgdorferi* protein.[122–125] However, in these models, other responses, including responses to OspB, OspC, and DbpA, also provide protection against cultured *B. burgdorferi*, and reactivity with OspF, DbpB, and BBK32 provides partial protection.[135] Although reinfection may occur in patients with early infection who are treated with antibiotic therapy, it has not been noted in patients with Lyme arthritis, a late manifestation of the illness, suggesting that long-term immunity in the natural infection is generated from reactivity with a combination of spirochetal proteins.

To identify uncharacterized outer-surface proteins, one group performed a comprehensive gene expression profiling analysis of temperature-shifted and mammalian-host-adapted *B. burgdorferi*.[180] They identified seven uncharacterized *B. burgdorferi* outer-surface proteins, all of which elicited bactericidal antibody responses. In addition, two glycolipid antigens of *B. burgdorferi* are known to be immunogenic,[55,181] and antigenic epitopes of ACG have been identified.[182] However, it is not known whether glycolipid antigens might have a role as an adjuvant or in protective immunity in Lyme disease.

Reverse Vaccinology

Reverse vaccinology makes use of the known sequence of genes of *B. burgdorferi* to determine vaccine candidate targets using in silico analyses. Selected vaccine candidates are formulated to generate prototype immunogens, which are then used to immunize naive mice prior to challenge with live, infectious *B. burgdorferi*.[182a]

Immunization With Tick Proteins

I. scapularis ticks, which transmit the Lyme disease agent, have been implicated in the transmission of five other infectious agents. Thus, host immune responses that interfere with tick feeding could potentially help in preventing not only Lyme borreliosis, but also other *I. scapularis*–associated diseases. In the last decade, several tick molecules with the potential to serve as vaccines have been identified.[183–185] The *Ixodes* salivary protein Salp15 specifically binds to *B. burgdorferi* OspC and thereby protects spirochetes against borreliacidal antibodies.[39] By using Salp15 as a vaccine candidate, specific antibodies not only neutralized the immunosuppressive effects of this protein but also bound *Borrelia* surface-coated Salp15, enhancing clearance by phagocytic immune cells.[186] As a next step, an adenovirus expression system was used to deliver four salivary proteins (Salp15, Salp25A, Salp25D, and Isac) derived from *Ixodes scapularis* ticks.[187] In a mouse model, vaccination with these tick proteins modulated a Th1 response and partially controlled spirochete load. Using a phage display library, another protein of *I. scapularis*, a metalloprotease (MP1), was shown to be immunogenic.[188] In another study, vaccination with vaccinia virus expressing subolesin, a conserved tick protein, inhibited tick infestation by 52% compared with control vaccination, and reduced uptake of *B. burgdorferi* among surviving ticks by 34%.[189] Moreover, vaccination targeting tick or spirochetal proteins are not mutually exclusive. In a mouse model, immunization with Salp15 and OspA provided better protection against *B. burgdorferi* infection than either alone.[186]

SUMMARY

An effective human vaccine could be very beneficial in preventing Lyme disease,[190] and experience gained with OspA vaccines in the 1990s has shown the feasibility of this approach. However, given the fiasco associated with the introduction of these OspA vaccines in the late 1990s,[165] a new vaccine would need to meet high standards of safety, efficacy, cost, and public acceptance.[190] Nevertheless, an effective vaccine has already been developed for the United States market for this potentially serious infection, but the Lyme disease advocacy community has prevailed in keeping it from the public. This represents a failure of disease prevention efforts in the United States.[165]

35 Malaria Vaccines

W. Ripley Ballou and Johan Vekemans

Human malaria is caused by five species of the protozoan *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. The life cycle and parasite-host interaction of each species determines the severity and pathogenesis of clinical disease.[1,2] *P. falciparum* has the highest case fatality rate, especially in young children. The ability of *P. vivax* to develop dormant intrahepatocytic hypnozoites results in clinical relapses and contributes to the greatest geographic distribution.[3] Malaria occurs where the environment supports competent *Anopheles* mosquito vectors with access to malaria-infected hosts.[3,4] Until the early 1900s, malaria was endemic across every continent except Antarctica. By the 1950s, malaria was controlled in the United States, Europe, and Australia through the use of insecticides and environmental strategies.[1] Recently, a multifaceted strategy including environmental control, insecticides, bed nets, and chemotherapy has allowed some countries to report a dramatic fall in malaria incidence.[5] Nevertheless, a safe and effective vaccine remains an essential missing tool in the fight against malaria.

BACKGROUND

All species of malaria have a complex life cycle that begins in humans when female *Anopheles* mosquitos deposit sporozoites subcutaneously during a blood meal. Sporozoites enter the bloodstream and lymphatics and rapidly migrate to the liver, invading hepatocytes to form schizonts, each of which eventually yields tens of thousands of merozoites. *P. vivax* hypnozoites may remain quiescent in the liver for months to years before emerging into the circulation. Once merozoites erupt and invade circulating red blood cells (RBCs), symptoms of clinical disease become apparent. Over 24 to 48 hours, each merozoite develops into 8 to 10 new merozoites that rupture through the erythrocyte membrane and infect other RBCs. Some parasites develop into sexual-stage gametocytes, which, if taken up by an *Anopheles* during a blood meal, develop into male or female gametes, undergo fertilization to form ookinetes, and penetrate the gut epithelium to form oocysts. Sporozoites develop during the next 2 to 3 weeks, emerge from oocysts, and localize to the salivary glands, where they become infectious for humans.

Characteristic signs and symptoms of malaria include fever, malaise, headache, photophobia, muscle aches, anorexia, nausea, and vomiting.[6] Symptoms appear to coincide with the synchronized lysis of RBCs by schizonts releasing malarial toxins along with merozoites. Severe disease occurs most frequently with *P. falciparum* because of its ability to multiply infect erythrocytes, leading to massive destruction of RBCs, and because mature schizont-infected RBCs cytoadhere and obstruct capillary walls.[2,6] Severe clinical sequelae (such as acute renal failure, severe anemia, hypoglycemia, cerebral malaria, and pulmonary edema) occur most commonly in malaria-naïve populations, such as children and travelers.[7] Pregnant women and the developing fetus are at special risk for severe disease, indicating unique mechanisms of pathogenesis.[8] Coinfection with HIV predisposes to more severe disease, especially in children and malaria-naïve adults.[9]

EPIDEMIOLOGY AND BURDEN OF DISEASE

Quantification of the clinical burden of malaria is imprecise and is impacted by variable access to diagnosis and treatment, species prevalence, case definition, and, in many malaria-endemic settings, low specificity of diagnosis.[10,11] Approximately 170 million to 300 million clinical cases occur per year globally, 25% of which are caused by *P. vivax*. Estimates of annual malaria-attributable deaths in 2013 ranged from 367,000 to 755,000,[12] with the majority of deaths occurring in children in sub-Saharan Africa who were infected with *P. falciparum*. *P. knowlesi* was recognized in 2008 by the World Health Organization (WHO) as the fifth human *Plasmodium* species potentially leading to fatal outcome.[13] Tourism and economic development in southern and Southeast Asia will likely lead to a further increase in cases among locals and travelers.

The number of malaria cases diagnosed within the United States has been stable at approximately 1000 to 1500 per year for the past decade, with most cases occurring in travelers and military personnel. The United States has a very small number of congenital, blood-transfusion, and locally acquired cases.[14] Cases of imported malaria in Europe have increased steadily for several decades, while in Central Asia, local malaria transmission has been largely interrupted, with Tajikistan and Turkey making significant progress toward becoming malaria-free.[15]

VACCINOLOGY

Multiple lines of evidence suggest that a malaria vaccine is feasible. Immunization of humans with radiation-attenuated sporozoites confers sterile protection in roughly 50% to 90% of naïve volunteers who are challenged within 12 months.[16–18,18a] Because this model requires exposure to approximately 1000 irradiated, malaria-infected mosquitoes over several months, it is impractical.[19] Naturally acquired clinical immunity develops during the first 2 decades of life in people living in malaria-endemic countries.[20,21] In general, immunity is imperfect, wanes rapidly, is linked to intensity of exposure, and primarily impacts the severity of clinical disease.[22–25] An immunologic correlate of naturally acquired protection has yet to be identified.

The approximately 5000 open reading frames of the *P. falciparum* genome are carried on 14 chromosomes.[26–29] Throughout its life cycle, the malaria parasite is susceptible to vector and host immunity and passes through several "biological bottlenecks" where the number of parasites in the vector or host is limited. These bottlenecks are logical targets for vaccine development. Most candidate vaccines currently in development focus on a single stage of the life cycle. Although some target antigens are expressed in multiple stages,[30–32] a highly efficacious vaccine might require distinct antigens from different stages.

Vaccines Targeting the Preerythrocytic Stages

Vaccine strategies targeting sporozoites aim to generate immune responses that neutralize its ability to invade or develop within hepatocytes (Fig. 35.1). Studies in rodent and simian models confirm that humoral and cell-mediated

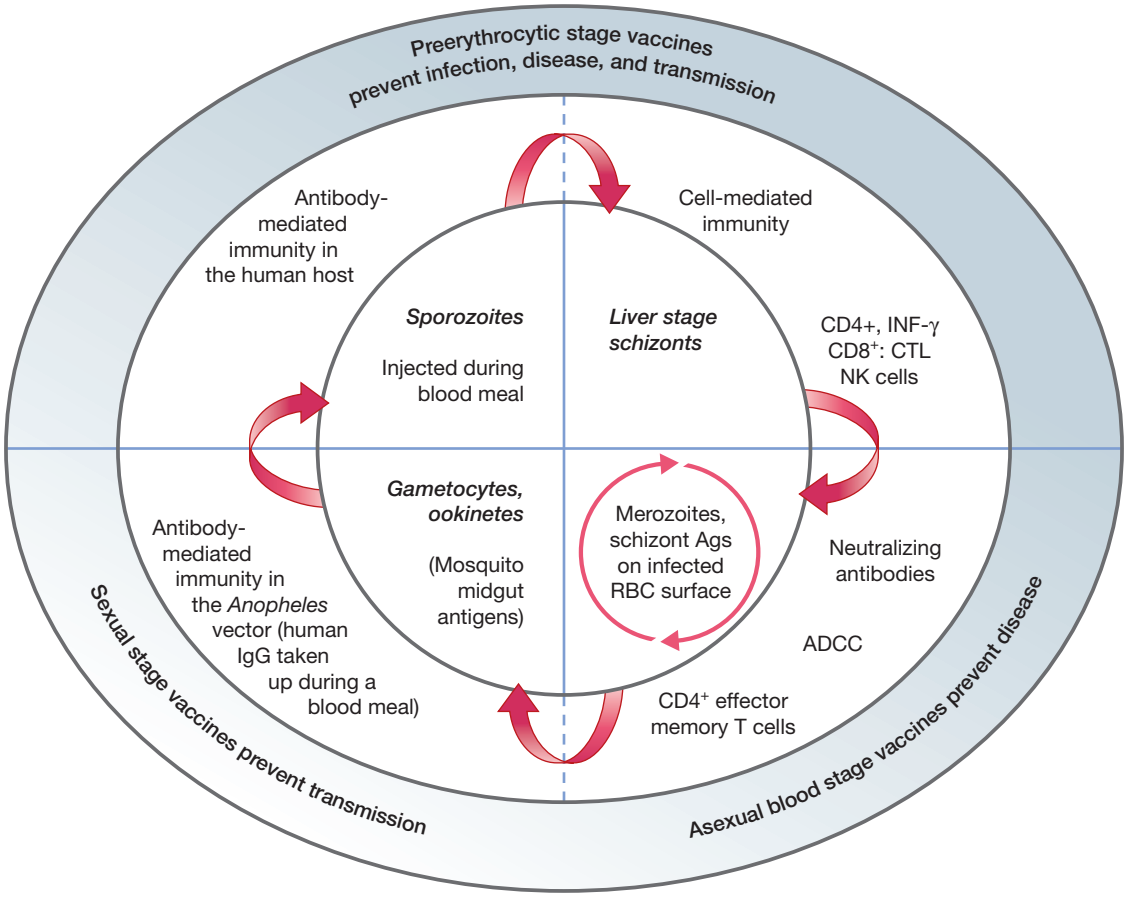

Figure 35.1. The inner circle highlights key stages of the parasite life cycle targeted by malaria vaccines under development. The middle circle shows the immune responses thought to be most important in protective immunity against these stages. The outer circle shows the major classes of malaria vaccines under development and the potential effect that a highly effective vaccine of that class might have on malaria. Stages in italics represent biological bottlenecks where relatively few parasites (<100) must be targeted to break the life cycle. For comparison, the total number of merozoites/schizonts in the human host can exceed 10^{12}. ADCC, antibody-dependent cellular cytotoxicity; Ags, antigens; CTL, cytotoxic T lymphocyte; Ig, immunoglobulin; INF, interferon; NK, natural killer; RBC, red blood cell.

immunity contribute to protection.[33–37] Experiments involving irradiated sporozoite challenge models have implicated $CD4^+$ and $CD8^+$ T cells, natural killer T cells, and γδ T cells in the inhibition of intrahepatic schizogony.[38–40] A highly effective preerythrocytic stage vaccine that confers sterilizing immunity, delivered widely within a malaria endemic region, should logically reduce malaria transmission.[41] Partially protective preerythrocytic vaccines that significantly decrease the load of merozoites emerging from the liver[42] could have a large public health impact if, like other partially effective malaria interventions (insecticide-treated bed nets, intermittent drug therapy), they reduced the risk of clinical malaria.[43–45]

Vaccines Targeting the Asexual Blood Stages

Merozoites enter the bloodstream after erupting from hepatocytes and within seconds invade RBCs. Neutralizing antibodies can inactivate merozoites before invasion or engage antibody-dependent cytotoxic effector mechanisms against target malarial antigens expressed on schizont-infected RBC membranes, but as these antigens are generally subject to significant antigenic variation, are large, and/or are structurally complex, most candidate vaccines based on these stages target only a portion of the native protein.[46–48] Rodent models have implicated CD4 T cells, nitric oxide, and γδ T-cell activity against blood-stage parasites,[49] and CMI likely has a role in naturally acquired immunity in humans.[50,51] Vaccines against these stages ideally would prevent disease by limiting the number of infected RBCs, but generating immune responses sufficiently broad to cover the many antigenic variants that circulate in communities will be challenging.[52–54]

Vaccines Targeting the Sexual Stages

Transmission-blocking vaccines rely on human antibody and complement taken up by mosquitoes during a blood meal. Within the mosquito, sexual-stage parasite surface antigens or mosquito mid-gut binding sites can be targeted to prevent successful development of infectious sporozoites.[55–57] This type of vaccine would not prevent disease in a vaccinated person, but would prevent the further spread of malaria.[58,59] If effective, such a vaccine could be particularly useful in areas of low-to-moderate transmission intensity or as an important component of a multiantigen vaccine.

VACCINES IN LATE-STAGE DEVELOPMENT

Currently, there are no registered malaria vaccines. A large number of malaria vaccine candidates have been tested preclinically or in Phase I/II clinical trials,[60–63] but only one is in late-stage development. The RTS,S Clinical Trials Partnership has recently completed a large Phase III trial of the RTS,S

vaccine candidate conducted in 11 sites across seven sub-Saharan African countries. An application for a Committee for Medicinal Products for Human Use (CHMP) scientific opinion through the European Medicines Agency (EMA) Article 58 procedure was placed.[64] A positive opinion was received from EMA in July 2015, and the WHO recommended pilot introduction of the vaccine in January 2016.[64a,64b] The program was designed in consultation with the WHO to demonstrate that RTS,S can provide significant durable protection against clinical malaria, including severe malaria, in young children and infants when administered via the Expanded Programme on Immunization (EPI).

RTS,S was developed and tested by GlaxoSmithKline Biologicals (GlaxoSmithKline), the Walter Reed Army Institute of Research (WRAIR), Programs for Appropriate Technology in Health (PATH) Malaria Vaccine Initiative, and several other academic partners in a collaboration that spanned many years.[65] The vaccine is based on the circumsporozoite (CS) protein of *P. falciparum*, a major sporozoite surface protein that contains B- and T-cell epitopes.[66] The CS protein undergoes important conformational modification as it transits from the mosquito to the mammalian host, permitting motility and invasion of hepatocytes.[67] RTS,S consists of a chimeric virus-like particle protein construct expressing 19 NANP repeats of the central region and the entire C-terminal flanking region (amino acids 207 to 395) fused to the hepatitis B virus surface antigen (HBsAg).[68] The vaccine is produced using recombinant DNA technology that uses a *Saccharomyces cerevisiae* fermentation process. The overall manufacturing process is similar to that used for production of commercial HBsAg vaccine. The fusion protein is coexpressed with HBsAg, yielding a product that is composed of CS-HBsAg fusion protein and HBsAg in a ratio of approximately 1 : 3.

A series of pivotal clinical trials conducted at WRAIR that incorporated an experimental malaria sporozoite challenge demonstrated an absolute requirement for adjuvantation of RTS,S with a formulation containing the Toll-like receptor (TLR)-4 agonist monophosphoryl lipid A and a purified saponin derivative QS21 (*Quillaja sapanaria* Molina, fraction 21; licensed by GSK from Antigenics Inc, a wholly owned subsidiary of Agenus Inc).[68–72] Two related adjuvant formulations were studied subsequently during Phase II, AS02 in which the immunostimulants are combined with an oil-in-water emulsion, and AS01, in which the immunostimulants are combined with liposomes.[73] Based on superior immunogenicity, an equivalent safety profile and a trend toward better efficacy, the AS01 formulation was ultimately selected for Phase III.[71,74–76] RTS,S induces immune responses in humans that are believed to protect against infection with malaria sporozoites. These include high levels of antibodies against CS capable of inhibiting sporozoite infection of liver cells in vitro. It also induces CMI responses against CS that have been shown in numerous animal models to associated with protection.[77–80] The vaccine also induces very high levels of antibodies against HBsAg.

RTS,S was studied in more than 4000 subjects before Phase III, including malaria-naïve and malaria-experienced adults, as well as young children and infants, in malaria-endemic settings. The vaccine is generally well tolerated and immunogenic in all age groups and has an acceptable safety profile.[68–71,74–76,81–91] Because of the complexity of falciparum malaria as a disease target and the use of novel adjuvant technology in RTS,S, the Phase II/III program in Africa was complex and included more than a dozen clinical trials designed to select the proper vaccine dose, formulation, and schedule, while evaluating vaccine safety and immunogenicity in progressively younger age groups down to neonates. The program also included specific studies to demonstrate that RTS,S could be coadministered with routine EPI vaccines, including diphtheria, tetanus toxoid, whole-cell pertussis (DTPw), *Haemophilus influenzae* type b (Hib), hepatitis B (HepB), oral polio, measles, rotavirus, pneumococcal conjugate, and yellow fever, and to HIV-infected children. Interim and final results of the Phase III trial have now been published.[64,92–94] Overall, 8922 children and 6537 young infants were enrolled, randomized to receive either three doses of RTS,S plus a booster (R3R), three doses of RTS,S without a booster (R3C), or three doses of control vaccine plus a booster control vaccine (3C3). Follow-up in the older children and younger infants continued for approximately 48 and 38 months respectively. The trial was conducted in the context of high coverage of bednets (approximately 80%) and different transmission settings. Malaria incidence in the infant group that received the control vaccines ranged from 0.03 to 4.27 episodes per infant during the first 12 months of the study. As a consequence of intense monitoring and ready access to medical care, all-cause mortality in the trial was low (1.8% in children, 2.3% in infants). Tables 35.1 and 35.2 summarize the data on vaccine efficacy.

TABLE 35.1 Vaccine Efficacy in Infants Age 6–12 Weeks at First Dose

	Vaccine Efficacy Against All Episodes of Clinical Malaria (95% CI)	Vaccine Efficacy Against Severe Malaria (95% CI)	Vaccine Efficacy Against Hospitalization Caused by Malaria (95% CI)
>12 months follow-up from dose 3 (ATP[a] cohort, n = 6003)	33% (26–39)	37% (5–58)	32% (7–50)
>18 months follow-up from dose 3 (ATP[a] cohort, n = 6003)	27% (20–32)	15% (–20 to 39)	17% (–7 to 36)
PRIMARY VACCINATION ONLY (ATP[a] COHORT, n = 5997)			
>30 months follow-up from dose 3	20% (13–27)	11% (–22 to 35)	10% (–15 to 30)
36 months follow-up[b] from dose 3	18% (11–25)	13% (–17 to 35)	13% (–9 to 31)
PRIMARY AND BOOSTER VACCINATION (ATP[a] COHORT, n = 5997)			
>30 months follow-up from dose 3	28% (22–34)	17% (–14 to 40)	25% (3 to 42)
36 months follow-up[b] from dose 3	27% (21–32)	21% (–7 to 42)	27% (7 to 43)

[a]According-to-protocol (ATP) cohort, all children were immunized according to schedule.
[b]Median time to follow-up after dose 3.

Vaccination with RTS,S reduced the number of cases by half in children and by a quarter in infants over the first 18 months.[94] Vaccine efficacy waned over time. Over the 4 years of follow-up, vaccine efficacy against clinical malaria in children was 39% (95% confidence interval [CI], 34–43) for the R3R group and 26% (95% CI, 21–31) for the R3C group, suggesting that the booster dose helped to maintain vaccine efficacy. In children, protection against severe malaria was likewise higher over the 4-year study period in the R3R as compared to the R3C group (29%, 95% CI, 6–46 vs. −6%, 95% CI, −35.0 to 17). Similar patterns of vaccine efficacy were detected against secondary end points such as severe malaria anemia, hospitalization for malaria, and requirement for blood transfusion during the trial, reflecting the overall impact of vaccine efficacy against clinical malaria provided by RTS,S. The number of cases averted varied according to exposure, age category, and whether a booster was administered. Depending on study site, 205 to 6565 cases of clinical malaria were averted per 1000 children (older age category) vaccinated with the R3R vaccine regimen. The R3R booster dose was more reactogenic than R3C and C3C boosters for both age groups, although grade 3 reactions were infrequent. The incidence of serious adverse events was similar in groups, but postvaccination febrile seizures were more frequent in children receiving RTS,S as compared with control vaccines. Compared with the control groups, rates of meningitis reported as an serious adverse event were higher in children, but not in infants, who received RTS,S. This imbalance could be a chance finding as events were caused by various pathogens, were clustered to a few sites, and occurred without temporal association with vaccination. This signal would be followed up during postregistration studies.

VACCINES IN EARLY-STAGE DEVELOPMENT

Candidate vaccines targeting each of the distinct stages of the parasite in humans are currently in early development, and some are progressing to field trials (Fig. 35.2). Asexual-stage candidate vaccines based on adjuvanted recombinant *P. falciparum* MSP-1, AMA-1, and alum-adjuvanted GLURP+MSP-3 (GMZ2) vaccine have failed to demonstrate compelling vaccine efficacy in Phase II field trials.[95–98a] PfRH5 is a reticulocyte binding-like homologue protein for which compelling preclinical data are accumulating, including protection in Aotus monkeys.[99] A thorough discussion of the many candidate malaria vaccines in early development is beyond the scope of this chapter, but the WHO maintains a regularly updated website that follows their progress and is useful for monitoring their progress.[100] The desire to induce strong cell-mediated responses has led investigators to explore the use of live attenuated recombinant bacterial and viral vectors.[62,101] Recently, a number of prime-boost regimens have been explored,[102–105] the most advanced of which uses a recombinant chimpanzee adenovirus 63 vector expressing multiple preerythrocytic-stage antigens (ME-TRAP) followed by boosts with modified vaccinia Ankara (MVA) vector expressing the same antigens.[105] Experimental challenge studies indicate that this vaccine can induce partial protection against infection and a Phase Ib study in Kenyan adults has shown evidence of protection from infection over 8 weeks of follow up.[106] It is currently in exploratory field trials in African children.

Vaccines against *P. vivax* are also entering clinical development.[107,108] These have targeted antigens for which homologous protection has been seen in human or animal models of falciparum malaria, including the vivax forms of MSP-1, CSP, TRAP, AMA-1, and the Pvs 25 and Pvs 28 ookinete antigens. In addition, several unique vivax asexual-stage antigens, including the Duffy binding protein, have received considerable focus.[109] As the *P. vivax* life cycle cannot currently be maintained in the laboratory, developing a vivax sporozoite challenge model for use in vaccine challenge trials is much more complex. Progress is being made, but clinical vivax relapses constitute an unresolved complexity for this model.[110,111]

Another innovative strategy relies on the large-scale manual dissection and purification of radiation-attenuated sporozoites from mosquitoes and delivering them by intramuscular, subcutaneous or intravenous injection.[112] The basis of this vaccine strategy is the high level of protection seen in human volunteers immunized by the bites of large numbers of malaria-infected irradiated mosquitoes, but the translation of this approach to a practical delivery method has been challenging.[113] A Phase IIa study has reported that five intravenous doses of 135,000 sporozoites fully protected six of six volunteers against experimental infection. These six protected volunteers subsequently underwent repeat CHMI 21 weeks after the initial challenge, but vaccine efficacy had declined

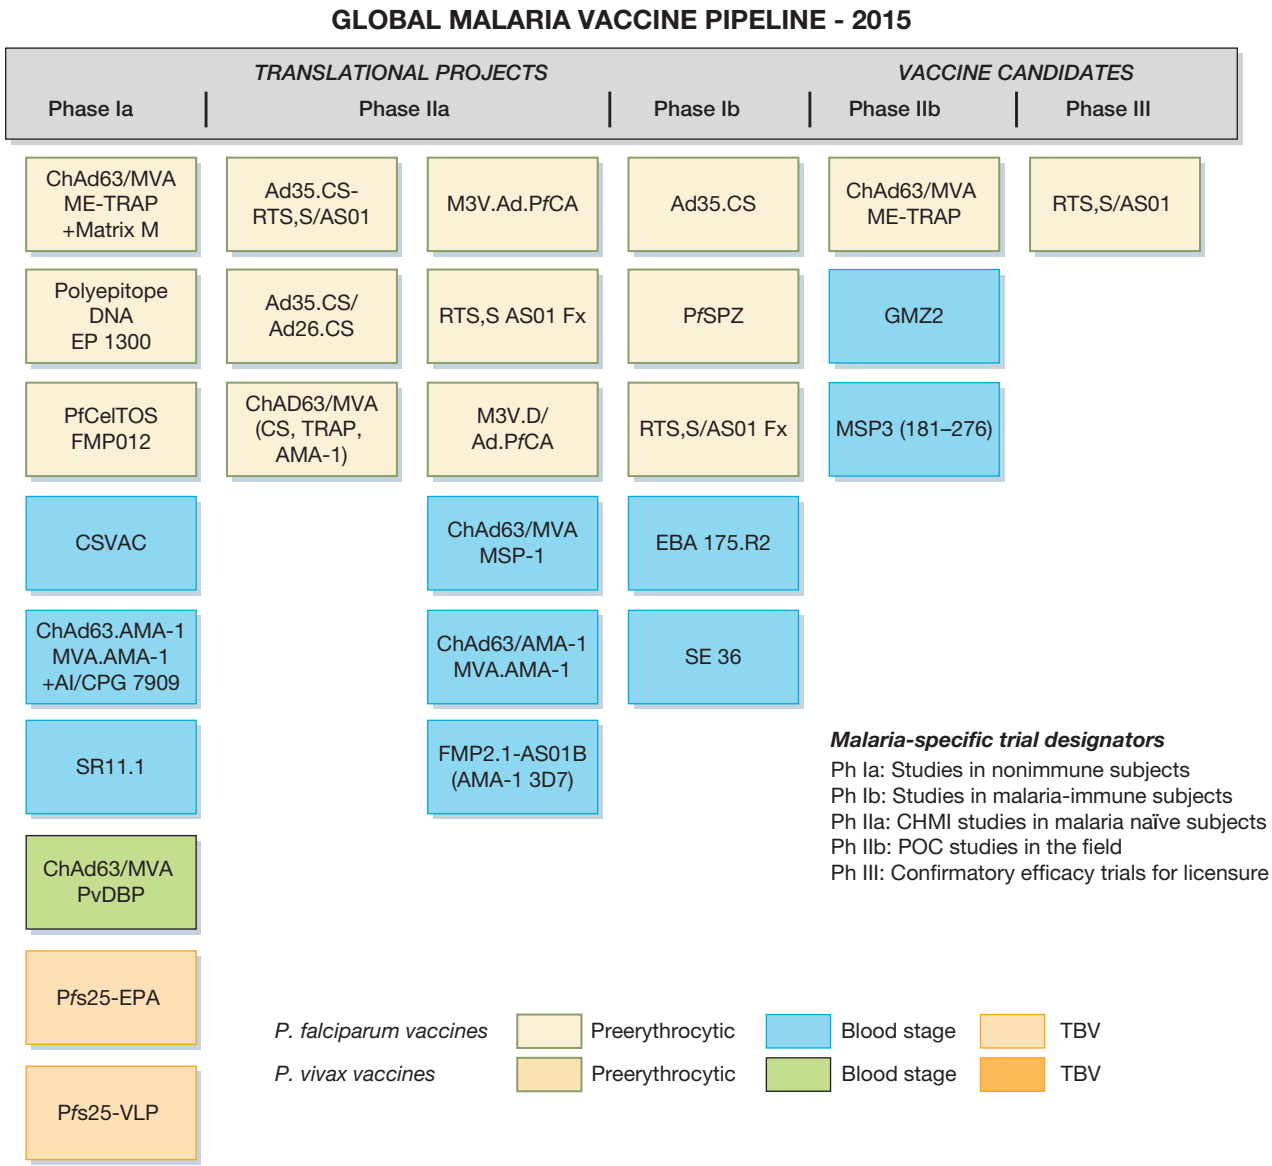

Figure 35.2. Overview of the global malaria vaccine pipeline currently in clinical development. The figure is organized according to stage of clinical development and color coded to identify the target species and life-cycle stage being targeted. Note that trial designations (Phases Ia, Ib, IIa, IIb) in common use within the malaria vaccine community may not be identical to those used for other vaccine development programs. CHMI, controlled human malarial infection; POC, proof of concept; TBV, transmission-blocking vaccine. *(Modified from World Health Organization.* Tables of Malaria Vaccine Projects Globally: Rainbow Table. *Available at: http://www.who.int/vaccine_research/links/Rainbow/en/index.html.)*

to 25%. In addition, 8 of 8 previously immunized subjects who were not protected at the first CHMI were similarly not protected after the second CHMI, indicating that exposure to malaria parasites was insufficient to boost immunity to protecctive levels.[114]

The impact of higher intravenous doses of irradiated sporozoites and the durability of protection was explored in a subsequent trial in which subject were randomized to receive from twofold to 3.3-fold the number of sporozoites administered in the previous trial, and were challenged at 3 weeks; those who remained protected were rechallenged at approximate or 12 months.[114a] Cumulative vaccine efficacy was approximately 55% and protection was correlated with Pf-specific antibodies up to 6 months, but levels waned thereafter. No correlation was seen between protection and numbers of circulating $CD4^+$ or $CD8^+$ T cells. A substudy in nonhuman primates that underwent a similar immunization procedure suggested that the long-term protection seen at 12 months may have been due to liver-resident $CD8^+$ T cells not detectable in the peripheral circulation.[114a]

Protection was associated with the development of both antibodies and cellular responses against sporozoite antigens. To eliminate the requirement for irradiation attenuation, genetically attenuated sporozoites are being developed, and whole-parasite blood-stage vaccines are also being explored,[62,115,116] but these strategies face additional challenges in establishing a balance between safety from malaria breakthroughs and induction of adequate immunogenicity. These strategies remain highly experimental and face enormous hurdles for large-scale manufacturing, formulation, and delivery.[117]

In the midterm (5–10 years), improvements on RTS,S may be feasible through repeated dosing, the use of more immunogenic regimen, or combination with other vaccines, targeting the same or other antigens.[118] Chimpanzee adenovirus type 63

(ChAd63) and Modified Vaccinia Ankara (MVA) expressing the synthetic pre-erythrocytic antigen ME-TRAP have been administered in a prime boost regimen along with RTS,S/AS01B and studied for safety, immunogenicity, and vaccine efficacy following CHMI.[118a] Both regimens were well tolerated. The combination regimen (RTS,S/AS01B ×3 plus Chad63/MVA ME-TRAP) protected 14 of 20 volunteers while the RTS,S/AS01B protected 12 of 16. Rechallenge of protected volunteers at 6 months revealed sustained high levels of protection (83–88%). Protection correlated with antibodies against CS on the day of challenge, but not with T-cell responses against either CS or TRAP or antibodies against TRAP. The recent finding that postpriming avidity increase is associated with a lower risk of clinical malaria suggests that this may be a useful surrogate for schedule optimization.[119] Priming with a single dose of attenuated human adenovirus 35 expressing the CS protein and boosting with two doses of RTS,S/AS01B (ARR) was compared with three doses of RTS,S/AS01B (RRR).[119a] Both regimens were well tolerated and immunogenic, but while vaccine efficacy at CHMI was similar (ARR, 44%; RRR, 52%), protection appeared to be mediated by different mechanisms, with the ARR schedule inducing great polyfunctional $CD4^+$ T-cell responses than did RRR, while the RRR schedule induced higher levels of antibodies to CS.

An alternative dosing regimen of RTS,S in which the third vaccination was delayed and reduced from 0.5 mL to 0.1 mL (delayed fractional third dose schedule [Fx]) was compared to a standard 0, 1, 2 months full dose (STD) schedule for safety, immunogenicity, and efficacy following CHMI.[119b] The Fx schedule recapitulated that used in the landmark RTS,S/AS02A CHMI trial[70] that first demonstrated high level efficacy against sporozoite challenge (7 of 8; 86% of the volunteers were protected). This unusual schedule resulted from a concern about reactogenicity (severe headache and malaise) observed in one volunteer after dose 2 and resulted in a pause in the trial and an 80% reduction in the volume of the third dose. Subsequent studies using the STD schedule were reassuring in their safety profile, and the high level of vaccine efficacy for Fx attributed to small numbers. To confirm that this was not the case, 30 subjects received RTS,S/AS01B on the Fx schedule and underwent CHMI, 26 (87%) were protected compared to 10 of 16 (63%) who received the STD schedule ($P = .04$, log rank). Antibody titers to CS were marginally lower in the Fx group than in the STD group, but avidity against CS on the day of challenge was higher in protected than in nonprotected individuals. The Fx schedule also significantly increased antibody somatic hypermutation. Fx dose boosting at 6 months was highly effective at maintaining or restoring protection upon rechallenge.

Finally, a global scientific effort is underway to understand what will be necessary to eliminate and eventually eradicate malaria. This has led to the concept of "vaccines that interrupt malaria transmission" (VIMT), which may include components from one or more of the parasite stages described in this chapter.[120–122] It is likely that a significant proportion of future funding for malaria vaccine development will focus on the long-term elimination/eradication goal and that such vaccines are developed within a framework that will position their use in context with other new tools being developed to support the malaria eradication agenda.

36 Maternal Immunization

Saad B. Omer and Denise J. Jamieson

WHY MATERNAL VACCINATION?

The term *maternal immunization* has been used to describe vaccination of women prior to, during, and after pregnancy. We use *maternal immunization* to refer to vaccination of women during pregnancy and/or in the immediate postpartum period. Maternal vaccination can be used for the benefit of the mother, for the benefit of the infant, or for the benefit of both.

Several infections disproportionately impact pregnant women. Although infections such as influenza, herpes simplex virus, and hepatitis E virus are not associated with increased susceptibility during pregnancy, they result in more adverse outcomes among pregnant women compared to nonpregnant women. On the other hand pregnancy makes women more susceptible to infections such as malaria, listeriosis, and (possibly) HIV. In the case of malaria, but not HIV, pregnancy is associated with more-severe outcomes after infection.

In addition to maternal benefits, maternal immunization has the potential to impact early childhood morbidity, and in some cases, mortality. Infections such as respiratory syncytial virus (RSV), influenza, and pertussis are associated with adverse outcomes in young infants. Influenza vaccines are generally not recommended for children younger than 6 months of age and pertussis vaccines are not started during an infant's most vulnerable period, the first month of life. Similarly, vaccines against Group B streptococcus and influenza could have a protective effect on birth outcomes such as low-birth-weight, preterm, and small-for-gestational-age births.

Gains in reducing global childhood mortality mostly have been outside the neonatal period. Approximately 40% of global childhood deaths occur in the neonatal period. Many of these deaths are caused by infections that can be prevented through existing maternal vaccines and those vaccines in development.

IMMUNOLOGY OF PREGNANCY

The increased susceptibility to and/or severity of several infections in pregnancy may be explained by immunological changes in pregnancy. Moreover, understanding these immunological changes might provide insights into vaccine responses in pregnancy. While there are several human studies on the immunological changes in pregnancy, a substantial portion of the evidence base comes from animal models.

Conventionally, pregnancy has been perceived as a generalized state of immune suppression with the biological goal of preserving the embryo/fetus by avoiding its potential allogeneic effects.[1] However, emerging evidence suggests that this conventional model may be too simplistic. For example, fetus-specific cytotoxic T cells with broad functional capacity can be detected in approximately half of all normal pregnancies—often as early as the first trimester. These cells are not deleted through the course of pregnancy. These data demonstrate that a fetus-specific adaptive cellular immune response is a part of normal human pregnancy.[2] In fact, a lower number of decidual cytotoxic $CD8^+$ lymphocytes is associated with development of preeclampsia.[3]

It is more appropriate to consider pregnancy as a physiologically dynamic state in which the immune response is progressively altered and not across-the-board suppressed.[4] There is an overall increase in the levels of sex hormones during the course of pregnancy (Fig. 36.1). As most of the changes in the immune responses during pregnancy are mediated by sex hormones, the responses during pregnancy vary by trimester. Low estradiol levels are associated with T-helper (Th)-1 type responses and higher cell-mediated immunity.[4,5] Conversely, high estradiol levels generally result in enhanced Th2 type responses. Increased progesterone levels are associated with overall suppression of maternal immune responses. During pregnancy, the number of T lymphocytes as well as B lymphocytes decline, with a resulting decline in Th1 and Th2 responses. By contrast, phagocytic activity, α-defensin expression, and the numbers of neutrophils, monocytes, and dendritic cells are maintained and may even increase during the second and third trimesters, representing some enhancement of innate immunity. The altered cell-mediated immunity may be the reason for severe disease in pregnancy after infection with organisms such as influenza virus in which cell-mediated immune responses are important to suppression of pathogen replication.[6–8] Enhancement of other aspects of the immune system may help explain why pregnancy does not result in overall immune suppression and how pregnant women are able to mount adequate immunologic responses when vaccinated.

