48 Poliovirus Vaccine–Inactivated

Emmanuel Vidor

HISTORICAL INTRODUCTION

Not since the introduction of rabies vaccine by Louis Pasteur was public interest in vaccines stirred as much as by the development and testing of inactivated poliovirus vaccine (IPV), and not since Einstein had a scientist received the public adulation accorded to Jonas Salk, the vaccine's inventor. Contributing to this phenomenon were the rise of poliomyelitis as an epidemic disease, its notoriety with the public (augmented by the paralysis suffered by U.S. President Franklin Roosevelt), the publicity disseminated by the March of Dimes Foundation in its efforts to raise money for research, and the involvement of hundreds of thousands of U.S. children in the trial that demonstrated the efficacy of IPV. The trial was organized by Dr. Thomas Francis and sponsored by the National Foundation for Infantile Paralysis. It was a hallmark in vaccinology and the prototype for many later efficacy trials.[1–5] The trial began in April 1954, and the successful results were announced on April 12, 1955.[5] Licensure followed rapidly, with rapid and broad vaccine adoption in many countries.

Nevertheless, in the early 1960s, IPV was eclipsed by oral poliovirus vaccine (OPV), except in some northern European countries. Sixty years after its initial development IPV is renascent, owing to improvement in its manufacture and scaling up of capacities, its outstanding safety record, the major progress toward eradication of wild polioviruses, and the recognition that safety concerns associated with OPV (i.e., both sporadic vaccine-associated paralytic poliomyelitis [VAPP] cases and outbreaks of circulating vaccine-derived poliovirus [cVDPV]) require eventual cessation of OPV use. IPV, without those safety concerns, can provide a safety net to prevent reemergence of polio as OPV is removed from routine use.[6]

Disease caused by polioviruses is ancient. A famous Egyptian stele dating from 1403 to 1365 BC shows a man with flaccid paralysis of a leg. However, presumably owing to almost universal infection under the clinical protection of maternal antibodies, only sporadic cases were described until the 19th century. Early in that century, small outbreaks were noted in Europe, usually among infants living in rural areas. In 1870, Jean-Martin Charcot described the lesions in the gray matter of the spinal cord, and in 1890, Oscar Medin described a major outbreak in Sweden, where epidemics subsequently continued to occur. Epidemics were reported in the United States at the end of the 19th century, and in 1916 thousands of children were paralyzed during an epidemic in the northeastern United States. Fortunately, in 1908, Karl Landsteiner and Eric Popper isolated the virus of poliomyelitis, and studies of the agent began.[7]

The key discoveries that led to IPV development were as follows:

- Definition of the three serotypes of poliovirus by Bodian, Burnet, and colleagues.[8]
- Determination that poliovirus viremia precedes paralysis.[9]
- Confirmation that neutralizing antibodies protect against disease.[10]
- Demonstration by Enders and colleagues that the virus could be grown in cell culture.[11]

These discoveries permitted Salk, fresh from his success in developing an inactivated influenza vaccine as well as experienced in working with poliovirus, to start IPV development. Large quantities of virus were grown in roller tubes from monkey testicular and kidney cells and the kinetics of inactivation by formalin were studied. Salk concluded that if aggregates of virus were removed by filtration, poliovirus could be inactivated at a constant first-order rate, permitting complete killing if the process was of sufficient duration. Pools of trivalent vaccine were prepared at Connaught Laboratories in Toronto for use in the field trial of efficacy, which was conducted by Francis and associates in 1954. Although it did have some flaws,[12] the trial decisively demonstrated that IPV was protective, and in 1955 several U.S. manufacturers obtained licenses for their IPV and launched their products in the United States.[13] Very soon after, similar IPVs derived from the same concepts and developed by private or state-owned institutions were launched in different countries.[14–16] The Cutter incident (see "Adverse Events" later) in which recipients of IPV were paralyzed by residual live virus in the vaccine, underlined the necessity of removing viral aggregates to permit inactivation, but did not stop the use of IPV in many countries.

Years later, major developments improved the quality of IPV. The first, by van Wezel of Holland, was the development of techniques to select the best sources of monkey kidney cells, to grow the cells to high density on microbeads, and to concentrate the virus produced.[17] The second was the adaptation of the continuous African green monkey (*Cercopithecus aethiops*) kidney cell line (denominated Vero) to the production of poliovirus by Montagnon and colleagues at the Institut Mérieux (now Sanofi Pasteur) of Lyon, France.[18] The result of these improvements was the historically named enhanced-potency IPV (eIPV) which is the subject of this chapter, but because all IPVs now in use are of enhanced potency, hereafter the designation IPV will be used to refer to enhanced-potency IPV vaccines. (Later in the chapter, the cIPV will be used to distinguish the conventional IPV manufactured from wild-type poliovirus strains from sIPV, the Sabin IPV manufactured from the Sabin poliovirus strains. The IPV acronym will be used when referring to statements applicable to both types of IPV.)

The description of poliomyelitis as a disease, in addition to its virology, pathogenesis, and epidemiology, is discussed in Chapter 49. However, it is important to mention that the polioviruses are made of four capsid proteins, numbered VP1 to VP4 (Fig. 48.1). The first three are arranged on the surface with icosahedral symmetry whereas VP4 is an internal protein.[19] There are five epitopes present on VP1 to VP3 that are important to neutralization: sites 1, 2a, 2b, 3, and 4. These vary between serotypes and between strains, and precise mapping of their tridimensional structure helps identify their key immune targets.[20]

PASSIVE IMMUNIZATION

A field trial using human γ-globulin established the importance of viremia in the pathogenesis of the disease and the concept that antibodies were protective against paralysis. This trial, conducted in 1952 by Hammon and colleagues,[10]

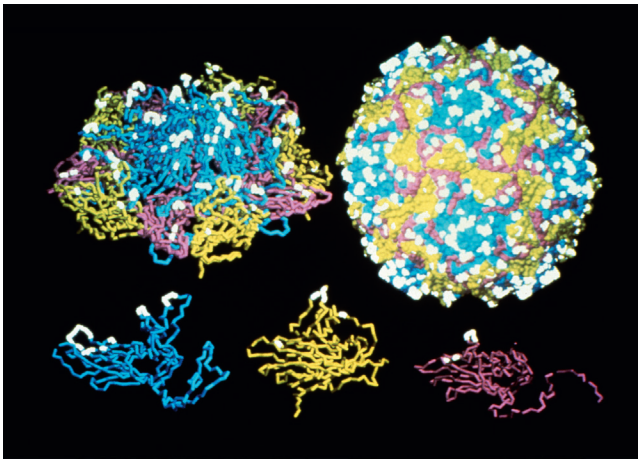

Figure 48.1. Antigenic sites of poliovirus are highlighted in white on the structure of the virus *(top right)*, a pentamer consisting of five copies of each of the capsid subunits *(top left)*, and the individual major capsid proteins VP1, VP2, and VP3 *(bottom left to right)*. VP1, blue; VP2, yellow; and VP3, red. *(Courtesy James Hogle and Arthur Olson.)*

involved more than 54,000 children, half of whom received γ-globulin and half of whom received gelatin. From the second to the eighth week after injection, paralytic poliomyelitis was reduced by 80%. Unfortunately, despite the large γ-globulin dose used in subjects (0.3 mL/kg), the protection proved temporary (8 weeks), rendering γ-globulin impractical as a public health strategy except in household contacts. Maternally produced antibodies transmitted via the placenta are also protective, and their half-life is only 28 days (see "Effect of Maternal Antibodies and of Neonatal Vaccination" later).

ACTIVE IMMUNIZATION

General Principles

IPV is a mixture of the three polioviruses made by harvesting cell culture supernatants and submitting them to purification and inactivation by formalin (one of the historical IPVs, developed by Lepine[21] at the Pasteur Institute in Paris, was inactivated by formalin and β-proprionolactone). The first IPV were produced from rhesus monkey (*Macaca mulatta*) primary kidney cell cultures, with all the problems of simian viruses that might be latent or replicating actively in cultured cells. The poliovirus strains used by Salk and by most manufacturers are wild-type polioviruses including Mahoney (type 1, the Brunhilde strain is still used by one manufacturer in Denmark), MEF-1 (type 2), and Saukett (type 3). During the past several years, IPV based on cultured and inactivated Sabin poliovirus strains (sIPV) has been developed and produced by a few manufacturers (see "Inactivated Polio Vaccine Manufactured from Sabin Strains" later).

Although the results of the historical Francis trial were positive (see "Efficacy of Inactivated Polio Vaccine Against Acute Flaccid Paralysis and Immune Correlates of Protection" later), the Cutter incident (see "Adverse Events" later) led to a change in manufacturing processes that lowered the immunogenicity of the early vaccine[22] and resulted in the resurgence of paralytic polio in vaccinated children during the late 1950s, which, in turn, weakened confidence in IPV.[23]

Fortunately, several technical advances during the 1970s permitted the rejuvenation of IPV, which, although based on principles similar to those of the first-generation vaccine, differs in three important aspects:

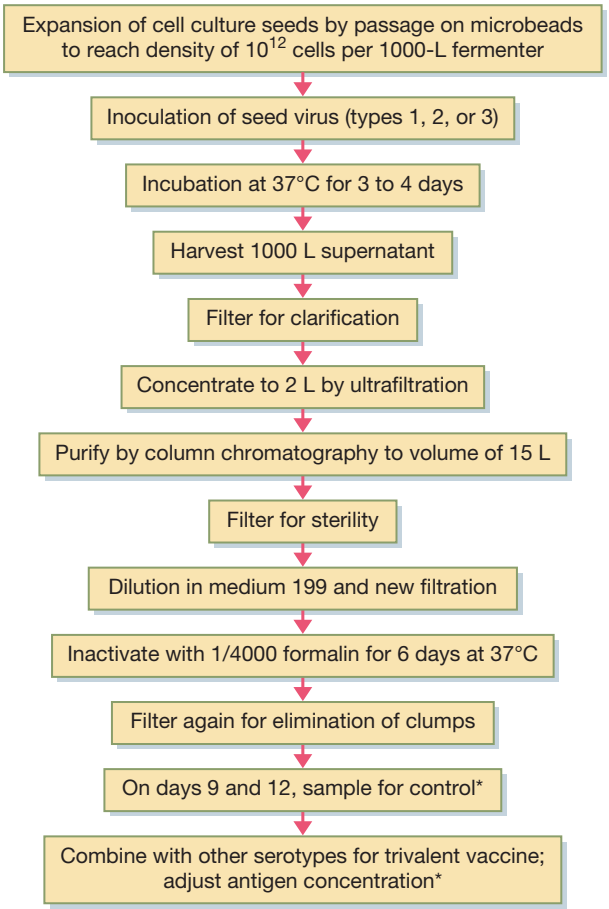

Figure 48.2. Production of enhanced-potency inactivated poliovirus vaccine. *, Sampling of an equivalent of at least 1500 human doses for control of effective inactivation.

1. The cell substrate on which the virus seeds are inoculated include continuous cultures of human diploid or simian cell lines, rather than primary, secondary, or tertiary cell cultures from captured or bred monkeys.
2. To increase density, cells are grown on microbeads dispensed in large bioreactors.
3. The virus harvest is concentrated before inactivation to increase the final antigen content.

Fig. 48.2 outlines the production steps of IPV.[24–30] The cells are expanded from a working cell bank adapted to grow on microbeads (Fig. 48.3) in large bioreactors (Fig. 48.4) until high cell density is reached. Growth medium is then removed, the cells are washed, and one of the three types of poliovirus is inoculated. By 72 to 96 hours of incubation at 37°C, the cells have been lysed by viral replication and the supernatants are collected. After clarification, the virus is concentrated 500-fold by ultrafiltration. To remove cellular proteins and DNA, the concentrated virus is passed through size exclusion and ion-exchange chromatography to yield purified material. At this point, there is less than 10 ng of DNA per human dose, a level considered to pose no hazard to recipients.[31] The concentrated purified virus is then inactivated by the addition of formalin and incubation at 37°C for 12 days. By day 4 viral inactivation should be almost complete, as confirmed by sampling for residual live virus. During inactivation of the virus, it is important to avoid viral clumping and to maintain a neutral pH. An extra filtration is included during inactivation

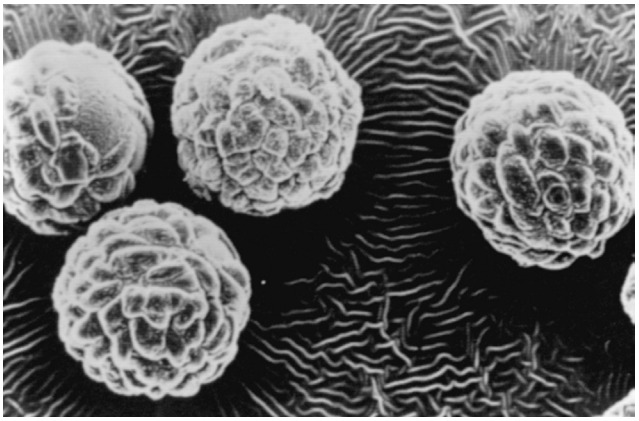

Figure 48.3. Kidney cells from African green monkeys (Vero cells) grown on microcarrier beads. *(Courtesy Dr. B. Montagnon, Institut Mérieux, Lyon.)*

Figure 48.4. Bioreactors of 1500 L capacity in which cells are grown for virus cultivation. *(Courtesy Sanofi Pasteur, Lyon.)*

to remove viral clumps.[32] Growth of polioviruses in Vero cells in serum-free conditions[33,34] or using other cell lines[35,36] improves yield with the hope of reducing costs of production. The final monovalent material from each serotype is subjected to tests for residual infectivity, which must be negative. The three monovalent inactivated viral pools are then mixed to form standardized for antigen content trivalent bulk antigen stored in concentrated form until formulation of the final vaccine is executed.

Content of the three poliovirus types in the final product, and also in intermediates, is expressed as D antigen (D-Ag) units (D-Ag are expressed only by intact virus particles). This determination was historically measured using gel diffusion (where 100 units were arbitrarily defined as the amount of D-Ag able to induce a 22-mm diameter precipitation circle in a gel diffusion assay[37] and shown to correlate with immune responses in the historical trials done with the enhanced potency IPV[38]) but is now assessed using enzyme-linked immunosorbent assays (ELISA). The measurement done on the trivalent bulk antigen constitutes the measure of in vitro potency of the product (antigenicity) and is the basis of the final vaccine formulation. All products target a specific amount of D-Ag content for poliovirus types 1, 2, and 3 in the final product, depending on the type of strain used for vaccine manufacture (conventional inactivated polio vaccine [cIPV] or sIPV), the reference material used in the assay, and the data treatment algorithm used to compute the optical density values measured in the ELISA (multiple or linear regression methods). Determination, standardization, and specifications for the D-Ag content of IPV are important issues and have been complicated with the emergence of the sIPV vaccines. Successive international reference vaccines have been characterized by the World Health Organization (WHO)[39,40] and suggestions have been made for the improvement of the ELISA that measures D-Ag content.[41] The key parameters in the performance of this assay include: (a) the nature (poly- or monoclonal and their specificity[ies]) of the antibodies used for antigen capture, (b) the nature (poly- or monoclonal and their specificity[ies]) of the antibodies used for antigen detection, (c) the method of calculation of results (multiple or linear regression methods), and (d) the nature of the reference antigen used in the assay. In addition, some reagents may detect the presence of polio C antigens (associated with noninfectious viruses). Consequently, using those reagents can provide a falsely high evaluation of the antigenic properties associated with D-Ag content of the vaccine (i.e., the final product may actually be subpotent resulting in decreased immunogenicity). Thus, given the variability in how D-Ag is measured, comparing the projected immunogenicity of various products based on the reported D-Ag content may not be always accurate (see the following section).[42,43]

The immunogenicity (in vivo potency) of IPV is measured by immune responses obtained in monkeys, rats, guinea pigs, mice, or chickens. The rat model is still used in some countries for in-process controls and/or release purposes. The variability of the methods of measuring poliovirus neutralizing antibodies in these assays complicates the comparison of potencies of different IPVs. Finally, prediction of immunogenicity in rats from antigen content as measured by ELISA has been uncertain[39] and the relationship between immunogenicity observed in animal models and in humans might not be straightforward.

All these parameters are surrogates for the clinical protective effect anticipated in humans vaccinated with IPV. To more closely approximate that effect, new potency assays have been evaluated like the use of transgenic mice, which express the CD-155 poliovirus receptor.[44,45] These mice can be immunized with IPV and then challenged with polioviruses to evaluate whether paralysis is prevented or not.

Inactivated Polio Vaccine Manufactured From Sabin Strains

Several studies have evaluated the biochemical differences between sIPV and cIPV, and particularly the effect of formaldehyde inactivation on the antigenic structures of polioviruses.[46,47] Using reactivity to monoclonal antibodies profiled by ELISA, it has been shown that inactivation with formaldehyde destroys some antigenic sites of the polioviruses.[48,49] Depending on the characteristics (reagents) of the D-Ag assay to measure the potency of resulting inactivated viruses, such alterations might not be measured.[50,51] Because of their genomic differences, the epitopes presented by the Sabin strains are different from the epitopes presented by the wild-type strains; therefore, they have a different sensitivity to formalin inactivation. A study[48] documented that the antigenic site 1 of the Sabin poliovirus 1 can be damaged by formalin, whereas the same antigenic site present at the surface of the wild-type Mahoney poliovirus 1 strain is not damaged by formalin. The consequence of this is that sIPV and cIPV do exhibit differences in their antigenicity profile,[48,52] with the result that the repertoire of antibodies induced by cIPV or sIPV might differ.[53,54] In a study done at the U.S. Food and Drug Administration (FDA) using the transgenic poliovirus receptor mice model, a type 2 sIPV prepared by the Japan Poliomyelitis

Research Institute (JPRI), elicited fivefold lower levels of MEF-1 neutralizing antibodies than Sabin 2 neutralizing antibodies and lower protection (20% to 100% paralysis, depending on dose and regimen) after virulent challenge than a type 2 cIPV prepared from MEF-1 strain (0 to 20% paralysis, depending on dose and regimen).[45] Similar findings were observed previously with a type 3 sIPV,[39] but not for a type 1 sIPV.[51] Whether these differences have any clinical implications with regard to protection in humans against paralysis induced by cIPV versus sIPV is not known.

Historically, the first attempts to develop sIPV occurred at the JPRI during the mid-1980s[55,56] and at the Lederle Laboratories in the United States[57] followed by the Rijksinstituut voor Volksgezondheid en Milieu (RIVM) in The Netherlands.[50] In addition, since 2004 the WHO has been promoting the emergence of new players in the field of IPV vaccination by helping manufacturers develop sIPV. A major advantage of sIPV is the capability to open its manufacture to developing-country manufacturers. An escape of wild polio viruses from a manufacturing plant in an industrialized country with good hygiene and sanitation would not likely have the same consequences as escape in a developing country with crowding and poor hygiene and sanitation. That is why developing-country manufacturers cannot manufacture IPV made from wild polio viruses. However, escape of a Sabin strain does not have the same consequences as escape of a wild virus. Hence, developing-country manufacturers can produce vaccines in their own countries and offer the potential for reduced prices. The WHO's strategy is to help current OPV manufacturers to expand and transform their manufacturing facilities, allowing them to make sIPV. To accomplish this the WHO relies on Intravacc (ex-RIVM) for technology-transfer partnerships.[58]

Several groups have developed sIPVs independently from the WHO. The JPRI initiative, ongoing since the mid-1980s in Japan, has resulted in the licensure in Japan of two diphtheria, tetanus, and acellular pertussis (DTaP)-sIPV products by Biken and Kaketsuken[59,60] in 2012. In addition, JPRI is claiming to be engaged in technology transfer activities with Polyvac in Vietnam and with Biofarma in Indonesia. The Institute of Medical Biology, Chinese Academy of Medical Sciences (Kunming Institute) in China has developed a standalone sIPV product,[61,62] which is licensed in China, and is working on more complex combinations.[63] Finally, Intravacc (ex-RIVM) has developed a sIPV technology platform available for technology transfer[64–69] under the sponsorship of the WHO and work on optimization of the upstream (cell culture density, viral culture step, serum free media) and downstream (clarification, purification, inactivation) process to improve overall yields. Several companies have been awarded WHO support and are claiming to be engaged in such developments.[69a]

Inactivated Polio Vaccine Manufactured From Other Poliovirus Strains

Within the scope of developments that are undertaken toward lower-cost and/or safer (from a manufacturing perspective) IPV vaccines,[70] several groups are developing new poliovirus strain seeds that could be used for vaccine production.[71–73] Approaches are focused on developing more stable attenuated strains by manipulating the 5′ noncoding region of the viral genome, by increasing polymerase replication fidelity, or by codon deoptimization. Some groups are even trying to develop noninfectious seed strains.

Adjuvanted Inactivated Polio Vaccine

The positive role of adjuvants on the immunogenicity of IPV antigens has been known since the pioneering work done with mineral oil and oxide aluminum salts.[74,75] Later, through several IPV-containing whole-cell pertussis (wP)-based combinations, the positive role of calcium aluminum salts has been advocated.[76] Since then, it has been largely demonstrated through several randomized controlled trials (RCTs) that the immunogenicity of the IPV antigens contained in diphtheria, tetanus, and pertussis (DTP)-backboned combination vaccines (and therefore containing aluminum salts as adjuvant) is improved compared to standalone IPV vaccines.[77–83] This is particularly visible after an infant primary series where RCTs do consistently show geometric mean titers (GMTs) approximately twofold higher with combined vaccines. Therefore, reducing the amount of antigen in standalone IPV vaccines formulated with aluminum salt adjuvants might produce similar responses. This is an avenue followed by some groups[84] (two clinical trials sponsored by Statens Seruminstitut are ongoing in Denmark and in the Dominican Republic).

In addition, new adjuvants are being considered for IPV hoping that the reduction of antigen needs will allow more affordable and/or better mucosal immunity inducing IPVs.[85] Preclinical studies with cIPV or sIPV antigens show that several new adjuvants (squalene-based or oil-in-water emulsions supplemented or not with Toll-like receptor–agonists, polymers, chitosan, alphavirus, cytosine phosphate guanine oligodeoxynucleotides, cationic liposomes, saponin, lipopolysaccharide derivatives, double-mutant labile toxin [dmLT]) may decrease the amount of antigen needed to achieve the desired immune responses and/or skew the response toward higher secretory immunoglobulin A levels.[67,86–93] In a more futurist approach, IPV antigens incorporated into thermoresponsive gels with the dmLT adjuvant allowing sublingual immunization are being considered in some preclinical models.[94]

Vaccine Constituents Other Than Immunizing Antigens

Streptomycin, neomycin, and polymyxin B are used in the manufacturing steps to control bacterial bioburden, and they are largely eliminated during purification. Many of the manufacturers are engaged in removing these antibiotics during the viral culture step; nevertheless, the use of polymyxin B does have some effect on the quality of viral replication.[95] Trace amounts of these antibiotics may still be present in the final vaccine. When used as part of multivalent combination vaccines, the quality of the IPV bulk antigens and of their other constituents are of extreme importance in the behavior, potency, and stability of the formulated final drug product.

Thimerosal cannot be used to preserve multidose presentations of IPV-containing vaccines because it destroys the polio antigens,[96] but preservation of the final product is conferred by residual formalin and 2-phenoxyethanol. The recently updated WHO multidose vial policy[97] states that multidose (two-, five-, or 10-dose) vial presentations of IPV can be used up to 28 days after first use provided they are handled according to good vaccination practices and stored between usages at 2°C to 8°C. Incorporation of this policy into the licensure labeling of several IPV products will limit product wastage in the field compared to previous policy, which required disposal of vaccine after a single vaccination session.

Stability

IPV is stable for 3 years at 2°C to 8°C. Its thermoresistance varies, as expected, with levels and durations of high temperature excursions. At 37°C, loss of potency is observed in

a matter of days according to virus types. Most multidose products used in tender-driven markets are equipped with Vaccine Vial Monitors able to measure cumulated temperature exposure. Freezing diminishes the potency of IPV and should be avoided.

Producers of Inactivated Polio Vaccine Antigen and Available Vaccines

Table 48.1 lists the current manufacturers of IPV bulk antigen (drug substance) used in the licensed vaccines as of mid-2016. Eighteen to 36 months are needed from engaging working viral seed lots in the production of the vaccine antigens up to the packaged final IPV-containing batch release by all concerned (internal and external) control laboratories for a given market. During 2014, the global production capacity for IPV bulk antigen was estimated to be enough to allow 200 to 300 million doses of final product to be released in 2016. With the ongoing scale up of the historical manufacturers and the recent entry of new players, the global annual capacity for production of IPV vaccines will further increase.

All available IPVs contain inactivated viruses for serotypes 1, 2, and 3, and are available as standalone vaccines and as trivalent (Td-IPV), tetravalent (DTaP-IPV and Tdap-IPV), pentavalent (DTaP-IPV-Hib and DTaP-IPV-HB), and hexavalent (DTaP-IPV-HB-Hib) combination vaccines (see also Chapter 15). Those vaccines are used worldwide for infant/toddler primary immunization series and/or for booster immunization in children at the time of school entry, and for adolescents and adults. Some of these vaccines are also used for immunization in persons (most often adolescents or adults) not previously immunized or with unknown or incomplete immunization history. In some countries, standalone IPV vaccines formulated, filled, labeled, packaged, and released by a national manufacturer using IPV bulk antigens imported from another manufacturer are licensed or are under development.

TABLE 48.1 Manufacturers of Inactivated Polio Vaccine Bulk Antigen Used in Licensed Vaccines (as of Mid-2015)

Manufacturer	Where Made	Cell Substrate	Poliovirus Strains
Bilthoven Biologics (Serum Institute of India)	Netherlands	Vero	Mahoney, MEF-1, Saukett
GlaxoSmithKline	Belgium	Vero	Mahoney, MEF-1, Saukett
Japan Poliomyelitis Research Institute	Japan	Vero	Sabin 1, Sabin 2, Sabin 3
Kunming Institute	China	Vero	Sabin 1, Sabin 2, Sabin 3
Novartis (Glaxo SmithKline)	Italy	Vero	Mahoney, MEF-1, Saukett
Sanofi Pasteur	France	Vero	Mahoney, MEF-1, Saukett

Most of the IPV standalone vaccines are WHO prequalified and all are compliant with the recently updated recommendations to assure the quality, safety, and efficacy of poliomyelitis vaccine (inactivated).[98] Some of them are manufactured in compliance with the third edition of the global action plan to minimize poliovirus facility-associated risk after type-specific eradication of wild polioviruses and sequential cessation of routine OPV use (GAPIII).[99] The feasibility (and timing) of adoption by all manufacturers of these requirements is the subject of intense discussions, and the requirements imposed upon the manipulation of Sabin type 2 strain from April 2016 (which should be similar to those applicable for wild-type strains, which are mainly about manipulating viruses in BSL3+ environments) are adding complexity for Sabin IPV manufacturers or developers.

Historically, cIPV had been combined with diphtheria and tetanus toxoids combined with whole-cell pertussis (DTwP). The first combinations were licensed in 1964 in France and the United Kingdom, but today DTwP-cIPV–containing combinations no longer exist. Several manufacturers have embarked on the (re)development of wP-based hexavalent combination vaccines including IPV antigens.[100,101] One of the technical challenges is to manage the bidirectional deleterious effect on polio and pertussis potencies caused by residual thimerosal (associated with the non-IPV antigens) and residual formaldehyde and 2-phenoxy-ethanol (associated with the IPV antigens) present in the final vaccine formulation.

DOSE RESPONSES, DOSING, AND ROUTE OF ADMINISTRATION

Salk established that the immune response to cIPV is directly related to the dose of antigen.[102] The antigen content of all current cIPV proceeds from a series of dose–response clinical trials[38,103,104] performed in infants from 1977 to 1979, which were aimed at determining the optimal D-Ag content necessary for providing reliable protection after two doses of the cIPV antigens combined with other vaccine antigens (D, T, and wP, which were already routinely administered in infants at that age). This strategy was implemented by Jonas Salk and Charles Mérieux with the objective of developing and qualifying a cIPV formulation that was useful in Africa and that required two doses with a relatively long interval between them that could overcome the negative effect of circulating maternally transmitted poliovirus antibodies on the immune responses. These studies led to the current cIPV formulations with 40, 8, and 32 D-Ag units for poliovirus types 1, 2, and 3, respectively (corresponding to a formulation target resulting from measurements done by multiple-regression D-Ag ELISA on monovalent antigen bulks). These trials showed that the 40:8:32 D-Ag unit formulation was immunogenic in schedules consisting of two consecutive priming doses followed by a booster administered at least 6 months following the last infant priming dose to generate persistent immunity.[105] It should be noted that some of the historical studies documented the capacity of cIPV to induce antibody levels after the first dose,[38] which was confirmed later by a one-dose clinical efficacy of 36% (95% confidence limits, 0% to 67%) measured in Senegal during a WPV1 polio outbreak (see "Efficacy of Inactivated Polio Vaccine Against Acute Flaccid Paralysis and Immune Correlates of Protection" later).[106,107] Two clinical trials have been conducted with a high potency type 2 (monovalent) cIPV (32 D-Ag units compared to the standard 8 D-Ag units in trivalent IPV), exploring whether such vaccine will be more immunogenic should there be a need to quickly close the type 2 immunity gap that may exist in cohorts should

a poliovirus type 2 reemerge, particularly with plans to switch the OPV in routine use from trivalent oral poliovirus vaccine (tOPV), which contains type 2, to bivalent oral poliovirus vaccine 1 and 3 ($bOPV_{1\&3}$) which does not.[108,109]

Numerous infant/toddler/school-entry primary immunization regimens are currently used in many countries (Table 48.2). All IPV-only countries are in fact relying on IPV-containing combination vaccines. The subject of additional boosters after the school-entry age is discussed later (see "Duration of Immunity"). In some countries, along with routine pediatric IPV-only schedules, supplemental immunization activities with OPV are organized (see "Results of Vaccination Programs with Inactivated Polio Vaccine" later). Ideal dosage for cIPV in truly unvaccinated adolescents and adults is three doses. The first two doses can be given 1, or preferably 2, months apart, with the third dose given 6 to 12 months later. If there is urgency, the third dose can be given earlier, but the achieved antibody titers will not be as high. Adolescents or adults who are already primed and whose last polio vaccination occurred 10 to 20 years ago need only one booster dose to redevelop high titers.[110,111] In adult subjects with an unknown polio vaccination history, two doses of any kind of cIPV-containing combination vaccines given 1 month apart are sufficient to induce very high seroprotection rates and persisting circulating antibodies.[112,113]

IPV may be given subcutaneously or intramuscularly, and there is no published information from RCTs on the relative immunogenicity of IPV administered intramuscularly versus subcutaneously; however, as IPV is and will be administered increasingly frequently as part of IPV-containing DTP-backboned combination vaccines, and as the objective is to minimize local adverse events, IPV is now almost exclusively administered intramuscularly, even when used as a standalone vaccine.

TABLE 48.2 Schedules of IPV Administration for Primary Immunization in Infants, Toddlers, and School-Entry Children in Countries Recommending IPV-Only Schedules[a]

Schedule	Age	Countries
3+1+0	3, 4, 5, and 18 mo	Japan
	2, 4, 6, and 18 mo	Spain

[a]As of June 2015, http://www.who.int/immunization/monitoring_surveillance/data/en/ and http://vaccine-schedule.ecdc.europa.eu/Pages/Scheduler.aspx

[b]OPV is recommended for the school-entry booster for children 7 years of age.

[c]Official recommendations are for the third dose to be given any time between 6 and 18 months of age, therefore falling in the "2+1+1" or the "3+0+1" schedule. Consider also the "3+1+1" schedule as acceptable.

IPV, inactivated polio vaccine; OPV, oral polio vaccine.

RESULTS OF VACCINATION

Measurement of Immune Responses

Although it is possible to measure serum antibodies to poliovirus by a variety of methods, the poliovirus-neutralizing antibody assay is the assay that best correlates with clinical protection.[114] Cell-mediated immunity responses have been explored in response to cIPV[115,116] but are not routinely performed nor they have been used by national regulatory agencies. They have shown the presence of specific T cells (by lymphoproliferation tests and flow cytometry) in the blood following vaccination. Measurement of mucosal immunity and protection induced by IPV is discussed later (see "Mucosal Immunity/Protection Induced by Inactivated Polio Vaccine").

IPV is a killed antigen; as a result, immune responses depend on the amount of antigens, the number of doses (when used for primary immunization), the interval between doses, the age at first dose (and, consequently, the level of maternally acquired poliovirus antibodies that can be present at time of vaccination, which can possibly diminish immune response), and the type of IPV-containing product used (standalone unadjuvanted vs aluminum-adjuvanted IPV-containing combinations). Several parameters are used to express the levels of neutralizing antibodies against polioviruses when assessing the overall responses obtained in a group of vaccinated individuals: the GMTs (sometimes median titers are used, which can lead to different results compared with GMTs); the percentage of subjects with neutralizing antibodies above the 1:8 threshold now considered as the serologic correlate of protection (historically the 1:4 threshold had been used) and very often referred to as the seroprotection rate; and the percentages of subjects presenting with a fourfold or greater rise in their neutralizing antibody titers between their prevaccination titers and postvaccination titers, adjusted or not for maternally derived antibody decay, and referred as to seroconversion. If maternal antibody decay is not factored in, seroconversion rates could be lower than the actual proportion of persons who make a significant immune response. It is known that maternal antibody does inhibit the immune response to IPV.[117] The percentage of subjects with neutralizing antibodies above the 1:8 threshold at a time when

maternally transmitted antibodies should have disappeared probably gives the best measure of the proportion of persons with protective immune responses to IPV.

The poliovirus neutralization antibody assay is used by the vast majority of laboratories assessing the immunogenicity of these vaccines.[118] The assay procedures are variable and have been shown to be sensitive to the nature of the cells used to grow the target virus (HEp-2 or Vero), the viral inoculum size, the duration and temperature of serum–virus interaction before viral growth, the number of serial dilutions of the tested sera, and the nature of the viral strains (Sabin or wild type) used in the test.[119,120] In addition, the type of assay readout (cytopathic effect or metabolic inhibition) has an influence. Attempts have been made to standardize this assay,[121,122] but there is no broad acceptance of international standards for its use.[123] Under some assay conditions, neutralizing titers are higher when sera from subjects vaccinated with cIPV are tested against wild-type strains compared to when tested against Sabin strains.[119,120] Lack of specific description of the serum panels used in standardization studies makes evaluation difficult. Some studies refer to the use of the trivalent reference serum lot IIA4 from the FDA that was prepared from vaccinated monkeys, whereas others refer to pools of sera obtained from humans in the United Kingdom, who were probably vaccinated with OPV or naturally infected. As described in "Inactivated Polio Vaccine Manufactured from Sabin Strains" earlier, it is conceivable that the paratopes (antigen-binding sites) of the neutralizing antibodies exhibited by sIPV-vaccinated subjects might differ from the paratopes exhibited by cIPV-vaccinated subjects, and that the overall levels of neutralizing antibodies measured in these subjects might be influenced by the nature of the viral strains used in the detection system. All the landmark historical studies, which led to the current cIPVs,[38,103,104] have based their neutralization assay on wild-type–derived poliovirus strains. The absence of indication that the type of strain used in the assay might be important, and the risks taken by laboratories manipulating wild-type–derived strains, particularly for those located in polio-free areas or in low- or middle-income countries, have induced many laboratories to switch to the use of the Sabin strains for this assay. This parameter should be considered when comparing data from clinical trials, particularly those done with sIPVs. The development of human or chimpanzee–human monoclonal antibodies that neutralize poliovirus strains, opening some therapeutic potential[124–127] and the three-dimensional mapping of the poliovirus epitopes antibody interactions[128] will provide additional information on this question.

Immunogenicity of Conventional Inactivated Polio Vaccine

An enormous number of studies and trials have been conducted over the last 35 years with cIPV-containing vaccines given in schedules of two or three doses during the first year of life. These studies used different formulations of cIPV, study designs, and schedules, and were conducted in a variety of countries with different ethno-ecological situations. A number of reviews of these studies have been published.[129–131] For example, Table 48.3 summarizes data collected from 30 study groups where cIPV-containing vaccines were administered to more than 4500 subjects in a two-dose primary series, usually at 2 and 4 months of age.[130] At completion of the two-dose immunization series, seroprotection rates ranged from 89% to 100% for poliovirus type 1, from 92% to 100% for poliovirus type 2, and from 70% to 100% for poliovirus type 3. Table 48.3 also summarizes responses after three doses. Seroprotection rates after three doses are clearly higher than after two, particularly when the schedule is 2-4-6 months. However, schedules of 3-4-5 and 2-3-4 months also give good responses, although lower than after 2-4-6 months, particularly with regard to GMTs. To achieve rapid protection in developing countries, vaccines are given on a 6-10-14–week schedule, which is not optimal for immune response against a variety of antigens because of the early age for starting immunization and the short interval between doses. Since the initial studies sponsored by the WHO,[132–134] many studies have been done in a wide range of epidemiological settings with different cIPV-containing vaccines. Many of these studies were conducted in countries where OPV was the routine vaccine used and therefore IPV vaccinees could have been exposed to Sabin polioviruses via direct contact with OPV or OPV-vaccinees (Table 48.4) (Sanofi Pasteur, studies HIT40498, EUV07199/HE9810, and A3R25 and A3R38; unpublished, data on file).[132–142] High seroprotection rates were achieved at completion of immunization in studies reporting this outcome. However, seroconversion rates, when reported, were more variable, presumably because of high maternal antibody levels observed in some studies. In one study in South Africa (Sanofi Pasteur, study A3R25 and A3R38; unpublished, data on file), antibodies were measured at 17 months of age after three doses of cIPV contained in a hexavalent combination vaccine given in infancy, and persistence of antibodies with good anamnestic response to a fourth dose were noted. At 17 months of age, 100%, 99.5%, and 97.8% of children still had neutralizing antibodies at titers greater than or equal to 1:8 against poliovirus types 1, 2, and 3, respectively, and a 40- to 56-fold increase in their GMT was observed from prebooster to

postbooster. Similar observations were noted in another trial.[142] A direct comparison of the 2-4-6–month and the Expanded Program on Immunization (EPI) schedules was performed in Puerto Rico, where OPV was no longer used.[138] Seroconversion rates for types 1, 2, and 3, respectively, after three doses of the 2-4-6–month schedule were 100%, 100%, and 99%, whereas after the EPI schedule they were 85.8%, 86.2%, and 96.9%. Overall, the data clearly demonstrate that cIPV is immunogenic in an EPI schedule, although the titers achieved and the seroconversion rates may be lower compared with vaccination of infants at older ages. The humoral immunogenicity of cIPV in an EPI schedule appears to be superior to the use of OPV in such schedules in developing countries. After two or three doses in the first 6 months of life, antibody levels fall although the vaccinees usually retain seroprotective titers until the first booster is given during the second year of life, and this third or fourth injection gives a marked anamnestic response. Table 48.5 presents five studies conducted in the United States.[143–149] Nearly all infants were already seropositive after the second dose, although their antibody titers were generally below 1:100. Ethnicity background has never been observed to play a clinically relevant role in the immunogenicity profile of IPV.

Immune responses can be detected after the first dose of cIPV-containing vaccines[150,151,152] and depending on study designs, up to 50% seroconversion rates against the three poliovirus types can be observed (on average 33%, 41%, and 47% of vaccinees do seroconvert against types 1, 2, and 3, respectively, with better seroconversion at older ages). Persons who fail to seroconvert may be primed, and, when using as a definition of priming the detection of neutralizing antibody 7 days after vaccination in persons seronegative prior to that dose, one trial revealed that up to 90% of seronegative vaccinees were primed.[153] As summarized later under "Efficacy of Inactivated Polio Vaccine Against Acute Flaccid Paralysis and Immune Correlates of Protection," a one-dose schedule provides limited clinical efficacy (36% with 95% confidence limits ranging from 0% to 67%) against wild poliovirus type 1 in a case-control study in Senegal, suggesting seroconversion is the most appropriate correlate of protection, not priming.

[c]Number of enrolled subjects at beginning of study.
IPV, inactivated poliovirus vaccine; OPV, live oral poliovirus vaccine.

However, in contrast, Hungary, which had a major problem with VAPP, decided to institute a sequential schedule with one dose of IPV followed by OPV, and VAPP was eliminated, more compatible with priming offering clinical protection against paralyis.[154] These data are important in the context of current efforts by WHO toward development of affordable IPV solutions for the developing world (see "Rationale and Role of Inactivated Polio Vaccine in Poliomyelitis Eradication" later).

When considering all the factors, the data clearly indicate that the main drivers of the immunogenicity of IPV antigens, when used for the infant primary vaccination series, are the number of primary series injections, the age at first dose, the interval between doses, the presence of maternally transmitted antibodies, and the use of IPV in the form of an IPV-containing combination vaccine.

Immunogenicity of Sabin Inactivated Polio Vaccine

As a comparison of the relative D-Ag contents between sIPVs and cIPVs is not possible because of the different in vitro (D-Ag determination by ELISA) and in vivo (immunogenicity in animals) potency assays used to formulate and release these vaccines[39,40,42,43,50,155,156] the results of the clinical evaluations of sIPVs can only be summarized product by product.

Murph and colleagues[57] at Lederle in the United States manufactured a sIPV containing 20-12.5-35 D-Ag units (per 0.5 mL) of polioviruses types 1, 2, and 3, respectively, grown on primary monkey kidney cells. A study done in 1986 comprised 18 seropositive adults who received vaccine containing 10-6.25-17.5 of D-Ag units, 20-12.5-35 of D-Ag units, or 40-25-70 of D-Ag units per dose and nine seronegative adults who received one dose of a 20-12.5-35 of D-Ag units formulation. In the seropositive adults, the three vaccine formulations were able to boost serum neutralizing antibody levels with a noticeable dose–response effect. In seronegative adults, a response against the three polioviruses was observed. The drawback of this study was that no subject was naïve to polio antigens as they all had previously received OPV or cIPV during infancy. Infant studies with this vaccine were never reported.

Two early clinical trials have been done by the JPRI in the early nineties with a standalone sIPV vaccine. Phase I[156] was conducted in adults and in 108 infants 3 to 90 months of age. The D-Ag content of the vaccine was 30-30-50 D-Ag U/dose (types 1, 2, and 3, respectively). In the first trial, the vaccine was given in two subcutaneous doses to 10 seropositive adults at 4-week intervals. Safety was excellent. Antibody data obtained 2 weeks after the second dose (against Sabin and wild-type strains) showed high neutralizing responses in all volunteers. In the second trial, the vaccine was given by the same regimen to 108 infants (3 to 90 months old). Most infants were seronegative (titer <1:4) before immunization, except for type 2 where 40% were seropositive. Immunogenicity results 2 weeks after the second dose showed a high neutralizing response in all infants against types 1 and 3, but a low neutralizing response for type 2. Seroneutralizing GMTs against the homotypic Sabin strains were approximately 2000 for polio type 1, 300 for polio type 2, and 500 for polio type 3. Seronegative titers were fourfold to 1.3-fold lower against wild-type strains compared to the homotypic Sabin strains. Following this early development, the standalone JPRI sIPV development stopped in 2002, and JPRI initiated studies to reformulate the sIPV on the basis of new immunogenicity data obtained from rats and monkeys, resulting in modification of the D-Ag content to 1.5-50-50 D-Ag U/dose. JPRI embarked on an antigen supply agreement with several Japanese DTaP manufacturers, which allowed Biken and Kaketsuken to develop and license in Japan two similar DTaP-sIPV combination vaccines based on their Phase II and III trials in 2012.[157] Results showed 100% seroprevalence of Sabin strains neutralizing antibodies following a three-dose primary series in infants 3 to 8 months of age and with a 1-month interval between doses with durable antibody levels. When assessed against wild-type strains, 97.4% to 100% of sera exhibited levels above the 1:8 threshold, but their GMTs were lower (10- to 20-fold less for type 1, twofold less for type 2, and 1.5-fold less for type 3) than when tested against Sabin strains.[158,159]

The Kunming Institute has performed a multistep Phase I study in adults, children, and infants with several formulations of sIPV products containing from 15-16-22.5 to 45-64-67.5 D-Ag units for poliovirus types 1, 2, and 3, respectively, with good immunogenicity and a dose–response effect.[160] Following this study, a Phase II dose–response (three formulations) and comparative against OPV and cIPV study was done in infants.[161] The 30-32-45 content of D-Ag units for this Chinese vaccine was then selected for a Phase III comparative trial versus cIPV.[162] This vaccine was licensed in China in early 2015. Cross-neutralization evaluation of Phase II vaccinees' sera against a panel of strains (Mahoney, MEF-1, and Saukett, Sabin, recent wild-type isolates, and recent vaccine-derived polioviruses [VDPVs] Chinese isolates) have shown that the levels (titers) of antibodies able to neutralize the non-Sabin strains in sIPV vaccinees are lower compared to levels induced in cIPV vaccinees. Nevertheless, more than 95% of vaccinees are able to develop antibody levels above the clinically protective level (≥1:8) in both assays (against Sabin viruses and against wild type viruses) (Kunming Institute, personal communication, 2014).

Finally, Intravacc (former RIVM) has initiated a clinical program with a sIPV by exploring the dose–response effect of several unadjuvanted and aluminium-adjuvanted vaccine preparations. Phase I clinical trials have been conducted in adults in Poland[163] and Cuba[164] with a standalone sIPV product (20-32-64 D-Ag U/dose) versus an aluminium-adjuvanted standalone sIPV product (10-16-32 D-Ag U/dose) versus a cIPV. In addition, a Phase IIa dose-escalating trial has been completed in infants[165] in Poland, with three formulations of an aluminum-adjuvanted sIPV or three formulations of an unadjuvanted sIPV standalone product (six arms) versus a control standalone cIPV. All the results have shown the adequate safety of the products and the capacity of the different formulations to induce neutralizing antibody against Sabin strains (and against wild type strains with as expected lower levels) with a dose–response effect and a moderate adjuvant effect.

As noted earlier (see "Inactivated Polio Vaccine Manufactured from Sabin Strains"), sIPV differs from cIPV. Because of the biochemical differences between the poliovirus strains used for the manufacture of vaccine, sIPV does present to the immune system a collection of neutralizing epitopes different from the epitopes present in cIPV. Consequently this can lead to different populations of antibodies in the sera of vaccinees, which, in turn, could exhibit different neutralization profiles (more in terms of height of the titers than differences in proportion of seronegative to different wild poliovirus strains) vis-à-vis the diversity of viruses that might be encountered by vaccinees after vaccination (wild type, VDPV, and Sabin-like). It is not yet known whether by altering the amount of antigen contained in the sIPV, these differences can be overcome, or if these differences are clinically relevant or not. Some argue that as long as the early proportions of individuals able to

neutralize wild-type strains are high, the levels of antibodies achieved after vaccination do not matter. The polio outbreak in 2010 in the Congo-Brazzaville,[166] where a mutated type 1 poliovirus caused disease in OPV vaccinated persons, suggested poor "heterotypic immunity," which was contradicted by the fact that this outbreak had been cleared by subsequent OPV supplemental immunization activities. These observations are raising questions from a regulatory perspective.[167] It will be critical to continue to document the immune performance of the licensed sIPVs and to assure that antibody response in humans is broadly cross-reactive against all types of strains. In addition, the level of intestinal and oropharyngeal mucosal protection, relative to cIPV's protection, achievable with the licensed sIPV is not yet documented.

Effect of Maternal Antibodies and of Neonatal Vaccination

Studies document that maternally transmitted poliovirus antibodies present at the initiation of an infant primary series diminish the height of the antibody response to a cIPV primary series and can decrease seroconversion rates.[132,133,168–174] This is particularly evident on seroconversion rates but less so on seroprotection levels achieved at completion of immunization. This effect can be minimized by giving three doses of IPV during the first year of life with optimal spacing.

Neonatal vaccination with cIPV has been evaluated on several occasions.[175] Swartz and colleagues[176] showed that a single dose of cIPV at birth primed infants for a uniform response to a second dose given at age 6 months. Israeli infants immunized at birth with cIPV concomitantly with hepatitis B vaccine showed higher mean antibody levels for polio types 2 and 3 at 1 and 3 months of age than did infants who received cIPV at 2 months of age, but the difference disappeared at 7 months of age after both groups had received one additional dose of cIPV and two doses of OPV.[172] Hovi and colleagues[177] showed priming for higher titers in Pakistani infants whose three OPV doses at 8, 12, and 16 weeks of age were preceded by a birth dose of cIPV. Linder and colleagues[178] documented the immunogenicity of cIPV given at 2 months of age with or without a preceding cIPV given at 5 to 10 days of age in Israeli preterm infants. In infants who received cIPV within the first 2 weeks of life, 100%, 100%, and 97.9% had neutralizing antibodies at titers greater than or equal to 1:8 against poliovirus types 1, 2, and 3, respectively, 1 month after the dose given at 2 months of age versus 96%, 100%, and 71% of infants who had not received prior cIPV.

Jain and colleagues[179] documented the immunogenicity of a cIPV-only schedule given at 0, 6, and 10 weeks of age in Indian neonates and was able to demonstrate better seroconversion (80% seroconverted against all three poliovirus types) with this schedule than with an EPI schedule using OPV (at 6, 10, and 14 weeks of age) preceded by cIPV or OPV at birth (72% and 72% seroconverted against all three poliovirus types, respectively). Thus all these data do show that cIPV at birth appears to prime the immune system, and these data are aligned with results from cIPV-followed-by-OPV sequential schedule trials (see "Immunogenicity of Mixed/Sequential Schedules with Inactivated Polio Vaccine and Oral Polio Vaccine" later).

Immunogenicity of Inactivated Polio Vaccine When Injected Intradermally

The first reports of use of the intradermal route with IPV came from Salk.[180,181] These studies showed that the intradermal injection of 0.1 mL of aqueous formulation of the historical Salk IPV was immunogenic in children and adults. Soon after the launch of the first commercial historical IPVs in 1955, several countries obtained good results from vaccination programs with cIPV delivered intradermally (using the Mantoux technique) to maximize the use of the limited quantity available at that time.[182–188] Three proof-of-concept studies were conducted during the early 1990s by John's team in India using the modern cIPV. These studies demonstrated that one-fifth of the intramuscular dose is immunogenic in humans when delivered intradermally with needles, but none of these studies were randomized against a full intramuscular dose.[189–191]

In the context of WHO efforts to promote more affordable IPV, and supported by preclinical studies,[192] several trials have been done to document the performance of cIPV when intradermally delivered (under a volume of 0.1 mL corresponding to one-fifth of the regular volume intramuscularly delivered) either through needles or through disposable-cartridge jet injectors (DCJIs) under development, and used with different types of infant/toddler primary series immunization regimens (IPV-only or OPV-followed-by-IPV sequential regimen).

The WHO sponsored two RCT studies in Cuba[193,194] and in Oman[195] with two different cIPV preparations administered through two cIPV-only three-dose infant primary series schedules (6-10-14 weeks and 2-4-6 months). The vaccines were administered by the intradermal route with a DCJI (Biojector 2000 from Bioject, customized for intradermal administration) or by the intramuscular route with regular syringe and needle. The primary study objectives were to show noninferiority (20% clinical margin) of the seroconversion rate against poliovirus between the intradermal group versus the intramuscular group. Both studies demonstrated clinically relevant immunogenicity but lower responses with the 6-10-14–week schedule than with to the 2-4-6–month schedule. In the Oman study, infants were challenged at 7 months of age with monovalent oral poliovirus vaccine type 1 ($mOPV_1$), and 7 days later viral shedding prevalence was 74.8% in the intradermal group versus 63.1% in the intramuscular group. A third RCT done in the Philippines[142] compared the two routes of administration using the classical Mantoux technique for intradermal injection with a cIPV-only 6-10-14–week schedule, demonstrating noninferiority (5% clinical margin) of seroprotection post–dose 3 between the intradermal group versus the intramuscular group, but lower GMTs in the intradermal group.

A study from Cuba[153] evaluated whether a schedule of two consecutive 0.1-mL cIPV doses administered intradermally with a DCJI (Pharmajet) provided comparable seroconversion with a two-dose schedule of full 0.5-mL cIPV doses administered intramuscularly at 4 and 8 months of age. Seroconversion was assessed in each group after the first and second dose of study vaccines, and the proportion of subjects that responded with a priming immune response after the first dose of cIPV was determined. Results showed high seroconversion after the first dose of both fractional and full-dose cIPV, with significantly lower median titers for the intradermal arm, and priming evidence in more than 90% of the subjects who did not seroconvert after the first dose. The second cIPV dose, delivered by either route, closed the remaining seroconversion gaps and resulted in high antibody titers, although the titers were higher in children vaccinated by the intramuscular route.

A study conducted in India[196] (Moradabad district) reported inferior immune responses with cIPV administered by the intradermal route with another under-development DCJI (Pharmajet) customized for intradermal administration. The study included vaccination of several groups of

infants, 6 to 9 months of age, who had previously received multiple $mOPV_1$ and tOPV doses, randomized to receive two different cIPV vaccines delivered intramuscularly or one cIPV administered intradermally or two different $mOPV_1$ vaccines. Because of the very high levels of prevaccination antibodies against all three polioviruses and a suspected high rate of failure of the injection device to adequately deliver the full 0.1-mL volume of vaccine intradermally, the study failed to show that a fractional dose of cIPV was as immunogenic as full-dose cIPV intramuscularly, but did reveal an undisputable booster effect of the intradermal administration.

A study conducted in Cuba[197] evaluated one cIPV delivered intradermally (by needle or with two different underdevelopment DCJIs or with one established DCJI) versus intramuscularly in toddlers 12 to 20 months of age who had previously received two doses of tOPV through the routine Cuban campaign immunization program. Results showed similar and very high seroprotective rates in all groups 21 days after vaccination, and variable but lower median titers and booster responses in the four intradermal groups compared to the intramuscular group.

Finally, data have been generated in Dutch cIPV-only primed adults[198] ("3+1+1+1" regimen) with a cIPV delivered intradermally (DCJI) or intramuscularly. At day 28, the study showed lower mean antibody levels in the intradermal group versus the intramuscular full-dose group. In HIV-infected mostly OPV-primed adults with a cIPV delivered intradermally by a microneedle device versus intramuscularly, similar booster responses were obtained with a 40% intramuscular dose content delivered intradermally as a full-dose intramuscularly.[199]

Additional approaches, supported by the WHO, Programs for Appropriate Technology in Health (PATH), and the Bill and Melinda Gates Foundation, are aiming to develop hollow microneedle or dissolvable micro(bio)needle transdermal patches coated with lyophilized and stabilized IPV antigens.[200,201] Several groups have embarked on developmental work involving microneedle patches.[202–204]

In conclusion, as recently reviewed,[205] studies of intradermal administration of cIPV do provide evidence that this route is immunogenic but slightly less immunogenic than the administration of the regular intramuscular dose. In addition, as a consequence of the differences observed between needle intradermal and DCJI intradermal administration, further studies are required for optimization of dose and development of intradermal administration through industrialized DCJIs. A critical factor in making intradermal IPV use programmatically feasible is the development and licensure of ergonomic and high-injection-quality DCJIs.[206] This is because of concerns that intradermal delivery via needle and syringe can be difficult in the field; hence, having a device to assure appropriate intradermal administration would give greater confidence that the required antigen is being adequately delivered into the proper site. A clear licensing pathway, including what data on safety and immunogenicity will be required by national regulatory agencies, for intradermal administration is still not identified. In addition, this licensure pathway would imply a partnership between a given vaccine manufacturer and a given device manufacturer to assemble a specific application file supporting the use of a given IPV with a given intradermal device in a given regimen. Finally, the real affordability advantage of this approach still needs to be demonstrated.

Fractional Dosing and Supply Shortage

Due to the current insufficient supply of IPV (see "Producers of Inactivated Polio Vaccine Antigen and Available Vaccines" earlier and "Rationale and Role of Inactivated Polio Vaccine in Poliomyelitis Eradication" later), WHO has recently incorporated in their recommendations the use of fractional dosing through the intradermal (ID) route as an alternative to the intramuscular (IM) route.[206a,206b] This use is currently envisaged either in the context of the routine immunization activities or in campaign modes should VDPV2 be isolated in environmental samples or as cVDPV2,[206c] should the available quantities not be enough to ensure at least one IM dose of IPV in every child in all countries willing to introduce IPV.

Several trials have shown that two consecutive doses of fractional (ID) IPV compared well to one dose of full (IM) dose of IPV in infants regardless of whether they received tOPV or bOPV. Type 2 seroconversion, antibody levels, and priming were similar, if not better, after two fractional IPV doses (each one-fifth of a full dose).[153,193,195,206d,206e] These data will help vaccination recommending bodies to propose this alternate use of IPV as a way to maximize the available, but too limited, quantities of IPV.

Immunogenicity of Inactivated Polio Vaccine in Preterm Infants and in Immunocompromised Subjects

Prematurity does not appear to reduce the response to cIPV-containing vaccines when the vaccines are given at the usual postnatal age. Preterm infants all develop neutralizing antibodies after three doses of cIPV, although titers might be lower than in term infants,[116,178,207–210] particularly if the infants are chronically ill.[211]

Because IPV is the indicated polio vaccine for immunocompromised subjects even in countries that recommend OPV, the immunogenicity of IPV in these subjects is an important issue. Children infected with HIV who were given two doses of cIPV in early infancy responded reasonably well, probably because their immune systems were largely intact.[212] Similar observations were done in HIV-infected mostly OPV-primed adults following one booster dose.[199] In hemophiliac adults, however, HIV seropositivity had a negative effect on titer levels after cIPV, although all adults responded to some degree.[213] Chronic renal dialysis subjects also seroconverted in 90% or more of cases.[214] In patients who had undergone bone marrow transplantation and were reimmunized after transplantation, vaccination was usually successful in inducing antibodies, although at least two, and often three, doses were needed.[215,216] Follow-up of 134 stem cell transplant recipients who were given three doses of cIPV at 12 months after transplantation following a 0-2-6–month regimen found that 94%, 94%, and 90% were still seroprotected 10 years later for types 1, 2, and 3, respectively. Those patients who had chronic graft-versus-host disease had less-persistent antibody.[217] Taken together, these results demonstrate that cIPV-containing vaccines are immunogenic in many immunocompromised subjects.

Immunogenicity of Mixed/Sequential Schedules With Inactivated Polio Vaccine and Oral Polio Vaccine

When considering IPV/OPV mixed/sequential regimens, one must carefully distinguish the regimen under consideration: IPV-followed-by-OPV sequential schedule, OPV-followed-by-IPV sequential schedule, or mixed/combined IPV/OPV regimens where the two vaccines are administered at the same time for one or more occasions during the vaccination course. In addition, with the recent licensure of new OPVs ($bOPV_{1\&3}$,

$mOPV_1$, and $mOPV_3$), the type of OPV used in these trials has to be considered. Many trials have been performed to document these different types of IPV/OPV regimens, and key results are provided below, regimen by regimen. All these trials have been done with cIPV, as no data are yet available on the performance of sIPV when used in such schedules. In addition, many of these trials have investigated the prevalence, intensity, duration and genetics of poliovirus excretion after OPV vaccination/challenge administrations (see "Mucosal Immunity/Protection Induced By Inactivated Polio Vaccine" later).

cIPV-Followed-By-OPV Sequential Schedule Trial

cIPV-followed-by-tOPV sequential schedules consisting of one or two doses of cIPV followed by one or two doses of tOPV have been documented in many clinical trials with several cIPV-containing vaccines (standalone or wP/aP [acellular pertussis] combinations) in eight countries (Brazil, China, France, Guatemala, Mexico, Taiwan, United Kingdom, and United States) since 1986 (Sanofi Pasteur, studies HE9812 and IPV33-EXT, unpublished, data on file).[143,144,146,148,149,207,218–231] These trials have been either nonrandomized open studies or RCTs between cIPV-followed-by-tOPV sequential schedules versus cIPV-only and/or tOPV-only schedules. Results of these studies demonstrate that the introduction of at least one dose of cIPV at the start of the schedule increases post–primary series serum antibody levels compared to tOPV-only schedules, as well as induces a certain degree of mucosal intestinal protection (see "Mucosal Immunity/Protection Induced By Inactivated Polio Vaccine" later). From 1997 to 1999 the United States relied on a cIPV-followed-by-tOPV sequential schedule, in which two doses of cIPV were administered at 2 and 4 months of age, followed by two doses of tOPV administered at 6 to 18 months of age and again at school entry. Table 48.5 summarizes the excellent immunogenicity of this schedule.[143–149] Israel and Denmark have also used such sequential schedules for a while, with successful results. In Israel, two schedules have been used: cIPV at 2, 4, 6, and 12 months of age with tOPV administered at 7 and 13 months of age or cIPV at 2, 4, and 12 months of age plus tOPV at 4, 6, and 12 months of age. Persistent polio in the Gaza Strip despite extensive use of tOPV induced the authorities to change to a mixed sequential schedule, which caused a prompt drop in wild-strain isolations.[232] A study in the United Kingdom showed the advantages of a sequential schedule comprised of one dose of cIPV followed by two doses of tOPV in terms of immunogenicity.[222]

A particular use of this sequential schedule was also undertaken in Romania because of an unusually high rate of VAPP triggered by concurrent intramuscular injections.[233] For a limited time, infants in one province of Romania received cIPV at 2, 3, and 4 months of age together with tOPV at 4 and 9 months of age.[234] The schedule was well tolerated and highly immunogenic. No cases of polio occurred subsequently in this region, but too few children were involved to draw conclusions about the prevention of VAPP.

A completed trial in Chile[235] using $bOPV_{1\&3}$ compared humoral and intestinal immunity after three doses of cIPV against two sequential cIPV-followed-by-$bOPV_{1\&3}$ schedules (cIPV-cIPV-$bOPV_{1\&3}$ or cIPV-$bOPV_{1\&3}$-$bOPV_{1\&3}$) at 8, 16, and 24 weeks of age. All received oral $mOPV_2$ challenge at week 28. At week 28, more than 98% of all group subjects seroconverted against types 1 and 3, and type 2 seroconversion exceeded 96% after three or two cIPV doses. Interestingly, in the cIPV-$bOPV_{1\&3}$-$bOPV_{1\&3}$ group, 77.6% seroconversion to type 2 was achieved. Importantly, two-thirds of the type 2 nonresponders at 28 weeks in that group seroconverted within 1 week of $mOPV_2$ challenge, indicating priming against type 2, giving a combined 92% type 2 protection/priming rate for the cIPV-$bOPV_{1\&3}$-$bOPV_{1\&3}$ sequential regimen. As expected, maternally derived antibodies significantly interfered with immune responses. A key observation from that trial was that $bOPV_{1\&3}$ appeared to boost antibody levels (and also intestinal immunity, measured by type 2 shedding after $mOPV_2$ challenge) against type 2, suggesting some cross (heterotypic)-booster effect against type 2 (in the one-dose cIPV-primed subjects) by the two other serotypes included in $bOPV_{1\&3}$.

A key advantage of a sequential regimen of cIPV preceding OPV is to address the VAPP risk as it has been now well documented that starting polio immunization with cIPV can eliminate the occurrence of the VAPP associated with the first doses of OPV. This has proven to be a very successful strategy in the United States[236] and in Hungary.[154] From 1992 to 2006, Hungary switched from three annual mOPV campaigns to sequential schedule of one dose of cIPV-followed-by-tOPV and saw a complete cessation of VAPP.

With the recent data described above, this type of schedule might be advantageous in a context where $bOPV_{1\&3}$ will be the exclusive OPV vaccine used and where it will be crucial to guaranty that anti–polio type 2 immunity will be as high as possible in populations in case of reintroduction of poliovirus type 2 in those communities.

OPV-Followed-by-cIPV Sequential Schedule Trials

When first tested, this type of sequential schedule had the objective to close the immunity gap resulting from deficiencies in responses to tOPV use in tropical settings. Tested in the Ivory Coast,[237] a single dose of cIPV or tOPV was given after three doses of tOPV. Of those 9-month-old children who remained seronegative after the third dose of tOPV, 81%, 100%, and 67% seroconverted to types 1, 2, and 3 polio, respectively, after the single dose cIPV. The corresponding percentages for the tOPV administration were 14%, 27%, and 5%.

Another trial[238] evaluated the performance of cIPV versus three OPVs ($mOPV_3$ and tOPV from two manufacturers) used as a booster in 9-month-old Omani infants who had received five previous doses of tOPV. This supplemental dose of cIPV had excellent immunogenicity and led to higher increases in polio type 3 antibodies than did tOPV. In addition, intestinal mucosal immunity was assessed by administering a challenge dose of $mOPV_3$ at the 15-month visit. Overall, 13.2% of the infants excreted poliovirus type 3 and there were no significant differences in the rate of excretion of poliovirus type 3 among the study groups.

More recently, a study in India in 6- to 9-month-old infants who had previously received multiple doses of tOPV and $mOPV_1$ were given a single dose of cIPV. Nearly 100% of children who were seronegative to types 2 and 3 at the time of the dose seroconverted.[196] In addition, the dose of cIPV was associated with a marked boost in intestinal immunity as documented by decreased fecal shedding following an OPV challenge (see "Mucosal Immunity/Protection Induced By Inactivated Polio Vaccine" later).

A study in The Netherlands showed that cIPV vaccination was able to boost systemic and salivary immunoglobulin (Ig) A responses in previously tOPV-vaccinated people. In contrast, persons who received only past cIPV did not produce a salivary IgA response.[239]

John[240] evaluated the performance of cIPV to boost humoral (and also intestinal) immunity in 1- to 4-year-old

Indian infants who had received previous doses of tOPV. This supplemental dose of cIPV had excellent immunogenicity and led to higher increases in antibodies in all three polio types than did the $bOPV_{1\&3}$ challenge dose administered for intestinal immunity evaluation. Similar observations were obtained in parallel trials completed in tOPV- or $bOPV_{1\&3}$-primed infants in India,[241] Bangladesh,[242] Pakistan,[243] Nigeria,[243a] and Latin America.[244]

In conclusion, all studies do clearly show that one dose of cIPV administered in OPV-primed subjects is able to boost humoral (and, more importantly, intestinal) immunity (see "Mucosal Immunity/Protection Induced By Inactivated Polio Vaccine" later) much better than one additional OPV dose. Interestingly, results obtained with the most recent trials where OPV priming was done with $bOPV_{1\&3}$, seem to suggest that a cross(heterotypic)-priming is induced by $bOPV_{1\&3}$ and that a one-dose cIPV boost is able to achieve substantial humoral (and intestinal, see below) responses against type 2 poliovirus. These observations do confirm the wisdom of the current position recommended by the WHO in the scope of the polio endgame strategy.[6]

Mixed/Combined Inactivated Polio Vaccine/Oral Polio Vaccine Schedule Trials

The previously mentioned WHO study[132–134] compared four doses of tOPV, three doses of cIPV, and a schedule consisting of four doses of tOPV mixed with three doses of cIPV. Seroconversion rates and GMTs were highest in the mixed/combined OPV/IPV groups. In addition, when children of the three groups were challenged with tOPV, virus excretion was as low in the mixed/combined vaccine groups as in the tOPV group, confirming the presence of intestinal immunity.

In Pakistan, infants were randomly vaccinated with tOPV alone; tOPV and cIPV at 6, 10, and 14 weeks of age; or were given tOPV at those times plus a single dose of cIPV at 14 weeks. The immune responses (seropositive children at week 24) were better for types 1 and 3 when tOPV and cIPV were administered simultaneously at each visit (97% vs 89% and 98% vs 92% against types 1 and 3, respectively), but the single dose of cIPV at 14 weeks did not improve the tOPV-only responses (91% vs 89%, 98% vs 96%, and 95% vs 92% against types 1, 2, and 3, respectively).[245]

Mucosal Immunity/Protection Induced by Inactivated Polio Vaccine

When analyzing the level of mucosal immunity and protection afforded by IPV, it is important to distinguish the target body compartment (nasopharynx vs intestine), the type of immunization schedule (IPV-only, sequential, or mixed/combined) used, and the nature of the effect measured (presence of poliovirus neutralizing antibodies at the mucosal surfaces or prevalence, duration, and intensity of poliovirus shedding following a subsequent poliovirus exposure). In addition, as mentioned previously, all the data presented below have been done with cIPV, as no data are yet available on the performance of sIPV in terms of mucosal immunity/protection.

It was recognized early on that cIPV vaccinees could excrete poliovirus in stools and in nasopharyngeal secretions after challenge,[246–249] which was seen as an important disadvantage versus OPV. Time has tempered this vision, particularly because of the progressive observations that cIPV-induced nasopharyngeal immunity could limit the virus shedding from this site after challenge. Studies in monkeys demonstrated that pharyngeal excretion of poliovirus was inhibited in cIPV vaccinees equally or even more than in tOPV vaccinees.[250–252] Then, Marine,[253] who followed families exposed to natural wild-type 1 virus, found that pharyngeal infection was prevented by low levels of circulating neutralizing antibodies induced by cIPV; higher levels were associated with reduced intestinal infection (Table 48.6). Nasopharyngeal immunity induced by cIPV-only schedules, as measured by the levels of secretory IgA or IgG in secretions, may be less than the levels of such antibodies induced by OPV-only schedules. However, nasopharyngeal immunity as measured by resistance to a challenge by OPV viruses appears equivalent to such immunity induced by OPV. Many of the data come from Ogra who found that tOPV recipients developed nasopharyngeal, and sometimes duodenal, poliovirus-specific secretory IgA, whereas cIPV recipients produced lower quantities.[143,144,254,255] Nasopharyngeal and systemic antibody responses after three doses of cIPV, tOPV, or a cIPV-followed-by-tOPV sequential schedule have been observed (summarized in Table 48.7),

From Faden H, Modlin JF, Thoms ML, et al. Comparative evaluation of immunization with live attenuated and enhanced-potency inactivated trivalent poliovirus vaccines in childhood: systemic and local immune responses. J Infect Dis. *1990;162:1291–1297.*

but nasopharyngeal antibody levels were the highest following the tOPV-only schedule. Nevertheless, another study showed equal secretory IgA levels in pharyngeal and stool samples of prior cIPV and tOPV vaccinees.[147] It has been shown on many occasions that both premature and full-term infants are able to develop nasopharyngeal IgA after immunization.[256] Thus, in epidemiological settings where the primary mode of inter-human transmission in affected communities is oral-to-oral (vs fecal-to-oral), cIPV-only schedules can effectively prevent transmission.