Infections that result in more severe clinical outcomes among pregnant women compared to nonpregnant women often vary in severity by stage of pregnancy. For example, compared to early pregnancy, influenza infection results in more severe outcomes in later stages of pregnancy.[9–12] In contrast, *Plasmodium falciparum*–associated malaria is more severe in the first half of pregnancy compared to the second half.[13,14] These pregnancy-stage–dependent differences in postinfection outcomes may be, in part, a result of the types of immune responses involved in the control of various pathogens and the progressive alteration of the immune system during the course of the pregnancy.[15] For example, during implantation and placentation in the first trimester, extensive tissue remodeling is associated with a local inflammatory reaction. Later in pregnancy when the tissue remodeling substantially diminishes and when there is rapid fetal growth, there is a switch to an antiinflammatory *milieu*—ostensibly to ensure fetal survival.[15] As the pregnancy approaches the final phase, fetal development is complete and there is a resurgence of inflammatory processes in the uterus to initiate parturition-related events such as smooth muscle contraction. It has been hypothesized that the increased severe outcomes after parasitic infections (e.g., *P. falciparum* malaria) may be a result of predominantly local inflammatory Th1 and Th17 responses associated with enhancement of local tissue damage.[15–19] In contrast, the higher severity of influenza virus infections during late pregnancy may reflect the reduced Th1 type response.[19]

While there is an overall decrease in maternal $CD4^+$ and $CD8^+$ T cells and in natural killer cells with increasing gestational age, components of the innate immune system are either maintained or enhanced with the progression of pregnancy. It has been suggested that the reduced clearance of pathogens resulting from the decrease in $CD4^+$ and $CD8^+$ T cells is balanced by increases in the cells of the innate immune

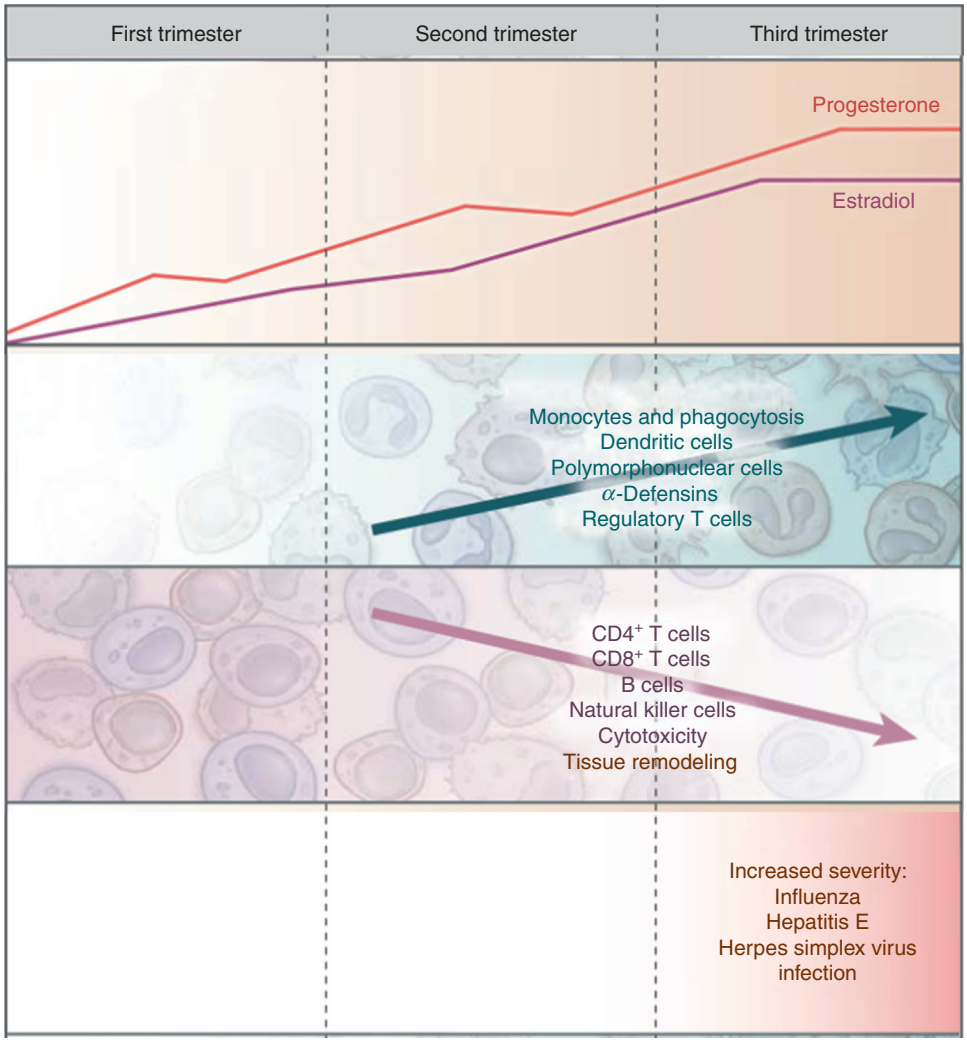

Figure 36.1. Physiologic and immunological changes in pregnancy and their association with infection severity. *(Modified from Kourtis AP, Read JS, Jamieson DJ. Pregnancy and infection.* N Engl J Med. *2014;371[11]:1077.)*

system, resulting in no change in susceptibility to many infections.[4]

RESPONSE TO VACCINES IN PREGNANCY

The evidence regarding the quality and magnitude of response to vaccines in pregnancy, most frequently measured as immunogenicity, is scant but developing. Most of the evidence base is composed of studies of inactivated influenza vaccine. These studies paint a mixed picture: studies involving 1962–63 seasonal vaccine,[20] the monovalent A/New Jersey/8/76 influenza vaccine,[21] and the 2010–12 seasonal vaccines documented equivalent responses among pregnant versus nonpregnant women.[22] However, other studies reported lower immunogenicity of influenza vaccine among pregnant women compared to nonpregnant women.[23–25] Similarly with yellow fever, some evidence suggests that the vaccine is potentially less effective because of the decreased immunogenicity in pregnancy[26]; however, other studies report no difference in response between pregnant and nonpregnant women.[27] Recently, Munoz and colleagues reported lower titers of anti–pertussis toxin, anti–filamentous hemagglutinin, antipertactin, and anti–fimbriae-2/3 antibodies in pregnant women who received tetanus, diphtheria, and pertussis (Tdap) vaccine compared to nonpregnant women.[28]

Timing of vaccination during pregnancy may have implications for quality of vaccine responses. In a study evaluating quality of cord blood immunoglobulin (Ig) G after Tdap vaccination in pregnancy, there was higher avidity of cord blood anti–pertussis toxin antibodies with pertussis immunization at 27 to 30 weeks of gestation compared to the group that received Tdap after 31 weeks of gestation.[29] These findings, may reflect the effect of additional time available for affinity maturation in mothers vaccinated relatively early in pregnancy, rather than differences in immune response later in pregnancy.[29] On the other hand, two studies conducted in Belgium and Vietnam, respectively, did not find an association between gestational age at pertussis vaccination and avidity of antipertussis antibody in cord blood samples.[30] The variable findings in studies evaluating the association between gestational age at maternal vaccination and avidity may be a result of their small sample size, prior disease and/or vaccine exposure, composition of any prior pertussis vaccine received (acellular vs whole cell), and underlying differences in study populations and study designs.[30] Moreover, in another relatively small study, women immunized with Tdap during pregnancy had a substantial decline in antipertussis IgG levels 9 to 15 months postpartum.[31]

Coinfections such as HIV and malaria could also potentially impact responses to vaccines in pregnancy. Lower

antibody responses to seasonal inactivated influenza vaccine have been observed among HIV-positive pregnant women compared to HIV-infected nonpregnant women in the United States[32] and South Africa.[33] Interestingly in the South African study, compared with HIV-unexposed infants, HIV-exposed infants had lower antibody levels at birth but similar antibody levels after 8 weeks of life.[33] Moreover, HIV-infected South African pregnant women had similar influenza vaccine efficacy as nonpregnant women,[34] which highlights the limitations of using antibody levels alone as predictors of influenza vaccine efficacy, particularly, in HIV-infected pregnant women.

PLACENTAL TRANSFER

The immune system in newborns and young infants is functionally immature at birth. Notably, this functional immaturity is not universal, as some functions are mature even in preterm infants.[35] Antibody responses in neonates have an overall delayed onset, reach lower peak levels, and have a shorter duration.[35] Moreover, neonates have low levels of several components of the complement system.[36] Neonatal $CD4^+$ T cells have diminished Th1 effector capacity and a limited ability to generate memory cells.[37]

Placental transfer of antibodies provides a mechanism to compensate for functional deficiencies in some aspects of the immune responses among newborns and young infants. Maternal IgG is efficiently transferred across the placenta using active transport through syncytiotrophoblasts. This transfer is mediated by neonatal Fc receptors (FcRns).[35] Two cell layers are encountered by substances that are transferred from maternal to fetal blood. The first layer consists of syncytiotrophoblasts, the multinucleated cells of placental villi. The second layer consists of endothelial cells of fetal capillaries. Moreover, the villous stroma is inhabited by placental macrophages (Hofbauer cells) and fibroblasts that may play a role in binding and trapping immune complexes.[38]

There are multiple mechanisms for transfer of substances from maternal to fetal blood. Substances smaller than approximately 500 Da are transferred through diffusion across the placental tissue. Very large molecules such as IgG (which is approximately 160 kDa) are transferred through active transport.[35] IgG from maternal blood is taken up by syncytiotrophoblasts through fluid-phase endocytosis followed by binding with FcRns in the acidic endosomal environment.[39] The endosomes with bound IgG may move across the syncytiotrophoblast and release the bound IgG when it reaches the basolateral side of the cell upon exposure to neutral pH (i.e., pH 7.4).[40–42] This pH-dependent IgG transport enables movement of antibodies against the concentration gradient and often results in a higher concentration of maternal antibodies in the fetus compared to maternal circulation. After being transcytosed through syncytiotrophoblasts, the IgG passes through the fetal capillary epithelium, either directly or after passing through the villous stroma, and enters fetal circulation.

The mother-to-fetus transfer of IgG may begin as early as 13 weeks of gestation; however, the largest amount of antibodies is transferred in the third trimester.[43] The IgG_1 subclass is more effectively transferred from the mother to the fetus compared to other IgG subclasses. The quantity of IgG transferred is dependent on maternal IgG levels, gestational age, coinfection, and (possibly) nutritional factors. IgG titers are generally lower in preterm infants compared to term infants.[44] Similarly, low birth weight is associated with reduced transfer of maternal IgG to the infant.[45] However, this transfer is not influenced by parity, maternal age, weight, height, and type of delivery.[46,47]

There may be differences in transfer for antibodies against polysaccharide versus protein antigens. In a study of paired maternal delivery and cord blood samples, antibodies specific for *Neisseria meningitidis* serogroup C polysaccharide, *Haemophilus influenzae* type B (Hib) polysaccharide, diphtheria toxin, tetanus toxin, and multiple antigens from *Bordetella pertussis* were examined.[48] In this study, antibody concentrations directed toward polysaccharides were equal in maternal and cord blood, whereas antibody concentrations to proteins were 1.6 times higher in cord blood than in maternal blood.[48]

Infection with "unrelated" pathogens (i.e., pathogens not specifically targeted by a given vaccine) can potentially impact mother-to-fetus antibody transfer. Studies of the effect of malaria infection during pregnancy on placental antibody transfer, mainly focusing on antimeasles and anti–tetanus toxin antibodies, have produced contrasting results.[49–59] In mothers immunized against tetanus, malaria infection during pregnancy is associated with reduced infant antibodies against tetanus antigens.[60,61] Among women with documented placental malaria, there was a 48% reduction in neonatal tetanus antibody titers when compared with neonates born without evidence of placenta malaria infection.[60] However, malaria during pregnancy was not associated with reduced measles antibodies in neonates using the same set of specimens.[57] A study in Papua New Guinea clearly showed interference with placental antibody transfer of tetanus antibodies associated with severe malaria in the mother.[52] Other studies in Malawi and the Gambia found no association between placental malaria and tetanus antibody levels in the newborn.[56] It is possible that the differing results relate to variations in prevalence of severe malaria. Nonetheless, these considerations need to be assessed with regard to maternal immunization.

HIV infection may also reduce transplacental antibody transfer of measles and tetanus antibodies.[60,63] However, there is a need for further evaluation of the impact of infection on maternal antibody transfer, particularly in the context of nonparasitic infection.

Kinetics and decay of transferred maternal antibodies in infants may vary by source of antibody. For example, after the mother's vaccination, RSV antibodies have a relatively shorter half-life in infants compared to maternally derived RSV antibodies after natural exposure.[64–69] Moreover, at least for influenza, the half-life of maternal antibody depends on the specific viral antigen (e.g., H3N2 vs H1N1 vs influenza B) included in an (inactivated) vaccine.[70] However, limited evidence suggests that there may be no difference in antibody decay by study population/location, but this evidence primarily comes from evaluation of measles antibody transfer and may not be generalizable to other antigens.[71]

Maternal antibodies, particularly after vaccination in pregnancy, can potentially interfere with vaccine responses in infants—particularly humoral responses. The impact of maternal antibodies on infant vaccine responses is not only variable by vaccine but could also vary by population specific factors.[72] Most of the evidence for mechanisms of inhibition have been generated in contexts other than vaccination (e.g., passive intravenous antigens).[15] The mechanisms for inhibition of infant vaccine responses by maternal antibodies that have supporting evidence include F(ab')2-dependent mechanisms such as inhibition of B-cell recognition of vaccine antigens through masking; neutralization of (live viral) epitopes; and opsonization, phagocytosis, and clearance of vaccine antigens mediated by maternal IgG.[73–76] Moreover, hypotheses focusing on Fc-dependent inhibition have found supporting evidence. These potential Fc-dependent mechanisms include inhibition of infant B-cell activation and antibody production, FcγR-mediated postopsonization phagocytosis resulting in vaccine antigen clearance, maternal IgG saturation of infant

endothelial or myeloid FcRn and acceleration of catabolism of vaccine-induced infant IgG, inhibition of infant dendritic cells by ingested and absorbed maternal IgA via FcαRI and FcαμR.[15,76–84]

CLINICAL ISSUES REGARDING VACCINATIONS DURING PREGNANCY

Whereas inactivated vaccines are fairly safe in pregnancy, live vaccines are generally avoided during pregnancy and during the 4 weeks preceding a pregnancy. For many live vaccines, immunization poses a theoretical rather than a documented risk. For example, measles, mumps, and rubella vaccine (MMR) has not been linked to fetal infection, congenital anomalies, or other adverse pregnancy outcomes.[85–88] By contrast, vaccination with live smallpox vaccine has resulted in fetal infection with vaccinia, the virus contained in the vaccine. However, this risk is very low; a recent systematic review of the worldwide literature identified only 21 presumed cases from 1809 to 2014.[89]

Some vaccines contain adjuvants which are added to boost the immune response and potentially provide better protection against antigenically drifted viruses. For example, aluminum salts have used in a variety of vaccines such as hepatitis A, hepatitis B, and tetanus vaccines. Data from aluminum-based adjuvanted vaccines in pregnancy are reassuring with no increased risk of adverse pregnancy outcomes. Newer adjuvants such as oil-in-water emulsions (e.g., AS03, MF59) were used in some H1N1 influenza vaccine preparations. These adjuvanted vaccines were administered to pregnant women in several European countries and no increased risk of adverse outcomes was found.[90] Thimerosal is a mercury preservative used in some vaccines (thimerosal has been removed from most vaccines in the United States). Despite speculation about a link between childhood vaccine exposure and autism, extensive epidemiologic investigation does not support such an association.[91] Furthermore, there is no evidence that thimerosal-containing vaccines administered in pregnancy are harmful to offspring.[92] Consequently, the Advisory Committee on Immunization Practices (ACIP) does not recommend that pregnant women avoid thimerosal-containing vaccines. However, thimerosal-free formulations of most vaccines, such as seasonal influenza, are available.

Women are vaccinated during pregnancy for variety of reasons. Table 36.1 summarizes the recommendations and rationale for use of vaccinations in pregnancy.

Currently, there are only two vaccines routinely recommended in pregnancy in the United States and many other high-income and middle-income countries: the seasonal influenza vaccine and Tdap (several low-income and middle-income countries include maternal tetanus toxin or diphtheria and tetanus toxoids in their immunization programs). For these recommended vaccines, rates of vaccination use in pregnancy remain disappointingly low in the United States. Although there has been a sustained increase in vaccination coverage rates for seasonal influenza among pregnant women since the 2009 H1N1 influenza pandemic, coverage rates in the United States remain at approximately 50% among pregnant women.[104] When healthcare providers specifically recommend to their pregnant patients that they receive the influenza vaccine, vaccination rates are higher. Rates of Tdap vaccination during pregnancy are even lower.[119]

Maternal Immunizations for Maternal Benefit

Vaccination during pregnancy may be particularly important for infectious diseases to which pregnant women are more susceptible or more likely to develop severe disease. For influenza, there is evidence that infection is more severe in pregnancy, that vaccination reduces the risk of maternal influenza illness, and that the vaccine is safe in pregnancy.[120–128] Because of the maternal as well as fetal and infant benefits, seasonal influenza vaccine is routinely recommended in pregnancy. The ACIP recommends that women who are or will be pregnant during influenza season receive the vaccine as early as possible in the season, regardless of trimester.[129]

For other vaccine-preventable illnesses, the calculation of risks and benefits may be less straightforward, particularly with live vaccines. For example, yellow fever is a mosquito-borne illness that can cause severe disease and death. Therefore, the ACIP recommends that people be vaccinated with the live vaccine before traveling to endemic areas. Because live vaccines are generally not recommended in pregnancy, pregnant women should be advised to avoid travel to areas with endemic yellow fever. However, if travel is unavoidable, then vaccination is not contraindicated and should be considered.[118]

Both smallpox and anthrax are potential bioterrorism agents that could be intentionally introduced. With both pathogens, pregnant women are at risk for severe disease. However, due to benefit versus risk considerations, vaccination is not recommended in a preevent setting. In postevent settings, the recommendations for vaccine are the same for pregnant women as they are for nonpregnant adults.[89,93]

Maternal Immunizations for Neonatal Benefit

Maternal antibodies that are transferred across the placenta may provide passive immunization of the fetus and infant. These antibodies may protect the fetus from maternal in utero or intrapartum transmission. In addition, because young infants fail to mount an adequate immune response to vaccination, persistent maternal antibodies may provide immunologic protection until the child is old enough to be vaccinated.

Worldwide, neonatal tetanus has been a leading cause of neonatal death in resource-limited countries where aseptic obstetric and safe umbilical cord practices are not commonly practiced. Immunization of pregnant women with tetanus toxoid was first recommended by the World Health Organization (WHO) in 1974 to prevent neonatal tetanus. Despite this recommendation, only about one-quarter of eligible pregnant women were receiving the recommended two doses of tetanus toxoid in the 1980s and the burden of neonatal tetanus remained high. In 1990, WHO launched its neonatal tetanus elimination program which emphasized the importance of maternal tetanus immunization. In 1999, WHO renamed this initiative the Maternal and Neonatal Tetanus Elimination Program to emphasize the role of maternal tetanus and its contribution to maternal mortality. Although great strides have been made, neonatal tetanus continues to cause a substantial number of neonatal deaths worldwide. Continued efforts to promote maternal immunization, in addition to clean delivery practices, are critical.[113,130]

In the United States, Tdap is recommended for pregnant women close to delivery, ideally at 27 to 36 weeks of gestation. Tdap was recommended as a strategy to protect infants from pertussis as young infants are at the highest risk for morbidity and mortality from pertussis. This ideal gestational age was chosen to maximize passive immunity as antibody levels wane fairly rapidly. The ACIP has recommended Tdap in pregnancy since 2011 and in 2012 the ACIP updated the guidance to include reimmunization with each subsequent pregnancy.[112] Although this is one of the two vaccines specifically recommended in pregnancy, coverage rates for Tdap during pregnancy remain low in the United States.[119,131]

TABLE 36.1 Recommendations and Rationale for Use of Vaccinations in Pregnancy

Infection/Vaccine	Recommendations	Type of Vaccine	Rationale and Clarification
ANTHRAX			
Anthrax Vaccine Adsorbed (AVA)[93]	Per the CDC, AVA is not recommended for pregnant women in a preevent setting. Postexposure vaccination is recommended for pregnant women at high risk for inhalational anthrax, regardless of pregnancy trimester.	Inactivated	Although it is not clear whether pregnant women are more susceptible to anthrax or more likely to develop severe disease, anthrax in pregnancy has resulted in maternal and neonatal deaths. Given the severity of anthrax, pregnant women should receive the same postexposure prophylaxis as the general population, which includes AVA vaccination. From reports of vaccination during pregnancy, largely from inadvertent predeployment vaccination of women in the military, no concerning maternal or infant safety patterns were reported.
GROUP B STREPTOCOCCUS DISEASE			
Group B Streptococcus (GBS) vaccine[94–96]	Not available.	Inactivated	In development. GBS infection remains a source of infant morbidity and mortality. Although intrapartum antimicrobial prophylaxis reduces early onset disease, it does not prevent later onset disease (beyond 7 days of life). Maternal vaccination with a GBS vaccine could potentially reduce the burden of GBS disease in both infants as well as women (e.g., postpartum endometritis).
HAEMOPHILUS INFLUENZAE			
Haemophilis influenzae type b (Hib) vaccine[97]	In developing country settings where Hib remains an important cause of meningitis in children, maternal vaccination may provide early protection.	Inactivated	The ACIP does not have recommendations for Hib as childhood vaccination programs in the U.S. have dramatically reduced morbidity and mortality from Hib. However, in settings where Hib is still a common cause of bacterial meningitis in children, maternal Hib vaccination may provide some protection for children <18 months of age who have not yet completed their vaccination series. There are reassuring safety and immunogenicity data from vaccination in the third trimester of pregnancy.
HEPATITIS			
Hepatitis A Vaccine (HAV)[98,99]	Per the ACIP, high-risk susceptible pregnant women may be vaccinated after weighing the potential risks and benefits.	Inactivated	Risk factors for hepatitis A include, but are not limited to, chronic liver disease, HIV infection, and travel to countries with high prevalence of disease. If a pregnant woman is exposed to hepatitis A, she should receive HAV and immunoglobulin. In the VAERS, no concerning patterns of adverse events in pregnant women vaccinated with HAV or their infants have been observed.
Hepatitis B Vaccine (HBV)[100]	High-risk susceptible pregnant women may be vaccinated.	Recombinant	Risk factors for hepatitis B include, but are not limited to, chronic liver disease, HIV infection, multiple sex partners, injection drug use, working in healthcare, chronic hemodialysis, and travel to countries with high prevalence of disease. The recommended schedule is 0, 1 month, and 6 months but an accelerated schedule is possible in pregnancy. Safety data indicate no concerning patterns of adverse events in vaccinated pregnant women or their infants.
Combined HAV and HBV[98–100]	High-risk susceptible women may be vaccinated.	Inactivated, recombinant	In VAERS, no concerning patterns of adverse events in vaccinated pregnant women or their infants.
HUMAN PAPILLOMAVIRUS			
Human Papillomavirus (HPV) vaccine[101,102]	Not recommended for use in pregnancy.	Inactivated	Although harmful effects from vaccination in pregnancy have not been found, HPV vaccine is not recommended in pregnancy. If a woman who started the vaccine series is found to be pregnant, she should delay completion of the vaccine series until completion of the pregnancy. Trial data, registry data, and VAERS found no unexpected patterns in maternal or fetal outcomes among pregnant women inadvertently vaccinated with the bivalent or quadrivalent vaccine.
INFLUENZA			
Inactivated influenza vaccine[103]	Per the ACIP, women who are or will be pregnant during influenza season should receive as early as possible in pregnancy regardless of trimester. In some non–U.S. countries, the vaccination is recommended after the first trimester.	Inactivated	Pregnant women with influenza are more likely to develop severe disease and die compared with nonpregnant women. Multiple studies including randomized controlled trials in Bangladesh and South Africa have demonstrated the benefits of influenza vaccine for pregnant women and their infants. In the U.S., influenza vaccination was first recommended in pregnancy in 1960 and has a long record of safety and effectiveness data.

Continued on following page

TABLE 36.1 Recommendations and Rationale for Use of Vaccinations in Pregnancy *(Continued)*

Infection/Vaccine	Recommendations	Type of Vaccine	Rationale and Clarification
Live-attenuated influenza vaccine (LAIV)[104]	Per the ACIP, LAIV is not recommended for use in pregnancy.	Live	Live vaccines have the potential for fetal infection and in general should be avoided in pregnancy. From VAERS, there are no concerning patterns of birth outcomes following inadvertent vaccination with LAIV.
JAPANESE ENCEPHALITIS			
Japanese encephalitis (JE) vaccine[105]	Per the ACIP, JE vaccination should generally be deferred. However, pregnant women who must travel to an area where JE risk is high should be vaccinated if the benefits outweigh the risks.	Inactivated	Although little is known about Japanese encephalitis virus infection in pregnancy, intrauterine transmission likely occurs. However, even in endemic areas, Japanese encephalitis virus infection is rare.
MEASLES, MUMPS, AND RUBELLA			
Measles-mumps-rubella (MMR) vaccine[85,106]	Per the ACIP, should not be used in pregnancy.	Live	Because of theoretical risks of this live vaccine, pregnant women or those planning to become pregnant should not receive this vaccine. Women should be counseled to avoid pregnancy for 28 days following receipt of the vaccine.
MENINGOCOCCAL DISEASE			
Meningococcal polysaccharide vaccine (MPSV4)[107]	Per the ACIP, pregnancy should not preclude vaccination if indicated.	Inactivated	Quadrivalent (serogroups A, C, W, Y) meningococcal polysaccharide vaccine was licensed in the United States in 1981. Generally used when person has a contraindication to the quadrivalent vaccine *and in adults aged ≥55 years*. No reports of concerning patterns of adverse effects in vaccinated pregnant women or their infants.
Meningococcal (MenACWY)[107]	Per the ACIP, pregnancy should not preclude vaccination if indicated.	Inactivated	Conjugated quadrivalent (serogroups A, C, W, Y) vaccine. In VAERS, no concerning patterns of adverse effects in vaccinated pregnant women or their infants.
Meningococcal B (Men B)	Per the ACIP, no recommendation for pregnant women.	Inactivated	Serogroup B vaccine. No randomized controlled clinical trials have been conducted to evaluate use of MenB vaccines in pregnant or lactating women. Vaccination should be deferred in pregnant and lactating women unless the woman is at increased risk, and, after consultation with her healthcare provider, the benefits of vaccination are considered.
PNEUMOCOCCAL DISEASE			
Pneumococcal polysaccharide vaccine (PPSV23)[108]	Vaccination is not routinely recommended in pregnancy but can be given to those at increased risk of disease.	Inactivated	Although the ACIP states that there is inadequate information to make a recommendation, it has been used in the second and third trimester without an apparent increased risk of adverse outcome. There is less information about use in the first trimester. A Cochrane review summarizing 6 randomized trials concluded that there was insufficient evidence to assess whether vaccination during pregnancy reduces infant infections. Women with indications for vaccination (e.g., those with asplenia, cochlear implants, emphysema, chronic heart disease, chronic liver disease) should be vaccinated prior to pregnancy.
Pneumococcal conjugate vaccine (PCV13)[108]	If vaccination against pneumococcal disease is indicated in pregnancy, it may be reasonable to preferentially vaccinate with PPSV23.	Inactivated	Conjugated vaccine. The ACIP has not published pregnancy recommendations owing to lack of information about use in pregnancy. Although there are no data from pregnant humans, animal studies have not shown adverse effects of the vaccine in pregnancy. Use of PCV13 is limited among women of childbearing age.
POLIOVIRUS			
Inactivated polio vaccine (IPV)[109]	Vaccination should be avoided in pregnancy unless the pregnant woman is at increased risk for polio infection and requires immediate protection.	Inactivated	Polio has been eliminated from many countries including the United States, where routine vaccination is no longer recommended. Pregnant women should avoid travel to polio endemic countries if possible. If they do travel to these areas, they should be vaccinated. IPV is the only vaccine available in the United States; live-attenuated oral polio vaccine is available outside of the United States. No reports of concerning patterns of adverse effects in vaccinated pregnant women or their infants.

TABLE 36.1 Recommendations and Rationale for Use of Vaccinations in Pregnancy *(Continued)*

Infection/Vaccine	Recommendations	Type of Vaccine	Rationale and Clarification
RABIES			
Rabies vaccine[110]	Pregnancy is not a contraindication to postexposure vaccination. If a woman is at high risk for exposure, preexposure vaccination may also be considered.	Inactivated	No increased risk of adverse events among women vaccinated in pregnancy or their infants. For postexposure prophylaxis, immunoglobulin may also be given.
RESPIRATORY SYNCYTIAL VIRUS			
Respiratory syncytial virus (RSV) vaccine[97]	Not available	Inactivated (products being considered for maternal use)	In development. RSV is an important cause of morbidity and mortality among young infants. Because of poor immunogenicity of vaccines given to young infants, maternal vaccination might be an effective strategy for prevention of RSV in infants. A recombinant RSV fusion protein nanoparticle vaccine (RSV F vaccine) candidate was immunogenic and safe in a Phase II trial in women of childbearing age.[111]
SMALLPOX			
Smallpox vaccine[89]	Per the ACIP, pregnant women should not be vaccinated in a preevent setting. Per the CDC, pregnant women should be vaccinated in a postevent setting if they are exposed to or at high risk for developing disease.	Live	Although smallpox has been eradicated, there is concern that it could be intentionally reintroduced. Pregnant women are at increased risk for severe disease and death from smallpox. Fetal infection with vaccinia (live virus in the vaccine) is a possible but rare outcome from vaccination in pregnancy. The overall risk of adverse outcomes from vaccination in pregnancy is low, but there may be a small increased risk of congenital defects from vaccination during the first trimester of pregnancy.[110–112]
TETANUS, DIPHTHERIA, AND PERTUSSIS			
Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine[112]	Per the ACIP, pregnant women should receive a dose of Tdap during each pregnancy, ideally between 27 and 36 weeks of gestation.	Toxoid, inactivated	As a consequence of recent increases in the number of cases of neonatal pertussis in the United States, the ACIP recommends Tdap vaccination during pregnancy to protect young infants who are most susceptible to severe illness and are unable to be vaccinated. This vaccine is recommended in each pregnancy close to the time of delivery because of waning antibody levels. Maternal vaccination close to delivery provides passive immunity to infants.
Tetanus and diphtheria (Td) vaccine[112]	Per the ACIP, pregnant women without 3 prior doses of tetanus and diphtheria vaccination should receive 3 vaccinations in pregnancy including 1 dose of Tdap, ideally at 27–36 weeks of gestation.	Toxoid	The recommended schedule is 0 and 4 weeks, and 6–12 months. Tdap should replace 1 dose of Td.
Tetanus toxoid[113]	Per the WHO, in areas with maternal and neonatal tetanus cases, pregnant women without adequate tetanus vaccination should receive 2 doses of tetanus toxoid during pregnancy and 1 dose in each subsequent pregnancy up to a total of 5 doses.	Toxoid	In some developing countries, mainly in Asia and Africa, tetanus contributes substantially to maternal and neonatal mortality, largely because of unclean delivery practices such as the care of the umbilical cord. To reduce mortality, the WHO implemented the Maternal and Neonatal Tetanus Elimination initiative to promote vaccination of women of childbearing age, including those who are pregnant.
TUBERCULOSIS			
Bacille Calmette-Guérin (BCG) vaccine[114]	Per the ACIP, not recommended in pregnancy.	Live	Although harmful effects have not been shown, BCG is not recommended for use in pregnancy.
TYPHOID			
Typhoid vaccine[115]	If indicated, the inactivated vaccine should be used rather than the live vaccine in pregnancy.	Inactivated	Although the ACIP has not published guidance, the inactivated vaccine should be used rather than the live vaccine in pregnancy. If possible, pregnant women should avoid travel to typhoid affected areas.
Typhoid oral vaccine[115]	Avoid the live vaccine in pregnancy.	Live	Although the ACIP has not published guidance, the inactivated vaccine should be used rather than the live vaccine in pregnancy.

Continued on following page

TABLE 36.1 Recommendations and Rationale for Use of Vaccinations in Pregnancy *(Continued)*

Infection/Vaccine	Recommendations	Type of Vaccine	Rationale and Clarification
VARICELLA			
Varicella vaccine[116]	Per the ACIP, pregnant women should not be vaccinated.	Live	Varicella vaccine should not be given during pregnancy because it is a live vaccine. If a nonimmune pregnant woman is exposed to varicella, immunoglobulin should be given.
Zoster vaccine[117]	Per the ACIP, zoster vaccine is not recommended for use in pregnancy.	Live	Because this vaccine is generally used in older adults (>60 years), pregnant women are unlikely to require vaccination. Also, because it is a live vaccine, herpes zoster vaccine should not be used in pregnancy. There is no safety information available in pregnancy.
YELLOW FEVER			
Yellow fever (YF) vaccine[118]	Per the ACIP, pregnancy is a precaution but not a contraindication for vaccination; in cases where the risks of exposure are felt to outweigh the vaccination risks, a pregnant woman should be vaccinated.	Live	In cases where a pregnant woman is traveling to an endemic country and she is not vaccinated because the vaccination risks seem to outweigh her risk of exposure, she should be issued a medical waiver to fulfill travel requirements.

Group B streptococcus (GBS) is a leading cause of infection-related neonatal deaths. Although intrapartum antibiotic prophylaxis has resulted in a dramatic drop in the incidence of early-onset neonatal sepsis caused by GBS, the rates of early-onset disease have plateaued and late-onset GBS disease is not reduced by intrapartum prophylaxis. Therefore, efforts have been focused on development of a safe and effective GBS vaccine that could be administered to pregnant women to protect their infants. Since the 1990s, the safety and immunogenicity of several candidate GBS polysaccharide–protein conjugate vaccines have been under investigation. Currently, a trivalent GBS polysaccharide–protein conjugate vaccine is in Phase II trials among pregnant women in Europe, North America, and Africa.[94,95,132]

Globally, RSV is the most significant cause of viral acute lower respiratory tract illness.[133,134] RSV has a particularly high burden among young infants, making this disease a potential target for maternal immunization.[135] There are ongoing efforts to develop a maternal RSV vaccine. Phase II trials of an RSV vaccine were recently completed. A recombinant RSV fusion protein nanoparticle vaccine (RSV F vaccine) candidate was shown to be immunogenic and safe in a Phase II trial in women of childbearing age.[111]

Maternal Immunization and Impact on Birth Outcomes

Pathogens such as influenza and GBS have been associated with adverse birth outcomes including fetal loss, preterm birth, low birth weight, and small for gestational age.[120,136–139] The evidence for influenza's impact on birth outcomes is strongest for pandemics, although such evidence also exists for seasonal influenza.[120,136,138,140–145] A significant proportion of this evidence comes from studies conducted prior to the development of modern methods for assessing quality of epidemiological evidence, making it challenging to apply modern quality criteria to these data. However the consistency of evidence, particularly in the context of pandemics, strongly suggests that influenza infection in pregnancy is associated with adverse birth outcomes.[120,136,140]

Potential biological mechanisms through which pathogens can result in adverse birth outcomes include local/placental infection and systemic inflammation.[146] Inflammation, irrespective of the cause, is thought to play a substantial role in adverse birth outcomes. For example, inflammation may be a contributory factor in as much as 40% of preterm births.[146] Increase in proinflammatory (and decrease in antiinflammatory) cytokines is associated with physiological cascades that eventually result in increased levels of mediators of parturition such as prostaglandins and matrix metalloproteinases.[147] Many viral and bacterial pathogens have been associated with systemic increases in proinflammatory cytokines and, in some cases, preterm birth.

Because (with only a few exceptions) influenza does not cause direct placental or fetal infection, the most probable mechanism for adverse birth outcomes after influenza infection of pregnant women is through inflammation. On the other hand, GBS infection can result in bacteremia, chorioamnionitis, or endometritis. These infections can result in spontaneous abortion, preterm delivery, and stillbirth.

Adverse birth outcomes, such as preterm birth and low birth weight, are associated with significant morbidity and mortality worldwide. Given the role of maternal infection in adverse outcomes, maternal vaccination can potentially act as a useful tool for countering the burden and consequences of adverse birth outcomes.

There is compelling, but as yet inconclusive, evidence that maternal influenza immunization protects against outcomes such as preterm birth,[138,148–153] small for gestational age,[138,145,148] and stillbirth.[120,154] Most of this evidence comes from observational studies, although data are also publically available from three trials of maternal influenza immunization. Generally, larger observational studies and studies that account for influenza virus circulation tend to show a protective effect of maternal influenza vaccination on outcomes such as preterm birth and stillbirth, often restricted to the influenza virus

circulation period.[138,148] In a randomized, controlled trial in Bangladesh, maternal immunization during pregnancy was associated with a lower proportion of infants who were small for gestational age and an increase in mean birth weight during the period when influenza virus was circulating.[145] In contrast, trials in South Africa and Mali reported no impact of maternal influenza immunization on birth outcomes,[34,154a] although data stratified by the time of influenza circulation have not been published for these trials. A large randomized, controlled trial in Nepal demonstrated a 15% reduction in low birth weight among newborns of mothers who received influenza vaccination in pregnancy, compared to newborns of unvaccinated women.[155]

A few considerations should be kept in mind when interpreting the trial results in regard to bird outcomes.[155a] For example, the Nepal trial is unique as, in addition to lab-confirmed influenza, it was designed and powered to evaluate the impact against low birth weight—the only trial with a birth outcome as a (co-) primary end point.[156] This translated into a lower liklihood of type II error and a more robust assessment of birth outcomes, such as measuring birth weight in grams rather than kilograms (hence, having a higher ability to detect a difference in birth weight). Moreover, the women in the Nepal trial were vaccinated at an earlier gestational age,[156] providing an opportunity to protect the fetus for a longer period. Maternal influenza immunization may be particularly useful in reducing adverse birth outcomes at locations where influenza tends to circulate for more months than most other regions, therefore potentially exposing a higher proportion of pregnancies to influenza. Similarly, assessment of gestations age is suboptimal if it is conducted for the first time in late pregnancy (e.g., for women enrolled in the third trimester) or at delivery. In the otherwise high-quality Mali trial, the main approach to assess gestational age was the New Ballard score. However, ultrasound information was available for approximately 13% of the women. In the subgroup of women with ultrasound data, the correlation between ultrasound and Ballard core-based gestational age was only 0.4.[154a]

Importantly, newborns in areas where the Nepal and Bangladesh trials were conducted had lower birth weight compared with populations where the South Africa and Mali trials were conducted.[156] A potential implication of lower baseline birth weights in trials showing a protective effect of maternal influenza vaccination on birth outcomes is that maternal influenza vaccine may be more useful for vulnerable populations.