With regards to the question of intestinal immunity (and protection) induced by cIPV, the situation is more complex to analyze. It is true that cIPV-only schedules, whether measured by secretory IgA, by transuded IgG, or by resistance to a challenge (prevalence, duration, and intensity of viral shedding), appear to be inferior to such immunity generated by OPV-only schedules; nevertheless, the difference between cIPV- and tOPV-only schedules is variable and seems influenced by multiple factors. It is undisputed that cIPV vaccinees can excrete poliovirus following infection by wild-type or Sabin viruses. In one trial, 93% of cIPV-only vaccinated Finnish infants excreted type 3 virus in stools after a $mOPV_3$ challenge with 300,000 median tissue culture infective doses ($TCID_{50}$), but there was no control group.[257] The median length of poliovirus excretion was 35 to 42 days, and the excreted peak virus titers were $10^{5.6}$ $TCID_{50}$ per gram.[169] In another trial, children who had received three doses of cIPV or tOPV were challenged with two different potencies of $mOPV_1$.[147] The results (summarized in Table 48.8) revealed that, whereas few subjects in either group excreted virus from the pharynx, intestinal shedding was significantly lower in the tOPV group (82% vs 31% for the high-titer challenge and 46% vs 18% for the low-titer challenge). One study done in the United States had the advantage of a control group that was unvaccinated. In this study, two doses of cIPV or tOPV were followed by a dose of tOPV.[223] Viral excretion in stools was measured after that dose, in comparison to a group receiving tOPV for the first time. Table 48.9 summarizes the results, which show, in line with prior studies, that excretion of poliovirus in cIPV vaccinees is lower and shorter than in the unvaccinated, but higher and longer than in tOPV vaccinees. One Cuban study of cIPV given by the EPI schedule showed virus isolation prevalence 1 week after challenge with tOPV of 94%, and a mean log_{10} viral titer of any serotype of 3.46. The titers of virus shed were approximately 0.5 log lower in cIPV-vaccinated children postchallenge compared to unvaccinated children being vaccinated for the first time with tOPV.[258] Many additional studies have documented the lower prevalence, the possibly shorter duration, and the lower intensity of poliovirus shedding following cIPV schedules compared to unvaccinated control (first-time OPV recipients).[195,224,226]

In the two tOPV-followed-by-cIPV sequential schedule trials mentioned above,[240,241] a $bOPV_{1\&3}$ was used as the challenge vaccine to evaluate the quality of the intestinal immunity and protection induced by the cIPV boost done on a tOPV-priming. Results clearly indicated that the supplementary dose of cIPV boosted intestinal immunity against types 1 and 3, as evidenced by less shedding (in terms of prevalence, duration, and intensity) compared to tOPV-only vaccinated subjects. Similar observations were obtained in a parallel trial done in Bangladesh.[242]

With the recent introduction of $bOPV_{1\&3}$, new data have been generated on the quality of the intestinal immunity and protection against type 2 of cIPV-followed-by-$bOPV_{1\&3}$ sequential schedules. In the Chile study mentioned above,[235] the sequential regimen resulted in lower type 2 shedding incidence compared to the cIPV-only regimen, illustrating again the heterotypic (cross)-booster effect induced by $bOPV_{1\&3}$ against type 2 on the one- or two-dose cIPV-primed subjects mentioned before. In addition, several studies have assessed the effect of cIPV on boosting intestinal immunity against type 2 following a $bOPV_{1\&3}$-followed-by-cIPV sequential schedule.[244] Results confirmed that heterotypic (cross)-priming effect against type 2 on humoral and mucosal immunity can be induced by $bOPV_{1\&3}$, and that it can be boosted by cIPV.

Finally, studies have also examined the effect of prior cIPV-induced immunity on the mutation profile of tOPV viruses in the intestinal tract.[259–261] This phenomenon, referred to as reversion to virulence, is a regular feature of the replication of attenuated poliovirus strains, whereby the mutations in those strains responsible for attenuation in humans can revert to the virulent genotype. Although the suggestion has been made that prior cIPV immunization potentiates that reversion,[224,225] a relatively large study failed to show a significant difference in the mutations of excreted virus between cIPV- and tOPV-vaccinated subjects.[262] Analysis made on virus samples isolated during use of a tOPV-followed-by-cIPV sequential schedule in the United Kingdom[222] found that reversions occurred faster in vaccinees given cIPV or tOPV than in previously unvaccinated infants, suggesting that the virus attempts to increase its fitness in the presence of antibodies.[226,227]

What makes cIPV-only vaccinees excrete less poliovirus upon challenge? Hovi[169] studied IgA production in the intestine

of cIPV vaccinees and found little IgA until the vaccinees had been challenged with tOPV. A correlation was found between the detection of intestinal IgA and diminution of virus excretion, and between the height of the serum antibody titer and prevention of excretion in Israel.[263] A recent study did show that presence by day 7 of IgA in stool with neutralizing activities was associated with cessation of virus shedding and that previous cIPV administration was able to prime subjects for an early response to a poliovirus challenge.[264] In addition, some preliminary data on circulating antibody-producing B cells demonstrate that this might be a useful marker for prediction of mucosal immunity.[264a] In one trial where infants received $bOPV_{1\&3}$ at 6, 10, and 14 weeks plus IPV at 14 weeks,[244] an inverse correlation was noted between type 2 virus shedding following challenge and both serum type 2 neutralizing antibodies and mucosal type 2 neutralzing antibodies.[264b] Whether high serum-neutralizing antibodies are a correlate of intestinal protection is still debated and data are conflicting.

To summarize, the accumulated evidence on whether or not cIPV is able on its own to limit the prevalence of intestinal poliovirus excretion and/or its duration and/or its intensity following a challenge are not definitive.[265,266] Assuming it does, the key difficulty is to evaluate the epidemiological impact of such an attribute at the community level in situations where fecal-to-oral is the main mode of poliovirus transmission, and, consequently, to estimate the potential for herd protection with IPV.[267] In the city of Cordoba, Argentina, use of cIPV greatly reduced the circulation of OPV strains; although Sabin viruses were still occasionally detected in sewage, some of which had reverted to a more neurovirulent phenotype, no circulating VDPVs (cVDPVs) were detected.[268] A study showed that revertant and nonrevertant Sabin-strain viruses could be isolated from cIPV-vaccinated infants 10 weeks after the campaign and from sewage for at least 13 weeks.[269] The recent Israel episode[270–272] where wild type 1 polioviruses were regularly and widely isolated from environmental samples for 14 months, clearly indicated that an IPV-only schedule (with accumulation of nine consecutive annual birth cohorts from 2005 to 2013) could not prevent sustained wild poliovirus circulation, albeit silent without paralytic cases, in well-vaccinated Israeli communities that have been subject to poliovirus importations. While IPV may not be sufficient to prevent sustained transmission of wild poliovirus it may be adequate to prevent sustained transmission of Sabin viruses, which have a lower force of infection than wild viruses. Thus, IPV may reduce the potential for emergence of cVDPVs. The experience in Yogyakarta province of Indonesia, which switched to an all-cIPV schedule in 1997, and where during 5 years, despite being surrounded by OPV-using populations and intensive surveillance, no cVDPVs were detected, is interesting.[273]

Efficacy of Inactivated Polio Vaccine Against Acute Flaccid Paralysis and Immune Correlates of Protection

The clinical efficacy of cIPV in its original version was proved beyond a doubt in the original field trial conducted by Francis and colleagues.[1–5] In that trial, approximately 400,000 children randomly received vaccine or placebo, and another 200,000 were vaccinated and observed together with unvaccinated children. There were 71 cases of paralytic polio in vaccinees versus 445 in control subjects. In the placebo-controlled part of the study, 70 cases occurred in the placebo arm versus 11 in the vaccinated arm. The calculated efficacy of the vaccine was 80% to 90% against paralytic polio and 60% to 70% against all forms of polio. The efficacy of cIPV was later confirmed in several settings. Melnick[274] measured an efficacy of 96% through two polio seasons in Houston, Texas. In Senegal, two doses of a DTwP-cIPV vaccine were given in the Kolda area, which subsequently suffered an outbreak of type 1 polio. A case-control analysis revealed an efficacy for one dose of 36% (95% confidence limits, 0% to 67%) and for two doses of 89% (95% confidence limits, 62% to 97%).[106,107] In another study conducted in the North Arcot region of India, John[275] compared tOPV in one district with cIPV vaccination in two other districts. Vaccination coverage with three doses rose to 85% to 90% in the tOPV districts and 75% to 80% in the cIPV districts. Case-control analysis revealed an efficacy of 92% for cIPV and 66% for tOPV. During the introduction of cIPV into Canada, efficacy of the vaccine was calculated at greater than 90%.[276]

Poliovirus neutralizing antibody levels above the 1 : 8 dilution threshold are now well accepted by all national regulatory agencies as correlates of protection against clinical paralysis when reviewing license applications for cIPV-containing vaccines,[114,277] although a 1 : 4 dilution may also be protective. The question of whether the same threshold should be applied to sIPV-containing vaccines is still debatable (see "Inactivated Polio Vaccine Manufactured from Sabin Strains" and "Immunogenicity of Sabin Inactivated Polio Vaccine" earlier).

Community Protection

The best evidence for a community protection effect of cIPV is the experience in the United States where cIPV was introduced into routine use in 1955 and was replaced by OPV in 1962. A sharp drop in the numbers of cases of paralytic and nonparalytic polio was evident during the years 1955 to 1962 (Fig. 48.5). The apparent reduction in the number of cases observed exceeded the expectation based on the percentage of children vaccinated (Fig. 48.6).[278] More specific regional data were published that suggested a greater-than-expected reduction in polio cases.[279] A second example of community protection effect comes from The Netherlands where vaccination is refused by a religious community that is well dispersed throughout the country, although cIPV is routinely administered to the rest of the population. Two outbreaks of polio have occurred in this religious group, one caused by type 1 virus in 1978 (110 cases) and the second caused by type 3 virus from 1992 to 1993 (71 cases). Despite the wide circulation of the virus in this community, there was only one case of polio in other Dutch communities. Approximately 400,000 unvaccinated individuals not belonging to this religious community also remained unaffected.[280–285] The virulent viruses also spread to similar religious groups in North America, but cases only resulted from the 1978 outbreak.[286–288] Oostvogel and colleagues[289] did an analysis of the circulating viruses in schools affected by the outbreak in the Netherlands from 1992 to 1993. Proof of recent type 3 infection was found in 59.5% of the unvaccinated children and in 22.2% of the vaccinated children. The evidence for community protection comes from communities where oral-to-oral transmission was probably the dominant mode of interhuman poliovirus transmission. It is less clear if cIPV is able to induce community protection in communities where the fecal-to-oral route is thought to be the primary method of poliovirus transmission (see "Mucosal Immunity/Protection Induced By Inactivated Polio Vaccine" earlier).

Duration of Immunity

Studies have assessed the persistence of antibodies following different infant primary series regimens with cIPV-containing vaccines with or without a first booster administered during

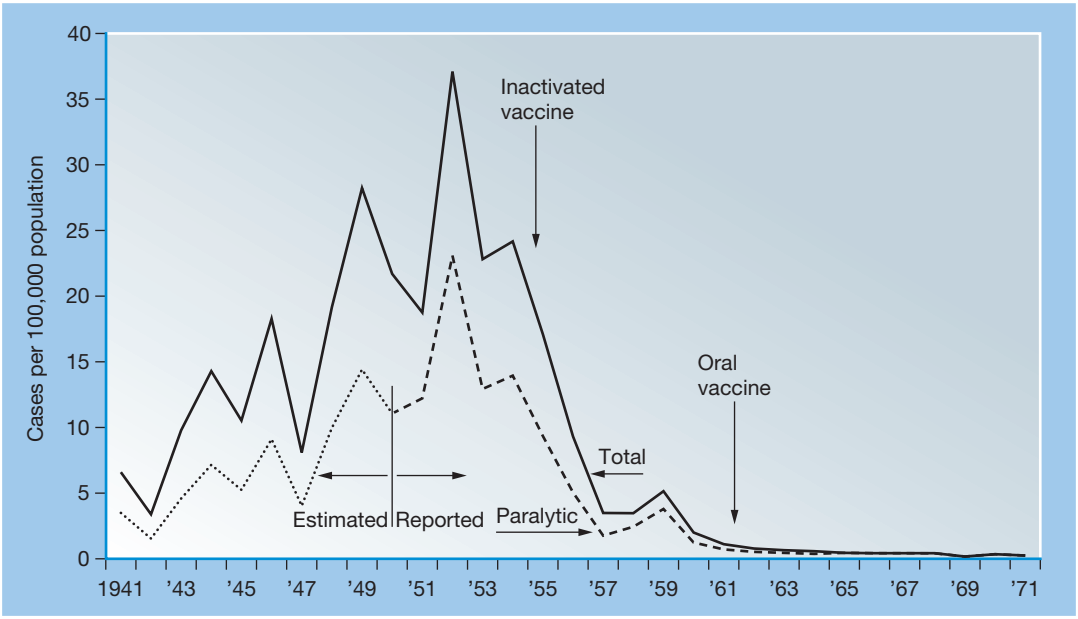

Figure 48.5. Incidence of polio in the United States. The oral polio vaccine was introduced from 1961 to 1962. The dashed line indicates the incidence of paralytic polio only; the solid line measures the incidence of both paralytic and nonparalytic polio. *(From Centers for Disease Control and Prevention (CDC).* Immunization Against Disease–1972*. Atlanta, GA: CDC; 1973.)*

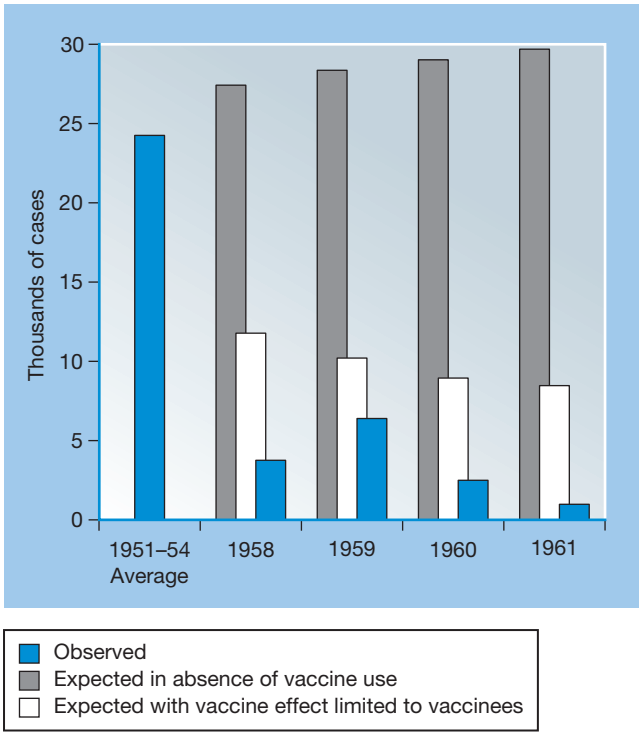

Figure 48.6. Herd effect induced by inactivated polio vaccine in the United States from 1958–1961. The number of observed cases of paralytic poliomyelitis was consistently lower than the number that would have been expected if vaccination had benefited only vaccinated individuals. *(From Stickle G. Observed and expected poliomyelitis in the United States, 1958–1961.* Am J Public Health*. 1964; 54:222–229.)*

the second year of life and/or at school-entry age. These studies have involved cohorts followed for varying periods of time vaccinated in trials aimed at documenting the early responses induced by cIPV-containing vaccines under development and/or licensure. The studies have been grouped by type of cIPV vaccine used first and then by type of primary series regimen for the trials done with the modern cIPV.

The first group of data includes studies done with the historical cIPV-containing vaccines. These low-potency vaccines contained quantities of antigen that were lower than the current formulations. Bottiger[290] evaluated 30 children given two doses of cIPV at approximately 9 and 10 months of age and a first booster dose at 2 years of age. When tested at 10 years of age (8 years after the last dose), 100% of the children still had seroprotective levels (≥1:4) of antibody to all three poliovirus types. In addition, in the same study, 220 Swedish children given the same low-dose vaccine with three doses at 9 months, 10 months, and 2 years of age, and a later second booster dose at 6 years of age were evaluated. At 18 years of age (12 years after the last dose), 100% of subjects were still seropositive (≥1:4) to all three serotypes. The decline of antibody titers was greater during the first 3 years after the 6-years-of-age booster (0.13–0.22 $\log_{10}$ fold-reduction per year) than during the next 9 years (0.05–0.10 $\log_{10}$ fold-reduction per year). In another study conducted in Sweden,[291] two primary series schedules were evaluated. All subjects were given a low-dose 20-4-16 D-Ag units cIPV concomitantly but at separate sites from DTaP and *Haemophilus influenzae* type b (Hib) vaccines. One group of 103 children were immunized using the standard Swedish schedule at 3, 5, and 12 months of age; the other group of 118 children were immunized at 2, 4, 6, and 15 months of age. At 4 years of age, 93% to 100% of children on the 3-5-12–month schedule and 96% to 100% of children on the 2-4-6-15–month schedule still had seroprotective titers (≥1:4) to the three poliovirus serotypes.

The second group of data includes studies done with modern cIPV-containing vaccines, and is further subgrouped according to the type of infant/toddler schedule used. That is,

two doses in infancy followed by one dose in the second year of life (2+1), three doses in infancy with no booster dose in the second year of life (3+0), or, finally, three doses in infancy followed by a booster in the second year of life (3+1). Table 48.10 summarizes the results (Sanofi Pasteur, studies A3R22 and TD517; unpublished, data on file).[229,262,292–301] Data show persistence of antibodies only up to the school-entry age, because all cohorts have received a school-entry booster with a cIPV-containing vaccine. No data are available in cohorts of subjects primed with these different infant/toddler schedules and having not received a school-entry booster with a cIPV-containing vaccine. Overall, these studies show that the persistence of poliovirus-neutralizing antibodies is well established at least until school-entry age by the 3+1, 2+1, and 3+0 schedules, with slightly higher titers in favor of the most complete schedule (3+1). In studies where evaluated, antibody titers declined more rapidly during the first 2 years after the last dose (0.45–0.60 $\log_{10}$ fold-reduction/year for each of the three serotypes) but remained more stable during the following years. When a school-entry booster is given following these different infant-toddler primary immunization schedules, there is evidence of a marked anamnestic response with very high titers when measured in the following month.[294,295,297–300] No data have yet been published on the persistence of poliovirus-neutralizing antibodies induced by sIPV.

Based on the historical Swedish data noted earlier, duration of protection is expected to be long term, and whether additional boosters after the toddler and/or the school-entry booster will induce lifelong protection is still debated.[302] No studies have yet evaluated persistence of poliovirus-neutralizing antibodies beyond childhood following complete primary immunization as the first countries who put in place routine

and exclusive use of modern cIPV-containing vaccines schedules started in the mid-1980s. Thus, the cohorts who received such schedules are in their mid-thirties. Nevertheless, some countries recommend post–school-entry age additional dose(s) (see Table 48.2). The availability of IPV-containing vaccines licensed for adolescents and adults and with boosting indications (IPV, Td-IPV, and Tdap-IPV) facilitates implementing such boosting strategies. Studies show that one (third) booster dose with a cIPV-containing vaccine in IPV-only 3+1+1 primed 11- to 14-year-old adolescents is able to induce persisting antibodies for at least 10 years.[303]

Salk argued that immune memory is established by primary vaccination with IPV and that no further immunizations are necessary.[304–306] He showed that, whereas unprimed subjects reacted with only low responses to a single dose of cIPV, primed individuals, even those originally given fractional doses, developed anamnestic responses. In his opinion, the vaccinees would respond similarly to an infection, thus preventing viremia and disease. Swartz[176] showed that newborns could be primed to develop an anamnestic response to cIPV at age 6 months if they were given a dose at birth. In contrast, from a group of elderly cIPV-vaccinated and seronegative who were challenged with tOPV, only a third had anamnestic serum antibody responses, suggesting immune memory.[307]

A minimal position would be to recommend four to five doses of an cIPV-containing vaccine with the last one administered at school-entry age, as, for example, the current U.S. schedule, which is ages 2, 4, and 6 to 18 months and 4 to 6 years (2+1+1 or 3+0+1); or in the United Kingdom, which is ages 2, 3, and 4 months and 3 to 5 years (3+0+1) (but in this case, the UK recommends a fifth dose at 13–18 years of age); or in some other European countries, which is ages 2, 4, 6, and 15 to 18 months and 4 to 6 years (3+1+1). No data are available on the long-term persistence of circulating antibodies and waning of intestinal immunity conferred by a single IPV dose to be administered per WHO recommendations (e.g., OPV at 6, 10, and 14 weeks along with IPV at 14 weeks) whereas it has been shown that intestinal immunity conferred by OPV can wane.[308] With the switch from tOPV to $bOPV_{1\&3}$, the single dose of IPV will be the only exposure children on this schedule have to the type 2 antigen.

ADVERSE EVENTS

The "Cutter incident" is probably a unique event in the field of vaccine safety and for sure in the history of IPV. Between April and June 1955, shortly after licensure in the United States, 204 acute flaccid paralysis (AFP) cases of type 1 polio were observed in association with use of vaccines manufactured by Cutter Laboratories.[309,310] After investigation, 60 cases in vaccinees and 89 in family contacts were judged to be caused by two lots of vaccine in which infectious virus had not been completely inactivated. Approximately 70,000 children received the two lots, and studies revealed infection in 10% to 25% of vaccinated children and found an incidence of one paralytic case in every 100 to 600 infections. The incriminated lots all had passed release tests, including monkey neurovirulence and tissue culture infectivity, but other lots similarly manufactured had failed. As a consequence, a requirement for all lots to pass safety tests was introduced at that time. The Cutter incident was the result of a lack of regulatory supervision of companies that had no experience in making IPVs, and served as a lesson in vaccine safety management.[311] Since the Cutter incident and the safety measures instituted as a result of that experience, there has been no evidence for defective manufacture of IPV, and since the initial launches of the modern IPVs, it can be estimated that more than 1 billion doses of cIPV-containing vaccines produced by the major manufacturers have been used without subsequent polio or other serious reaction.[130,262]

IPV is very well-tolerated. When infants are injected intramuscularly with cIPV standalone vaccine, injection-site erythema is seen in 0.5% to 1.5% of infants, induration in 3% to 11%, and tenderness in 14% to 29%.[312] The combination of cIPV with other vaccines, such as DTwP/DTaP (supplemented or not with Hib and hepatitis B), do not add to the reactions observed with those vaccines alone.[130,262] cIPV-containing vaccines are now licensed in almost all countries, and in 2014 it was estimated that 30 to 40 million newborn infants and 20 million school-entry children, adolescents, and adults had received at least one dose of a cIPV-containing vaccine. Overall, the numbers of adverse events reported to the manufacturers are low, and the types of reactions reported are within what is expected with this kind of unadjuvanted inactivated vaccine and without concentration in a single category. The data collected in the United States by the Centers for Disease Control and Prevention's (CDC's) Vaccine Adverse Event Reporting System database between 1991 and 1998 was reviewed for reactions attributed to cIPV[313] and there was no suggestion of causally related serious adverse events. In the cases when IPV is administered subcutaneously, as seen with other inactivated vaccines when injected subcutaneously,[314] the incidence of local reactions at the injection site are slightly higher compared to what is seen when using the intramuscular route.[315] Pharmacovigilance experience accumulated on IPV-containing vaccines have also not shown unexpected reactions attributable to IPV.

Finally, a safety concern had been raised because older versions of cIPV were contaminated by a simian virus 40 (SV40) brought by the primary rhesus monkey kidney cells used to grow polioviruses used in some historical IPVs and that such vaccines may have been involved in the late occurrence of mesothelial tumors, brain tumors, and non-Hodgkin lymphomas in individuals exposed to polio vaccines before the vaccines were cleared of the virus in 1963.[316–319] Similar concerns were raised regarding older OPVs. Although epidemiologic studies have been negative so far, some controversy still remains on the clinical implications of human exposure to SV40.[320,321]

Recommendations for Inactivated Polio Vaccine

Infants and Toddlers

All high-income and an increasing number of middle-income countries rely on IPV-only schedules in their routine public childhood vaccination programs (see Table 48.2). In addition a growing number of middle-income countries recommend either IPV-only schedules supplemented by National Immunization Days (NIDs) with OPV organized once or twice a year in all subjects younger than 5 years of age (e.g., Mexico), IPV-followed-by-OPV sequential regimens (e.g., Russia, Brazil, Malaysia, Israel), or mixed/combined IPV/OPV regimens where the two vaccines are administered at the same time for one or more occasions during the vaccination course (e.g., South Africa). It is anticipated that many more countries will soon adopt one of those schedules (India, China, Indonesia, etc). The multiplicity of the regimens currently in place in these countries is driven by potential differences in country-specific basic immunization programs and perceived risks from wild virus and vaccine poliovirus. Key factors considered are epidemiological (VAPP incidence, level of risk for poliovirus importations), sociological (lack of acceptance of VAPP risk), performance of the routine immunization program, presence of national manufacturer(s), vaccine procurement, and pharmacoeconomics.

With the recent adoption by the WHO and all Global Polio Eradication Initiative (GPEI) stakeholders of a revised strategy for the polio endgame strategy,[6] all remaining OPV-using countries (mainly low-income countries) are introducing IPV in their routine vaccination programs (as of the end of 2016, approximately half of them, the most at risk, have introduced at least one dose of IPV and the remaining may introduce IPV later with modalities to be defined depending on supply availability and on willingness to adopt the use of fractional dosing of IPV). The current recommendation is that at least one dose of IPV should be administered at the time of the third routine DTP visit where infants should simultaneously receive their third OPV infant series dose (the fourth OPV dose in those countries with a birth dose of OPV). The main rationale for this OPV-followed-by-IPV sequential regimen is to make sure that cohorts of infants acquire a minimal level of poliovirus type 2 immunity because tOPV has been replaced by $bOPV_{1\&3}$. Without IPV these cohorts could be vulnerable if poliovirus type 2 (wild type or VDPV) is reintroduced in their communities (see Chapter 49). In addition, as summarized above (see "Immunogenicity of Mixed/Sequential Schedules with Inactivated Polio Vaccine and Oral Polio Vaccine" and "Mucosal Immunity/Protection Induced by Inactivated Polio Vaccine") it is expected that this IPV dosing will boost poliovirus intestinal immunity induced by previous tOPV or $bOPV_{1\&3}$ administrations. Furthermore, potential heterotypic(cross)-priming effect against type 2 that has been observed in some $bOPV_{1\&3}$-followed-by-IPV sequential regimen studies[244] is particularly relevant in that context.

As of the end of 2016, IPV-containing vaccines are routinely recommended for infant vaccination against poliomyelitis in approximately 177 countries[322] (as of publication, the number of countries might be higher than this number) and it is hoped that by 2018, all countries will have achieved their IPV introduction. Several factors are driving the pace of this introduction (see "Public Health Considerations" later) and with the progressive ramp up of manufacturing capacities, the development of new IPV-containing products, and successful eradication of wild polioviruses, eventually the world will move to an all IPV schedule, once use of all OPV is stopped.

Children

In countries relying on IPV-only schedules in their routine public pediatric vaccination programs (see Table 48.2), a school-entry (or a later childhood, e.g., United Kingdom) booster is recommended as the last dose of the series. Several countries recommend subsequent boosters during adolescence (Austria, France, The Netherlands, Canada, United Kingdom, Greece).[323,324] For children who have not been vaccinated previously, or with unknown or incomplete vaccination history who need rapid protection because they are traveling to a zone where polioviruses are circulating, the recommended schedule is two doses 1 month apart followed by a booster 6 months later (or, if pressed for time, at least 1 month later).

Adults

In almost all countries relying on IPV-only schedules in their routine public childhood vaccination programs (see Table 48.2), routine (re)vaccination of adults or the elderly is not recommended. Very few countries recommend such routine boosting strategy (Austria, France, Greece).[323,324] Adults who have not been vaccinated previously, or with unknown or incomplete vaccination history, who need rapid protection because they are traveling to a zone where polioviruses are circulating, should always receive IPV, because VAPP after OPV appears to be more common in adulthood. In addition to the IPV standalone vaccine, IPV-containing combination vaccines including low-dose diphtheria and tetanus toxoids (some also including low-dose aP antigens) have been developed and licensed in many countries.[325–329] Similarly to children, in such situations the recommended schedule is two doses 1 month apart followed by a booster 6 months later (or, if pressed for time, at least 1 month later). Depending on the vaccination history, in some cases only one dose might be enough to boost adequately immune response. Many vaccination policy recommending bodies are regularly updating recommendations related to travel to polio-epidemic or polio-endemic area, and the WHO has acted similarly.[330] In principle, vaccination of previously unvaccinated adults is recommended when they are in contact with children excreting Sabin poliovirus[331] and adults who have been fully immunized but who are traveling to a wild poliovirus infected area should receive a one-time IPV booster.[332] In addition, the WHO recently amended its international travel recommendations stating that persons traveling from "recent polio exporting countries" should receive a dose of IPV or OPV no less than 4 weeks prior to departure and no more than 12 months prior to departure.[333]

High-Risk Groups

Personnel manipulating wild polioviruses should have previously completed vaccination. Healthcare workers should also be vaccinated because they may come into contact with wild poliovirus or reverted viruses excreted by vaccinees. IPV is universally recommended for subjects with known congenital or acquired immunodeficiency, in view of the VAPP risk in those subjects following contact (direct or indirect) with Sabin viruses even knowing their potential poor responses against vaccine antigens.[334] Family contacts of immunocompromised subjects should receive IPV instead of OPV to avoid being a source of vaccine viruses to their immunocompromised contacts. Those receiving systemic steroids or chemotherapy are included in this indication.

CONTRAINDICATIONS TO INACTIVATED POLIO VACCINE

Formal contraindications to IPV consist of a previous severe reaction to IPV vaccine or known or documented allergy to streptomycin, neomycin, or polymyxin B. In real life, these situations are extremely rare. Neither pregnancy nor breastfeeding is a contraindication.

SIMULTANEOUS USE WITH OTHER VACCINES

No clinically relevant interference effects have been described when IPV is used in association or in combination with licensed DTwP/DTaP, Hib, or hepatitis B vaccines. The largest experiences with IPV-containing combinations have been accumulated between the mid-1980s and the mid-1990s with DTwP-IPV and DTwP-IPV/Hib in France and Canada, and since the mid-1990s with DTaP-IPV–backboned combinations including hepatitis B and/or Hib in the United States, Canada, Europe, and elsewhere (see Chapter 15). In combination vaccines, IPV is compatible with DTaP, Hib, and hepatitis B, although generalization is difficult owing to the pharmaceutical specificities of all these drug substances, which are the key driver of whether these antigens can be combined. Extemporaneous mixing of two distinct liquid finished products should not be made by vaccinators. As mentioned earlier (see "Producers of Inactivated Polio Vaccine Antigen and Available Vaccines"), several IPV-containing DTwP-backboned hexavalent products are under development,[70,100,101] and in this case, the

key technical challenge is to manage the bidirectional interference between the wP and IPV antigens (caused by the presence of residual inactivating and bioburden control agents, e.g., thimerosal) on their respective potencies.

PUBLIC HEALTH CONSIDERATIONS

Results of Vaccination Programs With Inactivated Polio Vaccine

Experience with IPV in national public programs has been longest in Europe and in Canada. Some countries have used IPV exclusively since the mid-1950s, and some have used IPV as part of sequential or mixed/combined schedules with OPV.[131,262,335] Most of these experiences are reviewed in the following sections. It should be noted that in many countries listed below, a growing and significant proportion of immunization against polio is done in the private sector and that IPV-containing vaccines are the only products used in that sector (mainly driven by desire to avoid the risk of VAPP).

European Region

Many countries of this region have been early adopters of IPV.

Sweden has used IPV since 1957.[336] In 1989, modern IPV replaced the original vaccine and indigenous circulation of wild polioviruses was stopped by 1962,[337] although a subsequent outbreak occurred in an unvaccinated religious community without spread to the whole population.[285]

Similarly, IPV has been used in Finland for many years, starting with first-generation vaccine and changing to modern IPV in 1986. The only outbreak of polio reported since the introduction of IPV involved 10 cases in 1984–1985.[338–340] The type 3 component of the first-generation IPV was of low potency, with only 60% of three-dose vaccinees responding with neutralizing antibodies. Furthermore, vaccination coverage with the recommended six doses had slipped to 80% before onset of the outbreak. Investigations revealed that a type 3 wild-type virus was introduced, probably from Turkey, which was genetically distinct from the Saukett virus strain used to manufacture the vaccine and, because of that it escaped neutralization. A trypsin-treated vaccine was developed in an attempt to correct the specificity of the type 3 response,[257] but tests showed that it did not improve the immunogenicity. tOPV was brought in to stop the outbreak, after which the Finns returned to using IPV, but in the form of the modern vaccine. The modern IPV did induce neutralizing antibodies to the Finnish mutant virus.[337]

Denmark started with a sequential schedule in 1968. Starting in 1970, Danish infants received cIPV at 5, 6, and 15 months of age, followed by OPV at 2, 3, and 4 years of age. Single polio cases were diagnosed in 1969, 1976, 1980, and 1986, and the last two were imported. No wild-type virus has been identified in sewage samples since 1968. Not surprisingly, seroimmunity has been virtually 100% at all ages of the Danish population.[341] No VAPP has occurred among 1.5 million Danes who have received two or more doses of IPV, and in 1997 Denmark changed to an IPV-only schedule.

In The Netherlands where modern cIPV had its roots in the late 1970s,[342] polio has been prevented in the population by the use of a DTwP-cIPV combination vaccine and, more recently, a DTaP-cIPV vaccine. Regular serosurveys revealed high seroprevalence rates for polioviruses types 1, 2, and 3.[343,344] As described earlier, however, two outbreaks have occurred in Protestant religious communities refusing vaccination without spread to others (see "Community Protection").

Polio disappeared from Iceland in 1960 after the introduction of cIPV in 1956.[337]

Norway started vaccination with cIPV in the late 1950s but switched to tOPV in 1965. After that switch, there were six cases of VAPP, of which five were in unvaccinated people and the sixth in an individual given cIPV 10 years earlier (L. Flagstrud and H. Nokleby, personal communication). Because most of the population had received cIPV previously, it appears that VAPP had been almost completely prevented by prior IPV vaccination. Norway switched back to cIPV in 1979, and since then the only reported poliomyelitis has been imported from abroad.[337]

France is a good example of a country exposed to regular poliovirus importations that has kept the disease at bay with cIPV vaccination only. France started vaccination with cIPV in 1956, but in 1965 tOPV became the recommended vaccine. Both tOPV and cIPV were in use until 1983, when modern cIPV was exclusively recommended. VAPP occurred sporadically during the use of tOPV but ceased to be seen after 1986. The last wild poliovirus AFP case was reported in 1989, and attempts to find indigenous wild-type viruses in sewage have not been successful since 1989, whereas imported Sabin-like virus have been sporadically detected from 2000 to 2010.[345]

The United Kingdom switched from tOPV use to exclusive use of cIPV in 2004 when a pentavalent DTaP-IPV/Hib combination became licensed and was then recommended.

Russia adopted IPV in 2009 with initially cIPV at 3, 4.5, and 6 months of age followed by OPV at 18 and 20 months of age and 14 years. In 2011, following the 2010 wild poliovirus type 1 outbreak in Uzbekistan,[346] Russia decided to replace the 6 months of age cIPV dose with OPV.

All other European countries use cIPV-only schedules, based on the use of DTaP-backboned pentavalent and hexavalent combination vaccines.

Americas Region

All Canadian provinces have used cIPV-only, OPV-only, or cIPV-followed-by-OPV sequential schedules since the inception of vaccination in 1955, and the experience has been particularly large in Ontario, Canada's most populous province. Since 1997, all provinces are using cIPV-only schedules through the use of cIPV-containing DTaP-backboned pentavalent and hexavalent combination vaccines. The last indigenous case of polio occurred in 1988, and was related to an imported virus. Introductions of poliovirus from The Netherlands in 1979 and 1992 and from the Indian subcontinent in 1996 failed to spread to the general population.[276,347] Ontario, the province with the largest immigrant population, has had the most introductions, but other provinces using tOPV have also had wild poliovirus introduced. In every case, the wild virus was confined to unvaccinated immigrant groups or unvaccinated religious communities, while the general population was unscathed.

The early use of first-generation IPV in the United States was discussed earlier (see "Community Protection"). Despite incomplete application of the vaccine, polio incidence fell 95% between the introduction of the vaccine in 1955 and its abandonment in 1961 (see Fig. 48.5). The remaining cases, many of them in IPV vaccinees, sapped confidence in the vaccine and caused its replacement by tOPV.[262] The last cases of indigenously acquired wild-type paralytic poliomyelitis in the United States occurred in 1979 among unvaccinated Amish children in Pennsylvania, Missouri, Iowa, and Wisconsin. Table 48.11 summarizes the evolution in polio vaccination policy in the United States. Opinion gradually shifted away from tOPV and toward cIPV, but with the preference for a combination vaccine. Although a combination vaccine containing cIPV was not licensed at that time, cIPV

TABLE 48.11 Steps in U.S. Decisions Regarding Polio Vaccination

1955	Historical IPV licensed
1961	Polio outbreak shows partial effectiveness of IPV; epidemiologic data show that IPV does not completely prevent poliovirus circulation
1963	tOPV licensed, replaces IPV as recommended vaccine
1964	Surgeon General's committee concludes that 57 cases of VAPP occurred between 1961 and 1964 (reversion to virulence first recognized in 1955)
1970s	Van Wezel and Cohen at RIVM improve manufacturing processes of IPV
1977	IOM report recommends OPV for children, IPV for adults
1978	Institut Mérieux develops technologies for manufacturing IPV in Vero cells; monkey cells no longer needed
1988	IOM report recommends staying with OPV until IPV combination available or 90% coverage reached
1995	IOM workshop recommends moving toward IPV
1997	Sequential schedule adopted by ACIP
1999	ACIP recommends sequential schedule or all IPV; OPV alone not recommended
2000	IPV only schedule recommended

ACIP, Advisory Committee on Immunization Practices; IOM, Institute of Medicine; IPV, inactivated poliovirus vaccine; OPV, oral poliovirus vaccine; tOPV, trivalent oral poliovirus vaccine; RIVM, Rijksinstituut Voor Volksgezondheid en Milien; VAPP, vaccine-associated paralytic poliomyelitis.

was reintroduced into recommended use in the United States (in its enhanced-potency form) in 1997 as part of a sequential schedule consisting of two doses of cIPV at 2 and 4 months of age, followed by two doses of tOPV at 12 to 18 months and 4 to 6 years of age.[348] VAPP cases immediately decreased to three in 1997 and one in 1998. All these cases occurred in children whose physicians had elected to start immunization with tOPV rather than the recommended cIPV.[236] Three years later, in 2000, the United States chose an cIPV-only regimen.[331] The primary reason for the reintroduction of cIPV was the perception that polio was vanishing from the world, whereas paralysis associated with tOPV was exacting an average yearly toll of 8 cases.[334,349,350] A study done in 2006 in contiguous Mexico border towns showed that IPV-vaccinated U.S. infants did not become infected with Sabin virus despite high-level poliovirus importation.[351] Before the switch occurred, concern was expressed that the use of standalone cIPV vaccine might decrease immunization rates because of the necessity of additional injections. However, this was not the case, and immunization rates were unaffected by the change to sequential and then cIPV-only schedules.[352–354]

Mexico (since 2007) and Costa Rica (since 2010) rely on an cIPV-only schedule, in the form of a pentavalent DTaP-IPV/Hib combination vaccine, with continuation of NIDs with OPV twice a year in Mexico in all children 6 months to 5 years of age (and who have received two or more IPV vaccinations). In Mexico, studies monitoring circulating Sabin viruses and VDPVs after the May 2009 biannual OPV NID revealed that Sabin viruses were isolated for 5 to 8 weeks after the NID (as expected) and that VDPV types 1 and 2 (which could have emerged from previous NIDs) could be isolated.[355] The suboptimal coverage reached both for the 2009 routine immunization program (71%, 73%, 78%, and 95% for the four cities sampled) and for the 2009–10 OPV NIDs (57%, 65%, 93%, and 80% for the four cities sampled) were probable factors favoring emergence of these VDPVs.

Brazil adopted OPV in 1960 and progressively deployed routine and high coverage programs. In addition, biannual OPV NIDs were instituted at the beginning of the 1980s. This led to termination of wild poliovirus transmission with the last case of wild-type AFP detected in 1989. In 2012, Brazil switched to cIPV in the form of a cIPV-followed-by-OPV sequential regimen (IPV at 2 and 4 months followed by OPV at 6 and 15 months), supplemented by an annual OPV NID for all children 6 months to 5 years of age.[356] This move was mainly driven by the objective to control the VAPP risk.

Eastern Mediterranean Region

Israel has used both polio vaccines in an attempt to prevent polio. After a brief experience with the original low-potency IPV,[16] Israel started routine tOPV vaccination in 1960. Vaccination coverage reached high levels among both Jewish and Arab children. Nevertheless, sporadic poliomyelitis continued among Jews, and small epidemics continued to occur in the West Bank and Gaza.[357–359] In view of the failure of tOPV to control polio, in 1978 Israel introduced a mixed/combined schedule where tOPV was administered at 1, 2.5, 4, 5.5, and 12 months of age, and cIPV (as a DTwP-cIPV vaccine) was given at 2.5 and 4 months of age. For a time in the 1980s, there were no cases in Israel proper and only sporadic cases in the Palestinian areas.[357,358] All went well until 1988, when an epidemic of 15 cases of type 1 polio occurred in Israel,[359] localized in one of two districts that had adopted cIPV-only vaccination of infants. Although the analysis of this epidemic is controversial, it is clear that antibody responses to tOPV were suboptimal among Israeli young adults, resulting in a low level of resistance. Conversely, the wild virus may have circulated among infants immunized with cIPV only, allowing spread to their parents. The response to the epidemic included mass vaccination with tOPV and the institution of three doses of DTwP-cIPV in the routine vaccination scheme together with four simultaneous doses of OPV.[359] Since 1988, no cases of polio have been reported in Israel or its territories, despite an outbreak in neighboring Jordan from 1991 to 1992 that caused wild virus circulation in Gaza.[360] In 2005, Israel adopted a cIPV-only (3+1+1) regimen. More recently, the episode of silent circulation of a wild-type 1 poliovirus from February 2013 to March 2014[270–272] illustrates the limits of cIPV-only schedules when deployed in communities with high poliovirus transmissibility potential[361] (see "Mucosal Immunity/Protection Induced By Inactivated Polio Vaccine" earlier). To extinguish this circulation, Israel modified its immunization regimen by adding $bOPV_{1\&3}$ at the 6- and 18-months-of-age vaccination visits, after having conducted IPV and $bOPV_{1\&3}$ supplemental immunization activities.

Western Pacific Region

Malaysia switched to cIPV in eight provinces in 2008 and then nationwide in 2010. The regimen is a 3+1 cIPV-only regimen followed by an OPV boost at school-entry age (7 years). As of the end of 2012, no polioviruses have been isolated from AFP cases, and a few Sabin-like polioviruses (and no VDPVs) have been isolated from environmental samples.[362]

Australia decided to switch to a cIPV-only regimen in 2005 when a cost-effective cIPV-containing aP combination became available.[363,364]

New Zealand switched to a cIPV-only regime in 2002 and documented a very rapid elimination of the infants excreting Sabin-like viruses and a disappearance of these viruses within

4 months in environmental samples. In addition, despite recurrent events of isolations of Sabin-like viruses indicative of importation events from OPV-using countries, no VDPVs emerged.[365]

After a very short and limited usage of the historical IPV, Japan relied on OPV from 1961 until September 2012. AFP cases caused by wild polioviruses disappeared in 1980; all remaining cases were VAPP, which continued to occur with an incidence of 1 per 1.4 million recipients of any OPV doses. This situation progressively undermined public acceptance and vaccination coverage for the biannual two-dose infant tOPV schedule dropped to a low of 67.2% during the spring 2012 round. In late 2012 two DTaP-sIPV products were licensed (see "Inactivated Polio Vaccine Manufactured from Sabin Strains" earlier), and with the already licensed cIPV (early 2012), Japan switched to an IPV-only (3+1) schedule in September 2012. Since then environmental surveillance has confirmed the disappearance of Sabin viruses.[366–368]

Southeast Asia Region

In Yogyakarta province of Indonesia, a cIPV-only schedule was adopted starting in September 2007, with administration at 2, 3, 4, and 9 months of age. Surveys showed no drop in vaccination coverage from the preexisting greater than 95% level. Seroprevalence surveys revealed 100% of recipients of three doses or more of cIPV had high seroprotective levels. Finally, Sabin-like polioviruses were only isolated a few times in sewage samples after the switch to cIPV (5% of samples compared to 58% of samples before the cIPV introduction) and no VDPVs were detected.[273] As expected this demonstration project showed the rapid elimination in the environment of the Sabin-like viruses with the only source being surrounding regions still using tOPV. During the 5-year surveillance period, no VDPV emerged illustrating the extreme importance of high vaccination coverage. As a result this province has adopted a cIPV-only schedule and Indonesia is on the verge deploying this schedule nationwide.

Africa Region

The Republic of South Africa introduced cIPV in their routine immunization program in 2009,[369] and is following a unique regimen consisting of tOPV at birth followed by tOPV and cIPV at 6 weeks of age, cIPV at 10 and 14 weeks of age and at 18 months of age. In addition, cIPV is administered in the form of a DTaP-IPV/Hib pentavalent combination vaccine. In addition, tOPV NIDs are conducted every 3 years, targeting vaccination of all children younger than 5 years of age, regardless of prior immunization status.

The 2013 wild poliovirus type 1 outbreak which occurred in the Horn of Africa, originating from Nigeria, prompted Kenya to use cIPV in a campaign together with tOPV as an outbreak response in more than 100,000 refugees younger than 5 years of age. Surveys indicated that greater than 90% coverage could be achieved with both vaccines. This program showed that both IPV and OPV could be used in mass campaigns with high coverage obtained for both vaccines in an actual field setting.[370]

Rationale and Role of Inactivated Polio Vaccine in Poliomyelitis Eradication

Since the early 1960s, there has been controversy regarding which polio vaccine should be chosen for routine immunization of infants—IPV or OPV. This led to considerable debate.[335,371–375] However, it is now recognized that both vaccines are necessary to achieve and sustain the eradication.[6,376–379] The data and experience to date show that IPV may be used in a variety of ways to support eradication, which is influenced by a multitude of specific factors that are reviewed below.[380,381] WHO even before the recently amended strategy[6] stated that "The national choice of vaccines and vaccination schedules during the preeradication period must include OPV or IPV, or a combination of both, and should be based on assessments of the probabilities and consequences of wild poliovirus importation."[382] Nevertheless, it is clear that after eradication of the circulation of polioviruses, the use of OPV will have to stop.

For the three countries still endemic for wild poliovirus and the more numerous countries at high risk of importation and reestablishment of transmission, especially countries with crowding and poor hygiene and sanitation, which would facilitate the fecal–oral spread of virus, OPV is critical. This is because OPV induces higher levels of intestinal immunity than IPV. However, IPV can have an important role because it induces high levels of individual protection even in developing countries with fewer doses than OPV and overcomes OPV deficiencies by bypassing the intestines, which can impede OPV seroconversion in developing countries. IPV also boosts intestinal and humoral immunity in prior OPV vaccinees who have not seroconverted, particularly against type 2 after $bOPV_{1\&3}$ administration. Thus, IPV following OPV can improve protection against the current circulating wild virus types because it improves on both the systemic and mucosal immunity induced by OPV.

IPV also has a major role to play in preventing VAPP and emergence and transmission of VDPVs. As cVDPV can be considered a complication of a suboptimal usage of OPV, then only two possibilities exist to alleviate this risk completely where OPV is used: either total elimination of the use of any form of OPV or achievement of extremely high vaccination coverage in all populations, subpopulations, and geographies. This may be an unreasonable expectation; as long as OPV is used, there is potential for generation of more cVDPVs. Furthermore, even with good and universal coverage with OPV, VAPP will occur. The elimination of VAPP is a key driver for many of the countries that have adopted a regimen in which polio immunization starts with IPV (one or two doses), as this is the only way to eliminate the risk of VAPP when continuing to use OPV in the schedule.[154,236] The prevalence of poliovirus antibodies in pregnant mothers (reflecting the past dynamic of the circulation of the poliovirus in the communities) is also a factor that has been taken into consideration to determine the best timing for using IPV, and to maximize its immunogenicity benefits should only a limited number of doses (e.g., one dose) be used in the schedule. The nature of the IPV-containing vaccine desired to be used in the program is also an important element as some countries may decide to switch toward aP-containing vaccines, and therefore may decide to rely on DTaP-IPV combination vaccines to simplify the logistics and programmatic aspects of their routine national immunization program. The existence of a national manufacturer, engaged or not in the manufacturing of OPV and/or of an IPV-containing product (particularly the Sabin IPV), continues to be an important driver in the choice of the products to be used. Finally, pharmacoeconomic considerations based on cost-to-benefit evaluation of several potential strategies have been major drivers in many countries. A dose of OPV costs approximately $0.15 for UNICEF or for other types of high-volume public markets. The cost of one dose of IPV standalone varies largely depending on the type of market (UNICEF procurement, Global Alliance for Vaccines and Immunization (GAVI)-funded; direct procurement, nationally funded; private) and the type (and presentation) of vaccine used, so no unique number can be provided as the financial conditions

of these markets are extremely diverse. Several funding mechanisms and tiered pricing approaches have been put in place to make IPV affordable and introducible in all the countries that have not been able to use it previously because of price considerations. As a general rule, product cost drives the decision as to the type of IPV-containing vaccine considered (standalone or aP combinations), the type of presentation (syringe, 1-, 2-, 5-, or 10-dose vials), the country(ies) where manufacturing operations are performed (distinguishing antigen, product formulation, filling of the finished product, and packaging operations), and the volumes considered. Although the price per dose of any IPV-containing vaccine is greater than the price of OPV, the human and financial costs of VAPP and VDPV, the high amount of wastage with OPV, and the cost of keeping the oral vaccine frozen also must be taken into account when deciding which vaccine to use. Several evaluations have been done on the evolution of the overall supply and its effect on price dynamic and several pharmacoeconomic models have been developed.[383–391] As mentioned in previous sections, in the scope of its GPEI Strategic Plan 2013–18,[392,393] WHO and all its stakeholders are engaged in promoting research and development activities toward the emergence of more affordable IPV solutions. As of today, the only concrete and available option is the Sabin IPV that has been developed by two manufacturers but because of their scale and location of production whether they are truly making IPV more "affordable" is not fully clear (see "Inactivated Polio Vaccine Manufactured from Sabin Strains" earlier).

Table 48.12 summarizes the advantages and disadvantages of each of the key regimens listed above. In essence, the key arguments for IPV usage are safety (no VAPP if starting first and no risk of inducing VDPVs if used alone), predictable and consistent humoral responses, and the possibility of its inclusion in combination vaccines. The key arguments for OPV usage are induction of better mucosal intestinal immunity, ease of administration to large populations, and possibility of indirect vaccination of contacts not reached by the routine immunization program. The arguments for using the two products in the schedule (whatever sequence) are to fuse the immunogenicity advantages of each vaccine with less or null

TABLE 48.12 Advantages and Disadvantages of OPV-Only, IPV-Only, Sequential, and Mixed/Combined Vaccination Schedules

Feature	OPV Only	IPV Only	IPV Followed by OPV	OPV Followed by IPV	Mixed/Combined
VAPP	1 case per 250,000 to 800,000 first vaccinations	No cases	VAPP cases eliminated when regimen starts with IPV (birth dose OPV not being a risk factor)	Same as with OPV only	VAPP risk linked to the timing of IPV use in the regimen
VDPV	Risk associated with performance of routine program	No risk	Risk associated with performance of routine program	Risk associated with performance of routine program	Risk associated with performance of routine program
Safety (other than VAPP and VDPV)	Excellent	Excellent	Excellent	Excellent	Excellent
Systemic immunity	Variable by-dose responses in some settings	Good	Good	Good	Good
Intestinal immunity	The gold standard	Much lower than with OPV, but shorter excretion and reduced titers in excreta after infection compared to unvaccinated Transmission impact variable	The gold standard	Ability of IPV to boost OPV-induced intestinal immunity	The gold standard and ability of IPV to boost OPV-induced intestinal immunity
Oropharyngeal immunity	Excellent	Excellent	Excellent	Excellent	Excellent
Prevention of AFP	Excellent	Excellent	Excellent	Excellent	Excellent
Transmission to contacts and secondary vaccination	Yes	No	Yes	Yes	Yes
Extra injections	No	Yes if IPV used as a standalone vaccine	Yes if IPV used as a standalone vaccine	Yes if IPV used as a standalone vaccine	Yes if IPV used as a standalone vaccine
Reduced compliance	No	Possible if standalone vaccine. Limited if used as an IPV-containing vaccine	Possible if standalone vaccine. Limited if used as an IPV-containing vaccine	Possible if standalone vaccine. Limited if used as an IPV-containing vaccine	Possible if standalone vaccine. Limited if used as an IPV-containing vaccine

AFP, acute flaccid paralysis; IPV, inactivated polio vaccine; OPV, oral poliovirus vaccine; VAPP, vaccine-associated paralytic polio; VDPV, vaccine-derived poliovirus.

risk of VAPP when IPV is started first (depending on the first OPV dosing timing) (discussed in detail in Chapter 48).

Endemic wild poliovirus circulation has been stopped in four of the six WHO regions, and wild poliovirus type 1 seems to be the only one serotype still circulating in three remaining endemic countries (Nigeria, Pakistan, and Afghanistan). The data as of the end of 2016 do clearly show that the circulation of wild polioviruses is at its lowest ever level.[394] It is undisputed that OPV has been the main driver in the successful eradication efforts in much of the developing world and has brought the progress of a greater than 99% reduction in cases since the GPEI began in 1988. It is also true and undisputed that the difficulties and the limits of OPV-only programs will never be able to achieve total and sustained eradication of disease caused by polioviruses because OPV itself can cause disease, either as VAPP or cVDPVs. This has been recognized by the WHO and its stakeholders after years of debate. As long as OPV is used, VAPP will remain a burden,[395] and VDPV a real threat to eradication.[396] The stated strategy of the WHO is to stop using any form of OPV once global eradication of wild polioviruses has been certified. The successful switch from tOPV to $bOPV_{1\&3}$ is a first step toward this OPV use eradication. After that milestone, it is likely that IPV will continue to be used in countries that manufacture IPV, and it is also likely that IPV will be made available to the other countries that wish to use it. The risk for countries that will stop using IPV is the potential for late recognition of a return of polioviruses.[397,398] Because so many infections are subclinical, by the time AFP cases are recognized, they are very difficult to contain, particularly if the underlying population immunity is low among cohorts born following the stoppage of all polio immunization. This strategy of not relying on IPV involves simply observing for poliovirus circulation in the environment and for cases of poliovirus-induced paralysis in the absence of vaccination and then use outbreak-specific monovalent OPV to contain the viruses when they are detected.[399] In this context, the well-known existence of immunocompromised individuals excreting immunodeficiency-related VDPVs for long periods of time[400] raises concern that in future years they could reseed the population. In addition, the theoretical risk of deliberate use of infectious virus derived from synthetic viral genomes as a biologic weapon also has to be considered.[401–403] Therefore, it is not possible to say today if (and possibly when and why) IPV usage will cease. The last GPEI Strategic Plan 2013–18 stated that "Recognizing that the risks associated with eventual bOPV cessation may be similar to those associated with OPV2 cessation, it is recommended that countries plan to continue administering at least one dose of IPV in their immunization programmes for at least 5 years after bOPV cessation."[392] With the new WHO strategy, the world has engaged in a larger use of IPV,[404–406] and the challenges are high.[407] Companies have multiple incentives to produce more IPV and develop new approaches to immunization against poliomyelitis. The more cogent response to cost is that IPV should not be used as a standalone vaccine with the attendant expenses of separate administration, but as part of combination vaccines.[408] Combinations containing IPV based on DTaP backbones are readily available, but one missing product is an affordable pentavalent or hexavalent combination made on a DTP backbone for low-income countries. As mentioned previously (see "Producers of Inactivated Polio Vaccine Antigen and Available Vaccines" earlier) several developments are ongoing. Sixty years after the birth of IPV[409] a very diverse experience has been accumulated with several IPV-containing vaccines. The appropriate IPV policy for a given country and the world should be driven by country and global goals, as well as societal values, epidemiologic characteristics, and other considerations.[410] In that context, many countries have adopted IPV but with different approaches in terms of immunization regimen, each approach adapted to the adopting country's specificities and objectives. It is undisputed that IPV will remain a tool in the fight against poliovirus and poliovirus-induced paralysis.

Acknowledgments

I am profoundly grateful to Stanley Plotkin who introduced me to the fascinating world of poliovirus and vaccination against poliomyelitis. This chapter could not exist without mentioning his essential contributions in all the previous editions. In addition, this chapter is dedicated to Dr. Charles Mérieux, the visionary founder of the Mérieux Institute (the pivotal root of Sanofi Pasteur) who played a pioneering and instrumental role in the rejuvenation of modern IPVs in the late 1970s.

References for this chapter are available at ExpertConsult.com.

49 Poliovirus Vaccine–Live

Roland W. Sutter, Olen M. Kew, Stephen L. Cochi, and R. Bruce Aylward

The written history of poliomyelitis can be traced back more than 200 years to the first description of the disease as a separate clinical entity by Michael Underwood in 1789.[1] Since then, many important scientific discoveries and public health milestones have been associated with poliomyelitis. Undoubtedly, the most consequential of these was the development of effective poliovirus vaccines,[2] which paved the way for the implementation of control programs, and a resolution by the World Health Assembly that established the goal of global eradication of poliomyelitis by the year 2000.[3]

Implementation of the eradication strategies led to elimination of poliomyelitis caused by wild poliovirus in the World Health Organization (WHO) Regions of the Americas, the Western Pacific, Europe, and South-East Asia, comprising more than 80% of world's population, and to substantial decreases in polio incidence in the rest of the world. Indigenous wild poliovirus type 2 was last detected in India in 1999, and indigenous type 3 was last detected in Nigeria in November 2012. By mid-2016, only three countries (Afghanistan, Pakistan, and Nigeria) have never interrupted indigenous wild poliovirus type 1 transmission, and the introduction of innovative new tools, such as monovalent oral poliovirus vaccines (mOPVs) in 2005 and bivalent OPV (bOPV) in 2009, and the greater use of inactivated poliovirus vaccine (IPV) since 2014 have facilitated progress toward eradication.

Although the written history of poliomyelitis is relatively succinct, an Egyptian stele from the 18th dynasty (dated between 1403 and 1365 BCE) depicts a "crippled young man, apparently a priest, with a withered and shortened right leg, and with his foot held in a typical equinus position characteristic of flaccid paralysis."[4] This stele demonstrates that poliomyelitis probably has affected humankind since ancient times. Underwood[1] introduced the term *debility of the lower extremities* in 1789; other researchers suggested a series of alternative terms, including *Lähmungszustände der unteren Extremitäten* in 1840,[5] *morning paralysis* in 1843,[6] *paralysie essentielle chez les enfants* in 1851,[7] *paralysie atrophiques graisseues de l'enfance* in 1855,[8] *spinale Kinderlähmung* in 1860,[9] *tephromyelitis anterior acuta parenchymatose* in 1872,[10] and *poliomyelitis anterior acuta* in 1874.[11] *Poliomyelitis anterior acuta* is based on anatomic location of lesions within the spinal cord—which was discovered in the early 1870s—and constructed from the Greek words *polios* (i.e., gray) and *myelos* (i.e., marrow, the gray matter of the spinal cord) with the ending "-itis" to imply inflammation. Although the terms *Heine-Medin disease* in 1907[12] and *infantile paralysis* were proposed subsequently, *poliomyelitis* (and the shortened term, *polio*) prevailed and became the standard designation for the disease.

In the late 19th and early 20th centuries, a change in the epidemiology of poliomyelitis from a predominantly endemic to an epidemic form was observed in Sweden and Norway,[12–14] heralding similar changes in other industrialized countries. Our understanding of these changes in the epidemiology was greatly aided by groundbreaking investigations of the three largest poliomyelitis outbreaks of the time: (a) 132 cases in Rutland County, Vermont, in 1894 by Charles Caverly[15]; (b) 1031 cases in Sweden in 1905 by Ivar Wickman[12,14]; and (c) more than 9000 cases in New York in 1916.[16] Wickman[14] was the first to recognize that abortive cases might equal or outnumber cases with paralytic manifestations and that these cases may be significant in the propagation of the infection. These outbreaks were caused by an accumulation of a sufficient number of susceptible children to sustain epidemic transmission of poliovirus, presumably because improvements in hygiene and sanitation had delayed poliovirus exposure from infancy to later in life.

Landsteiner and Popper[17] reported in 1908, on the basis of microscopic examination of spinal cords from two monkeys that had been injected intraperitoneally with a suspension of ground-up cord from a fatal human case, that a "filtrable agent" (i.e., virus) was the cause of poliomyelitis. In 1931, Burnet and Macnamara[18] determined that more than one serotype of virus could cause poliomyelitis and that immunity to one serotype did not confer immunity to another serotype. These investigators based their findings on cross-immunity and serologic tests; most importantly, they showed that three monkeys that had recovered from one serotype (and might have been expected to be immune) developed paralytic disease after injection of another serotype. This report had profound implications, although not immediately appreciated at the time, in terms of redefining the epidemiology of the disease and with respect to directing the subsequent development of vaccines. In 1948, an effort was launched to determine the number of distinct poliovirus strains. This effort was coordinated by the Committee on Typing of the National Foundation for Infantile Paralysis, which reported in 1951 that three and only three serotypes of poliovirus, designated types 1, 2, and 3, were the cause of poliomyelitis.[19] In 1949, Enders and colleagues[20] demonstrated that poliovirus could be grown in nonnervous, human embryonic tissue, work that was later honored with the Nobel Prize. Thus, the determination of the number of poliovirus serotypes, the ability for large-scale growth of the virus, and the finding that circulating antibody had a protective effect against poliomyelitis[21–26] were essential preconditions for the development of effective poliovirus vaccines.

Two approaches for vaccine development pursued at the time were successful: inactivation of poliovirus by formalin,[27] fully developed by Jonas Salk and colleagues, licensed as IPV in 1955 after one of the largest controlled field trials ever conducted[2]; and the attenuation of the three serotypes of poliovirus by Albert Sabin, licensed in 1961 as mOPV and in 1963 as trivalent OPV (tOPV).[28] The widespread use of IPV and OPV rapidly controlled poliomyelitis in industrialized countries.

The invention of the Drinker respirator (i.e., the "iron lung") beginning in 1928 and its widespread use in the 1930s and 1940s rapidly decreased the case-fatality rate of bulbar forms of poliomyelitis.[29] Epidemic poliomyelitis in the early part of the 20th century was associated with a high case-fatality rate (27.1% during the New York epidemic of 1916).[16,30,31] Further improvements in hygiene and sanitation delayed the median age of poliovirus infection from younger than 5 years in the 1910s to 5 to 9 years in the 1940s,[32,33] and allowed the accumulation of large numbers of people susceptible to poliomyelitis. Epidemics of ever-increasing magnitude began to occur in the United States and Europe until the mid to late 1950s, when vaccines became available

and changed the epidemiology anew. Because increasing age seemed to be the primary risk factor for bulbar paralysis—the basis for the "central dogma" of the epidemiology of poliomyelitis[34]—an increasing proportion of cases required respiratory support, and whole wards of iron lungs were devoted to caring for bulbar poliomyelitis victims in the 1940s and 1950s.

Poliomyelitis is intimately linked with some of the greatest triumphs in medicine, including scientific breakthroughs, public health achievements, and advancements in social justice. The concept of social justice, the indiscriminate benefit of scientific discoveries or access to care and rehabilitation, was pioneered by the National Foundation for Infantile Paralysis, which raised funds through annual March of Dimes campaigns that covered treatment and rehabilitation costs of poliomyelitis victims.[35] The Omnibus Budget Reconciliation Act (1993), which established the Vaccines for Children Program, ensures that poliovirus vaccines are available for poor children in the United States. Ultimately, the successful conclusion of the Global Polio Eradication Initiative (GPEI) will benefit all children equally.

The history of poliomyelitis has been reviewed in detail by Paul[4] and Eggers.[36]

WHY IS THE DISEASE IMPORTANT?

Poliomyelitis was the leading cause of permanent disability in children in the prevaccine era.[32] Besides the considerable disease burden, poliomyelitis was much feared in the prevaccine era because it could strike anybody, no means existed of protecting oneself or one's children, and, unlike the situation with other diseases such as measles, from which most children recover or die rapidly, society was reminded every day of the devastating effects of this crippling disease.

Disease control programs using poliovirus vaccines have prevented and continue to prevent millions of children from becoming paralyzed. In 1988, when the global eradication target was adopted, the WHO estimated that approximately 350,000 cases of paralytic poliomyelitis were occurring annually,[37] despite availability of effective vaccines during the prior 3 decades. Poliomyelitis has gained renewed attention in recent years because the feasibility of its eradication has been demonstrated[37,38] and because of the visibility of the ongoing global effort to eradicate poliovirus.[39–41]

BACKGROUND

Clinical Description

Poliomyelitis is an acute infectious disease caused by any of three serotypes of poliovirus that replicate initially in the gastrointestinal (pharyngeal and intestinal) tract and, rarely, in the motor neurons of the anterior horn cells in the spinal cord, where replication of virus results in cell destruction and flaccid paralysis of the muscles the cells innervate (i.e., spinal poliomyelitis). On occasion, brainstem cells innervating respiratory muscles can be affected, resulting in difficulties in breathing (i.e., bulbar paralysis). In addition to the acute paralysis, late manifestations with exacerbation of weakness or new paralysis (i.e., postpolio syndrome) can be observed in a significant proportion of patients decades after the acute paralytic episode.

Poliovirus exposure in a person susceptible to poliomyelitis results in one of the following consequences: (a) inapparent infection without symptoms, (b) minor illness, (c) nonparalytic poliomyelitis (aseptic meningitis), or (d) paralytic poliomyelitis.[32,42–44] Inapparent infection without symptoms is the most frequent outcome (72%) after poliovirus exposure in susceptible people.[45] Minor illness is the most frequent form (24%) of the disease, characterized by transient illness associated with a few days of fever, malaise, drowsiness, headache, nausea, vomiting, constipation, or sore throat, in various combinations.[45] Nonparalytic poliomyelitis (aseptic meningitis) is a relatively rare outcome (4%) of poliovirus infection. It begins usually as a minor illness characterized by fever, sore throat, vomiting, and malaise, and 1 to 2 days later, signs of meningeal irritation become apparent, including stiffness of the neck or back; vomiting; severe headache; and pain in the limbs, back, and neck.[42] This form of the disease lasts 2 to 10 days, and recovery is usually rapid and complete. In a small proportion of these cases, the disease advances to transient mild muscle weakness or paralysis.

Paralytic poliomyelitis is a rare outcome (usually <1%) of poliovirus infections among susceptible persons. Its clinical course is characterized by a minor illness of several days and a symptom-free period of 1 to 3 days, followed by rapid onset of flaccid paralysis with fever and progression to the maximum extent of paralysis within a few days. This characteristic clinical course of a minor illness followed by the major illness with paralysis has been likened to the two humps of the dromedary.[46,47] (In actuality, this is a misnomer, because the dromedary is a one-humped camel.) Among adolescent and adult cases of poliomyelitis, the minor illness is often absent, and these groups also seem to experience more severe pain in the affected extremities. After the resolution of fever, usually there is no further progression of paralysis. If paralysis of an extremity is not complete, it is more pronounced proximally. Paralysis is usually asymmetric, associated with diminished or complete loss of deep tendon reflexes and an intact sensory system. Paralytic manifestations in extremities begin proximally and progress to involve distal muscle groups (i.e., descending paralysis). Depending on the anatomic location of motor neuron damage in the spinal cord or in the brainstem, spinal, mixed spinal-bulbar, or bulbar paralysis involving primarily respiratory muscles may be observed. The anterior horn cells (and brainstem cells), just like other nerve cells of the central nervous system (CNS), cannot be regenerated or replaced and paralysis is permanent. Nevertheless, because of compensation of other, still functioning muscles, partial or total recovery can be achieved, usually within the first 6 months after onset of disease. Detailed clinical descriptions may be found in a number of reviews and books.[48–51]

Postpolio syndrome, a term invented in the early 1980s, refers to a disease entity that encompasses the late manifestations of acute paralytic poliomyelitis.[52] Aside from previously published case reports and case series, the first systematic investigation of postpolio syndrome was published in 1984.[53] After an interval of 15 to 40 years, many people (25% to 40%) who contracted paralytic poliomyelitis in their childhood may experience muscle pain and exacerbation of existing weakness or may develop new weakness or paralysis. Factors that enhance the risk of postpolio syndrome include: (a) increasing time since acute poliovirus infection, (b) presence of permanent residual impairment after recovery from the acute illness, and (c) female sex. The exact cause of these late effects is unknown, although it is not a consequence of persistent infection. The pathogenesis of postpolio syndrome is thought to involve late attrition of oversized motor units that developed during the recovery process of paralytic poliomyelitis.[52] Postpolio syndrome has been described in people infected during the era of wild poliovirus circulation. An excellent summary of the current scientific knowledge of postpolio syndrome has been published.[54]

Virology

General Properties of Polioviruses. Polioviruses, as members of species-C of the *Enterovirus* genus of the family *Picornaviridae* (*piccolo*, Italian, small; *rna*, RNA genome), share most properties with other members of that species and genus.[55–57] Polioviruses are small (~30 nm in diameter[58]), nonenveloped viruses with capsids of icosahedral symmetry enclosing a single-stranded, positive-sense RNA genome. Poliovirus capsids contain no essential lipids, and infectivity is insensitive to inactivation by detergents and lipid solvents such as ether, chloroform, and alcohol.[59] The viruses are stable at pH 3 to 5 for 1 to 3 hours, and can therefore pass through the stomach without inactivation. Exposure to 0.3% formaldehyde, pH of less than 1, pH of greater than 9, or free residual chlorine at 0.3 to 0.5 parts per million causes rapid inactivation. Infectivity is stable indefinitely at −20°C or lower, and stable for weeks at 4°C, but is rapidly inactivated at temperatures above 50°C.[60] Molar concentrations of $MgCl_2$ significantly increase the thermal stability of poliovirions,[61] both at elevated and ambient temperatures, and $MgCl_2$ is added to many OPV preparations to preserve potency.[62,63]

The genome is approximately 7500 nucleotides long, has a small (22-amino acid) basic protein, VPg, covalently linked to the 5′ end, and is polyadenylated at the 3′ end. The single open reading frame is flanked by a long (~740 nucleotides) 5′-untranslated region (5′-UTR) and a short (~70 nucleotides) 3′-UTR. Complete genomic sequences have been determined for numerous representatives of each the three serotypes, including those of the three Sabin OPV strains.[64] Only the sequences encoding the capsid proteins are unique to polioviruses, as the flanking sequences are frequently exchanged by recombination with the closely related species-C enteroviruses during circulation.[65–69] The poliovirion consists of 60 copies each of four capsid proteins (VP1–VP4) that form a highly structured capsid shell.[58] The three major proteins (VP1, VP2, VP3) share a similar basic architecture and were probably derived from a common ancestral protein.[58] The smallest protein, VP4, internalized in the native virion, is formed by the cleavage of the precursor VP0 (VP4 + VP2) during final maturation of the virion. The external surface of the poliovirion is decorated by peptide loops extending from VP1, VP2, and VP3, which form the neutralizing antigenic sites.[70,71] Polioviruses attach to and enter cells via the specific poliovirus receptor (PVR) on the cytoplasmic membrane; the PVR was later identified as CD155 (cluster of differentiation 155) or Necl5 (nectin-like molecule 5), a transmembrane glycoprotein with three extracellular immunoglobulin-like domains.[72–75] CD155 normally functions as a cell adhesion molecule that controls cell movement and proliferation, especially during embryonic development,[75] a function that is "misused" by poliovirus to gain entry into human cells.[76] The key distinguishing properties of poliovirus capsids are their antigenic surfaces and their abilities to specifically bind to CD155, as the sequences and structures of the internal capsid domains are largely conserved among species-C enteroviruses.

Antigenic Properties. There are three poliovirus serotypes (Table 49.1).[19,77] The three-dimensional X-ray crystallographic structures of representatives of all three serotypes have been determined.[58,79,80] Three (or four) neutralizing antigenic sites have been identified by patterns of reactivity with neutralizing murine monoclonal antibodies,[70] and the assignments have been confirmed by high-resolution X-ray crystallography.[79–81] Neutralizing antigenic site 1 is continuous and formed by a loop in VP1; sites 2 and 3 are discontinuous and formed from loops contributed by different capsid proteins. The major type-specific differences in the capsid polypeptides primarily reside on the most surface-accessible peptide loops, which represent less than 4% of the total capsid protein.[64] Although the neutralizing antigenic sites vary within each serotype,[82–90] the range of variability is constrained, possibly because of steric requirements for interaction with CD155,[91,92] such that all polioviruses within a serotype can be neutralized by type-specific antisera and poliovirus vaccines (both IPV and OPV) can induce protective immunity to all known antigenic variants. Poliovirus antigenic evolution differs importantly from that of influenza virus in that there is no cumulative antigenic divergence from ancestral viruses during person-to-person transmission, and genetically unrelated viruses may have similar antigenic properties and shared epitopes.

Limited cross-neutralization has been observed for all three poliovirus serotypes,[95] and a shared epitope between types 1 and 2 has been identified by mapping escape mutants to cross-reactive neutralizing monoclonal antibody.[96] Recently, chimeric chimpanzee–human monoclonal antibodies have been produced showing patterns of strong cross-neutralization.[97] Epitope mapping with these primate monoclonal antibodies have identified shared determinants not previously recognized by studies using murine monoclonal antibodies,[97] suggesting that the poliovirus antigenic surface may be more complex than previously thought.

Poliovirus antigenic properties have been reviewed by Minor.[70]

Poliovirus Replication Cycle. Poliovirus (and picornavirus) replication has been reviewed in depth.[55,98,99] Virus attaches to cells through specific interactions between the aminoterminal variable domain 1 of CD155 and a "canyon" that surrounds the fivefold axis of the virion.[92,100–104] After endocytosis, viral RNA is uncoated and released into the cytoplasm,[104] VPg is cleaved from 5′ end of the RNA, and the RNA is translated. Translation is under the control of the internal ribosome entry site (IRES), an element (nucleotides ~130–600) within the 5′-UTR that has a highly conserved stem–loop structure.[99,105] The translation product is a single polypeptide, the polyprotein, which is cleaved by virus-encoded proteinases, $2A^{pro}$ and (primarily) $3C^{pro}$, into mature viral proteins.[106] Host protein synthesis is rapidly inhibited by the cleavage by $2A^{pro}$ of the translation initiation factor eIF4G, which is required for initiation of translation of capped host messenger RNA but not for the internal initiation of translation from the poliovirus IRES.[99,107] One cleavage product is $3D^{pol}$, an RNA-dependent

RNA polymerase, that catalyzes the synthesis of negative-polarity (−) RNA strands from the genomic and messenger RNA–polarity (+) strands forming a duplex called the replicative form.[108,109] Multiple copies of positive RNA strands are produced from negative-strand templates in replicative intermediates arrayed in intracellular membrane complexes.[108,109] VPg is cleaved from some newly synthesized positive RNA strands for programming as messenger RNA and further translation.[106] Other positive strands are encapsidated during the maturation step in which the VP0 precursor to VP4 and VP2 is cleaved followed by release of infectious virions from the infected cell. The entire replication cycle takes place within the cytoplasm, and poliovirus can replicate in anucleate cells. Infected cells show cytopathic effects within 6 hours, and can release up to 10,000 infectious virus particles upon cell lysis and death. This rapid rate of cellular destruction accounts for the rapid progression of paralysis when poliovirus infects motor neurons.[110]

PATHOGENESIS AS IT RELATES TO PREVENTION

The pathogenesis of poliovirus infection indicates that prevention through immunization can be accomplished by inhibiting replication at and dissemination from the gastrointestinal tract, by inhibiting the viremia that follows, or by doing both. After a person is exposed to poliovirus by way of the oral cavity, the virus attaches and enters specific cells that express the PVR.[72] The virus replicates locally at the sites of virus implantation (e.g., tonsils, intestinal M cells, and Peyer patches of the ileum) or at the lymph nodes that drain these tissues. The first approach to prevention requires the presence of local secretory immunoglobulin (Ig) A antibody. The second approach, because spread occurs primarily by way of the bloodstream to other susceptible tissues (i.e., other lymph nodes, brown fat, and the CNS) or by way of retrograde axonal transport to the CNS, requires the presence of circulating neutralizing antibody.

The host range of poliovirus and tissue tropism is determined by the expression of the PVR.[72] Tissue tropism refers to the ability of poliovirus to replicate in specific cells.[111] Early studies on poliovirus pathogenesis were conducted in primates, but the development of PVR transgenic mice has led to a renaissance in pathogenesis studies.[112,113] Most of the earlier observations with primates[48,49,51] have been confirmed in the PVR transgenic mouse model,[113] and new tools have been used to investigate important unresolved questions about poliovirus pathogenesis. For example, in situ hybridization with nucleic acid probes of the PVR in transgenic mice suggested PVR expression was limited to the CNS, thymus, lung, kidney, and adrenal glands, and, more recently, to monocytes (mononuclear phagocytes).[114] Replication of poliovirus in motor neurons results in cell destruction and paralysis. The chief limitation of the mouse model is the low level of expression of the PVR in mouse intestinal tissue, resulting in inefficient replication of virus at the primary site of natural infection.[113] The transgenic mouse model has facilitated neurovirulence studies but has limited usefulness in assessing the infectivity or transmissibility of the different poliovirus strains because of the difficulties in orally infecting the mice. Thus, the lack of an animal model to study infectivity and transmissibility of poliovirus remains a major obstacle in learning more about these aspects of the poliovirus.

Poliovirus may be found in the blood of patients with the abortive form ("minor illness"), and it can be detected several days before onset of clinical signs of CNS involvement in patients in whom nonparalytic or paralytic poliomyelitis develops.[24,115] The virus is regularly present in the throat and in the stools before the onset of illness. In persons who have clinical or subclinical infection, virus is excreted in the feces for several weeks[45] and in saliva for 1 to 2 weeks. The mean duration of wild poliovirus type 1 excretion in fecal specimens is 24 days (median, 20–29 days), with an observed range of 1 to 114 days.[45]

For further details of pathogenesis and pathology, see Bodian,[48] Bodian and Horstmann,[49] Sabin,[51] Racaniello and Ren,[113] Mueller, Wimmer, and Cello,[116] Nathanson,[117] and Koike and Nomoto.[118]

DIAGNOSIS

Paralytic poliomyelitis caused by imported wild poliovirus or by vaccine-related poliovirus has become a rare disease in the United States and other industrialized countries. Therefore, physicians may not be familiar with the disease or consider the diagnosis of poliomyelitis until other more frequent causes of acute flaccid paralysis (AFP) have been ruled out. The diagnosis of paralytic poliomyelitis is dependent on the following: (a) clinical course, (b) virologic testing, (c) special studies, and (d) residual neurologic deficit 60 days after onset of symptoms. For surveillance purposes, any case with physician-diagnosed suspected poliomyelitis is investigated in the United States, and a case is confirmed if a panel of independent experts determines that the case definition* for paralytic poliomyelitis has been met. The WHO is using a sensitive screening case definition: any case of AFP in a person younger than 15 years of age or a case in a person of any age in whom poliomyelitis is suspected. This definition attempts to capture all cases of paralysis that might be caused by poliovirus, including cases erroneously diagnosed as other clinical syndromes such as Guillain-Barré syndrome. This sensitive screening definition is balanced by a specific case classification system (i.e., virologic case classification scheme) that relies on isolation of poliovirus from stool specimens to confirm cases of AFP as poliomyelitis. As countries improve the quality and timeliness of AFP surveillance, the virologic case classification has replaced the clinical case classification scheme in all endemic and recently endemic countries (see "Disease Control Strategies" later).

Clinical Course

The clinical course (see "Clinical Description" earlier) is helpful in ruling in or ruling out paralytic poliomyelitis. Several studies in the developing world have attempted to assess the sensitivity and specificity of different clinical case definitions for paralytic poliomyelitis and compared these with the "gold standard" of virologically confirmed poliomyelitis based on poliovirus isolation from stool specimens. These studies reported similar findings.[119–121] The largest study reported a sensitivity of 64% and a specificity of 82% for a case definition that included age younger than 6 years, fever at onset, and rapid progress to maximum extent of paralysis (≤4 days).[119] The addition of a specific pattern of paralysis (proximal, unilateral, or absence of paralysis in all four extremities) increased the specificity with varying degrees of loss in sensitivity. The case definitions and case classification schemes have been reviewed.[122] Data from India suggest that residual paralysis 60 days after onset of paralysis is the strongest predictor for confirmed poliomyelitis (i.e., isolating wild

*"A patient must have had paralysis clinically and epidemiologically compatible with poliomyelitis and, at 60 days after onset of symptoms, had residual neurologic deficit, had died, or had no information available on neurologic residua." This case definition was formerly known as best available paralytic poliomyelitis case count.

poliovirus in stool samples during the initial examination). These findings highlight the importance of a 60-day follow-up examination to assess whether areas with wild poliovirus circulation may have been missed.

Virologic Testing

Because AFP has many etiologies, including Guillain-Barré syndrome, transverse myelitis, and infection with nonpolio enteroviruses (see "Differential Diagnosis" later), laboratory confirmation is critical to establishing the diagnosis of poliomyelitis. The basic approach is to attempt to isolate poliovirus from the stools of patients with AFP, and to characterize any poliovirus isolates to determine whether they are vaccine-related or wild. Detailed descriptions of standard laboratory principles and procedures for investigation of enterovirus infections are available.[123] The WHO has published a manual for the virologic investigation of poliomyelitis cases that includes protocols for the isolation of poliovirus.[124] This manual has become the standard guide for the isolation and characterization of polioviruses for laboratories in the WHO's Global Polio Laboratory Network (GPLN, see "Surveillance" later) for poliomyelitis eradication and is widely used in other diagnostic laboratories.

Poliovirus Isolation

Polioviruses can be grown in a wide range of human and simian cells (see http://www.atcc.org/),[123] but two cell lines are routinely used in combination by the GPLN for virus isolation[124]: (a) RD cells (a continuous line from human rhabdomyosarcoma[125]), which are highly sensitive to poliovirus infection and yield virus at high titers,[59] and (b) L20B cells (a derivative of the mouse L cell line engineered to express the human PVR, CD155), which are highly selective for growth of poliovirus.[124,126] RD cells have the advantage of being very sensitive to poliovirus infection and yielding high poliovirus titers in culture. RD cells will support the replication of other human enteroviruses, but not Coxsackie B viruses. L20B cells will support the replication of polioviruses, but, like their parenteral mouse L cells, are resistant to infection by most nonpolio enteroviruses. Thus L20B cells are used for the selective cultivation of polioviruses.

Poliovirus may be recovered from stool, throat swabs, or cerebrospinal fluid taken soon after the onset of illness and from stool specimens collected over longer periods of time (usually up to 8 weeks after the start of infection).[127] Poliovirus isolation rates from cerebrospinal fluid are generally low; however, when virus is found, a causal relationship between a poliovirus serotype and paralytic disease is strongly suggested. The WHO recommends that two stool samples be collected at least 24 hours apart to confirm the diagnosis, because excretion of virus can be intermittent and the sensitivity of isolation is less than 100%. Wild poliovirus has been found in stool samples of 63% to 93% of patients during the first 2 weeks of illness, in 35% to 75% during the third and fourth weeks, and in less than 50% during the fifth and sixth weeks.[127] The duration of viral shedding is reduced among children who were previously vaccinated, had preexisting homologous antibody induced by live poliovirus, or had a previous intestinal infection with homologous poliovirus.[127]

Clinical specimens are processed to produce a virus suspension largely free of bacteria and other debris, to which antibiotics are added to inhibit the growth of residual bacteria, and the suspension is inoculated onto cell cultures. Cells are monitored daily for cytopathic effects, which appear typically within 3 to 6 days of incubation.

Molecular Identification Methods

Intratypic differentiation (ITD) of poliovirus isolates (testing whether they are vaccine-related or wild) is performed throughout the GPLN using real-time reverse transcriptase-polymerase chain reaction (rRT-PCR).[124] A series of primer pairs and specific fluorescent probes have been developed that identify isolates hierarchically: (a) as enteroviruses (panEV), (b) as polioviruses (panPV), (c) by poliovirus serotype (Sero1, Sero2, Sero3), and (d) whether vaccine-related (Sab1, Sab2, Sab3).[128–130] The sets of rRT-PCR reagents are deployed as kits for routine use by the GPLN.[131] Molecular reagents and technical conditions for rRT-PCR are regularly updated to improve diagnostic sensitivities and meet changing GPEI needs. For example, current ITD kits no longer use the Sero1, Sero2, Sero3 reagents and new rRT-PCR reagents have been introduced that identify wild polioviruses by genotype and facilitate screening for genetically divergent vaccine-derived polioviruses (VDPVs) (VDPV1, VDPV2, VDPV3).[132,133] The rapid evolution and high genetic diversity within and across poliovirus serotypes presented special challenges to development of the panPV and serotype-specific primer and probe sets, as it was necessary to use degenerate and inosine-containing oligonucleotides to base-pair with the appropriate specificities at positions of codon degeneracy.[128,129] Although the nondegenerate Sabin vaccine strain-specific rRT-PCR reagents can be used in a multiplex format, the complexity of the degenerate reagents limits the number of reactions that can be combined in multiplex.

ITD screens for wild polioviruses and VDPVs and screens out OPV-like polioviruses that are unlikely to be of current epidemiologic importance. Since 2001, all wild poliovirus and VDPV isolates are sequenced by GPLN laboratories following standardized procedures and using standardized sequencing primer sets. The approximately 900-nucleotide interval (representing ~15% of the total genome) encoding the major capsid protein, VP1, is routinely sequenced. VP1 sequences are used for routine comparisons because they encode several serotype-specific antigenic sites[70] and evolve primarily by successive fixation of nucleotide substitutions rather than by recombination.[88,134] Wider genomic intervals, up to the complete genome, may be sequenced to obtain higher epidemiologic resolution or to address specific virologic questions.[66,85,135,136] Serotype- and genotype-specific sequencing primers have been developed to specifically amplify components of heterotypic and homotypic poliovirus mixtures, bypassing selective cultivation in the presence of neutralizing antibody or incubation at supraoptimal temperatures.[137] Sequence relationships among poliovirus isolates are summarized in phylogenetic trees and genotypic maps that are distributed monthly by GPLN laboratories to Ministries of Health, WHO Country and Regional Offices, WHO-Geneva, and other GPLN laboratories. The use of genomic sequencing has given rise to a new discipline that combines the tools and concepts of classical epidemiology with those of microbiology, biochemistry, genetics and evolutionary biology (see "Molecular Epidemiology of Poliovirus" later).[138]

Environmental Surveillance

Environmental surveillance by sampling of sewage is an important supplement to AFP surveillance that can increase the sensitivity for detecting poliovirus circulation and excretion because most poliovirus infections are inapparent.[139] Environmental surveillance is widely implemented in Europe (conducted by 20 countries, including Israel[140–144]) and Japan[145] as a component of enterovirus (and poliovirus) surveillance. In 2013–14, sustained circulation in Israel of wild poliovirus

type 1 originating from Pakistan was detected by routine environmental surveillance in the absence of polio cases.[146,147] Israel responded by conducting nationwide vaccination campaigns with IPV and bOPV whose impact on wild poliovirus circulation was monitored by environmental surveillance.[146,147] Routine environmental surveillance has been conducted in Egypt since 2000,[148–150] and has been extended to India,[151] Pakistan,[152] Nigeria,[153] and Afghanistan,[139] with plans for further expansion in countries at high risk of reestablishment of poliovirus circulation either by importation or by the emergence of circulating vaccine-derived polioviruses (cVDPVs).[139] Environmental surveillance has also provided supportive evidence for the eradication of wild poliovirus type 3.[154]

Environmental surveillance has also helped inform the endgame strategy for the GPEI. A key question is the persistence of vaccine-related viruses in the population and environment following cessation of OPV use. In Cuba, where OPV is delivered only in mass campaigns in the form of two rounds of National Immunization Days (NIDs), vaccine-related viruses were detected in stool surveys for up to 8 weeks and in the environment for up to 15 weeks after the second NID round.[155] New Zealand shifted from OPV to IPV in February, 2002, and vaccine-related viruses were regularly detected in sewage samples until May, 2002. Sporadic vaccine-related isolates detected subsequently showed very limited sequence divergence from the parental OPV strains, indicating that they were recent imports from OPV-using countries rather than persistence of vaccine-related viruses in the community.[156] The pilot IPV project in Yogjakarta Province in Indonesia has by-and-large confirmed these findings.[157]

An important difference between environmental sampling and AFP surveillance is that environmental sampling is most sensitive in locations with developed sewage systems or open sewage canals in large slums, and therefore is usually established in more urbanized settings. Sewage sampling sites in urban centers are selected to include communities of migrant populations from rural areas. Environmental surveillance is necessarily localized, targeted, and intermittent, in contrast to a well-functioning AFP surveillance system that monitors the entire population on a continuous basis. Consequently, poliovirus isolates obtained by the two surveillance approaches may yield different kinds of public health information. For example, a wild poliovirus isolate from an AFP case is directly linked to a specific patient from a specific locale, and usually signals many other inapparent infections in the community. In contrast, the high sensitivity of environmental sampling can result in multiple poliovirus isolations from a single infected person, but does not yield further information about the specific source of infection. However, some information about the extent of poliovirus circulation can be obtained from the extent of genetic diversity of polioviruses obtained at a sampling site.[150,158]

Serologic Testing

Serologic testing may be helpful in establishing the diagnosis but often does not contribute, and sometimes may cause confusion, because (a) antibody rises have already occurred by the time the first specimen has been collected, (b) antibody may be present to one or more serotypes because of previous or recent vaccination, and (c) heterotypic responses may be observed to one serotype after exposure to another serotype. There are no reliable means of distinguishing antibody induced by vaccine-related versus wild poliovirus. Standard protocols for neutralization assays to determine levels of antibody to poliovirus are available.[124,159] Paired serum specimens are required to demonstrate a fourfold or greater rise in antibody titer between acute and convalescent sera. The first serum specimen should be collected as soon as possible after onset of paralytic manifestations, and the second specimen should be collected 2 to 3 weeks later. Neutralizing antibodies appear early and are usually already detectable at the time of onset of paralysis. However, if the first specimen is taken early enough, a rise in titer may be demonstrated during the course of the disease. In a study from Louisiana, specimens were collected as soon as possible after hospital admission from poliomyelitis patients and approximately 6 weeks later; in 36% of patients, a fourfold rise in poliovirus antibody titer could be demonstrated; in 61% of patients, reciprocal titers were above 320 and did not change; and in 3% of patients, reciprocal titers were below 320 and remained unchanged.[160]

Neutralizing assays using Sabin strains continue to be the gold-standard method for the detection of type-specific antibody in sera.[22,160a] Neutralization antibody induced by a single serotype may not be completely serotype specific. In practical terms, this seldom constitutes a problem because the heterotypic response results in low levels of neutralizing antibody. Because of the limitations described, serology may be more important in excluding (e.g., no detectable antibody) the diagnosis of poliomyelitis than in confirming it. However, intrathecal immune responses can be measured and offer the advantage of attributing a causal relationship between a poliovirus serotype and paralytic disease.[161] The GPLN has developed standardized tests for poliovirus IgA and IgM antibody in serum.

Special Studies

Nerve conduction and electromyography studies can point to the anatomic location of the paralysis[162]—destruction of anterior horn cells in the spinal cord versus a demyelinating or axonal degenerative process in the peripheral nerves—helping to exclude the most frequent cause of nonpolio AFP, Guillain-Barré syndrome. Magnetic resonance imaging has been used infrequently, but, in at least one patient with poliomyelitis, it highlighted the anterior column of the spinal cord.[163] Analysis of spinal fluid may be helpful in ruling out other causes. In paralytic poliomyelitis, the cerebrospinal fluid contains an increased number of leukocytes, usually 10 to 200/mL, and seldom more than 500/mL.[164,165] At the onset of signs of CNS involvement, the ratio of polymorphonuclear cells to lymphocytes is high, but within a few days, the ratio is reversed. The total white blood cell count slowly subsides to normal levels. The protein content of the cerebrospinal fluid initially is elevated only slightly (average, in nonparalytic cases, is approximately 46 mg/100 mL [range: 15–165 mg/100 mL]; in paralytic cases, the average is approximately 68 mg/100 mL [range: 25–250 mg/100 mL]), but it rises gradually in paralytic cases until the third week, generally returning to normal by the sixth week.[164] Glucose levels are usually within the normal range. In fatal cases, spinal cord and brainstem tissue samples should be examined for the typical lesions caused by viral replication and destruction of the motor neuron cells.

Residual Neurologic Deficit

The clinical case definition for paralytic poliomyelitis requires a residual neurologic deficit at 60 days after onset of paralysis. Such a neurologic deficit may be apparent as complete flaccid paralysis of one or more extremities or partial paralysis or weakness of muscles or muscle groups. In the latter instance, because of functional recovery (intact muscles may compensate for muscles that are not innervated), it may be more difficult to establish a neurologic deficit. The most severe cases of poliomyelitis in terms of complications and fatal outcomes occur in persons with underlying immunodeficiency disorders.

Differential Diagnosis

The differential diagnoses of AFP have been reviewed.[166] The list of underlying causes of AFP is extensive (Table 49.2). The causes can be classified according to the pathophysiologic mechanisms and anatomic sites of the etiologic factors. For example, poliovirus damages primarily the anterior horn cells of the spinal cord. This damage leads secondarily to paralysis of extremity muscles (Fig. 49.1). The distinguishing features of poliomyelitis—Guillain-Barré syndrome, transverse myelitis, and traumatic neuritis (neuritis secondary to the trauma of injections)—are given in Table 49.3.

In general, in the absence of wild virus-induced poliomyelitis, Guillain-Barré syndrome accounts for 50% or more of the cases of AFP in industrialized countries such as the United Kingdom and Australia, and in developing countries in Latin America.[167–169] At times, nonpolio enteroviruses have been associated with cases of polio-like paralytic disease, but this has been uncommon. Coxsackie virus A7 has been associated with outbreaks of paralytic disease,[170,171] and enterovirus 71 has been involved in several outbreaks of CNS disease, including polio-like paralysis, resulting in fatal cases,[172] with recent large outbreaks in East Asia.[173,174] More recently, a novel enterovirus D68 strain was associated with AFP in the United States.[175,175a] Two motor neuron diseases in childhood are Werdnig-Hoffmann disease, a rapidly progressing, often fatal disorder of early childhood, and Wohlfart-Kugelberg-Welander disease, a more benign disorder with a generally later onset.[176] Electromyographic findings are useful in establishing the diagnosis of these disorders.[177] China paralytic syndrome, a distinct disease entity that appears different from Guillain-Barré syndrome and poliomyelitis, has been described among children and adults in northern China.[178] Early symptoms of this disease include leg weakness and resistance to neck flexion. The weakness ascends rapidly, affects symmetrically the arms and respiratory muscles, and progresses to a maximum extent of weakness within 6 days on average. Electromyography indicates denervation potentials in weak muscles and suggests

TABLE 49.2 Causes and Differential Diagnosis of Acute Flaccid Paralysis

INFECTIOUS	
VIRAL	
Enteroviruses	Poliomyelitis, Coxsackie A (A7, A9, A4, A5, A10) and Coxsackie B (B1–B5), echoviruses (6, 9; 1–4, 7, 11, 14, 16–18, 30) enterovirus D68, enterovirus 70, enterovirus 71
Other viruses	Myxoviruses (mumps virus), togaviruses, and arborviruses, Epstein–Barr virus; HIV, Japanese B encephalitis virus, West Nile virus
Bacterial	*Campylobacter jejuni* (leading cause of Guillain-Barré syndrome)
METABOLIC: TRANSIENT AND PERIODIC PARALYSES	
Hypokalemic	Familial, Sjögren syndrome, hyperthyroidism, gossypol-induced (toxic phenolic pigment in cottonseed), association with barium poisoning, association with hyperaldosteronism
Normokalemic or hyperkalemic	Familial, adynamia episodica hereditaria of Gamstorp
Hypophosphatemia	
DRUG INDUCED	
Heroin	
Antibiotics	Aminoglycosides, polymyxin B, tetracyclines
ORGANIC	
Volatile hydrocarbons	Hexane, methyl butyl ketone, carbon disulfide
Tricresyl phosphate	Jamaican ginger tonic; contamination of cooking oil, mustard oil, or flour
Other	Cantharidin, diethyltoluamide (DEET), dithiobiuret (rat poison), triethyldodecyl ammonium bromide (mouse poison)
TOXIN	
Bacterial	Botulinum, diphtheria, tetanus (cephalic form), *Moraxella*
Fungal: mycotoxins	*Penicillium citreoviridae, Penicillium islandicum, Penicillium citrinum*
Insect	Tick paralysis; spider venom; cockroach, beetle; wasp venom; Lepidoptera larvae
Parasite, protozoa, dinoflagellate	Paralytic shellfish poisoning–saxitoxin, ichthyotoxism (sardines)
Reptiles: snake venom	Cobra, Australian elapid, krait, mamba, sea snake
Plants and plant toxin	*Gloriosa superba* (daisy [root]), *Lathyrus* species (sweet pea), *Aconitum* (monkshood), hemlock (parsley), *Karwinskia humboldtiana* (*Coyotillo*; buckthorn [berries]), *Calliopsis* species (daisy), *Cassia* (bean), *Cycas* (evergreen [seeds]), *Gelsemium* (blossoms), *Heliotropium* (bush tea shrub), *Melochia* species (stems), *Oenanthe* species (parsnips)
Metals	Organic tin compounds, lead
Pesticides	EPN, trichlorfon (Dipterex), dichlorvos (DDVP), DEF, isofenphos (Oftanol), leptophos (Phosvel)
Inherited, congenital, acquired	Werdnig-Hoffmann disease, Wohlfart-Kugelberg-Welander disease, porphyric polyneuropathy
Unknown, multiple causes	Guillain-Barré syndrome, China paralytic syndrome, Bell palsy, transverse myelitis
Asthma	Polio-like Hopkins syndrome

EPN, ethyl *p*-nitrophenyl thionobenzene phosphonate.

that this entity may be a reversible distal motor nerve terminal or anterior horn lesion. Tick-bite paralysis occurs infrequently and is manifested by flaccid ascending paralysis that usually resolves rapidly after tick removal. Botulism toxins can also cause descending paralysis—characterized by symmetric impairment of cranial nerves, followed by a descending pattern of weakness or paralysis of the extremities and trunk.[179] A relatively frequent complication among approximately 10% to 15% of patients with diphtheria is paralysis of the soft palate and peripheral nerves resulting from diphtheria toxin[180]; tetanus toxin can cause flaccid paralysis of the muscles innervated by the affected cranial nerves (i.e., cephalic tetanus).[181] Case reports have linked AFP and West Nile virus (a flavivirus) infection among elderly adults in Mississippi and Louisiana, suggesting that West Nile virus may damage the anterior horn cells of the spinal cord to cause paralytic disease.[182–184] Japanese encephalitis infection seems to be an important contributing cause of AFP in areas where this virus is endemic.[185]

The following signs and symptoms help in distinguishing poliomyelitis from other causes of AFP: (a) fever present at onset of paralysis, (b) rapid progression to maximum paralysis, (c) usually asymmetric paralysis, and (d) more pronounced paralysis proximally than distally (i.e., descending paralysis). However, as poliomyelitis becomes an increasingly rare disease, unusual clinical manifestations, such as symmetric paralysis of the lower extremities (many cases caused by intramuscular injections, which increase the risk of paralytic manifestations in the extremity that, in the absence of intramuscular injections, would not have become paralyzed)[186] or mild paralysis or weakness in partially immune children, may be seen.

EPIDEMIOLOGY

General Epidemiology

Poliomyelitis was once a ubiquitous, highly contagious, seasonal viral disease (more pronounced in moderate-climate countries) caused by three serotypes of poliovirus (types 1, 2, and 3) that infected nearly every person in a given population in the absence of vaccination.[32] Paralytic manifestations are a rare outcome (<1%) of poliovirus infections. Important exceptions are island or isolated populations (e.g., Eskimo), which can remain unaffected by the virus for varying periods and, after reintroduction, can experience outbreaks of poliomyelitis that affect all age groups that were not affected by the previous wave of infection.[187] Poliovirus type 1 seems to be the most neurovirulent of the three serotypes.[188] Most epidemic and endemic cases of poliomyelitis are caused by poliovirus type 1, followed by type 3. The last naturally acquired cases of wild virus type 2 were detected in India in 1999 and the wild type 2 virus was declared eradicated in 2015,[46,189,190] and the last case of poliovirus type 3 was reported in November 2012 in Nigeria (as of January 3, 2017).[191] Peak transmission occurs among infants and young children (tropical areas) and school-age children (temperate zones).

Poliomyelitis is transmitted by person-to-person spread through fecal–oral and oral–oral routes or, less frequently, by a common vehicle (e.g., water, milk).[192,193] People remain most infectious immediately before and 1 to 2 weeks after onset of paralytic disease, although poliovirus replicates for substantially longer periods and is excreted for 3 to 6 weeks in feces and approximately 2 weeks in saliva.[45] Thus, the period of communicability may be 4 to 8 weeks. Secondary infection rates of susceptible household or institutional contacts,

TABLE 49.3 Distinguishing Features of Four Common Diagnoses of Acute Flaccid Paralysis

Feature	Poliomyelitis	Guillain-Barré Syndrome	Traumatic Neuritis (After Injection)	Transverse Myelitis
Development of paralysis	24- to 48-h onset to full paralysis	From hours to 10 days	From hours to 4 days	From hours to 4 days
Fever at onset	High; always present at onset of flaccid paralysis; gone when progression of paralysis stops	Not common	Commonly present before, during, and after flaccid paralysis	Rarely present
Flaccid paralysis	Descending	Ascending		
Muscle tone	Reduced or absent in affected limbs	Global hypotonia	Reduced or absent in affected limb	Hypotonia in affected limbs
Deep tendon reflexes	Decreased or absent	Globally absent	Decreased or absent	Absent in lower limbs early; hyperreflexia late
Sensation	Severe myalgia; backache; no sensory changes	Cramps; tingling; hypoesthesia of palms and soles	Pain in gluteus; hypothermia	Anesthesia of lower limbs with sensory level
Cranial nerve involvement	Only when bulbar involvement present	Often present, affecting nerves VII, IX, X, XI, XII	Absent	Absent
Respiratory insufficiency	Only when bulbar involvement present	In severe cases, enhanced by bacterial pneumonia	Absent	Sometimes
Autonomic signs and symptoms	Rare	Frequent blood pressure alterations; sweating; blushing; body temperature fluctuations	Hypothermia in affected limb	Present
Cerebrospinal fluid	Inflammatory	Albumin-cytologic dissociation	Normal	Normal or mild elevation in cells
Bladder dysfunction	Rare	Transient	Never	Present
Nerve conduction velocity, third wk	Abnormal: anterior horn cell disease (normal during first 2 wk)	Abnormal: slowed conduction; decreased motor amplitudes	Abnormal: axonal damage	Normal or abnormal; no diagnostic value
Electromyography at 3 wk	Abnormal	Normal	Normal	Normal
Sequelae at 3 mo and up to 1 y	Severe, asymmetric atrophy; skeletal deformities developing later	Symmetric atrophy of distal muscles	Moderate atrophy; only in affected limbs	Flaccid diplegia; atrophy after years

probably mediated by fecal–oral spread, are high—greater than 90%.[45] The incubation period between infection and first symptoms (minor illness) is 3 to 6 days and from infection to onset of paralytic disease is usually 7 to 21 days, with a range of 3 to 35 days.[194] Most exposures to polioviruses result in inapparent infections.[32,42,43] On the basis of serologic surveys in the prevaccine era[195,196] and lameness surveys in developing countries, it seems that, in the absence of a control program with vaccines, paralytic disease will develop in approximately 1 in 200 children (0.5%).[197]

Until recently, excretion of poliovirus was thought to be limited to 4 to 6 weeks among immunocompetent persons and those younger than 3 years of age among immunodeficient persons. In 1997, a case report suggested that an immunodeficient patient with common variable immunodeficiency disorder (CVID) who acquired vaccine-associated paralytic poliomyelitis (VAPP) in 1981 may have excreted VDPV for approximately 7 years before onset of paralysis.[198,199] The WHO maintains a registry for such cases (prolonged, poliovirus excretion among immunodeficient individuals). The data in the registry (data as of July 2016) contain 94 persons with CVID, agammaglobulinemia, severe combined immunodeficiency disorder, or other immunodeficiency disorders, who have excreted poliovirus for prolonged periods, most for 6 months or longer (prolonged excretion), including seven persons who excreted poliovirus for 5 years or longer (chronic excreters), based on epidemiologic data and molecular sequencing information[200] (see "Molecular Epidemiology of Poliovirus" later) and WHO unpublished data.[85,198,199,201–208] Table 49.4 displays an analysis of the cases contained in the registry. Many of the long-term carriers stopped excreting poliovirus spontaneously. As of mid-2016, only one of the seven chronic excreters is known to continue to excrete polioviruses (probably >25 years),[209] one has stopped excretion spontaneously, four have died, and for one, the excretion status is unknown. None of the viruses examined from these carriers showed recombination with other nonpolio enteroviruses. The absence of recombination may suggest that the poliovirus had replicated in a single person rather than through person-to-person transmission in the community (see "Vaccine-Derived Polioviruses" later).[85,198–206] A recent literature review summarized the epidemiology of 69 immunodeficiency-related vaccine-derived poliovirus (iVDPV) cases.[210] To mitigate the risks of iVDPV cases, an ambitious antiviral development effort is underway and has identified promising capsid-binding inhibitors and protease inhibitors that may be effective to eliminate

prolonged or chronic excretion of poliovirus.[211] Because of the likelihood of resistance, a combination therapy is likely needed. Furthermore, work continues to identify neutralizing monoclonal antibodies that could be used to clear these poliovirus infections, either as standalone or in combination with antiviral agents.

Between 1976 and 1995, 48 outbreaks involving approximately 17,000 cases of paralytic poliomyelitis were reported in the literature.[212] These outbreaks involved primarily unvaccinated or inadequately vaccinated subgroups and were caused predominantly by poliovirus type 1 (74%). On the basis of this review, cases in developing countries occurred mostly among children younger than 2 years of age, whereas cases in industrialized countries tended to occur in older people who had remained susceptible to poliomyelitis. As an expression of the changing epidemiology resulting from the progress of polio eradication efforts, outbreaks in Albania (1996),[213] Namibia (2006),[214] Cape Verde (2000),[215] Tajikistan (2010),[216] and Congo-Brazzaville (2010)[216,217] have involved a substantial proportion of cases in adolescents and young adults associated with a high case-fatality rate. The changing epidemiology of poliomyelitis has also been documented by analyzing outbreaks occurring between 1996 and 2012.[218]

Besides age and being unvaccinated or inadequately vaccinated, several factors have been shown to increase the risk of acquiring paralytic manifestations, including intramuscular injections with diphtheria and tetanus toxoids and pertussis vaccine (DTP)[219,220] or antibiotics,[221,222] strenuous exercise,[223–225] injury such as fractures, and pregnancy.[226] Provocation poliomyelitis describes the enhanced risk of paralytic manifestations that follows injection in the 30 days preceding paralysis onset. More than 40 years ago, Nathanson and Bodian[227,228] demonstrated that retrograde axonal transport is responsible for the poliovirus invasion of the CNS in provocation poliomyelitis. More recently, Gromeier and Wimmer[112] and Gromeier and colleagues[229] suggested that the temporary expression of the human PVR on peripheral neurons during the repair process of injured nerves may enhance poliovirus access into peripheral neurons. Retrograde transport in the axon via the fast system seems to shorten further the period from initial access of the poliovirus to the peripheral neuron to the virus reaching the motor neuron cells of the CNS.[230] This limits the time during which the immune system could develop an effective response. Aggravation poliomyelitis describes the elevated risk of paralytic disease that follows strenuous exercise shortly before paralysis onset (in the preceding 24 to 48 hours).

Removal of tonsils and adenoids predisposes to bulbar poliomyelitis.[231] Clinical observations on this fact were reported in the early 20th century.[231,232] Rhesus monkeys, when inoculated with poliovirus in the tonsillopharyngeal region, developed poliomyelitis with greater frequency than when they were inoculated by other routes.[4] Later, von Magnus and Melnick[233] demonstrated that, if cynomolgus monkeys were given poliovirus by the oral route, their susceptibility was greatly enhanced in animals that had recently removed tonsils. Ogra[234] and Ogra and Karzon[235] studied 40 children before and after removal of tonsils and adenoids. The children ranged from 3 to 11 years old and had been immunized with live attenuated poliovirus vaccine 6 months to 6 years previously. Before tonsillectomy, IgA poliovirus antibody was present in appreciable titers in the nasopharynx of all children, but no IgM or IgG antibody was detectable. Significantly, however, after tonsillectomy, the preexisting IgA poliovirus antibody level in the nasopharynx sharply declined in all children studied. Mean antibody titers decreased threefold to fourfold. Thus, removal of tonsils may eliminate a valuable source of

immunocompetent tissue particularly important in conferring resistance to poliovirus.

Lower socioeconomic status is a risk for paralytic poliomyelitis in developing countries,[236] probably because children belonging to the lower socioeconomic group experience more intense exposure to poliovirus (i.e., a higher virus inoculum, which has been shown in experimental studies to be a risk factor for paralytic disease[30]). In addition, the children are also at higher risk for primary vaccine failure after OPV because of more frequent concurrent enterovirus infections.[236–239]

In a study of twins, concordance with regard to paralytic poliomyelitis was found in 36% of monozygous pairs compared with 6% of dizygous pairs.[240] The authors concluded that the data were consistent with "the theory that susceptibility may be conditioned by the homozygous state of a recessive gene."[240] A human leukocyte antigen complex study suggested that human leukocyte antigen–encoded genetic factors control resistance to the paralytic form of poliomyelitis.[241] Data on genetic susceptibility to poliomyelitis were reviewed by Wyatt,[242] who proposed that multiple-linked genes determine whether an infection with poliovirus results in paralytic disease.

The case-fatality rate is variable and depends primarily on the age groups affected. The highest case-fatality rates have been reported from epidemic cases in the early 20th century[16,30,32] and among adolescents and young adults, but are commonly between 5% and 10%.[30,32] Even in the 1990s, the case-fatality rate could be high, as occurred in a large outbreak of poliomyelitis in Albania in 1996, which reported a case-fatality rate of 10%.[213] More recently, an outbreak of poliomyelitis occurred on the Cape Verde Islands in 2000. Of the 33 reported cases, seven people died, for a case-fatality rate of 21%. The case-fatality rates were 0%, 20%, and 57% among cases in person younger than age 5 years, 5 to 14 years of age, and 15 years of age or older, respectively.[215] In 2011, a large outbreak of poliomyelitis caused by poliovirus type 1 centered in Pointe Noir, western part of Congo-Brazzaville, involved a substantial proportion of young adult men. As might be expected with this age distribution, the corresponding case-fatality rate was high (>30%).[217,243–245] Apes, such as chimpanzees, gorillas, and orangutans, are susceptible to poliovirus and can experience paralytic disease after poliovirus infection; outbreaks of poliomyelitis in apes have been reported in captivity and in the wild.[246–248] It is unlikely that apes have any role in the sustained transmission of this virus[249] because of the limited size of the ape populations. Most monkeys cannot be infected by oral administration of poliovirus and would not be expected to participate in the chain of transmission. In short, there is no significant animal reservoir for poliovirus.[249]

Results from mathematical modeling suggest that the force of poliovirus infection, measured primarily by the average age at infection among populations in the prevaccine era, is substantially higher in developing countries compared with industrialized countries. For example, the basic reproductive number (a measure of infectivity) of wild poliovirus is between 3 and 5 in the United States, which means that, on average, an infected person introduced into a fully susceptible population would transmit the poliovirus to three to five contacts. In contrast, the average infected person in a developing tropical setting would be expected to have transmitted the infection to 10 to 12 contacts.[250,251] As population immunity increases and many of the contacts of an infected person are no longer susceptible, the number of transmissions decreases. When the reproductive rate is less than 1 because of high population immunity, transmission will eventually cease. The herd immunity threshold is the level of immunity in the population (e.g., in the "herd") at which an infected person, on average, would transmit the infection to less than one susceptible contact.

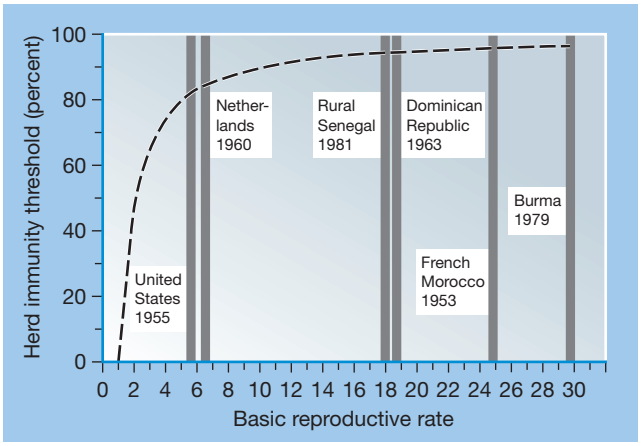

Figure 49.2. Herd immunity threshold levels for selected industrialized and developing countries, based on basic reproductive rate, or R_0. Threshold values for herd immunity were calculated using $1 \approx (1/R_0)$, where R_0 is 1 (life expectancy/average age at infection with poliovirus). Herd immunity threshold values are shown by the dashed line. The solid bars are the basic reproductive rate in a given population. *(From Patriarca PA, Sutter RW, Oostvogel PM. Outbreaks of paralytic poliomyelitis, 1976–1995.* J Infect Dis*. 1997;175[Suppl 1]: S165–S172.)*

Whereas poliomyelitis outbreaks in industrialized countries can be prevented with overall population immunity levels of approximately 66% to 80%, outbreaks in developing countries with inadequate sanitation and hygiene could still occur with immunity levels as high as 94% to 97% (Fig. 49.2). These findings may be helpful in explaining why there was no spread to the general population after the outbreaks in The Netherlands, Canada, and the United States[252,253] and why widespread transmission among well-vaccinated populations occurred in many outbreaks in developing countries.[254,255] A seroprevalence survey of poliovirus antibodies during the final stage of polio eradication in Egypt suggested that between 97% and 100% immunity against poliovirus type 1 may have been needed to interrupt type 1 transmission in a country with almost ideal conditions for poliovirus circulation.[256] Recent seroprevalence surveys in Northern India, conducted in the 2009–11 period, after introduction and widespread use of bOPV (types 1 and 3), have demonstrated high seroprevalence levels of antibodies against poliovirus type 1 (98% to 99%) among infants 6 to 7 months old, but considerably lower levels against poliovirus types 2 and 3.[257]

Epidemiologic Patterns and Incidence of Poliomyelitis

The epidemiology of poliomyelitis changed substantially during the last century. Three epidemiologic patterns have been observed: (a) endemic, (b) epidemic (prevaccine), and (c) vaccine era. Polioviruses probably circulated in an uninterrupted endemic manner for many centuries, infecting new cohorts of susceptible infants continuously, almost all early in life, when maternally derived antibody transferred from mother to newborn still provided some protection against paralysis.

A change from endemic transmission to periodic epidemics was first observed in some temperate-climate countries (e.g., Norway, Sweden, the United States) late in the 19th century and at the beginning of the 20th century.[12–15] The delay in median age of poliovirus exposure permitted the accumulation of sufficient children susceptible to poliomyelitis to

permit periodic outbreaks. In the United States, the median age of poliovirus infection increased from younger than 5 years of age at the beginning of the 20th century to 5 to 9 years of age in the 1940s, before poliovirus vaccine licensure.[32] In contrast, approximately 80% of the cases were in children younger than 5 years of age during the large epidemic in New York in 1916.[16] The generally accepted explanation, supported by numerous studies, is that, in a temperate-zone climate with increased economic development and correspondingly improved resources for community sanitation and household hygiene, exposure to polioviruses was postponed to later in life. Epidemic transmission became the primary epidemiologic pattern in temperate-climate countries, such as the industrialized countries in Europe and North America, until poliomyelitis was brought under control after introduction of effective vaccines (Fig. 49.3).

In developing countries, particularly tropical areas, an endemic epidemiologic pattern predominated until recently. Poliovirus exposure occurred early in life. Although earlier theories suggested that paralytic poliomyelitis was not a health burden in tropical countries because of early exposure of infants to virus at a time when levels of maternally derived antibodies protected them from paralytic disease, more recent studies have disproved these theories. The history and scientific evidence for this misconception—that poliomyelitis was not a significant public health problem in developing countries—was reviewed in detail in the corresponding chapter of the second edition of *Vaccines*.[258] In the last three decades, a series of lameness surveys were conducted in many developing countries that reported between five and 10 lameness cases per 1000 children in the age group studied,[197] suggesting that approximately one in 100 to one in 200 children acquire paralytic disease attributable to poliovirus. The WHO estimates that, in the absence of vaccination, at least one of every 200 children would become paralyzed by poliovirus and there would be approximately 650,000 cases of paralytic disease annually, the great majority of which would occur in children from developing countries. With improving vaccination coverage, a shift from an endemic to an epidemic pattern of poliovirus transmission has been observed in some developing countries that experienced large epidemics.[212,255,259–261]

The vaccine era began in the United States and in many European countries, Canada, Australia, New Zealand, and Japan after introduction of IPV in 1955.[2] The incidence of paralytic poliomyelitis decreased rapidly from 18,308 reported cases in the United States in 1954, the year immediately preceding IPV licensure, to 2499 cases in 1957, a decline of 86% only 3 years after the availability and widespread use of IPV. The relative upswing in reported cases in 1959 (6289 cases), with many cases having a history of receiving several prior doses of IPV, raised concerns regarding the clinical efficacy of IPV in preventing paralytic disease.[262] Nevertheless, continued and accelerated IPV use decreased the incidence of paralytic poliomyelitis to nearly record low levels (2525 cases) in the United States by 1960. Widespread use of IPV in other countries was followed by substantial decreases in the incidence of poliomyelitis and, in some European countries, including Finland, Iceland, The Netherlands, and Sweden, resulted in the apparent elimination of indigenous wild poliovirus transmission.[263,264]

The OPV era started in the United States with licensure of mOPV in 1961, followed by licensure of tOPV in 1963.[28] Although live attenuated OPV was developed in the United States, the first large-scale production and the large field trials that proved the safety and efficacy of the vaccine took place in the former Soviet Union. A mass immunization program was initiated in the Soviet Union in 1959 and completed in 1960, covering 77.5 million people, or 36.7% of the entire population. The immunization campaign was followed by a sharp decrease in the incidence of poliomyelitis, from 10.6 per 100,000 population in 1958 to 0.43 per 100,000 population in 1963. Between 1964 and 1979, the incidence remained at a level of 0.01 to 0.1 per 100,000 population.[265] Similar declines in the incidence of poliomyelitis were observed in other European countries, Australia, New Zealand, Canada, and the United States after the introduction of OPV. In the United States, mOPV was administered initially in mass vaccination campaigns in 1962, called Sabin Oral Saturdays/Sundays, followed by a routine vaccination program that administered vaccine to infants year-round.[28,266,267] The impact of administering OPV to a population that already had high immunity levels generated by previous natural infection or vaccination with IPV was impressive. Substantial reductions in the reported number of poliomyelitis cases were observed from 988 cases in 1961 to 61 cases in 1965. In 1973, only seven cases of poliomyelitis were reported. Epidemic poliomyelitis

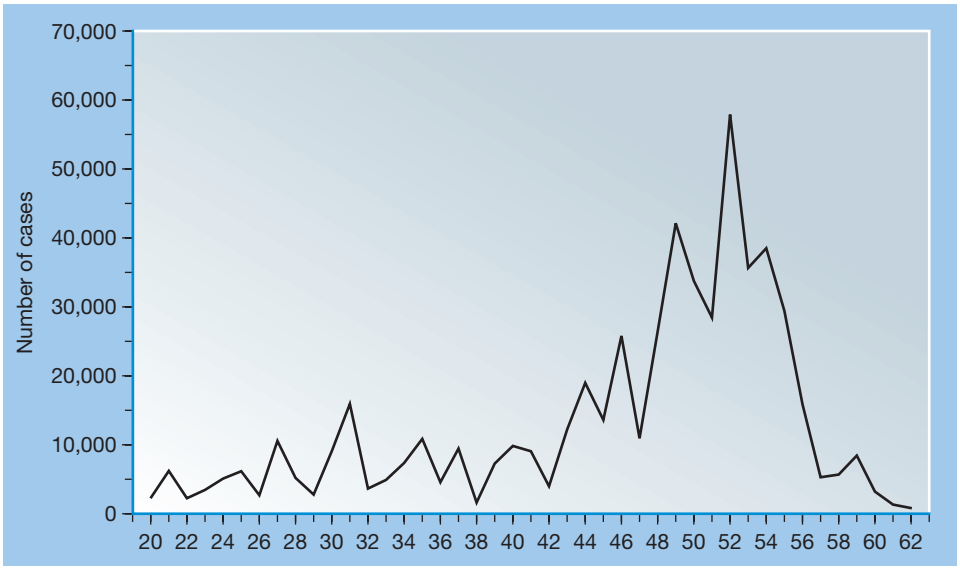

Figure 49.3. Reported cases of poliomyelitis, United States, 1920–1962. *(From Centers for Disease Control and Prevention.)*

also was brought under control, with the last outbreak in the general population occurring in Texas along the U.S.–Mexico border in 1970, followed by small outbreaks in 1972 and 1979 among religious groups whose members object to vaccination.[253] The last indigenously acquired case of poliomyelitis caused by wild poliovirus was detected in 1979. Between 1985 and 2000, aside from three imported cases of poliomyelitis (the most recent was reported in 1993), all cases have been vaccine-associated.[268] Rarely has a serious disease been controlled as rapidly and dramatically as has poliomyelitis in the United States and other industrialized countries.

The history of controlling poliomyelitis in many developing, particularly tropical, countries has been more recent. There is a notable exception: Cuba seems to have interrupted wild poliovirus after two rounds of mass vaccination campaigns in 1962.[269] In many other developing countries, however, national vaccination programs were not operational until the late 1970s and early 1980s, and global OPV coverage with three doses among children 1 year of age only reached 80% by 1990.[270] Wherever moderately high levels of OPV coverage were achieved, the incidence of poliomyelitis decreased by more than would be expected,[271] but endemic transmission of polioviruses continued, and cases of poliomyelitis continued to be reported. In addition to achieving high routine coverage with three doses of OPV, control of poliomyelitis required additional supplemental doses of OPV that were incorporated into the routine vaccination schedule in some countries; other countries needed to administer supplemental doses of OPV in mass campaigns. For example, in Brazil, control of poliomyelitis could not be accomplished until mass vaccination campaigns were initiated in 1980 (Fig. 49.4). The impact of these mass campaigns on poliomyelitis incidence was dramatic; the number of reported cases decreased from 1290 in 1980 to 122 in 1981, a decrease of more than 90%.[272] Based on the experience of the GPEI, once a poliovirus serotype has not been detected for 6 months or longer, it seems that circulation has been interrupted in that geographic location. However, while this may be valid in general, the length of "silent circulation" (without detection of overt cases of paralytic disease) is very much dependent on surveillance sensitivity and serotype. For example, for type 3, because of the lower case-to-infection ratio, a minimum period of at least 12 months may be needed, even under conditions of adequate surveillance. For certification purposes, a minimum period of 3 years or longer is anticipated to ensure confidence.[273]

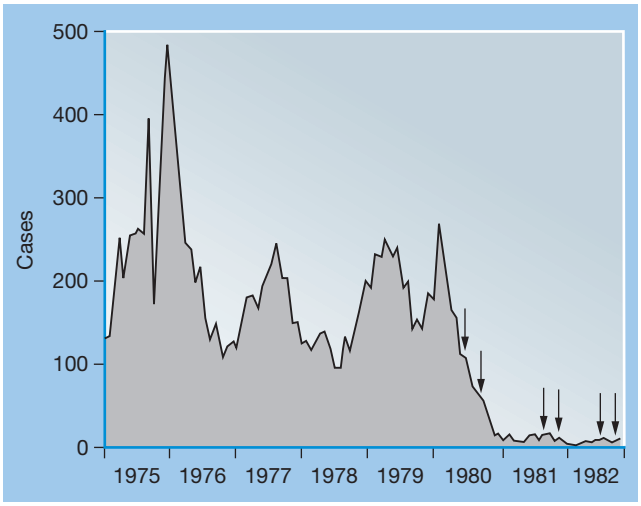

Figure 49.4. Cases of poliomyelitis by 4-week periods in Brazil, 1975–1982. Arrows indicate national immunization days. *(From Risi JB. The control of poliomyelitis in Brazil.* Rev Infect Dis. *1984;6[Suppl 2]:S400–S403, with permission.)*

Significance as a Public Health Problem

In the absence of effective control programs with poliovirus vaccine, paralysis develops in approximately one of every 200 children (see "General Epidemiology" earlier) after exposure to polioviruses,[197] followed in most cases by permanent disability; 5% to 10% of patients with paralytic disease have a fatal outcome.[30,31] Thus, with a global birth cohort of approximately 130 million surviving infants in 2015, approximately 650,000 children would be expected to acquire paralytic poliomyelitis resulting in permanent disability each year, and between 32,500 and 65,000 of the cases would result in poliomyelitis-associated deaths. In the United States, a report estimated that, in the absence of a control program, more than $3 billion ($926 million in direct costs and $2.1 billion in indirect costs) would be required each year to cover the treatment and other related costs of patients with poliomyelitis.[274] A recent study modeling different control scenarios suggested these scenarios will be more costly in the long run than finishing the eradication effort.[275] In addition to the acute manifestations of poliomyelitis, patients may experience postpolio syndrome decades after the acute episode; postpolio syndrome is associated with new muscle pain, exacerbation of existing muscle weakness, or the development of new weakness or paralysis[52] that may require additional therapy, rehabilitation, and respiratory support.

Despite the availability of two highly effective vaccines, poliomyelitis still exerts a significant public health impact in the world. In the United States in the prevaccine era, the peak incidence year of poliomyelitis was 1952, when 57,879 cases of poliomyelitis were reported (including 21,269 cases of paralytic disease).[276] After the availability and widespread use of poliovirus vaccines beginning in 1955, poliomyelitis was rapidly controlled in industrialized countries and in other areas where vaccines were used effectively. Globally, the Expanded Programme on Immunization, a program of the WHO established in 1974, provided leadership and technical guidance to national programs in most developing countries to improve vaccination coverage. Coverage levels apparently reached 80% with three doses of OPV among children 1 year of age for the first time in 1990,[270] resulting in substantial decreases in the global morbidity and mortality burden of poliomyelitis. Despite this success, the WHO estimated that approximately 350,000 cases of paralytic poliomyelitis associated with permanent disability occurred in 1988, the year the global polio eradication target was adopted.[37] Because of rapid progress toward polio eradication, the worldwide reported incidence of poliomyelitis was only 494 cases in 2001[39] (and the number of cases associated with wild poliovirus isolation was 483). Between 2005 and 2010, the number of poliomyelitis cases globally has fluctuated between 1293 and 1997, and the number of countries reporting any wild poliovirus has varied between 20 and 23. During this same period, the reporting completeness has further improved[39,277]; thus, it is unlikely that many cases of poliomyelitis remained undetected in 2010 (and even more unlikely that significant areas of poliovirus circulation were missed, but there are areas not accessible owing to conflict and populations that are difficult to survey, such as nomads). As of November 29, 2016, 74 virologically confirmed poliomyelitis cases were reported to WHO for 2015, and 34 virologically confirmed cases had been reported thus far to the WHO from Afghanistan, Pakistan, and Nigeria.[39,278]

Paralytic poliomyelitis continues to be a serious, albeit declining, threat to children in polio-endemic countries and

occasionally to people residing in industrialized countries that have primarily achieved good control of poliomyelitis for many years.[279,280] Even in countries with well-vaccinated populations that have eliminated indigenous wild poliovirus circulation for decades, gaps in population immunity may persist, particularly in groups objecting to vaccination (e.g., religious groups such as the Amish in the United States, The Netherlands Reformatory Church, and related groups in Canada) or groups that are not reached effectively by national vaccination programs (e.g., Roma, previously referred to as "gypsies").[252,281–283] In the United States, the last two outbreaks of poliomyelitis occurred in 1972 and 1979 among members of religious groups objecting to vaccination.[253] The 1979 outbreak was an extension of an outbreak affecting first The Netherlands in 1978 and then Canada.[252,282] An outbreak of poliomyelitis affecting the same religious group in The Netherlands also occurred in 1992 to 1993.[280] On the basis of genomic sequence,[284] the poliovirus type 1 strain causing the epidemic in The Netherlands in 1978 had its origin in Turkey. The recent outbreak was caused by poliovirus type 3, which was most likely imported from the Indian subcontinent.[285] In Spain, the last cases of poliomyelitis in 1980 to 1981 were detected among Roma children.[281] In both outbreaks in Bulgaria in 1990–91 and in 2000,[286,287] as well as in the Romanian outbreak in 1991–92,[288] Roma children were exclusively affected or constituted a substantial proportion of poliomyelitis cases. Although no cases of paralytic poliomyelitis were detected in the outbreaks in the United States (1979), Canada (1978), and The Netherlands (1978 and 1992–93) beyond the affected unvaccinated or inadequately vaccinated subpopulations, wild poliovirus exposure of people in the general population and the establishment of subsequent endemic and epidemic transmission remain a concern.

Molecular Epidemiology of Poliovirus

The application of genomic sequencing of poliovirus isolates has added a new dimension to the understanding of the epidemiology of poliomyelitis.[289] Because fewer than 1% of susceptible children infected with wild poliovirus show signs of paralysis,[46] AFP surveillance alone has limited ability to track the patterns of poliovirus spread, especially over wide geographic areas. However, the combined genetic and surveillance data can be used to detect links between poliomyelitis cases, reconstruct chains of transmission at high-resolution, and unequivocally establish the sources and timing of importations from the remaining poliovirus reservoirs.[8,136]

The high resolution of poliovirus molecular epidemiology follows from the very high rate of evolution of the poliovirus RNA genome.[88,290–292] Most of the nucleotide substitutions generate synonymous codons[88] and the basic biological properties of wild polioviruses remain unchanged. Estimates of the rates of total nucleotide substitution into poliovirus capsid regions average approximately 10^{-2} substitutions per site per year (Table 49.5).[66,85,88,290,291,293,294] The rates appear to be similar across the three poliovirus serotypes and for both circulating polioviruses and polioviruses associated with chronic infections, and constitute a robust poliovirus molecular clock. The clock is stochastic, and estimates of dates of infections obtained over short time periods may have wide confidence intervals such that wider sequence windows may be needed to improve estimates.[85,136,294] In addition, the Sabin strains are subject to selection against the attenuating substitutions during the early phases of replication in the human intestine,[293] which, when coupled with active recombination[294] and incorporation of "hitchhiker" mutations, can accelerate the initial rates of substitution. Consequently, estimates from the molecular clock of the duration of shedding of newly emergent VDPVs can be longer than those inferred from the vaccination records,[63,293,295] even as molecular clock estimates for the duration of more prolonged infections may closely match the clinical data.[90,205,294] After approximately 10 years of divergence, variable nucleotide sites become increasingly saturated, yielding underestimates of the total time of virus replication, and requiring special analytic methods to obtain more robust estimates.[88,296]

Sequence analyses offer an additional tool to monitor the progress of the GPEI, and has shown that poliovirus genotypes (viruses within a genotype differ by <15% in their nucleotide sequences) and genetic clusters within genotypes (viruses within a cluster differ by <5% in their nucleotide sequences) disappear sequentially through intensive immunization efforts (Fig. 49.5).[152,153,297] Experience shows that in settings of sensitive surveillance a genotype that is not detected for more than a year has probably become extinct.[289,299] Molecular epidemiology has established the existence of numerous poliovirus genotypes that had been endemic to different regions of the world (Fig. 49.5).[297,289] The last wild poliovirus type 2 isolate (detected in India 1999) was a representative of the South Asian type 2 genotype, the last of many wild type 2 genotypes in circulation during the prevaccine era (Fig. 49.5).[69] Similarly, representatives of the last two wild poliovirus type 3 genotypes were most recently detected in Pakistan in April 2012 and in Nigeria in November 2012.[154] The most recent detection of wild poliovirus type 1 in Borneo State, Nigeria, in August 2016 was a genotype indigenous to northern Nigeria[299a]; thus only the wild poliovirus type 1 genotypes indigenous to Afghanistan, Nigeria, and Pakistan were detected in 2016 (Fig. 49.5).

TABLE 49.5 Poliovirus Molecular Clock Rate Estimates

Poliovirus	Location	Interval (y)	VP1 Substitution Rate (nt s/s/y)	Reference
Wild poliovirus type 1	Andean countries	10	1.03×10^{-2}	Jorba et al[88]
Wild poliovirus type 1	Central Asia	4.1	1.19×10^{-2}	Gavrilin et al[290]
Wild poliovirus type 1	China	2.5	1.15×10^{-2}	Liu et al[291]
iVDPV type 1	Taiwan	2.5–3.0	1.14×10^{-2}	Yang et al[294]

CDC, Centers for Disease Control and Prevention; cVDPV, circulating vaccine-derived poliovirus; iVDPV, immunodeficiency-associated vaccine-derived poliovirus; nt s/s/y, total nucleotide substitutions per site per year.

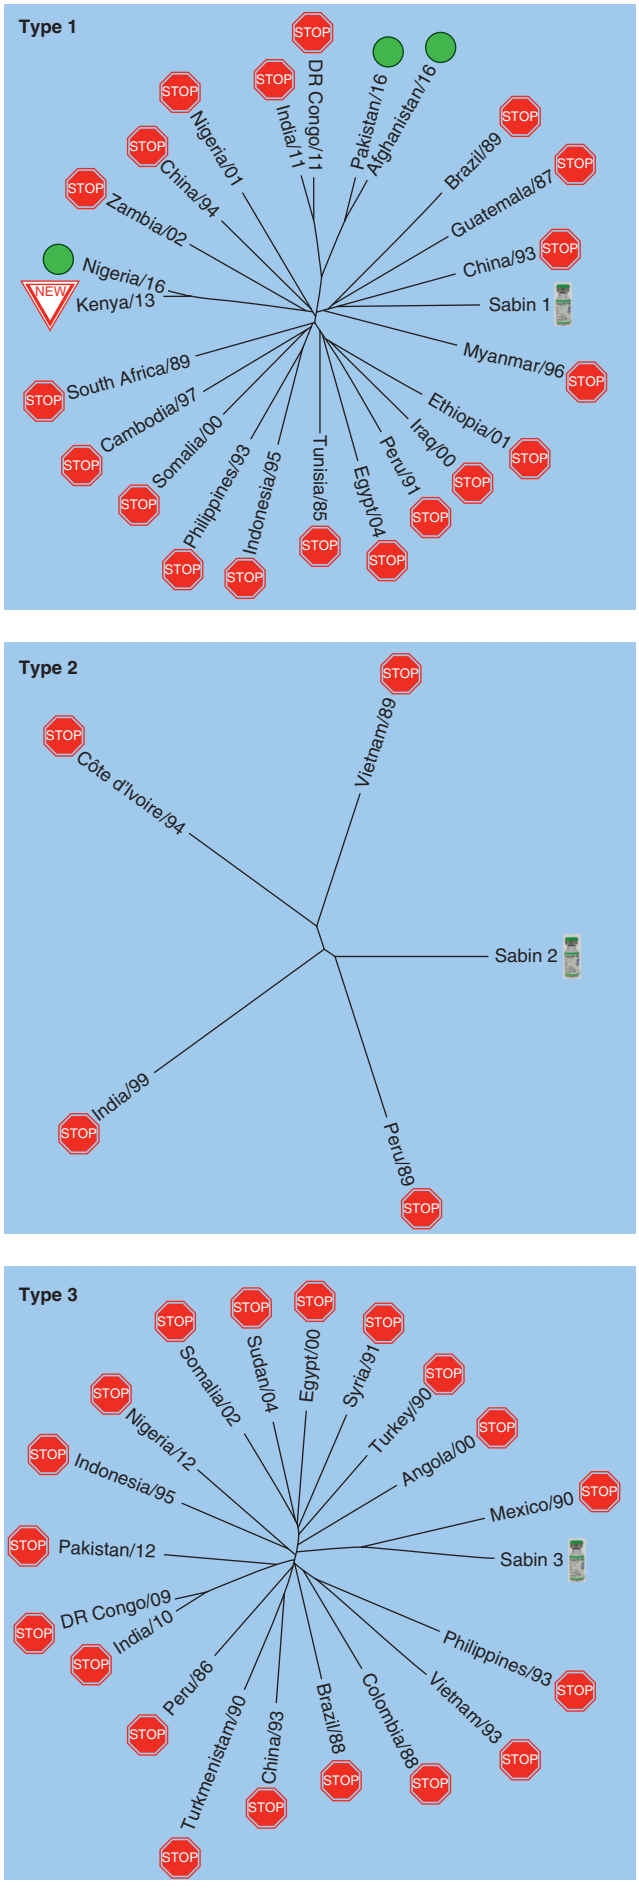

Figure 49.5. Progressive eradication of wild poliovirus (WPV) genotypes,* 1986–2015. Radial phylogenetic trees summarize the VP1 sequence relationships among representatives of each WPV genotype (a genotype shares less than 85% nucleotide sequence identity in the VP1 region with another genotype of the same serotype) detected since the launch of polio eradication activities in the Americas in 1985. Genotypes believed to be extinct are represented by stop signs; genotypes where evidence is accumulating that circulation has stopped (but less than 3 years since the last isolate) are represented by yield signs; the WPV1 genotype circulating in Pakistan and Afghanistan is indicated by the green circles. Isolates (identified by country and year of isolation) of the extinct genotypes are usually the last known representative of that genotype (exception: Cambodia/97 is represented by a closely related WPV1 isolate from Vietnam). *(VP1 sequences of isolates from Pakistan and Afghanistan courtesy Salmaan Sharif and Sohail Zaidi of the National Institutes of Health, Islamabad, Pakistan; isolate sequences from India courtesy Jagadish Deshpande of the Enterovirus Research Centre, Mumbai, India.)*

Molecular epidemiologic analyses show that poliovirus type 3 appears to circulate more locally than type 1,[299] and that poliovirus type 1 appears to be most commonly associated with importations from neighboring countries and with intercontinental or global spread of the virus.[134,218,298–304] In some settings, different genotypes of poliovirus type 1 have been found to have cocirculated in a geographically limited area.[134,260,300,305]

Molecular epidemiologic methods are routinely used to help identify reservoir communities with low population immunity, and where demographic and environmental conditions favor poliovirus circulation. During the peak months of poliovirus circulation, virus spreads from the reservoir communities to adjacent nonreservoir indicator communities (where the density of nonimmune, susceptible children can support some poliovirus circulation during the peak transmission season). This has led to a refinement in the concept of virus importation, which, in previous usage, referred to virus transmission across national boundaries. Although many importations over long distances have been documented,[212,299] reservoir communities and their associated indicator communities frequently overlap international borders,[299,306] underscoring the importance of regional synchronization of NIDs and Subnational Immunization Days. Equally important are the patterns of importation from reservoir communities to indicator communities within a country.[136,306,307] High vaccine coverage in the reservoir communities, especially in mass campaigns conducted during the low transmission season, prevents the subsequent spread to indicator communities.

Sequence analysis led to the recognition of highly divergent iVDPVs[85,199] and cVDPVs[66,69,308] (see "Vaccine-Derived Polioviruses" later), and it has been used to resolve, at high resolution, chains of cVDPV transmission[69,309–311] and separate iVDPV lineages in individual immunodeficient patients with prolonged infections.[85,199,293–295]

Molecular epidemiologic methods have also opened a new avenue for detecting gaps in polio surveillance. In areas with good surveillance, poliovirus isolates representing frequent sampling of a single chain of transmission are typically closely related (usually >99.5% VP1 sequence identity among the closest relatives). These closely related viruses are routinely visualized as sequences connected by short branches on phylogenetic trees. Long-branch connections between isolate sequences indicate missing information. If the virus is imported, the missing information may be recovered from the

sequence relationships to viruses from the source reservoir.[298] However, in many other circumstances, no closely related viruses can be found, and the recent virologic history of the isolate lineage is indeterminate. For example, gaps in AFP surveillance in southern Egypt were inferred from the sequence data, because indigenous type 3 isolates in 1999 appeared as "orphan viruses" at the tips of long branches on phylogenetic trees (orphan virus is an isolate that at the time of its detection had no other virus more closely related than 1.5% difference in the VP1 region), and the closest relatives were isolated nearly 3 years earlier,[312] observations that highlighted the importance of environmental surveillance to improve sensitivity. Orphan viruses had been repeatedly found in areas with insensitive surveillance. The GPLN regularly monitors for the appearance of poliovirus orphan lineages as a means to assess surveillance sensitivity.

Contamination of cultures was once a potentially serious challenge to the integrity of poliovirus surveillance data. Improved procedures and facilities in GPLN laboratories have all but eliminated contamination, despite high workloads. Moreover, sequence analysis can distinguish contaminants from true clinical isolates. Contaminants are easily recognized when they are standard wild reference strains, but are more difficult to recognize when they are the wild polioviruses indigenous to a country or community. However, when wild polioviruses isolated at different times and locations have identical VP1 sequences, contamination is suspected, because such sequence identities are inconsistent with the rapid rate of evolution of the poliovirus genomes. Contamination can be definitively confirmed (or ruled out) by genomic sequencing of complete genomes.

PASSIVE IMMUNIZATION

Therapeutic use of convalescent serum for poliomyelitis was first suggested as early as 1915.[313] Several trials using convalescent serum, administered by a single intrathecal injection, intraspinally, intravenously, or subcutaneously, reported conflicting results.[314] However, convalescent serum use was advocated by some until a well-controlled trial during a poliomyelitis outbreak in 1931 provided no statistical evidence that the therapy was of value.[315]

Administration of antibody was pursued again in the late 1940s and early 1950s as a means of preventing poliomyelitis by passive immunization. It had been demonstrated previously that low levels of circulating neutralizing antibody were protective against the paralytic manifestations of poliomyelitis in experimental animal models and in humans.[315] In addition, infants in the first few months of life rarely acquired paralytic poliomyelitis, presumably because maternally derived, type-specific poliovirus antibodies provided some protection. However, this protective effect is relatively short-lived. Maternally derived antibody declines with a half-life of approximately 28 days and can rarely be detected in infants older than 6 months.[316]

A large field trial funded by the National Foundation for Infantile Paralysis demonstrated in 1952 that immunoglobulin (i.e., gamma globulin) was effective in preventing paralytic disease if it was administered before the presumed exposure to poliovirus, but that the protective effect was relatively short-lived, approximately 5 to 8 weeks.[317] In this study, a single dose of 0.14 mL/kg body weight was administered intramuscularly.[317] However, evaluation of large-scale use of gamma globulin in 1953 by the National Advisory Committee for the Evaluation of Gamma Globulin in the Prophylaxis of Poliomyelitis concluded that "its preventive effect in community prophylaxis during 1953 has not been demonstrated." Also, no modification of the severity of paralysis was shown. Nevertheless, the committee could not say that the use of gamma globulin by mass inoculation produced no effect.[318] Although these conclusions were modified somewhat by Hammon and colleagues,[317] who pointed out that this evaluation had serious, perhaps fatal flaws—the gamma globulin was given far too late to be expected to have much or any effect and this was not a controlled experiment with appropriate controls—the committee report, nevertheless, dampened enthusiasm for this approach. In addition, in view of the progress toward the subsequent development of effective poliovirus vaccines that induced active immunity, presumably for life, gamma globulin as a tool to prevent poliomyelitis was not further pursued.