Inadvertent Vaccination During Pregnancy

A common clinical question that arises is what to do when a pregnant woman inadvertently receives a vaccine not recommended for use in pregnancy. These inadvertent exposures often occur during the first trimester, before pregnancy is recognized and during the period of organogenesis. For many vaccines, there is less known about safety in the first trimester compared with other trimesters, even for well-studied vaccines such as influenza. As pregnant women are often excluded from prelicensure clinical trials of vaccines, postmarketing surveillance is important and several systems and registries are in place to monitor safety in pregnancy. There are also some efforts underway in the United States to include pregnant women in future vaccine trials.[157]

Safety of Maternal Vaccines

Safety of vaccines administered in pregnancy should be conceptualized in the context of a developing embryo/fetus (Table 36.2). Embryonic and fetal development is often categorized into three stages relevant to teratogenesis: preimplantation, embryonic, and fetal stages. Each stage is associated with a different profile of potential adverse effects. For example, one would be concerned about spontaneous abortions in the preimplantation period (gestational age 2–4 weeks); organ malformations during the embryonic period

TABLE 36.2 Gestational Time Periods Relevant to Vaccination in Pregnancy

Period	Gestational Age (Weeks Since LMP)[a]	Events	Potential Teratogenic Effects
Preimplantation	2–4 wk	Fertilization, cell division, blastocyst formation, implantation	Injury to large number of cells → spontaneous abortion *or* Injury to small number of cells → survival without abnormalities
Embryonic	4–11 wk	Organogenesis	Malformations, altered function Onset for major defects in organs: • CNS: 5 weeks • Heart: 5 weeks • Sensory organs (eyes, ears): 6 weeks • Limbs: 6 weeks • Palate: 8 weeks • Teeth: 8 weeks • Genitalia: 9 weeks
Fetal	11 wk to term	Growth, differentiation, maturation	SGA/IUGR, fetal death, minor malformations, and altered function Continued susceptibility period for minor defects in organs: • CNS: to end of period • Sensory organs: to end of period • Palate: through 11 weeks • Teeth: to end of period • Genitalia: to end of period

[a]Note: Gestational age values, as presented, specifically reference time since LMP. Embryonic age is considered to be 2 weeks less than gestational age.

CNS, central nervous system; IUGR, intrauterine growth restriction; LMP, last menstrual period; SGA, small for gestational age.

Modified from Bednarczyk RA, Adjaye-Gbewonyo D, Omer SB. Safety of influenza immunization during pregnancy for the fetus and the neonate. Am J Obstet Gynecol. *2012;207:S38–S46; Buhimschi CS, Weiner CP. Medications in pregnancy and lactation: part 1. Teratology.* Obstet Gynecol. *2009;113:166–188; and Hill MA. Early human development.* Clin Obstet Gynecol. *2007;50:2–9.*

(i.e., 4–11 weeks of gestation); and outcomes such as preterm birth, stillbirth, small for gestational age, and functional malformations during the fetal (11 weeks through term) period (Table 36.2).[158,159,160]

MATERNAL VACCINES IN CLINICAL USE

Influenza Vaccine

Pregnant women with influenza are more likely to develop severe disease and die compared with nonpregnant women, particularly during pandemics.[97]

The live attenuated influenza vaccine is not recommended for use in pregnancy based on theoretical risks of adverse events potentially associated with live vaccines. In the United States, inactivated influenza vaccine was first recommended in pregnancy in 1960 and has substantial safety and effectiveness data.[103,158,161] According to the ACIP, women who are or will be pregnant during influenza season should receive the inactivated influenza vaccine as early as possible in pregnancy regardless of trimester.[103] In some non-U.S. countries, the vaccination is recommended after the first trimester.

Multiple studies, including randomized, controlled trials, have demonstrated the benefits of influenza vaccine for pregnant women and their infants. In a randomized, controlled trial in Bangladesh, the vaccine reduced the risk of influenza like illness among women vaccinated in the third trimester of pregnancy by approximately one-third.[162] The efficacy for lab-confirmed influenza among infants younger than 24 weeks of age in the Bangladesh trial was 63%.[162] Similarly, in a randomized, controlled trial in South Africa, the efficacy of inactivated influenza vaccine administered in second and third trimesters of pregnancy was approximately 50% among HIV-uninfected women and their infants younger than 24 weeks of age.[34] In a parallel cohort including HIV-infected women, the vaccine efficacy was 58% among mothers.[34] However, there was no statistically significant impact among infants of HIV-infected women, although with a study cohort of 194, there was very limited statistical power to detect a difference. The South Africa study also documented substantially higher attack rates among HIV-infected women compared to noninfected women.[34] In a trial in Mali, where pregnant women were randomized to either receive influenza vaccine or meningococcal vaccine, the efficacy for protection against influenza in infants younger than 6 months was 33%. In another randomized trial conducted in Nepal, the infants of women who received influenza vaccine between 17 and 34 weeks' gestation were 30% less likely to have influenza compared with infants of women who received placebo.[155]

An important consideration for clinical and public health maternal immunization recommendations is the duration of protection for infants. In the Bangladesh trial, the maternally derived antibodies in infants had a half-life of approximately 6 to 7 weeks.[70] In the South Africa trial the vaccine was only protective through the first 8 weeks of life.[162a] On the other hand, in the Mali trial vaccine efficacy was 68% through 4 months of age.[156] Although the efficacy diminished to 57% in the fifth month, the vaccine continued to provide protection through the first half of infancy.[156] Further detailed results are awaited from the randomized controlled trials of maternal influenza immunization in Nepal, Mali, and South Africa aimed at evaluating the impact of inactivated influenza vaccine on pregnant women and their infants.[156]

Randomized controlled trials have been very useful in establishing the efficacy of maternal influenza vaccine for pregnant women and their infants. However, the trial sample sizes ranged from approximately 300 to approximately 4000. Therefore these trials are limited in their ability to detect an impact on severe but relatively rare outcomes such as hospitalization. Fortunately, there are several recent large observational studies that have evaluated the effectiveness of maternal influenza immunization against severe outcomes. In a study of approximately 250,000 women in the United States, maternal immunization was associated with an 83% reduction in hospitalizations with laboratory-confirmed influenza. Similarly, in a series of studies in Western Australia, maternal influenza immunization was associated with a 25% reduction in infant hospitalization with acute respiratory illness, an 81% reduction in maternal emergency department visits, and a 65% reduction in hospitalizations during pregnancy.[162b,162c]

Overall, (inactivated) influenza vaccine administered in pregnancy has a good safety record.[103,122] However, most of the safety data come from the late second and third trimester and from studies evaluating the 2009 pandemic H1N1 vaccine and the data from the first trimester are limited. In a small retrospective cohort study with 439 first trimester births, there was no increase in major malformations, stillbirths, and neonatal pneumonia; however, there was increased risk of neonatal intensive care unit admissions among newborns of women vaccinated in the first trimester.[125] One of the larger retrospective studies that included approximately 8000 first trimester vaccinees did not find increased risk of stillbirth, early neonatal death, preterm birth, low birth weight, or small for gestational age.[163]

Data to support safety of maternal immunization in the second and third trimesters are substantial and robust.[103,122] However given the limited first trimester data and hitherto conflicting findings in studies evaluating the safety of first trimester influenza vaccination, there is a need to conduct further studies with first trimester vaccination. Further retrospective studies will continue to have limitations associated with retrospective studies (e.g., confounding associated with differential health seeking among vaccine recipients vs nonrecipients). Therefore, future efforts should focus on prospective studies. To capture early first trimester events, these studies may have to include reproductive-age women with a declared intention to get pregnant (e.g., presenting for prepregnancy consultation).

Vaccination Against Pertussis

Maternal immunization in pregnancy is a potential strategy to protect young infants against pertussis in two ways: first, passively transferred antipertussis antibodies can directly protect the infant; and second, prevention of pertussis in the mother can indirectly protect the child through decreasing exposure. Since 2012, both the United Kingdom's Department of Health and the United States' Centers for Disease Control and Prevention (CDC) recommended that all pregnant women receive a single dose of tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap) in the late second or third trimester with every pregnancy irrespective of previous Tdap history.[164,165] Although Tdap is already recommended for pregnant women in the United Kingdom and the United States, as well as in a few other countries such as Argentina and Brazil, it is not part of routine antenatal care in developing countries where the burden of pertussis is much higher.

There have been no Phase III trials of maternal Tdap administration. Therefore, data on efficacy of Tdap administration in pregnancy are not available. However, estimates of vaccine effectiveness from the United Kingdom suggest that, in a high-income-country context, pertussis vaccine in pregnancy has high effectiveness in preventing pertussis in early infancy. In the United Kingdom, pertussis vaccine administered in pregnancy was estimated to be 91% effective

(95% confidence interval [CI], 84 to 95) using the screening method, and 93% (95% CI, 81–97%) using the case-control method.[166,167] Similarly, data from a Phase I/II trial of Tdap in pregnancy, conducted in the United States, documented high concentrations of antibodies against pertussis in the first 2 months of life.[168] Another small trial in Vietnam reported higher geometric mean concentrations for all three measured pertussis antigens (i.e., pertussis toxin, filamentous hemagglutinin, and pertactin) in the infants of the Tdap group compared to the tetanus toxoid group, up to 2 months of age.[169]

Overall, the safety data for pertussis vaccination in pregnancy is reassuring. The data from United Kingdom's maternal pertussis program did not find any safety signals among mothers or infants. In a large study evaluating safety of Tdap administration in pregnancy using the Vaccine Safety Datalink (VSD) project, vaccination was not associated with increased risk of small-for-gestational-age, preterm birth, and hypertensive disorders of pregnancy.[170] However, compared to nonvaccinated women, approximately 20% more vaccinated women were diagnosed with chorioamnionitis (5.5% vs 6.1%). This finding needs to be interpreted with some context. In the United States, as a consequence of litigation-related concerns, many fevers in the third trimester are thought to be labeled as chorioamnionitis without further investigation. In fact, in the VSD study, chart reviews revealed that only half of the chorioamnionitis cases had a clinical presentation consistent with chorioamnionitis.[170] Moreover, in this study, the lack of increased risk of preterm birth, the most significant clinical consequence of chorioamnionitis, was reassuring.[170]

With the expansion of the maternal immunization platform, a theoretical concern is a potential for an increase in adverse events with concomitant administration of multiple vaccines. Reassuringly, a retrospective cohort study comparing adverse events among pregnant women receiving concomitant Tdap and influenza vaccination and women receiving these vaccines sequentially did not find a difference in adverse events between the two groups.[171] In another study, there was no difference in rates of acute postvaccination events (fever, allergy, local reactions) and adverse birth outcomes (small for gestational age, preterm delivery, low birth weight) in women vaccinated with Tdap vaccine in pregnancy, regardless of the time since the previous dose of a tetanus-containing vaccine.[172] Similarly, there was no elevated risk of structural birth defects, including microcephaly, among the offspring of women who received Tdap in pregnancy compared with offspring of women who did not.[172a] However, like influenza vaccine, most of the safety data for pertussis vaccination comes from the late second and the third trimesters.

Theoretically, maternal pertussis vaccination during pregnancy could result in attenuation of the infant immune response to childhood doses of pertussis vaccine. However, the evidence regarding attenuation of infant immune response to pertussis vaccines in the presence of maternal antibodies as a result of maternal vaccination in pregnancy or infection during or prior to pregnancy is inconsistent. Multiple studies published in the 1990s[173–175] evaluated differences in infant response to pertussis vaccines by presence of maternal antibodies prior to receipt of infant doses of (whole-cell or acellular) pertussis vaccine. As these studies were conducted prior to the recommendation of pertussis vaccination in pregnancy, the maternal antibodies were a result of infection or childhood immunization. Although there was considerable variability in findings from these studies, generally maternal antibodies were associated with greater attenuation in infant response to diphtheria and tetanus toxoids combined with whole-cell pertussis (DTwP) than that observed for diphtheria, tetanus, and acellular pertussis (DTaP).[173–175]

There are limited data on attenuation of infant DTaP responses after pertussis vaccination in pregnancy and there are no published studies assessing attenuation of DTwP response. A U.S. study found 0.7- to 0.8-fold lower concentrations of antipertussis antibodies after three doses of DTaP at 2, 4, and 6 months.[176] However, both prior to and following the recommended 12- to 18-month pertussis vaccine booster, antipertussis antibody levels in children of both vaccinated and control mothers were similar.[176] In a Phase I/II trial of maternal pertussis vaccination in the United States, the infant post-DTaP primary series responses were lower among the maternal vaccination group compared to infants of mothers who did not receive pertussis vaccine in pregnancy.[28] However, these differences did not persist after the 12-month booster dose. Another study from the United Kingdom documented substantially (0.51- to 0.67-fold) lower antipertussis antibodies after completion of the 2–3–4-month primary series with DTaP among infants of mothers who received pertussis vaccine in pregnancy compared to infants of women who were not vaccinated.[177] In a small trial in Vietnam of Tdap vaccination in pregnancy, potential attenuation was evaluated 1 month after completion of the 2–3–4-month primary infant vaccination with the acellular vaccine. In this trial, antipertactin antibodies (but not anti–pertussis toxin and anti–filamentous hemagglutinin antibodies) were lower in the infants born to mothers in the Tdap group.[169] The findings from the United Kingdom and Vietnam are particularly important because, like most countries, no pertussis booster is given the second year of life in the United Kingdom and Vietnam.

As there is no immunological correlate of protection for pertussis, the clinical significance of attenuation of infant DTaP responses is uncertain. Moreover, there is a need to evaluate attenuation of infant responses in countries that use DTwP for infant vaccination and countries with the 6–10–14-week schedule.

Tetanus Toxoid

Tetanus, caused by an exotoxin produced by *Clostridium tetani*, is an often fatal disease characterized by muscular rigidity and spasm.[113] Maternal and neonatal tetanus, which are associated with unhygienic birth practices such as unclean deliveries and care of the umbilical cord, are common causes of maternal and neonatal mortality in some resource-limited settings.[130] The Neonatal Tetanus Elimination Program, launched by the World Health Assembly in 1989, was later expanded to include maternal tetanus and renamed the Maternal and Neonatal Tetanus Elimination Program.[180] The aim of the initiative was to eliminate maternal and neonatal tetanus through promotion of clean birth and neonatal care practices, as well as maternal immunization with tetanus toxoid. Since these programs were launched, there has been a dramatic reduction in neonatal deaths worldwide and many more countries are now deemed free from neonatal tetanus (defined as less than 1 case of neonatal tetanus per 1000 live births). In addition to a commitment to safe delivery and neonatal care practices, this was accomplished by maternal immunization with tetanus toxoid. Because tetanus spores are widespread in the soil, it is not possible to eliminate them completely from the environment. Therefore, it is important to continue to immunize populations and in many settings pregnant women are routinely immunized.

The tetanus toxoid vaccine is considered very safe and effective in pregnancy. Neonates born to women immunized against tetanus are protected by passively acquired maternal antibody.[181] Furthermore, through widespread vaccination programs many pregnant women have been vaccinated with tetanus toxoid without any resulting safety concerns.

The ACIP recently began recommending routine Tdap vaccination during pregnancy because of recent neonatal and young infant pertussis cases.[112] Although pertussis is of current concern, protection against tetanus is a minor issue in the United States where tetanus is exceedingly rare.

PRECONCEPTION AND POSTPARTUM VACCINES

The postpartum period during the delivery hospitalization may represent an ideal time for vaccination given that pregnant women are accessible and known not be pregnant. For example, rubella immunity is routinely tested for during prenatal care and susceptible women are generally vaccinated prior to discharge from the hospital. Vaccinated women are advised to avoid pregnancy for 28 days following vaccination (the manufacturer recommends 3 months) based on a theoretical risk of embryopathy. Postpartum women who have not previously received Tdap are recommended to receive Tdap in the United States immediately after delivery.[112] A recent outbreak of measles also highlights the importance of ensuring that all women are up to date on measles-containing vaccine.[106] It is critical that healthcare providers review vaccination history in preconception care, during pregnancy, and postpartum. Furthermore, they need to actively recommend vaccines and facilitate vaccination (e.g., vaccinate in their office).

RESEARCH CONSIDERATIONS

Maternal immunization is an emerging and active area of research. There are several issues that deserve specific attention in the context of research on maternal immunization. For example, a review of adverse event definitions reported that there was substantial heterogeneity in how outcomes such as stillbirth were defined by various studies of maternal immunization[183] making it very challenging to compare rates of adverse outcomes across studies and populations. Therefore, there is a need for standardized outcome definitions. Moreover, assessing impact of maternal vaccines on birth outcomes could be one of the most important public health contributions of maternal vaccination. However, few studies are specifically designed and adequately powered to evaluate birth outcomes, resulting in an evidence base comprised mostly of retrospective studies and post hoc analyses of trials. Given that potential protective birth effects of maternal vaccines are likely to work through reduction of infections, it is essential to account for infection at the individual or community level when conducting such analyses. In fact, it is inappropriate to interpret data on protective effects of vaccines on birth outcomes without accounting for infection. Moreover, as mentioned in a previous section of this chapter, there is a need to conduct additional studies evaluating safety of first trimester vaccination.

In summary, maternal immunization has the potential for preventing substantial morbidity and mortality among mothers and infants.[155a,184] However, immunological changes specific to pregnancy should be kept in mind when considering clinical and research implications of vaccines in pregnancy.

37 Measles Vaccines

Peter M. Strebel, Mark J. Papania, Paul A. Gastañaduy, and James L. Goodson

The written history of measles is classically traced to the writings of the Persian physician Rhazes, also known as Abu Becr, who lived during the 10th century.[1–3] However, the disease was apparently recognized as early as the 7th century by such persons as the Hebrew physician Al Yehudi.[2] Rhazes referred to measles as hasbah, which means "eruption" in Arabic.[2] *Rubeola* and *morbilli* are descriptive Latin words first used in the Middle Ages. The latter is a diminutive of *morbus*, meaning "disease," which was reserved to refer to the bubonic plague; *morbilli* referred to a minor disease. *Measles* is probably derived from *mesels,* the anglicized form of *misellus,* which, in turn, is a diminutive of the Latin word *miser,* meaning miserable and referring to the sufferer of various eruptions or sores. The presence of nonspecific leprous sores was incorrectly identified with the disease called morbilli in Latin. Thus, mesels came to be equated with the disease and not the sufferer of ill-defined skin lesions.[3]

Rhazes appears to have been the first to make the distinction between measles and smallpox.[2,3] He considered measles to be a severe disease, "more to be dreaded than smallpox." Although Rhazes did distinguish between the two diseases, he and others still probably considered them to be closely related.[3] Furthermore, although he was aware of the seasonal nature of measles, he did not think the disease was infectious.[2]

The distinction between measles and smallpox was becoming clearer by the beginning of the 17th century, when annual bills of mortality in London in 1629 listed the two diseases separately.[3] Thomas Sydenham clearly described the clinical characteristics of measles during this period and believed the disease to be infectious.[2–4] It was, however, Francis Home, a Scottish physician who worked in Edinburgh in the mid-18th century, who truly recognized the infectious nature of the illness in his attempts to prevent it.[5] Understanding of the epidemiology of measles was greatly enhanced by the classic investigation of a measles epidemic on the Faroe Islands in 1846 by the young Danish physician Peter Panum.[6] He not only confirmed that measles was contagious but also defined the 14-day interval between exposure and appearance of exanthem, recognized the higher mortality at the extremes of age, and observed that infection provided lifelong immunity.

In 1911, using infected material from acute cases, Goldberger and Anderson[7] transmitted human measles infection to monkeys, clearly demonstrating the existence of an infectious agent or substance responsible for measles. This finding antedated the technology to isolate and culture the measles virus. In 1954, John F. Enders and Thomas C. Peebles[8] successfully isolated the measles virus in human and monkey kidney tissue cultures. Adaptation of the virus to chicken embryos[9] and cultivation in chicken embryo tissue culture[10] paved the road to vaccine development and licensure in 1963.[11–21]

Widespread vaccination of children in the United States[22–27] and others[28–41] has had a dramatic effect on the incidence of measles and its associated complications. Reductions in morbidity and mortality have been so great that global eradication has been proposed[42–44] and judged feasible.[45–47] This would be a fitting end to a disease once confused with smallpox, the first infectious disease eradicated from the world.

BACKGROUND

Clinical Description

Usual Clinical Course

The first symptoms of measles occur after a 10- to 14-day incubation period that follows wild measles virus exposure from a measles-infected person. A systematic review estimated the median incubation period to be 12.5 days (95% confidence interval [CI], 11.8–13.2) based on 55 observations from eight observational studies.[48] Measles incubation periods vary by setting depending on population dynamics, measles virus transmission patterns during outbreaks, and the nature of infection events.[49] For example, if infection occurs after parenteral exposure, the incubation period is shortened by 2 to 4 days. Individual case reports have suggested potential exposure events occurring at least 21 days prior to rash onset[2,11,49–53]; therefore, to ensure high sensitivity for disease surveillance, an incubation period of 7 to 21 days is often used for the purposes of conducting epidemiological investigations, and identifying contacts and potential transmission events to guide control activities.[54] Immunosuppressed persons may have a prolonged incubation period because host immune responses, which are responsible for the signs and symptoms of measles, may be absent or delayed in persons with cellular immune deficiencies.[55,56] The prodromal stage is heralded by the onset of fever, malaise, conjunctivitis, coryza, and tracheobronchitis (manifesting as cough) and lasts 2 to 4 days. This symptom complex is similar to that seen with any upper respiratory infection. The temperature rises during the ensuing 4 days and may reach as high as 40.6°C. Koplik spots, the enanthema believed to be pathognomonic of measles, appear as multiple 2- to 4-mm bluish-white plaques on the buccal mucosa, usually on the inside of the cheek opposite the first or second molar, 1 to 2 days before the onset of a rash and may be noted for an additional 1 to 2 days after rash onset.[57–59] Koplik spots are believed to occur in greater than 70% of measles patients and because they usually first appear prior to rash onset, their early finding by a clinician during physical examination can prompt laboratory testing for rapid confirmation of measles, early treatment, implementation of infection-control practices, and postexposure vaccination of close contacts. Measles rash is an erythematous maculopapular eruption that usually appears 14 days after exposure and spreads from the head (face, forehead, hairline, ears, and upper neck) over the trunk to the extremities during a 3- to 4-day period. The exanthem is usually most confluent on the face and upper body and initially blanches on pressure. During the next 3 to 4 days, the rash fades in the order of its appearance and assumes a nonblanching brownish appearance.

Virus can be isolated from subcrevicular oral fluid, the nasopharynx, and blood during the latter part of the incubation period and during the early stages of rash development.[8,60] Although virus has been isolated from the urine

as late as 4 to 7 days after rash onset,[61] viremia generally clears 2 to 3 days after rash onset in parallel with the appearance of antibody.[62] Persons with measles are generally considered to be infectious 4 days before through 4 days after rash onset.

Measles virus infection causes simultaneous activation and suppression of the immune system.[63–67] Measurement of cytokines released during measles suggests activation of $CD8^+$ T cells, which are important for viral clearance, and type 2 $CD4^+$ T cells, which provide optimal antibody production. Measles virus infection leads to a decrease of $CD4^+$ lymphocyte counts that begins before the onset of rash and lasts for up to 1 month.[68] A study of measles patients in The Gambia found marked suppression of the production of interleukin-12, a known regulator of cellular immunity, and suggests a mechanism for the immune suppression associated with measles infection.[67] Recovery from infection is associated with the production of serum and secretory antibodies[62,69–77] as well as the establishment of cellular immunity.[65,66,78–84] Although subclinical infection with boosting of antibody may occur with subsequent exposure,[70,72] immunity after natural infection is believed to be lifelong.[6,85]

Complications

The complications associated with measles infection have been the subject of much description and review.[50,52,86–111] Measles illness severity, complication rates, and clinical outcomes vary by the person's age, preexisting health and nutritional status, comorbidities, access to treatment, and quality of care. In industrialized countries and settings with access to optimal care, the most commonly cited complications associated with measles infection are otitis media (7–9%), pneumonia (1–6%), diarrhea (8%), postinfectious encephalitis (1–4 per 1000–2000 cases of measles), subacute sclerosing panencephalitis (SSPE) (1 per 2500–10,000 measles cases),[112] and death (1.0–3.0 per 1000 cases).[113] Complications are likely to be present if the fever has not lysed within 1 to 2 days of rash onset. The risk of serious complications and death is increased in children younger than 5 years and adults older than 20 years.[2,97,98,102,105] Pneumonia, which is responsible for approximately 60% of deaths, is more common in young patients, whereas acute encephalitis occurs more frequently in adults.[97,105] Pneumonia may occur as a primary viral pneumonia (Hecht pneumonia) or as a bacterial superinfection, most commonly with staphylococcus, pneumococcus, or typeable (encapsulated) *Haemophilus influenzae*. Other described complications include thrombocytopenia, laryngotracheobronchitis, stomatitis, hepatitis, appendicitis and ileocolitis, pericarditis and myocarditis, glomerulonephritis, hypocalcemia, and Stevens-Johnson syndrome.[50,52] Based on clinical observations, it has long been assumed that measles infection exacerbates active tuberculosis and activates latent tuberculosis because of the theoretical risk from the measles virus–induced immunosuppression[114]; however, results from available published studies attempting to determine the occurrence and frequency of this potential additional measles complication are inconclusive.[115–117]

Measles infection runs a devastating course in children in developing countries and settings with minimal care, where measles mortality rates can be as high as 2% to 15%.[2,50,52,110,118–133] The rash is intense and may be hemorrhagic (black measles), and it resolves after marked desquamation. Pneumonia is the most common severe complication from measles and is associated with the greatest number of measles-associated deaths.[134,135] Inflammation of the mucosa leads to stomatitis and diarrhea. Diarrhea is a frequent cause of death because it may persist long after the acute insult and further aggravate a preexisting malnourished state.[106,136,137] Mediastinal and subcutaneous emphysema, keratitis, corneal ulceration, and gangrene of the extremities are not uncommon. The combination of vitamin A deficiency and keratitis results in a high incidence of blindness.[138–140] Secondary bacterial infections, often with staphylococci, produce pustules, furuncles, pneumonia, osteomyelitis, and other pyogenic complications. Neurological complications, including acute viral or bacterial encephalitis, which often result in permanent brain damage, occur in approximately 1 to 4 per 1000 cases.[3,56,113,141]

Following acute measles virus infection, a persistent infection in the central nervous system tissue with a defective measles virus may occur causing SSPE, a degenerative central nervous system disease that is characterized by behavioral changes, intellectual deterioration, mental and motor deterioration, seizures, and death.[141–145] SSPE signs and symptoms begin an average of 7 years after the primary measles infection. Once symptoms start, the person with SSPE develops progressive personality changes, myoclonic seizures and motor disability, and eventually lapses into a coma and dies.[146] Because SSPE symptoms are nonspecific and have very late onset after the initial measles infection,[147] SSPE cases largely go undetected, particularly in resource-limited settings. The global burden of SSPE is unknown; and the previous estimate of 1 SSPE case per 100,000 measles cases is now thought to have been an underestimation. During the resurgence of measles in the United States during 1989–91, the occurrence of SSPE was estimated to be 22 per 100,000 reported measles cases.[144] In Germany, among reported measles cases during 1994–2001, the risk of developing SSPE for children younger than 5 years of age contracting measles infection was estimated to be 1:1700 to 1:3300.[112,144] SSPE incidence depends on the measles epidemiology of a particular setting, in part because the risk for SSPE is higher when the primary measles infection occurs at a younger age,[141,148] and among reported SSPE cases, males outnumbered females 2:1 to 4:1.[4,100,104,149] The pathogenesis of measles in SSPE cases is not fully understood; it is thought that measles virus enters the brain, likely during the acute primary measles infection, then persists in the nervous system. Patients with SSPE have high titers of measles-specific antibodies in their sera and cerebrospinal fluid, and measles virus can be detected in affected brain tissue by electron microscopy and polymerase chain reaction (PCR).[150] Measles viruses isolated from affected brain tissue of SSPE cases have been found to have critical mutations in *M*, *H*, or *F* genes that prevent normal virus replication and budding from the host membrane. Measles viruses from SSPE cases do not play a role in virus transmission.[142,151]

Measles infection during pregnancy is associated with an increased risk of maternal, fetal, and newborn complications including miscarriage, preterm birth, neonatal low birth weight, and maternal death.[152–156] Because physiological adaptations in the immune system during pregnancy can increase a woman's susceptibility, pregnant women infected with measles are more likely to be hospitalized, develop pneumonia, and die than nonpregnant women.[25,26] Clinical illness in the newborn after intrauterine exposure follows a shortened incubation period and may vary from mild to severe, and fatal.[157,158] There is no convincing evidence that maternal infection with measles is associated with congenital malformations.[157,159]

Exploratory studies of other potential measles-related complications have been conducted. For example, a team of investigators in the United Kingdom has suggested that infection with measles virus or measles vaccine virus may result in a persistent infection of the gastrointestinal tract, leading to Crohn disease or ulcerative colitis later in life.[160–163] They proceeded to study a subset of children with developmental

disorders and ileocolonic lymphonodular hyperplasia by using reverse transcriptase–PCR (RT-PCR) techniques, and reported finding evidence of measles virus in biopsies from the terminal ileum of these children.[164] The findings of this group of investigators have led to speculation that combined vaccination with measles-mumps-rubella (MMR) vaccine may be responsible not only for some forms of inflammatory bowel disease but also the increasing reported incidence of childhood autism. Other researchers, however, have been unable to replicate earlier laboratory findings by using similar or more sensitive and specific methods.[165,166] Several subsequent well-conducted epidemiologic studies have found no association between measles vaccination and development of inflammatory bowel disease[167–169] or autism.[169–171] In fact, the available laboratory and epidemiologic evidence does not support hypotheses that measles or measles-containing vaccines might contribute to or induce inflammatory bowel disease or autism[172] (see "Vaccine Safety"). Furthermore, in 2010, the editors of *The Lancet* retracted the original article that led to the controversy,[173] and in January 2011, the *British Medical Journal* published an investigative review that found the medical records had been incorrectly abstracted to falsely implicate the vaccine.[174]

Measles has been proposed to be a causal factor for several other diseases. Studies from different laboratories have revealed conflicting evidence for persistence of measles virus in affected tissues from patients with otosclerosis[175] and Paget disease.[176] Also, current evidence is inconclusive regarding a possible role of measles infections in the pathogenesis of multiple sclerosis.[177]

Clinical Variants

The typical course of measles described in the preceding section can be modified by the presence of previously acquired cell-mediated immunity or antibodies.[2,50,52] This situation usually arises in the infant with residual maternal transplacental antibody, in a person given immunoglobulin (Ig) or vaccination after exposure, in an attempt to prevent or attenuate disease, or in previously vaccinated persons exhibiting an anamnestic immune response following measles virus exposure.[72,178–181] In these persons, subclinical infection[182] or a mild abbreviated illness may occur that confers lasting immunity.[181,183] However, if immunity is incomplete,[184] a second clinical measles infection may occur.[52,185] Typical or modified measles illness also may (rarely) follow reinfection after either natural infection[186,187] or vaccination.[187–196] Schaffner and colleagues[186] reported a case of typical, albeit mild, measles in a 16-year-old girl who reportedly had measles 8 years earlier. She had a hemagglutination inhibition (HI) antibody titer of 1:200 on the second day of rash and titers of 1:1600 and 1:320 at 23 days and 6 months, respectively, after rash onset. The rapidity of antibody appearance, the high titer achieved, and the absence of IgM antibody in all the specimens suggested a secondary immune response. Although reports examining immunity after infection rely on antibody determination, immunity relies heavily on T-lymphocyte memory and function.

Measles infection in the immunocompromised host (e.g., persons with malignancies or HIV infection) can be prolonged, severe, and frequently fatal.[197–202] Infection in these persons may occur in the absence of rash.[197,200–203] The severity of illness is believed to be primarily a result of impaired cell-mediated immunity.[204–207] Two especially severe complications are an acute progressive encephalitis (measles inclusion body encephalitis)[103,208,209] and a characteristic giant-cell pneumonia (Hecht pneumonia).[197–199,210] Measles has been found to be more severe in persons with HIV infection. In the United States, the case-fatality rate has been reported to be as high as 50% in HIV-infected children.[211]

An atypical variant of measles occurred in some recipients of killed measles vaccine who were subsequently exposed to wild-type virus.[50,52,185,187,212–224] Early studies found that patients with atypical measles lacked antibody to the measles virus fusion (F) protein[141,224,225] and had exaggerated cellular responses to measles antigen.[80,226] Affected patients had extremely high levels of measles-specific circulating antibody.[52,80,81,213,224] Studies in monkeys show that this illness is caused by antigen–antibody immune complexes.[227] The formalin-inactivated vaccine induced complement-fixing antibodies that failed to undergo affinity maturation; after exposure to measles, an anamnestic production of nonprotective, complement-fixing antibodies resulted in immune complex deposition and atypical measles.[228] After an incubation period of 1 to 2 weeks, a prodrome consisting of high fever, headache, abdominal pain, myalgia, and cough ensued. In the next 2 to 3 days, an unusual rash erupted on the extremities and spread centripetally. Whereas the exanthem could be erythematous and maculopapular, it was frequently petechial or vesicular and accompanied by edema; occasionally it was pruritic. Hepatocellular enzymes were sometimes strikingly elevated. The illness was frequently mistaken for Rocky Mountain spotted fever and had to be differentiated from meningococcemia, Henoch-Schönlein purpura, and drug eruptions.[50,52] A nodular pneumonitis with pleural effusion was common.[221,229] Despite the potential for serious illness, there was only one report of a possible atypical measles-related fatality.[230] This syndrome also has been reported (rarely) after receipt of live measles vaccine exclusively.[231,232] Persons with atypical measles are believed to be noncontagious.[52,213,214] On the basis of humoral and cellular immunity studies, they also are thought to be protected from subsequent illness after exposure to measles.[80,81,224] The syndrome probably can be prevented by appropriate immunization with live vaccine.[80,81,233,234]

Virology

The measles virus is a pleomorphic, nonsegmented, single-stranded, negative-sense RNA virus with a diameter of 120 to 250 nm.[141,225,235] It is a member of the genus *Morbillivirus* in the family Paramyxoviridae. There are six known species in this genus and family: measles virus in humans, rinderpest virus in cattle, peste-des-petits-ruminants virus in goats and sheep, canine distemper virus in domestic dogs, phocine distemper virus in seals, and cetacean morbillivirus in cetaceans. These viruses are all lymphotropic, induce highly contagious and devastating diseases with marked immunosuppression in their host, and have high host specificity.[236,237] Phylogenetic analysis suggests divergence of measles virus from its closest relative, rinderpest virus, occurred as early as the 5th century, which is consistent with the earliest recorded clinical descriptions of measles disease.[238] The only natural host for the measles virus is humans. In susceptible human populations, measles is one of the most transmissible viruses known. The viral structure is composed of eight proteins encoded within a 16-kb genome, including replication factors (polymerase [L] and phosphoprotein [P]), structural proteins (hemagglutinin [H], fusion [F], nucleoprotein [N], and matrix [M]), and two accessory proteins of unknown function (C and V).[225] The H and F proteins are essential in viral pathogenesis. The measles H protein is involved in the attachment and entry of measles virus into host cells via interaction with cell surface receptors. The F protein is involved in the viral/host-cell membrane fusion and viral entry into the host cell.

The entire 15,894-nucleotide–long genome of the prototype Edmonston strain of measles and the genomes of the predominant measles vaccine strains[239–241] have been fully sequenced, as well as an increasing number of wild-type strains, including some isolated from SSPE cases.[242–244] Although measles virus is considered a monotypic virus, sequence analysis of the *N*, *H*, *P*, and *M* genes has shown that there are multiple, distinct lineages of wild-type viruses.[245–252] This sequence variability has made it possible to use molecular techniques to help monitor transmission pathways of measles virus.[253,254] Molecular epidemiologic data, when analyzed in conjunction with standard epidemiologic information, can confirm or suggest the source of outbreaks and, over time, can provide a measurement of the effectiveness of vaccination control programs and monitor elimination.[251] For example, genetic analysis of wild-type viruses detected in the United States from 1988 to 2000 helped document the interruption of endemic transmission in the United States.[255] Comparison of genetic sequences from wild-type strains isolated in the United States with those isolated elsewhere in the world has suggested international importations of measles virus as sources of outbreaks.[253] To facilitate the expansion of virologic surveillance activities, the World Health Organization (WHO) has recommended a standard nomenclature and analysis protocol, and established a global database of measles virus sequences.[256] The WHO currently recognizes 24 genotypes (Fig. 37.1) of measles virus based on phylogenetic analysis of the *N* gene and has established a set of reference sequences.[257] In 2000, the WHO established the Global Measles and Rubella Laboratory Network to provide standardized procedures for case confirmation and virus characterization. This network was built on the existing network for global polio eradication; it continues to expand and now includes more than 730 laboratories in all six WHO regions.[258] Although virologic surveillance is incomplete, increased laboratory capability and improved surveillance since 2000 has allowed for monitoring the global distribution of genotypes (Fig. 37.2).[259] Following elimination efforts globally, circulating genotypes of wild-type measles virus have decreased; of the 24 known measles virus genotypes, 13 were detected and reported during 2005–14.[260] Although the biologic significance of differences in the genetic sequence of wild-type strains is not known, there is no evidence that strains vary by transmissibility or virulence. The immune response generated through vaccination protects against all measles virus strains.

Measles virus can be cultured from clinical specimens and is best isolated in the Vero/hSLAM cell line comprised of Vero cells transfected with a plasmid encoding the gene for the human signaling lymphocyte activation molecule (SLAM).[261] The sensitivity of Vero/hSLAM cells for isolation of measles virus is equivalent to that of the previously used B95a cells, which were coinfected with Epstein-Barr virus. In addition, Vero/hSLAM cells are sensitive to laboratory-adapted measles strains, including vaccine viruses.[262] Measles virus can also be detected directly from clinical specimens, such as oral fluid or throat swabs, through molecular techniques that are being used to monitor measles transmission patterns without the need for virus culture. Measles virus is inactivated rapidly in the presence of sunlight, heat, and extremes of pH.[141] It can, however, be safely stored for long periods at −70°C.

In cell cultures, the virus causes two distinct cytopathic effects.[19,141,263,264] The first is formation of multinucleated syncytia (giant cells) containing numerous nuclei of fused cells. This corresponds to the predominant pathologic process observed in infected tissues, including skin and Koplik spots.[265] When observed in lymphoid tissue, the giant cells are referred to as Warthin-Finkeldey cells; otherwise they are known as epithelial giant cells.[141] Whereas this cytopathic effect is characteristic of wild-type virus isolates, the cytopathic effects of passaged virus may additionally include spindle-cell transformation. This difference in cytopathic effects as well as other factors, such as ability to grow in chick embryo fibroblasts, plaque morphology, interferon production, and optimal growth temperature, help differentiate wild-type virus from attenuated vaccine virus strains, as does sequencing.[141,266–268]

Pathogenesis as It Relates to Prevention

Until recently, standard theoretical models of measles virus pathogenesis suggested that in a person who has exposure to measles virus during contact with another person who is infectious with measles, transmission occurs with initial cell entry of the virus in the epithelium of the upper respiratory tract, nasopharynx, and possibly of the conjunctivae,[50,52,86–88,268–273] However, based on recent findings from molecular studies, our current understanding of measles virus pathogenesis suggests that the initial infection actually occurs in the lower respiratory tract, where measles virus likely first enters alveolar macrophages and subepithelial dendritic cells.[273a] Following this initial cell entry, measles virus is rapidly transported to regional lymph nodes, leading to extensive measles virus replication in the lymphatic system and an acute viremia and leukopenia. During viremia, measles virus spreads systemically via infected immune cells, primarily B cells, T cells, and monocytes, to organs throughout the body, as well as to the epithelial cells in the upper airway and nasopharynx.[274] Once the virus reaches epithelial cells systemically, the virus enters the basolateral side[275] of epithelial cells in the upper respiratory system. Following virus entry into upper respiratory epithelial cells, rapid spread of infected cytoplasm occurs laterally through intercellular pores to adjacent epithelial cells creating multinucleated epithelial giant cells that can be detected in nasal secretions and conjunctivae at the end of the incubation period, during the prodrome and the first days of the rash. This leads to sloughing of infectious tissue in the upper airway mucosa that induces coughing and sneezing of aerosolized respiratory droplets, marking the start of the infectious period and thereby, facilitating the survival of measles virus through continued transmission from person to person.[276] Measles transmission can occur during the infectious period, lasting a total of approximately 9 days, starting 4 days before, until 4 days after rash onset. The onset of rash marks the start of the adaptive immune response and virus clearance from the body.[277–279]

This current model of measles virus pathogenesis is based on the results of extensive research, including human and animal studies of the measles virus genome, structure, cellular receptors, and immunology. Measles virus is known to target dendritic, epithelial, endothelial, and blood cells, including activated B cells, T cells, and monocytes[280–282]; however, all specific measles virus cellular receptors have not yet been identified. Three known cellular receptors that interact with the measles virus H glycoprotein are (a) membrane cofactor protein or CD46, (b) SLAM or CD150, and (c) nectin-4, also known as poliovirus receptor-like 4 (PVRL4). CD46 is a human complement regulatory protein that is prolific in humans and expressed on all nucleated cells, including epithelial, endothelium and ependymal cells. CD46 functions as a cofactor for proteolytic inactivation and binds to measles virus transmembrane hemagglutinin (H),[283] and acts as a costimulatory molecule for CD4 T cells.[283,284] Generally, CD46 is an important cellular receptor used by measles vaccine strains but not by wild-type measles strains.[285–287] The two receptors that allow morbilliviruses to circulate in nature are SLAM, expressed in immune cells, and nectin-4, expressed in polarized epithelial cells.[288] The SLAM family is a group of

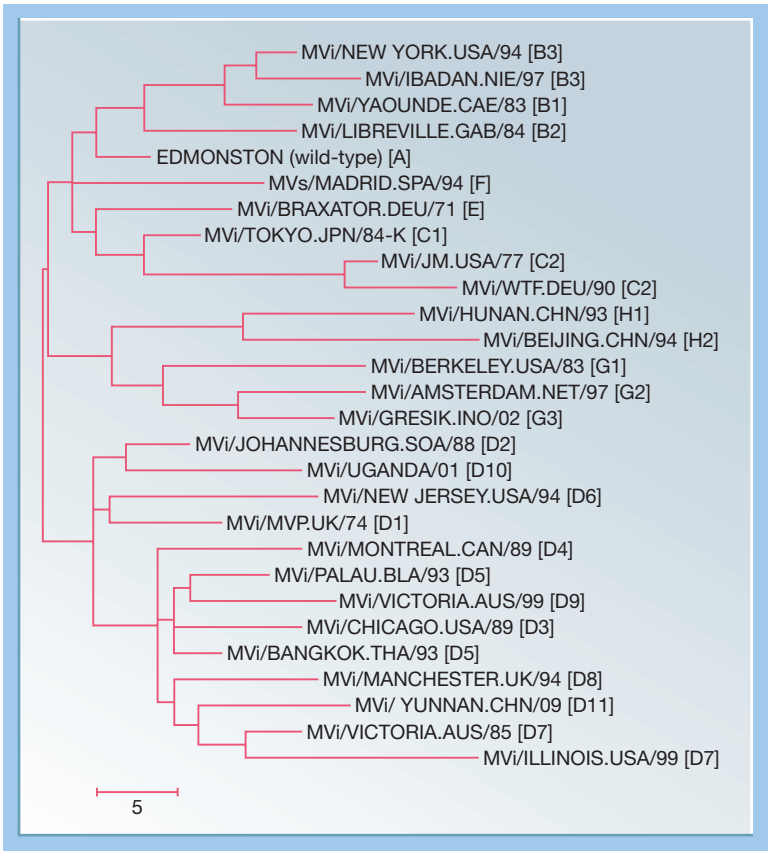

Figure 37.1. Genetic variation in wild-type measles viruses, 2015. The World Health Organization (WHO) recognizes 24 genotypes of wild-type measles virus (A, B1, B2, B3, C1, C2, D1, D2, D3, D4, D5, D6, D7, D8, D9, D10, D11, E, F, G1, G2, G3, H1, and H2). Figure shows phylogenetic tree based on the sequences of the 450 nucleotides that code for the 150 amino acids at the COOH terminal of the nucleoprotein gene of the WHO references strains for each genotype. Length of horizontal lines corresponds to genetic distance. Scale at lower left shows length for 5 nucleotide substitutions.

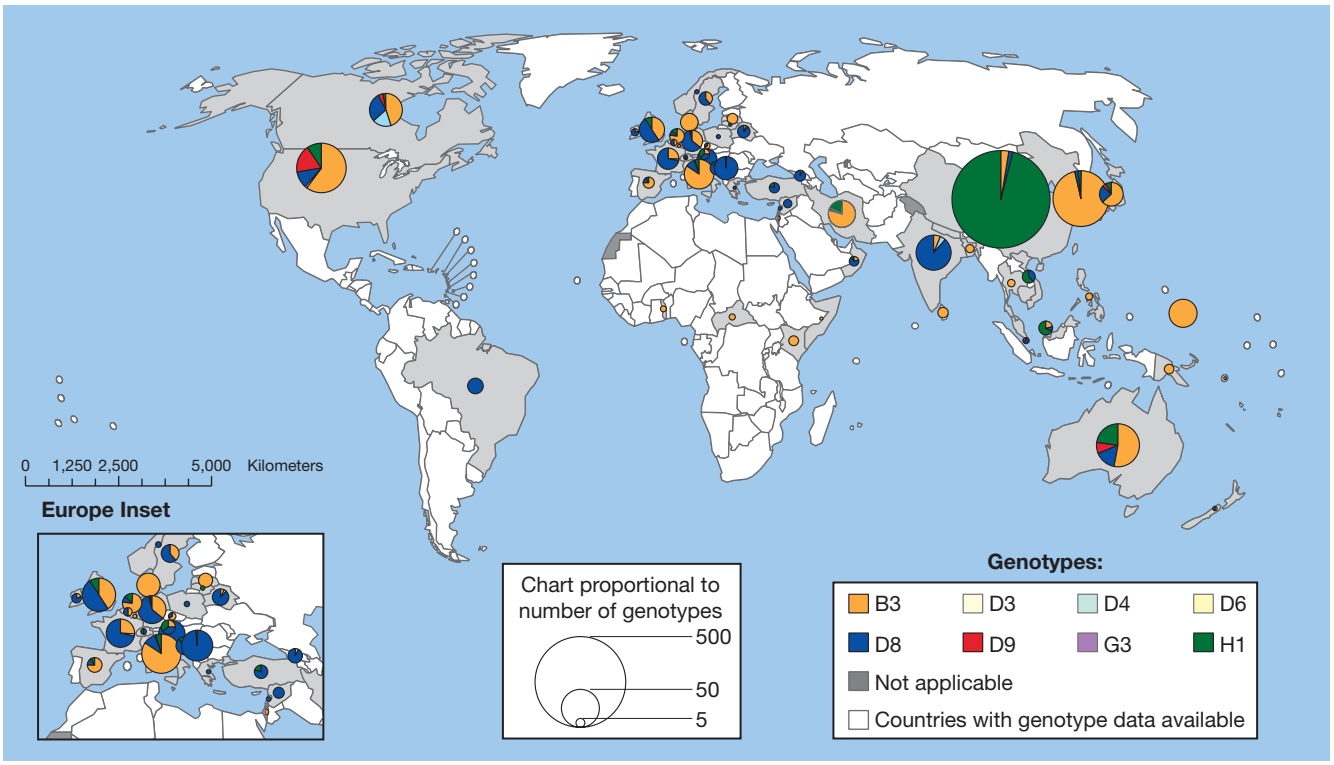

Figure 37.2. Worldwide distribution of measles virus genotypes, March 2014 to February 2015.

transmembrane receptors found in animals and humans, and were likely the major determinant[289] for the evolution of the host-virus specificity of morbilliviruses. In humans, SLAM/CD150 is a membrane glycoprotein expressed on cells of the immune system, including activated T and B lymphocytes, activated monocytes, immature thymocytes, and mature dendritic cells.[290] The initial cell entry of measles virus leading to primary measles infection occurs in alveolar macrophages or dendritic cells that express the immune cell–specific protein SLAM/CD150. After extensive replication in SLAM-expressing cells in lymphatic organs, the virus is likely delivered systemically by circulating SLAM-expressing immune cells to the basolateral side of epithelial cells. SLAM/CD150 is used by both measles vaccine strains and wild-type viruses.[291] Nectin-4 is a cell receptor on epithelial cells that has been found in animals and humans, and plays a critical role allowing measles virus in humans to rapidly spread laterally in the airway epithelium. In airway epithelial cells, measles virus uses the adherens junction protein nectin-4/afadin complex to initiate a viral membrane fusion apparatus opening intercellular membrane pores allowing infected cytoplasm transfer between columnar epithelial cells. This causes large infectious centers in the tracheae and upper airway that likely eventually detach, triggering coughing and sneezing of aerosolized[276] measles virus. Because the spectrum of measles disease affects multiple organs and tissues, additional measles virus cellular receptors that play a role in measles pathogenesis are known to exist, but have not yet been identified or have mechanisms that are not fully understood. For example, CD147 has been identified as potentially facilitating measles virus entry into epithelial and neuronal cells, a finding that could help explain the causes of central nervous system complications.[273] The development of new techniques in reverse genetics and recombinant virus strains that express enhanced fluorescent proteins have recently advanced tropism and pathogenesis studies, leading to important findings, including the identification of nectin-4 as the receptor that facilitates the virus passing through epithelial barriers to complete measles virus transmission from an infected person to a susceptible person. The pathogenesis of measles virus infection indicates that prevention of transmission from person to person could be accomplished by inhibiting replication at the initial site of infection, inhibiting the viremia that occurs during the incubation period, or preventing cell entry and invasion of the upper respiratory epithelial cells which allows shedding of virus for sustained transmission. The first approach requires the presence of local secretory IgA antibody or transudated IgG[292]; the second approach requires a sufficient titer of neutralizing antibody. Infectious measles can be prevented by an immune response with neutralizing antibodies.[178–182,268] Children with primary agammaglobulinemia do not have more-severe measles infections than do children with normal immune systems, and both develop long-lasting immunity after infection.[205,206] These observations indicate that measles antibodies prevent infection whereas cellular immunity acts to close off infection if it occurs.

Diagnosis

Measles should be suspected in persons who present with an acute erythematous rash and fever, preceded by a 2- to 4-day prodrome of cough, coryza, conjunctivitis, and photophobia. Recent experience suggests that clinical measles may be difficult to distinguish from other causes of febrile rash illness, particularly in areas where the incidence of measles has been low. Clinical features that support the diagnosis of measles include the presence of Koplik spots, the characteristic 2 to 4 days of intensifying prodromal symptoms, the progression of the rash from the head to the trunk and out to the extremities, and the lysis of fever shortly after the appearance of the rash. Healthcare providers working in measles-endemic areas may be more familiar with these clinical findings than are healthcare providers working in areas with a low incidence of measles. A clinical case definition for epidemiologic purposes is the presence of rash lasting 3 or more days; a fever (temperature ≥38.4°C, if measured); and cough, conjunctivitis, or coryza.[234] Its use for clinical diagnosis is limited, particularly because of the criterion requiring at least 3 days of rash before the diagnosis is made. In some parts of the world, a less-specific clinical definition not requiring rash duration of 3 days is being used for epidemiologic purposes. Laboratory tests are necessary to confirm the diagnosis, especially when measles is rare. Other illnesses, such as rubella, dengue, parvovirus B19, human herpesvirus type 6, and measles vaccine reactions, can meet these clinical definitions.[293–295] In the United States, it is recommended that clinicians obtain a blood or other suitable specimen for laboratory confirmation from all patients suspected of having measles.

Although virus isolation, direct cytologic examination of clinical material, or demonstration of virus antigen can be used to diagnose measles,[60,61,296–301] detection of measles-specific IgM antibody from a single blood specimen is the most commonly used method. An increase in measles antibodies between acute and convalescent serum specimens is also diagnostic but requires the collection of two blood specimens. RT-PCR can be used to identify measles virus RNA in urine, blood, oral fluid, and nasopharyngeal mucus.[302–305] Because measles is an RNA virus, RNA must be reverse transcribed to DNA before PCR analysis, resulting in a much reduced sensitivity for diagnosing measles compared with diagnosing DNA viruses.[306]

In primary acute infection, detectable antibodies generally appear in the serum within the first few days of rash onset, peak within approximately 4 weeks, and subsequently decline somewhat but persist for life (Fig. 37.3).[50,52,69–72,307–309] Both IgG and IgM antibodies are initially produced.[310–313] However, IgG antibodies are detectable long after infection, whereas IgM antibodies are rarely detected after 6 to 8 weeks. Serum and secretory IgA antibodies are also produced.[75–77,314,315] Reexposure usually induces a characteristic anamnestic response with a rapid boosting of IgG antibody; IgM may not be detected

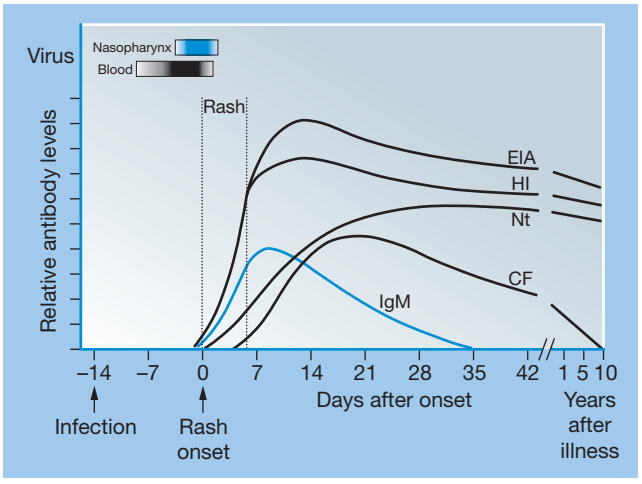

Figure 37.3. Schematic of the immune response in acute measles infection. CF, complement fixation; EIA, enzyme immunoassay; HI, hemagglutination; IgM, immunoglobulin M; Nt, neutralization.

after reexposure with use of some currently available serologic assays.[72,193,311,312] If IgM is detected after reexposure, it will be at a lower ratio to IgG than the IgM-to-IgG ratio in a previously unexposed person.[316]

The tests for complement fixation (CF), HI, and neutralization (Nt) have been the assays historically employed to detect fourfold rises in measles IgG antibody between acute and convalescent sera.[141] However, the CF test is less sensitive,[70–72,85,317] and the HI and Nt tests have undergone technical modifications over time.[318] The plaque-reduction neutralization test remains the gold standard to which other more rapid and simpler methods are compared, but, because it is time and personnel intensive, it is generally limited to specialized reference laboratories and research work.[318] Fluorescence tests are available,[319] as are enzyme immunoassays (EIAs), also referred to as enzyme-linked immunosorbent assays (ELISAs).[320–326] Currently EIA tests for measles IgG are the most widely used because they are generally sensitive and convenient. Good correlation has been shown between HI and Nt antibody in many studies,[327] as well as between EIA and other serologic methods for the diagnosis of acute measles.[321,322,328] The EIA for measles IgG is based on significant changes in optical density values and cannot be translated directly to antibody concentrations or titers.

Currently, the recommended laboratory method for the confirmation of clinically diagnosed measles is a serum-based IgM EIA collected at the time the patient is first seen for medical care.[329] A single specimen is adequate to detect the presence of IgM antibody.[315,325,326] A number of commercial kits using an indirect EIA method (with removal of the patient's IgG antibody before testing for IgM) or an antibody capture EIA technique (without removal of IgG) are now available and have been shown to have similar sensitivity (83–92%) and specificity (87–100%).[330] However, if measles disease prevalence is low (e.g., 1%), a modest reduction in the specificity of the assay from 99% to 95% will decrease the positive predictive value of the assay from 48% to 15% (i.e., only 15% of IgM-positive clinical cases will be true measles). Patients with parvovirus B19 or rubella infections may have false-positive reactions (rate of approximately 4%) when tested with measles IgM EIAs.[293,331]

Correct interpretation of serologic data depends on proper timing of specimens relative to rash onset. This is especially important in interpreting negative IgM results. For example, in one study, the sensitivity of an antibody capture IgM assay was approximately 80% within the first 72 hours after rash onset and rose to 100% between 3 and 14 days after rash onset.[332] Sensitivity of the assay within the first 3 days of rash onset is thought to be similar for other commercially available kits. If the validity of the initial measles IgM test is in doubt, a second convalescent specimen should be taken and tested for IgM and for a rise in IgG titer compared with the initial specimen. In some cases, interpretation may be difficult and requires precise information regarding dates of rash onset, prior measles vaccination, and specimen collection.

Two approaches provide alternatives to venipuncture for collection of diagnostic specimens: oral fluid and blood spots on filter paper. In the United Kingdom and elsewhere, commercial IgM EIA-based assays have been developed and used to test oral fluid specimens for measles. Compared with serum IgM results, reported sensitivities and specificities of oral fluid IgM assays ranged from 92% to 100%.[333–335] Use of oral fluid samples has appeal because the technique is noninvasive, can be used for rubella and mumps testing, does not require processing in the field, can be shipped without cold chain, and can be used to detect not only measles IgM and IgG but also the measles virus genome for molecular characterization. Although still considered an invasive technique, fingerstick as a method for sample collection may be more acceptable to parents than phlebotomy.[306] Blood spots collected onto filter paper do not require processing in the field, or a cold chain for transport to the laboratory, and can be used to test for measles and rubella as well as for molecular characterization of the measles virus genome. In addition, the eluted serum can be tested by using commercially available EIAs with minimal loss of sensitivity or specificity.[336–339]

Treatment

A number of preparations, such as interferon,[340,341] thymic humoral factor,[342] thymostimulin,[343] levamisole,[344] ribavirin,[345] and Ig,[178] have been used to treat measles. None of these is commonly used to treat uncomplicated measles, although limited studies with ribavirin have shown reduced duration of illness.[345] Ribavirin and interferon may be effective in treating severe measles in immunocompromised persons.[346] Recent research has identified anti-viral compounds that potentially could be developed as specific anti-paramyxovirus therapeutics.[347,348]

As antiviral therapies are not commonly used to treat measles, case management is focused on supportive care, as well as the prevention and treatment of measles complications and secondary infections to reduce morbidity and mortality. Clinical outcomes improve with early case detection and treatment. High doses of vitamin A have been shown to decrease mortality and morbidity in young children hospitalized with measles in developing countries.[349–353] The WHO currently recommends vitamin A for children with acute measles.[354] Vitamin A oral dosage is once daily for 2 days at 200,000 IU for children ages 12 months and older, 100,000 IU for infants 6 to 11 months of age, and 50,000 IU for infants younger than 6 months of age. In the United States, as well as in developing countries, children with measles have been found to have low levels of serum retinol, and those with more-severe illness have lower levels.[355–357] The American Academy of Pediatrics (AAP) recommends using two doses of vitamin A (200,000 IU) on consecutive days, which is associated with a reduction in the risk of mortality in children younger than 2 years of age (relative risk [RR], 0.18; 95% CI, 0.03–0.61) and the risk of pneumonia-specific mortality (RR, 0.33; 95% CI, 0.08–0.92). There is no evidence that vitamin A in a single dose is associated with a reduced risk of mortality among children with measles.[233,358] In addition, vitamin A therapy should be administered to children with measles who are immunosuppressed, have clinical evidence of vitamin A deficiency, or have recently immigrated from areas with a high mortality rate from measles.[233] Antibiotics, in the absence of pneumonia, sepsis, or other signs of a secondary bacterial complication, are generally not recommended.[359] However, a recent clinical trial in Guinea-Bissau found that case-patients who received prophylactic antibiotics (co-trimoxazole) had less pneumonia and conjunctivitis and higher weight gain, suggesting a beneficial role of prophylactic antibiotics in the treatment of measles in low-income countries.[360]

Various chemotherapeutic agents have also been used in patients with SSPE in an attempt to treat or at least alter the clinical course of the disease.[144,361–364] Of these, inosiplex (Isoprinosine) and interferon have been the most extensively studied[362–366]; despite anecdotal evidence of their effectiveness, controlled trials are lacking.

EPIDEMIOLOGY

General Epidemiology

In the absence of an immunization program, measles is a ubiquitous, highly contagious, seasonal disease affecting

nearly every person in a given population by adolescence.[2,367–369] Important exceptions are island and other isolated populations, which can remain free of infection for variable periods and then, after reintroduction of the virus, experience epidemic disease that involves all age groups not affected by the last wave of infection.[2,6,85,90,94,368] Thus, whereas peak transmission usually occurs among young children, outbreaks in isolated communities involve many older persons. This is exemplified by Panum's description of measles on the Faroe Islands,[6] in which the disease affected persons of all ages who were not affected by the last epidemic that had occurred 65 years earlier.

Measles is transmitted from person to person primarily by airborne aerosolized droplet nuclei.[2,370–373] The period of maximal contagion occurs during the prodrome.[7,50,52,95] Secondary attack rates in susceptible household (and institutional) contacts are high and can be on the order of 90% or greater.[51,70,307,374–376] Traditionally the incubation period for measles was thought to be 14 to 15 days.[375] Using a novel estimation method the mean incubation period and generation time for measles are estimated to be 11 to 12 days.[49] Almost all primary infections (except those modified by maternal antibody or parenteral Ig) are thought to be clinically overt.[2] Transmission from asymptomatic exposed immune persons has not been demonstrated.[377,378] Although susceptible monkeys may become infected with measles, there is no significant animal reservoir.[2,50,141]

Before the introduction of vaccines in most developed countries, school-age children had the highest risk of infection and accounted for the largest proportion of cases.[2,367] However, in dense urban areas, transmission among preschoolers took on greater importance.[367] Although serious complications did occur, they were relatively rare compared with the situation in developing countries. In the United States before the introduction of vaccine in 1963, major epidemics occurred approximately every 2 to 3 years.[2,379–381] Each year, disease peaked in late winter and early spring. The highest occurrence of disease was in children 5 to 9 years of age, who accounted for more than 50% of reported cases (Table 37.1). More than 95% of cases had occurred by age 15 years.[2,367] The highest risk of death was in children younger than 1 year of age and in adults.[97,98]

The measles virus is so contagious that it can be expected to circulate wherever a relatively large number of susceptible persons congregate, even in the face of a low population-susceptibility rate.[2] This explains the outbreaks that were typical among military recruits before the institution of routine measles vaccination.[382] Outbreaks among high school and college students, most of whom have been vaccinated, demonstrate the virus's capability to seek out the small number of remaining susceptible persons.[382–386]

Before widespread vaccination, in many developing countries, the average age at infection was much lower than that observed in developed countries.[2,118–125] In some areas of Africa, more than 50% of 2-year-old and 100% of 4-year-old children may be expected to have had measles. Poor nutrition and rapid loss of maternal antibody may explain why a greater proportion of these infants are susceptible at an earlier age than are those in developed areas,[327,387–391] and infection, in turn, results from the early age at which infants are exposed to the community at large.[118] Young age at infection contributes to the high risk of serious complications and death. Malnutrition, especially vitamin A deficiency, may also be an important factor leading to the marked severity of measles in the developing world because of defects in cellular (and possibly humoral) immunity.[126,392] However, there is some evidence that crowding, which leads to a potential increased dose of transmitted virus, may be a more significant determinant of the severity of infection than is protein-calorie malnutrition.[393–395]

Significance as a Public Health Problem

Although remarkable control of measles has been achieved in some areas of the world,[39,396] in 2000, measles was still the leading cause of vaccine-preventable deaths in children and the fifth leading cause of all deaths among children younger than 5 years of age.[397] Measles is also responsible for much diarrhea, respiratory disease, and blindness in the developing world.[130,135,136] Through mass vaccination campaigns and increased routine immunization coverage, the estimated number of measles deaths worldwide dropped 79% from 546,800 deaths in 2000 to 114,900 deaths in 2014 and measles vaccination was estimated to have prevented 17.1 million measles-related deaths during this period.[398,399] A comparison of the proportion of all-cause mortality resulting from measles among children less than 5 years of age found that measles accounted for approximately 7% of all child deaths in 1990 and 1% in 2008, contributing 23% to the overall reduction in mortality in this age group.[400]

In the United States in the prevaccine era, approximately 500,000 cases of measles were reported each year, but, in reality, an entire birth cohort of approximately 4 million persons was infected annually.[401] Associated with these cases were an estimated 500 deaths, 150,000 cases with respiratory complications, 100,000 cases of otitis media, 48,000 hospitalizations, 7000 seizure episodes, and 4000 cases of encephalitis, which left up to one quarter of patients permanently brain damaged or deaf. An economic analysis of the two-dose MMR vaccination program in the United States adjusted to 2001 dollars, found the direct and societal benefit-to-cost ratios to be 14.2 and 26.0, respectively.[403] Although endemic measles has been eliminated in the United States, importations continue to result in small but costly outbreaks. The total economic burden on public health institutions that dealt with 16 measles outbreaks involving 107 confirmed cases during

PASSIVE IMMUNIZATION

Passive immunity to measles can be acquired through physiologic transfer of maternal measles antibodies from mother to child or by administration of immunoglobulin preparations containing measles antibodies to persons at risk of measles.

Maternal antibodies provide time-limited protection against measles during the first months of life when infection can be most devastating.[70] Women who have antibodies to measles, either from measles infection or vaccination, transfer antibodies to their children during pregnancy via the placenta and after delivery by breastfeeding.[405,406] Among newborns, the duration of protection by transplacental measles antibody varies from some being unprotected at birth (i.e., their mother lacked immunity) to others being protected for up to 15 months of age. The factors that affect the duration of transplacental measles antibodies among infants and the effect of these antibodies on response to measles vaccination are presented in the section "Maternal Antibody and Age at Vaccination" below. Measles-specific antibodies, including secretory IgA, are excreted in the breast milk of immune mothers and have been shown to neutralize measles virus in vitro.[405,406] Many of the key factors related to breast milk antibodies against measles are not well determined. In two studies in Africa in the 1980s, one showed a significant reduction in the measles mortality rate of hospitalized children who were breastfed compared with those who had been weaned, while the other study showed no protective effect of breastfeeding.[407,408]

Administration of measles antibodies as immunoglobulin provides short-term protection from measles for susceptible persons. Preexposure prophylaxis against measles and other diseases is provided to persons with primary humoral immune deficiency diseases via frequent administration of immunoglobulin given intravenously (IgIV) or subcutaneously (IgSC). Postexposure prophylaxis with IgIM or IgIV is recommended for persons exposed to measles or at high risk of exposure for whom vaccine is either contraindicated or was not given within 3 days of exposure (see "Postexposure Prophylaxis" and "Use of Immunoglobulin" below).[409]

In 1926, Zingher[410] summarized early efforts to prevent measles by injection of whole blood, serum, or plasma from donors who had a previous measles infection. A significant reduction in the measles attack rate among persons who received convalescent blood products after exposure to measles was shown, and convalescent blood products were widely used as postexposure prophylaxis in the 1920s and 1930s. In the 1940s, Janeway demonstrated that administration of Ig within 6 days after intimate exposure prevented measles in about three of four persons, with mild measles occurring in the fourth.[179]

Multiple Ig preparations are available in the United States and include IgIM, IgIV, and IgSC. Ig products are prepared from plasma pools derived from thousands of donors. Measles disease results in higher antibody titers than does vaccination. Therefore, donor populations with predominantly vaccine-induced measles immunity yield lower measles antibody titers in Ig preparations. A Cochrane Review concluded that Ig was effective at reducing the risk of measles; however almost all the studies included in the review were conducted in the last century, when donor populations would have had higher titers as the result of predominantly disease-induced immunity.[411] A study in Japan showed lower measles antibody titers in IgIM may result in a reduced level of postexposure protection from measles.[412] Audet demonstrated a progressive decrease in measles virus neutralizing antibodies in IgIV lots in recent years in the United States, correlated with an increase in the proportion of plasma donors who were born in the vaccine era.[413] In the United States, the Food and Drug Administration (FDA) requires that all Ig preparations contain a measles-neutralizing antibody level that demonstrates adequate potency when compared with the U.S. standard.[414] In 2007, the FDA Blood Products Advisory Committee reduced the potency requirement from 0.60 to 0.48 of the standard lot titer for both IgIV and IgSC, which are given in much higher volumes than IgIM. The new potency requirement for IgIV and IgSC lots is calculated to provide a protective measles antibody titer given the recommended minimum doses and dose frequency.[409,415] The potency requirement for IgIM remains 0.60 of the standard lot titer.

Historically, IgIM has been the blood product of choice for short-term measles prophylaxis.[409] IgIV has been available since 1981 and is used primarily for the prevention of common infectious diseases for patients with primary immunodeficiency disorders. Although a larger dose can be administered with IgIV compared with IgIM, clinical use of IgIV has important disadvantages, including high cost and administration requiring extended observation in specialized settings by skilled professionals (e.g., hospital setting). IgSC has been available since 2006 with the same major indication as IgIV. However, administration requires a pump and advanced training. Also, multiple, consecutive weekly doses are needed to establish a steady-state with protective antibody levels.[409]

ACTIVE IMMUNIZATION

Vaccine Strains

Origin and Development

After the isolation and propagation of measles virus in tissue culture by Enders and Peebles[8] in 1954, vaccine development, testing, and licensure quickly followed.[11–21] The Edmonston strain, named after the youth from whom the virus was isolated, was used for many of the vaccines developed worldwide (Fig. 37.4).[416–433] To make the now-famous Edmonston B vaccine, Enders and colleagues[12,19,268] further passaged the Edmonston strain at 35°C to 36°C 24 times in primary kidney cells and 28 times in primary human amnion cells, adapted it to chicken embryos (six passages), and then passaged it in chicken embryo cells. This attenuated Edmonston B vaccine was licensed in the United States in March 1963 along with another Edmonston B virus strain that had been adapted to primary dog kidney cells.[434–436] Although the administration of the Edmonston B vaccine was associated with a high rate of fever (temperature of 39.4°C or higher in 20% to 40% of vaccinees) and rash (approximately 50%), the recipients remained remarkably well. However, simultaneous administration of a small dose of Ig with the vaccine (eventually set at 0.02 mL/kg) reduced the occurrence of high fever and rash by approximately 50% (Fig. 37.5).[307,419,422,423,434,435,437–442] Approximately 18.9 million doses of Edmonston B vaccine were administered in the United States between 1963 and 1975 (Table 37.2 and Fig. 37.6).

Killed Vaccine

A formalin-inactivated, alum-precipitated vaccine derived from the Edmonston strain was also licensed in the United States in 1963 and used until 1967 (see Table 37.2 and Fig. 37.6). This vaccine was also used in some provinces in Canada. Usually, three doses of killed

and one dose of live vaccine were administered at monthly intervals with few side effects.[72,307,419,422,443–450] Use of killed vaccine was eventually discontinued when it became apparent that this vaccine produced short-lived immunity and placed many recipients at risk for atypical measles infection.[451] It has been estimated that between 600,000 and 900,000 persons in the United States received the 1.8 million doses of killed measles vaccine that were administered (see Table 37.2 and Fig. 37.6).[452]

Further Attenuated Live Vaccines

Many further attenuated vaccines have been developed and are in active use worldwide (Table 37.3; see Fig. 37.4). Most were derived from the Edmonston strain. These further attenuated vaccines differ from each other in the viral isolate of origin, the number and temperature of cell culture passages, the type of cell culture used for passage and production, and whether plaquings were performed during the passages.[12,19,425,429,430,433,453] Although differences in plaque size,[425,454] subgenomic particles,[455] temperature sensitivity,[456] and pathogenicity in severe combined immune-deficient mice containing human thymic tissue implants[457] have been described among the further attenuated vaccine strains, their significance is uncertain.

Nucleotide sequence analysis of the *F*, *H*, *N*, and *M* genes showed no more than 0.6% variability among vaccine strains derived from the Edmonston strain.[250] Complete genomic sequence analysis of different measles vaccine strains have been compared with the Edmonston wild-type virus. AIK-C, Moraten, Schwarz, and Zagreb were all found to be of the Edmonston lineage, whereas CAM-70, Changchun-47, Leningrad-4, and Shanghai-191 were derived from four different wild-type isolates.[456,458] However, all the vaccine strains, whether derived from Edmonston or from other wild-type viruses, are members of the same genotype—genotype A.[250,259]

Studies have identified nucleotide sequence substitutions in the *H* gene that appear to mediate some of the biologic characteristics of the Moraten strain of vaccine.[459] Comparison of the noncoding regions of a low-passage Edmonston wild-type strain and five Edmonston vaccine viruses found 21 nucleotide positions at which the wild type and one or more of the vaccine types differed. Five nucleotide substitutions

were conserved in all the vaccine strains. Comparison of protein-encoding nucleotide sequences of the *N*, *P*, *M*, *F*, *H*, and *L* genes of these vaccine strains with Edmonston wild-type virus identified amino acid substitutions in each of the genes; however, the overall level of heterogeneity did not exceed 0.3%.[240,241] The role that these sequence differences in both the coding and noncoding regions of the genome play in attenuation of measles viruses is being characterized by using specialized genetics systems.[460]

Two further attenuated live measles vaccines derived from the Edmonston strain that were licensed in the United States were the Schwarz strain in 1965 and the Moraten strain in 1968 (see Table 37.2 and Fig. 37.4). The Schwarz vaccine was derived from Edmonston virus passaged an additional 85 times at 32°C in chicken embryo cells.[461–464] The Moraten strain was also passaged at this lower temperature, but only an additional 40 times.[465] Compared with the Edmonston B vaccine, the frequency and severity of side effects attributed to these and other further attenuated vaccines were significantly lower (see Fig. 37.5).[307,419,424,461–466] A temperature of 39.4°C or higher occurred in only 5% to 15% and rash in only 3% to 5% of vaccinees. Simultaneous administration of the Schwarz strain and specially titered Ig in a low dose (0.2 mL) further reduced the incidence of high fever and rash to approximately 3% each (see Fig. 37.5).[307] These doses of Ig did not interfere with seroconversion, but the peak geometric mean antibody titer was lower than that observed without Ig administration. The further attenuated vaccines are used without Ig.[467]

The Moraten vaccine (Attenuvax contained in MMR II; Merck) is now the only measles vaccine used in the United States; the Schwarz vaccine is the predominant product in many other nations.[428] Several different further attenuated measles vaccines, including AIK-C, Schwarz F88, CAM-70, and TD97, have been developed and are being used in Japan.[429,430,433,453] The vaccine developed by Smorodintsev (Leningrad-16) was introduced in Russia in 1967 and was the principal vaccine virus strain in eastern Europe.[426] The CAM-70 and TD97 vaccines were derived from the Tanabe strain.[433,453] These vaccines, as well as those in use in China since 1965,[431] are the few not derived from the Edmonston virus.

Whereas most measles vaccines were attenuated and are produced in chick embryo fibroblasts, a few currently used vaccines were attenuated in human diploid cells. The Edmonston-Zagreb vaccine, used extensively in the former Yugoslavia since 1969, was derived from the Edmonston strain and underwent additional passage in WI-38 cells.[425] This vaccine is now produced by several other manufacturers and is the most widely used vaccine in developing countries (see Table 37.3). Other vaccine strains have been adapted to MRC-5 and R-17 human diploid cells in Iran[427,432] and in China.[431]

Dosage and Route of Administration

According to current regulations in the United States, measles vaccine must contain at least 1000 median tissue culture infective doses ($TCID_{50}$) at the end of the expiration date of the vaccine.[468] The vaccine is administered in a 0.5-mL dose. The minimum dose required to immunize a seronegative child has been found to be as low as 20 $TCID_{50}$ in some studies, but higher in others.[469–472] The regulated minimum dose in the commercial product is designed to compensate for some of the virus deterioration that may result either from improper storage or reconstitution or from exposure to light or heat before injection.