Passive immunity to poliomyelitis (and other diseases) among immunodeficient people, particularly people with agammaglobulinemia or hypogammaglobulinemia, is achieved through substitution therapy, namely, the regular administration (monthly) of intravenous immunoglobulin. Doses of 100 to 400 mg/kg body weight are used.[319] Intramuscular immunoglobulin also may be used, but it seems less effective. Immunoglobulin, whether it is formulated to be administered intramuscularly or intravenously, must pass the requirements of the U.S. Food and Drug Administration, which include a minimum titer for antibody to poliovirus type 1. In addition, immunoglobulin or hyperimmune sera may be used to eliminate chronic enterovirus infections,[320] including chronic infections with poliovirus,[321] and the oral route of administration sometimes has been used.[320] High-titer monoclonal antibody preparations are being evaluated for prevention of paralytic poliomyelitis as postexposure prophylaxis or to clear prolonged chronic poliovirus excretion among immunodeficient persons.[97]

ACTIVE IMMUNITY

Early Approaches

Research on inducing active immunity in monkeys by administering ground-up spinal cord and observing whether the animals died of poliomyelitis began as early as 1910.[315] Inactivation of poliovirus by formalin was first reported in 1911.[322] Brodie and Goldblum[323] and Brodie[324] first used subinfective doses of live poliovirus and later mixed live poliovirus with hyperimmune serum before using phenol and formalin as inactivating substances. After further small-scale experiments to optimize formalin inactivation and administration of the inactivated vaccine to small numbers of rhesus monkeys, adult volunteers, and children, the vaccine was administered to approximately 3000 children.[325,326] However, this approach was controversial and not pursued further because of concerns about efficacy and safety. In 1935, Kolmer[327] pioneered the use of attenuated live poliovirus that had been passaged continually in monkeys and prepared a suspension of monkey spinal cord in 1% sodium ricinoleate. The vaccine was administered to approximately 10,000 children, at least 10 of whom acquired paralytic poliomyelitis shortly after vaccination, for a rate of approximately one case per 1000 children vaccinated.[327,328] In short, both approaches—inactivation by formalin and attenuation of live poliovirus—that were successfully used later by Salk and Sabin had been used during these trials. In retrospect, it is clear that, without knowledge of the number of poliovirus serotypes and a better understanding of the differences between attenuation and chemical inactivation, these early vaccine development efforts were doomed to failure.

Advances in tissue culture growth of poliovirus in the late 1940s[20] renewed interest in poliovirus vaccines, and some of the first reports on attenuation of wild poliovirus for vaccine purposes were published in the early 1950s.[329–332] Essentially,

attenuated strains were developed by several passages of virus at high concentration in cell cultures of rodent CNS tissue or non–nervous system tissue from monkeys, followed by selection of attenuated variants at limiting dilutions or from single plaques.

Description of Vaccine

How Strains Were Developed

The history of early developments of oral vaccines can be reviewed in detail in reports of meetings published between 1958 and 1961[333–336] and in the corresponding chapter of the second edition of *Vaccines*.[258] As with most major scientific achievements, crucial contributions came from a number of investigative teams.[28,337–339] Koprowski and colleagues[329] reported the successful immunization of humans against poliomyelitis with a live poliovirus vaccine as early as 1950. Although these attenuated strains were not selected for licensing, this work meant that, by 1960, when not only their strains, but also several other candidate vaccines, were well into their testing and field trial use, a 10-year record of evidence was available on patterns of response in humans who had received the type 2 strain in 1950.[340]

Continued development and testing of candidate strains were conducted in three institutions: the Children's Hospital Research Foundation, Cincinnati, Ohio (A. B. Sabin); Lederle Laboratories, Wayne, NJ (Herald Cox and colleagues); and the Wistar Institute, Philadelphia (Koprowski and colleagues).[335,336] The work with attenuated polioviruses was advanced toward practical usefulness, particularly by Sabin, who meticulously studied a number of progeny of single virus particles for neurotropism in monkeys and finally selected three for small experimental trials in humans.[341] Much of the early efforts in the development of candidate strains were devoted to (a) maintaining high degrees of infectivity in cell culture and the human intestinal tract, (b) inducing detectable levels of neutralizing antibody in a high proportion of susceptible (seronegative) recipients, (c) displaying low neurovirulence in monkeys, (d) demonstrating a lack of association with paralytic disease in humans, and (e) maintaining genetic stability after replication in the human host.[254] The efforts of a number of investigators to develop and test suitable attenuated poliovirus strains came to fruition during 1955 to 1959, and large-scale field trials were held in many countries under a variety of conditions. Many of these trials in humans involved the sequential administration of monovalent formulations of poliovirus types 1, 2, and 3. A number of investigators around the world participated in studies in which these candidate strains were fed to millions of people. At the two conferences held by the Pan American Health Organization (1959 and 1960), these investigators joined in assessing the results.[335,336]

The field trials[335,336] and subsequent studies focused not only on the human populations fed candidate virus, but also on the virus populations recovered from stool samples of vaccinees. Because the attenuated polioviruses are living systems that must multiply to immunize, it was essential to know as much as possible about the progeny viruses let loose in nature—agents that still retain their property of infecting humans. All poliovirus strains, regardless of how highly attenuated, retain the property of multiplying and destroying cells in the monkey spinal cord. The degree to which this property is retained, however, varies over an enormous range as one progresses from the virulent strains to the highly attenuated ones suitable for vaccine use. The laboratory techniques are such that different degrees of neurotropism, even among attenuated strains, can be detected.

In 1958, a detailed comparison of candidate strains was conducted.[342,343] The attenuated strains that had been developed at the Yale Poliomyelitis Study Unit had already been shown to have too high a degree of reversion in chimpanzees and were dropped from consideration.[331,344] At Baylor College of Medicine, Houston, Texas, extensive comparison was made of the Sabin strains and the Lederle-Cox strains for neurovirulence in hundreds of monkeys inoculated by the intracerebral and intraspinal routes.[342–345] At the Division of Biologics Standards of the National Institutes of Health, Murray and colleagues[346] compared three sets of candidate strains as follows: Lederle-Cox, Sabin, and Koprowski-Wistar. Although the studies were done in two different laboratories and with some variations in methods, the overall findings were essentially in agreement. It was clear that the Lederle and Wistar strains were more neurotropic for monkeys than the Sabin strains. Because the results favored the Sabin strains, these strains are the ones that have been licensed, manufactured, and used almost universally since then.

Tables 49.6 through 49.9 show the passage histories of the three Sabin vaccine seeds now in use.[347] For example, the type 1 strain was derived from the Mahoney strain, initially isolated by Francis and Mack in 1941. Salk made additional monkey

kidney and monkey testicular passages. In 1953, Li and Schaeffer made 11 monkey kidney tissue culture passages, yielding the partially attenuated LS strain, and additional passages in monkey kidney and skin to yield the further attenuated strain LS-c. Then Sabin, in 1954, carried the LS-c strain through terminal dilutions and single-plaque passages, carefully selecting by neurovirulence testing, finally obtaining strain LS-c, 2ab. Two further passes, in cynomolgus kidney, yielded LS-c, 2ab/KP_2, designated SO (Sabin original). Bettylee Hampil, at Merck Sharp & Dohme, made one additional passage in rhesus monkey kidney tissue culture to derive LS-c, 2ab/KP_3, designated SO + 1, or SOM. The current vaccine is SO + 4, four tissue culture passages beyond the SO. A maximum of five passages is permitted, after which earlier (grandmother) seeds must be thawed and used to prepare new mother seeds. Because of inherent difficulties in maintaining the genetic stability of the Sabin type 3 seed stock, manufacturers have turned to an RNA-derived passage and clone of the strain, labeled SOR. This seed has yielded a vaccine of greater consistency and stability than the original Sabin seed. Grandmother seeds are potentially available through the WHO.

Genetic Determinants of Attenuation of the Sabin Oral Polio Vaccine Strains

Identification of the genetic determinants of attenuation of the Sabin OPV strains has been comprehensively reviewed.[71,73,113,348] Two basic approaches have been taken: (a) sequence comparisons between the Sabin strains and their neurovirulent wild parents (types 1 and 3) or neurovirulent revertants (types 2 and 3) obtained from patients with VAPP; and (b) investigation of the contribution of specific nucleotide substitutions to attenuation using infectious complementary DNA (cDNA) clones (see "Genetic Stability of Vaccine Seed Strains" later). A common feature of the Sabin strains is the presence of nucleotide substitutions in the IRES in the 5′-UTR, which have been clearly shown to be critical attenuating mutations (Fig. 49.6). Additional mutations encoding amino acid substitutions in the capsid region contribute to and stabilize the attenuated phenotype.

Sabin 1. The 57 nucleotide substitutions distinguishing the Sabin 1 strain from its neurovirulent parent, Mahoney/USA41, are scattered throughout the genome.[353] Six map to the 5′-UTR, 49 map to the coding region (21 of which encode amino acid substitutions), and two map to the 3′-UTR. Infectious cDNA constructs containing different combinations of blocks of Sabin 1 and Mahoney sequences were tested for neurovirulence in monkeys or transgenic mice expressing the CD155 receptor, for temperature sensitivity, and for other phenotypic properties distinguishing the two strains.[349,354] The single most important determinant of the attenuated phenotype of Sabin 1 was the A→G substitution at position 480 (abbreviated A480G) in the IRES.[355] Four other substitutions contributing to the attenuated phenotype mapped to the capsid region (one in VP4, one in VP3, and two in VP1), and a substitution contributing to the temperature-sensitive phenotype (but not to the attenuated phenotype) mapped to the $3D^{pol}$ region encoding the RNA-dependent RNA polymerase (see Fig. 49.6).[349,354,356] The relatively high stability of the attenuated phenotype of Sabin 1 is attributed to multiple attenuating substitutions and their relative contributions to the phenotype. However, neurovirulent revertants have been selected in the laboratory that have only two (U525C, a suppressor that restores base pairing at 480G [see below] and C6203U, a histidine→tyrosine back-mutation in the 3D-polymerase) or three mutations.[357]

Sabin 2. Only two nucleotide substitutions (G481A in the IRES, and C2909U encoding a threonine→isoleucine substitution at position 143 of VP1) appear to be main determinants of the attenuated phenotype of Sabin 2 (see Fig. 49.6).[350,358] Because P712 has inherently low neurovirulence,[359] identification of critical attenuating sites in Sabin 2 involved determination of the effects of introduction of sequences derived from a minimally divergent neurovirulent revertant of Sabin 2 (obtained from a case of VAPP) into infectious cDNA constructs derived from Sabin 2.[350,358] Weakly attenuating substitutions mapped to nucleotide positions 437 in the 5′-UTR, and/or 868 (VP4 region), and/or 4076 (2B region).[358]

Sabin 3. Detailed analysis of the attenuated phenotype of Sabin 3 has been possible because the neurovirulent parental strain, Leon/USA37, differs from Sabin 3 by only 10 nucleotide substitutions.[360] In addition, numerous neurovirulent revertants of the Sabin 3 strain have been isolated from patients with VAPP[347] and from healthy OPV recipients.[351] Only two substitutions—C472U in the IRES and C2034U encoding a serine→phenylalanine substitution at position 91

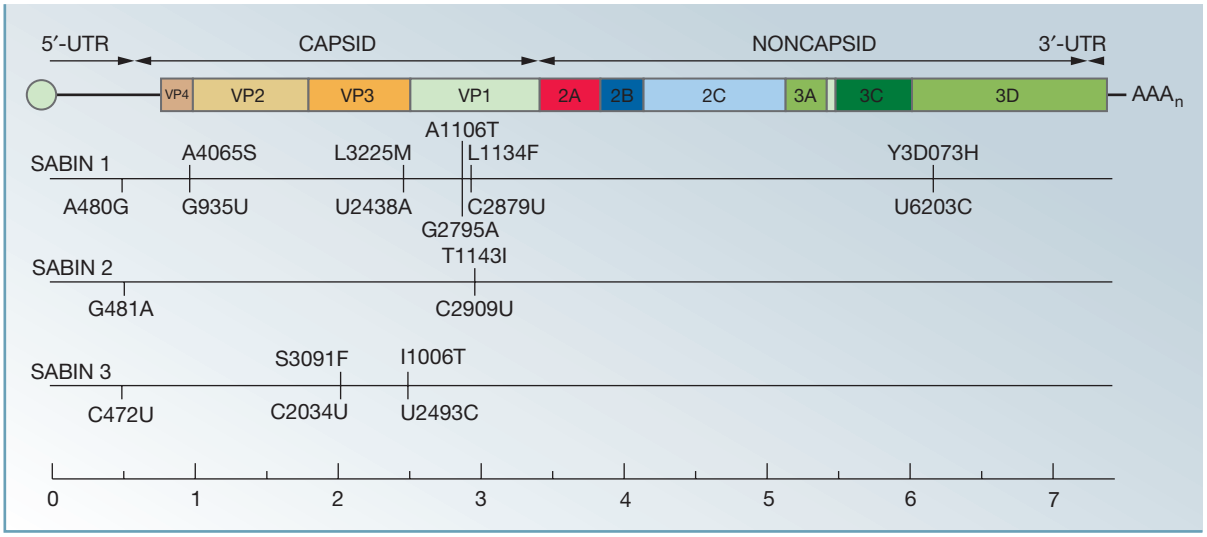

Figure 49.6. Location of principal attenuating nucleotide (lower bars) and amino acid (upper bars) substitutions in each of the three Sabin oral polio vaccine (OPV) strains. Abbreviations of nucleotide residues: A, adenine; C, cytosine; G, guanine; U, uracil. Abbreviations for amino acid residues: A, alanine; C, cysteine; F, phenylalanine; H, histidine; I, isoleucine; L, leucine; M, methionine; S, serine; T, threonine; Y, tyrosine. Substitutions are shown as nonattenuated parent-position–Sabin strain; nucleotide positions are numbered consecutively from residue 1 of the RNA genome; and amino acid positions are indicated by the abbreviated name for viral protein (4, VP4; 2, VP2; 3, VP3; 1, VP1; 3D, 3D-polymerase) and numbered consecutively from residue 1 of each protein. For example, a guanine (Mahoney) → uracil (Sabin 1) substitution at RNA position 935 (G935U) encodes an alanine (Mahoney) → serine (Sabin 1) replacement at residue 65 of VP4 (A4065S). The Y3D073H substitution in Sabin 1 and the S3091F substitution in Sabin 3 are important determinants of temperature sensitivity. UTR, untranslated region. *(Data from references 347, 349, 350, 351, and 352.)*

of VP3—appear to be the main determinants of the attenuated phenotype (see Fig. 49.6).[71,347,351] A third substitution, U2493C encoding an isoleucine→threonine substitution at position 6 of VP1, appears to be a minor determinant of attenuation that also reduces the replicative fitness of Sabin 3.[352] The U2493C substitution is strongly selected against during cell culture passage and during replication in the human intestine.[361]

Quantitative determination of the contributions of each substitution is complicated by several factors: (a) the role of minor determinants of attenuation is difficult to measure, (b) some substitutions have pleiotropic effects on phenotype, (c) some Sabin strain phenotypes require a combination of substitutions, (d) second-site mutations can suppress the attenuated phenotype in various ways, and (e) the outcome of experimental neurovirulence tests may vary with the choice of experimental animals (monkeys vs transgenic mice) or the route of injection (intraspinal vs intracerebral).[358,361,362] Examples of substitutions with pleiotropic effects are: (a) the serine→phenyalanine substitution at position 91 of VP3 which confers both attenuation and temperature sensitivity to Sabin 3[363] and (b) the tyrosine→histidine substitution at position 73 of the 3D polymerase of Sabin 1, which is an important determinant of temperature sensitivity[349,364] and a minor contributor to attenuation.[364] The relationship between poliovirus neurovirulence in experimental animals (where virus is introduced directly into the CNS) and pathogenicity for humans (where virus is introduced by ingestion) cannot be measured in controlled experiments, and remains ambiguous. Clearly the Sabin OPV strains are several orders of magnitude less neurovirulent than wild polioviruses, as indicated by the very low incidence of VAPP[365] compared with the high incidence of paralytic poliomyelitis in areas where wild polioviruses are circulating.

The attenuating substitutions of the Sabin strains are sometimes described as mutations impairing the specific determinants of poliovirus neurovirulence. However, attenuation is a specific phenotype of each Sabin strain. Poliovirus neurovirulence, by contrast, is a much more complex property. Expression of a neurovirulent phenotype requires the efficient function of numerous steps in the natural life cycle of the virus and, thus, the efficient expression of several viral genes.[55] Impairment in the expression of any of these poliovirus genes can reduce replicative fitness and confer a more attenuated phenotype. However, such mutants may not be suitable candidates for live-virus vaccines. The Sabin strains contain specific genetic defects that are not found among the highly diverse population of circulating wild polioviruses. These exceptional defects are unstable to replication in the human intestine, and variants with higher replicative fitness are regularly selected. Other combinations of substitutions can produce highly attenuated polioviruses potentially suitable for vaccine use.[366] However, the attenuating substitutions of the Sabin strains were shown to confer highly favorable biological properties, making these strains the best available candidates in the early 1960s for licensure as OPVs (see "How Strains Were Developed" earlier).

Functional Basis for Attenuation of the Sabin Oral Polio Vaccine Strains

The determination in the early 1980s of the complete genomes of the Sabin strains and their neurovirulent parents (in the case of types 1 and 3),[64,353,360,367,368] and the availability of infectious cDNA poliovirus clones[347,354,369] opened the way for detailed analysis of the biological mechanisms for the attenuated phenotype of the Sabin OPV strains.[71] The most detailed analyses have been of the substitutions in the IRES (A480G in Sabin 1, G481A in Sabin 2, and C472U in Sabin 3) that are the principal attenuating mutations of the respective Sabin strains. These substitutions map to a specific domain of RNA

secondary structure (stem–loop region V) within the IRES of the 5′-UTR which is highly conserved among polioviruses and related enteroviruses. The attenuating substitutions in the IRES alter stem–loop structures[71,370–372] and are not found in natural wild poliovirus isolates. Mutations restoring the original stem–loop structure in the IRES (Sabin 1: G480A [back-mutation] or U525C [suppressor]; Sabin 2: A481G [back-mutation]; Sabin 3: U472C [back-mutation]) are frequently found in vaccine-related isolates from healthy OPV recipients[370,373] and patients with VAPP,[71] as well as from the environment.[145] The localization of these important determinants to the IRES,[374] the initiation site for translation of the poliovirus polyprotein, suggested that an important aspect of attenuation may involve a deficiency in translation for the Sabin strains. Indeed, in vitro translation experiments demonstrated that decreased efficiency in the initiation of translation is associated with the U472 substitution in Sabin 3[375,376] and the G480 substitution in Sabin 1.[370,371] This view is further supported by the finding that replication of the Sabin strains is similar to that of neurovirulent polioviruses in HeLa (Henrietta Lacks) cells, but is differentially reduced in neuroblastoma cells.[377,378] The reduced Sabin strain yields are associated with lower efficiencies of translation in neuroblastoma cells.[371,377,378] A possible molecular mechanism for the translational deficit involves the polypyrimidine tract–binding protein (PTB), a cellular protein that interacts with the IRES and which facilitates poliovirus translation.[379] The attenuating mutations weaken the interaction of PTB with the IRES in neuroblastoma cells, but not in HeLa cells.[379] Moreover, the translational deficit for Sabin 3 is moderate in intestinal cells, where PTB levels are high, but severe in neurons, where PTB levels are low. Intact spinal cords from chick embryos have reduced levels of PTB and translation of Sabin 3 in the neuronal cells is less efficient than that of neurovirulent parental Leon strain.[380]

Despite the strong experimental support for the hypothesis that a preferential defect in translation in motor neurons is a major contributor to the attenuated phenotype of the Sabin strains, this view has been challenged by newer studies in mice in which translation from the Sabin 3 IRES was equivalently reduced in cells of neuronal and nonneuronal origin.[381] It was suggested that attenuation is determined after internal ribosome entry, that the Sabin strains have a reduced fitness for replication in all cells, and that reduced efficiency of replication in intestinal cells may permit the development of an immune response before sufficient numbers of virus reach the spinal cord and brain.[381]

The major attenuating determinants in the IRES are the ones that have been most intensively studied, particularly that of Sabin 3 because substitutions at position 472 have more pronounced effects on the attenuated phenotype than do substitutions at position 480 in Sabin 1 or 481 in Sabin 2. Results of similar studies with Sabin 1 and Sabin 2 are usually in agreement with the Sabin 3 findings.[349,350,358] The capsid determinants may affect the attenuated phenotype in various ways such as by interfering with virus assembly,[363] by reduced efficiency of binding to the CD155 PVR,[349] or by reducing capsid stabilities.[81] It has been emphasized that the attenuated phenotype is composite in nature involving the complex interaction of multiple determinants.[73]

Sabin and other developers of OPV strains struck a balance between low neuropathogenicity, good immunogenicity, and acceptable levels of genetic stability.[382] The high genetic stability of the Sabin 1 vaccine strain is especially important, because wild type 1 polioviruses typically have high paralytic attack rates and can spread over wide geographic areas in explosive outbreaks.[212,289,299,301–303,383] Sabin 2 may revert more rapidly, but its immunogenicity is very high[63,382] and the paralytic attack rates of wild type 2 polioviruses are low.[46,384] Sabin 3 is associated with the highest rates of VAPP, which is probably a consequence of low genetic stability of the critical attenuating substitution,[385] relatively low immunogenicity,[386] and an intermediate paralytic attack rate for type 3 polioviruses.[46,384] Nonetheless, all three Sabin strains normally have very low pathogenic potentials, and incidence of VAPP in countries with high rates of OPV coverage[268] are several orders of magnitude lower than the incidence of paralytic poliomyelitis in areas with circulating wild polioviruses.

How Trivalent Vaccine Was Developed

Viral replication in the gastrointestinal tract and seroconversion were usually demonstrated in 80% to 100% of seronegative recipients with a single dose of monovalent vaccines at dosage levels of 10^5 median tissue culture infective doses ($TCID_{50}$).[387–391] However, when doses of 10^5 $TCID_{50}$ of each poliovirus serotype were mixed and administered as trivalent preparations, the replication and antibody production were consistently lower for some types compared with the sequential administration of monovalent vaccines.[392–398] This effect could be modified somewhat by increasing the doses of each type ($\geq 10^7$ $TCID_{50}$).[399,400] In addition, these studies showed that tOPV of similar potency for each serotype was associated with a predominance of poliovirus type 2 excretion and significantly higher type 2 antibody titers than for poliovirus types 1 and 3. These early trials did not evaluate the impact of increasing the quantity of one serotype or reducing the quantity of another on seroconversion to all three serotypes because the interference effect of type 2 often could be overcome by administering three or more doses of the trivalent vaccine.

In 1961, a large study in Canada tested a "balanced" formulation of tOPV (10^6 $TCID_{50}$ for Sabin type 1, 10^5 $TCID_{50}$ for Sabin type 2, and $10^{5.5}$ $TCID_{50}$ for Sabin type 3).[401] A single dose of this balanced (10:1:3) vaccine was administered to nearly 24,000 people, including 106 previously seronegative subjects, 103 (97%) of whom seroconverted to all three serotypes. Although one could conclude from this study that a single dose of OPV may be sufficiently immunogenic for a routine program, only triple-seronegative infants were included in this analysis of the Canadian trial, so the results represent the best possible scenario for inducing optimal levels of seroconversion because the infants lacked maternally derived antibody that can interfere with seroconversion. On the basis of these findings and an unpublished study from Guam, the balanced formulation of OPV was licensed in Canada in 1962 and in the United States in 1963.

Dosage and Route

In the United States, before discontinuation of OPV in 2000, the trivalent live attenuated OPV was formulated to contain at least $10^{5.5}$ $TCID_{50}$ for poliovirus type 1, $10^{4.5}$ $TCID_{50}$ for type 2, and $10^{5.2}$ $TCID_{50}$ for type 3.[402,403] However, the U.S. manufacturer routinely exceeded these minimum requirements, and an evaluation by a WHO reference laboratory found potency levels of $10^{6.5}$, $10^{5.4}$, and $10^{6.3}$ $TCID_{50}$ per dose of types 1, 2, and 3, respectively (WHO unpublished data). The WHO requires the following minimum $TCID_{50}$ values for each vaccine poliovirus serotype: $10^{5.9} \pm 0.5$ $TCID_{50}$ for type 1, $10^{5.0} \pm 0.5$ $TCID_{50}$ for type 2, and $10^{5.7} \pm 0.5$ $TCID_{50}$ for type 3. Because of evidence from an evaluation in Brazil that poliovirus type 3 immunogenicity is not satisfactory in a trivalent formulation with $10^{5.5}$ (300,000) $TCID_{50}$, particularly in tropical countries,[404] the WHO's Global Advisory Group recommended in 1990 that the type 3 component of OPV should

be increased to $10^{5.8}$ (600,000) $TCID_{50}$.[405] The OPV purchased by UNICEF beginning with the 1992 to 1993 tender period included this recommendation.

The recommended route of administration for OPV is oral, by releasing the vaccine volume (0.5 mL) contained in single-dose droppers into the oral cavity[406] for vaccine manufactured in the United States (before 2000, when OPV production was discontinued) or by providing 2 drops (≈0.1 mL) of OPV contained in multidose vials produced by many non–U.S. manufacturers.[407] Although in the early 1960s some manufacturers put OPV into dragées, at present, only OPV produced in China is in dragée form; before administration, the dragée must be ground up and mixed with water.

Producers

At least 10 manufacturers around the world are producing OPV using the Sabin vaccine seeds (Table 49.10). The list includes producers in Belgium, China (two), France, Indonesia, Iran, Japan, Mexico, Russia, and Vietnam. In addition, manufacturers in Brazil, Egypt, India (several companies), Pakistan, and Thailand have the capacity for filling and finishing bulk OPV produced by one of the primary manufacturers.

Most of these manufacturers use seed strains of types 1 and 2 no more than two passages away from the WHO master seed (SO + 1, i.e., Sabin original plus one passage). There is more

variation in the type 3 seed used; most manufacturers are now using the Pfizer RNA-derived seed (SOR + 1). The type 3 seed used by one manufacturer in China, the Zhong III strain, has been shown by oligonucleotide fingerprinting to be indirectly derived from Sabin type 3.[408] Vero cells and human diploid cells are used by at least one manufacturer each for growing their vaccine viruses; the others continue to use primary monkey kidney cells. It is recommended that the cells for cultivation be taken from monkeys bred in captivity. Like the cell cultures used, the monkey colony should be shown to be free of extraneous viruses and other pathogens.

Preparations Available (Including Combinations)

Although mOPV formulations of the three poliovirus serotypes were used widely in the early 1960s, they were replaced by tOPV starting in 1963 in the United States and other countries. Exceptions include Hungary, which used all three types of mOPV sequentially until the early 1990s,[409] and South Africa, which routinely used monovalent type 1 OPV (mOPV1) in its routine immunization program until the early 1990s.[410] The mOPV formulations, although used extensively in the early 1960s, were no longer licensed in 2004. To improve the immunogenicity of OPV in developing countries, the Advisory Committee for Poliomyelitis Eradication, the principal technical oversight committee for the GPEI at the time, recommended in 2004 the rapid development and large-scale use of mOPV1.[411] Currently, six manufacturers and fillers (fillers procure bulk OPV from an established manufacturer with bulk production and then blend, fill, and release the product) have developed and received regulatory approval for use of mOPV1 (Bharat Biotech International Ltd, Bio Farma, GlaxoSmithKline, Haffkine, Panacea Biotec Ltd, and Sanofi Pasteur). Three manufacturers and fillers developed and received regulatory approval for mOPV3 (Bharat Biotech International Ltd, GlaxoSmithKline, Sanofi Pasteur, and Panacea Biotec Ltd). Three companies (Panacea Biotec Ltd, GlaxoSmithKline, and Sanofi Pasteur) have licensed mOPV2. In addition to accelerating eradication, these mOPVs will also be used for a stockpile of vaccine available for potential outbreak control during the posteradication era.[391] The use of bOPV (types 1 and 3) was first proposed in 1997 coincident with the impending eradication of wild type 2 polioviruses, which occurred in 1999.[412–414] However, also in 1997, an unfavorable regulatory opinion highlighted the obstacles to proceeding with bOPV licensure and delayed further consideration until after mOPV formulations were licensed in 2005. A total of 10 manufacturers and fillers are producing bOPV (Table 49.10). bOPV has received regulatory approval or has been used in 48 countries for supplementary immunization activities, during which more than 5 billion doses have been administered between 2009 and 2014. After mOPV withdrawal in April 2016, bOPV became the vaccine of choice for routine immunization together with IPV (see "Routine Immunization" later). mOPV, bOPV, and tOPV are available in multidose vials (10-, 20-, and 50-dose vials); tOPV is also available in single-dose preparations. No combination products with OPV as one of the components have been licensed.

Constituents (Including Antibiotics and Preservatives)

The growth medium for the cells consists of Eagle basal medium, the components of which include Earle balanced salt solution, amino acids, antibiotics, and calf serum. After the cells have grown out, the medium is removed and replaced with fresh medium that contains the inoculating virus but no calf serum. The final vaccine is diluted with a modified cell culture maintenance medium that usually contains stabilizer. Each dose of OPV may contain trace amounts of penicillin, neomycin, polymyxin, and streptomycin (see "Contraindications and Precautions" later) and magnesium chloride or sugar (sucrose and sorbitol) as stabilizers. The vaccine contains phenol red as an indicator of pH.

Vaccine Stability

Before any vaccine lot, whether tOPV, mOPV, or bOPV, can be released, it must be tested and meet the requirements of the national control authorities. If the vaccine is purchased by UNICEF, it also must meet the WHO requirements for manufacture, safety, and potency. Because OPV is a live viral vaccine, it is labile unless it is stored at low temperatures (frozen). Thermostability requirements were defined by the WHO as OPV that loses less than 0.5 $\log_{10}$ of titer of each of the three vaccine strains after exposure to 37°C for 2 days.[415] In addition, current regulations require that, for maintenance of potency, the vaccine must be stored and shipped frozen, and that, after thawing, it must be held in the refrigerator at no more than 10°C for a period not to exceed 30 days, after which time it must be discarded.

In the early 1960s, it was found that the infectivity of the enteroviruses could be preserved even when they were heated at 50°C if molar magnesium chloride was added,[416] a property that is still used in their identification and characterization. This discovery was applied rapidly to live vaccines[94] not only in the laboratory,[417] but also in the field, where stabilized vaccines were used effectively to halt type 1 and type 3 outbreaks.[418] In laboratory studies with OPV containing magnesium chloride as a stabilizer,[419] the vaccine showed so little loss in virus titer after long-term storage at −20°C that the predicted half-life was calculated as 92 years. It also was noted that vaccine stabilized with magnesium chloride had no significant loss of potency after as many as nine cycles of alternate warm and cold conditions. Sucrose and sorbitol have also been used as stabilizers, but they have been less effective, particularly at high temperatures.[406] One manufacturer has introduced a concentrated phosphate buffer—lactalbumin hydrolysate—as a stabilizer; it works well at 4°C, but more data are needed to learn how effective it would be in the field at higher temperatures. It has been shown that deuterium oxide with magnesium chloride improves the thermal stability[420]; however, no OPV vaccines in use today contain deuterium oxide.

Individual vaccine vial monitors were introduced in 1996 for all OPV procured by UNICEF.[421] The vaccine vial monitors respond to heat exposure with a change in color. The potential benefits of vaccine vial monitors include (a) the ability to keep opened vials without having to discard partially used vials at the end of the day, (b) a decrease of at least 30% in vaccine wastage rates, (c) flexibility to take the vaccine beyond the cold chain to reach remote locations, and, most important, (d) reassurance for the vaccinator at peripheral vaccination sites that the vaccine is potent.[421]

Regulatory Requirements for Oral Polio Vaccine Licensure

National control or regulatory agencies, such as the U.S. Food and Drug Administration, the UK National Institute for Biological Standards and Control, and similar national regulatory authorities in other countries, provide guidance to manufacturers for the production and licensing of OPV.[402] In addition, the WHO provides regulations that manufacturers must follow to be eligible to sell vaccine through the UNICEF tender. The WHO regulations contain three sections:

(a) manufacturing requirements, (b) national control requirements, and (c) requirements for poliomyelitis vaccine (oral) prepared in primary cultures of monkey kidney cells. In addition, a summary protocol for poliomyelitis vaccine (oral) production is provided in Appendix 7 of that document.[415,422]

The WHO recommends that all candidate vaccine strains be evaluated in large-scale field trials before licensure because of the possibility that neurovirulence testing in monkeys may not always predict the actual behavior of vaccine strains (i.e., reversion to neurovirulence and potential for epidemic spread) in humans under field conditions.[423] USOL-D bac, a new poliovirus type 3 vaccine strain, was developed by the Institute of Sera and Vaccines in Prague, Czechoslovakia, in 1962.[424] Virus isolated in stool after administration of Sabin type 3 had a higher degree of neurovirulence than the corresponding mutants of USOL-D bac. In addition, this vaccine strain had passed all neurovirulence tests as determined in monkeys and seemed to be safer than the Sabin type 3 strain. In 1968, an extensive outbreak of poliomyelitis caused by poliovirus type 3 occurred in Poland 4 months after a small vaccine trial with Sabin type 3 and USOL-D bac vaccine strains had been carried out.[425] Subsequent molecular investigations indicated that USOL-D bac had been responsible for the epidemic.[408,426,427] This experience in humans indicates that monkey neurovirulence testing alone is insufficient to ensure vaccine safety. This conclusion is supported by data from the United States. Neurovirulence information, based on monkey neurovirulence tests, from more than 80 individual vaccine lots of Sabin type 3 virus produced between 1964 and 1983 was reviewed.[428] The authors of this study concluded that type 3 OPV is, if anything, less neurovirulent than is type 1 OPV. However, in field use, type 3 OPV is associated with vaccine-related poliomyelitis more frequently than is type 1 OPV.[428] The molecular mechanisms for poliovirus attenuation and experiences with neurovirulence testing during the prior 40 years were reviewed in a meeting in 1991.[429]

Genetic Stability of Vaccine Seed Strains

Live virus vaccines for RNA viruses present special challenges for development, manufacture, and administration because the mutation rates of RNA genomes are many orders of magnitude higher than those of DNA genomes.[430,431] The primary cause of this high mutability is that the viral RNA-dependent RNA polymerases lack the proofreading mechanisms associated with DNA polymerases of DNA viruses and cellular organisms.[432,433] The absence of proofreading mechanisms in most RNA polymerases limits the size of RNA virus genomes because the likelihood of incorporation of deleterious mutations increases with genome length.[431] RNA virus populations exist as "quasispecies," that is, as a heterogeneous collection of sequence variants distributed about an average "master" sequence.[434,435] Quasispecies are capable of rapid evolution under challenging environmental conditions because variants with higher genetic fitness for the new conditions may be preexistent in the populations.[434]

The above considerations are of relevance to poliovirus populations in general[435,436] and to OPV preparations in particular.[385,437] OPV preparations have been shown to be quasispecies, with revertant variants of the critical attenuating 5′-UTR mutations representing approximately 0.1% of the population.[385,437] The biologic pressures applied in the selection for the attenuated OPV strains[359] are partially reversed when the strains are propagated at large scale for OPV production.[438] The stringent growth and postproduction testing requirements for OPV are designed to limit the enrichment for variants with increased neurovirulence and to assure a product of uniformly high safety. Several key measures were implemented to limit the enrichment for variants: (a) use of cell substrates favoring maintenance of the attenuated variants, (b) limitation of the number of production passages from the original OPV seed strains, (c) reselection from the OPV seed stocks of clones with low neurovirulence, and (d) incubation of OPV production cultures at temperatures (~34°C) favoring the maintenance of the temperature-sensitive phenotypes of the OPV strains.

The master sequences of each Sabin OPV seed strain have been maintained indefinitely as infectious cDNA plasmids in the bacterium *Escherichia coli*,[439] and the quasispecies populations of OPV preparations have been preserved by polymerase chain reaction engineering.[440] Poliovirus sequences contained within the recombinant plasmids are genetically stable because the bacterial DNA polymerases replicating the plasmid sequences have high-fidelity proofreading mechanisms. However, RNA transcripts produced in vitro from recombinant DNA plasmids are not genetically homogeneous, because the RNA polymerases catalyzing the transcription lack proofreading mechanisms. Because there is no biologic selection during the transcription process for variant genomes with reduced attenuation, the RNA used to transfect cultured cells has more uniform genetic and biologic properties. Nonetheless, deep sequencing has shown that the distribution of minor sequence variants within the virus quasispecies population may fluctuate stochastically when OPV strains are again propagated in cell culture.[436,437] Choice of cell substrate and production conditions can minimize the selection of neurovirulent variants.[441] However, the most intense selection occurs when OPV is fed to a child, and both rapid selection of mutational variants and recombination can result in the excretion of virus with increased potentials for neurovirulence and transmissibility (see "Vaccine-Derived Polioviruses" later).[71,294] Deeper understanding of the genetic lability of OPV and other live RNA virus vaccines has prompted the recent development of more genetically stable OPV strains (see "New Oral Polio Vaccine Strains").[435,441–444]

New Oral Polio Vaccine Strains

Recognition of the appearance of VAPP soon after licensure of OPV[445] prompted efforts to develop more genetically stable OPV strains, especially to type 3.[424] However, a large poliomyelitis outbreak associated with an inadequately quarantined field trial of an experimental type 3 OPV strain discouraged further efforts to develop new OPV strains by traditional methods.[427] Advances in the understanding of the genetic basis for attenuation of the Sabin OPV strains[361] generated renewed interest in developing OPV strains with improved genetic stabilities. Nomoto and colleagues constructed chimeras with the capsid regions of Sabin 2 and Sabin 3 inserted into the genetic background of the more highly substituted and stable Sabin 1 strain,[446] and increased the attenuation of Sabin 1 by introducing deletions into the IRES in the 5′-UTR.[447] Agol and associates also constructed more highly attenuated strains by modification of IRES sequences,[448] while Gromeier and associates attenuated the neurovirulent Mahoney strain by replacement of its IRES with homologous IRES sequences from human rhinovirus type 2.[374] Macadam and associates introduced several mutations into the IRES of Sabin 3 that conferred high genetic and phenotypic stabilities to the type 3 strain and to type 1 and 2 strains in which the original Sabin 5′-UTR sequences are replaced by the engineered homologues.[449]

Heightened interest in more stable OPV strains followed the rising incidence of cVDPV outbreaks and the recognition of prolonged iVDPV infections (see "Vaccine-Derived Polioviruses" later).[136,450] However, the observation that the critical

determinants of attenuation in the 5′-UTR are frequently lost in cVDPVs by recombination with closely related non-polio enteroviruses[136,450] called for new approaches to reduce the frequency of cVDPV emergence, especially to type 2. A consortium of five research laboratories, supported by the Bill & Melinda Gates Foundation, has sought to develop a new, genetically stable type 2 OPV strain for possible use in emergency OPV stockpiles (see "New Polio Endgame"). Several approaches have been taken by the consortium: (a) further engineering of the IRES to stabilize the attenuated phenotype[441]; (b) relocation of a *cis*-acting replication element (*cre*) from the 2C noncapsid region to the 5′-UTR (to reduce recombination)[451]; (c) incorporation of additional CpG and UpA dinucleotides within and across synonymous capsid region codons (codon deoptimization or CpG/UpA desuppression; targeting the capsid region sequences limits the phenotypic effects of recombination)[442,443,452,453]; and (d) incorporation of amino acid substitutions into the 3D polymerase to increase replicative fidelity[435,454] and reduce recombination frequency.[444] The modular nature of the poliovirus genome, as illustrated by the properties of both natural recombinants[66,136] and engineered chimeras,[374,441,446] permits construction of strains that are both highly attenuated, genetically stable, and poised for clinical evaluation.

RESULTS OF VACCINATION

Immune Response

Administration of OPV, similar to natural exposure to polioviruses, initiates a complex process that eventually results in humoral (systemic) and mucosal (local) immunity. The kinetics of this immune response have been reviewed in detail by Ogra and Karzon.[235] Production of IgM antibody predominates initially, can be detected as early as 1 to 3 days after infection, and disappears after 2 to 3 months. IgG antibody increases during this same period, eventually constitutes the predominant class of persistent antibody, and may last for life.[187] Fig. 49.7 shows the development of serum and secretory antibody responses to OPV compared with IPV.[235] The broader response of nasal and duodenal IgA associated with OPV administration is apparent. The humoral immune response is not completely serotype-specific,[188,455] and some degree of cross-protection (heterotypic cross-reaction) has been observed. Preexisting antibody to poliovirus type 2 may modify the risk of paralytic poliomyelitis after exposure to poliovirus type 1.[456] The significance of cell-mediated immunity to poliovirus exposure remains to be shown,[457] although cytotoxic T-cell responses may contribute to the inflammation and cell necrosis that characterize poliovirus infections of the CNS.

Viremia has been demonstrated, commonly after ingestion of type 2 OPV. Free virus is present in serum between days 2 and 5 after vaccination, and virus, bound to antibody, can be detected for a few additional days.[458,459] Bound virus in serum is detected by acid treatment, which inactivates the antibody and liberates active virus.

The majority of infants (70% to 90%) who are susceptible to poliomyelitis excrete poliovirus after administration of OPV. A study conducted during the winter of 1960 in Houston reported that 72%, 88%, and 75% of infants 0 to 6 months old excreted homologous poliovirus types 1, 2, and 3, respectively, after vaccination with monovalent poliovirus vaccines (Fig. 49.8).[460] The same study showed that familial and extrafamilial contacts of vaccinated children are exposed secondarily to excreted poliovirus and, in turn, also excrete poliovirus in feces. The highest proportion of type 2 mOPV-vaccinated infants excreted homologous virus in the first week after vaccination, the highest proportion of familial contacts excreted virus during the second week, and the highest proportion of

nonfamilial contacts excreted virus during the fourth week (Fig. 49.9).

In industrialized countries, after complete primary vaccination with three doses of OPV, 95% or more of recipients seroconvert and develop long-lasting immunity to all three poliovirus serotypes. In a trial in the United States, 39% of vaccinees seroconverted to poliovirus type 1, 84% to poliovirus type 2, and 71% to poliovirus type 3 after a single dose of OPV.[461] After receipt of two doses of OPV, seroprevalence was 92% to poliovirus type 1, 100% to poliovirus type 2, and 96% to poliovirus type 3; and after three doses of OPV, 97% had antibodies to poliovirus type 1, 100% to poliovirus type 2, and 100% to poliovirus type 3.[461] This study used a formulation of at least $10^{5.5}$, $10^{4.5}$, and $10^{5.2}$ $TCID_{50}$ of types 1, 2, and 3, respectively, of tOPV vaccine produced in the United States and confirmed earlier studies conducted between 1959 and 1962, which administered OPV to infants and children who were initially seronegative. These earlier studies reported that after two doses, the proportion of recipients seroconverting was 90% to 93% for type 1, 99% to 100% for type 2, and 76% to 98% for type 3; after a third dose, 100% converted to types 1 and 2, and 87% to 100% seroconverted to type 3.[316,334–336,462]

However, OPV seems to be considerably less immunogenic in developing countries. A comprehensive review of the immunogenicity of OPV in developing countries reported that a weighted average of only 73% (range: 36% to 99%), 90% (range: 77% to 100%), and 70% (range: 40% to 99%) of children participating in these studies have detectable antibody to poliovirus types 1, 2, and 3, respectively, after three OPV doses (Table 49.11).[254] Results of controlled trials conducted after the review[254] have confirmed the lower immunogenicity of OPV, particularly to poliovirus type 3, in developing countries.[463–465] A number of hypotheses attempt to explain the differences in OPV performance between industrialized and developing countries. These include interference from concurrent infections with other enteroviruses or diarrhea, both of which are more prevalent in developing countries.[463–466] Recently, two hypotheses for the low immunogenicity were tested and could not be confirmed: (a) zinc deficiency in Pakistan,[467] and (b) insufficient buffering to counter stomach acidity in Bangladesh.[468] Furthermore, another study in Pakistan demonstrated that a dose of IPV is more efficient than a dose of OPV in closing the immunogenicity gaps among chronically malnourished infants.[469] In addition, there may be nonspecific factors not yet known; and colostrum contains secretory IgA, which can influence seroconversion.[470–472] Children with higher levels of maternal antibody have lower seroconversion rates. Maternally derived antibodies are higher in newborns in developing countries compared with newborns in the industrialized world,[461,463] and OPV is administered at an earlier age (birth, 6, 10, and 14 weeks) when the influence of maternally derived antibody on vaccine virus replication and, hence, seroconversion is more distinct.[254] Increasing the potency of OPV can correct some of these limitations of the currently formulated OPV[465,473]; this also can be achieved by administering additional doses of OPV in the routine program or through mass campaigns.[122]

mOPV or bOPV can overcome some of the limitations of tOPV, including the interference among the three Sabin strains. Because the type 2 component of the tOPV is considerably more immunogenic than the other components, vaccinees usually seroconvert to type 2 first (because type 2 interferes with seroconversion to types 1 and 3). In contrast, with monovalent vaccines, a type-specific immune response can be targeted according to programmatic needs. mOPV is more immunogenic than tOPV in inducing a type-specific immune response in industrialized and developing countries. A comprehensive review of experiences with mOPV demonstrated that following a single dose, median seroconversion rates in industrialized countries of 95% (range: 90% to 100%) to poliovirus type 1, 98% (range: 83% to 100%) to poliovirus

type 2, and 94% (range: 70% to 100%) to poliovirus type 3 were reported. In developing countries, the median seroconversion rates following a single dose of mOPV were lower, 81% (range: 53% to 89%) to poliovirus type 1, 89% (range: 77% to 93%) to poliovirus type 2, and 72% (range: 52% to 80%) to poliovirus type 3.[391] Considerable variation in immunogenicity of OPV has been documented in developing tropical countries, ranging from poor (e.g., Northern India) to excellent (e.g., Indonesia) immunogenicity.[474,475]

Monovalent OPV became the vaccine of choice for supplemental immunization campaigns between 2005 and 2009 in polio-endemic or polio-epidemic areas, including in previously polio-free countries with recent importation of wild poliovirus. The vast majority of these vaccines are formulated as mOPV1 corresponding to the programmatic need to control wild poliovirus type 1. A total of more than 1 billion doses of mOPV1 were administered during this period. A case-control study has reported that the efficacy of mOPV1 was

approximately threefold higher than that of the type 1 component of tOPV.[474] Massive use of mOPV1 resulted in the virtual elimination of poliovirus type 1 in the most difficult to control districts in western Uttar Pradesh, India. The mOPV3 has been used selectively in areas with imported or endemic circulation of poliovirus type 3. Finally, type 2 immunogenicity is high in tOPV,[476] but mOPV2 may be needed for potential applications in controlling an outbreak of type 2 cVDPV before and after cessation of OPV. A clinical trial in India confirmed that the immunogenicity of bOPV was superior to types 1 and 3 compared with tOPV, and not inferior to the respective mOPVs. The cumulative two-dose seroconversion for poliovirus type 1 was 90% for mOPV1 and 86% for bOPV compared with 63% with tOPV; for type 3 poliovirus, it was 84% for mOPV3 and 74% for bOPV compared with 52% for tOPV.[476] In 2010, more than a decade since wild poliovirus type 2 was last detected,[477] bOPV (types 1 and 3) became the vaccine of choice to eradicate the remaining chains of poliovirus transmission.[478] A recent study with bOPV confirmed these findings and furthermore reported similar immunogenicity whether the doses were given at shorter intervals (2 weeks) compared to standard intervals.[479] The main advantage of bOPV is that it enhances individual and population immunity simultaneously for poliovirus types 1 and 3, without any serious loss in immunogenicity compared with the mOPVs. Fig. 49.10 highlights the countries that have used bOPV between 2009 and 2014. Between 2009 and 2014, more than 5 billion doses of bOPV were used in campaigns by the GPEI.

Mucosal Immunity

Intestinal mucosal immunity, primarily mediated by locally produced secretory IgA after live poliovirus exposure, is measured primarily by resistance to poliovirus replication and excretion in the pharynx and intestine after challenge with mOPV or tOPV[335,336] or by measuring directly the IgA in stool or pharyngeal specimens.[480,481] After challenge, lower titers of virus are excreted for significantly shorter periods among vaccinees compared with unvaccinated children (Table 49.12).[482] Secretory IgA can be measured directly in stool, saliva, and

breast milk to assess the degree of mucosal immunity. These methods are difficult to perform, require tedious standardization, and are rarely used. Mucosal immunity may exist even when levels of serum antibody are negligible,[337,483] although the degree of mucosal immunity seems most closely correlated with the titer of homologous humoral antibody[484]: the lower the titer, the more likely excretion of challenge virus can be demonstrated. One study reported that mucosal immunity may be strain-specific and that mucosal immunity induced by one vaccine poliovirus strain may not induce mucosal immunity against another strain.[485] Intestinal mucosal immunity induced by IPV is less effective against infection than that induced by OPV, as measured by the proportion of vaccinees excreting virus or the duration of excretion. However, the clinical importance of these differences in reducing wild virus spread in highly immunized populations in industrialized countries is not clear because IPV seems to reduce shedding compared with no vaccine and pharyngeal spread may be important in industrialized countries, and IPV induces pharyngeal immunity.[486,487] IPV and OPV induce equivalent pharyngeal mucosal immunity based on studies in industrialized countries that rely on vaccine virus challenge to assess mucosal immunity.[488] In contrast, in developing countries with inadequate hygiene and great potential for fecal–oral spread of enteric viruses, the clear increase in mucosal (intestinal) immunity induced by OPV over IPV would seem to offer a major advantage to OPV in reducing the circulation of polioviruses. A recent study in India indicated that IPV compared to OPV can more effectively boost mucosal immunity in infants and children with a history of multiple doses of OPV.[489] Secretory IgA has an important role in defense against poliovirus infections,[235,488,490] and all available evidence indicates that the immune response after vaccination with OPV (or boosted in previously OPV-vaccinated infants by IPV) is similar to that after infection with wild poliovirus.

Few studies have provided data on the persistence of mucosal immunity. No data are available from developing countries about the duration of mucosal immunity for polioviruses. Several studies have assessed resistance to oral challenge by vaccine viruses years after the initial administration of OPV. One study reported that children were completely resistant to intestinal infection 10 years after vaccination, unless prechallenge serum antibodies were 1:8 or lower.[484] Another study reported similar findings on the relationship of humoral antibody and resistance to excretion.[491] A study in India reported that healthy contacts of poliomyelitis cases, despite multiple doses of previous OPV, may still be infected and excrete wild-type poliovirus, albeit in relatively low frequency (<1%).[481] If exposure is known, such as in vaccine trials, as many as 50% of 10-year old children may excrete poliovirus after bOPV challenge.[489] In addition, another study from India suggests that intestinal mucosal immunity is relatively short-lived (as low as ~6 months).[492] No data are available on the long-term persistence of secretory IgA for polioviruses. Recently, a study by Wright et al demonstrated a correlation between neutralizing antibody in stool and excretion of poliovirus following challenge.[492a] This offers a potential avenue for assessing mucosal immunity without reliance on challenge poliovirus. However, looking at the mucosal immunity induced by another enterovirus, echovirus type 6, might provide insights. A study assessing the falloff in secretory IgA titer to echovirus type 6 in the pharynx and intestine reported no declines during a 4-year follow-up period,[493] although the possibility of boosting with echovirus 6 or other enteroviruses in the follow-up period cannot be excluded.

When poliovirus is ingested, the virus has contact with proteolytic enzymes such as trypsin, which may alter viral antigens.[490] Secretory and humoral antibody responses after OPV include those against the new antigens associated with trypsin-cleaved virus. Such antigens are not accessible in IPV, and, consequently, the immune response after IPV is more limited.[494]

Evidence of Oral Polio Vaccine Effectiveness

A large body of empiric and scientific evidence has accumulated since the late 1950s that demonstrates the effectiveness of OPV in preventing paralytic disease. The use of OPV was pioneered in the former Soviet Union,[495–497] and the approaches developed in the Soviet Union led to rapid control or elimination of poliomyelitis in many countries. The most prominent example of the effectiveness of OPV is the success of the GPEI,[39] including the Western Hemisphere, and the WHO's Western Pacific, European, and South-East Asian Regions, which were certified free of wild poliovirus by Regional Certification Commissions in 1994, 2000, 2002, and 2014, respectively.[498–501]

OPV has curtailed epidemics and has greatly reduced the incidence of poliomyelitis, often eliminating the pattern of expected seasonal increase in poliomyelitis cases.[49,267,271,418,497,502–510] Two vaccine effectiveness studies were conducted in the 1990s.[255,511] The study in Oman estimated that the effectiveness of three doses of OPV in preventing paralytic disease was approximately 90%.[255] Much of the earlier evidence of small and large trials is contained in meeting reports.[335,336]

The ability of OPV to infect contacts of vaccine recipients (i.e., "contact spread") and "indirectly vaccinate" these contacts against poliomyelitis is considered by many to be another advantage of OPV compared with IPV. OPV vaccine virus spread has been demonstrated by prospective virologic studies and by serologic studies in industrialized and developing countries.[460,464,512–515] Serologic surveys have shown that the proportion of people who have antibodies is considerably greater than would be expected by vaccination or by the circulation of wild polioviruses. After OPV introduction in Yaoundé, Cameroon, the incidence of paralytic poliomyelitis decreased by 85%, although only 35% of children 12 to 13 months old received three doses of OPV.[271] Among infants who received IPV in Oman, the seroconversion rates were significantly higher among infants whose study period coincided with a mass OPV campaign that was conducted elsewhere in the country (Fig. 49.11).[464] A serologic survey among unvaccinated inner-city children in the United States also demonstrated that a substantial proportion of the children are exposed secondarily to vaccine viruses (Fig. 49.12).[514] In a study conducted in the United Kingdom, infants received a dose of IPV at 2 months of age. In the ensuing 1 month period and before any OPV was administered, 11% of infants excreted poliovirus type 1 and 4% excreted poliovirus type 2 in stool specimens.[515] These data indicate that vaccine virus spreads easily from OPV recipients to contacts in industrialized and in developing countries.

Correlate of Protection

A comprehensive review of the correlate of protection against poliovirus was published in 1995.[22] Briefly, the data suggest that any titer of homologous neutralizing antibody is protective against paralytic consequences of poliomyelitis. Furthermore, a large body of data suggests that immunity, once induced by wild poliovirus or the vaccine virus, is lifelong in immunocompetent individuals regardless of waning of circulating antibody.

Figure 49.11. Duration of Immunity

The immune response following vaccination or infection with wild poliovirus is similar, and thus the data on persistence of immunity following wild poliovirus infection can be generalized to vaccine viruses, and support that the related immunity is lifelong. In an isolated Eskimo population, immunity induced by wild poliovirus was shown to have persisted for at least 40 years in the absence of any further exposure during the intervening period.[187] The best evidence of the persistence of vaccine-induced immunity is the absence of disease in adolescents and adults who had been vaccinated previously with OPV and the persistence of type-specific antibody assessed in population-based surveys.[516,517] However, interpretation of these data is difficult because of potential repeated exposures to shed virus. In prospective studies in which the same vaccinees were observed for several years, antibodies to types 1 and 2 were found in more than 90% of children and to type 3 in 83% to 95%.[28,518–523] Data from population-based studies of antibody seroprevalence conducted among Army recruits in the United States in 1989 (>95% to poliovirus types 1 and 2 and >85% to poliovirus type 3),[517] among school-age children in Massachusetts in 1981 (>99% to poliovirus type 1, >99% to poliovirus type 2, and >99% to poliovirus type 3),[516] and in The Gambia (88.1% to poliovirus type 1 and 89.3% to poliovirus type 3 among 3- to 4-year-old children)[524]

demonstrate that poliovirus antibodies induced by OPV persist for many years. Similar data are available from Sri Lanka where the prevalence of detectable antibody reached a peak in 9- to 11-month-old infants (≥95% to all three serotypes), remained stable at this level for serotypes 1 and 3, but declined to ~75% for serotype 3.[525]

Of interest, the median titer against poliovirus type 3 was substantially lower compared with those against types 1 and 2 among 9- to 11-month-old infants.[525]

Adverse Events

Vaccine-Associated Paralytic Poliomyelitis

In the early 1990s, the Institute of Medicine reviewed adverse events associated with childhood vaccines, including poliovirus vaccines.[526] The major adverse event associated with OPV is VAPP. Shortly after licensure and widespread use of mOPV, cases with paralytic manifestations followed vaccination with monovalent type 3 vaccines. These cases were considered clinically consistent with poliomyelitis and were supported by laboratory findings that did not exclude a possible causal relationship to the administration of oral vaccine. The report by the Surgeon General describes the earliest cases of VAPP.[527]

In 1969, the WHO coordinated a collaborative study to obtain data on the potential risks associated with OPV use. The findings of the first 5- and 10-year follow-up studies were published.[528,529] During the 5-year period from 1980 to 1984, 395 cases of acute persisting spinal paralysis were reported from 13 countries with a total population of 547 million.[530] The risk of VAPP (in recipients or contacts of recipients) was less than 0.3 cases per million doses of OPV distributed (or <1 case per 3.3 million doses), and the average annual incidence of VAPP was 0.14 per 1 million people (range: 0.0–0.33), excluding Romania. Romania reported an average annual incidence of 2.7 per 1 million people.

Although some have challenged the existence of VAPP,[28,531,532] believing that the cases of paralysis have different etiologic factors, the following evidence supports vaccine viruses as causative:

- Clinical syndromes are typical of poliomyelitis.
- Vaccine virus is frequently isolated from cases.
- History of exposure to vaccine is often obtained.
- Recipient and contact cases cluster after receipt of the first dose of OPV. (One would expect virtually equal numbers of cases after each dose if there were other etiologic agents causing the illnesses.)
- Shed viruses have mutated toward neurovirulence.
- The incidence of VAPP is highest in immunodeficient people with B-cell deficiencies, a group that is also at higher risk of poliomyelitis from wild poliovirus.[533] The completeness of reporting of VAPP cases to the Centers for Disease Control and Prevention (CDC) was estimated to be 81%.[534]

Between 1990 and 2003, a total of 61 cases classified as VAPP were reported in the United States, including 27 (44%) among immunologically normal vaccine recipients, 10 (16%) among immunologically normal contacts of vaccine recipients, six (10%) among immunologically normal nonhousehold contacts, 16 (26%) among immunologically compromised OPV recipients or contacts of OPV recipients, one indeterminate case (2%), and one imported case (2%).[534,535] Fig. 49.13 shows VAPP by year from 1964 to 2003; no cases occurred after the United States implemented an all-IPV policy in 2000. Since then, no VAPP has been reported in the United States, with two exceptions: In 2005, the first case of imported VAPP in an immunologically compromised person was reported.

Adapted from Alexander LN, Seward JF, Santibanez TA, et al. Vaccine policy changes and epidemiology of poliomyelitis in the United States. JAMA. 2004;292:1696–1701.

The person had never been vaccinated because of a religious exemption and acquired the poliovirus infection during travel to an OPV-using country in Central or South America.[536] The second case occurred in 2009 in an adult with longstanding common variable immunodeficiency whose infection probably occurred through household contact with her child who had received OPV 12 years earlier.[90]

For the period 1990 to 1999, the risk of VAPP in the United States was estimated as one case per 2.9 million doses of OPV distributed; for children receiving the first doses of OPV, the risk was estimated as one case per 1.4 million children vaccinated (Table 49.13).[535,537] The risk of VAPP is highest after the first dose of OPV. Recipients of a first dose and their contacts had a 6.6-fold higher risk of VAPP than did recipients of subsequent doses and their contacts. People with immunodeficiency disorders are at highest risk for VAPP. The risk of VAPP among immunocompromised people is elevated to more than 3200 times the risk for immunocompetent people.[538] Almost

all cases occurred in people with congenital or acquired immunodeficiency. Immunodeficient people with VAPP primarily had abnormalities affecting the B-cell system (humoral immunity), with agammaglobulinemia or hypogammaglobulinemia most frequently associated with VAPP.[538] Except for one VAPP case with immunodeficiency disorder, in all other cases, the precipitating event for the diagnosis of immunodeficiency was the onset of paralytic disease. Poliovirus type 3 is the virus most frequently isolated from immunocompetent people with VAPP. In contrast, poliovirus type 2 is the most common virus detected in immunodeficient people with VAPP. Poliovirus type 1 is rarely isolated from cases with VAPP.[268]

The epidemiology of VAPP was summarized in the United States for the 1990 to 2003 period. During this period, three different vaccination schedules were in use: (a) almost exclusive use of OPV for primary prevention of poliomyelitis, 1990–96; (b) use of a sequential schedule of first IPV then OPV, 1997–99; and (c) the introduction of an exclusive IPV schedule in 2000. Overall, the VAPP estimates for the first period were consistent with earlier estimates (1 case per 2.9 million doses distributed). Although 13 VAPP cases occurred during the 1997–99 period, none occurred in recipients of the sequential IPV-OPV schedule. Finally, as expected, no VAPP cases were reported following the introduction of an all-IPV schedule, resulting in the final step toward polio control, the elimination of VAPP.[535]

Romania and Hungary have consistently reported higher rates of VAPP than other countries with well-developed surveillance systems. Until recently, Romania and Hungary used tOPV and mOPV, respectively, solely in campaigns.[288,409] The high risk of VAPP in Hungary was associated primarily with the administration of mOPV3.[409] The high risk of VAPP in Romania can be attributed to provocation poliomyelitis (i.e., multiple intramuscular injections in the 30 days before paralytic manifestations).[539] People with VAPP in Romania had received, on average, 16.8 intramuscular injections, primarily for antibiotics, in the 30 days before onset of paralysis. Analysis of VAPP cases in the United States between 1980 and 1993 suggested that cases with a history of intramuscular injections received an average of only 1.5 intramuscular injections in the 45 days before onset of paralysis; no clustering of injections during the 45-day period was observed.[540] In contrast, in Romania, most injections were received in the periods from 0 to 7 days and from 8 to 14 days before onset. It seems unlikely that intramuscular injections contribute substantially to the VAPP burden in the United States. The risk of VAPP in the Americas, where Latin America administered large quantities of OPV in mass campaigns (NIDs) to eradicate poliomyelitis, was similar to the VAPP risk reported in the United States and other countries.[541] An analysis in India further refined the risk estimates for one large developing country and demonstrated that the risk of VAPP is substantially lower in this country despite large quantities of OPV administered in mass vaccination campaigns and through routine immunization programs (>700 million doses of OPV in 1999 alone).[542] The risk among first-dose recipients was estimated as one case per 2.8 million children (compared with a first-dose recipient risk of one case per 1.4 million children in the United States). The lower risk estimates in India may be explained in part by the following: (a) The proportion with and the titers of maternally derived antibody are high among newborns because wild poliovirus circulated widely until recently and may have led to frequent virus exposure and boosting of titers in the general population. (b) A birth dose of OPV is recommended for institutional births (thus inducing immunity when the newborn is still under protection against poliomyelitis from maternally derived antibody). (c) The routine vaccination schedule calls for OPV doses at 6, 10, and 14 weeks of age (again inducing immunity at earlier ages than in industrialized countries). Thus, high levels of maternal antibody and OPV vaccination at an age when maternal antibody would be expected to protect against VAPP seem to be the main reasons why the observed risk of VAPP in India (and probably in other countries under similar circumstances) seems to be lower than that in industrialized countries.[542]

The global burden of VAPP has been estimated by the WHO as between 250 and 500 cases globally each year, based on a total incidence of two to four cases per million birth cohort.[543] A recent review of VAPP updates the epidemiologic information and provides more current the risk estimates.[365] The review reported that the majority of recipient VAPP cases were associated with type 3 poliovirus (42%), followed by type 2 (26%), type 1 (20%), and mixtures of more than one virus (15%). Immunodeficient children are subject to infection, frequently fatal, by a wide variety of normally benign or avirulent agents. Nonpolio enteroviruses may cause serious or fatal illnesses in immunocompromised people.[544,545] A prominent feature of such infections is the patient's difficulty or inability to eradicate the virus from the CNS; some patients continue to yield virus from cerebrospinal fluid for up to 3 years.[546] As of the end of 2015, 94 persons with immunodeficiency disorders have been shown to excrete poliovirus for prolonged periods of approximately 6 months or longer (see "General Epidemiology" earlier) since the early 1960s. Two cases in this series deserve special attention. A patient with VAPP in the United States may have excreted virus for approximately 7 years before the onset of paralytic disease in 1981,[198,199] and a person from the United Kingdom who does not have paralytic disease has excreted poliovirus for more than 25 years (as of 2015).[200] In immunodeficient persons, poliovirus infection, by a wild virus or a vaccine strain, may develop in an atypical manner, with an incubation period longer than 28 days, a high mortality rate after a long chronic illness, and unusual lesions in the CNS.[22,321,538,547]

Vaccine-Derived Polioviruses

In principle, all clinical and environmental vaccine-related poliovirus isolates are VDPVs. However, for the purposes of poliovirus surveillance vaccine-related isolates have been classified into two broad categories: (a) OPV-like isolates, which have limited divergence from their parental OPV strains and are ubiquitous wherever OPV is used, and (b) VDPV isolates, whose higher level of VP1 sequence divergence from their parental OPV strains (>1% [types 1 and 3] or >0.6% [type 2]) indicates prolonged replication (or transmission) of the vaccine virus. VDPVs are identified by the laboratories of the GPLN and reported for further epidemiologic and clinical investigations and classification into either of two well-defined categories: (a) cVDPVs and (b) iVDPVs. If the VDPVs cannot be definitively categorized, they are classified as ambiguous VDPVs (aVDPVs).[548]

Although the vast majority of vaccine-related isolates are OPV-like, VDPVs are of particular interest because of their implications for current and future strategies for global polio eradication.[251,450,548–550] VDPVs can cause paralytic polio in humans and have the potential for sustained circulation. The clinical signs and severity of paralysis associated with VDPV and wild poliovirus infections are indistinguishable. VDPVs resemble wild polioviruses phenotypically[450] and differ from the majority of vaccine-related poliovirus isolates by having genetic properties consistent with prolonged replication or transmission. Because poliovirus genomes evolve at a rate of approximately 1% per year (see Table 49.5), vaccine-related viruses that differ from the corresponding OPV strain by more

than 1% of VP1 nucleotide positions are estimated to have replicated for at least 1 year in one or more persons after administration of an OPV dose. This is substantially longer than the normal period of 4 to 6 weeks of vaccine virus replication in an OPV recipient.[127] The demarcation for type 2 VDPVs was lowered to 0.6% to increase sensitivity for early detection of type 2 cVDPV outbreaks.[133,136,551]

It seems likely that many OPV-like isolates have recovered the capacity for higher neurovirulence and possibly increased transmissibility. The small number of substitutions controlling neurovirulence (see Fig. 49.6) was found to have reverted among many OPV-like isolates, especially among isolates of types 2 and 3.[351,358,373] Because the critical attenuating mutations in the IRES of the Sabin strains also affect fitness for virus replication in the human intestine,[373] it appears possible that revertants at these sites would have a higher fitness for person-to-person spread. However, spread is normally limited by high OPV coverage, and the VDPVs represent viruses whose potentials for prolonged replication or transmission have been clearly demonstrated.

The three categories of VDPVs differ in their public health importance. cVDPVs pose the same public health threat as wild polioviruses because they have recovered the biological properties of wild polioviruses, have the potential to circulate for years in settings where poliovirus vaccination coverage to prevent that particular type is low, and require the same control measures. iVDPVs may be excreted by persons with certain primary immunodeficiencies for many (>10) years with no apparent paralytic signs.[90,209] Persons infected with iVDPVs without paralysis are at risk of developing paralytic poliomyelitis[90,199,205] and may infect others with poliovirus, presenting the potential risk of outbreaks in areas with low poliovirus vaccine coverage.[310] aVDPVs are heterogeneous: some represent the initial isolates from cVDPV outbreaks, whereas others, such as highly divergent aVDPVs detected in sewage, are probably iVDPVs from unrecognized chronic infections.

Circulating Vaccine-Derived Polioviruses. Among the two well-defined categories of VDPVs, cVDPVs are of the greatest current public health concern.[450,550] Traditionally, the cVDPVs definition required evidence of transmission (i.e., more than one case). In 2015, the definition was refined to increase the sensitivity for initiating an outbreak response action in preparation for the switch from tOPV to bOPV (i.e., the removal of Sabin type 2 poliovirus from the OPV). In short, a VDPV case can now be classified as cVDPV outbreak if the molecular findings suggest 15 or more nucleotide changes in the VP1 region of the genome. All cVDPVs, implying that transmission is ongoing, require programmatic action for outbreak response. Since 2000, cVDPV outbreaks have occurred in 23 countries, with the large majority (87%) of reported cases associated with type 2 (Table 49.14). Type 1 cVDPVs were associated with outbreaks in seven countries with the largest number of cases (n = 46) reported from Indonesia in 2005.[66,305] In contrast, type 3 cVDPV outbreaks are rare, accounting for only 1.5% of known cVDPV cases, an unexpected finding because the type 3 OPV strain is a major contributor to VAPP in OPV recipients.[549] Because the case-to-infection ratio for poliovirus type 2 infections is low, the number of type 2 cVDPV infections worldwide since 2000 is estimated at approximately 1 million.[136,552]

During 2005–15, a polio outbreak of 417 cases associated with type 2 cVDPV was reported from 11 northern and three north-central states of Nigeria (see Fig. 49.13 and Table 49.14).[136,556,557] The outbreak peaked at 153 cases in 2009, but 11 indigenous cases were reported in 2014 and a type 2 cVDPV of the major lineage group[136] was detected in sewage in 2015.[548] Genetic analysis resolved the outbreak into more than 20 independent type 2 VDPV emergences that occurred during 2004–12, at least seven of which established circulating lineages.[136,557] The outbreak occurred in states where routine immunization coverage with tOPV was low and NIDs and Subnational Immunization Days were infrequent and often did not include type 2–containing vaccine.[556,557] Spread of the type 2 cVDPV from northern Nigeria has been limited, with only six cases in Niger from multiple importations and one case in Chad from an importation in 2010 (see Table 49.14). The cVDPV lineage originating from Chad was most recently detected in a contact (of a wild poliovirus type 1 case) in Borneo State, Nigeria, in August 2016. The limited spread may indicate that surrounding areas have higher levels of population immunity to poliovirus type 2 (because of the high immunogenicity of Sabin 2 and its higher tendency to infect OPV contacts).[299]

Since 2006, 96% of cVDPV cases have also been associated with type 2 cVDPVs (see Fig. 49.13), several of which were associated with multiple independent emergences (see Table 49.14).[133] Other type 2 cVDPVs have emerged successively in the same geographic area.[554] In several settings, this reflects the continued weakness in routine immunization with tOPV and the extensive use of mOPV1 and bOPV in mass campaigns, which probably allowed substantial accumulation of susceptible persons to type 2 in the population allowing the type 2 virus in children who received tOPV in routine immunization to spread and mutate. In addition, it also probably reflects the greater tendency of the Sabin 2 OPV strain to revert and spread to contacts.[549]

Key risk factors for cVDPV emergence and spread are: (a) development of immunity gaps arising from low OPV coverage, (b) prior elimination of the corresponding wild poliovirus serotype (except Indonesia[305]), (c) emphasis on use of mOPV and bOPV in NIDs and Subnational Immunization Days,[133,556] leading to increasing susceptibility to type 2 in the population, and (d) insensitive AFP surveillance. Many of these factors exist in areas of insecurity and where rates of routine tOPV coverage remain low, such as in parts of Afghanistan, the Central African Republic, northern Nigeria, Pakistan, Somalia, and Yemen. In this context, type 2 VDPVs present the greatest threat for emergence,[133] and routine immunization was strengthened and, up to April 2016 (see "Laboratory Containment of Polioviruses"), regular immunization campaigns with tOPV were conducted to close any type 2 population immunity gaps.

The large majority of cVDPVs shown in Table 49.14 have vaccine/nonvaccine recombinant genomes, which are rare among OPV-like and iVDPV isolates.[549] Recombination with other species-C enteroviruses frequently occurs during wild virus circulation, and may be interpreted as an indication of person-to-person transmission. Whether recombination facilitates cVDPV emergence is unclear, because type 1 cVDPVs from China had nonrecombinant genomes[553] and recombination continues after emergence, similar to what is observed with wild polioviruses.[136]

Immunodeficiency-Associated Vaccine-Derived Polioviruses. It has long been recognized that patients with primary immunodeficiencies (defects in antibody production) could become chronically infected when exposed to OPV.[561] Unambiguous demonstration that vaccine-related poliovirus isolates from immunodeficient patients had unusual sequence properties awaited the application of molecular tools, such as oligonucleotide fingerprinting[199] and genomic sequencing,[85,199,205] to poliovirus diagnostics. The extent of sequence divergence is correlated with the duration of the prolonged infection.[85,90,199,205,294] Not all isolates from immunodeficient patients are classified as iVDPVs. Some isolates are from

specimens taken early in the prolonged infection and no subsequent specimens were taken. In other situations, either the prolonged infections had resolved spontaneously or the patient died from complications of the immunodeficiency (including fatal poliomyelitis).[562] Prolonged iVDPV infections are independent events, and the isolates obtained from such infection trace separate pathways of divergence from the original OPV strains.