The recommended route of administration is subcutaneous injection. Although there are only limited data on the intramuscular route, it appears to be as effective as subcutaneous vaccination.[473] Studies with the Edmonston B and further attenuated vaccines have examined the effectiveness of other routes of administration, such as intranasal and conjunctival inoculation.[11,15,51,292,434,435,474–476] Most of the results were not favorable. In contrast, aerosol administration, which was evaluated during the early 1960s and 1970s, showed promising results.[476] During the 1980s, studies were undertaken to determine whether aerosol administration of measles vaccine could overcome maternal antibody and immunize younger infants.[476–481] Many of these studies found the Edmonston-Zagreb vaccine strain to be more immunogenic than the Schwarz strain when it is administered by aerosol.[482] However, whereas some investigators reported high seroconversion rates after administration by this route in young infants,[477–479,481] others found it inferior to subcutaneous administration (see "Future Vaccines" below).[480]

Aerosol administration of measles vaccine in South Africa[483] and of combined measles and rubella vaccines in Mexico[484] resulted in boosting of antibody responses among schoolchildren. These studies led to enthusiasm about the possible use of aerosol administration as a less-invasive alternative to needle-and-syringe administration during mass vaccination campaigns, especially among schoolchildren. Subsequently, aerosol administration of the Edmonston-Zagreb strain was shown to induce a primary immunization response at 9 months of age.[485] However, in a recent randomized clinical trial, aerosolized vaccine against measles was immunogenic but inferior to the subcutaneous vaccine with respect to the rate of seropositivity (see "Future Vaccines" below).[486]

Combination With Rubella, Mumps, and Varicella Vaccines

In the United States, vaccination against measles is accomplished with combined live vaccines that also contain attenuated rubella and mumps vaccine viruses. Combined vaccines were licensed in the United States in 1971. They contain at least 1000 $TCID_{50}$ of the measles Moraten strain, at least 5000 $TCID_{50}$ of the mumps Jeryl Lynn strain, and at least 1000 $TCID_{50}$ of the RA27/3 strain of rubella vaccine virus. The RA27/3 strain of rubella virus replaced the HPV-77:DE-5 strain as the rubella component in 1979. Currently, the only licensed MMR vaccine is produced by Merck (M-M-R II). In September 2005, a combined measles, mumps, rubella, and varicella (MMRV) vaccine produced by Merck was licensed for use in the United States.[487] The measles, mumps, and rubella vaccine viruses in this quadrivalent vaccine are identical and of equal titer to those in MMR vaccine. The titer of Oka/Merck varicella-zoster virus is higher in MMRV vaccine than in single-antigen varicella vaccine (see Chapter 38).

Combination products were developed as other countries began vaccinating children against rubella or mumps along with measles.[31–34,37,488] For example, GlaxoSmithKline (Research Triangle Park, NC) produces a vaccine that contains Schwarz measles vaccine, RIT4385 mumps vaccine strain (derived from the Jeryl Lynn strain), and the RA27/3 strain of rubella vaccine. As of 2015, Sanofi Pasteur (Swiftwater, PA) has discontinued production of a combined formulation with Schwarz measles vaccine, Urabe mumps vaccine, and RA27/3 rubella vaccine, and will continue single-dose measles vaccine production only through 2017. In Japan, several formulations of combined vaccines are available, including one containing the AIK-C measles virus, the Hoshino mumps virus, and the Takahashi rubella virus strains.[489] Two other combined vaccines are also licensed: one containing the CAM-70 measles strain and one containing the Schwarz F88 strain. The MMR vaccine containing the Urabe mumps strain is no longer being produced in Japan. A triple vaccine with the Edmonston-Zagreb strain of measles vaccine is being produced by the Institute of Immunology (Zagreb),[490] and the Serum Institute of India (Mumbai; Leningrad-Zagreb mumps strain and RA27/3 rubella strain). Serum Institute of India also manufactures combined measles-rubella vaccine (Edmonston-Zagreb measles strain and RA27/3 rubella strain) that is increasingly being used in developing countries as part of measles and rubella elimination efforts.

Safety and immunogenicity data indicate that combining the measles antigen with rubella and mumps antigens[488–505] in the MMR vaccine is both safe and efficacious. Initial results also showed similar safety and efficacy for MMRV vaccine compared with MMR given with varicella vaccine at the same time but at different injection sites.[506–509] However, when given as the first dose to young children, more recent studies show that the risk of febrile seizures[510,511] appears to be higher after MMRV compared with MMR and varicella vaccine administered simultaneously at separate sites (see "Vaccine Safety").[511] Based on the increased risk of febrile seizures when MMRV is used as the first dose in young children, the Advisory Committee on Immunization Practices (ACIP) has modified its recommendations for use of MMRV (see "General Immunization Guidelines" below).

Production and Constitution of Vaccine

Preparation methods for the Merck vaccine provide generally applicable information regarding the production and constitution of measles vaccines.[512] Although there are minor differences in dose, antibiotic content, and other details among manufacturers, there are no reports of significant differences in side effects or vaccine effectiveness.

The vaccine virus is cultured in primary chick embryo cells. After an initial cell growth phase, the cultures are inoculated with the further attenuated Moraten strain of measles virus. After several days' incubation at 32°C, the cells are washed to remove fetal bovine serum, and the medium is replaced with one containing 50 μg/mL of neomycin, sucrose, buffered salts, amino acids, and human albumin. Fluids containing virus can be removed from the cultures for a time as the cells are maintained at the same temperature. These fluids are frozen until determinations of the virus titer have been performed on retained aliquots. Harvested virus fluids having sufficient virus potency and satisfactorily passing tests are thawed, pooled, sampled for safety testing, clarified, dispensed, and refrozen.

When bulk vaccine has passed all quality control tests, portions of the vaccine are thawed, dispensed into vials, and lyophilized. At the time of use, the vaccine is reconstituted with fluid (sterile distilled water) provided by the manufacturer. A preservative-containing reconstitution fluid is not recommended for general use because it may inactivate the vaccine. Each vaccine dose contains approximately 25 μg of neomycin. Sorbitol and hydrolyzed gelatin are added as stabilizers. When reconstituted with the provided diluent, the vaccine is clear and yellow in color.

In 1996, the existence of reverse transcriptase in several vaccines that were grown in chick embryo fibroblast tissue culture was reported, including measles vaccine,[513] by use of a new and highly sensitive technique to detect the reverse transcriptase activity. With use of similar assays, other laboratories have confirmed the existence of the reverse transcriptase activity.[514] Subsequent studies showed that this reverse transcriptase activity is associated with the endogenous avian retrovirus EAV-0[515] and the endogenous avian leukosis virus ALV-E.[516] Extensive efforts to identify a transmissible virus have failed to link the reverse transcriptase activity with a transmissible virus. A study of 206 recipients of combined MMR vaccine found no evidence of infection with either avian leukosis virus or endogenous avian retrovirus.[517] These findings and the fact that transmission of retroviruses across disparate species may be restricted[518] indicate no apparent risk to vaccine recipients.

Stability of Vaccine

Measles vaccine is extremely stable between −70°C and −20°C.[519] Although measles vaccine is affected adversely by higher temperatures, the introduction of more heat-stable vaccines in 1979 led to increased stability under normal working conditions, which is especially important in the developing world.[520] In the United States, manufacturers must demonstrate that a minimum titer of 1000 $TCID_{50}$ is maintained through the labeled expiration date when the vaccine is stored at 2°C to 8°C. The WHO has a requirement that lyophilized measles vaccine, after exposure to 37°C for at least 1 week, cannot lose more than 1 $\log_{10}$ and must maintain a titer of at least 1000 $TCID_{50}$.[521]

For the currently available vaccine in the United States, when it is stored at 2°C to 8°C, a minimum titer of 1000 $TCID_{50}$ can be maintained in unreconstituted vaccine for 2 years or more. This potency can be maintained for 8 months at room temperature (20°C–25°C) and 4 weeks at 37°C. Reconstituted vaccine loses 50% of its potency in 1 hour at 20°C to 25°C and almost all its potency when it is held at 37°C for 1 hour. Vaccine is also sensitive to sunlight; however, colored glass vials further minimize loss of potency. Notwithstanding its improved thermostability, the vaccine still needs

to be handled with care according to the recommendations of the manufacturer.

As stated in the package insert, Merck recommends that its product be shipped at a temperature of 10°C or less and stored, before reconstitution, at 2°C to 8°C and protected from sunlight. Reconstituted measles vaccines (M, MR, and MMR) should be used immediately. If reconstituted vaccine is not used within 8 hours, it must be discarded. MMRV vaccine must be stored frozen at an average temperature of less than or equal to −15°C. Unlike other measles-containing vaccines, MMRV vaccine cannot be stored at refrigerator temperature, and once reconstituted, it should be used immediately to minimize loss of potency and discarded if not used within 30 minutes.[487]

RESULTS OF VACCINATION

Immune Response

The immune response after successful vaccination is similar in most respects to that noted after natural infection. Although the interval between vaccination and an immune response is a few days shorter than that observed after natural infection,[11] immunization induces both humoral[21,72,75,77,307] and cellular[81–83] immunity and the production of interferon.[522–524]

Laboratory evidence of immunity is most conveniently documented by use of antibody assays because tests for cell-mediated immunity are not standardized. However, even with antibody assays, results of studies on vaccine-induced immunity may vary, depending on the sensitivity of the antibody assay used.[70–72,85,317–323,525–533] Although the presence of antibodies detected by HI, ELISA, or CF correlates with immunity, Nt antibodies are probably most important in clinical protection.[2,70,85,327] After measles vaccination, IgG, IgM, and IgA antibodies can be detected in both serum and nasal secretions.[75,77,311,313,534] IgM antibody can be detected in the serum between 2 and 6 weeks (peak at 3 weeks) after vaccination and disappears soon thereafter.[311,313,535] Although only small amounts of IgA have been detected in serum, IgA is the predominant antibody found in nasal secretions.[75,77] Although detectable serum IgA and IgM antibodies are transient, IgG antibodies generally persist for many years. The antibody titers elicited by vaccination do decline over time (as do those induced by natural infection) and may become undetectable.[72,308,309,536–542] A study done in 2007, found that measles antibody persisted in all vaccinees available for follow-up 10 years after a second dose of vaccine, with no seronegative results detected. However, declining titers suggested the need for vigilance in ensuring disease protection for the vaccinated population.[542]

Vaccine-induced antibody titers are typically lower than those induced by natural infection. Vaccine-induced immunity is subject to boosting on challenge by either vaccine or wild-type virus; likewise, similar boosting can be observed after natural infection.[70,72,308,309,463,534,538,539] Thus, as discussed in more detail later, immunization usually provides immunity similar to that induced by natural infection.

Many investigators have described the initial antibody response elicited by live measles vaccination.[72,182,307–309] In studies by Krugman and colleagues, depending on the assay used (CF, HI, or Nt), antibodies first appear between 12 (HI and Nt) and 15 (CF) days after vaccination and peak 21 to 28 days after vaccination. Although antibodies were detected in 95% or more of susceptible vaccinees, regardless of the vaccine strain, the CF geometric mean titer did vary by strain of vaccine (Table 37.4). The geometric mean titers among young children 1 month after receipt of Edmonston B vaccine alone, Edmonston B vaccine plus Ig, Schwarz vaccine, and Schwarz vaccine with Ig were 1:208,[182] 1:96, 1:56, and 1:24 to 1:32, respectively.[307] The titer observed in 33 children 1 month after natural infection was 1:128.[307] Hilleman and colleagues[465] also noted a difference in the geometric mean titer by vaccine strain when using the HI assay (Table 37.5). Although 98% or more of vaccinees seroconverted, the HI geometric mean antibody titer associated with the Edmonston B vaccine was 1:25, whereas that noted after vaccination with either the Schwarz or Moraten further attenuated strains was 1:16. Despite these differences in geometric mean antibody titer, receipt of these vaccines was associated with a markedly reduced risk of infection that did not decrease over time.[72,308,309]

Studies of measles-specific cell-mediated immunity after live attenuated vaccines are more challenging because of the lack of a simple in vitro assay. With the importance that

cell-mediated immunity plays in natural infection,[65,204–207] it would seem that successful vaccination would stimulate such immunity. Cell-mediated immune responses after live attenuated vaccine appear to be similar to but less pronounced than those after natural infection.[204–207,543] For example, Gallagher and colleagues[83] reported that a positive lymphocyte stimulation index was noted in nine of nine subjects with natural immunity and in 10 of 16 vaccinees. Pabst and colleagues[544] found good correlation between antibody titers and lymphoproliferative responses in 124 children receiving their first dose of MMR. However, a study of the immune response to measles vaccination at 9 months of age among 55 Peruvian children found that 93% developed a humoral response, and only 23% had lymphoproliferative responses.[545] Gans and colleagues[546] studied the ability of infants ages 6, 9, or 12 months to respond to measles vaccine and found that, unlike humoral responses, T-cell responses can be established despite the presence of passive antibodies. Outbreak investigations have documented vaccination before the first birthday as a risk factor for vaccine failure,[547–550] suggesting that vaccine-induced cell-mediated immune responses in young infants may not be protective. Ward and colleagues[551] found good lymphoproliferative responses after revaccination, even among those whose antibody titers dropped to low levels. It appears that both wild-type virus and vaccine infection result in a biphasic immune response, beginning with transient production of interleukin-2 and interferon-γ, followed by more sustained production of interleukin-4. First, $CD8^+$ T cells are activated, which is important for viral clearance. Later, beginning about the time of rash onset, $CD4^+$ T cells are activated and are involved in antibody production.[65] These responses by the cell-mediated immune system correspond to an initial T-helper 1 (Th1)-type response with a shift to a Th2-type response.[65]

Vaccination suppresses cell-mediated immune function (as does natural infection).[114,543,552–556] This manifests in vitro as suppression of lymphocyte stimulation or in vitro as suppression of cutaneous delayed hypersensitivity to various antigens. Fireman and colleagues[553] noted suppressed cellular immune function up to 4 weeks after administration of live vaccine. Suppression did not occur after receipt of killed vaccine. A study of Bangladeshi infants found that delayed-type hypersensitivity reactions to *Candida* antigen were significantly reduced at 6 weeks postvaccination.[557] Data suggest that this suppression is the result of downregulation of interleukin-12, which is needed for cell-mediated immunity.[558] Although there was concern initially that this temporary suppression of cellular immunity might be harmful (e.g., in patients with unrecognized tuberculosis[115]), no increased risk has been documented.[558,559]

One would assume that the presence of a rash after parenteral injection of vaccine would be associated with viremia. The generalized stimulation of T and B lymphocytes after vaccination also suggests viremia. Few studies documented viremia after vaccination. Early studies with the canine cell vaccine isolated vaccine virus from blood,[434–436] and, more recently, van Binnendijk and colleagues[560] have isolated Schwarz strain vaccine virus from monkeys 7 to 9 days after vaccination. There are no reports of isolation of vaccine virus from blood in normal humans.[11–13,18,51] Although Mitus and associates[197] did isolate vaccine virus from the throat and conjunctivae of a susceptible leukemic patient who died of giant cell pneumonia after administration of Edmonston B vaccine, they failed to isolate virus from the blood. The apparent difficulty of isolating vaccine virus may reflect the low level of viremia after vaccination.

Because wild-type virus is so highly transmissible, both virologic and clinical studies with susceptible contacts were conducted in early vaccine investigations.[11,13–18,51,434,436] These studies showed no evidence of virus excretion or transmission by vaccinees. Measles vaccine virus was isolated from a throat swab taken from a 3-year-old boy who presented with fever only 12 days after vaccination with MMR vaccine.[561] Measles vaccine virus was detected by PCR in a throat swab and urine sample from a 14-month-old infant with a postvaccination rash without fever.[562] These case reports indicate that subcutaneous vaccination with live attenuated measles virus can result in respiratory excretion of the vaccine virus. However, person-to-person transmission of vaccine virus has never been documented.

Response to Revaccination

The immune response after revaccination depends on the results of the initial vaccination. Persons who have no response to initial vaccination typically generate a primary immune response to revaccination, with a significant rise in antibody titer and the production of IgM antibody. After revaccination of a person with some level of immunity, a fourfold or greater rise in antibody may appear sooner than that seen after initial vaccination, but there are usually no clinical signs of infection.[72,308,309,311,313,532,533,540,563] IgG antibodies are first detected within 5 to 6 days and peak around 12 days. IgM antibodies are not usually detected. As is the case with immunity after natural infection, these are the characteristics of an anamnestic immune response.[310,312] Such a boost is more likely to occur in the presence of a low or undetectable preexisting antibody titer, whereas persons with a high level of circulating antibody may not boost.[72,308,309,526,538–540,564] Krugman and colleagues[72] reported that, after revaccination, a significant increase in HI titer occurred in only one of six children with HI titers of 1:16 or 1:32, but in 25 of 36 children with titers of 1:8 or less. Similar findings were noted in vaccinees exposed to wild-type virus.

Boosting of antibody titers appears to be transient, with several investigators finding decay of antibody levels to the prerevaccination level within months to years.[546,565–567] In one study, antibody titers against measles in children with low levels of antibody before revaccination decayed during a 6-month period after revaccination; however, cellular immunity, measured in a lymphocyte proliferation assay, appeared to persist.[551]

The booster phenomenon is not unique to vaccine-induced immunity. It can also be observed after exposure to measles or after vaccination in persons who have had measles, but it occurs less frequently because antibody titers after natural infection are usually higher than those after vaccination.[70,72] Stokes and colleagues[70] reported that, on reexposure to wild-type virus, 6 of 12 naturally immune persons with preexposure Nt titers ranging from 1:2 to 1:8 experienced a boost in titer. However, such boosts were not seen in any of 22 persons with titers between 1:16 and 1:128. These data indicate that subclinical reinfection may occur after both natural infection and successful vaccination.

Studies of the response to revaccination[546,568–570] show that a high proportion of vaccinated persons who lack detectable antibody to measles will respond to the second dose. Among persons initially vaccinated after 12 months of age, at least 95% will respond to the second dose.

Effectiveness of Protection

Correlates of Protection

The most direct method of measuring the personal immunity effect of measles vaccine would be to challenge vaccinees and controls with wild-type measles virus and document the

clinical outcome. Such studies are not done in humans because of the harmful effects of exposure to measles virus. In studies in animals challenged with wild-type measles virus, vaccinated animals have significant decreases in clinical symptoms and measles virus replication compared with unvaccinated animals.[571] These studies are performed to evaluate the response to new vaccines in terms of clinical protection, reduced viral load, and development of serologic and cellular immunity.[571–573]

Because tests of cell-mediated immunity to measles are less widely available, antibody titers are most often used as evidence of protection from measles (i.e., as a correlate of protection). Although any detectable level of measles antibody has been interpreted as evidence of protection after vaccination, the development of more sensitive antibody tests[318] has raised concerns that low levels of antibody[532] may not be protective.

Plaque reduction Nt antibody titers at the time of exposure to virus have been most closely correlated with immunity against measles. In one study, no one with a titer of 120 or greater at the start of an outbreak developed measles.[574]

Eight of nine students with low but detectable levels of measles antibody immediately before the outbreak (plaque reduction neutralization [PRN] titer ≤120) developed typical measles compared with none of 71 with preexposure PRN titers greater than 120. Seven of 11 students with preexposure PRN titers of 216 to 874 had a fourfold or greater rise in antibody titer compared with none of seven students with a preexposure PRN titer of 1052 or greater, indicating that high titers were associated with protection against both infection and disease. Although many persons with low antibody titers may not develop disease after exposure, available data suggest that these low levels of antibody may not be fully protective.

Protection also can be evaluated by examining the immune response of vaccinees challenged with vaccine virus through revaccination.[189,309,540,560,565,575,576] Such challenges most often result in an anamnestic immune response (see "Response to Revaccination" above).

Efficacy and Effectiveness

The most commonly used method to quantify the protective effect of measles vaccine is to identify persons with similar likelihood of exposure to measles virus and compare the attack rate of disease in unvaccinated and vaccinated persons. The decrease in attack rate among vaccinated compared with unvaccinated persons is called vaccine effectiveness or vaccine efficacy.[577,578] (Refer to Chapter 77 for a more detailed discussion of this topic, including formulas and methods for calculating vaccine effectiveness.) In outbreak settings in which a high proportion of the population is vaccinated, the proportion of cases that are vaccinated will also be high, and it may appear erroneously that the vaccine effectiveness is low.[579,580] However, approximately 50% of cases can be expected to be vaccinated, with vaccine effectiveness and vaccine coverage each 90%.[577] This proportion of cases will increase to 60% with a 95% coverage rate. The majority of available data indicate vaccine effectiveness after a single dose in the United States of 90% to 95% or greater,[581] consistent with seroconversion data.

Reduction in the occurrence of measles after the introduction of vaccine is a common measure of vaccine-induced protection at the population level. Both Krugman and colleagues[307] and Baba and colleagues[582] noted virtual elimination of measles from a population of institutionalized children after vaccination became routine, despite high levels of infection in the surrounding community. Similarly, nationwide surveillance in many countries with high levels of immunization has documented a significant reduction in reported measles cases after vaccine licensure, and many have eliminated endemic transmission of measles.[22–41] For more examples of the impact of measles vaccination on measles incidence, see "Experiences with Measles Control and Elimination in Various Countries" later in this chapter.

Monitoring the reproductive rate, or R value, is another method of assessing the impact of vaccination on a population. The basic reproductive rate (R_0) is the average number of cases that would be expected to spread from a single case of measles in a completely susceptible population. Measles is a highly infectious disease, and R_0 has been estimated to be 12 to 18.[583] The effective reproductive rate (R) incorporates the level of immunity in a population with the factors that determine R_0. In a completely susceptible population, $R = R_0$. In other populations, the difference between R and R_0 is the effect of population immunity. When R is greater than 1, the number of cases increases from one generation to the next and an epidemic begins. As the spread of disease increases immunity in the population, R falls below 1, the number of cases decreases from one generation to the next, and the epidemic ends. To achieve interruption of endemic transmission of measles, it is necessary to achieve a level of population immunity that maintains R less than 1 (see Chapter 77). In the United States, assessment of the reproductive rates through surveillance data documented R less than 1 for the period from 1992 to 1999.[584] In Canada, an analysis of reported measles cases between 2002 and 2013 enabled estimation of the effective reproductive number at 0.86 (95% CI, 0.81–0.92) which was consistent with maintenance of measles elimination.[585]

Population protection from measles can be evaluated without waiting for an outbreak to identify susceptible groups by using tools such as population surveys of measles antibody levels and by mathematical modeling of population immunity. Although antibody levels are a very useful measure of measles immunity, a proportion of persons who do not have detectable measles antibody may have a level of protection via cellular immunity. In a national serosurvey conducted from 1988 to 1994, Hutchins[586] reported that overall only 7% of persons older than 6 years of age in the United States lacked serum IgG antibodies to measles. However, 19% of those born between 1967 and 1976 were seronegative.[586] This time frame represents the early implementation phase of measles vaccination in the United States, when high coverage levels had not been achieved, yet the incidence of measles was significantly decreased; therefore, a proportion of children grew up without getting measles or vaccination. This pocket of seronegativity has not been a major focus of measles transmission; however, it may have a significant impact on the amount of antibodies mothers born in these years pass on to their infants.[586] In follow-up surveys conducted 1999–2004 and 2009–10 in the United States, the lowest levels of seropositivity were again found in persons born in early vaccine implementation years of 1967 to 1976.[587,588] Serosurveys in some other countries have demonstrated low levels of seropositivity in persons born in the early vaccine implementation years.[589,590] Serosurveys have also been used to plan vaccine strategies or assess their impact.[591–593] More recently, oral fluid surveys have assessed population IgG antibodies to measure the impact of mass campaigns on population immunity and susceptibility in Kenya and Ethiopia.[594–596]

Mathematical modeling can be used to compile and interpret the factors related to measures of vaccine protection, including patterns of transmission, vaccination coverage estimates, measles antibody surveys, and effects of primary and secondary vaccine failure.[596–600]

Host Factors Affecting Protection

The quality and durability of measles vaccine-induced immunity is dependent on a number of factors that relate both to the vaccine and to the host.[308,601] In considering factors affecting protection, it is important to distinguish between primary vaccine failure, that is, a failure to seroconvert after vaccination, and secondary vaccine failure, that is, loss of protection after demonstrated seroconversion.

Maternal Antibody and Age at Vaccination

A number of host factors may be responsible for primary vaccine failure. The most important and well described is maternal antibody. Passively acquired measles antibodies may neutralize vaccine virus before a complete immune response develops. The most common sources of these antibodies are maternal transfer, Ig, and other blood products. The presence of maternally derived transplacental antibody is particularly important in evaluating the immunogenicity of live measles vaccine in early childhood.[327,602] The effect of maternal antibodies in breast milk on response to measles vaccination is unknown.

As noted by Orenstein and colleagues,[602] recommendations for the age at vaccination must balance two factors: (a) the earliest age at which high rates of seroconversion can be obtained and (b) the age group with the greatest risk of severe infection. A balance must be met that optimizes vaccine-induced protection while minimizing the risk of morbidity and mortality that would occur by delaying vaccination.[327,379] The age at vaccination that achieves this balance is lower in developing countries than in developed nations because of the increased risk of measles exposure among infants and because of earlier loss of maternally derived antibody.[603,604] The reasons for the variation in duration of passive protection from maternal antibody include differences in (a) levels of measles antibody in mothers, (b) efficiency of transport of IgG across the placenta, and (c) rate of loss of passively acquired antibody by the infant.[327,605,606]

Early in the clinical investigations of live measles virus vaccine, it was recognized that maternal antibody interfered with seroconversion by in vitro Nt of vaccine virus before adequate replication had occurred.[601] On the basis of data available at the time, it appeared that maternal antibody rarely persisted beyond 7 months of age and that an adequate immune response could be achieved if vaccination was limited to infants 9 months of age and older.[70,72,528,530,607] Whereas only 60% to 70% of infants younger than 9 months seroconverted, 95% or more of older infants produced antibodies.[21,602] Accordingly, when vaccine was licensed in 1963 in the United States, the recommended age for routine vaccination was 9 months.[608]

In the first few years after licensure, it became apparent, however, that maternal antibodies actually persisted in many infants until 11 months of age.[72,527,528,531] On the basis of these data, vaccination before age 1 year would be expected to be associated with a high risk of primary vaccine failure and subsequent infection in exposed vaccinees.[185,189,530,609–612] Thus, in 1965, the recommended age for vaccination was raised to 12 months.[467] The importance of this change is illustrated by Krugman's[613] data showing that only 86% of 123 infants 9 months of age seroconverted after administration of Edmonston B vaccine and Ig, compared with 97% of 899 children vaccinated at 12 months of age or older.

In 1965, it was also recommended that children vaccinated before 1 year of age be revaccinated because a large proportion of these children were susceptible and were expected to respond well to revaccination. A number of studies confirmed these findings,[540,609,610,614] but there are also some data indicating that early vaccination may alter the immune response after revaccination. Wilkins and Wehrle[530] first raised concerns by reporting that 19 (51.4%) of 37 children who did not respond when they were initially vaccinated at 6 to 10 months of age did not have detectable HI antibodies 8 months after revaccination. All 37 did, however, have detectable Nt antibody. Similarly, Linnemann and colleagues[615] reported that 29 (40.3%) of 72 children vaccinated before 10 months of age were HI-negative at a mean of 4.8 years after revaccination. In contrast, Lampe and colleagues[576] did not find any difference in seroconversion rates in children vaccinated once at 15 months of age or later, compared with children revaccinated after first being vaccinated before 1 year of age. By using an EIA assay, Murphy and colleagues[616] observed high seroprevalence rates at a mean of 6 months after vaccination in 302 children revaccinated after early vaccination and in 300 vaccinated once at 15 months of age or older (98% seroprevalence rate for both groups). However, they did observe that the titers in the revaccinated group were lower than those in the children vaccinated once. These findings were confirmed by McGraw.[473]

One of the most complete descriptions of an altered immune response is provided by Stetler and colleagues.[533] These authors reported that children revaccinated after an initial vaccination before 1 year had no difficulty seroconverting; postrevaccination HI antibody was detected in 116 (95.9%) of 121 children lacking HI antibody before revaccination. Eight months later, HI antibodies were undetectable in 58 (47.9%) of 121 children, but, after retesting with a cytopathic effect neutralization (CPEN) test, only 5 (4.2%) of 120 sera were negative. Successful priming in some of the early vaccinees was also suggested by the finding that IgM was detected in the sera of only 14 (22.2%) of 63 revaccinated children lacking HI, EIA, and CPEN antibody, compared with 37 (74.0%) of 50 random control vaccinees. These findings were similar to those noted by Black and colleagues.[575]

Although there may be some alteration of the immune response, the most reliable indicator of the actual effectiveness of revaccination of these children is the evaluation of their risk of infection. Although revaccination may not provide 100% protection, available data indicate that revaccination is effective.[610,614] Shasby and colleagues[609] reported that, in an outbreak, the attack rate in 73 children vaccinated once before 12 months of age was 35.6% (26 of 73), whereas the attack rate in 55 children revaccinated after 12 months of age was only 1.8% (1 of 55). Davis and colleagues[614] noted that none of 80 students revaccinated after their first vaccination before 12 months of age became infected during an outbreak. For comparison, the attack rate in children vaccinated twice at 12 months of age or older was 1.4% (2 of 138), that in children vaccinated once at 12 months of age or older was 1.8% (21 of 1191), and that in unvaccinated children was 57.1% (4 of 7). Hutchins and colleagues[617] reported a vaccine effectiveness of 99.5% for children vaccinated with a first dose at age 6 to 11 months and a second dose after age 12 months. Thus, the available data indicate that revaccination of children first vaccinated before 1 year of age will result in good vaccine-induced protection, although it may be associated with an altered immune response, manifested as a lower antibody titer.[618,619] This conclusion is especially important because vaccination of U.S. children as young as 6 months, with subsequent revaccination, is recommended in certain outbreak situations and for children traveling internationally.[233,234]

The recommended age at vaccination was again changed in 1976 from 12 months to 15 months because newer data

indicated that children vaccinated at 15 months of age and older were even more likely to make and maintain antibodies and were less likely to be infected in outbreak situations than those children vaccinated earlier.[602] Although some studies provide contrary results, examination of data on seroconversion rates and prevalence of antibodies after vaccination indicates that, in general, 79% to 89% of children vaccinated at 12 months of age have detectable antibodies, compared with 87% to 99% of those vaccinated at 15 months or later.[527–529,531,602,609,620–622] Similarly, a number of studies measuring the risk of measles in vaccinated and unvaccinated children indicated that measles occurred in children vaccinated at 12 months of age approximately 1.5 to 5.0 times more frequently than in those vaccinated later than 12 months.[547–550,602,609,610]

Data on measles antibody titers in umbilical cord blood and in infants suggest that infants whose mothers have vaccine-induced immunity may be receiving less maternal antibody than infants whose mothers had natural measles.[544,622–627] Many mothers born in the vaccine era have antibodies induced by vaccination, which typically results in lower titers than does measles disease. Also, an increased proportion of mothers born since the introduction of measles vaccine may not have any measles antibodies because they have not had measles or been vaccinated. Serologic surveys show that up to 19% of women of childbearing age in the United States, born between 1967 and 1976, are measles seronegative.[586,587] Infants born to seronegative mothers would lack maternal antibody from birth onward. In 2009, greater than 99% of women giving birth in the United States were born after 1963, the year measles vaccine was licensed.[628]

Infants whose mothers were born in the vaccine era are susceptible to disease at a younger age and are more likely to respond to vaccination at an early age. In a 1992 cohort study in the United States, Papania and colleagues[629] documented a greater than 2.5 RR of measles among infants whose mothers were born in the vaccine era compared with infants whose mothers were born before 1963. Higher rates of seroconversion at 12 months also have been found in children born to women with vaccine-induced immunity.[623–625] Based on these findings, in 1994, the recommended age of vaccination in the United States was changed again to between 12 and 15 months.[234]

Factors that alter the efficiency of transport of IgG across the placenta also can affect the amount of antibody infants receive. Maternal measles antibody is transferred across the placenta from mother to infant via an active transport system, which results in a higher antibody titer in the infant than in the mother. Because the majority of the maternal measles antibody transfer occurs late in the third trimester, infants born prematurely often have low antibody titers.[630] Several diseases that affect the mother, most importantly HIV infection and possibly malaria, have been shown to decrease the placental transfer of maternal measles antibody and result in lower infant titers.[631,632]

Because infants in developing countries may lose maternal measles antibody at an early age and may be exposed to measles virus at an early age as a result of intense transmission, the WHO recommendations indicate that 9 months is the most appropriate age for delivery of the first dose of measles vaccine in most developing countries (see "Indications" below).[633]

Studies of early measles vaccination regimens have found that infants 6 months of age had lower seroconversion rates and geometric mean titers than older infants or toddlers. This effect was evident even among 6-month-old infants who lacked maternal measles antibody, suggesting an age-related delay in maturation of humoral immunity unrelated to passively transferred maternal antibody.[634] In contrast, markers of cell-mediated immunity (e.g., T-cell proliferation) were equivalent after vaccination at 6, 9, or 12 months, regardless of the presence of passive antibodies. In addition, infants initially vaccinated at 6 or 9 months experienced increases in both humoral and cell-mediated responses after administration of a second dose. Although the cell-mediated immunity resulting from a dose at 6 months alone may not be protective, early vaccination may prime the humoral response to the second dose, thereby providing clinical benefits.[635]

Intercurrent Illness and Malnutrition

There is a theoretic concern that interferon produced by an intercurrent infection may interfere with successful vaccination.[539,636] Studies addressing this question, which have been conducted in developing and in developed countries, have produced discordant results. Two studies in developing countries found no differences in seroconversion rates in ill and well children after receipt of measles vaccine.[390,637] A small study in the United States found that 80% of children with rhinorrhea seroconverted, compared with 98% of well children.[638] Subsequent studies conducted in the United States and Canada found equivalent seroconversion rates among children with upper respiratory infections or mild illness and well children.[639–641] In a study of 128 mildly ill and 258 well children given MMR, seroconversion to measles was 97% in well children compared with 99% in those with mild illnesses, mostly upper respiratory tract infection[641]; no differences were observed in seroconversion to mumps or rubella. A study conducted in Wisconsin found no association between vaccine failure and vaccination during the high-risk season for respiratory infections.[642] One study conducted in Thailand found lower geometric mean antibody titers for children vaccinated at 9 months of age among those who experienced an upper respiratory tract infection in the 2 weeks after vaccination.[643] However, the benefits of vaccinating mildly ill children outweigh any theoretic risk of lower seroconversion rates.[644] Several studies found seroconversion rates in malnourished children similar to those in children who are well nourished.[389,390,645,646]

Immunosuppression and HIV Infection

Measles vaccination is not recommended for most immunocompromised patients, and as a result, few data are available on the immune response in such patients. However, the increasing number of children with HIV infection, the high risk of severe measles in these children, and the limited side effects to measles vaccine found in HIV-infected children have resulted in recommendations for vaccination. Studies in the United States found that HIV-infected children have poor responses to vaccination, lose antibody more quickly after vaccination, and respond poorly to revaccination.[200,647–650] Retrospective studies found that only 3 (12.5%) of 24[200] and 22 (59.5%) of 37[648] vaccinated children with HIV infection had detectable measles antibody. Seroconversion rates in prospective studies range from 13 (33.3%) of 39 children to 15 (60%) of 25 children.[211,647] In the Democratic Republic of Congo, seroconversion rates after vaccination at 9 months were 77% in asymptomatic HIV-infected children and 36% in symptomatic HIV-infected children.[651] In two other studies in Africa, seroconversion rates after vaccination at 6 months were greater than 75% in HIV-infected children.[652,653] A study in Thailand found that by age 9 months, 100% of 30 infants of HIV-infected mothers had lost their maternally acquired antibodies

and that by 12 weeks postvaccination, HIV-positive infants had lower seroconversion and median antibody levels when compared with HIV-negative infants.[654] A recent study in Zambia found 88% of HIV-infected infants vaccinated at 9 months of age developed protective antibody levels; by 27 months after vaccination only 50% of children who survived had maintained protective antibody titers.[644] HIV-infected children may respond better when they are vaccinated at earlier ages, before they become severely immunocompromised.[655,656] In sub-Saharan Africa where the burden of pediatric HIV infection is greatest, antiretroviral treatment programs have scaled-up dramatically, increasing access to life-prolonging treatment for HIV-infected children. Revaccination with measles-containing vaccine (MCV) after immune reconstitution with highly active antiretroviral therapy (HAART) should be recommended to protect these children against measles, and ensure high levels of population immunity (see "Persons Infected with HIV" below).[657]

Adults who were vaccinated in childhood before becoming infected with HIV appear to retain protective levels of measles antibody. High seroprevalence of measles antibody in HIV-infected adults in the United States has been documented,[658] and antibody levels are maintained, even as immunosuppression progresses. In one study, measles seronegative HIV-infected adults who were vaccinated while on HAART (HAART) responded to measles vaccine but lost antibody rapidly after vaccination.[659]

Vitamin A Supplementation

Investigators in Indonesia found a lower rate of seroconversion among children vaccinated at 6 months of age who received supplementary vitamin A compared with children not receiving such a supplement.[660] Subsequent studies conducted in Guinea-Bissau, India, and West Java found similar rates of seroconversion among 9-month-old children receiving and not receiving vitamin A supplements.[661–663] Among malnourished children in the Indian study, the postvaccination geometric mean antibody titer was significantly higher in the group receiving vitamin A compared with the placebo group.[662] A large multicenter clinical trial confirmed the safety of vitamin A supplementation administered with routine immunizations at 6, 10, and 14 weeks of age and at 9 months with measles immunization.[664] The balance of evidence supports the WHO recommendation that, in vitamin A–deficient countries, infants should receive a vitamin A supplement at the time of measles immunization.[665]

Other Host Factors

Even after receipt of potent vaccine, approximately 2% to 5% of vaccinees will fail to respond for unknown reasons.[21,72,307] A group of investigators at the Mayo Clinic has explored the role of genetic factors and found associations with particular human lymphocyte antigen (HLA) types and nonresponse or hyperresponse to measles vaccination.[666] A study of monozygotic and dizygotic twins found a high degree of heritability of measles antibody level and subsequently showed associations between homozygosity for class I and class II HLA alleles and poor response to measles vaccination.[667] Of importance, two doses of MMR vaccine appear to induce sufficient antibody levels and lymphoproliferative responses against measles regardless of homozygosity status, suggesting genetically related nonresponse to the first dose is overcome by administration of a second dose.[668]

Although there may be some exceptions in the very young,[473,530,533,575] revaccination has been found in both epidemiologic and serologic studies to induce the same high rate of immune response that follows initial vaccination.[532,540,568–570,609,610,629]

Vaccine Factors Affecting Protection

Vaccine Antigen and Strain

Although most further attenuated measles vaccines are equally immunogenic in older children,[465,477] differences in the ability of vaccine strains to immunize young infants have been reported.[478,480,669–673] High measles morbidity and mortality in developing countries among infants younger than 9 months, the recommended age for vaccination,[674,675] has stimulated research on strategies for immunization of younger infants. In the early 1980s, Sabin and associates[477,478] investigated aerosol administration of two measles vaccines, the Edmonston-Zagreb and Schwarz strains. Their finding of higher seroconversion rates after Edmonston-Zagreb than after Schwarz vaccine focused attention on this vaccine strain. Several subsequent studies found that the Edmonston-Zagreb strain was more immunogenic than the Schwarz vaccine in this age group when given by injection (see "Vaccine Dose" below). The AIK-C strain of measles vaccine also has been found to be highly immunogenic in young infants and, in some studies, more immunogenic than either Schwarz or Edmonston-Zagreb vaccines.[676–678] The reasons for these differences are not known.

Vaccine Dose

Small doses of vaccine can effectively immunize older infants and children; however, the dose of vaccine administered is important in immunizing young infants.[669,670,672] Increasing the Edmonston-Zagreb vaccine dose from 10,000 to 40,000 plaque-forming units (PFU) in The Gambia resulted in an increase in response rate from 73% to 100% in 4- to 6-month-old infants.[669] In Mexico, serologic response to vaccination of 6-month-old infants increased for both Schwarz (66% to 91%) and Edmonston-Zagreb (92% to 98%) vaccines, with a 100-fold increase in dose[670]; the effect was greater for Schwarz than for Edmonston-Zagreb vaccine. Because of these data and interest in a vaccination strategy for children younger than 1 year of age in developing countries, in 1990 the WHO recommended that a higher dose (initially defined as >100,000 PFU and later changed to >50,000 PFU) of Edmonston-Zagreb vaccine be administered at 6 months of age in areas where measles mortality in young infants was a major health problem.[679] However, problems with vaccine availability resulted in little use of the vaccine on a large scale. Questions were raised regarding the safety of high-dose measles vaccine in several developing countries, with a higher all-cause mortality rate in girls (but not in boys) who received high-titer vaccines compared with those who received standard-titer vaccines.[678–682] Increased mortality rates after vaccination with a high-titer vaccine were not observed in developed countries or in countries with an infant mortality rate less than 100 per 1000 births.[683] High-titer measles vaccines are not currently recommended.[684]

Vaccine Handling

Vaccine failures with live vaccine have stemmed from improper handling. Loss of potency of live vaccines can result from poor shipping or storage practices.[685,686] Although administration of impotent vaccine had previously been implicated in outbreaks of measles in vaccinated persons, the likelihood of this occurring now is reduced because of the addition in 1979 of the stabilizers discussed previously.[471,519]

Persistence of Immunity

The majority of data suggest that a dose of live vaccine properly administered to an appropriate host that results in seroconversion will afford lifelong protection to nearly all vaccinees.[687] The duration of vaccine-induced immunity has been documented by studying the persistence of measurable antibody, the clinical characteristics and serologic response of measles cases in vaccinated persons, the effects of vaccine challenge, and the attack rate in vaccinees as a function of the time since vaccination.

Although vaccine-induced antibody titers are lower than those achieved after natural infection, this difference does not appear to result in decreased personal protection from measles. Serologic studies limited to children vaccinated at 12 months of age or older indicate that, although antibody titers do decline over time, detectable antibodies are present in most vaccinees.[72,308,309,525,526,529,532,534,536–538,542,688] Because titers can fall to levels undetectable with some assays, the test used is important in the assessment of immune status. Furthermore, many persons lacking detectable antibody manifest a secondary immune response on revaccination or exposure to wild-type virus, indicating persistence of some level of immunity.[316]

Krugman[72,308,309] followed the serologic status of a population of institutionalized children for 16 years. The HI geometric mean antibody titer in 70 persons who received further attenuated vaccine was 1:333 at 1 month but, in the absence of exposure, had fallen to 1:6 after 13 years (Fig. 37.7).[309] Thirteen percent had a HI titer of 1:4, 10% had a titer of 1:2, and 13% had no detectable antibody. In contrast, whereas 47 naturally infected children had a comparable 1-month HI geometric mean antibody titer of 1:410, 16 years after disease, the geometric mean titer was 1:22 (Fig. 37.7). Only 4% had a HI titer of 1:2, and none had undetectable antibodies. Sixteen sera with HI titers ranging from less than 1:2 to 1:4, obtained from persons vaccinated 6 to 15 years earlier, were retested with the more sensitive PRN assay[318]; the PRN titers ranged from 1:4 to 1:46.[309] Typical booster responses after revaccination of some of the HI-negative persons were also found.

Dine and associates[689] followed-up adults vaccinated in a vaccine trial as children in the 1970s. The 56 participants, who were all seropositive by HI tests after vaccination, all had detectable measles antibody by PRN at least 26 years after vaccination. PRN titers greater than 1:120 were found in 92% of the subjects, and the strongest predictor of lower titers was lower HI titers in the original study. None of the subjects had been revaccinated in the interim period or had had measles or known exposure to measles. Fewer than five cases were reported annually from Cincinnati, the study setting, over the 12 years before the follow-up study began. Therefore, boosting of antibody titers from exposure to wild-type measles virus was unlikely to play a major role in sustaining antibody titers in most of the study subjects.

Seroprevalence studies also provide useful information about duration of immunity, but, because information on seroconversion is lacking, one cannot be sure whether persons are seronegative because of primary or secondary vaccine failure. In addition, sensitivity of the assay procedure is important. These variables account for some discrepancies in reported findings. For example, Bass and colleagues[526] reported that HI antibodies were detectable in 29 (73%) of 40 children more than 8 years after vaccination; however, 39 (98%) of the 40 children had Nt antibody. Orenstein and colleagues[505] reported that the seroprevalence among 1871 high-school students (10th, 11th, and 12th graders), 1835 (98.1%) of whom had been vaccinated at 14 months of age or older and who had no history of measles, was 86.9% by an HI assay. However, 98.8% were positive with both the HI assay and the same PRN assay used in the Albrecht study.[318] Orenstein and colleagues[532] further documented the specificity of the PRN assay by vaccinating HI-negative children. IgM was detected in 14 (87.5%) of 16 students with a PRN titer less than 1:4, but in only 1 (1.5%) of 68 who were PRN positive.

Although live-virus vaccine-induced immunity typically provides lifelong protection, secondary vaccine failures occasionally result from waning immunity. Secondary vaccine failures are measles cases in persons who initially developed a protective immune response following vaccination which diminished over time to a nonprotective level. The most direct evidence of secondary vaccine failure comes from case reports of measles in persons whose post vaccination immunity was documented before the acute episode of measles.[192,194,690] In a study in Canada, 9 (5%) of 175 of persons who initially seroconverted after receipt of measles vaccine developed measles within 10 years of vaccination. In this study, persons who developed measles had lower postvaccination titers than those who did not.[192] Also, current laboratory analyses can be used to assess preexisting immunity at the time of acute measles onset. Absence of IgM antibody in cases confirmed virologically, IgG antibody at the time of rash onset, distinctively high levels of neutralizing antibodies and high IgG avidity all provide evidence of preexisting immunity. In vaccinated persons evidence of preexisting immunity indicates secondary vaccine failure[184,187–191,193,691,692] Some studies also suggest that the secondary vaccine failure cases can be mild and may be more likely to occur in persons vaccinated at younger than 12 months. In epidemiologic studies of persons vaccinated with live measles vaccine at 12 months of age or older, some studies show that persons with increased time since vaccination have slight increases in attack rates compared with those more recently vaccinated; however, none has yet documented a significant increase (Table 37.6).[548,609,610,612,626,693–695] During outbreaks, observed attack rates in persons vaccinated 15 years or more before infection have been on the order of 5% or less, and calculated vaccine effectiveness has been 90% to 95% or greater. These results are consistent with the expected frequency of primary vaccine failure that occurs in everyday practice. Data from the United Kingdom, the United States, and other countries[385,687,688,696,697] have not found significant increases in vaccine failures with time since vaccination. With overall incidence of measles in the United States at record low levels and no evidence of increasing incidence among

previously vaccinated persons, waning immunity does not appear to constitute a public health problem in the United States. Although secondary vaccine failures have been documented, taken collectively, the serologic and epidemiologic data during the past 50 years indicate that vaccine provides long-term immunity. However, increased measles transmission among adults has been reported in several countries, including China. Serologic studies show low seroprevalence in some adult age groups. It will be important to determine what portion of serosusceptibility, and of measles cases, is the result of failure to vaccinate, versus primary or secondary vaccine failure in populations that have different vaccine schedules with different measles vaccines.[698]

Combined Vaccines and Simultaneous Vaccination

Live measles vaccine has been administered successfully in combination or in conjunction with a variety of immunizing agents, such as yellow fever vaccine, poliovirus vaccine, diphtheria and tetanus toxoids and whole-cell pertussis vaccine (DTP), meningococcal vaccine, hepatitis B vaccine, and smallpox vaccine.[496,499,503,699–708] There is one report of interference with the measles antibody response after simultaneous administration of meningococcal A and C vaccines,[704] although a different team of investigators did not find interference with simultaneous administration of measles vaccine and meningococcal A vaccine.[703]

In developed countries, measles vaccine is administered today along with rubella and mumps vaccines as a combined vaccine (MMR) and as part of routine childhood immunization programs.[233,234] Use of MMR vaccine instead of single-antigen measles vaccine increases the benefit-to-cost ratio of the measles vaccination program in the United States from 17.2 : 1 to 21.3 : 1.[404] The varicella vaccine was included in the routine childhood schedule in 1996, licensure of a combined MMRV vaccine occurred in 2005, and the ACIP recommendation for a routine second dose of varicella vaccine occurred in June 2006.[709] Thus, in the United States, both recommended doses of measles vaccine could be administered as MMRV. However, given the increased incidence of febrile seizures with dose one of MMRV, most such doses are likely to be MMR.[510,511] MMR vaccine is also frequently administered to susceptible adults.

Studies consistently show that combinations of measles, mumps, and rubella antigens, regardless of the virus strain, elicit the same high rates of seroconversion seen with each component individually and that there is no increased risk of reactions in persons susceptible to all three antigens (Tables 37.7 and 37.8).[488–505] Furthermore, vaccination of persons already immune to one or more of the antigens, from either previous vaccination or infection, is not associated with any increased risk of vaccine-associated adverse events.[705,710–714] Although there are reports of directly mixing measles vaccine with DTP,[714] this should not be done routinely. Rather, the vaccines should be administered in separate syringes and at separate sites.[715]

Immunization against varicella along with measles, rubella, and mumps, either as two vaccines (varicella and MMR) or as a quadrivalent vaccine (MMRV), has been studied.[716,717] Seroconversion rates have been reported to be 95% or greater to all antigens, although titers against varicella were lower among persons receiving the quadrivalent vaccine. A second dose of MMRV administered 6 to 8 weeks after the first dose resulted in greater than or equal to 98% seropositivity for all four antigens.[506] Concomitant administration of MMRV, *H. influenzae* b/hepatitis B (Hib/HepB), and diphtheria-tetanus-acellular pertussis (DTaP) vaccines was found to be immunogenic and well tolerated.[507]

Postexposure Prophylaxis

Routine vaccination before exposure to measles provides the best protection against measles. However, persons without measles immunity who are exposed to measles can receive some protection through measles vaccination or Ig administration after exposure.

Use of Vaccine

Exposure to measles is not a contraindication to measles immunization. Available data suggest that live virus measles vaccine, if given within 72 hours of measles exposure, will prevent or modify disease.[447,559,718] Also, the vaccine should induce protection against subsequent measles exposures

TABLE 37.7 Antibody Response After Administration of Measles Vaccine Alone, in Combination With Mumps and Rubella Vaccines, and in Combination With Mumps, Rubella, and Varicella Vaccines

should the initial exposure fail to result in measles and protection. Therefore, vaccine given within 72 hours of measles exposure is the intervention of choice for persons older than 12 months of age who are exposed to measles in most settings (e.g., healthcare facilities, schools, colleges, healthcare facilities), unless contraindicated (see "Precautions and Contraindications" below). Infants 6 to 11 months of age may receive measles vaccine instead of Ig if the initial exposure is detected within 72 hours. Infants vaccinated before age 12 months must be revaccinated on or after the first birthday with two doses of MMR vaccine separated by at least 28 days (see "Indications" below).

Use of Immunoglobulin

Guidelines for Ig dosage and use in measles postexposure prophylaxis should be driven by local measles epidemiology, population immunity, and Ig product antibody levels. Current U.S. recommendations are to give human IgIM or IgIV to susceptible persons exposed to measles and for whom vaccine either is contraindicated or was not given within 72 hours of initial exposure. The United Kingdom has similar guidelines.[719] Measles is infectious during the prodrome and often is not diagnosed until the rash onset. Therefore, many exposed persons are not identified until more than 72 hours after

initial exposure, which is too late for prophylaxis with measles vaccine. Human Ig provides measles antibodies to prevent or modify the disease when given up to 6 days after exposure.[179–181,410] However, any immunity conferred is temporary (lasting approximately 3 to 4 weeks) unless modified or typical measles occurs.[179,410] Ig should not be used to control measles outbreaks.

Postexposure prophylaxis with Ig is especially important for exposed persons who are at increased risk for complications from measles (i.e., infants younger than 12 months of age, pregnant women, and immunocompromised persons). Because donor pool concentrations of antibodies are lower in the United States than in the prevaccine era, the ACIP increased the recommended dose of IgIM to 0.5 mL/kg within 6 days of initial exposure. However, because the maximum dose by volume is 15 mL, persons who weigh more than 30 kg receive less than the recommended dose and will have lower titers than recommended.[409] The recommended dose of IgIV is 400 mg/kg. Any nonimmune person exposed to measles who received Ig should subsequently receive MMR vaccine, which should be administered no earlier than 6 months after IgIM administration or 8 months after IgIV administration, provided the person is then 12 months of age or older and the vaccine is not otherwise contraindicated. Most infants younger than 5 to 6 months of age have partial or complete immunity to measles because of passive maternal antibody, if their mothers are immune. However, in some countries up to 19% of women of childbearing age do not have measurable measles antibody titers.[600,720] Infants born to these women would be susceptible to measles at birth. Human Ig is not indicated for exposed persons who have received at least one dose of measles vaccine at 12 months of age or older unless they are immunocompromised.

The following patient groups are at risk for severe disease and complications from measles and, if exposed, should receive Ig: infants younger than 12 months of age, pregnant women without evidence of measles immunity, and severely immunocompromised persons. IgIM can be administered to other, exposed persons who do not have evidence of measles immunity, but priority should be given to persons exposed in settings with intense, prolonged, close contact (e.g., household, daycare, and classroom). For exposed persons without evidence of measles immunity, a rapid IgG antibody test can be used to inform immune status, provided that administration of Ig is not delayed.[409]

Because infants are at higher risk for severe measles and complications, and infants are susceptible to measles if mothers are nonimmune or their maternal antibodies to measles have waned,[721,722] IgIM should be administered to all infants younger than age 12 months who have been exposed to measles.[409] For infants 6 through 11 months of age, MMR vaccine can be administered in place of Ig if administered within 72 hours of exposure.

Because pregnant women might be at higher risk for severe measles and complications,[721,722] IgIV should be administered to pregnant women without evidence of measles immunity who have been exposed to measles. IgIV is recommended to be administered in doses high enough to achieve estimated protective levels of measles antibody titers (400 mg/kg).

Severely immunocompromised patients who are exposed to measles should receive IgIV prophylaxis regardless of immunologic or vaccination status because they might not be protected by the vaccine. Severely immunocompromised patients include patients with severe primary immunodeficiency; patients who have received a bone marrow transplant until at least 12 months after finishing all immunosuppressive treatment, or longer in patients who have developed graft-versus-host disease; patients on treatment for acute lymphocytic leukemia within and until at least 6 months after completion of immunosuppressive chemotherapy; and patients with a diagnosis of AIDS or HIV-infected persons with severe immunosuppression, which is defined as a CD4 percent of less than 15% (all ages) or a CD4 count of less than 200 lymphocytes/mm^3 (age >5 years) and those who have not received MMR vaccine since receiving effective antiretroviral therapy (ART). Some experts include HIV-infected persons who lack recent confirmation of immunologic status or measles immunity.[409] For persons already receiving IgIV therapy, administration of at least 400 mg/kg body weight within 3 weeks before measles exposure should be sufficient to prevent measles infection. For patients receiving IgSC therapy, administration of at least 200 mg/kg body weight for two consecutive weeks before measles exposure should be sufficient.[409]

Vaccine Safety

Adverse reactions after receipt of live, further attenuated measles vaccines (alone and in combination) are generally mild.[722] Except for hypersensitivity reactions, adverse reactions are limited to susceptible vaccinees and occur primarily during the 6 to 12 days after vaccination when the peak in replication of the live virus occurs.[307,419–424,461–464,488,489,492,495–503,705,715,723–733] Fever of 39.4°C or higher occurs in approximately 5% to 15% of vaccinees between the 7th and 12th days after vaccination and lasts approximately 1 to 2 days. In a study of twins, when one twin received MMR vaccine while the other received placebo, increased rates of fever occurred almost exclusively 9 or 10 days after vaccination.[488,733]

Rash occurs in approximately 5% of recipients, beginning 7 to 10 days after vaccination and lasting for 1 to 3 days. Determining the etiology of a rash illness after measles vaccination can be difficult because other infections, such as human herpesvirus type 6 and human papillomavirus type 19, can often occur early in life and can be confused with a vaccine reaction.[294] Systemic adverse events have been reported less frequently among infants receiving MMR at age 6 to 8 months when compared with those aged 9 to 11 months and 12 to 14 months, indicating that early MMR vaccination is well tolerated.[733a]

MMR vaccine should be given to eligible persons who present with mild illness or low-grade fever. For persons with moderate or severe illness, including untreated, active tuberculosis, vaccination with MMR should be postponed and given after they have recovered. Although, there are no reports of persons being treated for tuberculosis, having experienced an exacerbation of tuberculosis following MMR vaccination, or of any adverse effect of MMR or MMRV vaccines on persons with untreated tuberculosis, a theoretical concern exists that measles vaccine might exacerbate tuberculosis. Therefore, for persons with known untreated active tuberculosis, antituberculous therapy should be started prior to administering MMR vaccine. However, testing for latent tuberculosis infection should not be a prerequisite for MMR vaccination.

When the vaccine is administered to a person already incubating natural measles disease, it is not usually possible to determine if fever and rash are caused by the vaccine or if the child has a modified case of measles, unless wild-type virus is detected by laboratory testing. Measles-like illnesses developing less than 6 days after vaccination are usually the result of the wild-type virus or other concurrent illnesses because the measles-like rash associated with the vaccine is very unlikely to occur within this time period.[488] The frequency of fever, rash, and other side effects after second doses of MCVs is lower than after the first because most children are already immune from the initial vaccination, thus preventing significant viral replication.[724,725] One study found a slightly higher rate of

adverse effects after a second dose of MMR when that dose was given to 10- to 12-year-olds compared with 4- to 6-year-olds.[731] This difference was most likely the result of a higher rate of susceptibility among 10- to 12-year-olds and the recognized increased rate of arthralgia caused by rubella vaccine in older children.[731] Adverse events resulting in medical visits within 1 month after vaccination of 10- to 12-year-olds were still rare (attributable risk 1.7/1000) and consisted mainly of rashes and joint pain.

A study conducted in the United States showed that during the 5 to 12 days after vaccination, children receiving the first dose of MMRV vaccine had significantly higher rates of elevated temperatures than those who had been vaccinated with MMR and varicella vaccine administered separately (27.7% vs 18.7%, respectively).[732] Measles-like rash was also more common after the first dose of MMRV than after MMR and varicella vaccine administered separately (5.9% vs 1.9%, respectively).[507] A multicenter study found rates of fever between days 5 and 12 postvaccination to be higher in recipients of MMRV compared with recipients of MMR and varicella vaccine administered separately (22.8% vs 15.6%); no statistical differences were observed for fever greater than or equal to 40°C between the study groups.[508] Another study conducted in Germany also showed a higher incidence of fever greater than 37.5°C within 15 days after vaccination among children vaccinated with MMRV when compared with children vaccinated with MMR and varicella vaccine (67.7% vs 48.8%). However, the incidence of fever greater than 39°C was not statistically different between the two groups.[506,510,511] No increased fever or rash was noted when these vaccines were administered as the second dose of MCVs.[511,734–737]

Measles vaccine is associated with a mild decrease in platelet counts within a few days after the vaccine is given, and rare cases of idiopathic thrombocytopenic purpura (ITP) have been associated with MCVs.[738] A review of 12 studies revealed a median incidence of 2.6 cases of ITP per 100,000 children receiving the first dose of measles vaccine. In two studies in the United Kingdom, an increased risk of ITP was documented after measles vaccination, at a rate of 1 case in every 25,000 doses in the 6 weeks after immunization.[739] The Vaccine Safety Datalink Project found an attributable risk of 1 case of ITP per 40,000 doses of MMR.[740] The disease was generally mild and resolved in 93% of children within 6 months. Recurrences were uncommon. Therefore, although advisory committees recommend caution when administering MCVs to children with thrombocytopenia or a past history of ITP, data from several small studies of children who had ITP did not reveal recurrences after the administration of MMR.[233,234,739,740]

Immediate hypersensitivity reactions, including hives and anaphylaxis, occur rarely.[741] The rate of anaphylaxis is approximately 1 to 3.5 per million doses administered. The rate of other immediate hypersensitivity reactions is estimated to be approximately 10 per million doses.[742] Measles vaccine is produced in chick embryo tissue culture, and for many years, there were concerns about administering these vaccines to children with egg allergy. Although rare cases of anaphylaxis have been reported in children with egg hypersensitivity, the allergen in the vaccine responsible for these reactions is uncertain.[743] The majority of children with immediate hypersensitivity reactions to MCVs have evidence of allergy to the gelatin stabilizer or neomycin.[744,745] Children with immediate hypersensitivity to eggs can be safely immunized with measles vaccines, and no special precautions are necessary.[744]

Febrile seizures are the most commonly reported neurologic adverse event after measles vaccination.[268,726,729–733] Fever from any source lowers the threshold for seizures, and a febrile seizure is not a sign of central nervous system (CNS) infection or disease. Febrile seizures occur primarily in the second and third year of life and are not associated with long-term sequelae. The risk of febrile seizures is approximately one case for every 3000 to 4000 doses of MMR vaccine administered,[733,746] and the risk typically occurs 6 to 14 days after receipt of MMR.[510,511,726,733,747,] Among children 12 to 23 months of age who received the first dose of MMRV vaccine compared with children who received MMR and varicella vaccines separately, there is an approximate twofold increased risk for febrile seizures. In children 4 to 6 years of age,[748] no increased risk for febrile seizures was observed after vaccination with MMRV vaccine. Having a personal or family history of seizures of any etiology is a precaution for children for the first dose of MMRV, but not MMR, vaccination.[749,750] In the United States, the ACIP has recommended that children with a personal or family history of seizures of any etiology generally should be vaccinated with MMR for their first dose of measles vaccine, because the risks of using MMRV vaccine outweigh the benefits in this group.[722] MMRV vaccine has not been studied in persons with HIV infection and should not be substituted for MMR vaccine. The rates of fever and febrile seizures after administering measles vaccines are much lower than the rates after measles disease.

There has been no increased risk of adverse neurologic events observed in children who received MMR vaccines compared with measles vaccine administered alone.[733]

Postinfectious encephalitis is a recognized complication of measles, but there is uncertainty whether or not encephalitis is caused by further attenuated measles vaccines in normal hosts. In children who have died during the rash phase of measles, measles virus has been found in brain tissue, but measles virus rarely has been found anywhere in the CNS with postinfectious encephalitis, which is thought to be the result of an altered immune response to myelin proteins.[234] Encephalitis has been reported after measles immunization at a rate of approximately 1 case per 1 million vaccine recipients.[751] This rate is lower than the background rate of encephalitis of unknown etiology in unvaccinated children in the general population. There is temporal clustering of reports in the 5 to 15 days after immunization when other adverse effects from the vaccine occur.[714] There has been one report of a vaccine isolate recovered from the cerebrospinal fluid of a normal person who received Edmonston B strain vaccine.[752] There have been no cases of vaccine-strain virus identified as the cause of encephalitis in persons with intact immune systems confirmed by neuropathologic studies. Nine cases of encephalitis after administering MCVs were reported in the United States during 1979 to 1986, when 22.7 million doses of measles antigen–containing vaccine were distributed, for a rate of 1 per 2.5 million doses (0.4 per 1 million doses).[713] In Albania, two cases of encephalitis were identified after 867,000 doses of measles and rubella (MR) vaccine were administered during a mass vaccination campaign.[753] This observed rate is lower than that noted for severe neurologic disorders of unknown etiology in unimmunized children of the same age range, suggesting a possible chance temporal association.[754] In Finland and the United States, there was no evidence of an increased risk of encephalitis after measles vaccines.[755,756] In the United Kingdom, studies found an increased rate of serious neurologic disease in the 6 to 11 days after vaccination.[757,758] However, some of the increase was from complex febrile seizures, and other viruses known to cause encephalitis (herpes simplex virus, human herpesvirus [HHV]-6, and HHV-7) were identified in some affected patients. The Institute of Medicine concluded, in 1994, that there was inadequate evidence to accept or reject a causal relation between measles vaccine and encephalitis or encephalopathy.[738] However, in a 1998 study, done by Weibel and colleagues,[758] the authors found a clustering of 17 cases of encephalopathy on days 8

and 9 after MMR vaccination, but they stated that with the large denominator of children vaccinated throughout 23 years, encephalopathy would be an extremely rare complication (0.06 per 100,000 vaccinees). If measles vaccines do cause acute encephalitis, the rate is at least 1000 times less than the rate after natural infection.

There are case reports but no evidence of increased risk or causal associations of several other disorders after measles vaccines, including Reye syndrome, oculomotor palsy, optic neuritis, retinopathy, hearing loss, cerebellar ataxia, arthralgia, arthritis, and soft-tissue reactions.[268,713,759–768] There is no increased risk of Guillain-Barré syndrome after measles vaccine.[769,770] In a cohort study of 167,240 children, no significant association between timing of the receipt of measles vaccine and asthma was found.[771]

SSPE is caused by persistence of defective measles virus in the CNS through as-yet undefined mechanisms.[147] No specific immune deficiency has been identified in children with SSPE to explain the failure of the immune system to eliminate the virus.[772] There was an initial concern that measles vaccine virus might cause a persistent CNS infection because some patients with SSPE who have received vaccine had no history of disease.[99,104,149,772] However, when investigated carefully, most of these persons have histories of measles-like illnesses and/or known exposures to measles followed by administration of passive Ig.[739,773] Genetic sequencing of viruses obtained from the brains of patients with SSPE, including patients with no history of having had measles, has revealed only viruses of wild-type origin.[143,144,774,775] Case-control studies and the marked decline of SSPE in parallel with the decline in measles after the introduction and widespread use of measles vaccine demonstrate that the vaccine protects against SSPE (Fig. 37.8).[147] It is not known if measles virus persists in immunologically normal persons who do not develop SSPE.[772] Measles virus genomic RNA was detected frequently in persons who had been immunized or exposed to measles more than 2 months before testing in one study, and one group of investigators found evidence for persistence of measles virus nucleocapsid in a variety of tissues many years after measles.[776,777] An HIV-infected intravenous drug user developed progressive measles retinitis and subsequent progressive CNS disease diagnosed as SSPE at 30 years of age.[778] His illness resembled measles encephalitis in immunocompromised persons. He had a history of measles at 2 years of age, and HIV infection most likely occurred in later life, secondary to intravenous drug abuse or sexual contact.

Measles encephalitis in immunosuppressed children, including children with HIV infection or leukemia, is sometimes referred to as subacute or inclusion body measles encephalitis and is caused by progressive measles virus infection.[779,780] Onset is usually 5 weeks to 6 months after acute measles, and virus has been identified in brain tissue and cerebrospinal fluid specimens. Virus isolated from brain tissue specimens from several patients has been shown to be wild-type measles virus.[143,779] One patient with an undefined immune disorder who developed this disorder at 21 months of age was found to have measles vaccine virus in brain tissue.[781] The Institute of Medicine concluded in 2011 that there was adequate evidence to accept a causal relation between measles vaccine and measles inclusion body encephalitis in persons with demonstrated immunodeficiencies (causation is attributed to the measles component of the vaccine).[773]

In persons with severe immune suppression, there is an increased risk of progressive measles vaccine virus replication and severe complications, including fatal pneumonia.[782,783] HIV infection is not associated with increased risks of adverse events in the few weeks after measles vaccination (see Chapter 70 for additional information on immunization of HIV-infected persons).[784,785] Only one well-documented instance of a severe complication after measles vaccine in an HIV-infected person has been reported. Measles vaccine virus was identified in the lung of a 20-year-old man who died of progressive pneumonitis that was recognized approximately 9 months after receiving a second dose of measles vaccine.[783,786] One

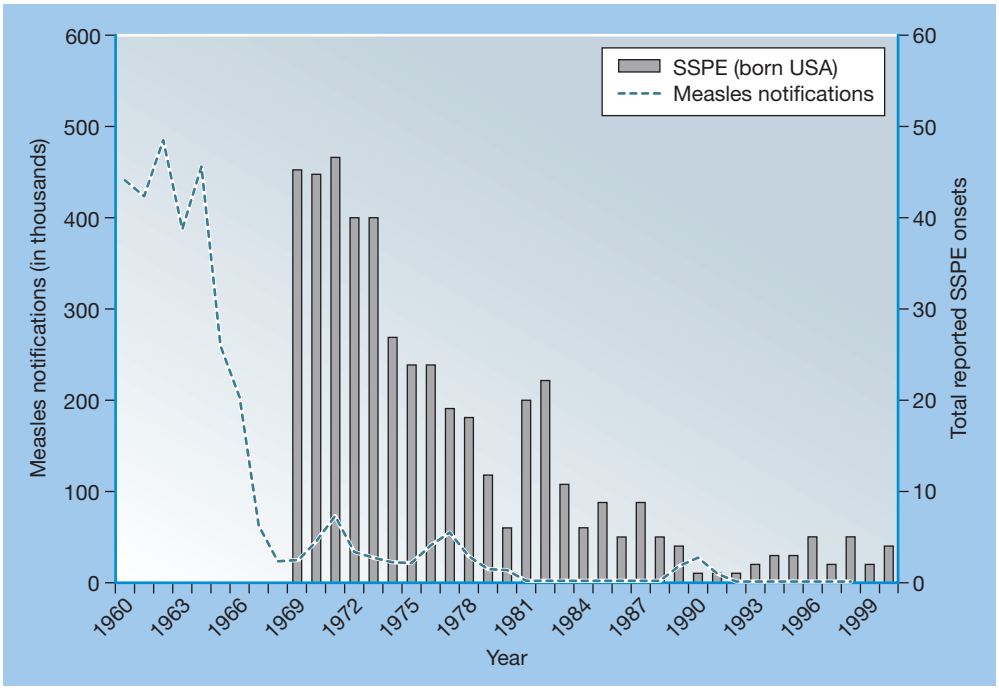

Figure 37.8. Subacute sclerosing panencephalitis (SSPE) cases and measles notifications in the United States, 1960–2000. *(Modified from Campbell H, Andrews N, Brown KE, et al. Review of the effect of measles vaccination on the epidemiology of SSPE.* Int J Epidemiol. *2007;36:1334–1348.)*

HIV-infected child who had received MMR vaccine at 15 months of age was found to have characteristic inclusion bodies on brain biopsy at 18 months of age, but no specific testing was performed to determine the source or identity of the virus.[779] Also, a 19-year-old HIV-infected man with hemophilia had paramyxovirus nucleocapsids in intranuclear inclusion bodies, and there was evidence of measles antigen on immunohistochemical staining, but the virus was not sequenced.[780] He had received measles vaccine at 10 years of age, and there was no history of measles exposure in the year preceding the biopsy. The ages at which he acquired HIV infection and possible subsequent exposures to measles were not reported. The WHO recommends measles vaccine for asymptomatic HIV-infected children and those with early signs of HIV-induced immunosuppression because of the high risk of serious complications from measles in HIV-infected persons.[622,785] In the United States, where the risk of measles exposure is low, the ACIP recommends withholding measles vaccine from persons with severe immunosuppression. The ACIP recommends two doses of MMR vaccine for HIV-infected persons who are 12 months of age or older and who do not have evidence of measles, rubella, and mumps immunity or evidence of severe immunosuppression.[722] Absence of severe immunosuppression is defined as CD4 percentages 15% or greater for 6 months or longer for persons 5 years of age or younger and CD4 percentages 15% or greater and CD4 count 200 lymphocytes/mm^3 or higher for 6 months or longer for persons older than 5 years of age. When only CD4 counts or CD4 percentages are available for those 5 years of age or older, the assessment of severe immunosuppression can be on the basis of the CD4 values (count or percentage) that are available. When CD4 percentages are not available for those 5 years of age or younger, the assessment of severe immunosuppression can be on the basis of age-specific CD4 counts at the time CD4 counts were measured (i.e., absence of severe immunosuppression is defined as ≥6 months above age-specific CD4 count criteria: CD4 count >750 lymphocytes/mm^3 while ≤12 months of age and CD4 count ≥500 lymphocytes/mm^3 while 1 through 5 years of age). The ACIP recommends two doses of MMR vaccine for older children and adults with newly diagnosed HIV infections and without evidence of measles, rubella, or mumps immunity, unless they have evidence of severe immunosuppression, which is defined as a CD4 percentage of less than 15% or, in persons older than 5 years of age, a CD4 count of less than 200 lymphocytes/mm^3.[722,787,788]

After bone marrow transplantations, advisory committees recommend waiting 2 years to administer measles vaccine to allow immune reconstitution.[234] However, in a study of 51 patients, vaccination 1 year after transplantation was not associated with any increased rate of adverse reactions.[789]

The possibility that measles virus persists in selected tissues after measles has been proposed by investigators who found evidence for measles antigen or genomic material in human tissues, including brain, lung, intestine, and bone, years after measles disease.[777] The investigators proposed that these viruses contribute to or cause inflammatory diseases in these organs, including Paget disease,[176,790] otosclerosis,[175] and inflammatory bowel disease.[791] However, other investigators have not found any evidence for measles viruses or measles genomic material in tissues from affected or normal patients.[792,793] The hypothesis that measles vaccine given in combination with mumps and rubella vaccines (MMR) caused inflammatory bowel disease and autism was promoted by one particular investigator who had unrevealed conflicts of interest. A later review of the clinical records from the original 12 patients found evidence of fraud in the data, and the article has been withdrawn.[791,794–797] Some of the other reports of persistent measles virus genomic material in children with autism were based upon PCR methods that amplified host genomic material, not measles virus.[793] In-depth reviews conducted by the Institute of Medicine[172,798–802] concluded that the evidence favors rejection of the MMR-autism hypothesis, and an expert review by the AAP[792] concluded that the evidence does not support either of these hypotheses. A systematic review of the literature by the Cochrane Collaboration reached similar conclusions.[803] Advisory committees in many countries recommend the use of MMR to protect against these three diseases.[233,234]

Indications

General

The goal of measles vaccination programs is to protect persons from the severe consequences of measles infection by providing lifelong individual immunity to vaccinees and by reducing susceptibility to measles in the population to prevent transmission of this disease. The major source of measles susceptibility in a population is the birth of children, who will all lose their maternal antibody and become susceptible in the first or second year of life. Maternal antibody interferes with the response to live measles vaccines. The most critical task of any vaccination program is the timely delivery of the first dose of measles vaccine to young children. The timing of the first dose must balance the proportion of infants who have lost maternal antibody and are able to respond to vaccination at a given age against the risk of measles infection before that age.[602] Therefore, recommendations for measles vaccination vary by country.

The WHO recommends measles vaccine be administered at 9 months of age in countries with ongoing transmission of measles in which the risk of measles mortality among infants is high.[804] In countries with low rates of measles transmission (i.e., those near elimination) the WHO recommends the first dose of measles vaccine be given at 12 months to take advantage of higher seroconversion rates achieved at this age.[622,804,805] In 2009, the WHO recommended that a two-dose measles immunization schedule should be the standard of care for all countries. The second dose may be offered either at a scheduled age through routine services or periodically through mass campaigns, depending on which strategy achieves higher coverage.[622,804]

All developed and many developing countries now have schedules for two routine doses of measles vaccine. In developed countries, the first dose is usually recommended early in the second year of life; the age for the second dose varies.[30–33,409,622] The following section provides detailed recommendations of measles vaccination for the United States.

General Immunization Guidelines

In general, use of licensed combination vaccines, such as MMR, is preferred over separate injections with equivalent component vaccines, to minimize the number of injections and reduce missed opportunities to protect through vaccination. ACIP, AAP, and American Academy of Family Physicians (AAFP) recommend that combination vaccines may be used whenever any components of the combination are indicated and its other components are not contraindicated.[806,807] Single-antigen measles, mumps, or rubella vaccines are no longer available in the United States.

MMR or MMRV vaccine may be administered simultaneously with other vaccines to persons at the recommended age to receive these vaccines. Neither theoretic considerations nor practical experience indicate that the simultaneous administration at separate anatomic sites of MMR or MMRV and other

live or inactivated vaccines will produce a diminished immune response or increase the incidence of adverse events among vaccinated persons.[409]

The combined live attenuated MMRV vaccine was licensed in 2005 in the United States and recommended in 2006 for use in children 12 months to 12 years of age.[487] In May 2010, ACIP updated its 2006 MMRV recommendations[709] based on study results showing a roughly twofold increased risk for febrile seizures after the first dose of MMRV compared with the first dose of MMR and varicella vaccine administered separately at the same visit.[510,511,808] The routinely recommended age for the first dose of MMRV vaccines is age 12 to 15 months; children not vaccinated according to the routine schedule may receive the first dose of MMRV vaccine up to age 12 years. For the first dose of MMRV vaccines at age 12 to 47 months, either MMR vaccine and varicella vaccine or MMRV vaccine may be used. Providers who are considering administering MMRV vaccine should discuss the benefits and risks of both vaccination options with the parents or caregivers. Unless the parent or caregiver expresses a preference for MMRV vaccine, MMR vaccine and varicella vaccine should be administered as separate vaccines for the first doses in this age group. Use of MMR vaccine and varicella vaccine avoids the increased risk for fever and febrile seizures after MMRV vaccine. The 47-month cutoff was selected on the basis of the epidemiology of febrile seizures. Approximately 97% of febrile seizures occur in children 47 months of age or younger.[510,511,808]

Although the routinely recommended age for the second dose of MMRV vaccines is 4 to 6 years, the second dose may be administered before age 4 years, provided it has been 3 months or longer since the first dose. MMRV vaccine is licensed for use among children from 12 months through 12 years of age. For the second dose of MMRV vaccines at any age (15 months to 12 years) and for the first dose at age 48 months or older, use of MMRV vaccine generally is preferred over separate injections of its equivalent component vaccines (i.e., MMR vaccine and varicella vaccine). Catch-up vaccination is recommended to ensure a second dose for all children, adolescents, and adults who previously had received one dose.[709]

At least 1 month should elapse between doses of any live virus vaccines. For children 12 months to 12 years of age at least 3 months should elapse between doses of varicella-containing vaccines. Simultaneous administration of the most widely used live and inactivated vaccines has produced seroconversion rates and rates of adverse reactions similar to those observed when the vaccines are administered separately.[806,809] Therefore, MMRV may be administered simultaneously with other vaccines recommended at ages 12 months to 12 years, although data are absent or limited for the concomitant use of MMRV vaccine with DTaP, inactivated polio, pneumococcal conjugate, influenza, and hepatitis A vaccines.[487]

Specific criteria for documentation of measles immunity have been established to identify the appropriate level of immunization for different groups. Persons can generally be presumed immune to measles if they have documentation of adequate vaccination, laboratory evidence of immunity to measles, laboratory confirmation of disease, or were born before 1957 (few persons in the United States born before 1957 escaped natural infection). Physician-diagnosed measles is no longer considered presumptive evidence of immunity.[409,810]

In general, one dose of MMR is considered adequate vaccination for preschool children and adults who are not at high risk of exposure to measles. Two doses of MMR are indicated for schoolchildren, students at post–high school educational institutions, healthcare personnel, persons in measles outbreak settings, and international travelers because these groups are at increased risk for exposure to measles. Criteria accepted as evidence of immunity for the purpose of meeting school or college entry requirements or other government regulations may vary among state and local jurisdictions.[233,409]

Proper documentation of immunization is critical to ensuring that every person receives the appropriate vaccines. Vaccination status and date of administration of all vaccinations should be documented in the patient's permanent medical record. Only doses of vaccine for which written documentation of the date of administration is presented should be considered valid. Healthcare professionals should provide a vaccination record for a patient only if they have administered the vaccine or have seen a record that documents vaccination.[233,409]

Because of reduced efficacy of measles vaccine when it is administered to young children, doses of measles vaccine administered to children younger than 12 months are not considered valid doses in the United States. Children who are vaccinated at ages younger than 12 months should be revaccinated at 12 to 15 months of age (provided at least 28 days have elapsed) to be considered to have received a single dose of measles vaccine.[233,409]

Routine Vaccination Schedule

Preschool Children. All children should receive the first dose of MMR or MMRV at 12 to 15 months of age (Table 37.9). Children exposed to measles or at high risk of exposure (e.g., during an outbreak or while on international travel) may be vaccinated with MMR as early as 6 months of age.