Since the introduction of OPV in 1961 (data as of mid-2016), 94 persons with primary immunodeficiencies have been found worldwide to be excreting iVDPVs (indicating prolonged infections); the majority of these immunodeficiencies were detected only after onset of AFP.[548] After implementation of intensified surveillance for VDPVs and special studies of iVDPV excretion among persons with primary immune deficiency syndromes in developing and middle-income

countries,[563] detection of new iVDPV infections increased.[548] The extent of sequence divergence is correlated with the duration of the prolonged infection (≤5 years).[85,90,199,205,294] Four of the iVDPV isolates are highly divergent (>10% VP1 sequence divergence from the parental OPV strain), suggesting that the chronic poliovirus infections (>5 years) had persisted for approximately 10 years.[450] Patients with the most divergent isolates and the most prolonged (chronic) infections have CVID, a group of late-onset immunodeficiencies that have multiple etiologies.[564] CVID is the most prevalent (~1 in 50,000)[564] of the primary immunodeficiencies, but only a small proportion of CVID patients exposed to OPV become chronically infected with iVDPVs.

Unlike cVDPV outbreaks, prolonged iVDPV infections cannot be prevented by high OPV coverage and can be prevented only by cessation of OPV use. Persons with prolonged iVDPV infections can transmit poliovirus to others, raising the risk for VDPV circulation in settings of low population immunity to the corresponding poliovirus serotype. So far, nearly all reports of persistent iVDPV infections have been from countries with high to intermediate levels of development, where the rates of vaccine coverage are high and where the survival times of immunodeficient patients may be extended by treatment with intravenous immunoglobulin. The survival rates for persons with primary immunodeficiencies are probably very low in developing countries at highest risk for poliovirus spread. The population of prolonged iVDPV excretors is declining in developed countries because some patients have died, some have cleared their infections, and no new iVDPV infections have been found in countries that have shifted to IPV. However, the prevalence of long-term iVDPV excretors might be higher than suggested by existing surveillance of persons with primary immunodeficiencies, and several aVDPVs have properties closely resembling iVDPVs (see below). The development of treatment for prolonged iVDPV infections might facilitate detection of and access to those with prolonged infections.[211]

Type 2 iVDPVs are the most prevalent (65%), followed by types 1 (18%) and 3 (17%).[548] Some patients have heterotypic iVDPV infections (i.e., types 1 and 2 or types 2 and 3), with the isolates having similar degrees of divergence from the parental OPV strains, consistent with a common OPV dose initiating the infections. In addition to the occasional heterotypic infections, iVDPV isolates generally have distinguishing genetic properties, including heterogeneity at sites of nucleotide variability within serotypes (indicative of mixed virus populations), extensive antigenic variability, and either nonrecombinant or vaccine/vaccine recombinant genomes.[450,548] The underlying reason for this pattern of recombination may be that individuals with prolonged iVDPV infections may be resistant to superinfection by other enteroviruses.

Ambiguous Vaccine-Derived Polioviruses. Unlike the well-defined cVDPV and iVDPV categories, aVDPVs are a heterogeneous collection of isolates. Some aVDPVs have diverged by just over 1% from the parental OPV strains, have no detected progeny, and may reflect the extremes of the usual distribution of vaccine-related variants in countries using OPV.[450] Detection of other aVDPVs have foreshadowed subsequent cVDPV outbreaks[133,565]; others indicate limited person-to-person spread of OPV virus in small communities with gaps in OPV coverage,[310,311,549,566,567] whereas others appear to indicate more prolonged circulation. Most of these latter aVDPVs have vaccine/nonvaccine recombinant genomes typical of cVDPVs.

Many of the aVDPVs are isolated from the environment, and some have genetic properties (mixed VDPV populations, extensive antigenic changes, and nonrecombinant or vaccine/vaccine recombinant genomes) typical of iVDPVs. Some highly divergent aVDPVs have been detected in Israel,[548,568] Estonia,[296] Slovakia,[569] and Finland,[570] countries with high rates of polio vaccination coverage that are unlikely to have extensive VDPV transmission. The sequence divergence of some of these isolates is consistent with more than 15 years of replication from the original initiating OPV dose. It is likely that the sources of these viruses are immunodeficient persons with asymptomatic VDPV infections, some of whom may be at risk for subsequent paralytic poliomyelitis, although the infected persons remain to be identified.[450]

Simian Virus 40

During the early years of OPV production, some cell cultures were contaminated with simian virus 40 (SV40), a virus that causes cancer in rodents.[571] Although concerns were raised about the carcinogenic potential of SV40 in vaccinees and their offspring, long-term follow-up studies do not support such an association.[572,573] A meeting convened at the National Institutes of Health in 1997 reexamined the available evidence and concluded that "no measurable increase in neoplastic diseases has occurred in humans exposed to SV40 contaminated polio vaccines."[574] Subsequently, a report evaluated the cancer risks of birth cohorts potentially exposed to SV40 and concluded that these cohorts did not experience a significantly increased risk for the cancer outcomes studied.[575] Nevertheless, the question of whether SV40 exposure can increase cancer risk continues to be debated. [576,577] A review by the Immunization Safety Committee (under the auspices of the Institute of Medicine) concluded in 2002 that because the epidemiologic studies were sufficiently flawed, the evidence was inadequate to conclude whether SV40-contaminated polio vaccine caused cancer.[578] Several subsequent cohort and case-control studies using more scientifically rigorous methods failed to support a relationship between SV40 and cancer.[579–582] Cell lines currently used for OPV production come from monkeys raised in colonies free of SV40 or from well-characterized continuous cell lines (Vero cells). In addition, OPV must be screened for known viruses; consequently, SV40 is not present in current lots of OPV vaccine.

Guillain-Barré Syndrome

A review by the Institute of Medicine in 1992 suggested that "the evidence favors acceptance of a causal relationship between OPV and Guillain-Barré syndrome."[526] This conclusion was based primarily on data from Finland, where an OPV mass campaign was conducted to control an outbreak of poliomyelitis and Guillain-Barré syndrome developed in 27 patients within 10 weeks after initiation of the campaign.[583,584] However, after the Institute of Medicine review was completed, the Finnish data were reanalyzed and an observational study was completed in the United States.[585,586] The observational study in the United States showed that rates of Guillain-Barré syndrome after OPV were similar to rates that would have been expected in the absence of vaccination. The reanalysis in Finland suggested that the increase in risk for Guillain-Barré syndrome began before the mass vaccination campaign had been initiated and noted that an influenza epidemic occurred concurrently with the mass campaign. Thus, the available data do not support a causal relationship between OPV and Guillain-Barré syndrome.

Contraindications and Precautions

Contraindications for OPV administration differ somewhat depending on where the vaccine recipient resides (Table 49.15). The risk-to-benefit ratio of OPV versus no vaccine

TABLE 49.15 Contraindications and Precautions for Use of Oral Poliovirus Vaccine in the United Kingdom,[a] United States,[a] and Developing Countries

Type[587,588]		United Kingdom[589]	United States[537]	Developing Country (WHO)[270]
Contraindications	Known or suspected immunodeficiency disorder or immunocompromised	Yes	Yes	Yes[b]
	Family member known to have or suspected of having immunodeficiency disorder or being immunocompromised	Yes	Yes	Yes[c]
	HIV infection	No[c]	Yes	No[d]
	Age ≥18 y	No	Yes (use IPV)	NA
	Allergic reaction to previous doses of OPV or one of its components	No	Yes	NA
Precautions	Pregnancy	Yes	Yes[e]	NA
	Diarrhea	Yes (postpone)	No	Yes (repeated doses)

[a]Recommendations formulated when OPV was vaccine of choice. United States switched in 2000, and the UK in 2004 to an all-IPV schedule.
[b]If immunodeficiency is known.
[c]For HIV-positive symptomatic individuals, IPV may be used instead of OPV at the discretion of the clinician.
[d]Yes, if clinical disease.
[e]If immediate protection against poliomyelitis is necessary, IPV or OPV can be used.
IPV, inactivated poliovirus vaccine; NA, not applicable; OPV, oral poliovirus vaccine; WHO, World Health Organization.

among children residing in countries with endemic poliomyelitis or recent endemic poliomyelitis favors OPV administration in almost all circumstances. Because of the availability of IPV in a number of industrialized countries and because the need for mucosal (intestinal) immunity is not as important compared with polio-endemic countries, industrialized countries may have more contraindications to OPV use than developing countries. However, because IPV is or soon will be available in most countries, some countries may revise the list of contraindications and precautions to ensure that known immunodeficient individuals and their family may only receive IPV. In general, OPV is contraindicated in people with known immunodeficiency disorders and people receiving cancer chemotherapy. Age older than 18 years and pregnancy were precautions in the United States, and OPV doses should be repeated in children who vomit within 30 minutes of OPV receipt. In developing countries, OPV doses administered to children with diarrhea also should be repeated. More details on contraindications and precautions are discussed in the following sections.

Altered Immune States

In industrialized countries, people with known or suspected immunodeficiency disorders, such as severe combined immunodeficiency, CVID, agammaglobulinemia, and hypogammaglobulinemia, should not receive OPV.[537,538,587,589] Similarly, in people with altered immune states resulting from diseases such as leukemia, lymphoma, or generalized malignant disease or with immune systems compromised by therapy with corticosteroids, alkylating drugs, antimetabolites, or radiation, OPV is contraindicated. Because of the potential for vaccine spread, OPV should not be given to a child who is a member of a family in which there are immunocompromised persons. Also, where there has been a family member with immunodeficiency in the past, OPV should not be given to another child unless that child is known to be immunocompetent.

Human Immunodeficiency Virus Infection

In many industrialized countries, OPV in people infected with HIV is considered a precaution or a contraindication. OPV also should not be used for immunizing household contacts of patients with the immunodeficiency disorder; instead, IPV is recommended.

In developing countries, the HIV status of infants is often not known and IPV is not available as an alternative vaccine. In these settings, OPV is administered early in life (i.e., 6, 10, and 14 weeks of age) on the basis of WHO recommendations; this is an age when HIV infection would not be expected to have caused immunodeficiency. Several studies showed that OPV induces antibody to polioviruses in a similar proportion of HIV-infected infants compared with the response in non–HIV-infected infants.[590,591] HIV infection does not seem to be a risk factor for paralytic poliomyelitis caused by wild poliovirus[592] or for VAPP. There are only two case reports in the literature, one from Romania and one from Zimbabwe, that link HIV infection and VAPP.[593,594] Studies in Kenya and from Côte d'Ivoire evaluated HIV-infected children and adults with AIDS for long-term excretion of poliovirus. These studies did not detect long-term excreters and suggest that the risk of long-term carriers of poliovirus among persons with acquired immunodeficiency syndrome may be low.[595] A study in South Africa demonstrated divergent vaccine virus in some HIV-infected persons; however, it is not possible to ascertain whether this reflects extended replication in an individual or recent exposure.[596]

Previous Allergic Reaction

The OPV may contain trace amounts of penicillin, neomycin, polymyxin, and streptomycin, and a previous allergic reaction to OPV or a similar reaction to these antibiotics constitutes a contraindication to further OPV receipt.[537,589]

Adult Use

The recommendations for use of OPV among unvaccinated adults 18 years or older in industrialized countries is not uniform. In the United States, adults should not receive OPV because of concerns about a slightly elevated risk of VAPP in adults.[527] In the United Kingdom, no such restrictions were recommended.[589] Nevertheless, at-risk adults in the United States may receive OPV if they had been primed by OPV previously.[537] However, to control wild poliovirus circulation among older age groups, such as in outbreaks in Israel,[597] Albania,[213] Cape Verde,[215] Namibia,[220] Tajikistan,[216] and most

recently in Congo-Brazzaville,[217,243] and the Democratic Republic of the Congo,[243] it has been necessary to extend the target age group for control measures with OPV and, in some instances, to target the entire population.

Pregnancy

In most industrialized countries, pregnancy is a contraindication or a precaution to OPV receipt.[589] Two evaluations have found no link between adverse outcomes and administration of OPV to pregnant women.[598,599] Nevertheless, most immunization authorities recommend that immunization during pregnancy generally should be avoided for reasons of theoretical risk. However, if immediate protection against poliomyelitis is needed, IPV or OPV can be used.[537,587]

Diarrhea

In developing countries, OPV may be given to a child with diarrhea; however, because of the lower immunogenicity of OPV in these countries, the dose should not be counted as a valid dose toward completing the routine schedule and should be repeated 4 weeks later.[463,464,537,587,600]

Simultaneous Administration With Other Vaccines

In industrialized countries and in developing countries, OPV is usually administered with other vaccines, including (where appropriate) bacille Calmette-Guérin (BCG), DTP, hepatitis B, measles, *Haemophilus influenzae* type b, and other vaccines used routinely,[537,600] because no interference between these vaccines and OPV has been observed. However, newer studies conducted in Guinea-Bissau suggest that simultaneous administration of BCG and OPV at birth could decrease immune responses to BCG.[601,602] In addition, with the licensure of rotavirus vaccines, the issue of potential interference between these vaccines has been raised. At this point, the evidence suggests that simultaneous administration of rotavirus with OPV will not decrease the immunogenicity of OPV.[603,604]

Intussusception

Following withdrawal of a specific rotavirus vaccine associated with intussusception in the United States in the early 2000s, the issue of OPV and intussusception gained renewed interest. Several studies in the United Kingdom and Cuba show that there is no evidence for an association between OPV and intussusception.[605,606]

Sequential and Combined Schedules

As of early 2014, the WHO does not recommend an all-OPV schedule for poliomyelitis prevention through routine immunization.[607] Thus, all countries should use schedules that are based either on IPV-only or sequential schedules using both IPV and OPV. Over time many countries have adjusted their routine immunization schedules. For example, the United States shifted from an exclusive OPV schedule to a preferred sequential schedule of two doses of IPV followed by two doses of OPV in 1997 and to an IPV-only schedule in 2000.[588,608] Many countries in Central and Eastern Europe and elsewhere have examined the advantages and disadvantages of sequential vaccination schedules for adoption into national vaccination policies. Sequential schedules offer the following scientific and programmatic advantages:

- The schedule should reduce the number of VAPP cases among recipients by at least 95% and to some degree among contacts because the oral mucosal immunity induced by two doses of IPV should reduce spread of vaccine virus.
- Continued use of OPV will induce effective intestinal immunity,[609] thereby enhancing community resistance to transmission of imported wild poliovirus.
- There is opportunity for spread of vaccine virus, thus immunizing people missed by routine immunization. (This becomes less important as immunization coverage reaches high levels.)
- The number of injections in the second year of life is reduced from what would be required with use of an IPV-only schedule, making compliance with the overall schedule easier.
- The schedule will lead to stocking of both poliovirus vaccines by healthcare providers, facilitating choice by parents and providers.

In April 2016, all previous OPV-using countries adapted a new routine immunization schedule for poliomyelitis prevention that relies on three or more doses of bOPV (given at [birth] 6, 10, and 14 weeks) supplemented by a dose of IPV at 14 weeks given concurrently with bOPV.[607] The global switch was implemented very efficiently.[609a] The immunogenicity of the new sequential schedules was assessed by reviewing data on the vaccines used, the age at administration, the number of doses, and the interval between doses. In addition to the results of the immunogenicity studies, there is a growing body of evidence suggesting the effectiveness of this approach in controlling VAPP and, by extension, poliomyelitis caused by wild poliovirus.[610]

In the United States, a small trial first demonstrated the immunogenicity of two sequential schedules of IPV and OPV in inducing antibody.[611] Subsequently, a series of studies were conducted in the United States to assess the immunogenicity of sequential schedules of IPV followed by OPV. In general, these studies showed that a series of at least three doses of either vaccine—IPV or OPV or with sequential or combined use—was necessary to induce antibody to all three poliovirus serotypes in more than 90% of vaccinees.[612–614]

To assess the effectiveness of three sequential schedules in inducing mucosal immunity in the United States, vaccinees received a dose of OPV at age 18 months (3 months after the last dose of poliovirus vaccine), and stool specimens were obtained before challenge (day 0) and 3, 7, and 21 days thereafter. One dose of OPV at 15 months after two doses of IPV at 2 and 4 months reduced shedding of poliovirus types 2 and 3 (after challenge with OPV at 18 months), but did not decrease poliovirus type 1 shedding. Two doses of OPV after IPV decreased shedding of poliovirus type 1 and further decreased shedding of poliovirus type 3. The study, conducted by The Johns Hopkins University, demonstrated that at least two doses of OPV were needed to induce mucosal immunity sufficient to significantly decrease the proportion of vaccinees excreting poliovirus.[609] The proportion of study subjects who had received prior IPV and excreted type 1 (18%) was much lower than expected based on other challenge studies with OPV. The reasons for this discrepancy are not known because other challenge studies of IPV vaccinees with tOPV led to 80% shedding of poliovirus type 1[615] and with mOPV led to 70% excretion.[490] We believe the most likely explanation is that the study duration (16 months) may have allowed participants (including participants receiving only IPV) to be exposed to vaccine virus excreted from other OPV-vaccinated infants, masking differences that may have existed shortly after the completion of the primary series.

No combined schedules of IPV and OPV have been evaluated in the United States, except for one study arm, which was part of a larger study of sequential schedules, that used one dose of OPV and IPV simultaneously at 4 months of age

(IPV at 2 months, IPV/OPV at 4 months, OPV at 6 and 15 months).[609] In this trial, two doses of IPV and three doses of OPV resulted in seroprevalence levels of 99% to 100% against poliovirus types 1, 2, and 3 compared with 99% to 100% after three doses of IPV and 96% to 100% after three doses of OPV.

In developing countries, the major issue is how to improve the immunogenicity of OPV with IPV use. In these settings, schedules using OPV followed by IPV were evaluated. These studies demonstrated that IPV after a primary series of OPV can correct the low immunogenicity of OPV alone that was commonly reported from tropical developing countries. A clinical trial conducted in India confirmed the excellent immunogenicity of bOPV at birth, 6, and 10 weeks, followed by bOPV and IPV at 14 weeks.[616] One month after the administration of the last doses of polio vaccines, 99% of participants seroconverted to poliovirus type 1, between 69% and 77% to poliovirus type 2, and 99% to poliovirus type 3. Similarly, a study conducted in Chile demonstrated an equally excellent immunogenicity of a schedule of one or two doses of IPV followed by one or two doses of bOPV.[617] In the Côte d'Ivoire, schedules that added a dose of IPV administered simultaneously with measles vaccine, after a course of three doses of OPV administered by the routine program, resulted in a significantly higher proportion of children with antibodies against poliovirus types 1 and 3 compared with a control group that received an additional dose of OPV. Administration of a dose of IPV increased seroprevalence from 85% to 97% for poliovirus type 1 and from 76% to 92% for poliovirus type 3.[618] The experiences in the Gaza Strip are of particular interest. In this area, a new combined and sequential schedule of OPV and IPV (mOPV1 during the first month, simultaneous administration of OPV and IPV at 2 to 3 and 3 to 4 months, and OPV at 5 to 6 and 12 to 14 months) reduced the incidence of poliomyelitis during the first 3 years after the change in vaccination schedule from an annual incidence of 10 per 100,000 population to 2.2 per 100,000 population.[610,619,620] In Israel, after the outbreak in 1988,[597] a sequential schedule of IPV and OPV was used for routine vaccination[621] until 2005, when Israel adopted an all-IPV schedule.[622] However, Israel modified the routine immunization schedule to include bOPV after the extensive "silent" type 1 circulation in 2013–14.

In the developing world, however, a large randomized trial in The Gambia, Oman, and Thailand compared the immunogenicity of the following: (a) a combined schedule of four doses of OPV administered at birth, 6, 10, and 14 weeks and IPV administered simultaneously with OPV at 6, 10, and 14 weeks; (b) four doses of OPV administered at birth, 6, 10, and 14 weeks; and (c) three doses of IPV administered at 6, 10, and 14 weeks. The combined schedule with seven doses of poliovirus vaccines performed significantly better (95% to 99% for poliovirus type 1, 99% seroconversion to 100% for poliovirus type 2, and 97% to 100% for poliovirus type 3) compared with four doses of OPV or three doses of IPV (Table 49.16).[464] In addition, the combined schedule was not affected by socioeconomic status or level of maternal antibody, in contrast with the comparison groups that received OPV or IPV, respectively. This study demonstrated that a combined schedule could correct the lower immunogenicity of OPV in developing countries, but additional doses of vaccine are required.[254] Intestinal mucosal immunity induced by the combined schedule in the IPV/OPV group was similar to that of the OPV group and significantly better than that of the IPV group.[464] A study in Guatemala comparing schedules of IPV, OPV, and IPV/OPV combined demonstrated high seroprevalence and found no significant differences between the groups after three doses.[623]

One study reported no benefit of one dose of OPV after three doses of IPV in terms of type 3 seroprevalence and geometric mean antibody titer[624]; however, a larger study in Oman demonstrated that additional doses of OPV significantly increased seroprevalence and geometric mean antibody titer to polioviruses types 1 and 3.[625] This study confirmed earlier observations about the incremental benefit of adding additional doses of OPV in terms of seroconversion and geometric mean antibody titer.[122,254,473,625] There is renewed interest in adding IPV to OPV for campaign use in limited places in the most difficult to control areas for poliomyelitis to boost both humoral and mucosal immunity and facilitate the interruption of poliovirus transmission.

Limited data are available on the persistence of poliovirus antibody induced by combined or sequential schedules of poliovirus vaccines. A single study in the United States evaluated the persistence of antibody 4 years after a primary series of sequential schedules.[626] Antibody persistence was excellent, but titers decreased by 10- to 100-fold during the first 2 years of follow-up, and thereafter the titers remained relatively stable.

Results of Controlled Trials of Protection Against Disease

There are no data from controlled trials of sequential schedules that were used as the outcome measure of the prevention of paralytic disease. Because detectable antibody to polioviruses provides an excellent correlate for protection, results of controlled trials are redundant and would be unethical to conduct.[22]

TABLE 49.16 Proportion Seropositive for Neutralizing Antibody to Poliovirus Types 1, 2, and 3 in Infants Immunized With OPV Alone, IPV Alone, or OPV and IPV Simultaneously in The Gambia, Oman, and Thailand

Age and Type of Vaccine Administered					Proportion Seropositive (%)		
Birth	6 wk	10 wk	14 wk	Serotype	The Gambia (N = 118)	Oman (N = 183)	Thailand (N = 145)
OPV	OPV	OPV	OPV	1	85	90	98
				2	97	98	100
				3	72	73	100
	IPV	IPV	IPV	1	81	88	66
				2	82	92	63
				3	92	91	92
OPV	OPV/IPV	OPV/IPV	OPV/IPV	1	97	95	99
				2	100	99	100
				3	99	97	100

IPV, inactivated poliovirus vaccine; OPV, oral poliovirus vaccine.

Potential Adverse Reactions With Sequential Schedules

Genetic sequencing studies suggest that reversion of Sabin strains to potentially more neurovirulent phenotypes occurs commonly after OPV administration.[330–347,349–351,627–633] Two relatively small studies[634,635] indicated that the use of a sequential schedule may not reduce the frequency of such mutations. However, one larger study suggests that the use of a dose of IPV before two or more doses of OPV may reduce the amount of type 3 virus shed, the most common cause of VAPP, but probably will not influence the shedding of type 1 or type 2 viruses or the extent of reversion.[636] VAPP has been rarely reported after sequential schedules using at least one dose of IPV before multiple doses OPV. In Hungary, a country that had a high risk of VAPP during decades, the switch to a sequential schedule (with one dose of IPV) was associated with the apparent elimination of VAPP. However, there is debate whether one dose of IPV is adequate to prevent VAPP.

Recommendations for Vaccine Use

Two major objectives of vaccination, protection at the youngest possible age and minimum rates of attrition (i.e., dropout) between OPV doses, govern the development of routine vaccination schedules in industrialized and developing countries. In each of these settings, an optimal balance must be found between these objectives.[122]

Industrialized Countries

Most industrialized countries, including many Western European countries, have recommended schedules in the past that relied exclusively on OPV for the prevention of poliomyelitis. More recently, encouraged by progress of the GPEI and by the desire to reduce or eliminate the burden of VAPP, many of the high- and middle-income countries are reevaluating their vaccination policy options. Since April 2016, all countries are using schedules that include at least one dose of IPV (Fig. 49.14). The world is now transitioning to introduce IPV. However, until all OPV is stopped, these countries rely primarily on tOPV, and after OPV2 withdrawal (see "New Polio Endgame" later), on bOPV for routine immunization. The major differences in the recommended schedules between industrialized and developing countries include (a) age at first dose, (b) vaccines used for each dose, and (c) interval between doses. The recommendations for poliomyelitis prevention in the United States were revised most recently in 2000.[588] A schedule relying only on IPV is now recommended by the CDC and the American Academy of Pediatrics for primary poliovirus vaccination of children in the United States. The schedule calls for three doses of IPV administered at 2 and 4 months and between 6 and 18 months. A preschool booster dose of IPV is recommended after age 4 years. Similarly, in the United Kingdom, an IPV-only schedule was introduced in 2004; doses are provided at 2, 3, and 4 months of age, and booster doses at pre–school-age (3 years and 4 months), and in adolescence (13 to 18 years) (Table 49.17).[589] The minimum recommended interval between doses of OPV for routine vaccination varies; in the United States, 6 to 8 weeks were recommended. For the United Kingdom, intervals between OPV doses of 4 weeks were preferred.[589] Table 49.18 shows the major advantages and disadvantages of the three poliovirus vaccination schedules.

Routine immunization for adults residing in the continental United States and many other industrialized countries is not believed to be necessary because of the small risk of exposure to wild poliovirus.[537,587,589] However, adults who are at increased risk because of contact with a patient infected with wild poliovirus or who are working with polioviruses and adults planning travel to an epidemic or endemic area should be immunized.

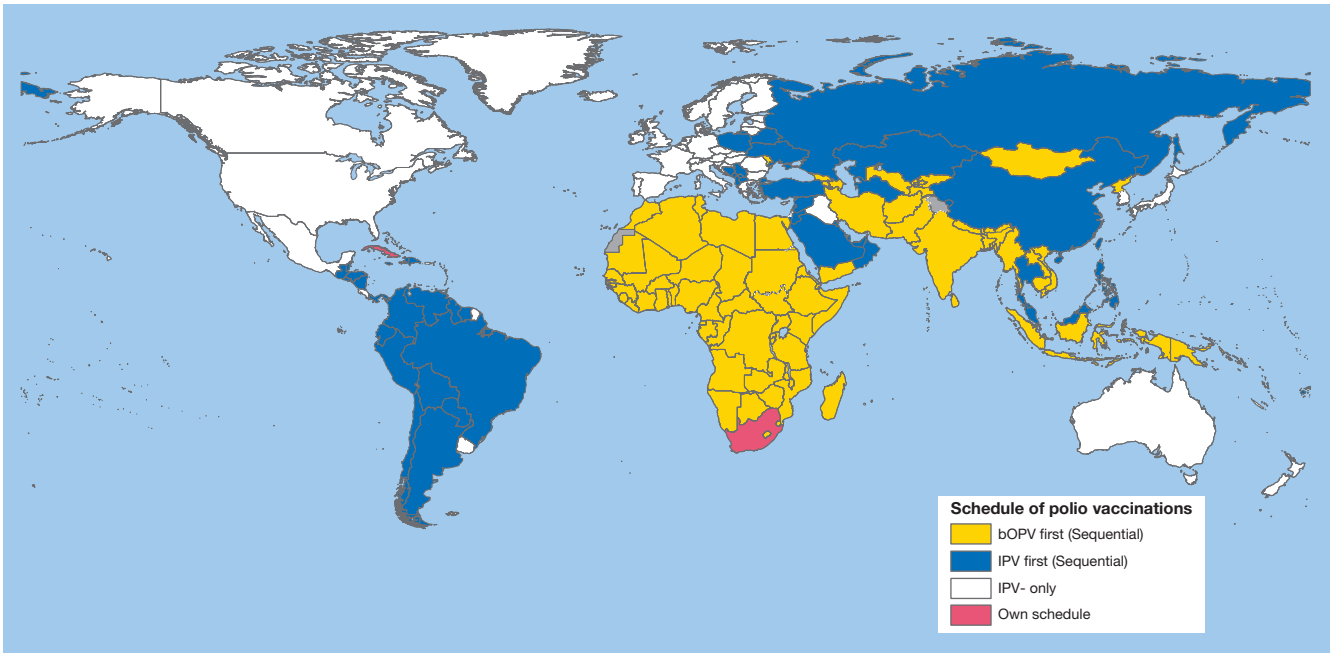

Figure 49.14. Countries using inactivated polio vaccine (IPV) only, a sequential schedule of IPV followed by bivalent oral poliovirus vaccine (bOPV), or a sequential schedule of bOPV followed by IPV in their national routine immunization program for the prevention of poliomyelitis following the withdrawal of Sabin type 2 from the oral polio vaccine (OPV) (implemented in April 2016). White, IPV only; blue, sequential schedule of IPV followed by bOPV; yellow, sequential schedule of bOPV and IPV; green, own schedule.

TABLE 49.17 Poliovirus Vaccination Schedules in the United States and the United Kingdom, 2000 to 2006, and WHO in 2013

Country	Vaccine	Age at Vaccine Administration				Recommendation Valid
United States	OPV IPV	2 mo 2 mo	4 mo 4 mo	6–18 mo 6–18 mo	4–6 yr 4–6 yr	Until 1999 From 2000
United Kingdom	OPV IPV	2 mo 2 mo	3 mo 3 mo	4 mo 4 mo	School entry[a] 3–5 yr; 13–18 yr	Until 2004 From 2005
WHO	OPV[b] IPV	6 wk	10 wk	14 wk 14 wk		From 2013

[a]At age 3 years and 4 months; in addition, an adolescence booster is provided at age 13–18 years.
[b]bOPV after April 2016 (OPV2 withdrawal).

Developing Countries

Until 2013, the WHO-recommended schedule called for the administration of four doses of OPV at birth, 6, 10, and 14 weeks of age for polio-endemic or recently polio-endemic countries. This is particularly important in areas in which frequent importation or endemic circulation of wild polioviruses takes place and in which a majority of infants are exposed to all three poliovirus types early in life.[212,254,610,619] For these areas, the primary immunization schedules not only should begin early, with the first dose being given to newborns, but also—and most important—should be completed as early as possible. Many countries also recommend a dose of OPV in the second year of life, usually at age 18 months given simultaneously with DTP.

This four-dose WHO-recommended schedule is supported by data from China,[637] where a schedule that included a birth dose of OPV performed considerably better than a schedule without a birth dose, particularly for type 3 (97% vs 74% seroprevalence). These recommendations have been further supported and extended by a review of the available literature on the efficacy of early immunization with DTP and OPV.[238,638–640] In 2010, the WHO issued a position paper on using polio vaccine in the preeradication era of poliomyelitis. This paper offers guidance to countries that are considering changes in routine immunization schedules for the preeradication era of polio eradication.[641] The new WHO recommendations for the choice of vaccine (and schedule) are determined by the potential for importation of poliovirus and the risk for transmission (coverage, socioeconomic status, hygiene) following importation. OPV and at least one dose of IPV are the vaccines recommended.[607]

Short-Interval Additional Dose Strategy

The short-interval additional dose strategy was developed to take advantage of limited access to high-risk, particularly inaccessible areas in order to provide multiple doses of OPV in a very short period, and was first piloted in parts of northwestern Kenya. By 2013–14, the strategy was widely used in polio-endemic countries, especially Pakistan, primarily in national and subnational vaccination campaigns to eliminate the remaining chains of poliovirus transmission. Two clinical studies have confirmed that the decrease from a 30-day interval, to a 14-day interval (for bOPV), or a 7-day interval (for mOPV1) is not associated with decreased immunogenicity.[479,642] These scientific data support the continued, and possibly expanded, use of this strategy.

Future Use of Poliovirus: The Role of New Oncolytic Poliovirus Immunotherapy of Cancer

The hope that oncolytic viruses could serve as effective antitumor agents predates the discovery of viruses and is rooted in 19th century clinical observations that cancer patients experienced (usually transient) remission following naturally acquired infectious diseases such as influenza, viral hepatitis, and chickenpox.[643] Clinical trials in the 1950s to 1970s demonstrated tumor regression in some patients following treatment with diverse viral agents, but serious side effects and the risk of secondary infections from the use of natural infectious agents appeared to dim the prospects for virotherapy.[643] Prospects again brightened in the 1990s with the availability of

genetically engineered attenuated oncolytic viruses and virotherapeutic application in animals of an engineered herpes simplex virus.[644] Currently, clinical trials of oncolytic viruses include representatives of at least 10 diverse virus families,[645] including the picornaviruses coxsackievirus A21[646] and poliovirus.[647] Prominent among these trials has been the complete radiographic and clinical responses of several patients with glioblastoma treated by direct injection of tumors with a highly attenuated derivative of Sabin 1, PVS-RIPO, engineered by exchange of the Sabin 1 IRES with that of a distant picornavirus relative, human rhinovirus type 2 (the rhinovirus IRES does not support replication in neurons).[648,649] Key to therapy with PVS-RIPO is its capacity to specifically target cells expressing the PVR, CD155, present at high levels on the cells of embryonic tissues and several tumors, including colorectal carcinoma, cutaneous melanoma, and glioblastoma.[650–652] Oncolytic activity is hypothesized to be mediated by a combination of direct and rapid lytic infection of some tumor cells, innate antiviral activation, and stimulation of an adaptive antitumor cytotoxic T-cell response.[652] The benefits of PVS-RIPO are potentially large for certain kinds of cancers whereas the containment risks (see "Laboratory Containment of Polioviruses") associated with its continued use appear to be very small because (a) PVS-RIPO is highly attenuated and genetically stable, (b) all patients must have high immune titers to type 1 poliovirus before treatment, (c) PVS-RIPO is injected directly into the tumor rather than systemically, (d) virotherapy induces an extremely strong neutralizing antibody response, (e) patients are regularly monitored for shedding of poliovirus in body fluids and none has been found, and (f) strict measures are implemented to prevent inadvertent exposure to poliovirus.[649]

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Results of Vaccination

Surveillance data since 1980 suggest that continuing transmission of indigenous wild poliovirus has been interrupted in the United States, during a period when the country relied on OPV for immunization.[268,533] As part of the certification of the Western Hemisphere as polio-free, all countries in the Americas, including the United States, were certified free of indigenous wild poliovirus in 1994 by an International Commission convened by the Pan American Health Organization on the basis of a detailed review of available data by national committees.[498] Fig. 49.15 shows data on poliovirus circulation during 1988 to 2015 by WHO region, a period during which the GPEI had been implemented in all WHO regions. Progress has been impressive. In 1988, 125 countries were polio-endemic; by the end of 2016 only three countries were considered polio endemic (i.e., had never interrupted indigenous virus transmission: Afghanistan, Pakistan, and Nigeria; importation with limited transmission in time and space does not constitute reestablishment of endemicity). Egypt was removed from the list of endemic countries at the end of January 2006 following a 12-month period without detection of poliovirus despite excellent surveillance performance from AFP surveillance and from environmental surveillance. Globally, cases of poliomyelitis decreased more than 99% from an estimated 350,000 cases in 1988 to 1349 in 2010, 359 in 2014, 74 in 2015, and 35 in 2016 (as of January 3, 2017). Wild poliovirus type 2 was last detected in October 1999 in Uttar Pradesh, India, and has been officially declared as eradicated.[39,190] Wild poliovirus type 3 was detected in seven countries in 2010 (Afghanistan, Chad, India, Nigeria, Niger, Mali, and Pakistan), but stopped in 2012, with the last case reported from Nigeria in November 2012. Wild poliovirus type 1 was detected globally in 2016, only in Afghanistan and Pakistan (a shared reservoir) and Nigeria. Outside the three polio-endemic countries, no importation events were detected in 2015–16 (data as of November 2016) (Fig. 49.16). The latest information on the status of the polio eradication initiative can be found at the GPEI (http://www.polioeradication.org).

Between 1988 and 2016, the GPEI prevented more than 15 million children from the crippling consequences of poliomyelitis and averted more than 1.5 million deaths, some as a result of poliomyelitis prevention but most because vitamin A supplements were administered to the same target children in many polio-endemic countries during national and subnational immunization campaigns.[658,659] Outside these three polio-endemic countries, no important events were detected in 2015–16 (as of November 29, 2016).

Disease Control Strategies

In 1988, the World Health Assembly, the governing body of the WHO, resolved to eradicate polio globally by the year 2000.[3] The global resolution followed the 1990 regional elimination goal established in 1985 by the countries of the Western Hemisphere. The last case of poliomyelitis associated with wild poliovirus isolation in the Americas was reported from Peru in 1991, and the entire hemisphere was certified free of indigenous wild poliovirus by an International Certification Commission in 1994.[498]

The following strategies to achieve polio eradication, developed in the Western Hemisphere, were adopted by the WHO for worldwide implementation in all polio-endemic countries[37]:

- Achieving and maintaining high routine coverage in infants younger than 1 year with at least three doses of OPV3.
- Administering supplemental doses of OPV to all young children (usually children younger than 5 years of age) during NIDs to rapidly interrupt poliovirus transmission.
- Conducting "mopping-up" vaccination campaigns—localized campaigns targeting high-risk areas where poliovirus transmission is most likely to persist at low levels.
- Developing sensitive systems of epidemiologic and laboratory surveillance, including establishing surveillance of cases of AFP.

Routine Immunization

Control of poliomyelitis and the global eradication initiative are greatly aided by well-functioning routine immunization programs that deliver potent OPV to a high proportion of infants in the first year of life. Indeed, there is a clear association between routine coverage and length of transmission of poliovirus following an importation into a previously polio-free country. The estimated global coverage with three doses of diphtheria-tetanus-pertussis (DTP3) vaccine (assumed to reflect the routine OPV3 coverage) among infants younger than 1 year of age was 86% in 2014. All WHO regions reported a coverage of more than 80% except for the African Region, where coverage improved from 57% in 1990 to 77% in 2014, but continues to be less than the coverage achieved in the other WHO regions.[270,660] However, these global and regional figures may mask substantial variation in coverage reported among and within individual countries.

National Immunization Days

Mass campaigns with OPV—administered during NIDs—are the only proven strategy to reduce widespread transmission of

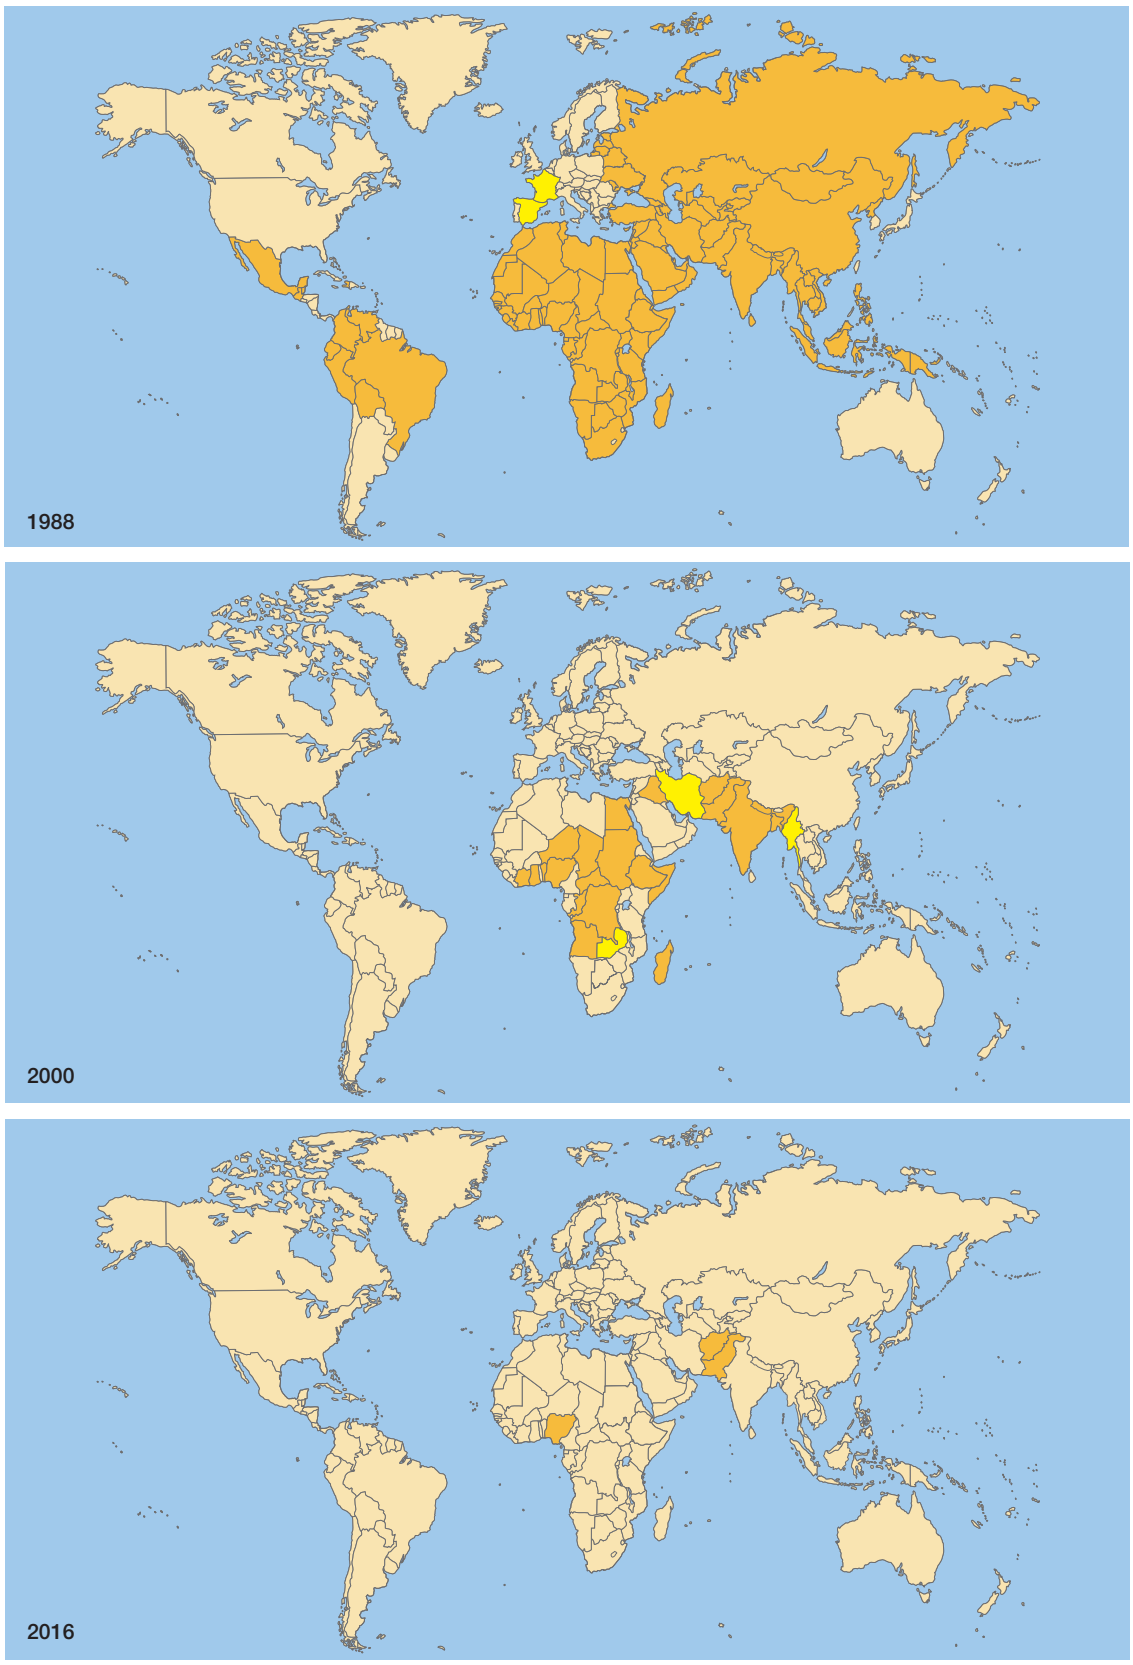

Figure 49.15. Progress toward global polio eradication, 1988–2016. Orange, countries with indigenous wild polioviruses (WPVs); yellow, countries with one or more cases associated with imported WPV; light brown, polio-free countries. Countries of the former Soviet Union were grouped together in the1988 map, reflecting endemicity in the Caucasus and Central Asian republics.

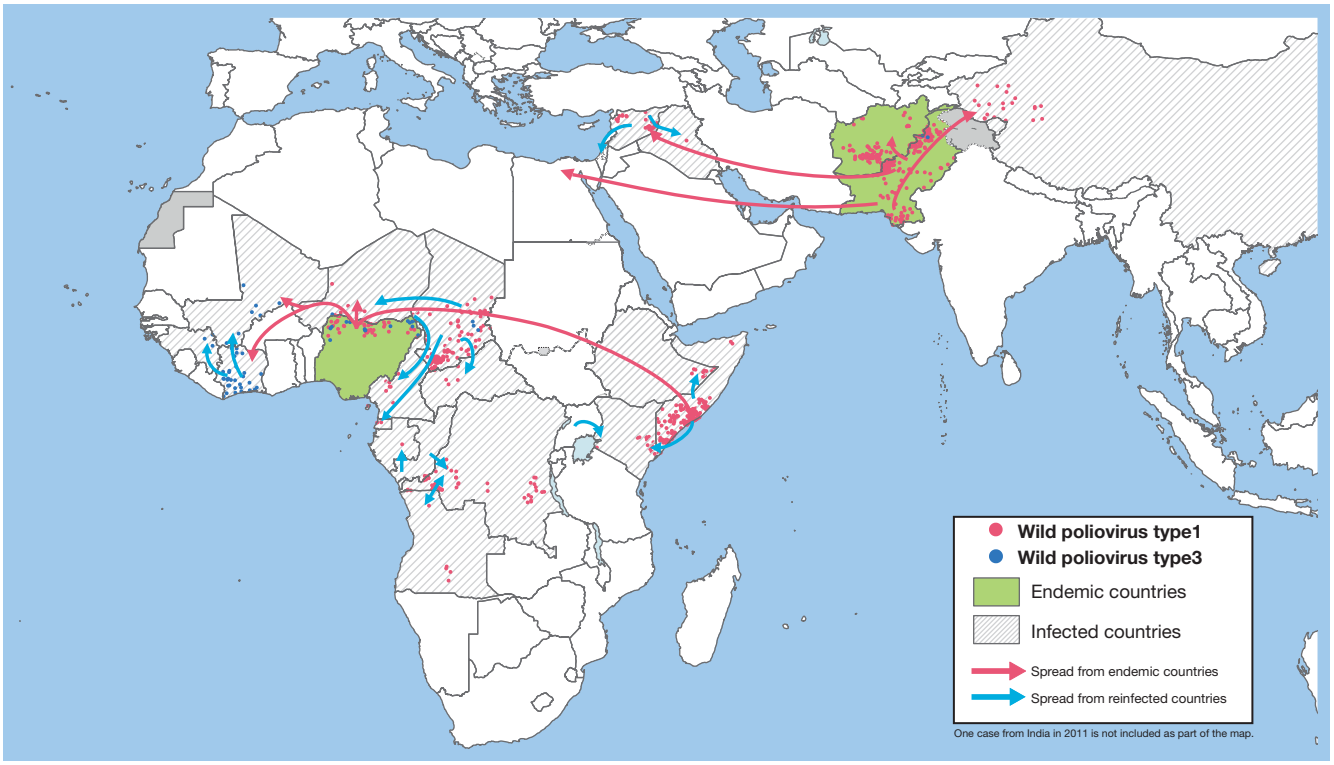

Figure 49.16. Wild poliovirus cases and importation routes, worldwide 2011–2014. Excludes virus detected from environmental surveillance and vaccine-derived polioviruses. *(Data from references 653 to 657.)*

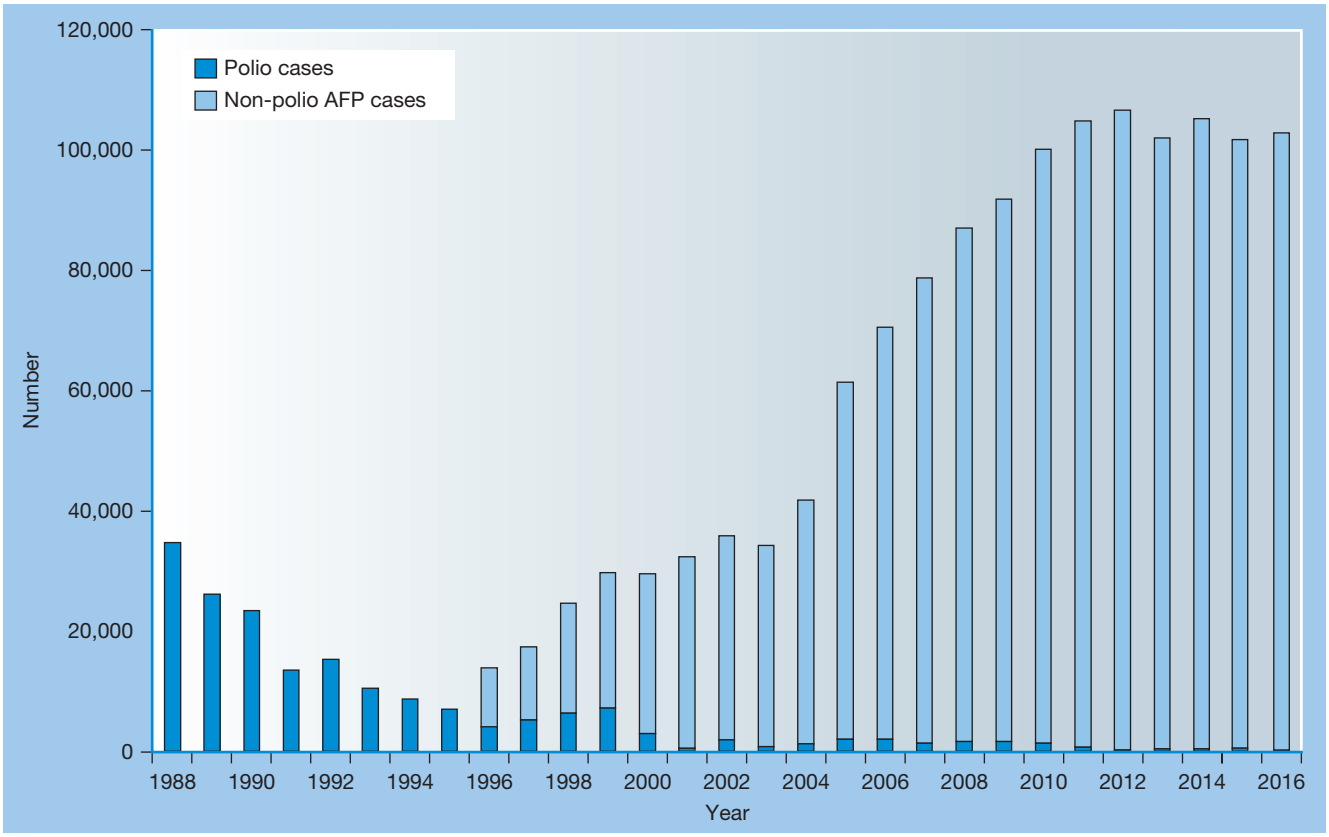
wild poliovirus in endemic countries.[661,662] The NIDs are conducted twice annually for a short period (1 to 3 days) during which one dose of OPV is administered to all children in the target age group, usually children younger than 5 years of age, regardless of prior vaccination history. A second dose is administered in the same way after an interval of 4 to 6 weeks. The NIDs usually take place during the low transmission season when conditions are optimal to interrupt the few remaining chains of poliovirus transmission. Most countries provide OPV during NIDs, relying primarily on fixed sites, including vaccination clinics supplemented by a large number of temporary vaccination sites. With the acceleration of eradication activities in 1999, many of the remaining polio-endemic countries began using a strategy relying on house-to-house administration of OPV during NIDs.

The NIDs are necessary in developing countries to rapidly increase immunity levels in the population to achieve and surpass herd immunity threshold levels for poliomyelitis and, hence, rapidly interrupt the transmission of poliovirus. OPV administered in campaigns also seems to be more immunogenic compared with OPV administered in the routine program,[663,664] probably for the following reasons: (a) NIDs are conducted during the low poliovirus transmission season because this is the period when the fewest chains of poliovirus transmission are maintained. (b) NIDs are conducted during the low transmission season for other enteroviruses that may interfere with poliovirus seroconversion.[665] (c) The cold chain can be better maintained for these short campaigns. (d) Massive use of OPV probably also results in intensive secondary spread of shed virus.[464] Children residing in polio-endemic countries using NIDs may receive 13 to 14 doses of OPV by the time they reach their fifth birthday.[122,473] These OPV doses are administered by the routine program (three or four doses) and through NIDs (two doses annually during the first 5 years of life). These additional doses of OPV, administered during NIDs, should correct the lower immunogenicity of OPV commonly observed in tropical areas.

In 2014, 332 supplementary immunization activities with OPV were conducted in 42 countries, reaching more than 1.8 billion people, the vast majority children younger than 5 years, administering approximately 2.2 billion doses of OPV. Each of the endemic countries conducted at least six large-scale supplemental immunization campaigns in 2014, while each of the reinfected countries with transmission conducted a minimum of four large-scale supplemental immunization campaigns in 2014. All countries used well-supervised, house-to-house vaccination in part or all of the target area for supplementary immunization activities to further increase the quality and reach the highest possible coverage among children younger than 5 years of age. The NIDs in India—vaccinating as many as 157 million children in a single round—represent the largest mass campaigns ever conducted.

Mopping-Up Campaigns

To eliminate the last potential or known reservoirs of wild poliovirus circulation, mopping-up vaccination campaigns are conducted. These mopping-up campaigns usually target children younger than 5 years of age with two doses of OPV separated by an interval of 4 to 6 weeks. These campaigns include house-to-house administration of OPV to reach any children who may have been missed during NIDs. Mopping up is a critical component to achieve interruption of the final chains of poliovirus transmission in all polio-endemic countries. Risk areas (often targeting more than 1 million children



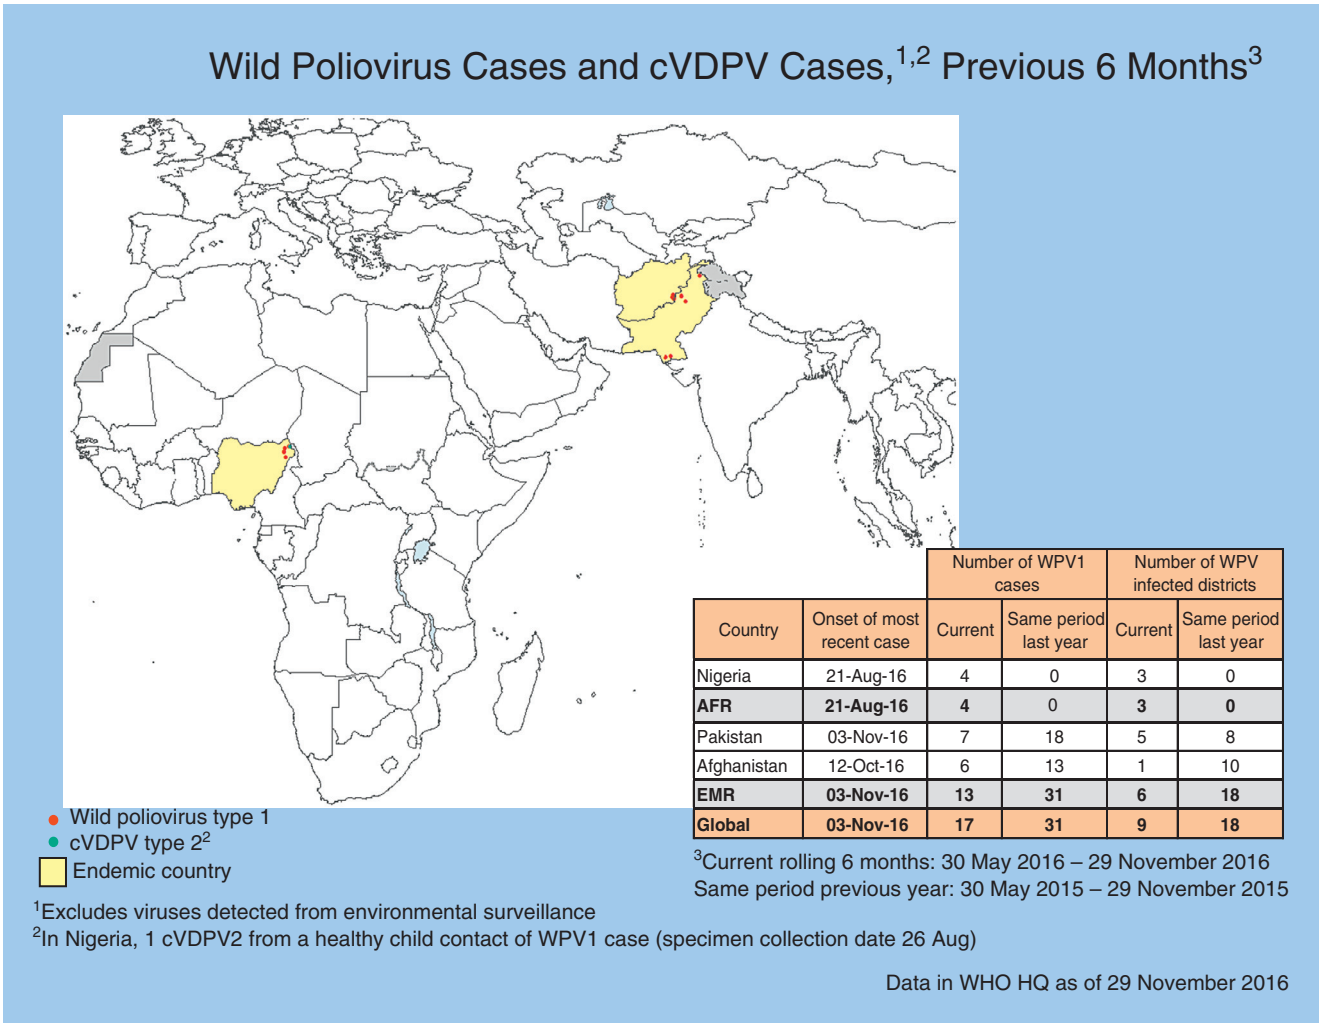


Figure 49.17. Total reported acute flaccid paralysis (AFP) cases and confirmed poliomyelitis cases, 1988–2016. *(From the World Health Organization.)*

younger than 5 years of age to have the optimal impact), usually defined at county or district levels, to be included in mopping up include those with recent circulation of wild poliovirus (usually within the last 3 years), low vaccination coverage, suboptimal surveillance, large migrant or refugee populations, and common borders with known poliovirus-endemic areas.

These supplemental immunization activities have been successful in decreasing the number of reported poliomyelitis cases globally from 35,251 (estimated to be approximately 350,000 cases) in 1988 (when the polio eradication target was adopted) to 359 in 2014, a decrease of more than 99% (Fig. 49.17).[39] Fig. 49.18 displays the remaining AFP cases associated with wild poliovirus isolation during a 12-month period in 2014. A detailed review of the current status of the GPEI was published in 1997,[669] with annual progress reports, the most recent in 2015.[39,667]

Surveillance

Surveillance for cases of AFP and for wild poliovirus is critical for guiding programmatic activities and for contributing to the eventual certification of polio-free status. Systems for AFP surveillance have been established in all polio-endemic or recently endemic countries. Surveillance relies on two complementary and mutually reinforcing components: (a) AFP case investigations and (b) virologic studies of polioviruses obtained from clinical specimens. The major reason for using a symptom (e.g., AFP) rather than a diagnosis (e.g., poliomyelitis) is to ensure that the sensitivity of the surveillance system can be maximized; all possible cases of poliomyelitis, including those with atypical manifestations, will be included in the surveillance system. In addition, AFP surveillance helps monitor the quality of surveillance even in the absence of cases of poliomyelitis. In the last stages of the eradication program, no cases of poliomyelitis (except for rare cases of VAPP) would be expected to be detected. Thus, it would be impossible to determine whether the absence of poliomyelitis cases represents "true" absence or deficiencies in surveillance. On the basis of the experience in the Americas, in each population, a rate of at least one case of nonpolio AFP per 100,000 population younger than 15 years of age would be expected annually (this rate was increased to at least two cases of nonpolio AFP for polio-endemic and recently infected countries), and achievement of such a rate would indicate adequate surveillance, defined as the ability of the surveillance system to detect wild poliovirus circulation resulting from indigenous transmission or virus importation, should it occur. A global network of 145 formally accredited laboratories has been established to process all stool specimens collected from AFP cases worldwide for virologic investigations (Fig. 49.19). The formal annual accreditation process relies on six criteria (Table 49.19). Standard methods and reagents are used to isolate virus in tissue cultures and perform ITD as wild, Sabin-derived (<1% genomic sequencing divergence from Sabin parent strains), or vaccine-derived (>1% genomic sequencing divergence from Sabin parent strains) poliovirus. For poliovirus type 2, 0.6% (six nucleotide changes) or greater qualify isolate to be included as cVDPV. All wild poliovirus strains and all VDPVs are sequenced in specialized network laboratories to guide programmatic action. Based on additional virologic and epidemiologic data, VDPVs can further be classified as

Country	Onset of most recent case	Number of WPV1 cases		Number of WPV infected districts	
		Current	Same period last year	Current	Same period last year
Nigeria	21-Aug-16	4	0	3	0
AFR	**21-Aug-16**	**4**	0	**3**	**0**
Pakistan	03-Nov-16	7	18	5	8
Afghanistan	12-Oct-16	6	13	1	10
EMR	**03-Nov-16**	**13**	**31**	**6**	**18**
Global	**03-Nov-16**	**17**	**31**	**9**	**18**

circulating (cVDPV) or associated with prolonged replication in an immunodeficient person (iVDPV) (see "Vaccine-Derived Polioviruses" earlier).

All six regions of the WHO have achieved a rate of slightly more than one nonpolio AFP case per 100,000 population younger than 15 years of age in 2001 and 2015. Table 49.20 shows the AFP cases and wild poliovirus cases for the WHO regions in 2001 and 2015.[39,668] In 2005, the Advisory Committee on Poliomyelitis Eradication recommended that the nonpolio AFP rate in polio-endemic countries should be at least 2/100,000 persons younger than 15 years of age. All three polio-endemic WHO regions reported a nonpolio AFP rate of more than 3/100,000 persons younger than 15 years of age in 2015 (African Region, 5.1; Eastern Mediterranean Region, 5.2; and South-East Asia Region, 7.3 (data as of June 16, 2015), greatly increasing the sensitivity of poliomyelitis detection. All WHO regions also surpassed the second most important quality indicator for adequate surveillance (i.e., the proportion of AFP cases from which two stool samples had been obtained within 14 days of paralysis onset). This indicator was 89% in 2015 globally. Table 49.21 provides a comprehensive list of performance indicators that are used to monitor the quality of AFP surveillance.

Remaining Obstacles to Eradication

The major obstacle to achieve eradication is the failure to implement adequately the current eradication strategies. The eradication strategies have been successful in almost all countries and regions within countries. However, the three remaining polio-endemic countries (i.e., those that never eliminated indigenous wild poliovirus transmission) pose special challenges. In Afghanistan, access in the southeastern part of the country is limited owing to security concerns. In Pakistan, access in the tribal territories (Federally Administered Tribal Areas and Khyber Pakhtunkhwa) along the border with Afghanistan remains a problem, and coverage in some accessible areas remains suboptimal. The killing of vaccinators further complicates the issue, requiring new security strategies to ensure the safety of these health workers. In Nigeria, access to areas not controlled by the government will be critical to wiping this reservoir in Borneo State. Innovative strategies and implementation of new tools must be tailored for each of these polio-endemic areas to achieve eradication. In addition, access to and reaching high immunization coverage among migrant and nomad populations is an issue for all these polio-endemic countries.

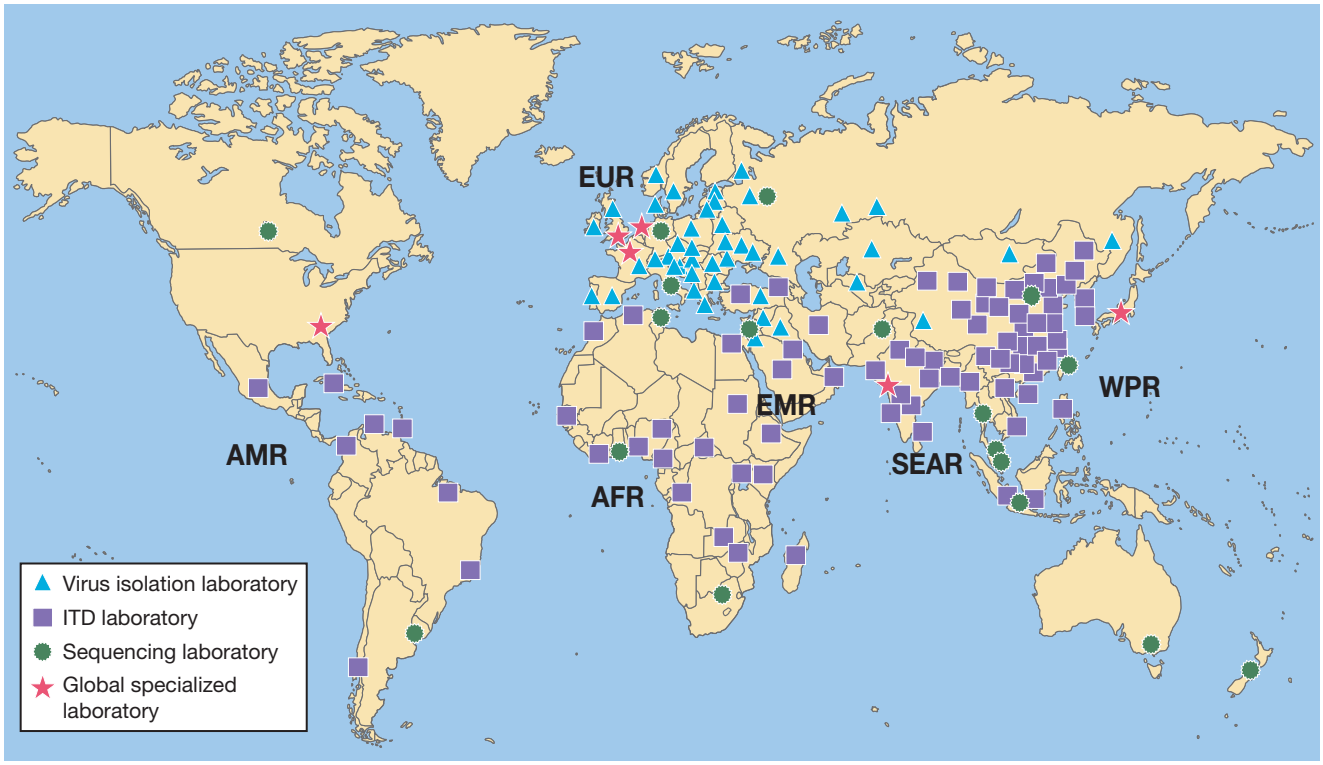

Figure 49.19. Laboratories of the Global Polio Laboratory Network (GPLN), organized by diagnostic function. Viral isolation laboratory *(blue triangle)*, ITD (intratypic differentiation) laboratory *(purple square)*, sequencing laboratory *(green circle)*, global specialized laboratory *(red star)*. TABLE 49.19 Indicators for Laboratories Included in the Global Polio Laboratory Network (GPLN) by Functionality Status (Virus Isolation, Intratypic Differentiation, and Sequencing)

VIRUS ISOLATION LABORATORIES	
1.	Tests are performed on at least 150 stool specimens annually.
2.	Results are reported on at least 80% of all acute flaccid paralysis (AFP) specimens within 14 days.
3.	At least 80% of suspected poliovirus isolates from AFP cases and contacts are forwarded for intratypic differentiation (ITD) within 7 days, if applicable.
4.	Accuracy of identification of polioviruses among all isolates obtained in L20B cells is at least 90%.
5.	Score on most recent virus isolation proficiency testing is at least 90%.
6.	Score on annual on-site review is at least 80%.
INTRATYPIC DIFFERENTIATION (AS WILD OR VACCINE-DERIVED) LABORATORIES	
1.	ITD test results on ≥80% of poliovirus isolates are reported within 7 days.
2.	Non–Sabin-like poliovirus and ITD-discordant isolates from ≥80% of AFP cases, contacts, and other sources are referred for sequencing within 7 days of detection, if applicable.
3.	Score on most recent intratypic differentiation PT is at least 90%. • Score for rRT-PCR ITD • Score for rRT-PCR VDPV screening
4.	Accuracy of poliovirus serotype and intratype is at least 90%.
5.	Score on annual on-site review is at least 90%.
SEQUENCING LABORATORIES	
1.	Nucleotide sequences are generated and analyzed on site for at least 25 polio or non-polio enterovirus isolates annually.
2.	Complete viral protein 1 (VP)1 nucleotide sequence results on ≥80% of poliovirus isolates are reported within 7 days.
3.	The score is ≥90% on the most recent WHO poliovirus sequence proficiency test.
4.	The score on annual on-site review is at least 90%.

TABLE 49.21 Indicators of Acute Flaccid Paralysis Disease Surveillance and Laboratory Performance

Indicator	Target
Nonpolio AFP rate in children <15 y in endemic countries	≥2/10000
Nonpolio AFP rate in children <15 y in nonendemic countries	≥1/10000
Completeness of monthly reporting	≥90%
Timeliness of monthly reporting	≥80%
Reported AFP cases investigated ≤48 h after report	≥80%
Reported AFP cases with 2 stool specimens collected ≤14 d since onset	≥80%
Reported AFP cases with a follow-up examination at least 60 d after paralysis onset to verify the presence or absence of residual paralysis	≥80%
Specimens arriving at national laboratory within 3 d of being sent	≥80%
Specimens arriving at laboratory in good condition[a]	≥80%
Specimens with a turnaround time of ≤28 d between receipt and reporting of results	≥80%

[a]*Good condition* means that, on arrival (a) there is ice or frozen icepacks or a temperature indicator (showing <8°C) in the container, (b) the specimen volume is adequate (>5 g), (c) there is no evidence of leakage or desiccation, and (d) appropriate documentation (laboratory request/reporting form) is completed.
AFP, acute flaccid paralysis.

Historically, most importation into polio-free countries has originated in India or Nigeria. However, given the progress toward eradication in these countries, Pakistan is associated with the most recent exportations of virus.

New Polio Endgame

Completion of polio eradication requires the elimination of all polioviruses from human populations, whether wild poliovirus (WPV) or those originating from the OPV.[278,477,672] While it was apparent for longer than a decade that the continued use of OPV was not compatible with polio eradication, only the *Polio Eradication & Endgame Strategic Plan 2013–2018* provides the detailed framework for interruption of WPV transmission in remaining reservoirs and lays out the plan for the new polio endgame, which includes the sequential withdrawal of Sabin strains, starting with type 2, and the concurrent (or earlier) introduction of IPV, for risk mitigation purposes.

The objectives and supporting data that form the backbone for the policy decision to switch from tOPV to bOPV (i.e., OPV2 withdrawal), to introduce one dose of IPV into routine immunization schedules, and describe the proposed implementation of this policy in tOPV-using countries are summarized below.

Although most infections with OPV are self-limited, in immunodeficient individuals such viruses may replicate for prolonged or chronic periods. Similarly, prolonged person-to-person transmission is possible in communities with low immunity against poliovirus. Both of these mechanisms could

potentially lead to the reestablishment of endemicity and negate the polio eradication efforts.[155,156] Therefore, strategies for the elimination of all polioviruses, including the attenuated Sabin vaccine viruses originating from the OPV, needed to be developed and implemented successfully to achieve polio eradication.

The Strategic Advisory Group of Experts (SAGE) on Vaccines and Immunization, a committee established to advise the WHO on global policies and strategies for vaccines and immunization, established a working group in August 2008 to advise the GPEI on two major programmatic issues: (a) the use of IPV in low- and middle-income settings; and (b) on the polio endgame strategy to reduce long-term risks associated with OPV.[673,674]

This SAGE process has led to the development of a comprehensive plan entitled the *Polio Eradication & Endgame Strategic Plan 2013–2018* for the interruption of WPV transmission and to achieve the long-term goals of the posteradication period.[550,675] The plan contains four objectives: (a) to interrupt WPV transmission; (b) to strengthen immunization systems and the withdrawal of OPV; (c) to implement containment of polioviruses and to certify the world as polio-free; and (d) to plan the legacy of polio eradication.

The plan addresses the cessation of the type 2 component of OPV (switch from tOPV to bOPV), and the global introduction of at least one dose of IPV into routine immunization schedules of all countries relying currently only on OPV for poliomyelitis prevention.

Switch From Trivalent Oral Poliovirus Vaccine to Bivalent Oral Poliovirus Vaccine and Inactivated Polio Vaccine Introduction Into Routine Immunization Schedules. Of the three serotypes of WPVs: types 1, 2, and 3 (WPV 1, WPV 2 and WPV 3), WPV 2 was successfully eradicated in 1999.[477,677] However, at the end of 2013, 144 countries relied on tOPV, containing Sabin type 2 live vaccine virus, for routine immunizations against poliomyelitis; 124 of these, including all Global Alliance for Vaccines and Immunization (GAVI)-eligible countries (except Ukraine), used exclusively tOPV, and 20 countries used both tOPV and IPV in sequential immunization schedules. The remaining 50 WHO member states use IPV exclusively; these are primarily industrialized countries (see Fig. 49.14).

Polioviruses contained in OPV are live-attenuated polioviruses (see "Virology" earlier), which, in rare circumstances, can revert to neurovirulent forms and cause VAPP, clinically indistinguishable from paralytic poliomyelitis caused by WPVs.[542,678–680] It is estimated that each year there are between 250 and 500 cases of VAPP worldwide (WHO, unpublished data).

However, more important and a potential obstacle to polio eradication, Sabin viruses may mutate and subsequently gain the ability to circulate in communities though person-to-person transmission. These polioviruses, referred to as VDPVs, also have lost their attenuating mutations, and therefore reacquired the neurovirulence and transmission characteristics of WPVs. In very rare occasions, VDPVs could potentially reestablish endemic and epidemic transmission, and are, therefore, incompatible with polio eradication (see "Vaccine-Derived Polioviruses" earlier).[549,681] Since WPV2 eradication in 1999, VDPVs caused by type 2 Sabin strains (VDPV2) have been reported from 17 countries causing 599 reported paralytic cases (data as of December 28, 2016).

OPV vaccine is needed to achieve eradication, but it also poses a grave risk to eradication. This paradox needs to be addressed proactively with the strategy of a phased withdrawal of all Sabin strains from OPV, starting with type 2: switching tOPV to bOPV.

Thus, OPV2 withdrawal will stop the introduction of Sabin type 2. Before the withdrawal of type 2 in April 2016, more than 2 billion doses were administered annually. Therefore, the withdrawal should eliminate the VAPP caused by Sabin 2 and the cVDPV2 outbreaks attributed to the type 2 Sabin virus. bOPV developed and licensed in 2009 for campaign use achieves higher seroconversion rates compared to tOPV for types 1 and 3.[476] In the Indian trial, after two doses of OPV vaccines, seroconversion to poliovirus type 1 was 86% for bOPV compared with 63% for tOPV ($P < .0001$), and to poliovirus type 3 it was 74% for bOPV compared with 52% for tOPV ($P < .0001$). Thus, the use of bOPV will likely increase population immunity against polioviruses (except for poliovirus type 2). Introduction of bOPV into campaign use in India has likely facilitated the elimination of polio in that country.[682]

As a consequence, and to eliminate the risks associated with continued use of Sabin type 2–containing vaccines, SAGE recommended the withdrawal all OPV vaccines containing Sabin type 2 poliovirus, adhering to the following three principles: (a) the switch must be universal; (b) the switch must be synchronized; and (c) IPV must be introduced in every country, ideally 6 months prior to the switch. The switch must be universal and synchronized because following the switch, the population immunity to type 2 polioviruses will decrease, increasing over time the risk for paralytic disease among individuals and the possibility of outbreaks. As a result, bOPV-vaccinated populations would become vulnerable to type 2 importations from areas where tOPV would still be in use, leading to circulation and mutation of those viruses resulting in the emergence of new cVDPV2 outbreaks. And potentially cVDPV2, if occurring in tOPV-using areas, could lead to exportations from those areas into bOPV-only using countries, leading to significant type 2 outbreaks.

Modeling data suggest that this potential risk (silent circulation leading to epidemic transmission) will be highest in the immediate post-OPV2 withdrawal period, when these viruses are still replicating and mutating in the intestinal tract of millions of recently OPV-vaccinated infants. This risk will likely rapidly decline as illustrated by the detection of OPV virus in environmental samples for only limited periods (i.e., 3 months) following cessation of OPV use.[155,156,683,684] To mitigate the consequences of type 2 cVDPV outbreaks (in terms of paralytic disease) in the immediate post–OPV2-cessation era and for the longer term, SAGE recommended the universal introduction of at least one dose of IPV into routine immunization schedules in OPV-only using countries. Data suggest that one dose of IPV will provide an immunity base that can be rapidly boosted in case of cVDPV2 emergence.[685] A priming immune response, as measured by induction of antibody within 7 days after vaccination in a child previously seronegative, was observed to poliovirus types 1, 2, and 3 in 97.6%, 98.3%, and 98.1% of infants who were revaccinated after failing to seroconvert after receiving a single dose of IPV at 4 months of age in Cuba.[685]

In addition to providing protection against cVDPV2, IPV boosts mucosal immunity to polioviruses in previously OPV-vaccinated recipients.[489] IPV also helps close the population humoral immunity gap in children who had not seroconverted following OPV vaccinations.[618,686] Overall, the bOPV and IPV schedule is expected to provide higher levels of protection against poliomyelitis than a schedule with tOPV alone.

Decision Points for Oral Polio Vaccine Type 2 Withdrawal. To make the decision when to switch from tOPV to bOPV (implemented in April 2016), several readiness criteria were assessed, including that all persistent cVDPV2 outbreaks (documented circulation for more than 6 months after

initially detected [i.e., failure of programmatic efforts to contain the outbreak]) be stopped. In 2013–14, three persistent outbreaks with cVDPV2 were ongoing: (a) the longstanding cVDPV outbreak in Nigeria[136,556,557]; (b) an outbreak with cases covering Chad, Cameroon, Niger, and Nigeria; and (c) an outbreak with cases detected in Afghanistan and Pakistan. While these persistent outbreaks appeared to have been stopped (data as of October 28, 2015), two new persistent outbreaks evolved in both Pakistan and Nigeria. Other readiness criteria included (a) the absence of WPV2 which was validated by the Global Certification Commission[190]; (b) a mOPV2 stockpile must be established and available for outbreak control following a possible postswitch poliovirus type 2 emergence; (c) the laboratory containment standards for type 2 polioviruses must be implemented (Phase I and Phase II); (d) sufficient vaccine supplies of bOPV must be available and licensed in all countries for routine immunization use; and (e) sufficient supply of affordable IPV must be available to meet the global demand.

The Strategic Plan (2013–18) for polio eradication includes as a key objective the sequential cessation of vaccination with Sabin strains (starting with poliovirus type 2). This objective makes it necessary to replace tOPV with bOPV for routine and supplemental immunization activities, and to add IPV into routine immunization schedules for risk mitigation.[686a] The withdrawal of Sabin type 2 from the tOPV is necessary to secure polio eradication for the future, since the live attenuated Sabin strains may mutate or recombine to reacquire greater neurovirulence and transmissibility. The resultant VDPVs are phenotypically indistinguishable from wild polioviruses and have the potential to reestablish sustained endemic and epidemic transmission.

The criteria for and the timing of the switch were monitored by the principal technical oversight committee for immunization (i.e., the SAGE).[686b] The programmatic responsibility for implementing the switch was with the GPEI. Within WHO, the Immunization, Vaccines and Biologicals Department (IVB) department, together with the regional and country offices, provided guidance to member countries. Soon after endorsement of the Strategic Plan by SAGE and the World Health Assembly, a cascading political and technical advocacy effort was implemented, starting with reviews of the switch objectives and endorsement by Regional Committees, Regional Technical Advisory Groups (TAGs), and National Immunization Technical Advisory Groups (NITAGs). Countries were encouraged to prepare comprehensive national switch action plans based on a standard global template.

Of great importance was the regulatory approval of bOPV in the 155 countries that needed to introduce this vaccine, and through using different regulatory approval channels (e.g., national registration, WHO-prequalification or emergency approval) it was possible that bOPV could be used in all countries that needed it. Furthermore, the same regulatory channels were used for the 125 countries needing to introduce IPV. In 2014, bOPV was the primary regulatory activity focus, and this shifted to IPV in 2015.[686c]

In addition, finding regulatory solutions for domestic producers of tOPV was another priority. Domestic producers in China, India, Indonesia, Iran, Mexico, Russian Federation, and Vietnam needed to license nationally produced bOPV. By implementing an intensive advocacy effort, and conducting the relevant clinical trial work, where required, all of these countries were able to license bOPV nationally or obtain approval for importation of WHO-prequalified bOPV.

Later, a growing and unexpected challenge emerged with the rapidly deteriorating IPV supply situation before and after April 2016. This has delayed IPV introduction (20 countries) and delayed re-supply of IPV (31 countries). IPV supply is prioritized by country risk category, with tier 1 countries (those with outbreaks of cVDPV2, or poliovirus type 1-endemic) receiving the highest priority.[686d] On the other hand, tier 3 and 4 countries, those assumed to be at lowest risk, constitute the majority of countries that currently do not receive IPV. In these countries new birth cohorts are growing up without any immunity to poliovirus type 2. It is anticipated that in 2018, the supply situation will return to normal (i.e., all countries should receive sufficient doses of IPV).

To respond to the IPV supply situation, some countries have introduced a schedule of two fractional doses of IPV, with doses administered at 6 and 14 weeks.[686e,686f] This schedule is both dose sparing and more immunogenic than the current single full dose IPV recommendation.

Once the timing for the switch was finalized by SAGE in October 2015 for April 2016,[686b] the implementation efforts were augmented with provision of funding, where needed, and consultants, where requested. Each country had to decide on a 2-week switch period during April 2016 in which tOPV was withdrawn and replaced bOPV. tOPV was then discarded according to national preference of an appropriate method. At the end of the switch period, an extensive monitoring phase was implemented that included national and international monitors to verify that tOPV had been discarded (i.e., could not be found in national, regional, and health center vaccine stores).

The switch was completed in virtually all countries within the selected 2-week period, and the monitors found very few vials of tOPV missed by the national implementation staff. This globally synchronized effort is a great example of success of what can be achieved if the global public health community unites behind an important public health goal and is willing to set in motion the necessary action.

Implementation of Inactivated Polio Vaccine Into Routine Immunization Schedules. In terms of progress toward IPV introduction, 124 countries have introduced IPV, 29 countries have introduced IPV but have not been resupplied (and are in stock-out), and 21 countries did not introduce IPV in 2016 because of IPV supply constraints. This progress is the result of an unprecedented effort by all immunization partners (Expanded Programme on Immunization, GAVI, GPEI) to facilitate and fund, by-and-large, the introduction efforts. At present, it is planned that the complete withdrawal of OPV vaccines (including bOPV) will be implemented 3 years after the last WPV is detected.

Major Risks Associated With Oral Polio Vaccine Cessation. While there are compelling benefits to eventually stop OPV, these must be weighed against the associated risks. The risks can be considered in three categories: the live attenuated poliovirus strains used for OPV production (e.g., Sabin strains), VDPVs, and WPVs. In each case, the risk is of human infection and subsequent transmission following ingestion of the virus. Poliovirus survival in the environment is finite; infectivity is lost during a period of days, under hot dry conditions, to weeks or several months under cool, moist conditions.[249]

The term *Sabin strain* poliovirus denotes one of the three live attenuated viruses that Albert Sabin developed for the OPV (see "Description of Vaccine" earlier). Sabin strain polioviruses are ubiquitous because of routine immunization programs that currently use approximately 2 billion doses of OPV each year globally to vaccinate children in more than 150 countries. Such live attenuated polioviruses are present in a variety of other settings owing to their use as seed viruses for OPV production, as reference standards in vaccine quality assurance and control testing, as controls for some polio

diagnostic tests, and for basic research in a number of laboratories and for teaching purposes in some academic centers. While the vast majority of OPV recipients will lead to time-limited (i.e., 3 to 4 weeks) intestinal replication and shedding of the virus, Sabin viruses rarely can give rise to cVDPVs or generate an iVDPV. Of particular importance for risk management planning is the danger posed by the emergence of one or more cVDPVs immediately after countries stop using OPV, when population immunity will already be starting to decline. Mathematical modeling suggests that even with simultaneous cessation of OPV use worldwide, a 60% to 95% chance exists of at least one such outbreak occurring somewhere in the world during the 12 months immediately after cessation, with that risk declining to 1% to 6% at 36 months and much lower thereafter.[687] To decrease the risks of cVDPV emergence, simultaneous type-specific OPV cessation worldwide is of critical importance. Should cVDPV outbreaks occur, mOPV will be used for rapid type-specific control and elimination. However, the use of mOPV itself may be associated with generating new cVDPVs. To minimize this risk, high coverage with mOPV is essential, and other strategies such as supplemental IPV or use of antiviral compounds may be needed in a ring campaign around the initial mOPV-targeted areas.[688] After global cessation of OPV, cohorts susceptible to poliomyelitis will accumulate rapidly, and the risk assessment would likely change.[689]

Retaining WPVs in laboratories represents another concern. These are currently used as seed viruses for the production of IPV, in vaccine quality control and assurance testing, as controls for some diagnostic tests, and in research laboratories. Although WPVs are no longer nearly as ubiquitous as Sabin polioviruses, the consequences of an inadvertent or intentional release in the post-OPV era pose a potentially far greater threat. A recent consequence assessment suggests that whereas transmission of a wild or Sabin strain virus may be self-limiting if released into an IPV-vaccinated population in a moderate climate zone in the post-OPV era, a WPV released into an unvaccinated population in a tropical developing country would almost certainly result in a large-scale outbreak with a real risk of eventually reestablishing endemic transmission globally.[689]

As a final concern, full-length poliovirus cDNA has been synthesized by assembling oligonucleotides of plus and minus strand polarity. The synthetic poliovirus cDNA was transcribed by RNA polymerase into viral RNA that translated and replicated in a cell-free extract, resulting in de novo synthesis of infectious poliovirus,[690] demonstrating that, even if poliovirus has become extinct (complete destruction of all virus globally), laboratories could create fully infectious polioviruses.

Fig. 49.20 summarizes, based on current knowledge, the expected evolution of these risks in low- and high-income countries during a probable 3- to 5-year "OPV cessation" phase following confirmation of global interruption of WPV transmission and appropriate biocontainment of all poliovirus stocks globally.

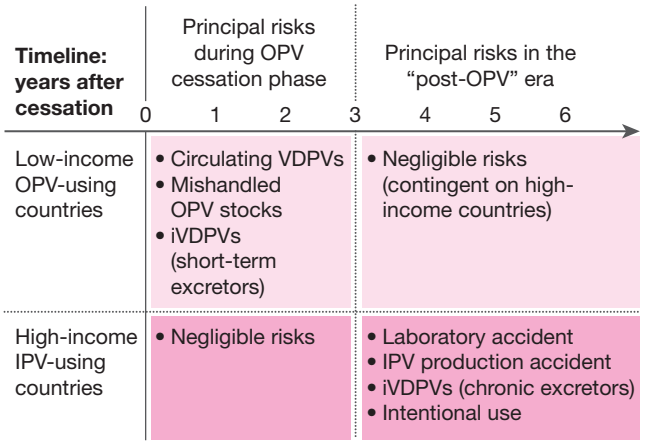

Figure 49.20. Evolution of risk of poliovirus following discontinuation of oral poliovirus vaccine (OPV) among high- and low-income countries. IPV, inactivated polio vaccine; iVDPV, immunodeficiency-related vaccine-derived poliovirus; VDPV, vaccine-derived poliovirus.

Risk Reduction and Management. A comprehensive approach must be taken to optimize the management of the risks associated with OPV cessation. The core principles forming such an approach must be to (a) simultaneously stop the routine use of OPV worldwide, while population immunity is high, with the subsequent recall and destruction of remaining OPV stocks; (b) reduce the number of procedures performed with polioviruses to those that are essential in the post-OPV era; (c) replace, where possible, WPVs with Sabin strain viruses for any procedure that must continue to be conducted in the post-OPV era; (d) minimize the number of sites handling or storing *any* polioviruses or potentially poliovirus-infectious materials (wild viruses before OPV cessation; Sabin strains immediately thereafter), and limit these sites to areas where the consequences of an inadvertent release could be minimized; (e) institute processes to ensure that residual poliovirus-containing sites fully implement appropriate biocontainment and biosafety procedures; (f) maintain high-level surveillance to identify and monitor iVDPVs and to detect an inadvertent or intentional release of any poliovirus into the human population; and (g) establish a stockpile of mOPVs with internationally agreed-on criteria for their use in mounting type-specific outbreak responses to circulating polioviruses in the post-OPV era.

Minimizing the risks associated with OPV cessation requires the endorsement of the international community. Additional risk reduction or risk management strategies may be required in areas that pose particular risks during or after OPV cessation. For example, OPV-using areas with large, high-density populations and low routine immunization coverage may be at high risk for generating cVDPVs and need special attention, such as maximizing the population immunity before stopping OPV. Countries or communities with facilities that continue to store or handle polioviruses in the post-OPV era for IPV production and quality assurance purposes, to provide international diagnostic services, or to conduct specialized research may constitute an international biohazard and require extraordinary measures to prevent or minimize the consequences of inadvertent virus release.

Interruption of Wild Transmission and Containment of Wild Poliovirus. The first and most critical prerequisite before OPV can be discontinued is to ensure that WPV has been eradicated globally. The processes for certification are well-established (see "Certification of Polio Eradication" later), and containment of WPV is an integral part of certification. The objective of containment is to minimize the possibility that poliovirus will be reintroduced into the community. Laboratories holding poliovirus or potentially infectious materials need to ensure safe handling and ultimately appropriate laboratory containment. At present, containment activities focus on a survey of laboratories and inventory for WPV and potentially infectious materials. Eventually, appropriate containment will be needed for all polioviruses (Sabin, VDPVs, and WPV), whether in laboratories or in vaccine production facilities.

Global Surveillance and Notification Capacity. Surveillance strategies relying on AFP to detect all paralytic cases will need to continue for at least 5 years after interruption of WPV circulation (2 to 3 years before OPV cessation and 3 years after detection of the last cVDPVs). At that point, the risk of undetected cVDPV should be negligible. Long-term surveillance strategies would then likely focus on the detection of events (i.e., clusters of paralytic cases), the prompt epidemiologic and virologic investigation of such events, and the institution of effective control measures. Future surveillance efforts will also focus on identifying persons with iVDPVs. The expanded use of environmental surveillance (i.e., sewage sampling) in selected areas to supplement AFP surveillance has been endorsed, particularly in the highest-risk areas. The study in New Zealand conducted before and after the switch to universal IPV provides useful information about the kinetics of vaccine virus disappearance.[156] The New Zealand study relied on three monitoring systems—pediatric inpatient surveillance, AFP surveillance, and environmental surveillance—to detect Sabin-like viruses before, during, and after the switch from OPV to IPV. One month after the switch, no Sabin viruses were detected from pediatric inpatient and AFP surveillance, but environmental surveillance detected Sabin-like viruses until May 2002 (4 months after the switch). After May 2002, Sabin-like viruses were isolated infrequently, and genetic studies showed that these isolates represented recent importations rather than continued circulation of Sabin-like viruses. Thus, in a developed, temperate-climate country, Sabin-like viruses did not circulate for more than 4 months after the switch from OPV to IPV.

Vaccine Stockpile and Response Capacity. This area of work has two major objectives: (a) short-term, to rapidly control outbreaks of cVDPVs, should these occur during a 3- to 5-year transition period after OPV cessation, and (b) long-term, to minimize the consequences of poliovirus reintroduction into the community until polio immunization can be reestablished globally. Therefore, in these countries, infants will no longer be vaccinated against polio, and population immunity to polioviruses will decrease over time. If poliovirus is reintroduced into these countries, rapid control efforts using large quantities of mOPV will be required for outbreak control.

The WHO has established a vaccine stockpile relying on mOPV to allow type-specific responses to the reintroduction of one or more poliovirus serotypes, maximize the immune response, and avoid introduction of unnecessary vaccine poliovirus serotypes. Since 2004–05, mOPV1 and mOPV3 have been licensed in several countries and widely used (see the discussion of mOPV1 development). In 2009, mOPV2 was licensed by a manufacturer and a filler. The WHO is also assessing the role of IPV in such settings, particularly to boost population immunity in high-risk areas not yet affected by such an outbreak.

A stockpile of polio vaccine is necessary after OPV cessation. Many of the basic stockpile issues, such as the size, the vaccine (mOPV) and the composition (filled vaccine vials, bulk, or a combination), number of storage sites, and release protocols (e.g., who retains the authority to release vaccine) have been refined.[691] The primary purpose of a stockpile-and-response capacity is to ensure that control efforts can be instituted immediately after detection of a cVDPV at any time during the 3- to 5-year period following OPV cessation. For the longer term after OPV cessation, other options need to be explored, such as restarting the production of polio vaccines. The immunogenicity and the kinetics of the immune response of stockpile vaccines become critical decision determinants. Monovalent (i.e., type-specific) OPVs are the vaccine-of-choice for the stockpile[391] for the following reasons: (a) immunogenicity per dose is substantially higher compared with tOPV or IPV (one dose of mOPV may provide an immune response to the specific serotype that is equivalent to three doses of tOPV); (b) mOPVs are faster in inducing a type-specific immune response (one would not have to wait for administration of several doses); and (c) their use would be directed against a specific serotype of poliovirus, without introducing unnecessary serotypes of vaccine virus. Since December 2004, regulatory approval for mOPV1, mOPV2, and mOPV3 has been obtained (see Table 49.10).

Inactivated Polio Vaccine Vaccination Requirements. The WHO has prepared position statements on IPV for the pre-eradication and posteradication eras that provide guidance.[641,692,693] In addition, a decision was made to introduce one dose (or more) of IPV in all OPV-using countries.[607] Recent work suggests that a one-dose fractional IPV given in the second half of the first year (to reduce the influence of maternally derived antibody on IPV immunogenicity) may provide a low-cost option to induce and maintain a basic immunity against all three poliovirus serotypes. The use of fractional-dose IPV has recently been endorsed for outbreak response by the GPEI to counter the current IPV supply limitations.

The introduction of IPV is funded in GAVI-eligible and graduated countries for at least 5 years.

Coordinated Oral Polio Vaccine Cessation. To minimize the risk of emergence of and exposure to cVDPVs during the period following OPV cessation, all countries will need to stop the use of type-specific OPV Sabin strains during a relatively short period (ideally, a few weeks) everywhere, and all must institute mechanisms to ensure that OPV from throughout the health system has been recalled and destroyed. There must be agreement that no country will again use OPV, unless specifically endorsed by the international community for control of an outbreak.

Sabin Poliovirus Containment. Shortly after global OPV cessation, Sabin polioviruses must be contained. The WHO has prepared a *Global Action Plan to Minimize Facility-Associated Risk in the Post-Eradication/OPV Era*, which was updated in 2014.[694,695] This update is responsive to the new endgame strategic plan which calls for the sequential cessation of Sabin strains (starting with Sabin type 2), and the introduction of IPV in all OPV-using countries for risk mitigation purposes.

The communication of the endgame issues is another very important objective of the GPEI. It is important to understand the current thinking and to appreciate that it is a work in progress, and that new scientific data, programmatic experiences, and expert advice all will feed into a program of work that allows the adoption of policies that minimize the paralytic burden of poliomyelitis to current and future generations of children.[696,697]

There have been voices that have questioned whether eradication is feasible.[698,699] However, if the program learned anything during the past few years, it is that if eradication efforts are stopped, the world will have to live with hundreds of thousands of cases of paralytic disease again because routine immunization coverage in many parts of the world has not improved substantially since 1988. Hence, susceptible populations will accumulate, leading to large polio outbreaks. Only the aggressive use of mass vaccination campaigns has led to control and elimination of polio transmission in many parts of the world. The experiences from outbreaks, particularly in Yemen, where imported poliovirus caused 479 cases in a country with suboptimal routine immunization, and interruption of mass vaccination campaigns for more than 1 year,

present an example of how polioviruses can exploit the immunity gaps in the population. Similar large-scale outbreaks that occurred in Tajikistan[216] and Congo-Brazzaville[217,243] in 2010 were the result of critical immunity gaps against polioviruses. To achieve eradication, such importations need to be controlled rapidly and, still better, prevented by eliminating the reservoirs in polio-endemic countries that export viruses into countries currently polio free.

Certification and Verification of Polio Eradication

The WHO has established a formal process for the certification of polio eradication to ensure that future immunization policy decisions are based on the best available evidence.[700] The certification process for polio is modeled on the International Smallpox Certification Commission, which certified in December 1979 that smallpox had been eradicated.[701] However, polio certification differs in important ways from the smallpox model. The Pan American Health Organization established its Regional Certification Commission (RCC) in 1990, and certified regional eradication of indigenous WPVs in 1994,[702,703] setting the standard for certification by individual regions and implicitly considering genetic evidence to distinguish indigenous WPVs from imported virus. Because of the high proportion of inapparent WPV infections, regional certification requires a period of at least 3 years of sensitive surveillance since the last reported case associated with indigenous WPV. Small outbreaks from imported virus occurred on the eve of certification in the Western Pacific (in China in 1999[704,705]) and in Europe (in Bulgaria[706] and Georgia[298,500] in 2001), but they were quickly controlled and followed by intensive surveillance. Certification of eradication of indigenous WPVs by four WHO Regions (comprising >80% of the world's population)—the Americas in 1994,[702,703] the Western Pacific in 2000,[707] Europe in 2002,[500] and South-East Asia in 2014[501,708]—has stood the test of time. No indigenous WPV circulation has been detected in these regions postcertification.[709,710] Cases and outbreaks associated with imported WPVs and cVDPVs (in addition to cases of VAPP) have occurred subsequently, but circulation has been promptly stopped by effective outbreak control measures.[66,309,311,553,669,670,711] Similarly, documentation in all countries except Pakistan and Afghanistan has been accepted by the Eastern Mediterranean RCC. Several countries in the African Region have also prepared detailed documentation of polio-free status.[550]

Review of documentation to assess polio-free status is organized into three tiers.[700] National Certification Committees (NCCs) meet to critically assess national data and prepare detailed reports to RCCs, which, in turn, report to the Global Certification Commission (GCC). The NCCs, RCCs, and GCC meet regularly, and in the regions already certified as free of poliovirus circulation, the RCCs, working with NCCs, are primarily responsible to oversee and support activities to maintain the polio-free status. The NCC reports contain current information on (a) national demographic data, including high-risk populations; (b) poliovirus vaccine coverage and any changes in vaccine policy; (c) surveillance data and indicators of surveillance sensitivity; (d) descriptions of any poliomyelitis cases; (e) information on the performance of laboratories serving each country; and (f) progress toward poliovirus containment. NCC, RCC, and GCC members are charged to serve as independent experts. Following certification of all WHO regions, the GCC reviews all RCC reports and other relevant information to determine when the world can be declared free of all poliovirus circulation.[700]

Before type 2 OPV cessation (the tOPV-to-bOPV switch) in April 2016, the GCC reviewed all available evidence that WPV type 2 circulation (see Fig. 49.5) has ceased (confirmation of eradication of wild type 2 poliovirus).[550,712] The evidence was overwhelming that all WPV type 2 circulation stopped after 1999. Although low-level type 2 cVDPV circulation continued into 2015 (see "Vaccine-Derived Polioviruses" earlier), aggressive tOPV campaigns were scheduled with the aim of interrupting all type 2 cVDPV transmission.

Laboratory Containment of Polioviruses

Containment is integral to poliovirus eradication.[713–715] Unlike smallpox, where very few facilities stored materials containing (virus stocks) or potentially containing (clinical specimens) smallpox virus (variola), many facilities worldwide have stored materials containing polioviruses. The purpose of containment is to minimize, as much as possible, the risk of reintroduction into the community of polioviruses stored in laboratories and vaccine production facilities. In 1995, the GCC approved the first *WHO Global Action Plan for Laboratory Containment of Wild Polioviruses*,[716] and established satisfactory completion of containment activities as a requirement for regional certification.[717] The third edition of the global action plan (GAPIII), endorsed by the World Health Assembly in May 2015, links containment to national and international milestones in polio eradication.[695] Under GAPIII, containment will be implemented by countries in three phases, starting with poliovirus type 2. Key activities of Phase I include (a) conducting national surveys of all biomedical laboratories, establishment of type 2 inventories, and reporting to the RCCs; (b) destroying all unneeded poliovirus type 2 materials (risk elimination); (c) transferring needed poliovirus type 2 materials to essential poliovirus facilities; and (d) certifying essential poliovirus facilities for containment (biorisk management). Phase II has started and includes two parts: (a) containment of WPV type 2 and type 2 VDPVs (began at the start of 2016), and (b) containment of type 2 OPV-related polioviruses (begins within 3 months of the bOPV-to-tOPV switch). Phase III begins 3 years after the last detection of any WPV and just before certification of global polio eradication, and also has two parts: (a) containment of all WPVs, and (b) containment of OPV-related polioviruses. The timetable for completion of each phase of containment is based on progress toward type-specific cessation of poliovirus transmission. Nationally certified essential facilities—which will be limited to the absolute minimum needed for vaccine production, quality control, reference, and research—must meet strict, standardized criteria for biorisk management and be located in areas of lowest population risk; performance may be verified by the WHO.[719]

In accordance with the original GCC requirement, Phase I containment of all WPV was completed in 154 of 194 WHO member states, in three WHO Regions certified polio-free, is nearing completion in the South-East Asia and Eastern Mediterranean Regions, and is in progress in the African Region.[715] Worldwide more than 225,000 facilities were included in national laboratory surveys (some facilities housed more than one laboratory storing WPV infectious or potentially infectious materials) and 532 facilities in 45 countries reported storing WPV infectious materials or potentially infectious materials.[715] For example, in the United States, among the 105,356 laboratories surveyed, 180 laboratories in 122 institutions were found to be storing materials containing or potentially containing WPV; 87 held WPV stocks, 56 stored materials potentially containing WPVs, and 37 stored both.[719] Europe completed national surveys in 2006, and the Western Pacific Region in 2009.[720]

A particular challenge will be the appropriate handling and containment of clinical materials (e.g., stool specimens or throat swabs) collected and stored for purposes other than

polio diagnostics,[721] especially specimens collected during the weeks following the last campaigns using type 2–containing OPV and, later, all OPV. The WHO and national health governments must continue to alert the broader health community of the need for containment of all poliovirus infectious or potentially infectious materials.

CONCLUSION

Poliomyelitis has affected humankind since ancient times. It appeared as an epidemic disease in industrialized countries in the 19th century and the beginning of the 20th century. Development and widespread use of poliovirus vaccines have effectively controlled poliomyelitis in all but two countries globally. Type 1 is the only circulating WPV serotype detected since 2012. The new endgame strategy with the objective to remove all polioviruses from populations will likely facilitate eradication, relegating this once much-feared crippling disease to one that future generations will know only by history.[41]

50 Rabies Vaccines

Charles E. Rupprecht, Thirumeni Nagarajan, and Hildegund Ertl

> *"I have seen agony in death only once, in a patient with rabies; he remained acutely aware of every stage in the process of his own disintegration over a twenty four-hour period, right up to his final moment."*
>
> **Lewis Thomas, *The Lives of a Cell*. New York, NY: Bantam Books; 1974.**

Rabies is an acute, progressive viral encephalitis transmitted from animal to animal or from animal to human by exposure to saliva via bites or other sources of infectious virus. After a bite, virus in saliva attaches to peripheral nerve endings and travels to the brain. Although all warm-blooded vertebrates are believed susceptible to experimental infection, in nature, rabies is a predominant disease of mammals, involving primarily the Canidae (e.g., dogs, wolves, foxes, coyotes, and jackals), Procyonidae (e.g., raccoons), Viverridae (e.g., mongooses), Mephitidae (e.g., skunks), Mustelidae (e.g., ferrets, badgers), and Chiroptera (bats) as reservoirs or vectors.

Human infection is nearly always secondary to animal bite (or very rarely by scratch or other routes), although exposures through the inhalation of virus, inoculation with improperly inactivated vaccine, or transplantation of infected corneas, tissues, and organs have occurred. In most of the world, the major reservoir for human rabies is the dog, responsible for an enormous incidence of bites. Although not functioning as actual reservoirs, per se, cats are known vectors of the disease.

HISTORICAL PERSPECTIVE

Besides focal communications on rabies vaccinology, tens of thousands of highly relevant scientific papers have been written on the diagnosis, epidemiology, immunology, molecular biology, pathogenesis, prevention, treatment, and control of this malady during the late 19th through early 21st centuries, of which only a very small fraction are cited in this chapter. Moreover, considering that rabies is one of the oldest infectious diseases, the following brief summary cannot do justice to the rich history accumulated over the past four millennia. Interested readers are directed to G.M. Baer's "Rabbis and Rabies: A Pictorial History of Rabies Throughout the Ages" (Tlaxcala, Mexico: Laboratorios Baer; 1996) for a more engaging and erudite introduction to this fascinating and overlooked topic.

It has been suggested that rabies existed before 2300 BC, because of a description in the Mesopotamian Laws of Eshnunna.[1] Ancient texts from Egypt, Persia, Palestine, India, and China also seem to contain allusions to this disease.[2] The first certain references to rabies appear in Greek literature. Homer, Democritus, and Aristotle referred to lyssa (related to a mythological Greek goddess of rage and fury) in their writings, and in the 1st century AD, the Roman scholar Aulus Cornelius Celsus provided an accurate description of the disease and the wide range of species susceptible to infection. Rabies is mentioned frequently in Arabic and Western writings during the Middle Ages. In the 15th century AD, the Italian savant Girolamo Fracastoro suggested the concept of the "incurable wound," that is, the disease was always considered lethal and not treatable. In the same vein, the Talmud also mentions that one should not believe people who say that they were bitten by a rabid animal, yet survived.

By the 1500s, shortly after Cortez's exploration of the Americas, the first Bishop of Oceania described "small animals" that bit the toes of Spanish soldiers during the night. The soldiers later died of a disease that may have been rabies. Other Spanish sources describe vampire bats that even now have a major role in the perpetuation of rabies throughout Latin America. As mentioned later, current virologic data suggest that carnivore rabies may have been absent in the New World until introduced with rabid dogs within the 16th century.[2]

Early in the 19th century, one school of thought held that rabies was purely a psychiatric disease. Nevertheless, the dramatic symptoms and nearly 100% fatality rate of rabies attracted the scientific curiosity of many of the first modern microbiologists.[1,3]

The German scientist, Gottfried Zinke, demonstrated experimental transmission of rabies virus in 1804 by inoculation of human saliva into animals. In 1879, in Lyon, France, Pierre-Victor Galtier transmitted rabies virus from dog to rabbit and from rabbit to rabbit and used intravenous injections of infected material to immunize sheep and goats. However, Galtier's work was overshadowed by that of his famous contemporary, Louis Pasteur. Much of the credit for applied rabies research belongs to Pasteur, but one must not overlook the contributions of his other collaborators, Roux, Chamberland, and Thuillier. These investigators conducted most of his critical laboratory manipulations because Pasteur was partially disabled by a stroke at the time.

In 1881, the Pasteur group established that the central nervous system (CNS) was the principal site of rabies virus replication. They transmitted the disease by submeningeal inoculation of infected material into rabbits and were able to maintain the virus in this host for more than 100 passages. Roux noticed that the virulence of infected rabbit spinal cords decreased rapidly when they were suspended in dry air and was extinguished almost completely in 15 days. From this observation, Pasteur developed a practical method of vaccination. Dogs injected subcutaneously with serial suspensions of fragments of infected spinal cords, beginning with cord dried long enough to be avirulent and using successively less-dried cords, resisted rabies when they were injected intracerebrally with a virulent virus.

At least 50 dogs were protected by Pasteur's protocol. Although experiments performed to demonstrate that animals could be made refractory to rabies by vaccination after bites by "mad" dogs were inconclusive, successful inoculation of one person, Joseph Meister, was attempted on July 6, 1885, after other unsuccessful and unpublicized attempts at human vaccination. Meister, who had been bitten 14 times by a rabid dog some 60 hours previously, received a subcutaneous inoculation of spinal cord suspension derived from rabid rabbits and preserved in a flask of potassium hydroxide for 15 days. Twelve successive inoculations were made with cords of increasing virulence, for a total of 13 inoculations during an approximately 10-day period. The boy not only resisted the original animal source of rabies virus infection, but also

survived large quantities of highly virulent virus that were contained in the final doses of vaccine.

This Pasteur method, as the first generation of rabies vaccination, aroused great interest in medical circles and, despite some major disagreements, was rapidly accepted. Thereafter, the Pasteur Institute of Paris was founded in 1888, and within a decade, there were Pasteur Institutes throughout the world providing rabies vaccination, and setting a precedent for vaccination well into the 20th century.

Criticism, however, was forthcoming. Occasional failures raised questions about the safety of the vaccine, especially because virulent material was inoculated into the patients by the end of the vaccine series. Moreover, there were no controls for comparison to confirm the efficacy of the method. Much later, one tragic accident in Fortaleza, Brazil, in which children died after vaccination, showed that the so-called fixed virus could be virulent if not prepared properly, which led to a century of focus upon the improvement of rabies vaccine purity, potency, safety and efficacy, which prevails to this day.

Understandably, few diseases have carried the historical blend of loathing and superstition attributed to this zoonosis, bridging the gap from scientific fact to folklore, including partial responsibility for the legends of vampires and werewolves. Curiously, in an interesting twist on the macabre, some believe Edgar Allan Poe may have died of rabies in Baltimore, which is not surprising given the variety of ways the disease may present clinically.[4]

CLINICAL PRESENTATION

Rabies vaccination is not successful once a patient presents with signs and symptoms of encephalitis. Such comprehensive clinical descriptions of human rabies have been published by many authors for centuries.[4–18]

While the specific disease may be considered a continuum because of a diversity of variables, in general, the clinical syndrome in humans consists of the following overlapping stages: incubation period, prodrome, acute neurologic phase, coma, and death.[9] Very rarely does recovery occur, even after heroic measures. Once clinical signs occur, death is nearly inevitable.

During the incubation period, there are no symptoms and no means of diagnosis. After exposure, the incubation time of rabies is highly variable in humans, ranging in extreme cases from approximately 5 to 6 days to several years.[5–7] Typically, humans develop symptoms after 20 to 60 days. The length of the incubation time is in part influenced by the site of exposure and tends to be shorter when the virus enters locations closer to the brain. Very long incubation periods in excess of several years have been reported.[8,19,20] Initially, these were viewed with doubt. Nevertheless, such lengthy periods have been substantiated by genetic analysis of the infecting virus, which can pinpoint where and how the infection was acquired initially. For example, immigrants or travelers became infected with a viral variant from a region they had not visited for many months to years and did not occur in the region where the patient eventually succumbed.[7,21,21] However, the specific anatomical location where lyssaviruses remain in vivo, during such long incubation periods, is unclear. Opinions differ if virus remains in the periphery, close to the site of infection, or becomes dormant after entry to the nervous system. After breaching the skin or mucosae, the virus may exist in a stable form within a cellular compartment, relatively shielded from proteolytic enzymes or detection by the immune system.

Most human rabies cases are caused by dog bites. Approximately 37% to 57% of unvaccinated individuals with known exposure to a rabid dog develop rabies. The risk of disease is linked presumably to the amount of virus present in saliva as well as the location and the severity of exposure.[9] The latter is supported by an increased (~80%) risk of disease, following attacks by rabid wolves. The incidence of symptomatic rabies in unvaccinated persons after exposure to other rabid animals, such as bats, is unknown, but may be lower, as suggested by documentation of viral seropositivity, in healthy humans residing in areas of Amazonia, where vampire bat rabies is common.[22]

The initial prodromal symptoms of rabies consist of general malaise, anorexia, fatigue, headache, vomiting, sore throat, fever, and in 50% to 80% of cases, pain or paresthesia close to the bite site, potentially indicative of neuronal damage. Some patients display psychological symptoms, such as anxiety, agitation, irritability, nervousness, insomnia, or depression. The prodromal phase, lasting for 2 to 10 days, is followed by neurological symptoms of rabies, which in humans can present as a furious or paralytic form. The furious form, generally associated with dog bites, is more common and afflicts approximately 65 to 70% of patients. Furious rabies is characterized by periods of hyperactivity, aggressive behavior, agitation, hallucinations, delusions, hypersalivation, muscle fasciculations, seizures, fever, excessive sweating, and priapism. Patients develop difficulties swallowing and hydrophobia (so-called fear of water) as a consequence of painful spasms of their throat muscles, which can be triggered by the mere sight, sound, or even mention of water. Patients may also develop fear of light (photophobia) and air currents (aerophobia). Hyperactive periods in humans last approximately 1 to 5 minutes. These periods may occur spontaneously or are triggered by a variety of stimuli. Between hyperactive periods, the patients are alert and able to communicate, although over time their mental faculties deteriorate.[10]

Paralytic, or "dumb," rabies seems more common after exposure to rabid bats. Patients develop ascending muscle weakness, loss of sensation, and paralysis starting in the extremities and then spreading upwards. Eventually, with either form of rabies, patients fall into a coma and die of cardiac or respiratory arrest. Without supportive care, death occurs within approximately 5 days of furious rabies and approximately 13 days of paralytic rabies. Intensive care can prolong life for a few days or even months, but in general does not prevent death.

In countries where canine rabies is enzootic, this zoonosis is fairly easy to diagnose, with the onset of classical symptoms in an encephalitic patient with a history of suspicious animal bite. However, rabies may not be suspected or easily diagnosed, especially in countries where human disease is rare.[13] This, in turn, is one explanation for the occurrence of human transplantation of tissues and organs, from individuals who succumbed to an undiagnosed illness, to recipients who later developed rabies, and thereby inadvertently allowing for a postmortem diagnosis in the donors, as to cause of death.[23,24]

Rabies may be confused with encephalitis caused by other infectious agents, such as herpes simplex virus, enteroviruses, arboviruses, toxoplasma, or prions, or toxins, such as tetanus toxin. Rabies may mimic atropine poisoning, intracranial malignancies, acute cerebral injuries (e.g., a stroke), or transverse myelitis caused by infections with measles virus or mycoplasma. Some individuals may exhibit rabies symptoms that result from a hysterical reaction to an animal bite. For a thorough diagnosis of rabies, careful history about contacts with animals, unprovoked animal attacks, availability of the animal for testing, vaccination status of the animal, camping with potential exposure to bats, and the like is essential. Physical examination should reveal autonomic instability in furious rabies and symmetric paralysis that may be mistaken for Guillain-Barré syndrome in paralytic rabies. Laboratory testing can be used to rule out other infectious diseases. Magnetic resonance imaging and computed tomography (CT) scanning of

the brain may show some abnormalities, but neither is specific for a diagnosis of rabies.[25–27]

Electroencephalography may show sudden drops in amplitude as a result of vasospasms of cerebral vessels, but, again, findings are not specific to rabies.[14] Cerebrospinal fluid (CSF) commonly shows lymphocytic pleocytosis, but few to no changes in glucose or protein content. Positive antemortem diagnosis requires several tests, performed by a qualified reference laboratory. Skin biopsy specimens can be tested with fluorescent-labeled antibodies for detection of viral antigen present in the cutaneous nerves at the base of hair follicles. Impressions of corneal epithelia can be analyzed using the same method. Harvesting of either type of sample should be conducted with topical anesthesia by a dermatologist or an ophthalmologist. Saliva, CSF, urine sediment, and pulmonary secretions may allow for isolation of virus within approximately 2 weeks after onset of symptoms or such samples can be tested for viral products upon reverse transcription and amplification by polymerase chain reaction (PCR). Antibodies to rabies virus can be detected from serum or CSF via neutralization by 1 to 2 weeks after onset of symptoms.

Clinical signs of rabies in animals are compatible with an acute, progressive encephalitis. An initial prodromal phase, often characterized by changes in behavior and loss of appetite, is followed by a phase where the animal becomes aggressive and may bite without provocation. Other animals may become somnolent. Animals may develop paralysis and quickly die thereafter. As a rule, rabies in animals is diagnosed postmortem from brain impressions using the direct fluorescent antibody test. Microscopic examination of stained sections demonstrates inclusion bodies in the cytoplasm of neurons, especially in the brainstem and Ammon's horn of the hippocampus. Brain impressions can be tested by a fluorescent-conjugated antibody for detection of viral antigens. Alternative methods, such as those based on biotinylated virus-specific antibodies that allow for easier and faster onsite diagnosis by routine light microscopy, rather than immunofluorescence, are being developed.[28]

Historically, isolation of rabies virus had been reported from as much as 0.5% of so-called normal dogs in Ethiopia and elsewhere, presumably in the late incubation stage or early prodromal phase, but the significance of this finding to human rabies occurrence is unknown.[29] The ultimate documentation of a true "carrier state" in rabies for any species awaits further rigorous, objective corroboration, given several alternative explanations.

Attempted Treatment of Symptomatic Rabies

Prevention by vaccination, which is highly effective, needs to be distinguished from medical treatment after clinical onset, which is highly problematic. Rabies has the highest case fatality of any infectious disease. During the 20th century, there were fewer than 10 cases of documented survival among humans who showed signs of disease, most of whom recovered with sequelae.[30–35] Until recently, there had been no serious attempts at therapy, and all putative survivors had received some form of preexposure or postexposure rabies vaccination before illness.[36]

Attempted treatment in the vast majority of cases tended to be palliative, rather than curative. The nearly 100% mortality rate, combined with agonizing symptoms, limited more aggressive treatment, which in most cases merely prolonged suffering for very few individuals that may have had a very low realistic chance of recovery. Routine treatment of human cases was restricted to sedatives, narcotic analgesics such as morphine or its analogues, anticonvulsants, and neuromuscular blockers.[37]

Although transmission of virus from patients to healthcare providers has not been documented, exposure should be minimized by appropriate containment and personal protective devices, as used through barrier nursing procedures. In some cases, more aggressive treatment could be attempted, but with a clear understanding of the patient or the patient's family that death may not be prevented and that in case the patient survives, the patient may suffer lifelong debilitating neurological symptoms. Historically, numerous treatments have been tried, but all ultimately failed. For example, hyperimmune serum, even if administered in high doses, rabies vaccination, treatment with interferon, interferon-inducers, or antiviral drugs, have not been effective.[38,39,40]

During 2004, however, a 15-year-old girl who developed rabies after a bat bite was treated with ketamine and midazolam to induce coma and the antiviral drugs ribavirin and amantadine. She survived with no major cognitive impairment and minimal neurological sequelae.[41] This so-called Milwaukee protocol was tested in its original form or in a revised version without ribavirin in other patients.[42–45] Of the more than 40 patients treated to date, at least five were reported to have survived, implying that aggressive treatment may have some benefits. Patients who survived tended to be young and developed robust immune responses to rabies virus before or during treatment. However, it has been suggested that treatment success was linked not only to superb intensive care, but also to genetic components of the survivors that enabled them to develop an unusually potent virus-neutralizing antibody (VNA) response early after infection. One could offer a counterargument that because passive transfer of rabies hyperimmune serum offers no long-term clinical benefit, that an antiviral B-cell response by itself does not suffice to clear the virus. Nevertheless, the kinetics of the endogenous immune response, potential secretion of antibodies by B cells that migrate into the CNS, as well as added drugs such as ketamine an *N*-methyl-D-aspartate acid receptor antagonists may have contributed to survival.[46,47,48] Another possibility is that positive treatment outcome is linked to peculiarities of the infecting virus. For example, rabies virus was never isolated from the majority of patients who had received experimental treatment protocols. This, in turn, could suggest that the infecting dose was small in the periphery or the virus was somewhat more "temperate" than other street virus variants. In summary, there is no reliable proven therapy for symptomatic rabies.[49] Given the renewed interest after initiation of the Milwaukee protocol, variations thereof might be tried in selected patients, especially if they had previously been vaccinated or presented with an already detectable immune response to virus. Additional research is needed on pathobiological insights, antiviral drugs and development of improved treatments using relevant animal models that will be practical for resource-poor countries, where rabies is most common.[50]

VIROLOGY

An introduction to applied virology yields important insights as to the basic immune mechanisms utilized during rabies vaccination. Rabies virus belongs to the family Rhabdoviridae, genus *Lyssavirus*, consisting of genetically related enveloped viruses with a single, nonsegmented, negative-stranded RNA. The virion is shaped like a bullet, approximately 200 nm long and 75 nm wide. The virus contains multiple copies of the following five structural proteins: virion transcriptase (L), glycoprotein (G), nucleoprotein (N), phosphoprotein (P), and matrix protein (M). The L, N, and P proteins are bound noncovalently to the virion RNA, and the resulting ribonucleoprotein (RNP) complex forms a helically coiled nucleocapsid

structure within the virion. The crystal structure of the RNP has been resolved.[51] The nucleocapsid sequesters the RNA and shields it from the cellular environment. This RNP complex is surrounded by a lipoprotein envelope consisting of the M protein and the surface projection of the trimeric G protein extends to the exterior of the virus.[52]

Like other RNA viruses, rabies viruses have been proposed by some to exist as quasispecies.[53,54] Phylogenetic analyses suggest rabies originated in bats.[55–57] Transfer of rabies viruses from the Old to the New World may have occurred at the time of colonization of the Americas, where it was already established in bats, and subsequently in carnivorous mammals, such as dogs, but the evidence is incomplete.[55,56,58]

The rabies virus G protein, which is a trimer of approximately 67 kDa, is the major antigen responsible for inducing production of VNAs and for conferring immunity against lethal infection with rabies virus.[59,60] The G protein also contains determinants of virulence.[61,62] The G gene was the first rabies virus gene to be cloned and sequenced.[63] From the nucleotide sequence, a polypeptide 524 amino acids long was deduced, which included a signal sequence of 19 amino acids.[52] An arginine at position 333 seems important as one virulence factor, expressed as an ability to spread faster throughout the nervous system, related to properties of neuroinvasiveness and transynaptic spread.[64,65]

Despite the importance of the G gene to virulence and attenuation, critical features related to viral pathogenesis are diverse.[66] For example, the P protein interferes with host interferon production.[67,68] The development of a reverse genetics system for application to rabies virus offers a more detailed analysis of virulence factors.[69] Attenuation may be appreciated as a mirror image to virulence and includes additional elements, such as inhibition of apoptosis of the infected nerve cell. The G and M proteins are responsible largely for blocking apoptosis after infection by virulent viruses, which is, in effect, a protective mechanism for the host. Highly attenuated strains have alterations in those proteins, rendering them proapoptotic.[70–72] Rabies virus genomic RNA is also protected from generating innate immune responses by its tight physical association with the N protein.[73] The immunogenic activity of purified native and smaller fragments of G protein, both naturally occurring and derived by chemical cleavage of the rabies virus G protein, has been compared in a variety of ways to determine the structural basis of VNA production after immunization.[52] Although the definitive role of the humoral immune response to rabies may be debated,[74–76] evidence for the importance of VNA in prevention of viral infection is convincing in humans and other mammals. With regard to a cellular response, T-helper cells are necessary for antibody induction, whereas cytolytic T cells directed against the N protein induced by vaccination may be important for destroying infected extraneural cells before entry of virus into the CNS. Interestingly, the cytolytic T-cell response may be suppressed in natural infection.

Routine sequence analysis of rabies virus variants has not revealed substantive differences accounting for the clinical appearance of furious or paralytic rabies.[77]

"Rabies-Related" Viruses

Rabies is not caused by rabies virus alone. Since the 1950s, viruses have been isolated from animals and humans that were serologically related to rabies virus. Although some members of this group showed a degree of immunologic cross-reactivity with rabies virus, they were sufficiently different to be originally classified as "rabies-related" viruses.[78] The *Lyssavirus* genus is now considered to contain at least 15 members: rabies virus, as the type species of the genus; Lagos bat virus, originally isolated from bats in Nigeria[79]; Mokola virus, isolated from a shrew in Nigeria and suspected in at least one human case[80]; Duvenhage virus, isolated from African bats and humans bitten by African bats[80]; European bat virus 1, isolated from European bats and a human case in Russia; European bat virus 2, isolated from European bats and a human case in Finland[81]; and Australian Bat *Lyssavirus*, isolated from Australian bats, horses, and persons exposed to these reservoirs.[82,83] By the end of the 20th century, in contrast with these six other genotypes, no human cases had been associated with Lagos bat virus. Additionally, Mokola virus was found to cause lethal infection in rabies-vaccinated dogs and cats and was one of the few lyssaviruses not proven to be harbored by bats.[84,85] European Bat *Lyssavirus* I was isolated from bats captured in Poland, Denmark, Finland, and northern provinces of Germany.[80] Both European Bat lyssaviruses are apparently widely distributed in European bats, and despite the belief that the United Kingdom was "rabies-free," European Bat *Lyssavirus*, transmitted by bat bite, was documented as the cause of a human case of rabies in Scotland.[8,86] Previously, four deaths from bat lyssaviruses had been reported in Europe.[87] Although tests using experimentally inoculated mice showed that human diploid cell rabies vaccine could protect against European bat viruses,[88] and vaccination of exposed humans has so far been uniformly successful,[86] only 73% of vaccinated patients developed VNA to these viruses, usually when they had mounted a strong antibody response to the rabies vaccine virus.[89] Both Lagos and Mokola are genotypically distant from typical rabies viruses and have been placed in a separate group, phylogroup 2. Experimental vaccines against Mokola do not protect against Lagos.[90] By the 21st century, other newly discovered agents were characterized and accepted as additional *Lyssavirus* species in Africa and Eurasia.[91] One example, West Caucasian bat virus, was described as one of the most phylogenetically disparate members of the genus. Notwithstanding the lack of vaccine cross-reactivity of these agents, the ultimate public health significance of such emerging lyssaviruses remains to be determined.[92] In many parts of the developing world, where these viruses reside, surveillance is much less than ideal. Renewed pathogen discovery, new agent characterization, and related epidemiologic investigations are desirable to ensure adequate public education and preparedness, especially as new lyssaviruses are described, because all have the ability to cause rabies and an ecological perspective on predicting the emergence of viral pathogens among the *Chiroptera* is poor, in developed and developing countries alike. For example, during 2010, Kuzmin and colleagues[93] reported the discovery of "Shimoni bat virus," isolated from a bat in Kenya. By 2011, they reported a likely reservoir of the Shimoni bat virus.[94] Concomitantly, during 2011, "Bokeloh bat virus," detected in Lower Saxony, Germany, and later in France, was characterized as a new *Lyssavirus*.[95] Clearly, others await characterization throughout this century.

PATHOGENESIS AS IT RELATES TO PREVENTION

Appreciation of viral pathogenesis is critical as a background as to how, when, and why vaccination may be used appropriately to prevent this fatal zoonosis. After inoculation in a wound, rabies virus may take days or weeks to reach the CNS. It is this fact, at least in part, which makes postexposure prophylaxis (PEP) possible. During this early period, the virus is susceptible to VNA, and even to mechanical removal by washing. There is some evidence that initial replication may occur in muscle cells surrounding the wound, providing an amplification of the original inoculum. However, experimental data show that CNS entry can occur without any prior

replication in muscle tissue.[46,96] Another site proposed for possible harborage of rabies virus before entry into the CNS is the macrophage, from which the virus could reactivate to cause disease[97]; but the importance of replication in nonneural cells to the pathogenesis of rabies remains highly controversial.[98] In any event, at some point the virus enters nerve cells through nerve spindles of sensory nerves or neuromuscular junctions of motor nerves.[99] Rabies virus G protein has sequences similar to certain neurotoxins,[100–102] and there are many viral receptors, including the α subunit of the nicotinic acetylcholine receptors of the neuromuscular junction,[100–104] the neural cell adhesion molecule, the neurotrophin receptor, p75NTR, and, perhaps, certain lipoproteins on the cell membrane. Thereafter, the virus enters the neuronal cytosol, where it replicates and spreads within the CNS.[105,106] Dietzschold and colleagues demonstrated that the action of rabies VNA was not exerted solely outside the cell.[107] In one animal model, the effectiveness of antibody was associated with entry into the cell by endocytosis and inhibition of viral transcription. Whether antibody may act directly or by signal transduction to inhibit viral protein synthesis is unclear.[108]

Once in a neuron, rabies virus travels rapidly within the axons at a rate of approximately 8 to 20 mm/day in rodents, probably faster in humans (15–100 mm/day). Experimental studies in rodents showed that virus can reach the CNS in 3 to 5 days, where it causes a widespread encephalitis.[109]

After establishment in the neurons of the CNS, the virus moves in the opposite direction, down the axons to replicate in peripheral tissues, most notably in the nerve plexus and acinar cells of the salivary glands, from which excretion in saliva permits viral transmission by bite to maintain the circuit of infection.[78] However, at the end stage of infection, other extraneural tissues also are affected, including the heart, pancreas, adrenal glands, and gastrointestinal tract.[110,111]

In addition, the finding of virus disseminated throughout the body, in patients who acquired rabies from virus-infected organ transplants, raises questions about the possibility of altered pathogenesis through such unusual routes. The presence of virus in nonneuronal cells may also explain cases with long incubation periods.

The pathophysiology of the fatal outcome is not completely understood.[112] Although encephalitis is widespread, neuronal destruction is not.[113] Death may result from the involvement and dysfunction of brain centers controlling the cardiorespiratory system. In general, the histologic presence of inclusions (i.e., Negri bodies) parallels that of rabies virus antigens, although many infected cells do not have these inclusions. Rabies virus antigens are most prevalent in the periaqueductal gray matter and the Purkinje cells of the cerebellum, but the quantity of rabies virus does not correlate with severity of symptoms.[114,115] Virulent rabies virus variants may be more capable of evading host innate immunity and of destroying neuronal processes.[116,117] The production of nitric oxide within the brain and general downregulation of host genes have been advanced as possible explanations for brain dysfunction.[46] Although the fatality rate in rabies is extremely elevated, recovery has been documented in some animals, such as the dog.[118]

Clinically, the neural mechanisms that distinguish furious from paralytic rabies are not well understood, but electrophysiologic studies suggest that denervation and anterior horn cell dysfunction are prominent in the former, whereas in paralytic rabies, there is inflammation and demyelination of peripheral nerves.[119,120] The mechanism causing demyelination could involve autoimmunity or a bystander effect of immune response to virus in the axons.[5] Hemachudha and colleagues emphasized the role of cellular immunity in the course of rabies.[5] They correlated strong T-cell responses and cytokine secretion (in particular, interleukin-6) with early death and the encephalitic form of the disease, and weak T-cell responses with paralysis and longer survival. Whereas it is certain that lack of an immune response to rabies virus, particularly antibodies, leads to fatal disease, there is thus some evidence that, on the contrary, some cellular responses are responsible for neural pathology.[121,122]

Evidence of a serologic response to rabies virus can be demonstrated by a variety of laboratory techniques, including mouse neutralization, fluorescent focus inhibition, indirect fluorescent antibody, plaque neutralization, immunolysis of rabies virus–infected cells, and binding techniques using radioimmunoassay or enzyme-linked immunosorbent assay procedures. Serum antibodies develop relatively late after natural infection in humans. In persons without a history of vaccination, serum antibodies may be first detected on or about the 6th to 10th day of illness, and thereafter can rise rapidly to high levels. Antibodies are also present in CSF later in the clinical course. Antibody titers of CSF are higher than would be expected from seepage into CSF from circulating blood, indicating local production. Because vaccination does not ordinarily induce CSF antibodies, the presence of CSF antibody titers supports the diagnosis of clinical rabies.[30,31]

The absence of most detectable serum antibodies until around the second week of illness (if at all) and of CSF antibodies until approximately the third week of illness (when significant systemic and neurologic problems occur) raises the possibility that some of the clinical symptoms result from the interaction of host antibodies with rabies virus–infected cells.[105] In mouse experiments, neutralizing antibodies and infiltration of cellular inflammatory cells were necessary to clear infection with an attenuated rabies from the CNS, but this process occurs too late in the usual clinical situation.[123]

Most persons who die of rabies develop specific antibodies to the virus, particularly if they received PEP. However, that response does not protect against a lethal outcome once illness is present, and might even contribute to the disease. Experimental findings suggest that the inflammatory response is associated with opening the blood–brain barrier, delivering antibody-producing B cells to the CNS. Nevertheless, this response usually fails or occurs too late to be therapeutic.

Immune Responses to Rabies Virus and Vaccines

Both innate and adaptive immune responses are operative during viral infection and vaccination. Innate responses to rabies virus are triggered by the intracellular RNA sensor retinoic acid–inducible gene 1 (RIG-I) and lead to secretion of proinflammatory cytokines.[124] At least in mice, one study showed that the innate response does not promote viral clearance.[125] Another study, also conducted in mice, showed that an attenuated rabies virus interacts with the Toll-like receptor (TLR) 7, which uses myeloid differentiation 88 (MyD88) as an adaptor molecule. Mice lacking MyD88 or TLR7 showed increased mortality, suggesting that in this model, innate responses provide some degree of protection.[126] Innate responses were also investigated in raccoons, which, unlike rodents, are a natural reservoir for rabies virus. In this species, the innate response upon rabies virus infection was not detected early at the site of inoculation but rather at late time points within the spinal cord, the brain, and the salivary glands.[127]

Adaptive immune responses also develop with a delay upon infection. Most humans lack neutralizing antibodies by the time their symptoms first develop. In general, such antibodies, once they become detectable, are only found in serum but not, or only at low titers, in CSF.[128,129] This very late and commonly weak antibody response may reflect that the dose

of the initial virus inoculum is too small to trigger T- and B-cell activation at the site of infection and that virus, once it replicates within the CNS, is relatively shielded from immune surveillance.

Humoral responses may also be impaired by viral immune-evasion mechanisms. In mice, rabies virus causes lymphopenia, presumably by causing lymphocyte apoptosis.[130,131] In addition, the P protein of rabies virus, upon interaction with STAT1, inhibits interferon signaling, which may prevent B-cell maturation.[68] Nevertheless, attenuated recombinant rabies viruses induce excellent B-cell responses, not only to transgene products but also to the viral G protein, in mice as well as nonhuman primates, indicating that low antibody responses in human rabies victims is unlikely to be linked only to active immunosuppression by viral antigens.[132]

Curiously, some humans as well as other mammals, without any evidence of an active rabies virus infection or a history of rabies vaccination exhibit rabies VNA, suggesting that they had been exposed, but then underwent an abortive infection and managed to clear the virus without progressing toward fatal or serious disease.[22] The presence of antibodies indicates that virus must have replicated to levels that sufficed to cause B-cell activation and expansion. As antibodies in patients with disease only become detectable several days after onset of neurological symptoms, this phenomenon may also suggest infection with a somewhat "attenuated" variant that replicates in the periphery. Knowledge on rabies virus–specific $CD4^+$ or $CD8^+$ T-cell responses in infected humans is virtually absent, limiting insights for therapy targeting such effectors.

Protection after vaccination is provided significantly by the induction of rabies VNA. Induction of such antibodies requires help from $CD4^+$ T cells, which are induced by inactivated rabies vaccine.[132–134] Experiments in mice showed initial responses by T-helper cell-independent short-lived plasma cells, that develop outside germinal centers and produce immunoglobulin (Ig) M antibodies for early protection.[135] This is followed by a wave of long-lived plasma cells that develop within germinal centers and produce switched, affinity-matured antibodies.[136] In one trial, upon booster immunization after a year, rather than the more typical schedule of shorter intervals between vaccine doses, antibody titers to rabies virus were sustained.[137,138] The vaccine also induces memory B cells that appear to persist for the life span of an individual, as they can be recalled 10 years or more later.[139] Apparently, $CD8^+$ T cells, which, as studies in mice indicate, do not contribute to protection against rabies virus, are not induced by current human rabies vaccines.[76,140]

DIAGNOSIS

Vaccination against rabies is recommended for persons at known or potential risk of exposure or those who have already been exposed. Persons exposed to virus do not have rabies and prophylaxis is intended to prevent such an occurrence. The history of an associated bite from a known or suspected rabid animal, coupled with the striking clinical manifestations, should provide a reasonably simple diagnosis of rabies. However, such straightforward attributes are not always present. Especially in the absence of a documented exposure source, clinical diagnosis of rabies requires differentiation from a wide variety of diseases that can cause neurologic symptoms. Because laboratory diagnosis may not be possible during the first week of illness, presumptive diagnosis based on clinical symptoms is important.

Definitive diagnosis of rabies virus infection of humans and suspected animal vectors depends on the detection and identification in infected brain tissue of rabies virus antigens or intracytoplasmic neuronal inclusions (Negri bodies); viral nucleic acid by reverse transcription–polymerase chain reaction (RT-PCR)[141]; the presence of rabies virus-specific antibodies in the CSF, or in the serum of unvaccinated patients; and on the isolation and identification of the virus from brain tissue, saliva, or other infected substances. The standard diagnostic technique is to search for rabies virus antigens in brain tissue by fluorescent antibody staining. The brainstem, cerebellum, and thalamus provide some of the best samples.[142] Identification of viral nucleic acid by RT-PCR is useful, particularly if specimens are in poor condition. Demonstration of Negri bodies has a variable sensitivity and is of only historical interest as a primary method, notwithstanding their detection microscopically upon postmortem examination of brain tissue, particularly when rabies is not suspected. Virus isolation is a procedure used for confirmation of other positive test results. Isolation can be accomplished in mouse neuroblastoma cell culture or by intracerebral inoculation of suckling mice.[143] Although diagnostic procedures generally are initiated in tissue specimens obtained postmortem, rabies virus infection also can be identified in during the extended course of the disease. In addition to its usefulness for brain biopsy specimens, the fluorescent antibody staining technique enables detection of viral antigens in impressions of infected cornea or in cryoscopic sections of skin biopsy samples from the hairline of the neck, where antigens can be detected in the nerves surrounding the hair follicles.[144]

In addition, as shown in Table 50.1, RT-PCR on saliva provides a rapid and sensitive test for rabies as early as 5 days after onset of symptoms.[145,146] Improved sensitivity was obtained when an RNA polymerase was included in the reaction and electrochemiluminescence was used for detection of product. This technique, called nucleic acid-based sequence

TABLE 50.1 Examples of Antemortem Diagnostic Test Results for 20 Human Patients With Rabies in the United States, 1980–1996

Test	No. of Patients Positive for Rabies Virus/Total Tested (%)	Earliest Positive Result, Day of Illness
RT-PCR of saliva for rabies virus RNA	10/10 (100)	5
Rabies virus antigen in brain biopsy	3/3 (100)	8
Rabies virus antigen in nuchal skin	10/15[a] (67)	5
Virus isolation from saliva	9/15[b] (60)	5
Serum antibody to rabies virus	10/18 (56)	5[c]
Rabies virus antigen in cornea	2/8 (25)	14
CSF antibody to rabies virus	2/13 (15)	15[d]

[a]Two patients had earlier skin biopsies that were negative but became positive on subsequent biopsy.
[b]One patient had an earlier test that was negative.
[c]Latest negative result on day 24; median to positive result was 10 days.
[d]Latest negative result on day 24.

amplification, detected the rabies virus genome in saliva, concentrated urine sediment, and CSF as early as 2 or 3 days after symptoms.[147,148] Serial tests should be performed to increase sensitivity.[148] One study in Thailand showed high sensitivity (91%) of rabies virus genome detection on the first day of hospitalization, particularly in saliva.[149] Both CSF and concentrated urine sediment specimens may also be useful. However, the genome was not detected in all patients before death. A latex agglutination test for viral antigen in dog saliva also has been developed.[150] One report found rabies virus–specific immune complexes in the CSF of 77% of patients with rabies 5 to 7 days after onset of disease.[151]

As an example of human rabies diagnosis in a developed country, between 1980 and 2005, more than 65 cases of human rabies were diagnosed in the United States, but not all were diagnosed before death, probably because a minority had a known history of exposure to potentially rabid animals. This problem arises in large part because many of the patients had been infected with rabies virus variants from bats, possibly as a result of undocumented or ignored bat bites.[152]

EPIZOOTIOLOGY AND EPIDEMIOLOGY

A thorough understanding of rabies as a fundamental disease of nature, affecting many other species, is essential, to properly conduct risk assessments for both human and domestic animal pre- and postexposure applications.

Mammals

Rabies is a disease of domestic and wild mammals, particularly dogs and related canid species, as well as raccoons, mongooses, skunks, and bats. Although birds are susceptible under experimental conditions, natural cases are very rare.[153] In areas in which domestic animal control programs are not extensively developed, dogs and cats account for most of the rabid animals reported and cause the majority (>90%) of human rabies exposures and deaths. After effective domestic animal rabies control programs in these areas, the numbers of rabid dogs and cats markedly decrease, as illustrated in the United States from the 1940s to the 1960s. Wildlife is then recognized as the main reservoir of rabies virus. In the United States since 1960, the majority of cases of animal rabies have been in wildlife species, and most human rabies cases have been secondary to bites by rabid wildlife, especially bats.[11,154] Luckily, bats do not often transmit virus to dogs or cats.[155,156]

Illustrating the relationship among different variants and hosts, Fig. 50.1 is a composite map of the United States showing the major carnivore reservoirs in each region.[157,158] The salient features shown are that skunks are the important vectors for rabies in the western and central United States, whereas raccoon rabies dominates in the east. The original focus of raccoon rabies was in the southeast, but a second front developed in the mid-Atlantic and northeast owing to translocation of infected animals, and now raccoon rabies is contiguous from Maine to Florida and west to Ohio.[159] Foci of red fox rabies are evident in Canada and Alaska. Rabies in Puerto Rico is caused by the mongoose, which was introduced as an invasive species. Rabies control is costly: in New York State alone, the cost of rabies prevention in humans was calculated to be $2.3 million per year.[160]

Table 50.2 delineates rabies cases by species for the United States in 2014.[158] Table 50.3 lists the principal animal vectors of rabies throughout the world.[146] In Western Europe, before oral vaccination foxes accounted for up to 80% of rabid animals. Infection in raccoon dogs is becoming more common in eastern Europe.[161,162] Molecular analysis of European viruses suggests that rabies originated in dogs, but now affects red foxes and raccoon dogs.[163] Infection in red foxes and raccoon dogs has gradually spread from east to west. Canine rabies is still widespread in Asia, Africa, and parts of Latin America. Between 1993 and 2009, there was a significant drop in canine and human cases in Latin America.[164] However, dogs remained the predominant vector for humans (65%), followed by bats (15%) and cats (3%). Vaccination of pet dogs is an effective strategy for protection of humans and has eliminated carnivore rabies in Great Britain, Iceland, Japan, and many other islands.[105,165] An immunization coverage of 60% to 70% is estimated to prevent canine rabies outbreaks.[166]

TABLE 50.3 Principal Global Animal Reservoirs/Vectors of Lyssaviruses[a]

Location	Reservoirs/Vectors
North America	Raccoons, skunks, foxes, bats, and mongooses
Western Europe	Bats and foxes
Eastern Europe	Foxes, dogs, raccoon dogs, wolves, and bats
Latin America	Dogs, bats, foxes, skunks, and marmosets
Caribbean	Mongooses, dogs, cats, and bats
Australia	Bats
Africa	Dogs, jackals, mongooses, foxes, and bats
Asia	Dogs, cats, ferrets, badgers, monkeys, mongooses, bats, and arctic foxes

[a]None listed in Antarctica, Oceania, and a few other, mostly insular locations, reported as presumably "rabies free" (even though laboratory-based surveillance may be entirely lacking or wholly inadequate by current global epidemiological standards).