The second dose of MMRV or MMR vaccine is recommended when children are 4 to 6 years of age (i.e., before a child enters kindergarten or first grade). This recommended timing for the second dose has been adopted jointly by the ACIP, the AAP, and the AAFP.[233,409] Evidence now indicates that (a) the major benefit of administering the second dose for measles is a reduction in the proportion of persons who remain susceptible because of primary vaccine failure; (b) waning immunity is not a major cause of vaccine failure and has little influence on measles transmission; and (c) revaccination of children who have low levels of measles antibody produces only a transient rise in antibody levels.[192,566]

For children 12 months of age and older who are exposed to measles or at high risk of exposure (e.g., during an outbreak or for international travel), the second dose may be given as early as 28 days after the first dose based on the principle that live-virus vaccines not administered at the same time should be separated by at least 1 month.[233,409] For vaccines containing varicella antigens, a 3-month interval between doses is required.

Schoolchildren. All children in school from kindergarten through 12th grade should have documentation of two doses of measles vaccine, unless vaccination is contraindicated. Children who do not have documentation of adequate vaccination against measles or other acceptable evidence of immunity should be admitted to school only after administration of the first dose of MMR vaccine. If required, the second MMR dose should be administered as soon as possible, but no sooner than 28 days after the first dose. The ACIP, AAP, and AAFP recommend the health maintenance visit at age 11 to 12 years should serve as a special opportunity to evaluate vaccination status and to administer MMR vaccine to all persons who have not received two doses at the recommended ages.[233] As of the 2012–13 school year, all states require two doses for school entry.[811] The estimated national two-dose coverage rate in the 2013–14 school year at kindergarten entry was 94.7%[812]; state

TABLE 37.9 Summary of Measles Vaccination Recommendations in the United States[a]

Preschool children	
Routine childhood schedule	First dose: age 12–15 mo Second dose: age 4–6 y
Special circumstances	
Outbreak settings or before international travel	First dose: may be given as early as 6 mo of age Repeat first dose: 12 mo of age Second dose: may be given as early as 13 mo of age[b]
HIV infection	First dose: 12 mo of age Second dose: may be given as early as 13 mo of age[b,c]
School children and adolescents	All children in kindergarten through 12th grade should have documentation of two doses of MMR unless they have other evidence of immunity[d]
Adults	Adults without other evidence of immunity[d] should have documentation of receipt of at least one dose of MMR
Special circumstances	Students and staff in colleges and other post–high school educational institutions, persons working in healthcare facilities, and international travelers should have documentation of receipt of two doses of measles vaccine unless they have other evidence of immunity[d]

[a]All recommendations exclude persons for whom measles vaccination is contraindicated.
[b]Wait at least 28 days after any dose before giving a subsequent dose.
[c]Revaccination is recommended for persons with perinatal HIV infection who were vaccinated before establishment of effective antiretroviral therapy (ART) with two appropriately spaced doses of MMR vaccine once effective ART has been established.
[d]Persons born before 1957 or who have laboratory confirmation of disease or laboratory evidence of immunity.

estimates ranged from 81.7% to 99.7% or greater.[812] However, there are limitations to the kindergarten survey data, because the methodology for collection of the data differs among the states.

Vaccination of High-Risk Groups

Colleges and Other Post–High School Educational Institutions. Risks for transmission of measles at post–high school educational institutions can be high because these institutions may bring together large concentrations of persons who may be susceptible to measles. College entry requirements for measles immunity substantially reduce the risk for measles outbreaks on college campuses where they are implemented and enforced.[813] Therefore, colleges, universities, technical and vocational schools, and other institutions for post–high school education should require that all undergraduate and graduate students have received two doses of MMR vaccine or have other acceptable evidence of immunity before enrollment. Students without documentation of any measles immunization or immunity should receive a dose on entry, followed by a second dose 4 weeks later.[233,409]

Outbreak Settings

During outbreaks in schools and other institutions, all students and personnel born in 1957 or later, should have documentation of two doses of MCV on or after the first birthday.[233,409] All persons who do not have such documentation or other evidence of immunity should be vaccinated or excluded from the school until 21 days after the onset of rash in the last case of measles. Persons receiving their second dose and unimmunized persons receiving their first dose as part of the outbreak control program may be readmitted immediately to school. In outbreaks where there is increased risk of exposure for infants younger than 1 year of age, vaccination with MMR vaccine is recommended for infants as young as 6 months of age. Children who are vaccinated before their first birthday should be revaccinated when they are 12 months of age (provided at least 28 days have elapsed since the first dose given before age 12 months) and again at school entry. During outbreaks, Ig should be administered to immunocompromised persons, susceptible pregnant women, and unvaccinated children younger than 12 months of age who are exposed to measles. However, Ig should not be used to attempt to reduce measles transmission or control outbreaks. Likewise, serologic screening before vaccination generally is not recommended during an outbreak because waiting for serology results can impede the rapid vaccination needed to curb the outbreak.

Every suspected measles case should be reported immediately to the local health department, and every effort must be made to rapidly verify that the illness is measles, especially if this may be the first case in the community. Subsequent prevention of the spread of measles depends on prompt immunization of persons at risk of exposure or already exposed who cannot readily provide documentation of measles immunity, including the date of immunization.[233,409]

If an outbreak occurs in a healthcare setting, healthcare facilities should recommend two doses of MMR vaccine for unvaccinated healthcare personnel regardless of birth year. All employees who were born in 1957 or later who cannot provide documentation that they have received two doses of measles vaccine on or after their first birthday or other presumptive evidence of immunity to measles should be offered the first dose of MMR vaccine immediately and receive the second MMR vaccination at least 28 days later. Some healthcare personnel who were born before 1957 have acquired measles while at work. Therefore, during an outbreak of measles, healthcare facilities should recommend completion of two doses of MMR vaccine for unvaccinated or undervaccinated personnel born before 1957 who lack laboratory evidence of measles IgG in their serum or laboratory confirmation of infection.[810] Healthcare personnel without evidence of immunity who are not vaccinated after exposure should be removed from all patient contact and excluded from the facility from day 5 after their first exposure through day 21 after the last exposure, even if they have received postexposure immunoglobulin. Healthcare personnel who become ill should be relieved of patient contact until 4 days after rash develops. Those with documentation of one vaccine dose may remain at work and should receive the second dose.[233,409]

Healthcare Personnel

Persons who work in healthcare facilities are at greater risk for acquiring measles than the general population. During 1985 to 1989, physicians had an eightfold increased risk and nurses a twofold increased risk of measles compared with non–healthcare workers of the same age.[814] In the 120 measles outbreaks that occurred during 1993 through 2001, healthcare

facilities were the most commonly reported settings, with 24 outbreaks reported.[815] In the postelimination years 2001 to 2008, 27 measles cases were reported in U.S. healthcare facilities, accounting for 5% of all reported U.S. measles cases.[816]

Because persons working in medical settings have been infected with measles and have transmitted the virus to patients and other staff, the ACIP recommends that persons born in or after 1957 working in healthcare facilities be required to provide documented receipt of two doses of MCV, laboratory evidence of measles immunoglobulin (IgG) in serum (i.e., a single specimen test for measles IgG), or laboratory confirmation of acute prior measles infection (i.e., positive serologic test for measles IgM antibody or fourfold rise in measles IgG antibody level or documentation of seroconversion by any standard serologic assay, detection of measles RNA in a clinical specimen, or isolation of measles virus from a clinical specimen).[810,817]

During 2001 to 2008, 12.5% (1 of 8) of measles cases reported to the Centers for Disease Control and Prevention (CDC) among healthcare personnel occurred in persons born before 1957.[810] Thus, because measles has occurred in persons born before 1957, healthcare facilities should consider vaccinating personnel born before 1957 who lack documented receipt of two doses of MCV, laboratory evidence of measles IgG in their serum, or laboratory confirmation of infection, with two doses of MMR vaccine at the appropriate interval.[233,409] Vaccine recommendations during outbreaks differ from routine recommendations for this group (see "Outbreak Settings" above).[810,817]

Serologic screening need not be done before vaccinating for measles and rubella unless the medical facility considers it cost-effective.[817,818] For healthcare personnel who have two documented doses of MMR vaccine or other acceptable evidence of immunity to measles, serologic testing for immunity is not recommended.

International Travelers

Measles is endemic in many countries, including industrialized countries in Europe and Asia. Measles importations reflect both the incidence of measles in countries around the world and travel patterns.[816] Of the 222 measles cases reported in the United States in 2011, 200 (90%) were associated with importations. Almost half of the imported cases occurred in people who acquired measles in Europe.[819] Among the 288 measles cases reported in the United States between January and May in 2014, 280 (97%) were associated with importations, and more than a half of the importations were travelers returning from the Philippines.[820] Protection against measles is especially important for persons planning international travel. Before their departure from the United States, children 12 months of age or older should have received two doses of MMR vaccine separated by at least 28 days, with the first dose administered on or after the first birthday. Children ages 6 to 11 months should receive a dose of MMR vaccine before departure. For infants vaccinated before 12 months of age, revaccination should be at 12 to 15 months of age (12 months of age for those remaining in areas of endemic or epidemic measles). The second dose should be administered at least 28 days after the first dose.[233,409]

Because the risk of complications from measles is increased in adults, it is also important to protect susceptible adults. Most persons born in the United States before 1957 are likely to be immune. However, for persons born after 1956 who travel internationally, two doses of measles vaccine should be administered separated by at least 28 days, unless there is documentation of receipt of two doses, other evidence of immunity, or a contraindication.[233,409]

Persons Infected With Human Immunodeficiency Virus

HIV-infected persons are at increased risk for severe complications if infected with measles.[203,211] Among HIV-infected persons who did not have evidence of severe immunosuppression, no increase in serious or unusual adverse events have been reported after measles vaccination.[211,821] Therefore, MMR vaccination is recommended for all asymptomatic HIV-infected persons who do not have evidence of severe immunosuppression and for whom measles vaccination would otherwise be indicated. MMR vaccination also should be considered for all symptomatic HIV-infected persons who do not have evidence of severe immunosuppression.[822] Testing asymptomatic persons for HIV infection is not necessary before administering MMR or other MCVs.[233,409]

Because the immunologic response to vaccines may decrease as HIV disease progresses, vaccination early in the course of HIV infection may be more likely to induce an immune response.[655] Therefore, HIV-infected infants without severe immunosuppression (as defined in "Vaccine Safety") should routinely receive MMR vaccine as soon as possible on reaching the first birthday (i.e., at age 12 months).[822] Consideration should be given to administering the second dose of MMR vaccine as soon as 28 days (i.e., 1 month) after the first dose rather than waiting until the child is ready to enter kindergarten or first grade. In addition, if at risk for exposure to measles (e.g., in an outbreak setting or for international travel), HIV-infected infants who are not severely immunocompromised should be administered MMR vaccine at age 6 to 11 months.[233,409,622] These children should receive another dose as soon as possible on reaching their first birthday, provided at least 1 month has elapsed since the administration of the previous dose of MCV. An additional dose of MMR vaccine can be administered as early as 28 days after the second dose. Newly diagnosed HIV-infected adults and children ages 12 months or older without acceptable evidence of measles immunity should receive MMR vaccine as soon as possible after diagnosis, unless they have evidence of severe immunosuppression.

Revaccination of Persons With Perinatal HIV Infection Who Do Not Have Evidence of Severe Immunosuppression

Persons with perinatal HIV infection who were vaccinated with MMR before establishment of effective ART should be considered unvaccinated and should receive two appropriately spaced doses of MMR vaccine (i.e., one dose once effective ART has been established and a second dose at least 28 days later). Established effective ART is defined as receiving ART for 6 months or longer in combination with CD4 percentages 15% or greater for 6 months or longer for persons 5 years of age and younger and CD4 percentages of 15% or greater and a CD4 count of 200 lymphocytes/mm^3 or greater for 6 months or longer for persons 5 years of age and older.[233,409]

Close Contacts of Immunosuppressed Patients

To minimize the risk of exposure to measles among patients with immunosuppression, including HIV infection, all family and other close contacts of these patients should be vaccinated with two doses of MMR vaccine, unless they are immunosuppressed, have other contraindications, or have other acceptable evidence of measles immunity.[233,234] No transmission of measles vaccine virus from a vaccinee to a contact has ever been documented, which suggests that the risk of exposure to

vaccine virus among immunosuppressed contacts is very low. However, because of the extreme vulnerability of hematopoietic cell transplantation (HCT) recipients, vaccine recipients who develop a fever and/or rash postvaccination should be excluded from visiting the HCT center while symptomatic and should avoid close contact with HCT recipients in the home setting.[823]

Patients Treated With Chemotherapy, Organ Transplantation, or Bone Marrow Transplantation

When cancer chemotherapy or immunosuppressive treatment is being considered, measles vaccination ideally should precede the initiation of chemotherapy or immunosuppression by at least 2 weeks.[822] Persons who were not immune to measles when diagnosed with leukemia may receive MCV during remission. Measles vaccination is contraindicated during the period of immunosuppression, and at least 3 months should elapse after termination of chemotherapy before measles vaccination.[234] Patients exposed to measles or at high risk of exposure while immunosuppressed should be given Ig regardless of previous immunization status (see "Postexposure Prophylaxis" above). Routine vaccination with MMR is recommended for all children and seronegative adults who have received hematopoietic stem cell transplants. The first dose should be given 24 months after transplantation if the recipient is presumed to be immunocompetent, is not on immunosuppressive medications, and is not affected by graft-versus-host disease. A second dose should be given 6 to 12 months after the first dose.[822–826] Regular testing of long-term HCT survivors for maintenance of measles antibody levels is recommended approximately every 4 to 5 years. The need for revaccination has to be assessed on an individual basis.[823]

Revaccination of Persons Vaccinated According to Earlier Recommendations

Anyone vaccinated at any age with inactivated (killed) measles vaccine alone or killed vaccine followed by live vaccine within a 3-month period, and anyone vaccinated between 1963 and 1967 with a vaccine of unknown type, should be revaccinated with the current live vaccine to ensure protection and to prevent atypical measles illness. Revaccinating persons who received an unknown type of vaccine is recommended because Edmonston B, inactivated, and further attenuated live vaccines all were in use during this interval (see Fig. 37.6). As noted previously, vaccination of an immune person is not associated with any increased risk of adverse events. However, revaccination of recipients of killed vaccine may be associated with local reactions of pain, swelling, erythema, and regional lymphadenopathy lasting 1 to 2 days.[80,81,213,214,727,728,827] These reactions have been reported to occur in 4% to 55% of vaccinees. More-severe reactions have been noted, but only rarely.[81] Whereas revaccination has not been proved to totally eliminate the risk for atypical measles,[220] available data suggest that the risk is reduced considerably.[80,81,224] Thus, the risk of these reactions is outweighed by the risk associated with atypical measles.[234]

A dose of further attenuated live vaccine with Ig administered simultaneously should not be considered adequate vaccination. This recommendation is based on the theoretical consideration that passively derived antibody might interfere with seroconversion. Whereas low doses of Ig do not appear to interfere with seroconversion,[307] there is no information available about the dose used in general practice shortly after the introduction of further attenuated vaccines in the United States. Furthermore, at least one study suggested that there is an increased rate of seronegativity when further attenuated vaccine was administered with Ig.[609] Finally, and perhaps most importantly, revaccination is indicated if there is any uncertainty about the validity of doses in the vaccination record.[550]

Precautions and Contraindications

In general, measles vaccination is contraindicated for patients with concurrent moderate or severe illnesses, immunosuppression, pregnancy, or a personal history of an anaphylactic reaction to neomycin or severe allergic reaction to any component of the MCV. After administration of IgIM or IgIV or IgSC or other blood product, vaccination should be delayed for the recommended interval, unless the patient is exposed to measles or at high risk of exposure.[409] Clinical judgment must be used in deciding whether to vaccinate a patient with a history of thrombocytopenia, but recent studies suggest that the risk of stimulating a recurrence of ITP is very low.[740,828] Mild illness, personal or family history of seizures, steroid therapy that is not immunosuppressive, and allergic reactions to eggs, chicken, feathers, or penicillin are not contraindications to measles vaccination. Persons with contraindications to measles vaccination should receive Ig if they are exposed to measles or at high risk of exposure. Unfortunately, this only provides protection for a short time (see "Passive Immunization" above). To reduce the risk of exposure to measles in persons for whom the vaccine is contraindicated, their household contacts should be immune to measles or be vaccinated (unless contraindicated). To prevent nosocomial exposure to measles in patients with contraindications, all healthcare personnel should be immune to measles or be vaccinated (unless contraindicated) (see "Indications" above).

Moderate or Severe Illness With or Without Fever

MCVs should not be administered to patients with concurrent moderate or severe illnesses, including those with significant fever or evolving neurologic conditions. To avoid confusing the evolution of the illness with possible adverse events resulting from measles vaccine, vaccination should be deferred until the acute severe illness is resolved.

Withholding vaccination for false contraindications is a major cause of late vaccination and low vaccine coverage. Measles vaccination should not be deferred in the presence of mild illnesses, with or without low-grade fever, such as mild upper respiratory infections, otitis media, or diarrhea.[602] Multiple large studies in the United States and in other countries have documented that children with mild illness have similar serologic responses to measles vaccination compared with well children. These studies also showed that the ill children had no increased risk of adverse events after vaccination compared with well children.[409,639–641]

Tuberculosis

Because of a theoretic concern that measles vaccination might exacerbate tuberculosis, patients with untreated active tuberculosis should begin antituberculosis therapy before measles vaccination. This theoretic concern is based on the reputed role of measles disease as an aggravating factor in tuberculosis and the similar suppression of delayed hypersensitivity for up to 4 to 6 weeks seen after both measles disease and measles vaccination.[552,554] However, a 1976 review of studies examining the effect of measles disease on tuberculosis patients concluded that none of the studies provided conclusive evidence that measles disease has a deleterious effect on tuberculosis.[115] A review of the incidence of tuberculosis after a measles outbreak in Korea did not reveal an increased risk of tuberculosis.[116] In several small studies in the 1960s, measles vaccine did not exacerbate tuberculosis in children receiving

antituberculosis therapy.[559,829,830] However, there are no data available on the effect of measles vaccine on patients with untreated tuberculosis.

Tuberculin skin testing is not a prerequisite for measles immunization. In patients for whom tuberculin skin testing is indicated, such testing can be undertaken at the same time that vaccine is administered. If skin testing is not done at that time, it is advisable to wait 4 to 6 weeks after vaccination before administering a tuberculosis skin test, because measles immunization temporarily may suppress tuberculin skin test reactivity.[233,409]

Immunosuppression

Live virus measles vaccine should not be administered to persons who are immunosuppressed because of medication (e.g., high-dose steroids, alkylating agents, and antimetabolites), other therapy such as radiation, or underlying illness (e.g., congenital immunodeficiency, leukemia, lymphoma, generalized malignant disease) (see "Indications" above). Although patients with severe immunosuppression related to HIV infection should not receive measles vaccine, HIV-infected persons who are not severely immunosuppressed may be vaccinated. Immunosuppressed patients who are exposed to measles or at risk of exposure should receive Ig regardless of their history of measles disease, vaccination, or serology, because they are at high risk of complications and death from measles (see "Passive Immunization" above). Replication of live vaccine virus may be augmented and prolonged in patients who are immunocompromised, and adverse events after vaccination, including death, are more common in immunosuppressed patients (see "Vaccine Safety").[779,781,786,831]

Systemic corticosteroid treatment can result in immunosuppression. Because the minimum dose and duration of steroid therapy necessary to induce immunosuppression are not well defined, clinical judgment must be used to assess whether a patient on steroid therapy is immunosuppressed. Most experts would consider a steroid dose equivalent to or greater than a prednisone dose of 2 mg/kg of body weight per day (or ≥20 mg/day for persons who weigh >10 kg) administered for 14 days or more to be sufficiently immunosuppressive to contraindicate measles vaccination.[409] Patients receiving immunosuppressive doses of steroids should not receive measles vaccine until 1 month after the end of steroid therapy. Vaccination is not contraindicated in persons receiving topical, localized (e.g., intraarticular, bursal, or tendon injection); low- to moderate-dose steroids; or physiological steroid replacement. Patients who receive high-dose steroids for less than 14 days generally can be vaccinated immediately after cessation of steroid therapy. Measles vaccine is contraindicated in any patient on any dose of steroids with clinical or laboratory evidence of immunosuppression or an underlying disease that is immunosuppressive.[409,822]

MMR and other MCVs are not recommended for HIV-infected persons with evidence of severe immunosuppression (as defined above) because of the risk of adverse events, the impaired immune response to MMR vaccination, and the current low risk of exposure to measles in the United States.[233,409,788,] One case of fatal vaccine-associated pneumonitis has been documented in a severely immunocompromised patient with HIV infection (see "Vaccine Safety").[786] Available data suggest that persons with HIV infection who are not severely immunosuppressed may be vaccinated safely.[211,652,653,788] Because measles has been documented to be severe in HIV-infected persons in both the United States and developing countries,[832] measles vaccine is recommended routinely for asymptomatic HIV-infected children and adults without evidence of measles immunity and should be considered for those with symptomatic HIV infections who are not severely immunosuppressed. Asymptomatic patients at risk for HIV infection do not need to be screened for HIV before vaccination (see "Indications").[233,409,788]

Pregnancy

On theoretical grounds, live-virus vaccines, including measles vaccine, should not be administered to a pregnant woman. However, in contrast to rubella and mumps vaccines, measles vaccine virus has not been shown to cross the placenta and infect the fetus. ACIP recommends that susceptible women of childbearing age be asked if they are currently pregnant or attempting to become pregnant before administering MMR vaccine. Vaccination should be deferred for those who answer "yes." Those who answer "no" should be vaccinated and advised to avoid pregnancy for 28 days after vaccination because of the theoretical risks to the fetus.

Allergies

Severe immediate hypersensitivity reactions (urticaria, angioneurotic edema, wheezing, hypotension, and shock) are very rare serious complications after measles vaccination. From 1991 to 2000, the U.S. Vaccine Adverse Event Reporting System received reports of events that were classified as probable or possible anaphylaxis at an average of two reports per 1 million doses of MMR distributed.[745] A detailed review of patients enrolled in health maintenance organizations in the U.S. Vaccine Safety Datalink Project found three cases of anaphylaxis among 848,945 persons who received MMR vaccine (two had also received other vaccines at the same visit) for an estimated risk of 3.5 episodes of anaphylaxis per million doses of MMR administered.[742,745] In China, the rate was 6.5 per million doses administered.[833] No anaphylaxis deaths have been reported in association with measles vaccination in the United States, but anaphylaxis can be life threatening. Most patients with anaphylactic reactions after measles vaccination do not have clinically evident risk factors for anaphylaxis. Adequate treatment for hypersensitivity reactions, including epinephrine injection, should be available for immediate use whenever measles vaccines are administered, along with staff trained in treatment of anaphylactic reactions.[233]

Measles vaccines typically contain hydrolyzed gelatin as a stabilizer. Allergic reaction to gelatin has been recognized as a major cause of anaphylaxis after MMR vaccination.[834–836] Patients with severe immediate hypersensitivity reactions have been shown to have high levels of antigelatin IgE and IgG and increased gelatin-specific T-cell responses.[834,835] In a study in Japan, 24 of 26 children who had allergic reactions to vaccines had antigelatin IgE. Only two of the children had allergic reactions to gelatin (in food) before vaccination.[836] In contrast, substantially fewer children (6 of 22) with severe allergic reactions to MMR in the United States had antigelatin IgE, and none had a reported history of allergic reactions to gelatin in food.[745] Previous severe allergic reaction to any component of the vaccine, including gelatin, is a contraindication to vaccination.[409]

Because measles vaccines contain trace amounts of the antibiotic neomycin, persons who have experienced anaphylactic reactions to topically or systemically administered neomycin should not receive these vaccines. However, allergic reactions to topical or systemic neomycin are rare and typically consist of delayed or cell-mediated immune responses, such as contact dermatitis. A history of contact dermatitis to neomycin is not a contraindication to receiving MMR-containing vaccine.[409]

Measles vaccines do not contain other antibiotics, such as penicillin; consequently, penicillin allergy is not a contraindication to vaccination.

Measles (and mumps) vaccines licensed in the United States are grown in chick embryo fibroblast cultures. Fasano and colleagues[837] measured a 37 pg/dose of ovalbumin cross-reacting protein in the MMR vaccine currently licensed in the United States. Because some children with egg allergy have had anaphylactic reactions to measles vaccines,[838] previous recommendations included an algorithm of vaccine skin testing and desensitization for children who have had anaphylactic reactions after egg ingestion.[839] However, more than 1200 children with severe allergic reactions to eggs have been vaccinated safely in two studies,[840,841] and the rare serious allergic reactions after MMR vaccination are not believed to be caused by egg antigens but by other components of the vaccine, such as gelatin or neomycin.[409] Vaccine skin testing and desensitization are no longer recommended for persons with severe egg allergies.[233] These persons may be vaccinated by using the same precautions (treatment for anaphylaxis immediately available) as for persons without severe egg allergy. Also, persons with less-severe allergic reactions to eggs, or allergy to chicken or feathers, may be vaccinated as usual.[233,409]

Administration of Immunoglobulin and Other Blood Products

Because passively derived antibody may interfere with vaccine seroconversion, vaccination should be deferred for 3 to 11 months after receipt of IgIM or IgIV or IgSC or other blood products, depending on the dose of the blood product received.[233,409,842] In addition, vaccination should precede receipt of Ig by at least 2 weeks whenever possible,. However, unvaccinated persons may not be fully protected by the passive antibodies received during the entire interval recommended prior to vaccination after receipt of blood products. Therefore, additional doses of Ig or measles vaccination may be necessary if the patient is repeatedly exposed to measles or at high risk of exposure to measles. If measles vaccination is given before the recommended interval has elapsed, the dose should be repeated (at least 28 days after the earlier measles vaccination and after the recommended interval from the time of blood product administration has elapsed).

Thrombocytopenia

Oski and Naiman[843] reported significant depression of platelet counts without clinical symptoms after vaccination with Edmonston B vaccine, including one infant who had thrombocytopenia repeatedly after three doses. Previous immunity to measles did not prevent depression of the platelet count. ITP is associated with MCVs currently in use.[738] The increased risk of ITP after MMR vaccination is estimated at three to four cases for every 100,000 doses.[844,845] There are no reports in which ITP solely associated with measles vaccines has resulted in death.

Two cases of recurrent MMR-associated ITP have been reported in patients with ITP associated with a previous MMR dose,[846,847] and one case of MMR-associated exacerbation of chronic ITP was reported in a 19-year-old female whose onset of chronic ITP was associated with rubella vaccination in the second year of life.[848] In a study that included 21 children with ITP before their first dose of MMR, Miller and colleagues[844] reported that none had a recurrence of ITP after vaccination. A recent review identified 131 children with a history of ITP who received MMR without a recurrence, including 26 children whose ITP followed a first dose of MMR.[739] Advisory committees recommend caution when administering MCVs to children with thrombocytopenia or a past history of ITP, especially when the prior episode of ITP was associated with measles vaccination.[233,409] Serologic assessment of immunity may be useful in assessing the risk and benefits of immunization in such patients.

Family or Personal History of Seizures of Any Etiology

Measles vaccination, like other causes of fever, may cause febrile seizures in young children. Studies suggest that children who have a personal or family history of seizures of any etiology are at increased risk for febrile seizures after measles vaccination compared with children who do not have such histories. In one study in Denmark, children vaccinated with MMR at 15 to 17 months had an increased risk of febrile seizure during the following 14 days of 1.6 per 1000 compared to unvaccinated children of the same age.[749] For siblings of children with a history of febrile seizures the increased risk was 4.0 per 1000 and for children with a personal history of febrile seizures the increased risk was 19.5 per 1000. Febrile seizures after vaccination do not increase the risk of epilepsy or other neurologic disorders. The benefits of administering measles vaccine to children with personal or family history of seizures substantially outweigh the risks, and these children should be vaccinated following the standard recommendations. Their parents should be advised of the benefits of the vaccination and the minimal increased risk of febrile seizures. The risk of febrile seizures after the first dose among children 12 through 23 months of age is higher for MMRV compared to receiving MMR and varicella vaccines separately at the same visit,[233] thus, a personal or family history of seizures of any etiology is a precaution for the first dose of MMRV but not MMR.[233,409] Because the fever induced by measles vaccine occurs between 6 and 12 days after vaccination and seizures may occur with the onset of fever, it is difficult to use antipyretics to prevent febrile seizures after measles vaccination. Patients taking anticonvulsants should continue these medications after measles immunization.[233,409]

FUTURE VACCINES

Currently available measles vaccines are safe, highly effective, and inexpensive; however, they have limitations and alternative measles vaccines and novel delivery methods remain a global priority for research,[849] particularly for measles eradication. Despite high immunogenicity, the effectiveness of currently available measles vaccines are limited by the presence of passively acquired maternal antibodies.[850] Moreover, these vaccines are formulated as lyophilized powder requiring cold chain storage at 4 °C to 8 °C until use. Prior to administration, lyophilized vaccine must be reconstituted with sterile water diluent from the manufacturer and administered via needle and syringe by trained medical staff. Once reconstituted, the vaccine must be discarded after 6 hours because of the risk of bacterial contamination and the loss of potency from exposure to light and increased temperatures. Multidose (i.e., five-dose, 10-dose) vials are commonly used in developing countries. Vaccinators' concerns of potential inefficient use of vaccine supply and vaccine wastage impact decisions for when to open a multidose vial for vaccinating individual children, and lead to missed opportunities for vaccination. Measles vaccinations are administered by subcutaneous injection and injection pain caused by hypodermic needles can be a deterrent for vaccination acceptance. Reconstitution errors and lack of adherence to strict vaccine storage and handling requirements have caused avoidable adverse events and deaths. Safe use and handling of currently available measles vaccines

requires considerable resources, trained medical staff, and maintenance of cold chain. These requirements and complex logistics make house-to-house vaccination campaigns, a strategy that proved to be a key to success for the smallpox and current polio eradication efforts, extremely difficult. Vaccination efforts, particularly in remote locations, could be facilitated by the availability of alternative measles vaccines that are thermostable, and have simplified requirements for storage, handling, and administration.[482]

Intradermal delivery of measles vaccines has been studied for decades and is the likely optimal alternative to current subcutaneous injection. Skin vaccination using needle-free jet injectors[851,852] with single-dose disposable cartridges and with microneedle (also called microarray) patches is currently being evaluated for MCVs. Promising new dissolving measles and MR microneedle patches have proven to be thermostable and fully immunogenic in cotton rats and rhesus macaques.[853,854] The micron-scale (500–800 µm), water-soluble microneedle patches encapsulate a dry formulation of vaccine that rapidly dissolves in the skin upon application. Microneedles cause little or no pain, are easily administered and transported, require minimal storage and disposal capacity, and because they dissolve in the skin, do not require reconstitution with diluent, cannot be reused, and do not generate sharps waste. Human clinical trials using MR microneedle patches are needed to evaluate safety and immunogenicity.

Pulmonary delivery of measles vaccine research has been ongoing for more than 30 years, and is focused on dry powder and nebulized liquid aerosol vaccine formulations, as well as multiple delivery devices for these vaccines in humans and macaques. A measles vaccine dry powder (MVDP) for pulmonary delivery being developed since 2005,[855,856] has demonstrated robust immune responses in macaques, including serum antibody, T-cell responses, and protection from viral challenge.[857,858] This MVDP, which uses two delivery devices, was recently evaluated in a randomized, controlled Phase I human clinical study in adult males 18 to 45 years of age. No adverse events were reported, and the MVDP was well tolerated and produced serologic responses similar to subcutaneous vaccination.[858a] Further studies will be needed to evaluate the safety and immunogenicity of the MVDP in children. Liquid aerosol administration techniques with practical devices and immune response rates of measles vaccine strains have improved over time.[859] The aerosol administration of the Edmonston-Zagreb strain as a second dose to older children and adults induced a booster response at least equivalent to vaccination by subcutaneous injection; however, the use of the Schwarz strain via the aerosol route is no longer being pursued because of low response rates.[860] Recognizing that aerosol administration could potentially simplify administration of measles vaccine to large numbers of children in community-based campaigns, similar to those used in the polio eradication effort,[502,861,862] the WHO, the CDC, and the American Red Cross established a Measles Aerosol Project to complete the necessary research and regulatory requirements to license aerosol delivery of measles vaccine in the developing world.[863] Although previous studies suggested that aerosol measles vaccine administration in infants might be equally immunogenic as the same vaccine administered by injection, a recent randomized, controlled trial found it was immunogenic, but inferior to the currently available injectable measles vaccine.[482,861,863–865] The study was a randomized, open-label, controlled trial of a single 0.2-mL dose of reconstituted measles vaccine administered by liquid aerosol using a nebulizer for 30 seconds through a single-use nonvented face mask in unvaccinated healthy infants 9 to 11 months of age. The nebulizer generated aerosol with a median diameter of 5.1 µm. At day 91 postvaccination, 673 (85.4%) of 788 infants in the aerosol group and 754 (94.7%) of 796 children in the subcutaneous group were seropositive, a difference of −9.3 percentage points (95% CI, −12.3 to −6.4), not meeting the a priori study noninferiority threshold. In this study, no serious adverse events were attributable to measles vaccination and adverse-event profiles were similar in the two groups.[864,865]

To effectively immunize infants at younger ages, research led to the development of subunit DNA and vectored measles vaccines that might be potentially immunogenic in young infants in the presence of maternal antibody.[866–869] A DNA vaccine expressing measles virus hemagglutinin and fusion glycoproteins induced long-lasting, high-avidity neutralizing antibodies in neonatal mice born to measles-immune mothers despite the presence of high levels of maternal antibodies.[868,870] Studies in the monkey model for atypical measles reveal that a DNA vaccine expressing hemagglutinin did not prime for atypical measles.[228] However, some vaccine constructs did induce antibodies of poor avidity.[869] Oral administration methods for measles vaccination have been theorized and studied in animal models. Vaccination using an enteric-coated live, attenuated measles vaccine was not successful in monkeys.[871] In mice, oral administration of a measles peptide incorporated into a vesicle induced a cell-mediated immune response to measles[872] and orally administered adenovirus modified to express measles nucleocapsid antigen induced both measles antibody and cytotoxic T-cell responses.[873]

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Results of Vaccination

Measles is one of the most contagious diseases of humans and is a classic communicable disease of childhood. The goal of measles vaccination is to prevent illness and death caused by measles directly among vaccinated persons and indirectly among unvaccinated persons as a result of decreased transmission.[874] In the absence of vaccination, measles occurs in epidemic cycles. The magnitude and frequency of the epidemics depends on the population size, contact rates between persons, and the rate at which new susceptible persons are added to the population through births or migration.[875] In England and Wales in the 1940s, epidemics occurred every second year, starting in the large cities of London, Manchester, and Liverpool, and spreading outward to towns and rural villages.[39,876] In the large population centers, chains of transmission were sustained during the periods between epidemics, and these cities were the reservoirs of measles. In towns and villages, transmission died out after an epidemic and had to be reintroduced for each subsequent epidemic. Epidemic cycles of measles also can be described in terms of the effective reproduction number, R, defined as the average number of secondary cases produced by a typical case in a population (see Chapter 77).[583,877,878] When R is less than 1, the average case gives rise to less than one case, and the number of cases occurring subsequently begins to decrease. R for measles varies between and within populations based on factors important for virus transmission, including overall measles susceptibility, population density, contact rates, age structure, heterogeneity of population immunity, and migration patterns.