In support of historical and epidemiologic observations in developed countries, one Thai study confirmed that rabid dogs and cats uniformly die within 10 days of the onset of illness.[167]

Foxes are important vectors in Canada, Alaska, and Russia. Mongooses imported into the Caribbean Islands now form a reservoir for rabies, and mongooses serve the same role in southern Africa and parts of Asia. The vampire bat is a major threat to livestock in Latin America and has been involved in many biting incidents in humans. Rabid cattle also may excrete rabies virus in saliva.[168] Like all mammals, rodents are susceptible to infection[105] but are infrequently rabid, and human transmission of disease by these animals has not occurred. In Thailand, 95% of the animals involved in biting incidents are dogs, often younger than 6 months,[169] with cats accounting for another 3%. The remaining 2% include monkeys, civets, tigers, and other animals, which testifies to the wide host range of rabies virus. Dogs randomly captured in Thailand developed rabies within 1 month in 3% to 4% of cases, and, interestingly, there was serologic evidence suggestive of prior rabies virus exposure or prior vaccination in approximately 15% to 20% of dogs.[170]

Rabies in animals (excluding bats) is absent in many islands such as the United Kingdom, Australia, and Japan. Much of Western Europe is also now "rabies free" in carnivores, although rabies still occurs in Central and Eastern Europe. For example, from 2000 to 2005, there were 45 non-imported cases of human rabies in Europe, but 44 occurred in Eastern Europe, and the remaining case was caused by a bat *Lyssavirus*.[171] Many of the large Asian countries (such as China), most of Africa, Russia and the republics from the former Soviet Union, and some parts of South America still report considerable rabies in domestic animals.

Travelers are at risk, as confirmed by the report of more than 17 human cases of rabies diagnosed in the United States but acquired abroad between 1990 and 2015.[158] The risk of rabies exposure in Nepal was calculated to be 5.7 per 1000 person-years for expatriates and 1.9 per 1000 person-years for tourists.[172] The epidemiology of rabies has been revolutionized by viral typing, initially with monoclonal antibodies since the late 1970s.[173] Panels of these antibodies, directed against epitopes specific to isolates from different animal species and from different geographic locations, are used to identify viruses. Thus, it is now possible to identify the source of an isolate from humans or animals and to demonstrate that the infection was transmitted far away in time and place. Significantly, genetic sequencing of the viral genome after RT-PCR amplification has supplemented greatly our knowledge of viral variability.[174] Laboratory "fixed virus" strains differ in sequence from wild "street viruses" by as much as 10% to 15% of nucleotides. Sequence data suggest that many viruses in the Western Hemisphere and in South Africa, and elsewhere, were imported from Europe.[175,176]

Bats

Bats are not incidental vectors of rabies virus, but more likely the original hosts of *Lyssavirus*, which in some distant past developed epizootiologic cycles in other mammals, such as dogs and other carnivores by spillover infections.[55] More genomic studies support this idea. The widespread infection of insectivorous bats throughout the United States was first documented in the 1950s. However, the importance of bat rabies, particularly from the silver-haired bat *Lasionycteris noctivagans*, to human transmission has become more evident (see "Human Rabies" later). The eastern tricolored bat *(Perimyotis subflavus)* is important in the East and Midwest.[177] Although most rabid bats appear ill,[178] an infected bat may act normally.[179,180] The rabies virus recovered from the silver-haired bat is one variant that seems to be able to replicate better in epidermal tissues.[181]

Experimental data also suggest that virus from silver-haired and possibly tricolored bats is more pathogenic for mice than other bat rabies viruses.[182] Analysis of natural transmission to other mammals supports the idea that rabies viruses associated with these two species are more infectious than viruses found in other bats.[177] The virulence of the viruses from silver-haired bats may relate to blockage of the passage of immune cells to the CNS.[183]

Bats are also important reservoirs of rabies for wild animals in the United States, as are vampire bats in South America.[184,185] Although neutralizing antibody titers are not always raised in humans against other rabies-related viruses maintained by bats,[89] there is good cross-neutralization of bat rabies virus variants by standard cell culture vaccines (CCVs).[186] Beyond the New World, bat lyssaviruses have been responsible for fatal rabies cases in humans and other animals in Africa, Australia, and Eurasia.[187–190]

NONBITE TRANSMISSION

Nonbite transmission has been reviewed by Gibbons,[191] who found at least 27 well-documented cases of transmission by means other than bites and 17 other less-well-documented cases. Of the total 44 cases, 18 were caused by improperly inactivated vaccine in Brazil, eight were from corneal transplants, eight from contamination of skin whose integrity had been impaired, four by aerosols created in laboratory or bat-infested caves, and six from human-to-human transmission. Among the alleged historical causes of human-to-human transmission were transplacental passage, lactation, kissing, intercourse, and providing healthcare. Gibbons[191] also found three reports of transmission by human bite.

Transmission to transplant recipients from organ donors is particularly worrisome. In one case, transmission occurred to four patients who received kidneys, liver, and an artery segment from a donor with undiagnosed rabies.[23] A similar scenario was reported for German transplant recipients in 2005. Additional cases were reported again recently in the United States from a donor infected with raccoon rabies virus.[24] Thus, these cases demonstrate that rabies virus is disseminated throughout the body, at least late in the disease, and that direct implantation of infected tissue may transmit rabies to humans. Deaths of suspected encephalitis should be investigated for

rabies or other etiologic agents before tissues from the donor are used.

Infection by aerosol has been suspected in unique cave habitats inhabited by millions of bats and implicated under certain laboratory conditions.[11,192] Other lyssaviruses potentially could also be transmitted by aerosol.[193] Unwitting corneal transplantation from patients who died of rabies also has resulted in transmission.[11,194] As mentioned, human-to-human transmission by bite is possible but extremely rare.[191,195,196]

HUMAN RABIES

The epidemiology of human rabies follows closely the epizootiology of animal rabies as regards exposures and case causality. The dog is the major global reservoir of rabies. In the United States alone, more than 1 million dog bites occur each year,[197] and the situation is worse in many other parts of the world.[198] Human rabies has been reported from all continents except Antarctica, but the majority of cases occur in countries where canine rabies is not well controlled. The World Health Organization (WHO) estimate for humans vaccinated due to exposure to rabies exceeds 15 million annually.[199] The WHO also estimated more than 34,000 human rabies cases during 2015, most of them in India.[199a] More recent global estimates suggest more than 70,000 human rabies cases annually.[200]

The annual incidence of rabies deaths per 100,000 population has been calculated as approximately 2 in India, 0.01 to 0.2 in Latin America, and an uncertain 0.0001 to 13 in Africa.[195,201] Human rabies is most common in people younger than 15 years of age, with approximately 40% of cases found in children 5 to 14 years of age; however, all age groups are susceptible. The majority of rabies victims are male. In one study in the United States, the highest incidence of human rabies PEP occurred among rural boys, primarily during the summer months.[202]

In the United States, bats have emerged as the leading transmitter of rabies virus to humans. Excluding transplant recipients infected by a common donor, between 1990 and 2015 bats were associated in most diagnosed human rabies cases of presumed domestic origin.[158,177] There were also other cases associated with nonindigenous canine rabies viruses during the same period.[203] No definitive contact with bats could be elicited in the majority of cases, and only a handful of patients had a documented history of a bite reported before diagnosis, suggesting that memory lapses, neural impairment, and, rarely, ignored or unperceived bites in some persons may have been responsible.[204–206] A similar situation exists in Canada, and this phenomenon should be operative in any areas in which bats serve as reservoirs.[196]

VACCINATION

Passive Immunization

Antiserum alone may not prevent rabies and is not recommended, except in combination with vaccine (see "Serum and Vaccine Prophylaxis" later). When antiserum is provided in advance of vaccine, it may interfere with active immunization.

Active Immunization

Vaccines

Typically, vaccines are administered before exposure to an infectious agent and are otherwise not very useful after exposure has occurred. Historically, rabies is an exception, in comparison to most other vaccine-preventable infectious diseases, because immunization proceeds as a critical intervention not only before but also after exposure to virus. Over the past century, a variety of substrates, such as whole animal tissues, primary cell cultures, diploid cells, and continuous cell lines, have been used widely for virus propagation. Interestingly, all these systems remain in use today for human rabies vaccine production, which is probably not the case with other human viral vaccines that remain in widespread use. The field of rabies vaccinology has progressed enormously, especially during the latter part of the last century, with regard to authentication of cell substrates and virus strains, a better understanding of the risks of using animal origin materials, design of commercially viable serum-free medium, improvement in downstream processes, knowledge of problematic impurities, and strategies to mitigate these concerns.

Prior Approaches

Table 50.4 summarizes the history of the development of rabies vaccines and lists major currently available vaccines. Many laboratory "fixed rabies virus" strains have been used for preparation of rabies vaccines. Fig. 50.2 gives the presumed history of some of these strains.

For more than 70 years after Pasteur's original work, only vaccines containing nerve tissue were available. Major modifications in nerve tissue vaccine preparation were introduced by Fermi[207] and by Semple,[208] who used phenol to partially or completely inactivate virus. Adverse reactions to rabies vaccines containing brain tissue have been recognized since the time of Pasteur. In addition to neurologic complications attributed to the presence of myelinated tissue in the vaccine, "fixed virus" may be pathogenic for humans, contrary to the "Pasteurian dogma," although it took 75 years before it was proved that some cases of paralysis after vaccination were caused by imperfectly inactivated vaccine virus. More than a century after development, adult animal neural tissue vaccines are highly discouraged but still used in some developing countries, such as Ethiopia.[209]

Myelin-free vaccines prepared from neonatal mouse brains were introduced by Fuenzalida and colleagues[210] in 1956 and are still used in parts of the world, such as in Latin America. Introduction of the duck embryo vaccine (DEV), prepared from virus propagated in embryonated duck eggs,[211] greatly reduced the number and severity of postvaccinal reactions, but DEV was less immunogenic than the brain tissue vaccine. For mouse brain and DEV vaccines, 14 to 23 daily inoculations were recommended, but even this "heroic" dosage did not always protect against rabies after severe exposure. Thus, there had long been a pressing need for a highly immunogenic antirabies vaccine that could be used safely and effectively at low doses for primary immunization and for prevention after viral exposure.

CELL CULTURE RABIES VACCINES

The solution to the problem of safety of rabies vaccines lay in the development of vaccines prepared from rabies virus grown in tissue culture free of neuronal tissue. The first attempts to develop a tissue culture vaccine were made by Kissling[212] in 1958 and by Fenje[213] in 1960. Both investigators used the primary hamster kidney (PHK) cell for rabies virus production.

All modern CCVs must contain rabies virus antigen with a potency of at least 2.5 IU per intramuscular dose. However, a metaanalysis of immunogenicity data revealed that higher concentrations of antigen did not translate into higher immune responses.[214] Historical fixed rabies virus strains for

TABLE 50.4 Important Past and Present Rabies Vaccines for Humans

Vaccine Name	Manufacturer	Type	Substrate	Remarks	Where Used
NERVE TISSUE					
Pasteur	None	Inactivated by drying	Rabbit spinal cord	Residual live virus	NLU
Fermi	None	Phenolized live virus	Sheep, goat, or rabbit brains	Contained nerve tissue, residual live virus?	NLU
Semple	Many	Phenol inactivated	Sheep, goat, or rabbit brains	Contains nerve tissue	Asia, Africa
Fuenzalida	Many	Inactivated	Suckling mouse brain	Decreased myelin	South America
AVIAN					
PDEV	Zydus Cadila	β-Propiolactone inactivated	Duck embryo	Purified by ultracentrifugation	Europe, worldwide
DEV	None	Inactivated	Duck embryo	Allergy to avian antigens	NLU
CELL CULTURE					
HDCV	Sanofi Pasteur	β-Propiolactone inactivated	Human cultured fibroblasts	Expensive, standard for rabies vaccine	United States, Europe, worldwide
RVA	Bioport (NLU)	β-Propiolactone inactivated	Fetal rhesus cell culture	Fewer allergic reactions	United States
PHKCV	Local	Formalin inactivated	Primary Syrian hamster kidney cell culture	Used historically in People's Republic of China	China, Russia

vaccine production include Pasteur, Pitman-Moore (PM), challenge virus standard, Flury low egg passage (LEP), Flury high egg passage (HEP), Kelev, and ERA/Street Alabama Dufferin (SAD).[215]

Human Diploid Cell Vaccine

In the early 1960s, workers at the Wistar Institute, Philadelphia, Pennsylvania, selected the human diploid cell strain WI-38 for virus propagation to avoid the difficulties inherent in the use of primary tissue cultures, such as induction of allergy to animal proteins.[216,217] The vaccine thus developed, the human diploid cell vaccine (HDCV), containing concentrated and purified virus, evoked much better immune responses in experimental animals and in humans than did DEV, suckling mouse brain, or adult brain tissue vaccines.[218,219] The technical advances leading to the development of the vaccine included the adaptation of the PM strain of virus to WI-38 cells,[219] the inactivation of cell-free virus by β-propiolactone, and the concentration of virus by ultrafiltration.[217]

Currently, HDCV is produced in MRC-5 human fibroblasts that are inoculated with the PM L503 3 M strain. Virus-containing supernatants are harvested and concentrated 10 to 20 times by ultrafiltration or ultracentrifugation, reaching a titer of approximately 10^7 median lethal doses per milliliter before inactivation, which is done with 1:4000 β-propiolactone. Potency is assessed by the National Institutes of Health test in mice (although new improved potency tests are under development) and is at least 2.5 IU/dose.

After 4 years of clinical studies in volunteers,[220] the vaccine was used in humans exposed to severe wounds by rabid dogs and wolves in Iran. All vaccinated people developed VNA, survived, and remained free of rabies.[221] The HDCV was first licensed in Europe for preexposure and postexposure immunization of humans in 1976 and was licensed in the United States in June 1980. Winkler[222] summarized the results of 5 years of clinical experience in the United States with no failures to prevent rabies. The vaccine is used for preexposure immunization and booster doses for maintenance of antibody and for postexposure immunization. It is estimated that more than 1.5 million people have been vaccinated with HDCV throughout the world.

In essence, HDCV is the concentrated supernatant of MRC-5 human embryo fibroblast cell cultures infected with rabies virus. Each dose of the vaccine sold in the United States contains rabies virus inactivated by β-propiolactone, 5% human albumin, phenolsulfonphthalein, and neomycin sulfate (<150 μg) as an antibiotic. The vaccine is lyophilized to a powder form and reconstituted in sterile water. The vaccine contains no preservative or stabilizer.

A HDCV was produced previously in the United States by Wyeth Laboratories, with use of N-tributylphosphate as the inactivating agent. As of 1984, all HDCV sold in the United States is manufactured by Sanofi Pasteur (Lyon, France) according to the method above. In Europe, Novartis Vaccines (formerly Chiron Behring) produced HDCV from the PM strain until 2004 before switching to Flury LEP. Neither of the two HDCVs contain human albumin or phenolsulfonphthalein (see "Allergic Reactions" later).

The Serum Institute of India also produced a β-propiolactone–inactivated rabies vaccine made in human diploid cells. The vaccine contains aluminum phosphate as an adjuvant and is presented in liquid form with thimerosal as a preservative.

Molecular epidemiology of rabies virus in France: comparison with vaccine strains.* J Gen Virol. *1992;73:1149–1158.)*

Ideal storage conditions are 2°C to 8°C, at which temperature the vaccine is stable for at least 3.5 years.[223] However, vaccine stored for 1 month at 37°C was still potent.[224,225]

Vero Cell Vaccine

There have been intense efforts worldwide to produce vaccines at lower cost that meet or improve on the levels of safety and efficacy achieved originally with HDCV. Table 50.4 lists several of these new tissue culture vaccines. All modern CCVs must have a potency of at least 2.5 IU/dose as measured by the National Institutes of Health test.

A continuous African green monkey kidney cell line, termed Vero (after an Esperanto abbreviation of "verda reno," meaning green kidney), was developed for use as a cell substrate for viral vaccines, and a purified Vero-cell culture rabies vaccine (PVRV) based on growth of virus in that cell line has been developed and licensed by Sanofi Pasteur in Europe and in many countries in the developing world.[226] For example, other countries producing a Vero-cell rabies vaccine include India (e.g., Bharat Biotech, Wockhardt, the Human Biologicals Institute) and China (e.g., Chengdu Biotechnology, Wuhan Institute, Liaoning Yisheng, Changsheng Life Sciences). An advantage of the Vero cell is that it can be grown and infected on microcarrier beads and cultivated in fermenters to produce large volumes of tissue culture fluid containing rabies virus.

The rabies virus strain in PVRV is the same as that used for HDCV production. The cells are grown in bioreactors in which titers of at least 10^7 median tissue culture infective dose ($TCID_{50}$) are obtained routinely. The harvested virus is concentrated and then purified by zonal centrifugation and ultrafiltration, followed by inactivation with β-propiolactone. The final product contains human albumin. Clinical studies have shown that the VNA responses after primary and booster injections of PVRV are equivalent to those seen after preexposure or postexposure vaccination with HDCV.[227] Postexposure protection after severe exposures has been demonstrated in Thailand[228] and China,[229] without unusual adverse reactions.

A chromatographically purified Vero-cell culture rabies vaccine (CPRV) has been developed to reduce cellular DNA and foreign protein content. This vaccine is well tolerated and highly immunogenic, although slightly less so than HDCV, as shown in Table 50.5.[230–233] CPRV was used successfully in the Philippines to protect against severe rabies exposures.[234]

Vero cell rabies vaccine has also been produced without the presence of serum in the cell culture medium.[235]

Purified Chick Embryo Cell Culture Vaccine

Purified chick embryo cell culture vaccine (PCECV), prepared by Novartis Vaccines (formerly Chiron Behring), has been evaluated together with HDCV in postexposure protection of animals and humans.[236–239] No significant differences in protection between the two vaccines were observed. To prepare PCECV, the Flury LEP-C25 strain is grown in primary chick embryo fibroblasts. The virus is inactivated by 0.025% β-propiolactone and then concentrated and purified by density gradient centrifugation. The lyophilized vaccine contains

processed gelatin as a stabilizer. The PCECV is now registered worldwide, including in the United States, and more than 80 million doses have been used. Reconstitution studies have shown that the rehydrated vaccine is stable for at least 1 week in the refrigerator.[240]

PCECV has been tested extensively in the United States, Germany, the United Kingdom, Thailand, Croatia,[241] and India.[242] During a 10-year experience with PCECV in India, the vaccine was well tolerated, with only 55 (4%) of 1375 people reporting reactions, although some urticarial reactions have been seen.[36] Immunogenicity was also good, with geometric mean concentrations of neutralizing antibodies after PEP of approximately 4 IU/mL and of less than 1 IU/mL in only 0.9% of patients. Table 50.6 shows a comparative study with HDCV.[243]

PCECV is licensed in the United States under the trade name RabAvert. Although not licensed for intradermal use in the United States, it is used by that route elsewhere (see "Schedules Using the Intradermal Route" later). A similar type of vaccine (Flury HEP strain) is produced in Japan with limited distribution.[244] PCECV vaccinees develop a positive skin test against yellow fever vaccine, probably because of chicken protein common to both vaccines, and the two should be administered with caution in egg-allergic patients.[245]

Hamster Kidney

Primary hamster kidney cell culture vaccine (PHKCV) was produced by the Institute of Poliomyelitis and Virus Encephalitides, Moscow, and by several institutes in China, including the Wuhan Institute of Biological Products. PHKCV was approved for use in China in 1980, where it completely replaced the Semple-type rabies vaccine. The Chinese vaccine contained the Beijing strain, which is inactivated by formalin. The final material contains 0.01% thimerosal, 10 mg human albumin, and aluminum hydroxide. Two types of PHKCV (adjuvant and freeze-dried concentrate) are available. The PHKCV with adjuvant is liquid and without adjuvant is freeze dried. The vaccine is supplied as a freeze-dried concentrate and is administered on a five- or six-dose schedule in China.[246] PHKCV was reportedly well tolerated and protective against proven rabies virus exposures.[247]

For development of an even less expensive rabies vaccine, a baby hamster kidney cell line (BHK-21) was considered as a vaccine substrate.[248]

Duck Embryo

The Swiss Serum and Vaccine Institute (Bern, Switzerland) introduced a purified duck embryo vaccine (PDEV) that used the PM strain. No duck protein was detectable by the immunodiffusion test. Concentration was achieved by density gradient ultracentrifugation. The virus was inactivated by β-propiolactone and thimerosal was added as a preservative. Antigenic potency and antibody responses evoked in humans were comparable to those of HDCV.[249] Mild local reactions were noted that occurred only slightly more frequently than with HDCV.

Production of PDEV was transferred to Zydus Cadila Health Care, Ltd, an Indian manufacturer.[250] This modern PDEV is registered and marketed in more than 25 countries; is highly immunogenic, safe, and well tolerated; and is similar to HDCV, PCECV, and PVRV.

Fetal Rhesus Lung

To provide an alternative to vaccine made in human cells, the Michigan Department of Health and Human Services (and later a commercial entity, Bioport) prepared a rhesus diploid cell culture vaccine. The Kissling–challenge virus standard rabies strain was adapted to DBS-FRHL-2 cell cultures (a fetal rhesus monkey lung fibroblast), inactivated with β-propiolactone, and adjuvanted with aluminum phosphate.[251,252] It was given on the same preexposure schedules as HDCV or PCECV and was considered equally safe and effective.[253] The rhesus diploid cell culture vaccine was licensed in the United States by Bioport, but is not currently available commercially.

IMMUNIZATION SCHEDULES

Table 50.7 shows the current immunization schedules and Warrell has published a review of the subject.[254,255]

Preexposure

The current recommended preexposure immunization regimen in the United States is three doses of HDCV or PCECV on days 0, 7, and 21 or 28. The dose is 1 mL administered

TABLE 50.7 Regimens for Human Preexposure and Postexposure Vaccination With Rabies Vaccines

Vaccination	Route	Days Doses Are Given	Remarks
Preexposure	IM[a]	0, 7, 21, or 28	Standard U.S. 3-dose regimen
	ID[b]	0, 7, 21, or 28	Economical, but not to be used in persons taking antimalarial medications; unlicensed route in U.S.
Postexposure[c]	IM[a]	0, 3, 7, 14	U.S. and WHO 4-dose recommendation
	IM[a]	0 (2 doses), 7, 21	Used in some countries, so-called 2-1-1 schedule
	ID[b]	0, 3, 7, 28 (2 doses each)	Used in Asia with PVRV, PCECV, so-called 2-2-2-0-2 schedule
	ID[b,d]	0 (8 doses), 7 (4 doses), 28, 90	Used in developing countries with HDCV, PCECV, or PVRV cell culture vaccines, so-called 8-0-4-0-1-1
	ID	0 (4 doses), 7 (2 doses), 28, 90	Simpler ID schedule
Booster	IM[a]	0, 3	Only after documented vaccination with cell culture vaccine[c,e]
(for preexposure)	ID[b]	0, 3	Only after documented vaccination with cell culture vaccine[c,e]

[a]Give 0.5 mL (PVRV) or 1.0 mL, depending on the vaccine, into the deltoid.
[b]Give 0.1 mL over the deltoids.
[c]Together with rabies immunoglobulin.
[d]Give 0.1 mL at multiple sites (see text).
[e]Or demonstrated presence of virus neutralizing antibodies after other vaccines.
HDCV, human diploid cell vaccine; ID, intradermal; IM, intramuscular; PCECV, primary chick embryo cell vaccine; PVRV, purified Vero-cell rabies vaccine; WHO, World Health Organization.

intramuscularly (see "Schedules Using the Intradermal Route" later). More than 60,000 people have received rabies preexposure immunization with HDCV in the United States and there have been no rabies cases in any of these persons. Recently, Khawplod and colleagues proposed a 1-day preexposure schedule, in which a single full dose of vaccine administered intramuscularly or two 0.2 mL doses administered intradermally were able to prime the immune system for a rapid anamnestic response to booster doses given 1 year later on days 0 and 3.[256]

Bat handlers in the United Kingdom received three doses of HDCV or PCECV. All seroconverted, but titers diminished with age.[257] An Australian group immunized more than 1500 travelers by the intradermal route, and only 0.46% failed to reach a level of 0.5 IU/mL.[258] On the other hand, a Japanese-made PCECV given by the same route raised only low titers of antibodies.[259]

An attempt was made to use suckling mouse brain vaccine in a preexposure schedule of 0, 2, 4, and 30 days, but the results were unsatisfactory.[260]

Postexposure

The postexposure regimen recommended in the United States and by the WHO from 1999 to 2009 was rabies immune globulin (RIG) on day 0 and a CCV on each of days 0, 3, 7, 14, and 28.[261] In Europe, a sixth dose had been previously recommended at 90 days, but this dose did not substantially raise titers beyond those obtained after five doses.[262] However, in part because of a vaccine supply limitation in the United States, during 2009 a four-dose schedule (0, 3, 7, and 14 days) was adopted after an analysis of epidemiological, clinical, and experimental effectiveness data.[263] Fig. 50.3 illustrates the immunogenicity of rabies vaccines, showing that a fifth dose does not increase titers substantially beyond those achieved by four doses. The WHO suggests a choice between a four- and five-dose schedule.[264] The dose inoculated intramuscularly is 0.5 or 1 mL depending on the manufacturer.

Exposed persons who have received prior preexposure or postexposure vaccination with a CCV or who have proven rabies VNA after other vaccines should receive an intramuscular injection on each of days 0 and 3, without RIG. Anamnestic responses are excellent.[260] Persons who have received a nerve tissue vaccine without a documented VNA response should undergo the full postexposure regimen.

Kinetics of neutralizing antibody response in humans to purified Vero-cell rabies vaccine after two regimens of primary and booster preexposure immunization given intradermally or intramuscularly. [a]Minimally adequate titers defined by the World Health Organization. [b]Minimally adequate titers defined by the U.S. Advisory Committee on Immunization Practices and Centers for Disease Control and Prevention.

Alternative Vaccine Routes

The application of rabies vaccination faces several practical problems, particularly in developing countries. These include the expense of the vaccine, the cost and the unavailability of antiserum, and the difficulty for patients to return enough times to complete the series of injections. Therefore, alternative schedules have been suggested to decrease the number of visits, and the intradermal route, rather than the intramuscular route of injection, has been used to decrease the volume of vaccine and the cost.

Schedules With Fewer Visits

An alternative schedule developed in Yugoslavia and also extensively used in France was designated 2-1-1.[265,266] It consists of two 1.0-mL injections intramuscularly on day 0 and one each on days 7 and 21. Suckling mouse brain vaccine also has been successfully used according to this schedule.[267] However, when passive immunization is simultaneously given, some reports[268–270] showed that the average antibody response and the persistence of antibody are compromised, whereas other reports[271,272] show no interference. Immunosuppression by human rabies immune globulin (HRIG) seems to be absent when HDCV is the vaccine used in the 2-1-1 schedule. However, a failure of the 2-1-1 schedule after a bite on the lip has been reported,[273] and perhaps the use of the 2-1-1 schedule is best restricted to nonbite exposures and situations where patient compliance is very poor. Given the high potency of most modern CCV today, the immunological utility of two simultaneous doses administered on day 0 may be questionable. Moreover, if supply is restricted, two vaccine doses may not be adequate for such basic consideration, as well as the limitation in available anatomic sites for combined immunoglobulin and vaccine, particularly in large-bodied persons.

Schedules Using the Intradermal Route

The expense of a full regimen of intramuscular HDCV (more than US$1000 in the United States for a five-dose regimen) led to attempts to reduce the cost by taking advantage of the intradermal route. For example, Aoki and colleagues,[274] Turner and colleagues,[275] and Nicholson and associates[276] demonstrated that rapid antibody responses could be induced by various intradermal regimens, including multisite postexposure inoculations.

Intradermal regimens have now undergone extensive evaluations and are indicated for postexposure vaccination in the circumstances of inadequate funds and the availability of staff experienced in intradermal injection technique.[277,278] The vaccines that may be used by this route include HDCV, PVRV, and PCECV. The antigenic content of the rehydrated vaccine should always be at least 0.25 IU/0.1 mL. The injection should be given with a 1.0-mL syringe and a 25- or 27-gauge needle, with the needle introduced parallel to the skin into the epidermal layer. A papule should always be produced at the site of the injection.[279]

For preexposure immunization, three doses are ideal (0, 7, and 21 or 28 days) although even one dose has been claimed to induce B-cell memory that responds to boosting.[225,256] Intradermal injection has been widely used to immunize veterinary students and others at high risk of rabies virus exposure. Antibody titers may be lower after intradermal than after intramuscular inoculation but still adequate (see Fig. 50.3). For example, an Australian study using HDCV demonstrated seroconversion in 98% of travelers.[280] Local reactions are annoying but tolerable after intradermal vaccination, and systemic reactions are virtually absent. However, in 1983, the death in Kenya from rabies of a Peace Corps volunteer who had been preimmunized with HDCV by the intradermal regimen (but not boosted after a rabid dog bite), raised questions regarding the efficacy of this route.[281] Intensive review of immunization records revealed that people vaccinated overseas, whether intramuscularly or intradermally, often had lower and shorter-lived antibody responses than expected from observations made in people immunized in the United States. One factor shown to be significantly associated with lower immunologic responses was the concurrent administration of chloroquine for antimalarial chemoprophylaxis.[227] People receiving concurrent antimalarial chemoprophylaxis or other immunogens are now recommended to receive the intramuscular and not the intradermal regimen for antirabies preexposure immunization to maximize their antibody responses, given the immunomodulatory effects that chloroquine may have upon dendritic cells.[282] The situation in some countries, such as the United States, is now complicated by the removal of the intradermal formulation from the market. Whereas multiple 0.1-mL intradermal doses can be withdrawn from vials containing an intramuscular dose, this practice is usually considered off-label use. However, postexposure intradermal immunization using vaccine from intramuscular vials is licensed in Thailand and other countries to make CCVs more readily available for rabies virus exposures.

Warrell and colleagues[283,284] developed a concept of multiple intradermal vaccinations. According to one regimen, HDCV or PCECV was given intradermally at eight different sites (deltoid, suprascapular, thigh, and abdominal wall on day 0; four 0.1-mL doses over the deltoid and thigh on day 7; and single doses over the deltoid on days 28 and 91).[285] However, antibodies were not induced any more rapidly by this regimen than by others, and concomitant antiserum is still indicated for bite and mucosal exposures.[286] Thereafter, a four-site intradermal postexposure regimen was proposed by the same authors, consisting of four inoculations of 0.1 mL on day 0, followed by two inoculations of 0.1 mL on day 7 and one inoculation on each of days 28 and 90.[287] When compared with the intramuscular, eight-site intradermal and two-site intradermal regimens, the four-site regimen proved to be equal or superior in immunogenicity (Table 50.8). Preliminary data have also been published on an accelerated four-site schedule administered on days 0, 3, and 7,[288] showing complete seroconversion.

Phanuphak and associates[289] developed another intradermal schedule that became a standard regimen used in Thailand. PVRV or PCECV was given over both deltoids in a volume of 0.1 mL on days 0, 3, and 7, followed by single injections on days 28 and 90. However, because many patients did not return for the 90-day dose, the Thai regimen was changed to give two injections on day 28, but none subsequently. Antibody titers with the new regimen were equivalent at 90 days.[290] The two intradermal regimens were compared in India, where the eight-site regimen induced higher antibody titers, particularly at 7 days.[285] Intradermal vaccination is considerably less expensive than the full intramuscular use of CCV.[170,289,291,292] Although not recommended, in practice, the vaccine is sometimes reconstituted and stored for several days under refrigeration to use the same vial for the first three injections of vaccine. So far, this specific practice has not resulted in known vaccination failures. Nevertheless, as these are single use vials intended to be used within a few hours, caution is urged to maintain the cold chain and to avoid contamination.[293]

Many clinical studies have occurred on the use of intradermal vaccination. For example, rabies virus VNA responses after intradermal vaccination with HDCV or PVRV were compared in Thailand.[291] All vaccinees in both groups were seropositive at day 14, whereas at day 90, adequate VNA levels were found in 95% of PVRV recipients and 96% of HDCV recipients. A comparison of intradermal PVRV or PCECV with intramuscular PCECV showed no important differences in antibody responses.[294] However, the intradermal regimen used by the Thai Red Cross, even with double doses, did not induce VNA faster than classical regimens, and administration of passive antibody is still necessary to provide immunity during the first week after exposure.[286] In addition, Thai workers simulated two-dose postexposure booster vaccination in subjects previously vaccinated intradermally or intramuscularly with PVRV. The subjects vaccinated and boosted intradermally all developed anamnestic responses, although these were slower and

TABLE 50.8 Current Human Rabies Postexposure Prophylaxis Schedule, United States

Vaccination Status	Intervention	Regimen[a]
Not previously vaccinated	Wound cleansing	All PEP should begin with immediate thorough cleansing of any wounds with soap and water. If available, a virucidal agent (e.g., povidone-iodine solution) should be used to irrigate the wounds.
	HRIG	Administer 20 IU/kg body weight. If anatomically feasible, the full dose should be infiltrated around and into the wound(s), and any remaining volume should be administered at an anatomical site (IM) distant from vaccine administration. Also, RIG should not be administered in the same syringe as vaccine. Because RIG might partially suppress active production of rabies virus antibody, no more than the recommended dose should be administered.
	Vaccine	HDCV or PCECV, 1.0 mL, IM (deltoid area[b]); 1 each on days 0,[c] 3, 7, and 14.[d]
Previously vaccinated[e]	Wound cleansing	All PEP should begin with immediate, thorough cleansing of all wounds with soap and water. If available, a virucidal agent such as povidone-iodine solution should be used to irrigate the wounds.
	HRIG	HRIG should not be administered.
	Vaccine	HDCV or PCECV, 1.0 mL, IM (deltoid area[b]), 1 each on days 0[c] and 3.

[a]These regimens are applicable for persons in all age groups, including children.
[b]The deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh may be used.
[c]Day 0 is the day dose 1 of vaccine is administered.
[d]For persons with immunosuppression, rabies PEP should be administered using all five doses of vaccine on days 0, 3, 7, 14, and 28.
[e]Any person with a history of preexposure vaccination with HDCV, PCECV, or RVA; prior PEP with HDCV, PCECV, or RVA; or previous vaccination with any other type of rabies vaccine and a documented history of antibody response to the prior vaccination.
HDCV, human diploid cell vaccine; HRIG, human rabies immunoglobulin; IM, intramuscular; PCECV, purified chick embryo cell vaccine; PEP, postexposure prophylaxis; RVA, rabies vaccine adsorbed.

[a]Values in parentheses are the GMT range. The GMT is given as IU/mL.
GMT, geometric mean titer of rabies virus neutralizing antibodies; n, number of patients per protocol; PCECV, primary chick embryo cell vaccine; PVRV, purified Vero-cell rabies vaccine.
From Briggs DJ, Banzhoff A, Nicolay U, et al. Antibody response of patients after postexposure rabies vaccination with small intradermal doses of purified chick embryo cell vaccine or purified Vero cell rabies vaccine. Bull World Health Organ. *2000;78:696.*

of lower magnitude than in the all-intramuscular group.[295] Conversely, a booster study done with a four-site intradermal regimen showed higher titers than after intramuscular immunization.[296] Using the Thai regimen, PVRV and PCECV were both shown to be immunogenic by the intradermal route if the intradermal dose was 0.1 mL and given on days 0, 3, 7, and 30, as shown in Table 50.9.[294,297,298]

Intradermal PCECV was also studied in Thailand[299] with and without concomitant administration of HRIG. Neutralizing antibodies peaked at a geometric mean titer (GMT) of approximately 10 IU in both groups, and there were no known failures of protection. A newer study in healthy volunteers showed that even at a dose of 0.032 antigen units, all subjects given the Thai Red Cross regimen (2-2-2-0-2) developed VNA by 14 days.[300,301] The same regimen, together with antiserum, was given to 113 patients severely exposed to rabid animals, of whom 112 developed titers higher than 0.5 IU/mL by day 14.[302] One current Thai Red Cross schedule used routinely consists of two intradermal injections of 0.1 mL given on each of days 0, 3, 7, and 28 and is referred to as the 2-2-2-0-2 schedule.[303] In India, an intradermal regimen of PCECV using two 0.1-mL doses on days 0, 3, 7, 14, and 28 resulted in all subjects having adequate levels of antibody by day 14, but titers were lower subsequently than in a parallel group given PCECV intramuscularly.[304]

In India, intradermal vaccination is practiced with WHO preapproved vaccines, enabling a reduction in cost from US$81 for the intramuscular regimen to approximately US$13 for an intradermal regimen.[305]

One microneedle device for intradermal injection has been studied. A four-dose regimen gave titers somewhat lower than by intramuscular administration, but all subjects seroconverted.[306]

In summary, intradermal regimens work as well as intramuscular regimens, except in some circumstances in which the host is likely to mount a lower antibody response from

immunosuppression. Although not now licensed in developed countries, such as the United States, intradermal vaccination is widely and successfully practiced in developing countries where cost of vaccine is comparatively high.

SERUM AND VACCINE PROPHYLAXIS

The proper postexposure prevention of rabies always includes combined vaccination and passive antibody administration in naïve patients, even when nerve tissue vaccine is used.[307] The use of antirabies serum in PEP goes back many years. During 1891, Babes and Cerchez[308] treated people severely bitten by rabid wolves with whole blood from vaccinated humans and dogs. In Iran, Baltazard and Ghodssi[309] observed an overall mortality of 25% in patients bitten by confirmed rabid wolves and treated with nerve tissue vaccine, regardless of the severity and site of the wounds. Among persons wounded in the head and face, mortality was 42%. When these results were compared with mortality rates observed in persons exposed to rabid wolves but untreated for various reasons, it seemed that the postexposure vaccination of severely exposed persons with vaccine alone conferred insignificant protection.

The efficacy of the combined use of vaccine and rabies serum to improve these results was established through collaborative studies proposed by a WHO Expert Committee on Rabies. The superior results obtained experimentally by Habel and Koprowski[310] were confirmed in a field study in Iran during 1954. Of five patients severely bitten by rabid wolves and treated with vaccine alone, three contracted rabies and died, whereas of 13 patients similarly bitten by the same wolf and treated with vaccine and serum, only one died. Thereafter, Cho and Lawson[311] performed an experiment on postexposure rabies vaccination in an animal model. When dogs were inoculated in the femoral muscle, vaccine alone was not protective because of the short incubation period in this experimental system, whereas serum alone protected approximately 50% and serum together with vaccine protected 100%. Similar results were reported by Hanlon and colleagues,[312] who used monoclonal antibodies against rabies virus as a successful alternative to RIG. Baer and Cleary[313] showed that HRIG had synergistic activity with HDCV in a mouse challenge model. Thus, these investigations demonstrated again the importance of rapid protection with antibodies and the synergy of serum with postexposure vaccination.

The intended purpose of RIG is to provide rabies VNA before an active response to the vaccine occurs. Isotyping of antibody after vaccination suggests that most IgG antibody may not appear for 14 days.[249] Evidence that the need for simultaneous RIG and HDCV is not merely theoretical is provided by reports of rabies that occurred after administration of HDCV without RIG.[314,315]

The first commercially available rabies antisera were produced in horses, but approximately 40% of adult recipients developed serum sickness.[316,317] A purified and pepsin-treated equine RIG (ERIG) was developed by the Swiss Serum Institute and Sanofi Pasteur and was widely used in Asia, but not in the United States. It was associated with only a 1% rate of serum sickness reactions,[318] after a recommended dose of 40 IU/kg.

Wilde and coworkers[318] and Tantawichien and colleagues[319] in Thailand carefully studied the use of ERIG. In their experience, the risk of anaphylaxis was only one in 35,000 people, and only 1% to 1.6% of recipients developed serum sickness. Moreover, although a skin test with 0.02 mL of a 1 : 100 dilution of ERIG is recommended before use, and the response is positive in 5% to 10% of patients, a positive test response was not predictive of serum sickness. They considered a risk of anaphylaxis to be present only if there is a wheal of 10 mm or greater in diameter or if a wheal of 5 to 10 mm is accompanied by a flare of 20 mm or more. A study of 286 Indian patients treated with ERIG showed no cases of anaphylaxis.[320] To ensure safety from contaminating equine viruses, a new heat-treated and more purified ERIG has been developed, which should give fewer reactions.[321,322] Both the older and new ERIG contain F(ab′)2 fragments rather than the whole equine globulin. The kinetics of ERIG fractions vary substantially between intact and fragmented immunoglobulin molecules, with obvious differences in experimental PEP studies of animals. Moreover, in the process of substitution of new for old, cost has increased and ERIG supplies have diminished, creating shortages in some areas.[323]

A recent review of PEP in the Philippines, in which purified ERIG was used, followed up 144 patients exposed to laboratory-confirmed rabid animals. There were two deaths due to rabies: one child with multiple deep wounds on the neck and another who did not also undergo vaccination.[324]

A HRIG was prepared originally by Bayer (formerly Cutter, Talecris, and now Grifols) and Sanofi Pasteur from the plasma of volunteers immunized with HDCV to provide an antibody preparation that would not produce serum sickness. The products sold in the United States currently are Imogam Rabies-HT (Sanofi Pasteur) and Bayrab (Grifols Biological Products). Administration of HRIG has not been associated with reactions other than occasional local pain and low-grade fever.[325] The dose is 20 IU/kg, with as much as possible of the volume instilled at the site of the bite, and the remainder, if any, given into the muscle at a distant site. The WHO recommends that HRIG be used in preference to ERIG for all severe multiple bites.[215] The recommended dose should not be exceeded, because too much passive antibody may have a dampening effect on the active antibody responses.[326] For the same reason, the dose should not be repeated. However, if the HRIG (or ERIG) was not given immediately with vaccine, it should still be given up to the seventh day after exposure, by which time an active response to vaccination should begin. After administration of HRIG, serum neutralizing antibodies can be detected within 24 hours, reach a level of about 0.1 IU at 3 days, and decay with a half-life of about 21 days.[327] In Thailand, patients started receiving vaccine up to 5 days before coming for RIG treatment, but this delay was not accompanied by suppression of the active immune response.[321]

An interesting case report describes a patient with furious rabies who became paralyzed after receiving intravenous HRIG.[77] An autoimmune mechanism involving deposition of immune complexes on axons has been suggested but not proven.

Local infiltration of antibodies is crucial because serum levels of VNA achieved after intramuscular administration alone may be low or negligible for several days.[321,322] Local infiltration provides additional VNA at the site of contamination with the infecting virus. To have a sufficient volume for infiltration in the case of multiple bites, particularly in children, the RIG may be diluted in normal saline.[328,329] Rabies developed in five children in whom local infiltration was not performed as recommended.[330]

Current recommendations of the U.S. Advisory Committee on Immunization Practices call for the local infiltration of the entire HRIG dose, if feasible. If not, the remainder should be given intramuscularly at a site distant from the vaccine injection. Where HRIG is not available, ERIG, such as in its new chromatographically purified and heat-treated form, should be used.[323]

For a discussion of antirabies monoclonal antibodies as an alternative for RIG, see "Monoclonal Antibodies" later.

RESULTS OF HISTORICAL IMMUNIZATION

Immune Responses

Nerve tissue vaccines are not optimal with regard to safety or efficacy.[331]

Extensive studies have been conducted of antibody responses to CCVs.[a] Several key findings of those studies may be generalized, as follows:

1. The most important immune response to rabies vaccines is production of relevant antibodies to the G protein of the viral envelope.[56,336] Antibody is normally measured by neutralization, such as the inhibition of fluorescent foci. However, the choice of the virus used in the neutralization test is important because the use of a virus homologous to the vaccine strain may yield approximately 30% higher titers than do heterologous viruses.[346]
2. Typically, IgM antibodies appear after approximately 4 days and IgG antibodies by 7 to 14 days after the first dose of vaccine.[347]
3. Vaccine given during the first 14 days prime the immune system, but for preexposure vaccination, at least one booster dose at 21 to 30 days or later seems necessary for high and persistent titers.
4. Three doses of CCV delivered over 21 to 28 days induce antibodies in virtually100% of healthy persons and can be used as a preexposure regimen.
5. With intramuscular vaccination, the primary regimen for postexposure use is four doses given during the first 2 weeks in healthy persons.
6. Intradermal regimens using multiple sites (two to four or more) administered on four to five occasions between days 0 and 30 also induce adequate antibody responses and use much lower volumes of vaccine, which is an economic advantage.
7. Antibody titers after vaccination with CCV are usually greater than 10 IU/mL, significantly higher than obtained in persons given nerve tissue vaccine. Antibody induction exceeding 0.5 IU/mL is nearly always achieved in healthy persons, and this level is used as a benchmark for a successful immune response after vaccination.
8. Given ideal immunization responses observed to date, it is not necessary to check rabies VNA titers after routine preexposure or postexposure immunization with CCV, unless the vaccinee is immunosuppressed (see later), has received chloroquine with intradermal vaccination, or has undergone a significant deviation from standard recommendations.[348] HIV-infected patients may respond poorly to rabies vaccines[349] and should be monitored serologically.
9. Age is a factor in response, as persons older than 50 years of age may respond less well than younger persons, but all should seroconvert.[350,351]
10. The place of cell-mediated immunity in routine prophylaxis remains uncertain. Clearly, although cellular responses of the T-helper and the human leukocyte antigen (HLA)-restricted cytotoxic T-cell types are produced, direct proof of a useful function of the latter is lacking, whereas VNA are demonstrably effective.[65,352–354]
11. Certain host response genes are important, as vaccinees of HLA groups B7 and DR2 show early and higher antibody responses, whereas those of HLA group DR3 respond later and with lower levels.[283]
12. There is apparent "molecular mimicry" of the nicotine receptor–binding motif between rabies virus G protein and HIV glycoprotein 120, which may induce antibodies to HIV in some rabies vaccinees.[355,356] False-positive tests for antibodies to HIV have been reported after rabies vaccination,[357,358] but the phenomenon seems to be quite uncommon.[359]
13. Seroconversion with VNA titers greater than 0.5 IU/mL was achieved in 33% of people receiving two doses of vaccine but in 100% of recipients of three or more doses.[360]
14. A preliminary study showed that vaccination elicited a range of cytokine and chemokine responses but failed to distinguish between intramuscular and intradermal vaccination.[361]
15. Modern CCV have been shown to protect against all known rabies viruses, but cross reactivity against other diverse lyssaviruses associated with bat reservoirs in Africa and Asia is much less than ideal.[362]

Tables 50.5 and 50.9 show the typical evolution of VNA after vaccination.[363]

Effectiveness

True efficacy trials for human rabies vaccines are difficult to undertake on the basis of both epidemiological and ethical grounds. Nevertheless, there are a variety of comparative data from various clinical trials conducted throughout the world that demonstrate the utility of vaccination. The effectiveness of Semple-type nerve tissue vaccine has been estimated to be approximately 84% in India,[364] although protection may be lower after severe exposures. For CCVs, Nicholson[365] estimated a failure rate of one in 80,000 in developed countries and between one in 12,000 and one in 30,000 in developing countries.

During the development of HDCV, comparative effectiveness studies were carried out in Iran, Germany, and the United States. In Iran, 45 people exposed in eight different incidents to eight proven rabid wolves or dogs were given six doses of HDCV after exposure. Antirabies serum also was given with the first vaccine doses. The presence of rabies virus in the brain was confirmed for all eight animals. In four animals tested, high virus titers also were found in the salivary glands. All human vaccinees developed antibodies, and none developed rabies.[221] In Germany, 63 persons bitten by rabid animals were uniformly protected. The accumulated experience in the United States was summarized in 1980, at which time 90 people exposed to rabid animals had all survived after HDCV vaccination.[366] Similar inferences can be made for PCECV, especially in the United States. Between a recall of HDCV in 2004 and its reintroduction during 2006, PCECV was the only human rabies vaccine available for routine PEP. These epidemiologic data are supported by multiple studies that demonstrate the effectiveness of PCECV in preexposure prophylaxis or PEP scenarios in developing countries.

The HDCV produced by Berna was subjected to trial in 100 Thai patients exposed to proven rabid animals. All patients were protected by the standard five-dose regimen, although the GMT of rabies VNA at 90 days after the first vaccination was relatively low, at 2.57 IU.[367]

Understandably, there have been no placebo-controlled studies of the efficacy of human rabies vaccines. The CCVs, including PVRV, PCECV, PDEV, and PHKCV, have been accepted based on the induction of VNA and lack of failures after postexposure vaccination.[a]

[a]References 36, 180, 193–196, 199, 202, 204, 206, 209, 210, 212, 213, 228, 236–239, 242, 244, 246, 251, 252, 332, 333

An analysis of rabies postexposure vaccination in the United States showed an average of more than 23,000 courses given per year, and although the decision to vaccinate was often made without consulting public health subject matter experts in rabies, no failures were seen.[368] A review of 20 years of use of PVRV revealed only one failure after a standard regimen, occurring in a child with multiple bites on the face.[369] Postmarketing surveillance of an Indian-made HDCV also showed broad protection.[370]

In addition, the efficacy of rabies vaccination has been well supported using a variety of animal species as human surrogates. For example, protection studies in mice showed that VNA induced by the G protein contained in HDCV neutralized 17 different street rabies viruses.[355]

PERSISTENCE OF IMMUNITY AND BOOSTER DOSES

Rabies VNA do not always remain at elevated levels for long periods after vaccination with the usual preexposure schedules. By 1 year, VNA may fall to geometric mean levels between 1 and 3.5 IU,[217,371,372] and by 2 years may fall below the minimum acceptable level of 0.5 IU in approximately 15% to 20% of subjects.[373] However, B-cell memory is prolonged,[139] and Thraenhart and colleagues[374] reported the presence of VNA in the serum of 18 people vaccinated 2 to 14 years earlier. Antibodies reacting with many virus proteins were still present, in addition to lymphocyte proliferation responses to the same proteins. A survey of travelers to Nepal vaccinated against rabies during the preceding 5 years showed antibodies in 37 of 38 people.[375]

Booster doses of vaccine are efficient in restoring VNA, with 100% of subjects showing a fivefold rise by day 7.[371] Apparently, two booster doses may enhance the speed of the booster response.[376] Therefore, previously immunized persons who are again exposed to rabies should receive two booster doses 3 days apart, without RIG. Boosters can be given intramuscularly or intradermally, although no preparation approved for intradermal use is available in the United States. Studies[240,377–379] have compared four-site intradermal inoculations with the standard two-dose intramuscular inoculations in previously vaccinated volunteers undergoing simulated reexposure to rabies and found that the intradermal group had better booster responses. Vietnamese children vaccinated 5 years earlier were easily boosted.[380] When maintenance of VNA is desired after preexposure vaccination, as in laboratory workers, a booster may be given at 1 year after primary vaccination, which invariably produces an anamnestic response (see further discussion in "Indications for Vaccination" later). However, because of allergic reactions to the HDCV used in the United States (see "Reactions to Cell Culture Vaccines" later), routine boosters are not recommended but rather serological surveillance should be performed to monitor VNA levels. Laboratory workers who have continuous exposure to rabies virus should have antibody levels checked every 6 months and should receive a single booster immunization if the titer falls below complete virus neutralization at a serum dilution of 1:5 (or approximately 0.1 IU/mL).

VACCINATION OF IMMUNOSUPPRESSED PERSONS

Briggs and Schwenke[381] compared the persistence of antibodies in civilians and in Peace Corps volunteers who receive chloroquine for prophylaxis of malaria. At 1.5 to 2 years after primary vaccination, adequate titers were found in 99% of civilians and 88% of Peace Corps volunteers who received the vaccine intramuscularly and in 93% of civilians and 64% of Peace Corps volunteers who received the vaccine intradermally, suggesting that chloroquine was immunosuppressive.

Numerous studies on HIV-infected patients have shown that, although rabies vaccination is safe and generally effective,[382,383] persons with $CD4^+$ cell counts less than $300/mm^3$ or 15% of lymphocytes are less likely to respond with VNA.[349,382,384–386] Patients receiving immunosuppressive drugs and persons with diabetes also should be monitored for proper VNA responses.[387,388] In contrast, pregnant women respond normally to rabies vaccine, and there is no suggestion of fetal risk.[389,390]

Malnourished children respond to PCECV rabies vaccine with satisfactory antibody titers.[391]

A study of intradermal rabies vaccination in patients undergoing hemodialysis showed adequate immune responses,[392] as did intramuscular vaccination in pediatric solid-organ transplant recipients.[393]

Replication-defective *Vaccinia* viruses carrying rabies G and N genes have been shown to protect B-cell–deficient mice, and future development of such biologics might be of value in B-cell–deficient persons exposed to rabies.[394]

PROTECTION AGAINST LYSSAVIRUSES OTHER THAN GENOTYPE I

The ability of vaccines formulated with classical rabies virus to protect against other rhabdoviruses in the *Lyssavirus* genus remains questionable. However, it seems that some antibodies are cross-neutralizing and that cross-protection is good in animals challenged with some species, such as the European bat and Australian lyssaviruses by parenteral routes, although not after intracerebral inoculation.[395] This is particularly comforting for prevention of rabies caused by European bat lyssaviruses, although titers may be more variable.[396] However, the results for more distant Asian and African lyssaviruses depend on relative genetic distance, with lower protection for the most distantly related lyssaviruses.[312]

CORRELATES OF IMMUNOPROTECTION

Preexposure vaccination with potent rabies CCV leads to the development of antibodies. Vaccination also induces production of T cells, which protect vaccinated mice in the absence of neutralizing antibodies. A high level of cell-mediated cytotoxic activity can be maintained by repeated inoculations of vaccine, and the presence of antibodies does not interfere with the secondary stimulation of sensitized lymphocytes.

Although the exact mechanism of protection of humans through postexposure vaccination is unknown, neutralizing antibodies have a major role.[397] The fact that only monoclonal antibodies that interact with macrophages are effective in protection of mice against disease may indicate that a complex mechanism is involved in antibody protection after challenge.

Concentrated and inactivated rabies vaccine of tissue culture origin is able to induce high levels of circulating interferon a few hours after its administration and can protect animals from rabies infection if it is given shortly before or after challenge with virus. This interferon-induced protection, however, is not specific because similar protection can be obtained with concentrated vaccines produced from unrelated viruses, such as influenza and Kern Canyon. However, only rabies vaccine can protect when it is given several days before challenge with rabies virus. The combined treatment with interferon or interferon inducers in addition to rabies vaccine is more efficacious than vaccine alone in experimental animals, when treatment is initiated several hours after challenge.[398]

Considering the critical usefulness of antibodies, the additional role of interferon and other cytokines in human prophylaxis is likely important, but less defined.

In reality, when humans are bitten by a rabid animal, the viral dose, route, and severity cannot be controlled in nature. As such, there is no distinct seroprotective antibody level defined for humans or other animals as an absolute predictor of outcome. The WHO international standard of 0.5 IU/mL is merely one arbitrary level chosen as a representative value that defines a given amount of VNA that can be measured in a serum neutralization test by reference laboratories. However, no vaccine is 100% efficacious, and no set level of VNA is acceptable as a facsimile of direct outcome. In practice, after viral exposure, previously vaccinated persons should receive immediate wound care and booster doses of vaccine to induce a rapid anamnestic response—and not rely on routine laboratory antibody testing, or a predetermined titer, to decide upon a course of immunization by medical providers. Similarly, in experimental testing of vaccine efficacy, animals having no detectable VNA may be protected against viral challenge, and animals with a titer even greater than 0.5 IU/mL can develop rabies. Clearly, the immune response during rabies prophylaxis after viral infection is complex, and VNA are obviously important, but understanding the basis for this repertoire should lead to knowledgeable intervention and the more strategic development of improved future biologics.[399]

VACCINATION FAILURES

Most human cases of rabies occur because no prophylaxis was given. Clearly, modern rabies postexposure vaccination is highly effective, but failures can occur when recommendations are not followed. As rabies in the biting animal is frequently untested and thus unknown, it is impossible to give a figure for the true rate of failure, but it is probably less than 1%. Most failures involve inadequate PEP, such as delays between exposure and initiation of care, and no administration of RIG, and often involve severe exposures, such as multiple bites on the head and neck.

For example, Thraenhart and colleagues[332] reviewed 28 cases of rabies that developed despite PEP with modern vaccines. In 90% of cases, RIG had not been administered or had been administered incorrectly. Other errors included passive immunization more than 24 hours before vaccine administration (which may have interfered with the active induction of immunity), incorrect local wound cleansing, injection of vaccine into the buttocks instead of the deltoid muscles, and late initiation of immunization. Only two patients, both of whom had severe facial injuries, were considered to be true prophylaxis failures. Wilde[400] described 15 cases of apparent vaccine failure in detail, and others have been described by Shantavasinkul and colleagues[401] and Hemachudha and colleagues.[402]

An early death phenomenon has been described in animals exposed to rabies and then vaccinated. In other words, some animals that are vaccinated but nevertheless develop rabies die sooner than challenged unvaccinated animals. It is unclear whether this phenomenon is mediated by antibodies, cytotoxic T cells, or a combination of the two. Willoughby[38] reviewed this subject and concluded that early death has not been convincingly demonstrated in humans, although there was a hint of it in patients bitten by rabid bats.

A follow-up study of effectiveness after 15 million doses of PCECV reported 47 suspected failures. All occurred in India and Thailand, and in no case were WHO guidelines followed completely.[403] Other failures also may relate to deviations from standard prophylaxis.[273,404,405] However, a bite on the face with a large inoculum of rabies virus may overwhelm PEP, especially if delays or perceived deviations from protocol occur.[362]

ADVERSE REACTIONS

Historically, it is not uncommon to encounter adverse reactions after human or veterinary vaccination. Today, products have improved greatly regarding safety, but there is no vaccine known that is completely free from all adverse events. However, vaccines differ specifically from each other in terms of the incidence and degree of adverse reactions. Moreover, although several adverse reactions are common to all vaccines, there also are some vaccine-specific adverse reactions. Vaccine components that may elicit an allergic response include active immunizing antigens, conjugating agents, preservatives, stabilizers, antimicrobial agents, adjuvants, and culture media used in the preparation of vaccines.[406] Components often implicated in vaccine allergies include egg and gelatin proteins. In general, vaccines contain both active and inactive ingredients that can cause adverse reactions, including anaphylaxis and allergy. Such ingredients include foreign proteins (e.g., albumin) used during manufacture, viral inactivants (e.g., β-propiolactone), preservatives (e.g., thimerosal), stabilizers (e.g., serum), adjuvants (e.g., alum), antibiotics (e.g., neomycin), and the antigen itself, especially when insufficiently purified.

Reactions to Rabies Vaccines Containing Animal Brain Tissues

There are several types of reactions to rabies vaccines containing animal brain tissue. These reactions include general systemic, local, and severe and fatal reactions.[219]

General Systemic Reactions

The various minor disorders that may develop during or after a course of antirabies vaccination include fever, headache, insomnia, palpitations, and diarrhea. Sensitization to proteins contained in older nerve tissue vaccines can cause a sudden shock-like collapse, usually toward the end of the course of treatment.

Local Reactions

Erythematous patches may develop approximately 7 to 10 days after the beginning of antirabies vaccination. Local erythema and swelling might also appear a few hours after vaccine injection and fade in 6 to 8 hours.

Severe and Fatal Reactions

A patient may have serious and often fatal illness after nerve tissue vaccine. These accidents are of two types: (a) *rage de laboratoire* (laboratory rabies infection), a disease induced by the non-inactivated fixed virus present in the vaccine, and (b) neuroparalytic accidents, which present the greatest prevalence of danger from rabies vaccination. All types of vaccine containing adult mammalian nervous tissues exhibit similar capacities for inducing neuroparalytic reactions. The neuroparalytic accident usually develops between the 13th and 15th days of vaccination and may assume one of the following forms:

- *Landry type*—In this type of accident, the patient rapidly develops fever and has pain in the back. Flaccid paralysis of the legs begins, and within 1 day the arms become

paralyzed. Later the paralysis spreads to the face, tongue, and other muscles. The fatality rate is approximately 30%; in the remaining 70%, recovery usually occurs rapidly. The incidence varies between one in 7000 and one in 42,000 recipients.[407]

- *Dorsolumbar type*—Less severe than the Landry type, this is the most common form of neuroparalytic accident. Clinical features are explicable by the presence of dorsolumbar myelitis. The patient may be febrile and feel weak, with paralysis of the lower limbs, diminished sensation, and sphincter disturbances. Typically, the fatality rate does not exceed 5%.
- *Neuritic type*—In this type of accident, the patient may be febrile and usually shows a temporary paralysis of the facial, oculomotor, glossopharyngeal, or vagus nerve.
- Optic neuritis has also been reported.[408]

Neuroparalytic accidents are caused by allergic "encephalomyelitis," attributable specifically to sensitization to adult nerve tissue antigen (i.e., myelin basic protein).[409] High-titered antibodies to human myelin proteins and to gangliosides often are detected in patients who are affected.[410] The incidence of these reactions to nerve tissue vaccine varies widely from 0.017% (1:6000) to 0.44% (1:230) and is definitely lower in people who received DEV (1:32,000) and in people receiving properly manufactured vaccine of newborn rodent brain (1:8000).

One study observed 1392 Tunisian adults who were given a Semple-type vaccine prepared by phenol inactivation of rabies virus–infected lamb brains.[411] In seven patients, neurologic complications developed, including paralysis or paresis in five. Most of the patients had elevated cell counts in their CSF. A rate of one neurologic complication in 200 vaccinations is unacceptable and illustrates the desirability of replacing nerve tissue vaccines with CCVs. Progress is ongoing, as demonstrated by the major progress in India, which switched to CCVs.

Reactions to Cell Culture Vaccines

General Reactions

The CCVs are widely accepted as well-tolerated rabies vaccines, although reported reaction rates to primary immunization have varied with the monitoring system. In large-scale testing of the safety and immunogenicity of HDCV performed on American veterinary students, adverse reaction rates observed in more than 1770 volunteers were as follows: significantly sore arm, 15% to 25%; headache, 5% to 8%; malaise, nausea, or both, 2% to 5%; and allergic edema, 0.1%.[217] In another study of postexposure vaccination, 21.0% had local reactions, 3.6% had fever, 7.0% had headache, and 5.0% had nausea.[412] The most common local reactions are erythema, pain, and induration. These results have been confirmed by newer studies.[230] When HDCV is administered to children, in whom psychological overlay is presumably less than in adults, there are fewer complaints.

An observational study of 290 healthcare workers given PCECV showed 53% had systemic reactions, including fatigue, malaise, headache, chills, and fever, and 5% of subjects discontinued vaccination. However, there was no control group.[413] Data concerning the same vaccine were collected by the VAERS (Vaccine Adverse Event Reporting System) passive reporting system. Headache was the most prominent symptom reported. Neurologic events did not seem to be related to the vaccine, and other reported reactions were usually nonserious or temporary.[414,415] A study comparing PDEV with PVRV and PCECV showed no differences in reactions.[416] PCECV was safely coadministered to Thai children along with Japanese encephalitis vaccine.[417]

Allergic Reactions

After licensure of HDCV in the United States and its widespread use, allergic reactions began to be reported, principally after booster doses.[418,419] The overall incidence of reactions was 11 in 10,000 (0.11%) vaccinees, but, after boosters, the incidence rose to 6%.[420] Anaphylactic type 1 (IgE) reactions occurred in approximately 10% of the reported cases, all during the primary series (one in 10,000 vaccinations), but the majority seemed to be type 3 hypersensitivity (IgG–IgM) reactions occurring 2 to 21 days after booster doses (Table 50.10). These reactions have been attributed to antigenicity conferred on human albumin used as stabilizer in the vaccine by the β-propiolactone used to inactivate the virus, which increases the capacity of the albumin to form immune complexes.[421–423] Fortunately, respiratory symptoms are mild, and there have been no deaths. Antihistamines, epinephrine, and, occasionally, steroids have been used in successful treatment of the reactions, which resolved in 2 to 3 days.

Newer vaccines are produced by use of additional purification steps to remove human albumin. Systemic reactions to booster doses are uncommon with these vaccines and allergies appear comparatively rare.[406,424,425]

Twenty cases of possible anaphylaxis after PCECV were reported to VAERS.[414]

Neurologic Reactions

Although several cases of CNS disease, including transient neuroparalytic illness of the Guillain-Barré type, have been reported among the millions of persons given HDCV,[426–431] this rate is considered too low to be causally related to vaccination because the background incidence of such diseases is approximately one in 100,000 per year. The low incidence after HDCV compares with a neurologic complication rate of one in 1600 people for nerve tissue vaccine, one in 8000 people for suckling mouse brain vaccine, and one in 32,000 people for DEV. A review of Guillain-Barré syndrome after vaccination described several cases after rabies vaccination, but at rates consistent with coincidence.[432]

In Thailand, a switch from Semple-type vaccine to HDCV resulted in a drop in the rate of neurologic complications from one in 155 to less than one in 50,000 treatments. At the same time, the failure rate dropped from one in 2000 to one in 25,000 treatments without the use of RIG.[433] If reactions occur after one CCV, a switch can be made to another produced in a different cell substrate without major concerns.

A case of bilateral neuroretinitis has been reported after PCECV.[434]

INDICATIONS FOR VACCINATION

Preexposure Vaccination

All high-risk professionals, such as veterinarians, hunters, trappers, animal control personnel, mail carriers, cavers, and laboratory workers contemplating working with rabies virus, should be prophylactically immunized against rabies. Table 50.7 gives the recommended regimens. After receiving a three-dose preexposure regimen, persons who are continuously exposed to high concentrations of rabies virus in the laboratory should have VNA levels checked every 6 months and should be given a booster dose intramuscularly or intradermally if the titer is less than adequate (complete virus neutralization at a serum dilution of 1:5 [~0.1 IU/mL], or 0.5 IU). Veterinarians and others exposed regularly to rabid animals or rabies virus should be similarly checked every 2 years.

Peace Corps workers, missionaries, or others who remain for long periods in rabies-enzootic countries certainly deserve consideration for preexposure vaccination.[435] A survey of travelers revealed that, after an average of 17 days in Thailand, 1.3% and 8.9% had been bitten or licked by a dog, respectively, and 0.5% had required rabies vaccination.[436] Moreover, postexposure vaccination in developing countries is often complicated by problems of availability of potent vaccine and RIG.[437] However, a decision analysis concluded that routine preexposure vaccination would cost US$275,000 per case averted and that it should be individualized according to the traveler's situation.[438] One recommendation would be to vaccinate the travelers who will be staying in remote areas of hyperendemic dog rabies for more than a few days, particularly children. Travelers should be warned about the dangers of rabies and other zoonotic diseases and educated about animal bite prevention strategies.[439]

In countries where rabies is endemic and children are frequently exposed to rabid animals (such as residents in Amazonia because of nightly feeding of blood meals by vampire bats), one might contemplate prophylactic vaccination against rabies as part of future pediatric immunization. Dog bites are a considerable problem in many areas of the world and accounted for more than 5% of visits to the emergency department of a Bangkok hospital, of which 55% were by children.[440] So far, prophylaxis has been restricted primarily to the children of Westerners going to live in areas enzootic for rabies,[441] but clinical trials in children have been performed in developing countries.[442] A preliminary study was done with the PVRV vaccine in Thailand, where two doses were given intramuscularly in association with routine pediatric immunizations at 2 and 4 months of age.[443] Seroconversion to rabies occurred in 100% of infants, without significant interference with the other vaccines. A similar study was done in Vietnam with three doses of intradermal rabies vaccine at 2, 3, and 4 months of age, with an adequate immune response (GMT, 12 IU/mL).[444] An economic analysis concluded that preexposure vaccination becomes cost-effective when the local suspect dog-bite incidence is between 2% and 30%.[445]

Preexposure Booster Vaccination

After preexposure vaccination, antibodies may decline sharply within the first year of vaccination. If a booster dose is given 1 year later, subjects segregate into two groups: "ideal" responders, who develop a titer greater than 30 IU by 14 days after booster, and "poor" responders, whose titers are much lower. The former, who represent 75% of subjects, may not need further booster vaccination for 10 years or more, whereas the latter may require more frequent boosters as long as they remain at risk.[137] This strategy may reduce costs.[446,447]

Primary vaccination by the intradermal route may provide less-sustained immunity, but the intradermal route is an effective means of administering a routine booster.[225]

Postexposure Prophylaxis

Guidelines and schedules for PEP are given in Tables 50.11 through 50.13.

The essential triad of PEP is local wound care, vaccination, and antiserum administration. Local first aid of bites and

TABLE 50.11 Current Human Rabies Postexposure Prophylaxis Guide for the United States

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10 days of observation Rabid or suspected rabid Unknown (e.g., escaped)	Persons should not begin prophylaxis unless animal develops clinical signs of rabies[a] Immediately vaccinate Consult public health officials
Skunks, raccoons, foxes, and most other carnivores; bats	Regarded as rabid unless animal proven negative by laboratory tests[b]	Consider immediate vaccination
Livestock, small rodents, lagomorphs (rabbits and hares)	Consider individually	Consult public health officials
Bites of squirrels, hamsters, guinea pigs, gerbils, large rodents (woodchucks and chipmunks, rats, mice and other small rodents, rabbits, and hares, almost never beavers), and other mammals		Require antirabies postexposure prophylaxis

[a]During the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be humanely killed immediately and tested.

[b]The animal should be humanely killed and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.

From Rupprecht CE, Briggs D, Brown CM, et al. Centers for Disease Control and Prevention (CDC). Use of a reduced (4-dose) vaccine schedule for postexposure prophylaxis to prevent human rabies: recommendations of the advisory committee on immunization practices. MMWR Recomm Rep. *2010;59(RR-2):1–9.*

scratches consists of vigorous washing with soap and water, ideally for at least 15 minutes. Surgical suturing should be avoided for approximately 7 days, if possible, but in any case, RIG (see later) should always be administered before suturing.[448] Antibiotics and tetanus toxoid may be indicated to prevent other infections.[449]

A decision to give PEP should be based on a risk assessment, in part on consideration of the following points[450,451]:

1. Was the patient's skin broken by a bite or scratch, or were mucous membranes contaminated? If not, no true exposure has occurred. Seeing or touching a rabid animal is not an exposure. The risk of rabies after a bite by a rabid animal has been estimated at 5% to 80%, whereas the risk after scratches is much less (0.1% to 1%). The risk after mucous membrane contact is extremely low.[443]
2. If the bite was by a dog or cat, is domestic animal rabies found in the particular geographic area? Many areas of the world, such as Oceania, Antarctica, and the United Kingdom, are free of rabies in carnivores. In many cities of the United States, even stray animals are unlikely to be rabid.
3. Was the dog or cat vaccinated against rabies? Vaccination diminishes the risk, but not completely. Proper vaccination of pets should not be accepted at face value. Documentation should be required to show at least two vaccinations with a potent vaccine, as one dose of inactivated vaccine is insufficient to always warrant efficacy, especially if administered in within the last 30 days.[448,452]
4. Is the biting animal a healthy domestic dog or cat and available for observation? If yes, PEP may be postponed. However, in rabies-enzootic areas, vaccination is advisable, even if the domestic animal appears normal, because of short incubation periods in humans and the frequent difficulty in being certain of the identity of the biting animal.[453]
5. If the bite was inflicted by a wild animal, was it a species likely (e.g., skunk or raccoon) or unlikely (e.g., squirrel or rat) to be rabid? Local conditions must be taken into account. For example, in the United States, rabies has been reported occasionally in larger bodied rodents, such as woodchucks or beavers, a very unlikely finding elsewhere. Rapid diagnostics, performed within 24 to 48 hours of exposure, will assist in PEP decisions.
6. Was the bite provoked or unprovoked? This criterion is useful only in areas of low incidence and not where the incidence of rabies in dogs is elevated.[448] In Thailand, even when the animal's behavior appeared normal, an assessment of provocation did not correlate with the presence of rabies at necropsy of the animal.[454] Attempts to play with wild animals should be considered provocative.
7. Was there exposure to a rabid human? Under these circumstances, use the same criteria for vaccination as with a biting animal. Only persons who were bitten or scratched, who had mucosal exposure, such as with mouth-to-mouth resuscitation, or who were otherwise exposed to infectious saliva or nerve tissues need to be vaccinated.[452]
8. Should RIG be administered? In naïve, previously unvaccinated persons, RIG should always be given in combination with vaccine for transdermal or mucous membrane exposure (see "Serum and Vaccine Prophylaxis" earlier). The dose of HRIG is 20 IU/kg and that of ERIG, 40 IU/kg. As much as possible of the RIG should be inoculated locally, diluted if necessary in saline to provide sufficient volume. If necessary, local anesthesia can be provided with procaine-type compounds.[455] The remainder of the RIG, if any, should be given in the deltoid or other muscles.