Introduction of measles vaccination leads to a reduction in the size of epidemics and an increase in the interval between measles epidemics.[874] The widened interepidemic interval has been referred to as the "honeymoon period."[879,880] Vaccination of successive cohorts of young children results in a decrease in incidence among vaccinated cohorts, an overall decline in measles incidence in all age groups (because of dampened transmission), and, when outbreaks occur, an increase in the

proportion of cases among older children.[385,880,881] Susceptibility to measles among older cohorts occurs most often because these persons missed natural disease as young children and either missed getting vaccinated (program failure) or failed to respond to vaccination (primary vaccine failure). Waning of vaccine-induced immunity (secondary vaccine failure) occurs in 0% to 5% of vaccinees but does not appear to play a major role in measles virus transmission or reducing overall population immunity to measles.[192,687,697]

Herd Immunity

As vaccination coverage increases among successive birth cohorts, measles transmission decreases, reducing the risk of measles even among unvaccinated persons. At some vaccine-induced immunity level lower than 100%, measles virus transmission is interrupted.[882–884] Mathematical models have estimated the herd immunity threshold for measles in the United States at 92% to 95%.[584] If this level of population immunity is maintained by a vaccination program, endemic transmission of measles will die out and measles elimination is achieved. Knowledge of the minimum level of vaccination capable of preventing measles transmission in an age group is helpful for establishing program targets for measles elimination. During the measles resurgence in the United States, 1989–91, epidemiological studies found that a minimum vaccine coverage of approximately 80% at the second birthday may be sufficient to prevent measles transmission among preschool-age children if population immunity is 93% among persons 6 years of age and older.[885] Similar differences in age-specific measles transmission rates have been observed in the WHO European Region, and mathematical modeling suggests a 6.4% susceptibility target for all age groups; however, achieving a lower level (5%) in age groups with the highest transmission rates, namely secondary school children and young adults, allows higher levels of susceptibility in preschool (15%) and primary school (10%) children.[583]

Elimination does not result in zero measles cases because importations of measles from endemic areas continue to occur. However, spread from these importations is short lived. Documenting the elimination of measles is challenging. De Serres and associates[584] have proposed using the proportion of cases imported and the distribution of outbreak sizes to monitor elimination. These surveillance parameters can be used to estimate R, which must be maintained at less than 1 to achieve elimination. Global eradication of measles will occur when the last chain of transmission of measles virus is interrupted and has been defined as the worldwide interruption of measles virus transmission in the presence of a surveillance system that has been verified to be performing well.[54]

In industrialized countries, a single dose of measles vaccine administered in the second year of life induces immunity in approximately 95% of vaccinees.[581] With a primary vaccine failure rate of 5%, 100% of the population would have to be vaccinated to reach a 95% immunity level with a single-dose strategy. Approximately 95% of persons who fail to respond to the first dose respond to a second dose,[568] and with high vaccine coverage, the herd immunity target can be reached if two doses are administered.

In developing countries, high morbidity and mortality resulting from measles among infants led to a recommendation to vaccinate infants at 9 months of age, a time when maternal antibody may interfere with seroconversion.[887] Studies have found the median seroconversion rate with vaccination at age 9 months is 85% (range: 70% to 98%).[888] This leaves three times more infants susceptible (15% of vaccinees) than does a rate of 95%. After a single dose with 90% coverage and 85% seroconversion, 77% of the population would be immune. To improve immunity, some have considered providing a second dose, usually through routine health services at an older age, when seroconversion is 95%. However, if only first-dose recipients were revaccinated through routine health services, given 90% coverage with both doses, immunity levels could rise to only 90%, leaving 10% susceptible. Alternatively, if vaccination activities were intensified both within and outside the routine health services, such that many children never vaccinated could receive a first dose while previously vaccinated children receive a second dose, the resulting population immunity level would be much higher. This is known as a second opportunity strategy.[805] For example, if the second opportunity reached 90% coverage of prior first-dose recipients and previously unvaccinated children, population immunity would increase to greater than 95%. In countries with poor access to preventive services, the second opportunity for measles vaccination is most often provided through nationwide supplementary immunization activities or mass campaigns, because these are more effective at reaching children who have never been vaccinated.

Nonspecific Effects

Wild measles infection is immunosuppressive and causes loss of memory responses to infections from other etiologies, which increases all-cause mortality. Observations in monkeys and humans, supported by immunological studies, suggest that measles vaccination reduces mortality beyond its protection against measles.[889–894] A recent study by Mina and colleagues suggests substantial nonspecific benefits of measles vaccination occur by preventing measles-induced adverse impact on the overall immune system, which, in turn, contributes to increased nonmeasles infectious disease mortality.[895] In April 2014, WHO's Strategic Advisory Group of Experts concluded that available evidence suggests possible beneficial effects of measles vaccination on all-cause mortality but found the evidence too weak to guide vaccination policy.[896]

Experiences With Measles Control and Elimination in Various Countries

Industrialized Countries

Experience in industrialized countries shows that a single dose of measles vaccine, widely administered, can reduce measles transmission, but a two-dose strategy is necessary for elimination of indigenous transmission.[28,897–899] Many countries introduced measles vaccine as a single-dose schedule and then added a second opportunity for vaccination because of the persistence of outbreaks despite high single-dose coverage (Table 37.10). Industrialized countries have found that the costs of patient care and outbreak control outweigh the cost of a second opportunity for immunization.[900] Some countries (e.g., Canada, United Kingdom, Australia, and New Zealand) have adopted a two-dose schedule and have conducted a one-time, nationwide vaccination campaign to reduce susceptibility among school-age children. Other countries (e.g., the United States, Finland, and Sweden) have relied on a two-dose schedule alone.

In the United States, the distribution and use of more than 450 million doses of live measles vaccine between the year of licensure (1963) and the end of 2014 (see Fig. 37.6) is associated with a marked reduction in measles (Fig. 37.9) and its associated complications, and estimated savings of billions of dollars.[26,404] In the years prior to vaccine introduction, approximately 4 million cases occurred annually, whereas on average 400,000 to 500,000 cases were reported. In 2010, only 64

confirmed cases were reported, with 56 (87.5%) of those cases linked to importations. This represented a reduction of more than 99.9% compared with the years preceding vaccine licensure. The reported occurrence of SSPE also declined greatly (see Fig. 37.8) and was virtually eliminated in the late 1980s and early 1990s. A small number of cases had been reported each year during the late 1990s as a result of the resurgence of measles during 1989 to 1991.

The United States has embarked on three elimination efforts (see Fig. 37.9).[22,23,883,901] The first, in 1966, was based on a single-dose strategy with vaccination at 12 months of age (see Table 37.10). The second, announced in 1978, had three components: (a) a high level of population immunity through vaccination with a single dose of measles vaccine, (b) disease surveillance, and (c) prompt response to outbreaks.[22,25] To reach high coverage, vaccination requirements for school entry were enacted and enforced in every state. These requirements, which mandated not only measles vaccination but also other childhood vaccinations, have become the major legacy of this elimination initiative. Although sustained interruption of transmission of measles was not achieved, measles was eliminated from most of the country; 54% of counties in the United States were measles free for the entire decade from 1980 to 1989, and only 17 (0.5%) counties reported measles every year during that period.[902] During this interval, outbreaks continued to occur in schools among school-age persons with histories of vaccination and among unvaccinated pre–school-age children.[383,550,610,614,693,903] In 1989, the United States introduced a routine second dose of measles vaccine at ages 4 to 6 years or 11 to 12 years to address the problem of school outbreaks (see Table 37.10).

After relatively low incidence during the 1980s, a 3-year epidemic of measles began in 1989 and resulted in more than 55,000 cases and 123 deaths.[904,905] The average annual incidence during 1989 to 1991 was 7.4 per 100,000 population compared with an average incidence for 1981 to 1988 of 1.8 per 100,000. Incidence was increased in all age groups; however, the greatest increases were in children younger than 1 year and 1 to 4 years, resulting in almost half of all cases occurring in children younger than 5 years (see Table 37.1). This epidemic was a consequence of low measles vaccination levels among pre–school-age children, particularly in inner cities,[906–909] and was part of a hemisphere-wide measles epidemic.

In 1993, the third elimination initiative was launched. In addition to the three components of the earlier strategy, this

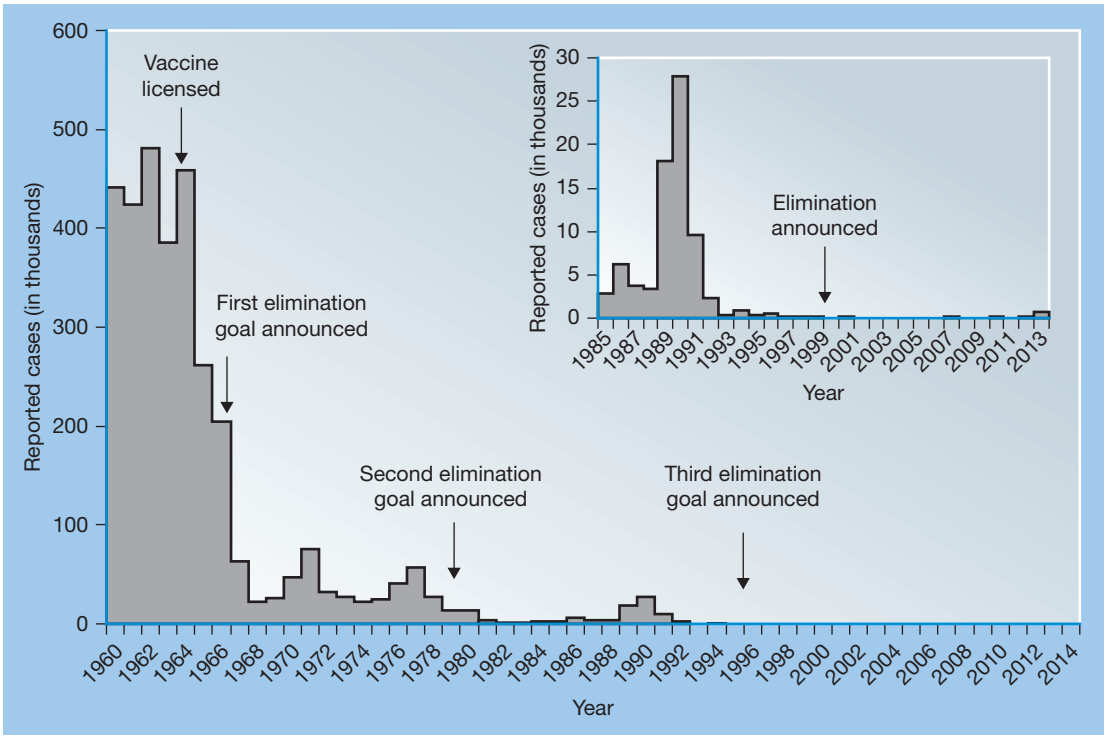

Figure 37.9. Reported measles cases, United States, 1960–2014.

initiative focused on increasing preschool immunization levels to greater than 90% and vaccination of all school children with a second dose.[901] To implement these vaccination strategies, between 10 and 16 million doses of measles vaccine were distributed annually between 1994 and 2005 (see Fig. 37.6). In March 2000, the CDC convened a panel of experts to review the pattern of measles transmission in the United States. Evidence presented included an annual measles incidence of less than 1 case per 1 million population since 1997,[910] a maximum outbreak size of 15 cases during 1999 to 2001,[815] an increase in the proportion of imported cases from 14% (1993 to 1996) to 35% (1997 to 2001),[911] an overall estimated population immunity against measles of 93%,[912] and the absence of an endemic measles virus genotype since 1994.[255] Based on this evidence, each participant concluded that measles was no longer an endemic disease in the United States.[26,913] In 2011 a second panel convened by the CDC concluded that elimination of endemic measles transmission had been sustained from 2001 to 2011. The data reviewed by the panel included continued measles incidence less than 1 case per million population, with 88% of measles cases imported or importation related and continued absence of an endemic genotype, all in the presence of an adequately functioning surveillance system and with documented high levels of population immunity. The four components of the current U.S. measles elimination strategy are to maximize population immunity through vaccination, to ensure adequate surveillance, to respond rapidly to outbreaks, and to work with other countries to achieve global measles control. The two key factors in the effort to maximize population immunity are to improve timely immunization of pre–school-age children and to deliver a second dose of measles vaccine to all school children.[901] National estimates of one-dose MMR coverage among children 19 to 35 months of age remained above 90% from 1996 through 2013.[914–917] Among the 49 states reporting coverage for children in kindergarten in 2014–15, the median vaccination coverage was 94.0% for two or more doses of MMR.[918] In 2014, a national survey estimated 91% of adolescents 13 to 17 years of age had received two or more doses of MMR.[919] The importance of maintaining very high vaccination coverage is illustrated by an analysis of age-specific measles vaccination data from the National Immunization Survey–Teen (2008–2013), which showed that 12.5% of U.S. children and adolescents are susceptible to measles.[919a]

Challenges to maintaining elimination in the United States include frequent international travel, large outbreaks of measles in highly traveled developed countries, and clusters of U.S. residents who remain unvaccinated because of personal belief exemptions.[920,921] As evidence of these ongoing challenges, from January 1 through May 23, 2014, a total of 288 confirmed measles cases were reported to CDC, surpassing the highest reported yearly total of measles cases since elimination.[820] By the end of 2014, the annual total had increased to 667 measles cases, the highest number reported since 1996. There were 63 imported measles cases, seven in foreign visitors and 56 in U.S. residents, including eight unvaccinated infants. The increase in cases following importations reflects recent increases in the incidence of measles in countries with high levels of travel to and from the United States. The source of almost half of the direct measles importations in 2014 was the Philippines. Most of the 288 measles cases reported between January and May 2014, were in persons who were unvaccinated (200 [69%]) or who had an unknown vaccination status (58 [20%]); 30 (10%) were in persons who were vaccinated. Among the 195 U.S. residents who had measles and were unvaccinated, 165 (85%) declined vaccination because of religious, philosophical, or personal objections; 11 (6%) were missed opportunities for vaccination; and 10 (5%) were too young to receive vaccination.[820] Similarly, from January 4 through April 2, 2015, 159 measles cases were reported to CDC, with one outbreak that originated in Disney theme parks in California accounting for 70% of cases.[921a] Among 110 California residents linked to this outbreak, the majority were either unvaccinated (49 [45%]) or had an unknown

vaccination status (47 [43%]); 14 (13%) had received one or more doses of a measles-containing vaccine or were immunoglobulin G seropositive.[921b] The outbreak spread to seven U.S. states, Mexico, and Canada, garnered considerable media attention, and led California legislators to pass laws eliminating nonmedical (philosophical and religious belief) exemptions to school immunization requirements in their state.[921c] Investigating and responding to measles outbreaks is time consuming and labor intensive, and imposes a significant economic burden on local and state health departments. Sixteen measles outbreaks occurred during 2011 and cost local and state health institutions an estimated US$2.7 to US$5.3 million.[922]

Canada began a measles immunization program in 1963 (see Table 37.10). Despite achieving coverage in excess of 95% with a single dose of measles vaccine throughout the 1980s, measles outbreaks continued to occur.[28] In 1995, 2362 measles cases were reported in Canada, more than one-third of the total number of cases reported in the Western Hemisphere. School outbreaks among children who had received a single dose of MCV accounted for most cases. Mathematical modeling predicted a sizable measles epidemic, and cost-to-benefit analyses showed that a national vaccination campaign to prevent the predicted epidemic would save $2.50 for every dollar spent.[900] On the basis of these analyses, 11 of the 12 provinces of Canada undertook mass vaccination campaigns targeting school-age children by using measles-rubella vaccine in the spring of 1996. A coverage level of more than 90% was achieved. In addition, a second dose was added to the routine schedule at age 18 months or 4 to 6 years of age (see Table 37.10). From 1998 through 2001, Canada interrupted endemic measles transmission as evidenced by the occurrence of only a few small outbreaks, many linked to importation.[28] In 2007, there was an outbreak of 94 cases characterized by transmission lasting 25 weeks in unvaccinated persons belonging to unrelated networks dispersed in the population.[923] Genotyping of measles virus in Canada supports epidemiologic information indicating importation as the source of current measles cases.[924] An analysis of the epidemiology of measles in Canada from 2002 through 2013 found a trend toward a greater annual number of importations over the period. While five chains of transmission had more than 30 cases, none of the importations resulted in sustained transmission for 12 months or longer, confirming that Canada has maintained elimination between 2002 and 2013.[585]

In 1968, the United Kingdom introduced measles vaccine for children between the ages of 1 and 2 years, but throughout the 1970s and early 1980s coverage remained below 80%. In 1988, combined MMR vaccine was introduced in place of measles vaccine at age 13 to 15 months (see Table 37.10) and coverage improved to greater than 90%. In November 1994, all children ages 5 to 16 years in England and Wales were offered combined measles-rubella vaccine, regardless of prior vaccination history, in an attempt to prevent a predicted epidemic of measles. During the campaign, 6.2 million doses were administered for a reported coverage of 92%.[898] Between 1995 and 2000, among 594 confirmed measles cases, 212 (36%) were sporadic and 382 (64%) were associated with 51 clusters. Forty-eight sporadic cases (23%) and 18 (35%) of 51 clusters were associated with an importation of infection from overseas. A wide variety of measles virus genotypes were identified during this period. The pattern of sporadic cases and small clusters associated with importations is consistent with elimination of sustained indigenous measles transmission.[898] However, unfounded concerns about vaccine safety, specifically the purported relation of MMR and autism, that began in 1998 (see "Vaccine Safety") contributed to a decline in MMR coverage that has resulted in a number of large outbreaks. In 2007, measles endemicity was reestablished with genotype D4 as the predominant genotype.[925] In 2013, based on an increase in the number of confirmed measles cases in children 10 to 16 years of age, the National Health System and Public Health England launched a national MMR vaccination campaign. This campaign increased MMR vaccination coverage to over 95% among 10- to 16-year-old children and resulted in a marked decline in the number of reported measles cases in the United Kingdom.[926]

Excellent control of measles has been achieved in other industrialized countries. In 1982, Finland initiated a measles elimination program based on a two-dose vaccination strategy. Efforts to improve vaccination coverage included mass media, a registry system to track defaulters, and an intensive outreach program. Measles elimination was achieved in Finland by 1996 and has been maintained as a result of consistently high (greater than 95%) two-dose vaccination coverage.[34,927] Sweden has reported similar success with a two-dose schedule.[32] Australia and South Korea have achieved elimination by using a two-dose routine schedule supplemented by a one-time catch-up campaign.[928,929] However, in other industrialized countries (e.g., Italy,[930] Germany,[931] France, and Switzerland[932]), measles remains endemic, with frequent large outbreaks, in part because of the perception that vaccination may be more risky than the disease itself.[933]

The European Region of the WHO, which includes the countries of the former Soviet Union, has updated its strategic plan for eliminating measles and rubella by 2015 and identified the accelerated actions needed to achieve the goal.[933] In addition to Finland and Sweden, a number of European countries are close to, or have already achieved, elimination (e.g., Hungary, Poland, the Netherlands, Slovenia, and the Russian Federation[934]). However, a review of the epidemiology of the 31,520 reported measles cases in Europe in 2013 found most cases occurred in nine countries: Georgia (7830), Germany (1773), Italy (2216), the Netherlands (2499), Romania (1074), the Russian Federation (2174), Turkey (7404), Ukraine (3308), and the United Kingdom (1900). The authors concluded that without sustained political commitment and accelerated action by Member States and partners, the elimination of measles in the WHO European Region may not be achieved on time.[935]

Less Industrialized Countries

Since the late 1970s, the Expanded Program on Immunization has played a major role in the development of immunization programs in less industrialized countries. Measles vaccination coverage in these countries rose from 18% in 1981 to 76% in 1990, and an estimated 1.7 million measles deaths were prevented in 1995 alone. During the 1990s, donor support for the Expanded Program on Immunization decreased substantially, and measles vaccination coverage levels plateaued or decreased, with the estimated annual number of measles deaths stabilizing at about 1 million.[396]

Worldwide in 2000, measles was estimated to cause between 535,300 and 777,000 deaths (i.e., 1.4% of 55.7 million total deaths).[397,398] Among children younger than 5 years of age, measles was the fifth leading cause of death, accounting for 5.4% of the 10.9 million total deaths in this age group. The vast majority of measles deaths (>95%) occur in less industrialized countries because of lower measles vaccination coverage (i.e., underdeveloped routine health services and lack of a second opportunity for measles vaccination) and a higher case-fatality ratio in these countries. The higher risk of death from measles in less industrialized countries compared with industrialized countries is associated with a younger median age of cases, increased intensity of exposure,

increased likelihood of secondary infections, and malnutrition, especially vitamin A deficiency. Poverty, crowded living conditions, and large family size are the underlying socioeconomic factors contributing to this epidemiologic pattern.[887] Global immunization programs have resulted in a decrease in worldwide measles mortality to an estimated 134,000 deaths in 2015 and prevented 20.3 million deaths since 2000.[936]

During the late 1980s and early 1990s in less industrialized countries, two different approaches were developed to address the problem of severe measles in children younger than 9 months, the age for vaccination recommended by the WHO (see Table 37.10). First, high-titer measles vaccines (e.g., Edmonston-Zagreb measles vaccine) were developed to overcome interference by maternal measles antibody when administered at 4 to 6 months of age. For a short period from 1989 to 1991, the WHO recommended use of high-titer Edmonston-Zagreb measles vaccines for 6-month-old infants in countries where measles was a significant cause of death for infants younger than 9 months.[679] Although high-titer vaccines were more immunogenic than standard-titer vaccines, they were unexpectedly associated with excess delayed mortality among females. For this reason, the WHO withdrew the recommendation for use of these vaccines in 1992.[684] The second approach, developed by the Pan American Health Organization (PAHO),[805] was based on the observation that older siblings were often the source of measles infection for infants. The concept of a one-time nationwide mass vaccination campaign for children ages 9 months to 14 years, regardless of prior disease or vaccination history, was pioneered in Cuba in 1987. The objective of this so-called catch-up campaign was to interrupt measles virus transmission by rapidly reducing susceptibility among older children and thereby prevent transmission to infants younger than 9 months of age. This approach proved highly effective and has been developed further into the PAHO strategy for measles elimination.

Pan American Health Organization Strategy

In 1994, ministers of health of countries of North and South America established the goal of eliminating measles from the Western Hemisphere by the end of 2000. To accomplish this goal, PAHO developed a strategy with three essential vaccination components: (a) catch-up—a one-time mass vaccination covering all children ages 1 to 14 years, regardless of prior disease or vaccination status; (b) keep-up—achievement of 90% or greater immunization coverage in each successive birth cohort; and (c) follow-up—subsequent mass campaigns conducted every 3 to 5 years, covering all children ages 1 to 5 years irrespective of prior disease or vaccination history.[805] Follow-up campaigns should be conducted before the estimated number of measles-susceptible pre–school-age children (determined by vaccination coverage and presumed vaccine effectiveness) reaches the size of the birth cohort. After the catch-up campaigns, most countries have increased the measles vaccination age to 12 months to maximize vaccine effectiveness. With the establishment of a rubella elimination goal in the Americas by the year 2010, countries in Latin America conducted nationwide vaccination campaigns targeting more than 450 million women and men up to age 39 years with MR vaccine. The addition of these "speed-up" campaigns to the PAHO Strategy resulted in the elimination of rubella in the Western Hemisphere by 2009 and reinforced efforts leading to measles elimination.[937] In addition to the vaccination strategy, case-based surveillance with laboratory confirmation of suspected measles cases has been established in all countries of the Americas.[938]

In Brazil, the National Immunization Program was created in 1973, and routine measles vaccination was recommended at 8 months of age.[939] National measles control was intensified in 1980–81 with campaigns focused in areas of low coverage. The minimum recommended age for measles vaccination was changed to 7 months in 1976, and then to 9 months in 1982. In 1992, with the adoption of a measles elimination goal by 2000, a second dose was recommended at age 12 to 15 months (see Table 37.10). Based on the success of statewide mass vaccination campaigns in Parana and Saõ Paulo in 1987, Brazil conducted a nationwide catch-up campaign in 1992 during which 48 million doses of measles vaccine were administered to children ages 9 months to 14 years. In 1995, the first national follow-up campaign for children ages 1 to 3 years was conducted; the state of Saõ Paulo did not participate in this campaign.

In 1997, after a 4-year period of low incidence, Brazil experienced a major resurgence of measles, with a total of 53,335 cases and 61 deaths.[939] Transmission was concentrated in the metropolitan area of Saõ Paulo State but subsequently spread to involve all states. The highest age-specific incidence rates were among children younger than 1 year (1577 per 100,000), young adults ages 20 to 29 years (539 per 100,000), and children ages 1 to 4 years (205 per 100,000). This age distribution was similar throughout Brazil, with 55% of cases occurring among adults 20 to 29 years of age, a cohort born between 1968 and 1977, when the vaccination program was being initiated. Characterization of measles viruses during the outbreak in 1997 identified the D6 genotype. This same genotype was identified in subsequent measles outbreaks in Argentina and Uruguay in 1998 and in Chile, Bolivia, and the Dominican Republic during 1999 to 2001.[940]

The resurgence of measles in Brazil in 1997 led to a nationwide follow-up campaign in 1997 for children ages 6 months to 4 years. A third follow-up campaign was conducted in 2000 for children ages 1 to 4 years. After two follow-up campaigns, measles transmission was interrupted. In 2008, as part of their rubella elimination strategy, Brazil conducted a national MR vaccination campaign for women and men ages 20 to 39 years, which both eliminated rubella and served to maintain measles elimination until 2013.[937]

Implementation of the PAHO strategy in the Western Hemisphere has resulted in a greater than 99% decline in reported measles cases, from a high of almost 250,000 cases in 1990 to 1824 cases in 2014 (Fig. 37.10). The pattern of measles importations into the United States confirms the success of the PAHO strategy.[911] In 1990, at the height of the regionwide resurgence in measles, 242 of 300 importations of measles were from Latin America; in contrast, of 27 importations in 2004, none was from Latin America.[27] During 2001, measles outbreaks in Haiti and the Dominican Republic were brought under control, ending known transmission of the D6 measles virus genotype in the Western Hemisphere. Following the interruption of transmission with the D9 genotype in Venezuela and Colombia in November 2002, the Western Hemisphere was free of endemic measles for more than 12 years. However, importation of D8 genotype in March 2013 into Pernambuco State in Brazil led to an outbreak of more than 1000 cases. This outbreak spread to the neighboring state of Ceara and lasted through May 2015, resulting in the reestablishment of endemic transmission of measles in the Americas. Intensive control efforts were successful in stopping transmission in Brazil and on 27 September 2016, PAHO announced that elimination of measles had been verified in all countries in the Americas.[940a]

The success of the PAHO strategy has led to expansion of its use outside the Western Hemisphere. In Africa, the PAHO strategy has been adopted in an effort to reduce measles mortality. Between 1996 and 1999, seven southern African countries (South Africa, Namibia, Zimbabwe, Swaziland, Malawi,

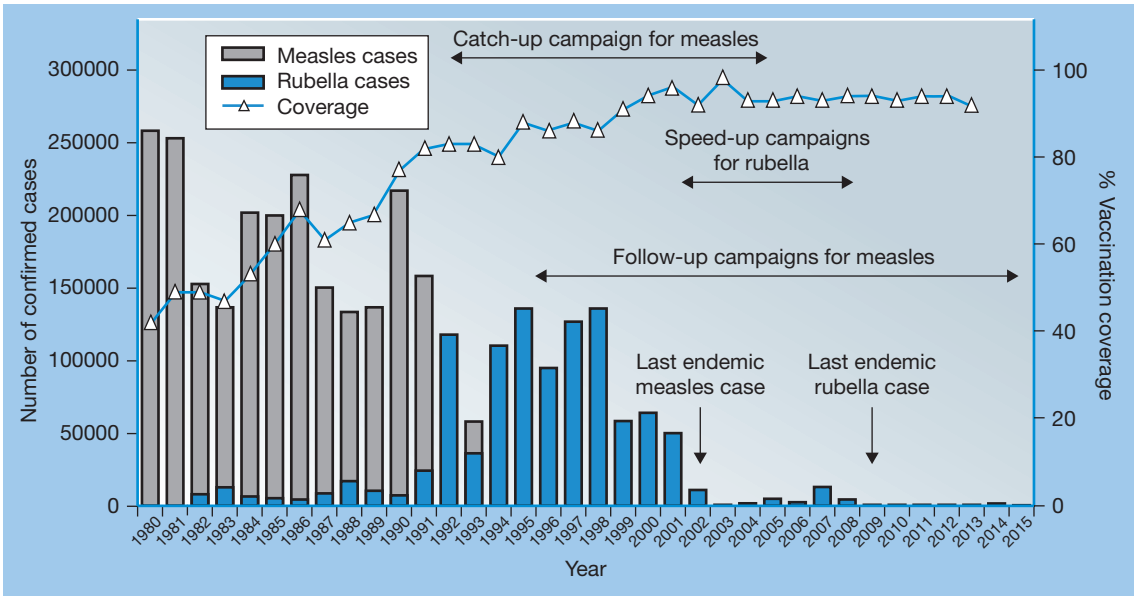

Figure 37.10. Reported measles cases, Latin America and the Caribbean, 1980 to June 2015. *(Data courtesy the Immunization Unit, Family and Community Health Area, Pan American Health Organization.)*

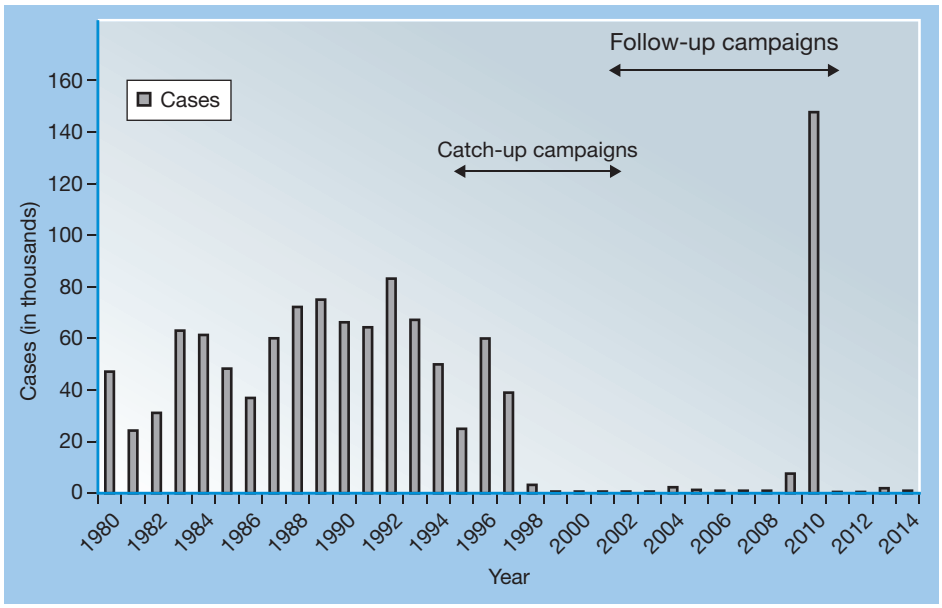

Figure 37.11. Reported measles cases, seven southern African countries, 1980–2014. *(Data courtesy the African Regional Office of World Health Organization.)*

Botswana, and Lesotho) conducted catch-up vaccination campaigns and introduced case-based measles surveillance.[941] Reported measles cases in these countries decreased from more than 50,000 in 1996 to between 20 and 2234 reported measles cases in the years 1998 to 2008 (Fig. 37.11). This period of low transmission was followed by a widespread resurgence across all countries in southern Africa that started in 2009 and peaked in 2010 with more than 140,000 reported measles cases and 764 measles deaths.[942,943] Possible reasons for the resurgence include build-up of susceptibles as a result of gaps in immunization coverage, both routine and during campaigns, and increased migration into South Africa following democratic elections in 1994. During 2011–14, reported measles incidence has remained low in southern Africa (Fig. 37.11).

Mortality Reduction Strategies

In February 2001, at a meeting hosted by the American Red Cross, a new partnership was formed to advocate for reduction of measles mortality in Africa.[944] Worldwide, during 2000 to the end of 2008, more than 650 million children received measles vaccine through supplementary immunization activities, and global routine immunization coverage with one dose of measles vaccine increased from 71% to 83%. These accelerated control efforts resulted in a 78% decrease in the estimated number of measles deaths worldwide by the end of 2008, thereby surpassing the 2005 global goal of a 50% reduction.[945] However, between 2009 and 2014 progress slowed and the estimated annual number of measles deaths remained above 100,000, with the result that the global goal set for 2015 to

reduce measles deaths by 95% compared with 2000 levels was not met on time.[936]

Based on the success of implementing the PAHO strategy in other regions of the world, a schedule that offers at least two doses of measles vaccine delivered either through routine services or mass campaigns has become the standard of care in all countries regardless of development status or routine vaccination coverage (see Table 37.10).[804]

Measles Eradication

The feasibility of measles eradication has been debated for many years.[42,44–46,946–948] Hopkins and colleagues[42] have proposed global measles eradication and pointed out both the similarities and differences between measles and smallpox. Measles will be substantially more difficult to eradicate than smallpox because of its higher contagiousness, younger median age at infection, and older age at which vaccine is effective.[949]

As of 2014, all six WHO regions have established target dates for measles elimination (the Americas by 2000, Europe and the Eastern Mediterranean initially by 2010 and revised to 2015, the Western Pacific by 2012, and Africa and Southeast Asia by 2020). The Region of the Americas stopped endemic measles transmission in November 2002 and remained free of endemic measles for over 12 years. At the global level, measles control targets have been set for 2015 to increase measles immunization coverage to 90% or greater at the national level and to 80% or greater in every district, to decrease the incidence of measles to less than five cases per million, and to reduce measles deaths by 95% compared with 2000 levels.[950]

In July 2010, the WHO convened a global technical consultation to review the feasibility of measles eradication.[47] There was a comprehensive review of the biologic, programmatic, vaccine supply, economic, and health systems aspects of measles eradication compared with mortality reduction targets. An epidemiologic and economic evaluation based on data collected in Bangladesh, Brazil, Colombia, Ethiopia, Tajikistan, and Uganda found that measles eradication by 2020 was the most cost-effective measles control option both in the six countries and globally, and it would cost an additional discounted $7.8 billion between 2010 and 2050.[951] After reviewing all the available information, the conclusion was that measles can and should be eradicated and that global eradication by 2020 is feasible. The report from the global technical consultation was reviewed and discussed by the Strategic Advisory Group of Experts in November 2010. They agreed that eradication of measles is technically and biologically feasible and recommended measurable progress toward existing regional elimination targets before establishing a target date for global eradication.[952] However, there has been little further progress since 2010, and the 2014 Annual Report of the Global Vaccine Action Plan concluded that regional elimination of measles by 2015 in the European, Eastern Mediterranean, and Western Pacific Regions was off-track.[953] In 2016, a midterm review of the Global Measles and Rubella Strategic Plan, 2012-2020,[953a] was conducted to determine the underlying causes for lack of progress toward regional elimination goals. The review concluded that the basic strategies articulated in the plan are sound; however, these require full implementation.[953b] The main impediments to full implementation have been inadequate country ownership and global political will, reflected in inadequate resources. The report recommends a shift in strategic focus toward greater reliance on ongoing services to administer two doses of MCV (rather than supplementary immunization activities) and toward use of disease incidence and epidemiology as a major indicator of progress (rather than vaccination coverage alone). The report emphasized that, while eradication is the ultimate goal, it is premature to set a date for its accomplishment, and existing regional elimination goals should be vigorously pursued to enable setting a global target by 2020.[953b]

Available evidence indicates measles meets the criteria for a disease that can be eradicated: (a) there is no animal or environmental reservoir, and humans are critical to maintaining transmission; (b) accurate diagnostic tests are available; (c) measles vaccine and existing vaccination strategies are effective and safe; and (d) measles transmission has been interrupted in a large geographic area (e.g., nationwide) for a prolonged period.[46] Major challenges to global measles eradication include (a) increasing urbanization and population density that will require very high vaccination coverage, (b) war and civil unrest, (c) the frequency of international travel and forced migrations that facilitate importations of measles, and (d) the HIV epidemic, which may reduce the effectiveness of measles vaccination and increase the transmissibility of measles.[832] Other potential impediments are lack of political will, risk of unsafe injections, and the possibility of sustained transmission among adults who are accounting for an increasing proportion of all cases. Measles in adults is emerging as a major challenge to elimination in countries with longstanding immunization programs (e.g., Western Europe[935] and China[954]) that experienced lower coverage in the early years of the programme. To address these challenges, research[849] is ongoing to improve diagnostic tests for measles by using filter paper blood spots[336,337] and oral fluid[334]; and to develop alternative routes for administration of existing measles vaccines (e.g., aerosol vaccination[482–485]), needle-free jet injectors, and microarray patches[853] to reduce the risk of unsafe injections; and new candidate vaccines that could be administered in the presence of maternal antibodies ("stealth vaccines").[955] In addition, strategies for disease surveillance, increasing vaccination coverage through routine immunization services and mass campaigns, and program monitoring are being strengthened to learn from recent field experience with measles mortality reduction and regional elimination activities. These efforts provide optimism that, in the future, the goal of global measles eradication may be achieved.

38 Meningococcal Capsular Group A, C, W, and Y Conjugate Vaccines

Lee H. Harrison, Dan M. Granoff, and Andrew J. Pollard

Epidemics of meningococcal meningitis were first described in Geneva, Switzerland in 1805[1] and Medfield, Massachusetts in 1806.[2] Such epidemics occurred in the United States until 1944. In sub-Saharan Africa, meningococcal epidemics have been recognized for more than 100 years.[3] In the early 1900s, Flexner[4] demonstrated that intrathecal administration of antimeningococcal serum decreased mortality of meningococcal meningitis. In the past 15 years, huge advances have been made in new meningococcal vaccines, which are changing the face of meningococcal disease epidemiology globally.

Meningococcal disease can progress rapidly. The case fatality rate, which was 70% to 85% before the advent of antibiotics, is now 10% to 15%.[5] Epidemics historically occured every 5 to 10 years in sub-Saharan Africa with incidence rates as high as 1000 per 100,000 population,[3] but the epidemiology has changed dramatically in the past few years. Epidemics have not occurred in the United States and Europe since the 1940s, and during the past decade endemic disease incidence rates have fallen to rates not seen in the last 60 years. A group B epidemic in New Zealand with more than 5000 cases during a 15-year period beginning in the early 1990s demonstrated the potential of *Neisseria meningitidis* to cause epidemic disease in an industrialized country. Control measures were unsuccessful in New Zealand until development of an epidemic-specific outer membrane vesicle vaccine and mass immunization.

BACKGROUND

Clinical Description and Manifestations

The clinical features of meningococcal disease are highly variable. Classic clinical features of meningococcal disease are fever, rash, and meningitis, but initial presentation is often nonspecific and therefore may be indistinguishable from those of other bacterial, rickettsial, or viral infections.[6,7] In fact, many serious cases of meningococcal disease are initially misdiagnosed as a benign viral illness, which can have devastating consequences because rapid progression to life-threatening disease may follow within hours.[7]

The most common clinical manifestation is acute bacterial meningitis.[8] Older children and adults typically have an abrupt onset of fever, headache, photophobia, myalgias, and malaise. Seizures occur in approximately 20% of patients. Signs of altered consciousness, such as hyperactivity or lethargy, can be prominent. Nuchal rigidity is a common sign except in infants in whom a more gradual onset of fever, poor feeding, and lethargy are the typical initial complaints, and a bulging fontanel may be the major sign of central nervous system involvement. A rash is present in the majority of cases of meningococcal disease, which consists of typical petechiae or purpuric lesions that usually are most apparent on the chest, upper arms, and axillae.[9] Maculopapular rashes also are common and may occur early in the absence of petechiae.