TABLE 50.13 World Health Organization Recommendations for Human Rabies Prophylaxis

Category	Type of Contact With a Suspected or Confirmed Rabid Domestic or Wild[a] Animal or an Animal Unavailable for Testing	Type of Exposure	Recommended Prophylaxis
I	Touching or feeding of animals; licks on intact skin	None	None, if reliable case history is available
II	Nibbling of uncovered skin; minor scratches or abrasions without bleeding		Administer vaccine immediately.[b] Stop vaccination if animal remains healthy throughout an observation period of 10 days[c] or if animal is proven to be negative for rabies by a reliable laboratory using appropriate diagnostic techniques.
III	Single or multiple transdermal bites or scratches, licks on broken skin; contamination of mucous membrane with saliva (i.e., licks); exposure to bats[d]	Severe	Administer rabies immunoglobulin and vaccine immediately. Stop vaccination if animal remains healthy throughout an observation period of 10 days or if animal is found to be negative for rabies by reliable laboratory using appropriate diagnostic techniques.

[a]Exposure to rodents, rabbits, and hares seldom, if ever, requires specific antirabies postexposure prophylaxis.
[b]If an apparently healthy dog or cat in or from a low-risk area is placed under observation, the situation may warrant delaying initiation of vaccination.
[c]This observation period applies only to dogs and cats. Except in the case of threatened or endangered species, other domestic and wild animals suspected as rabid should be euthanized and their tissues examined for the presence of rabies antigen using appropriate laboratory techniques.
[d]Postexposure prophylaxis should be considered when contact between a human and a bat has occurred unless the exposed person can rule out a bite or scratch or exposure to a mucous membrane.
From World Health Organization Expert Consultation on Rabies. Second Report. 2013. WHO Technical Report Series. *Geneva, Switzerland: World Health Organization; 2013:1–139.*

9. Is patient age important? The vaccine dose is the same regardless of age. Children tolerate vaccination well and demonstrate excellent antibody response, as demonstrated in different ethnic groups.[344,456–458]
10. What about bats? Rabies PEP is recommended for all people with bite, scratch, or mucous membrane exposure to a bat, unless the bat is available for diagnostic testing and is negative for evidence of rabies virus infection. If a report on the presence of rabies by laboratory diagnosis is not available rapidly, such as within approximately 3 days, PEP should be started if an exposure cannot be excluded reasonably after thorough investigation. The inability of care providers to elicit information surrounding potential exposures may be influenced by the sometimes tiny injury inflicted by a bat bite (in comparison with lesions inflicted by larger carnivores) or by circumstances that hinder accurate recall of events. Consequently, PEP is also appropriate even in the absence of a demonstrable bite or scratch when there is reasonable probability that such contact occurred under certain circumstances (e.g., a sleeping person awakens to find a bat in the room, an adult witnesses a bat in the room with a previously unattended child, a mentally deficient person, or an intoxicated person). Fortunately, tests for VNA obtained from humans after vaccination with HDCV or PCECV show ideal neutralization of rabies viruses associated with bats.[459]

Unnecessary PEP can be avoided if circumstances are found that make the chances of rabies virus exposure remote. When exposures occur to animals in which rabies is not suspected, large numbers of people often receive vaccine.[460] A survey of practice in 11 university-associated urban emergency departments revealed that rabies prophylaxis was administered inappropriately in approximately 40% of cases.[461] Exposure to bats in the absence of known bites is a complicated situation, and consultation with experienced public health providers is warranted. Tables 50.11 through 50.13 should be consulted as a guide for the selection of PEP in the United States and elsewhere in the world.[452,462] Table 50.7 describes both preexposure and PEP regimens.

Postexposure Prophylaxis Booster Vaccination

If a person has been vaccinated with a CCV and is later reexposed to rabies virus, two booster injections of a vaccine are recommended, because one dose may not be sufficient.[463] Persons who received vaccine intradermally for their primary series may be particularly at risk for a slower response to booster.[464] Another suggestion from Thailand is to give four simultaneous intradermal vaccinations as a single booster.[465] However, subjects who previously received CCV uniformly have long-lasting immunologic memory,[466] and there is no evidence that more than two boosters are necessary. Persons who gave a history of vaccination with nerve tissue vaccines responded poorly to boosters in 18% of cases[467] and should, therefore, receive a full primary regimen unless antibodies were previously shown to be present.

CONTRAINDICATIONS TO VACCINATION

In reality, when the disease is present, all individuals appear vulnerable for exposure to, for example, lyssaviruses, irrespective of age, nutritional status, immune competence, physiological status, when they visit or live in rabies endemic regions. However, not everyone is equal in response to active immunity, because vaccination necessitates immunocompetent subjects with a mature immune system. In contrast, this is not the case to conferring passive immunity, which involves transfer of preformed antibodies, which can mediate the desired pharmacological action independent of the recipient's immune system.

Obviously, there are no true contraindications to rabies vaccination, when viral exposure is documented. Because rabies is a highly lethal zoonosis, any theoretical contraindication should be considered very carefully before disqualifying a person for PEP.

Persons with histories of severe allergies are more prone to having allergic reactions to rabies vaccine. When persons with such allergies are vaccinated, prophylactic antihistamines should be given and epinephrine should be available. If an allergic reaction occurs, one may give an alternative vaccine of different tissue origin (e.g., PVRV or PCECV in the case of a reaction to HDCV). A similar strategy was applied in allergic persons in whom brain tissue vaccine caused symptoms of CNS involvement during the course of injections. Administration of nerve tissue vaccine was interrupted immediately, and the series was completed with vaccine produced in tissue other than brain.

Only severe reactions not controlled with premedication may be grounds for interruption of rabies vaccination. Treatment with steroids may control allergic reactions but may also inhibit VNA responses. Accordingly, VNA titers should be determined after the last dose if steroids have been used. Similarly, patients receiving immunosuppressive medications for other diseases should have VNA levels checked after immunization to verify an adequate response to the vaccine.[462] If titers are inadequate, a booster dose should be administered.

Pregnancy is not a contraindication to rabies vaccination.[468,469] For example, follow-up of 202 Thai women vaccinated during pregnancy revealed no excess of medical complications or abnormal births.[470] Under no circumstances should a pregnancy be terminated because of a theoretical concern of transplacental transmission of rabies virus. Vaccination of the newborn is probably unnecessary, but has been carried out successfully.[471]

PUBLIC HEALTH CONSIDERATIONS

Rabies Vaccination of Animals

From the beginning of his involvement with rabies, Pasteur recognized that indirect protection of humans could be achieved effectively through the vaccination of dogs. Although dogs were used to obtain most of the experimental data on protection from 1884 to 1885, it was not until the early 1920s that a practical and successful canine vaccine was developed.

The first use of mass vaccination of dogs was a modified Semple type prepared by Umeno and Doi[472] in Tokyo in 1921. It proved effective in controlling rabies in dogs in Japan and in other countries that produced and used this type of vaccine. The quality of vaccine improved greatly with the introduction by Habel[412] of a standard mouse potency test for the Semple-type vaccine, which ensured the potency of the vaccines in mass vaccination programs.

In 1945, Johnson[473] demonstrated that a single dose of a potent, phenol-inactivated vaccine protected dogs against a challenge with street rabies virus for a period of more than 1 year. From 1945 on, this was virtually the only type of vaccine used for control of rabies in dogs, cats, and other domestic animals.

A modified live virus vaccine was introduced by Koprowski[474] in 1948. Successive passages of a strain of virus of human origin, first in 1-day-old chicks and later in embryonated hens' eggs, resulted in the loss of pathogenicity for dogs, providing an attenuated virus strain safe for dogs, called Flury LEP. Further passages of Flury LEP virus in embryonated hens' eggs

resulted in a vaccine that was no longer virulent for adult laboratory animals yet was still lethal for newborn mice, called Flury HEP. Both Flury LEP and Flury HEP were given to many types of domestic animals in different parts of the world. However, the live attenuated Flury virus vaccine was discontinued in the late 1970s in the United States.

Another attenuated strain of rabies virus, ERA, was introduced by Canadian workers in 1964.[475] The ERA vaccine was shown to provide excellent immunity, lasting for at least 3 years. However, several vaccine-induced cases of rabies in cats and other animals resulted in the cessation of its routine use.

Inactivated rabies vaccines for animals prepared from brains of newborn mice or from virus of cell culture origin were introduced in the 1980s and are now in general use in Europe and the Americas. However, only cell culture inactivated virus vaccines and live recombinant vaccines are licensed for domestic animals in the United States.

Elimination of human rabies by control of canine rabies through vaccination, population management, and education about responsible pet ownership has been a successful strategy increasingly in developing countries, as demonstrated in Latin America and in parts of Asia, such as in Thailand.[476,477] In areas where canine rabies has been eliminated and the dog can be observed for 10 days by qualified persons, immediate vaccination may not be necessary and should be started only if the animal develops signs of rabies.

Oral vaccination of wildlife to prevent the spread of rabies in terrestrial animals such as foxes, raccoons, coyotes, and raccoon dogs has become possible. The SAD B19 attenuated strain has been placed into baits for the vaccination of foxes.[431,478] The virus is grown on a baby hamster kidney cell line and is stable even at high environmental temperatures. A dose of approximately 10^6 infectious units immunizes approximately 99% of foxes, which has allowed its wide application in Germany and elsewhere in Europe.[479,480] However, because the SAD B19 strain retains residual pathogenicity for rodents, a more attenuated strain, called SAG2, was developed successfully.[481,482]

Genetic engineering has been applied to rabies immunization by the construction of a *Vaccinia* virus recombinant containing the gene for the G protein (V-RG).[483] The recombinant is placed in baits, and, following ingestion by animals, multiplies only in the tonsils and the buccal area. Extensive tests conducted in many species have confirmed the safety and efficacy of vaccination with this construct, and field tests in Europe, Canada, and the United States have confirmed the promising laboratory results.[484–488] At least two human infections with the *Vaccinia* recombinant produced local lesions but no lasting effect.[489] Widespread application of V-RG in Belgium starting in 1989 reduced fox rabies from 841 cases in that year to 2 cases in 1993. Concomitantly, a marked drop occurred in human exposures requiring vaccination.[490] The widespread use of these oral vaccines has eliminated red fox rabies in Western Europe. In North America, more than 100 million doses of V-RG delivered by air have blocked the spread of raccoon rabies from the eastern seaboard, controlled gray fox rabies in Texas, eliminated coyote rabies from the U.S.–Mexican border, and suppressed red fox rabies in Southern Ontario.[491–493]

In the United States, two types of rabies vaccines are available for domestic animals: inactivated virus vaccines and recombinant vaccines. Both types require boosters, usually after 1 or 3 years.[493]

New rabies vaccines given orally have been shown to protect dogs from challenge with rabies virus, equivalent to other rabies vaccines.[494] This methodology may be of particular interest for developing countries. Recombinant adenoviruses also have shown usefulness in the laboratory and in the field as oral or parenteral vaccines.[495,496]

Utility of Rabies Vaccination of Humans

More than 15 million people are vaccinated each year after presumed exposure to lyssaviruses, particularly in Asia.[497] It is difficult to define precisely the effect of rabies vaccination on the incidence of human rabies because the risk of the disease is so variable. Nevertheless, when untreated persons who were bitten by proven rabid animals are followed up, disease rates of between 3% and 80% are observed,[6,498] depending on the location and severity of bites.[499] In the United States, relatively few of the 30,000 to 40,000 people vaccinated annually are actually at risk for rabies. However, the paucity of cases of rabies in persons given potent vaccines together with antiserum argues that countless cases of rabies are being prevented. In Texas in 1989, 34% of the skunks, 19% of the foxes, and 15% of the bats involved in biting incidents were rabid; the risk to humans is obvious.[500]

Control of dog rabies is jointly responsible with vaccination of exposed humans for the current rarity of human rabies in North America and Europe. In developing countries, even nerve tissue vaccine reduces the incidence of rabies in vaccinees,[498] but large numbers of exposed persons turn to indigenous methods of rabies control and never receive vaccine.[501] Thus, a great need exists for inexpensive rabies vaccines and for health education to aid in appropriate vaccine use.

THE "NEXT-GENERATION" RABIES VACCINES

Several vaccines can be considered next- or fourth-generation vaccines subsequent to the first three major contributions: post–19th century from the pasteurian, nerve tissue, and CCV products, listed in Table 50.4.[502,503]

Vaccinia and canarypox vectors containing the rabies G protein have been prepared and tested in humans.[504–506] With both vectors, two injections at 1-month intervals raised levels of rabies VNA, although less than two injections of HDCV were given at the same interval. A third dose of the vectors gave striking booster effects to persons who had received the vectors previously and to persons who had received the HDCV previously. Other new vectors that have been constructed include other poxviruses; human, canine, and chimpanzee adenoviruses; and nonpathogenic rhabdoviruses.[507,508] A rabies virus was deleted for the *M* gene and, although unable to replicate, was immunogenic and efficacious.[509,510] Another rabies virus with two attenuating mutations and two genes for the glycoprotein has been developed and is avirulent and protective in animals.[511] Plasmid vaccines containing the complementary DNA of the gene for the rabies virus G glycoprotein have been constructed and tested in animals.[512,513] Protection following challenge with rabies virus was demonstrated in mice, dogs, cats, and monkeys.[514–518] In one study, a single injection of 100 μg of a DNA expressing the rabies virus G protein protected dogs challenged 1 year later.[519] Similarly, DNA-vaccinated monkeys were also protected against challenge 1 year after a single intramuscular injection.[520] An intranasal DNA vaccine was also protective in animals. All the aforementioned experimental vaccines protected mice against rabies virus challenge, but, unfortunately, none except the canarypox-rabies has been tested in humans, which did induce antibodies, as mentioned.[505]

Besides the G protein, the rabies virus RNP protein also may be important in protection.[521,522] Although the G protein alone is protective in experimental animals, so is the N protein, but without the induction of VNA. After vaccination with CCV, antibodies appear to N and G proteins.[523] The function of

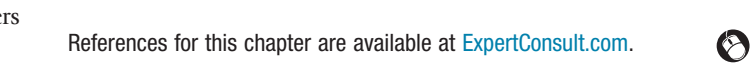
antibodies against N protein may be to help induce cellular immune responses, but also seem to enhance antibody responses to G protein.[74,524] The N protein might be used to sensitize hosts to viral proteins so that subsequent injection of CCV would result in prompt development of higher titers of VNA. However, the N protein does not seem to broaden the neutralizing responses against rabies-related lyssaviruses.[525] The N protein can be produced in a baculovirus vector, which is a potential source of antigen for large-scale preexposure immunization of humans and animals.[526] Large amounts of G protein also can be produced by baculovirus vectors.[527] Synthetic peptides have been constructed that produce antibodies in laboratory animals, but none of the peptides has so far induced development of VNAs or protection against rabies virus challenge. Antiidiotypic antibodies as vaccines are still experimental.[528] It is possible to genetically engineer attenuated rabies virus strains and to have them serve as vectors of foreign genes.[54] Engineering involving reverse genetics also may allow for the construction of species-specific rabies virus vaccines.

Two potentially inexpensive technologies for rabies vaccine production are expression of the G protein in genetically modified plants and the generation of recombinant plant viruses, both of which might be administered orally to humans. Genetically modified plants could also be the substrate for production of parenterally administered rabies virus antigen production.[529–531] However, the concentrations of antigen in plants may not be adequate for protective and long-lasting immunity to rabies for all species.

MONOCLONAL ANTIBODIES

The limited availability of HRIG or ERIG in developing countries remains a major problem.[532] Safety concerns on the use of human RIG plus its limited availability have generated attempts to find other means of providing rabies virus antibodies. Although ERIG has been a useful substitute, it too has safety issues and is not always available. Moreover, consistency of production has been a problem.[533] Monoclonal antibodies that neutralize rabies virus have been produced and might be an alternative to HRIG.[534–537] The first monoclonal antibodies were generated in mice at the Wistar Institute during the late 1970s, but more recently, cocktails of antibodies generated in human cells have been produced.[538–540]

For example, a cocktail of three monoclonal antibodies was developed by investigators in Philadelphia and at the Centers for Disease Control and Prevention.[541,542] Similarly, Crucell Holland developed two antibodies that were complementary to each other, because they are directed against two different epitopes on the G protein.[543] These two antibodies, called CR57 and CR4098, have been combined and tested against rabies in Syrian hamsters, in comparison with HRIG. The monoclonal antibodies efficiently neutralized 26 different street rabies viruses, did not block significantly the immunogenicity of concomitant vaccination, and protected hamsters against a challenge with a virulent rabies virus.[544]



Escape mutants were also neutralized by the combination. Such monoclonal antibodies may soon come into commercial use. The expression of monoclonal antibodies as single or double-chain antibodies in plants could make production less expensive.[545,546]

CONCLUSIONS

The majority of human and animal rabies cases could be prevented by control focused upon canine populations through more responsible pet ownership, surgical or chemical contraception, improved management of community dogs, and most importantly, mass canine vaccination. The last is a widely effective technique when the cost is acceptable, where booster vaccination of pets can be required, and where there is an adequate medical and veterinary infrastructure. In other areas, with different socioeconomic conditions, only the first three methods may be feasible, often with difficulty. An inexpensive, safe, and effective oral vaccine for dogs may provide a great advance in the control of rabies, and, as stressed earlier, oral vaccines for major wildlife species already have had a major impact on rabies epizootiology. Lethal control of animal reservoirs is not recommended and unlike the situation for wild carnivores, management of rabies in bats, such as by vaccination, is not presently feasible.

Preexposure vaccination with CCVs also could reduce the incidence of human rabies in high-risk areas and professions, as has been achieved among veterinarians and Peace Corps workers. Routine preexposure vaccination of children in areas where animal rabies is prevalent is under consideration as a paradigm shift to reduce health disparities, such as in Amazonia. Elimination of rabies in dogs should receive major emphasis, which will serve to markedly reduce vaccination of humans. Improving laboratory-based surveillance to document the burden of disease, applying dose-saving regimens of existing vaccines, understanding the fundamental immunological basis for host responses to emerging lyssaviruses for new biologics, appreciating the basic health economics of prophylaxis, and providing global outreach around World Rabies Day are major One Health opportunities today that were not appreciated during the early 20th century.[153,187–190,288,399,547–553] Within the next several years, the application of monoclonal antibodies and production of recombinant rabies virus antigen vaccines, perhaps produced in genetically modified plants, are considerations for renewed rabies prevention and control.[554] Comparative applied clinical trials with existing vaccines and basic scientific insights into the holistic immunology of human responses to rabies virus antigens will lead to the selection, development and use of purer, more potent, safer, less expensive, and more effective biologics from an objective, evidence-based perspective and more rational administration routes and schedules for specific populations at risk in the decades ahead.[555–570]

51 Respiratory Syncytial Virus Vaccines

Ruth A. Karron

Respiratory syncytial virus (RSV) is the most important cause of viral acute lower respiratory tract illness in infants and children worldwide.[1–3] In the United States, it is estimated that approximately 150,000 infants are hospitalized annually with RSV pneumonia or bronchiolitis.[4] A recent review of national databases in the United States estimated RSV mortality rates in children at approximately three to four per 10,000 admissions, or approximately 50 to 160 deaths per year,[5] although historic estimates were severalfold higher for premature infants[6] and for those with chronic lung disease,[7] congenital heart disease,[8] or primary immunodeficiency disorders.[9,10] RSV is the leading viral cause of hospitalization and reduction in pulmonary function for children with cystic fibrosis.[11–13] In Native American and Alaska Native children, the risk of hospitalization for RSV is three to five times greater than that of the general U.S. pediatric population.[14,15] RSV also accounts for a substantial proportion of outpatient visits in U.S. children younger than 5 years of age.[3] Globally, RSV was estimated to have caused 33.8 million (95% confidence interval, 19.3–46.2) cases of acute lower respiratory tract illness in children younger than 5 years of age in 2005.[16] The global burden of RSV-associated mortality has been estimated using various methodologies; values range from between 66,000 and 199,000 in 2005[16] to 234,000 in 2010.[17] Additional efforts are underway to provide more precise global estimates of RSV morbidity and mortality in children.

Although traditionally regarded as a pediatric pathogen, RSV also can cause life-threatening pulmonary disease in hematopoietic stem cell transplant (HSCT) recipients. The elderly are also at risk for severe RSV disease,[18–22] and nearly 180,000 RSV-associated hospitalizations of the elderly are estimated to occur annually in the United States.[20]

RSV was discovered in 1956 and its importance as a respiratory pathogen in infants was documented shortly thereafter, but a number of obstacles have impeded vaccine development. The peak of severe disease occurs in very young infants, who may not respond adequately to vaccination because of immunologic immaturity, suppression of the immune response by maternally derived antibody, or both[1,23] Because serious RSV disease can occur in high-risk persons who have experienced previous RSV infection as well as in RSV-naïve infants, it is likely that more than one type of RSV vaccine is needed to immunize all those who would benefit from vaccination. In addition, an RSV vaccine must not potentiate naturally occurring RSV disease, as was observed with the formalin-inactivated RSV (FI-RSV) vaccine (see "Past Experience: Formalin-Inactivated Respiratory Syncytial Virus Vaccine" later).[24–26]

Despite these challenges, there has been a tremendous surge in RSV vaccine research in the past 5 years, with more than 60 vaccine candidates in clinical development and more than 20 vaccines in clinical trials as of December 2016 (Fig. 51.1). This chapter describes recent efforts to develop safe and effective RSV vaccines for populations at risk, with a primary focus on vaccine candidates currently being evaluated in clinical trials.

BACKGROUND

Clinical Disease

Reinfection with RSV occurs throughout life, although disease manifestations differ. In young children, RSV infections are associated with a spectrum of respiratory illness, ranging from mild upper respiratory illness to life-threatening bronchiolitis and pneumonia. In infants younger than 6 weeks old, poor feeding and lethargy may predominate, and apnea may occur in the absence of other respiratory signs or symptoms.[27] Otitis media occurs frequently; RSV is the principal cause of viral otitis media in children.[28]

The nature of the relationship between RSV infection in early childhood and subsequent development of reactive airway disease remains an open question. Infants hospitalized with RSV infection frequently have demonstrable abnormalities in pulmonary function for years after the initial event (reviewed by Wu and Hartert[29]). However, it is not clear whether RSV causes abnormal airway function through lung injury and immunomodulation, whether RSV is only one of many triggers in susceptible persons, or whether both are true: genetic factors influence the immune response to RSV, and RSV elicits particular immune responses that may injure the developing lung.[29] Intervention studies may help resolve this issue. A recent placebo-controlled trial of the RSV monoclonal antibody (mAb) palivizumab in late preterm infants demonstrated that the infants who received palivizumab had a significant reduction in total wheezing days compared with those who received placebo.[30] Conversely, a placebo-controlled trial of the RSV mAb motavizumab in full-term Native American infants failed to show an effect on the incidence of medically attended wheezing through 3 years of age.[31] The planned RSV vaccine and mAb efficacy trials described later will provide important opportunities for further assessment of potential causal relationships between RSV and asthma.

In healthy young adults, RSV infections are typically associated with mild upper respiratory illness.[32] Elderly adults attending adult daycare or in long-term care facilities and who are infected with RSV may have a combination of symptoms that include rhinorrhea (67% to 92%), cough (90% to 97%), fever (20% to 56%), and wheezing (6% to 35%).[33] Pneumonia occurs in up to 10% of these persons.[19,34,35]

Immunocompromised patients, particularly those with hematologic malignancies and those undergoing HSCT or lung transplant, are at high risk for severe RSV disease.[36] In these patients, upper respiratory illness precedes lower respiratory illness, and the presence of rhinorrhea, sinusitis, or otalgia are clinical features that may help distinguish between RSV and cytomegalovirus pneumonia.[37–40] The severity of disease depends on the type and magnitude of immunosuppression, with rates of RSV pneumonia of up to 75% in leukemic patients[39] and of RSV pneumonia in 24% to 79% of HSCT patients.[41] For HSCT recipients, infection that occurs preengraftment is associated with the highest risk of pneumonia and death, but mortality is still high in those who develop pneumonia postengraftment.[41] In the United States, prior infection with HIV does not appear to increase the morbidity

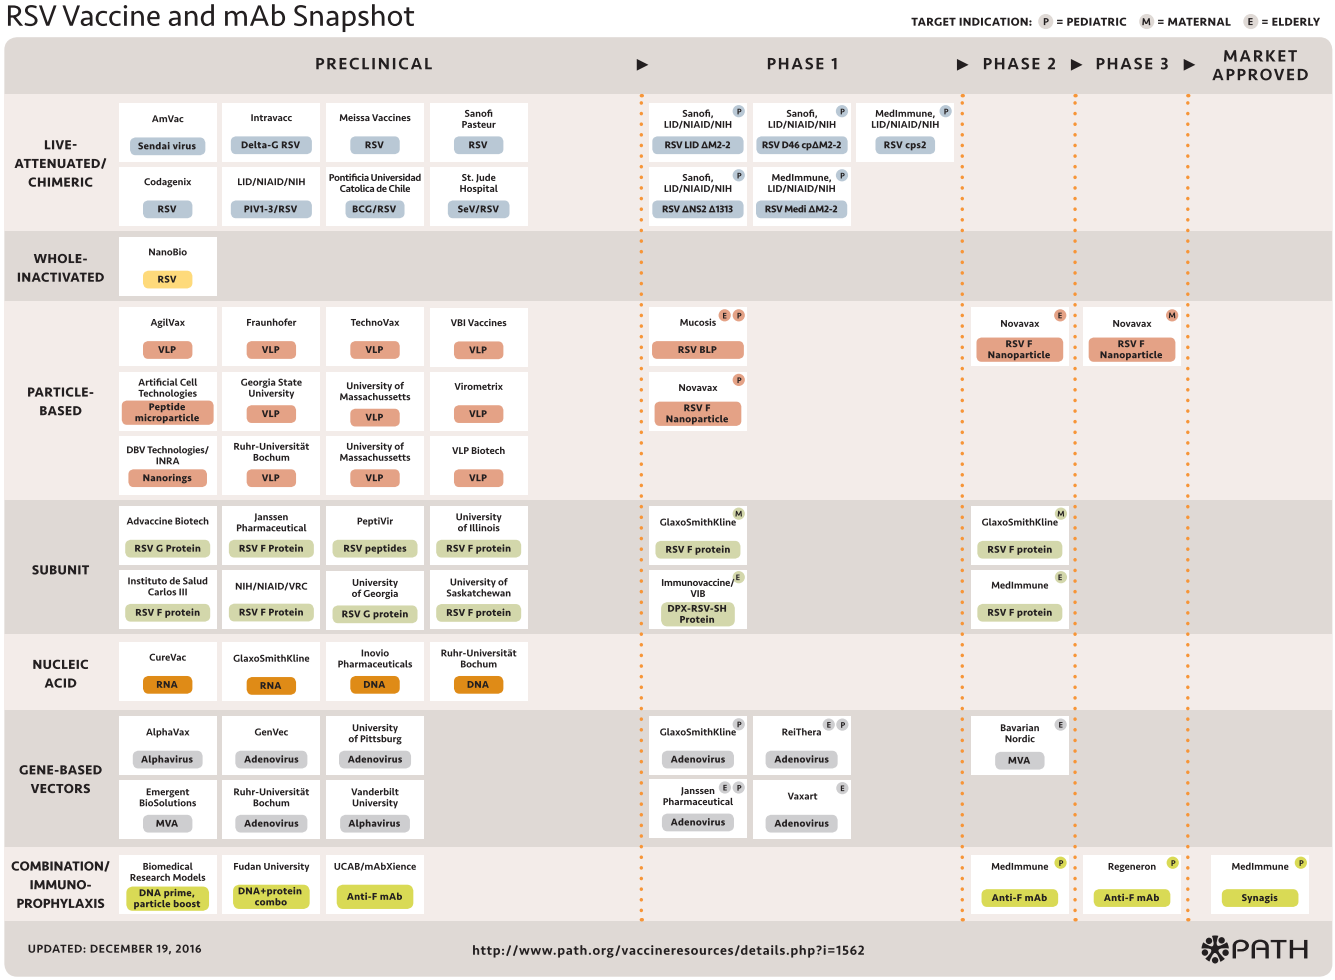

Figure 51.1. "Snapshot" of respiratory syncytial virus (RSV) vaccines in preclinical and clinical development. mAb, monoclonal antibody. *(Courtesy Carrie Trujillo and Deborah Higgins and PATH. Available at http://www.path.org/vaccineresources/details.php?i=1562.)*

and mortality associated with RSV infections in children, although prolonged viral excretion has been reported.[42] However, in South Africa, RSV is associated with greater morbidity and mortality in HIV-infected than in HIV-noninfected children, although the contribution of other illnesses cannot be excluded.[43]

Virus

RSV is a member of the family Paramyxoviridae. The viral genome is composed of a single strand of negative-sense RNA that is tightly associated with viral protein to form the nucleocapsid, and the viral envelope is a plasma membrane-derived lipid bilayer that contains virally encoded transmembrane proteins. A viral polymerase that transcribes genomic RNA into messenger RNA is packaged within the virion.

RSV is a member of the genus *Pneumovirus* and is composed of 15,222 nucleotides that encode three transmembrane surface proteins (F, G, and SH), two matrix proteins (M and M2), three nucleocapsid proteins (N, P, and L), and two nonstructural proteins (NS1 and NS2). The surface fusion (F) and attachment (G) glycoproteins are the only viral components that induce RSV neutralizing antibody and therefore are important targets for vaccine development. The F protein, in combination with proteins G and SH, is responsible for fusion of the viral envelope with the host cell membranes and for the characteristic syncytium formation in cell culture. Its genome is highly conserved between RSV groups. Along with the F protein, the G protein mediates attachment to the host cell surface and is largely responsible for the antigenic diversity observed between RSV groups (see below). A secreted form of the G protein that lacks the N-terminal signal/anchor region also is produced, and it is reported that up to 80% of the G glycoprotein released from cells 24 hours after infection is in this secreted form.[44] The function of the secreted G protein is not known, although it may serve as a decoy for RSV neutralizing antibody[1] or as an inhibitor of innate immune responses.[45] The NS1 and NS2 proteins suppress a key component of host innate immune defense by blocking induction (NS1) or signaling (NS2) of type I and type III interferons (IFNs).[46] The NS2 protein may also contribute to airway obstruction by promoting shedding of infected epithelial cells.[47]

Cross-neutralization studies show that RSV isolates can be classified into two groups, designated A and B.[48] Although RSV A and B strains differ in all 10 viral proteins, the G glycoprotein shows the greatest divergence between groups, with only 53% amino acid homology between prototype RSV A and B viruses.[49] Group A RSV infection may cause more-severe disease than group B RSV, although this has not been

definitively established.[50,51] The impact of this antigenic dimorphism is not completely understood, but young children experiencing their second RSV infection frequently are reinfected with virus from the same group.[52]

EPIDEMIOLOGY

By 2 years of age, almost all children will have been infected with RSV, and approximately 50% will have been infected twice.[53] Reinfection with RSV can occur throughout life and is often symptomatic; however, RSV generally does not cause lower respiratory illness in immunocompetent adults and healthy older children.[32]

RSV epidemics occur yearly during late fall, winter, and early spring in temperate climates and in the rainy season in some, but not all, tropical climates.[54] Group A and group B viruses cocirculate during epidemics, although one may predominate.[55–57]

Humans are the only known reservoir for RSV. Spread of RSV from contaminated nasal secretions occurs via large droplets rather than small-particle aerosols, so close contact with an infected person or contaminated environmental surface is required for transmission.[58,59] RSV can persist as a fomite on hard surfaces for several hours,[60,61] and for this reason is an important cause of nosocomial respiratory illness, particularly on pediatric wards.[61]

MECHANISMS OF IMMUNITY AND CORRELATES OF PROTECTION

Virus-specific immune responses are largely responsible for protection against RSV-associated lower respiratory illness and recovery from RSV infection. Immunity to RSV is mediated via humoral and cellular effectors, including serum antibody (acquired as a result of infection or maternally derived in young infants), secretory antibody, and major histocompatibility complex class I–restricted cytotoxic T lymphocytes. The RSV F glycoprotein also may elicit innate immune responses via Toll-like receptors and CD14.[62,63] Natural immunity to RSV is incomplete, and reinfection occurs throughout life, as has been demonstrated by epidemiologic[53,64] and challenge studies in healthy young adults.[65] Healthy older children and adults, however, usually are protected against RSV-associated lower respiratory illness. In general, humoral immune responses (secretory and serum antibodies) appear to protect against infection of the upper and lower respiratory tract, respectively, while cell-mediated responses directed against internal proteins appear to terminate infection and may contribute to viral clearance from the lungs.[66] RSV-specific cytotoxic T lymphocytes have been detected in infants recovering from RSV infection[67] and may contribute to short-term protection, such as reinfection during the same RSV season. Although the adoptive transfer of primed T cells will halt RSV replication in immunodeficient mice, the adoptive transfer of RSV-specific cytotoxic T lymphocytes also may potentiate disease,[68] suggesting that there may be an immune component to RSV illness. CD4 T-helper type 2 (Th2)-associated responses have been associated with eosinophilia, increased mucus production, and delayed viral clearance in some small animal models and may also contribute to the pathogenesis of RSV disease.[69–72]

The role of local immunity in the protection of the upper respiratory tract against RSV is suggested by experimental data from studies in cotton rats[73–75] and adult volunteers,[76] and by observational data from infants. In adults, the presence of secretory neutralizing antibody, but not serum antibody, correlated with protection of the upper respiratory tract against RSV infection.[76] In infants, the development of immunoglobulin A in nasal secretions correlated temporally with viral clearance following natural infection.[77]

RSV replicates exclusively in the respiratory epithelium. For this reason, serum neutralizing antibody does not prevent clinically apparent infection, as it does for pathogens that produce viremia, such as measles and varicella. However, high titers of RSV serum neutralizing antibody protect the lower respiratory tract against RSV infection or disease, as has been demonstrated by animal studies,[73–75] epidemiologic observations in infants and young children,[78–80] and clinical trials of RSV hyperimmunoglobulin and mAbs in high-risk infants (see "Passive Immunization Against Respiratory Syncytial Virus" later).

Primary infection with RSV does not always elicit an immune response that will protect the lower respiratory tract because RSV-associated lower respiratory illness can occur in young children experiencing their second episode of RSV.[53,79] Young infants often develop levels of neutralizing antibody and F and G glycoprotein antibodies to RSV that are only 15% to 25% of those observed in older children.[81] However, some of this reduction in antibody response may be because of suppression from maternally derived antibody rather than immunologic immaturity, because very young infants with low levels of maternally derived antibody can develop high titers of serum neutralizing antibody in response to RSV infection.[82] Young infants may also have suboptimal innate immune responses and dysregulated T-cell responses to RSV, although available data are limited.[83] The suboptimal response of some young infants to primary infection with RSV has important implications for vaccine development because it suggests that more than one dose of vaccine may be needed for active immunization of infants, particularly as these infants may have high levels of neutralizing antibody acquired from maternal immunization or from an extended half-life mAb (see "Vaccine Development" later).

The immunologic requirements for protection against severe RSV disease are not clearly defined. Although it is known that a high level of serum neutralizing antibody (titers >1 : 200, as measured in a 60% complement-enhanced plaque-reduction neutralization assay) is sufficient for protection of the lower respiratory tract,[84,85] it is not known whether it is necessary in the case of vaccines that induce a broad range of systemic and mucosal humoral and cellular immune responses. In adults and older children who have been previously infected with RSV, it is reasonable to expect that an effective RSV vaccine will boost levels of serum neutralizing antibodies. However, it is conceivable that vaccination may protect young RSV-naïve infants against severe RSV even if high titers of neutralizing antibodies are not induced. In these infants, "challenge" with a second dose of a live attenuated vaccine may help predict whether some protection has been conferred by the first dose (see "Biologically Derived Live Attenuated Vaccines" later).[86] Palivizumab-competing antibody is also being measured in the context of RSV F nanoparticle vaccine trials (see "Vaccine Development" later) and may be evaluated in clinical trials of other RSV F subunit vaccines. Binding and competition assays for other epitopes on the prefusion and postfusion forms of RSV F (see later) are also being developed and may be evaluated in the context of clinical trials. Ultimately, correlates of protection against severe disease in young infants may differ by type of vaccine used and will need to be evaluated in the context of efficacy trials. It will also be important to be able to compare the antibody generated in various trials, either through use of standardized neutralizing antibody assays or through development of a common biological standard so that results obtained using different assays can be directly compared. Work on standardization is being undertaken by

Programs for Appropriate Technology in Health (PATH) and the World Health Organization (WHO).

PASSIVE IMMUNIZATION AGAINST RESPIRATORY SYNCYTIAL VIRUS

Based on experimental data in animals[73–75] and epidemiologic data in humans[79] suggesting that RSV-neutralizing antibody protected against lower respiratory illness, two products containing high titers of RSV neutralizing antibody were licensed for clinical administration. The first of these, RSV Immune Globulin Intravenous (RSV-IGIV; RespiGam [MedImmune]), led to significant reductions in the rate and severity of lower respiratory illness when administered to high-risk infants at doses of 750 mg/kg.[84] The titer of RSV neutralizing antibody achieved in infants who received this dose of RSV-IGIV was comparable to that demonstrated to protect the lungs of cotton rats against RSV infection in earlier studies.[84,85] The protective effect of RSV-IGIV in these young infants was confirmed by a subsequent placebo-controlled trial.[87] RSV-IGIV was replaced by a monoclonal neutralizing antibody directed against antigenic site II on the RSV F glycoprotein (palivizumab/Synagis; [MedImmune]), which also reduces the risk of hospitalization for RSV disease in premature infants and infants with chronic lung disease.[88] Because palivizumab is 50- to 100-fold more potent than RSV-IGIV, it can be administered intramuscularly in monthly doses. In infants with cyanotic heart disease, RSV-IGIV was associated with an increased incidence of adverse events,[84] but a Phase III study demonstrated that palivizumab was safe and effective in preventing hospitalizations for RSV in children with congenital heart disease.[89] In July 2014, the American Academy of Pediatrics released revised guidelines for the use of palivizumab in high-risk infants and children in the United States, based on expected burden of disease and cost-effectiveness considerations. In otherwise healthy preterm infants, these new guidelines further restrict the use of palivizumab during the first year of life to those born at less than 29 weeks of gestation. Infants born between 29 and 32 weeks of gestation who have had a supplemental oxygen requirement, as well as infants with chronic lung disease of prematurity, hemodynamically significant congenital heart disease, neuromuscular disorders and certain immunodeficiencies, as well as Alaska Native and Native American children, may also be considered for prophylaxis during the first year of life. Children with an ongoing oxygen requirement or who are severely immunocompromised may receive palivizumab prophylaxis during a second RSV season (until 24 months of age). Detailed recommendations are provided in the American Academy of Pediatrics policy statement.[90] Phase I trials have also shown that palivizumab was well tolerated in a small number of HSCT recipients.[91] Although the prophylactic efficacy of RSV-IGIV and palivizumab have been established, neither appears to ameliorate RSV disease when given therapeutically.[92,93]

A more potent RSV mAb, designated motavizumab (MEDI-524), was also developed by MedImmune-AstraZeneca. Compared with palivizumab, motavizumab increases neutralizing activity in vitro and in vivo, and decreases RSV replication in both the upper and lower respiratory tracts in preclinical studies.[94,95] Two Phase III efficacy trials of motavizumab were conducted. In a noninferiority trial, 6635 preterm infants were randomized to receive motavizumab or palivizumab. Infants and children who received motavizumab had a 26% relative reduction in RSV hospitalization and a 50% relative reduction in medically attended lower respiratory illnesses compared with those who received palivizumab.[96] Motavizumab was also evaluated in a randomized, double-blind, placebo-controlled trial in more than 2000 full-term healthy Native American infants (NCT00121108). In this study, motavizumab was found to reduce RSV hospitalizations by 87% and outpatient RSV-associated medically attended lower respiratory illnesses by 71%.[31,97] Motavizumab was not licensed by the U.S. Food and Drug Administration (FDA) in 2010 because superiority to palivizumab was not clearly demonstrated and it is no longer in clinical development.

MedImmune is currently developing an extended half-life mAb directed against the site Ø neutralizing epitope on RSV F (see "Respiratory Syncytial Virus Subunit and Particle Vaccines" below). This mAb contains a YTE mutation in the Fc portion of the immunoglobulin. YTE mutations lead to increased binding to the neonatal Fc receptor and prolonged half-life.[98] This product, designated MEDI8897 (see Fig. 51.1), is intended for universal use in infants, to be administered seasonally or at birth depending on geographic location. As of this writing, MEDI8897 is being evaluated in healthy preterm infants (NCT02290340).

VACCINE DEVELOPMENT

Successful RSV vaccines should prevent serious RSV-associated lower respiratory illness in those at risk. The primary target populations for amelioration of disease through RSV vaccination are young infants and the elderly; however, toddlers and preschool children might also benefit from RSV immunization. Although the majority of RSV-associated deaths and hospitalizations occur in the first few months, there is a substantial burden of serious RSV lower respiratory illness throughout the first year of life,[3,99] as well as medically attended outpatient RSV illness throughout the first 5 years of life.[3] It is unlikely that a single RSV vaccine or type of vaccine will be able to address the total pediatric burden. For this reason, efforts are underway to develop nonreplicating vaccines for passive protection of the very youngest infants through maternal immunization, and replicating vaccines (live-attenuated RSV or vectored vaccines) for active immunization of slightly older infants and young children.[100] Nonreplicating vaccines might also be used to boost immunity in non–RSV-naïve toddlers, and are being combined with novel adjuvants to boost preexisting immunity in the elderly.

RSV is recognized as an important global pediatric pathogen and the stated goal of vaccine developers, regulators, funding organizations, and researchers is to evaluate and license RSV vaccines to protect children in low-, middle-, and high-income countries. As of this writing, global vaccine efficacy studies are being designed, with ongoing discussions of clinical end points that would be relevant in a variety of settings.[100]

Past Experience: Formalin-Inactivated Respiratory Syncytial Virus Vaccine

In the early 1960s, a FI-RSV was prepared and tested in infants and children. This vaccine, designated Lot 100, was administered as two or three intramuscular doses, separated by 1 to 3 months, to infants and children between 2 months and 7 years of age.[24–26,101] Lot 100 not only failed to protect against wild-type (wt) RSV disease, but induced an exaggerated clinical response to wt RSV infection in infants who were RSV naïve before vaccination. Many vaccinees were hospitalized with lower respiratory illness; in one study, the hospitalization rate of vaccinees approached 80% compared with 5% in control vaccinees.[24,25] Tragically, two infants who received Lot 100 died following wt RSV infection, one at 14 months and the second at 16 months of age.[24,25] RSV was readily isolated from the lower respiratory tracts of these infants.

The mechanisms responsible for the FI-RSV vaccine-associated disease enhancement are still not completely understood. However, data obtained from Lot 100 recipients[101–103] and from studies in rodent models[104,105] have led to the hypothesis that children vaccinated with FI-RSV remained susceptible to infection with wt RSV because vaccination produced inadequate levels of serum neutralizing antibodies and did not induce local immunity. Once infected with wt RSV, virus was not readily cleared because FI-RSV did not prime for a $CD8^+$ cytotoxic T-cell response, and the viral infection produced a direct cytopathic effect in the lower respiratory tracts of these infants. In addition, immunization with FI-RSV primed for a Th2-cell–like response, with increased local production of interleukins 4, 5, and 10; an influx of lymphocytes and eosinophils; the release of additional mediators, and resultant inflammation and bronchoconstriction.[106–108] Immunization with FI-RSV may have also induced low-avidity antibody, leading to immune complex deposition.[109,110]

The clinical experience with FI-RSV and the information gleaned from animal models of disease enhancement suggest key features of an RSV vaccine to be administered to RSV-naïve infants. The vaccine should induce protective levels of neutralizing antibody, as well as CD8 RSV-specific cytotoxic T cells, and a pattern of CD4 response similar to that evoked by wt RSV. A live attenuated native RSV or vectored vaccine is most likely to exhibit these characteristics.[1] Nonreplicating vaccines could be used to boost immunity in older children and adults at risk, or to provide passive protection to the infant through maternal immunization.[100,111]

Respiratory Syncytial Virus Subunit and Particle Vaccines

Considerable progress has been made in the development of RSV subunit and nanoparticle vaccines, with 28 vaccines in preclinical development and 8 vaccines in clinical development as of December 2016 (see Fig. 51.1). The primary target populations for these vaccines are the elderly and pregnant women, who would be immunized to prevent severe disease in their infants through passive transfer of antibody. Most of these vaccines contain the RSV fusion (F) glycoprotein. RSV F is required for viral infection, is the locus for most of the neutralizing activity detected in human sera, and is largely conserved between RSV A and B strains. In addition, palivizumab, which effectively protects high-risk infants against severe RSV disease, is directed against the site II epitope on the RSV F glycoprotein.

Development of RSV F vaccines has been greatly enhanced by recent progress in elucidating the antigenic structure of the RSV F glycoprotein.[112–116] RSV F is a class I fusion glycoprotein that requires proteolytic cleavage for activation. The mature F glycoprotein consists of two subunits (F1 and F2) that are linked by disulfide bonds and assemble as trimers. RSV F is present on the viral surface in both a prefusion and a postfusion conformation (Fig. 51.2). The prefusion conformation is metastable, and triggering of prefusion F leads to fusion of the viral and cell membranes and a change in conformation such that RSV F assumes the stable postfusion form.[116] Much of the neutralizing activity in human adult sera is directed against the prefusion form of RSV F.[117]

The crystalline structures of both prefusion[114] and postfusion F[112,113] have been solved, leading to the localization of neutralizing epitopes on both structures (see Fig. 51.2). The mAbs directed against each of these epitopes do not prevent virus binding but prevent fusion of the virus and cell membranes. Site II and site IV epitopes are present on both prefusion and postfusion F.[116,118] The site Ø epitope is unique to prefusion F (see Fig. 51.2), and antibodies directed against site Ø are highly neutralizing.[116] Recently, the mAb AM14 was found to recognize a novel potent

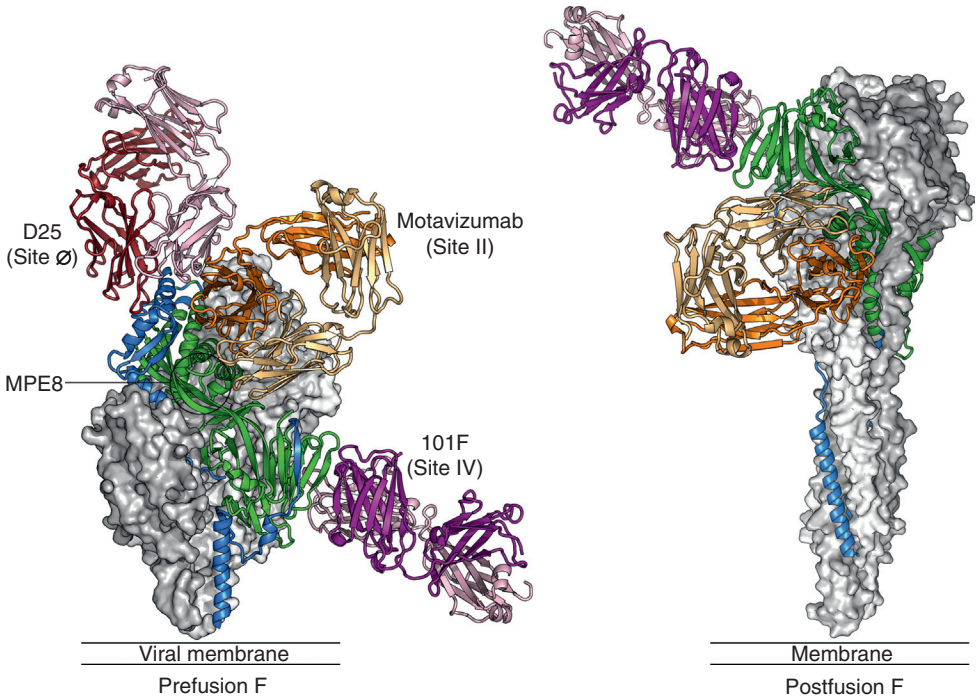

Figure 51.2. Molecular structure of the prefusion *(left)* and postfusion *(right)* conformations of the respiratory syncytial virus (RSV) F glycoprotein. The site II epitope (the palivizumab and motavizumab binding site) and the site IV epitope are present on the prefusion and postfusion conformations of RSV F, whereas site Ø (bound by D25, the monoclonal antibody used to develop MEDI8897) is only present on the prefusion molecule. *(Courtesy Jason McLellan. Modified from McLellan JS. Neutralizing epitopes on the respiratory syncytial virus fusion glycoprotein.* Curr Opin Virol. *2015;11:70–75.)*

neutralizing quaternary epitope that spans the RSV F prefusion trimer.[119]

Elucidation of the structures of RSV prefusion and postfusion F has enhanced the development and characterization of RSV F subunit vaccine candidates. The candidate furthest advanced in clinical trials is a baculovirus-expressed uncleaved RSV F in the postfusion conformation that forms rosettes (nanoparticles) and is manufactured by Novavax. In a Phase I dose-ranging study in healthy adults (NCT01290419), the RSV F nanoparticle vaccine was well-tolerated and a 60 µg dose with alum induced twofold increases in neutralizing antibodies as measured by microneutralization assay, although greater increases were observed in the subpopulation with lower baseline microneutralization titers.[120] In contrast, the vaccine elicited approximately 10-fold increases in immunoglobulin G antibody that bound to postfusion F, and similar increases in palivizumab-competing antibody immunoglobulin G that bound to antigenic site II and competed with palivizumab for binding to postfusion F. These data suggest that the RSV F nanoparticle vaccine induces higher levels of nonneutralizing antibody than neutralizing antibody. Similar results were obtained when the nanoparticle vaccine was evaluated in a Phase II study in women of childbearing age.[121] A Phase II study comparing an unadjuvanted 135 µg dose of this vaccine to placebo was completed in the elderly; 44% efficacy against all RSV disease and 46% efficacy against RSV lower respiratory illness were reported (unpublished data; Novavax press release, August 10, 2015, available at http://www.multivu.com/players/English/7590851-novavax-rsv/). In November 2015, Novavax initiated a Phase III efficacy trial of the RSV F nanoparticle vaccine (135 µg, unadjuvanted) in the elderly (NCT02608502) but failed to demonstrate efficacy.[121a] Additional studies with an adjuvanted formulation are being planned. In December 2015, Novavax initiated a Phase III efficacy trial of the RSV F nanoparticle vaccine (120 µg with alum) in women in the third trimester of pregnancy to prevent RSV illness in their infants (NCT02624947). Additional placebo-controlled trials of the alum-adjuvanted RSV F nanoparticle vaccine are ongoing in RSV-seropositive children (NCT02296463).

As of this writing, GlaxoSmithKline and MedImmune also have RSV F vaccines in clinical trials (see Fig. 51.1). The GlaxoSmithKline RSV prefusion F vaccine was well-tolerated in healthy men and elicited neutralizing antibody responses in most vaccinees (NCT01905215; RSV 2014, Stellenbosch, South Africa, abstract #114). Evaluation of this vaccine in healthy women is ongoing (NCT02360475), with plans for evaluation in pregnant women, the target population. An RSV postfusion F vaccine is also in development by GlaxoSmithKline (formerly by Novartis) and has been evaluated in healthy adults with and without the MF59 adjuvant (NCT02298179). MedImmune has developed a soluble RSV F (sF) vaccine adjuvanted with glucopyranosyl lipid A in a squalene-based oil-in-water stable emulsion (GLA-SE) for use in the elderly. RSV sF is currently being evaluated with different dosages of GLA-SE in adults older than age 60 years alone or in combination with inactivated influenza vaccine (NCT02289820). A number of additional RSV F subunit vaccines are in preclinical development (see Fig. 51.1), including DS-Cav1, a stabilized preF construct. In nonhuman primates, DS-Cav1 elicited neutralizing antibody responses that were approximately 10-fold greater than those elicited by postfusion F.[116,122]

Subunit vaccines targeting RSV G, the viral surface glycoprotein that mediates attachment, are also being developed (see Fig. 51.1). In addition, the RSV SH gene, which encodes a viroporin, has also been targeted for vaccine development[123] and a vaccine containing the extracellular domain of SH (SHe) and the DepoVax adjuvant (DPX-RSV) is currently being evaluated in healthy middle-aged adults (NCT 02472548; see Fig. 51.1).

Live Attenuated Respiratory Syncytial Virus Vaccines

Live attenuated vaccines may offer several advantages over nonreplicating vaccines, especially for RSV-naïve infants and young children. Intranasal immunization with a live attenuated vaccine should induce both systemic and local immunity and may therefore protect against both upper respiratory and lower respiratory illnesses.[124] Also, the immune response to a live vaccine should closely resemble the response to natural infection and therefore not produce enhanced disease on exposure to wild-type virus.[1] Similar to other live attenuated intranasal respiratory virus candidate vaccines,[125,126] live intranasal RSV candidate vaccines have been shown to replicate in young infants in the presence of maternally acquired antibody.[86,127] This feature will be critical for the success of live attenuated RSV vaccines in young infants. Multiple doses will probably be required for young infants.

Biologically Derived Live Attenuated Respiratory Syncytial Virus Vaccines

Several strategies for the development of a live attenuated RSV vaccine were originally explored, including the creation of host-range mutants, cold-passaged (*cp*) mutants, and temperature-sensitive (*ts*) mutants (which are unable to grow at high temperatures). In brief, these candidate vaccines were either underattenuated (*cp*RSV and RSV *ts*-1) and transmissible[1,127,128] or overattenuated (RSV *ts*-2).[1,129] Of importance, enhanced disease was not observed when infants who received RSV *ts*-1 or *cp*RSV were naturally infected with wt RSV.[128,130] A series of live attenuated RSV A *cpts* candidate vaccines were derived from further attenuation of *cp*RSV through chemical mutagenesis. Several of these candidate intranasally administered vaccines were evaluated in Phase I clinical trials in adults and children,[86,131] and one (*cpts*248/404) was evaluated in infants as young as 1 month old.[86] The *cpts*248/404 vaccine was highly attenuated in these infants but caused nasal congestion that in some instances interfered with feeding and sleeping.[86] Although the *cpts*248/404 vaccine was not sufficiently attenuated for young infants, evaluation of this candidate vaccine provided important information regarding replication and immunogenicity of a live attenuated RSV vaccine in the presence of maternal antibodies, phenotypic stability of a *cpts* vaccine, and preliminary evidence of protection against illness following wt RSV infection.[86]

Genetically Engineered (Complementary DNA–Derived) Live Attenuated Respiratory Syncytial Virus Vaccines

The ability to recover infectious virus from complementary DNA clones of RSV[132] has provided insight into the genetic basis of attenuation of biologically derived vaccines and hastened the development of additional live attenuated RSV candidate vaccines through the use of recombinant technology.[1,23,133] Mutations present in *cp*RSV and six of its *ts* derivatives were inserted into wt RSV singly and in combination, and the majority of attenuating mutations were found to occur in the polymerase gene, with a notable exception being the 404 mutation in the *M* gene start signal.[1,23,133–135] Using this information, attenuating mutations from biologically derived vaccines have been combined to produce further attenuated candidate vaccines.[1,133] In addition, deletion (Δ) of a nonessential gene (*SH*, *NS1*, *NS2*, or *M2-2*)[136] in combination with known attenuating *cp* and *ts* mutations has also been used to produce

highly attenuated vaccines.[137,138] Two of these candidates, designated rA2cp248/404ΔSH and rA2cp248/404/1030ΔSH, were evaluated in young children.[139] rA2cp248/404ΔSH was not more attenuated than its biologic parent, *cpts*248/404. However, addition of the 1030-amino-acid–point mutation to rA2cp248/404ΔSH yielded rA2cp248/404/1030ΔSH, which was highly attenuated in infants as young as 1 to 2 months and moderately immunogenic.[139] This candidate vaccine, now designated MEDI-559, was also evaluated in a Phase I/IIa trials in infants and children ages 5 to 24 months (NCT00767416). Vaccine "take," as measured by seroresponse or vaccine virus shedding was observed in 95% of vaccinees; 59% had an antibody response as measured by microneutralization assay. In the first 28 days postvaccination, a higher incidence of medically attended lower respiratory illness was observed in vaccinees compared to placebo recipients (9% vs 2%, not statistically significant). None of these episodes was associated with shedding of vaccine virus and the incidence of medically attended lower respiratory illness did not differ between groups after 28 days. The authors concluded that further safety evaluations would be needed prior to initiation of trials in younger infants.[140]

Rational vaccine design based on an understanding of RSV gene function has led to the design of deletion mutant vaccines. One such vaccine candidate, designated RSVΔM2–2, lacks the RSV *M2-2* gene. Compared with wt RSV, RSVΔM2-2 has increased accumulation of intracellular viral messenger RNA and increased expression of RSV proteins, which could enhance vaccine-induced immunity per infectious unit of virus.[141] This vaccine virus was attenuated in nonhuman primates.[142] RSV MEDI ΔM2-2 was evaluated in a Phase I clinical trial (NCT01459198, see Fig. 51.1) and was found to be highly restricted in replication yet more immunogenic than rA2 cp248/404/1030/ΔSH, the previous lead live attenuated RSV vaccine candidate. RSV MEDI ΔM2-2 also primed for a potent anamnestic response following natural exposure to wt RSV.[143] This apparent "delinking" of vaccine virus replication and immunogenicity is an important advance in the development of live-attenuated RSV vaccines. Further development of vaccine candidates containing the ΔM2-2 mutation is in progress.

An additional set of deletion mutant vaccines, rA2cpΔNS2, rA2cp248/404ΔNS2, and rA2cp530/1009ΔNS2, were also evaluated in clinical trials.[144] These vaccines all had deletion of the interferon antagonist *NS2* gene in common, which could, theoretically, enhance innate and adaptive immune responses.[145] rA2cpΔNS2 was overattenuated for adults, and rA2cp248/404ΔNS2 and rA2cp530/1009ΔNS2 were overattenuated for children at the doses studied.[144] Nevertheless, these studies demonstrated that deletion of *NS2* attenuates RSV infection. An alternative *NS2* deletion mutant, designated ΔNS2Δ1313I1314L,[146] is currently being evaluated in young children (NCT01893554, see Fig. 51.1). Similarly, deletion of the *NS1* gene, which also inhibits IFN-α and IFN-β induction,[145] may yield an attenuated recombinant RSV candidate vaccine.[142]

Vectored Respiratory Syncytial Virus Vaccines

Recombinant technology also provides the opportunity for creation of chimeric viruses containing the RSV F and G surface glycoprotein, with one or more internal genes provided by related respiratory viruses. A recombinant chimeric vaccine containing the bovine PIV3 backbone, human PIV3 surface glycoproteins (rB/HPIV3), and RSV F glycoproteins, designated MEDI-534, was evaluated in a Phase I trial in 49 RSV and HPIV3 doubly seronegative children ages 6 to 24 months. The children were randomized to receive three doses of vaccine or placebo. All children who received the highest dose of vaccine (10^6 median tissue culture infectious dose) were infected with vaccine virus, and seroconversion to RSV and HPIV3 occurred in 50% and 100%, respectively, of recipients of this vaccine dose.[147] Evaluation of the vaccine virus shed by study participants revealed nucleotide changes that were expected to reduce RSV F expression,[148] which might explain the suboptimal antibody response to RSV. No further evaluation of this vaccine candidate is planned. The National Institutes of Health has developed a new rB/HPIV3 vector containing the RSV prefusion F protein. In a hamster model, this vaccine induced high titers of RSV neutralizing antibody, protected against challenge with wt RSV, and was genetically stable.[149] Clinical evaluation of this vectored vaccine is anticipated.

Gene-based replication deficient vectors represent an additional approach to the development of RSV vaccines. GlaxoSmithKline (Okairos) completed the Phase I evaluation in adults of immunization with vectors expressing the RSV F, N, and M2-1 genes[150]: the chimpanzee adenovirus vector PanAd3-RSV and the modified *Vaccinia* virus Ankara (MVA)-RSV were tested in several prime-boost combinations, with some doses of the chimpanzee adenovirus vaccine administered intranasally (NCT01805921; see Fig. 51.1). RSV neutralizing antibody titers were boosted after the PanAd3-RSV prime, and RSV T-cell responses were greatest after the MVA-RSV boost.[151] Janssen (Crucell) is currently evaluating prime/boost combinations of adenovirus 26 and adenovirus 35 vectors expressing RSV F (Ad26.RSV.FA2 and Ad35.RSV.FA2) in adults (NCT02440035 and NCT02561871; see Fig. 51.1).

CONCLUSIONS

Over the past several years, increasing recognition of the global burden of RSV disease[16,17] has reinvigorated interest in the development of RSV vaccines. A large number of RSV vaccines and a new RSV mAb are in late preclinical or clinical development. Standardized methodologies for the assessment of clinical end points and for measuring antibody responses will be important for efficacy trials of lead candidates, which are anticipated to start soon. Development of safe and effective RSV vaccines for protection of vulnerable infant and elderly populations is more likely now than at any time since the discovery of this important respiratory pathogen.

52 Rotavirus Vaccines

Umesh D. Parashar, Margaret M. Cortese, and Paul A. Offit

Rotaviruses were the leading cause of severe dehydrating diarrhea in infants and young children throughout the world before rotavirus vaccines became available. Most children were infected by the time they reached 2 to 3 years of age.[1,2] Even in developed nations, where standards of hygiene are high, rotavirus was the most common cause of severe infant diarrhea.[3]

In the United States, before the introduction of a vaccine, rotavirus accounted for approximately 2.7 million illness episodes, 500,000 physician visits, 55,000 to 70,000 hospitalizations, and 20 to 60 deaths each year, and the economic burden of disease was estimated at approximately US$1 billion each year in medical and indirect costs.[4–7] In less-developed countries, rotaviruses ranked highest among the multiple microbial causes of severe gastroenteritis in children and contributed disproportionately to the mortality associated with the disease.[8–10a] Worldwide, rotavirus was estimated to cause approximately 200,000 deaths in children in 2013, with the highest mortality rates occurring in countries of sub-Saharan Africa.[11–16] Extensive global efforts to disseminate oral rehydration therapy in the developing world have contributed to a decline in diarrhea deaths.[17] However, the continuing mortality associated with rotavirus, 500 to 600 deaths per day, suggests that prevention through universal application of a safe, economical, and efficacious vaccine is the best means of drastically decreasing the morbidity and mortality from rotavirus.

The first rotavirus vaccine to be licensed (RotaShield, Wyeth Lederle) was introduced into the U.S. immunization program in 1998, but was withdrawn a year later when it was associated with intussusception. Two other rotavirus vaccines, RotaTeq (Merck) and Rotarix (GlaxoSmithKline) were introduced into the United States 7 and 9 years later, respectively. Following studies of more than 70,000 infants, the Advisory Committee on Immunization Practices (ACIP) recommended RotaTeq for routine use in the United States in February 2006. Following studies of more than 60,000 infants, Rotarix was licensed for use in the European Union and Latin America in 2006, and for use in the United States in April 2008. Globally, as of May 2016, a total of 81 countries, including 38 low-income countries that are eligible for support for vaccine purchase from the Vaccine Alliance, Gavi, have implemented rotavirus vaccines in their national immunization programs (Fig. 52.1).

This chapter describes the globally licensed RotaTeq and Rotarix vaccines and other rotavirus vaccines.

CLINICAL DISEASE

Evaluation of children admitted to the hospital with rotavirus infection reveals a consistent pattern. The disease is characterized by the sudden onset of watery diarrhea, fever, and vomiting.[18–21] Most disease is mild, but a small proportion (approximately <1%) of children infected with rotavirus[4,5] will develop dehydration associated with severe loss of sodium and chloride in the stools and a compensated metabolic acidosis. In children admitted to the hospital with dehydration, fever and vomiting usually persist for 2 to 3 days and diarrhea for 4 to 5 days.[18–21] Detection of rotavirus antigen in the plasma of infected children is common[22] and may be associated with disease severity.[23] Disease severity is also predicted by elevated hepatic transaminases and prolonged viral excretion in the feces.[24,25]

VIRUS

Rotavirus infection has been detected in most common species of domestic animals and in many species of wild mammals and birds. Eight groups (species) of rotavirus have been described (A to H) based on genetic and antigenic differences in the VP6 protein—only viruses in groups A, B, and C are known to cause disease in humans. Whereas the great majority of human and animal rotaviruses share one set of common group antigens (group A rotaviruses),[26] animal rotaviruses within group A can be distinguished from human strains on the basis of type-specific surface antigens. Animals appear to be neither a reservoir for human strains nor a common source for direct transmission of rotaviruses to humans.

Certain rotaviruses of bovine and simian origin were propagated in cell culture to high titer before development of methods to propagate strains from humans.[27,28] Therefore, the molecular structure of rotavirus was largely determined by studies of the bovine strain, Nebraska Calf Diarrhea Virus,[29] and the simian strain, SA11.[30]

Rotaviruses are 70-nm icosahedral viruses that constitute a distinct genus of the family Reoviridae.[26] The virus is composed of three layers (an outer and inner capsid and a core) that encase the genome of 11 segments of double-stranded RNA.[26] All but segment 11, which contains information for two proteins (NSP5 and NSP6), encode a single protein. Gene segments can be separated on the basis of their molecular weight by polyacrylamide gel electrophoresis.[26] When mixed infections with distinct rotavirus strains occur under experimental conditions or in nature, the gene segments may reassort independently, producing progeny viruses of mixed parentage. Analysis of reassortant rotaviruses has led to identification of the gene segments encoding each of the structural polypeptides. This identification, in turn, has made possible techniques to intentionally reassort rotavirus strains and prepare candidate vaccine strains that incorporate desirable phenotypic characteristics of different parental viruses.[31–33]

Three major structural and one nonstructural protein of rotavirus are of interest in vaccine development (Table 52.1). The outer layer of rotavirus contains two distinct proteins: VP4 and VP7 (Fig. 52.2).[26] Each of these proteins bears type-specific antigenic determinants, elicits serotype-specific neutralizing antibodies, and induces serotype-specific protective immune responses in vivo.[34–37] Protein VP7 is encoded by gene segments 7, 8, or 9 in different rotavirus strains; protein VP4 is encoded by gene segment 4.[26] The most highly represented viral structural protein is VP6, which is found in the internal capsid and bears group-specific antigenic determinants.[38] Three structural proteins (VP1, VP2, and VP3) form the viral core and six other nonstructural proteins (NSP1, NSP2, NSP3, NSP4, NSP5, and NSP6) are also made during infection.[26] NSP4 is an enterotoxin.[39]

Both of the surface proteins, VP4 and VP7, elicit distinct serotype-specific neutralizing antibodies as well as, in certain

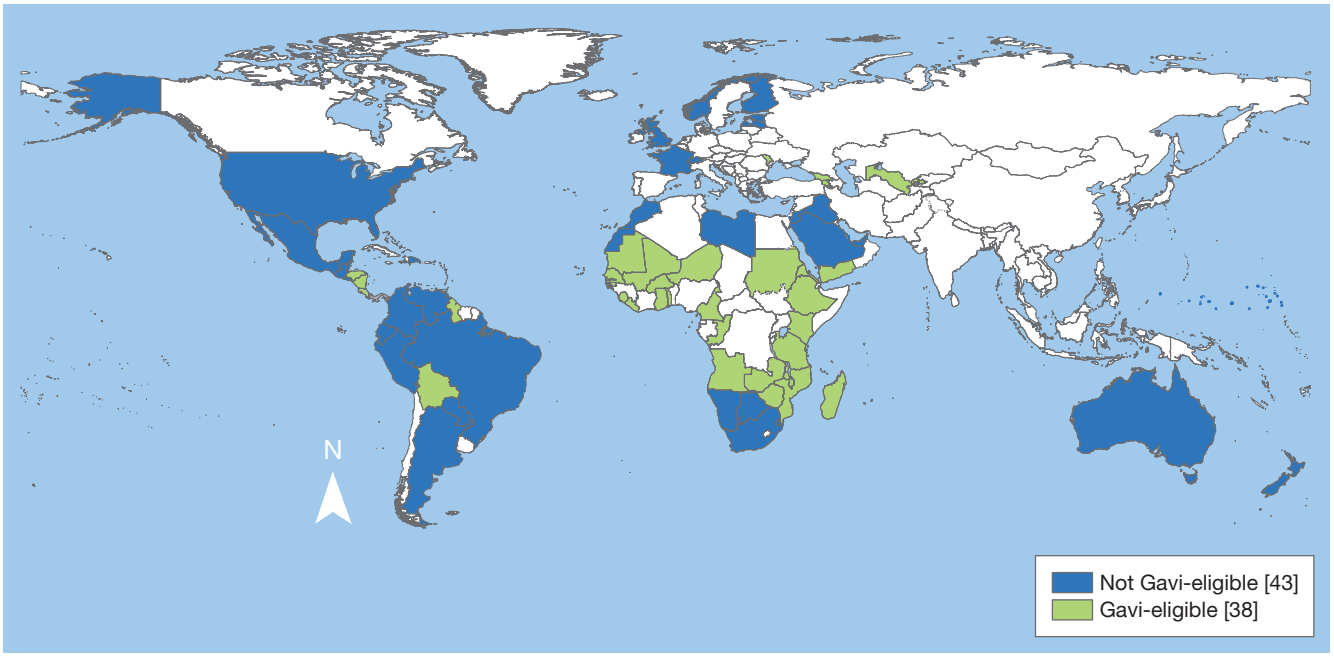

Figure 52.1. Countries that have included rotavirus vaccines in their national immunization programs, as of May 2016.

TABLE 52.1 Biologically Significant Structural and Nonstructural Rotavirus Proteins

Designation	Product of Gene Segment	Approximate Molecular Weight (kDa)	Virion Localization	Biological Significance
VP4[a]	4	88,000	Outer capsid	Type-specific antigen, hemagglutinin
VP6	6	44,000	Inner capsid	Major subgroup antigen
VP7	7, 8, or 9	38,000	Outer capsid	Type-specific antigen
NSP4	10	28,000	Nonstructural	Enterotoxin[a]

[a]Trypsin cleaves VP4 yielding VP5 (MW 60,000) and VP8 (MW 27,000).

Molecular biology of rotaviruses.* Adv Virus Res. *1990;38:1–43; and Ball JM, Tian P, Zeng CQY, et al. Age-dependent diarrhea induced by a rotaviral nonstructural glycoprotein.* Science. *1996;272:101–104.*

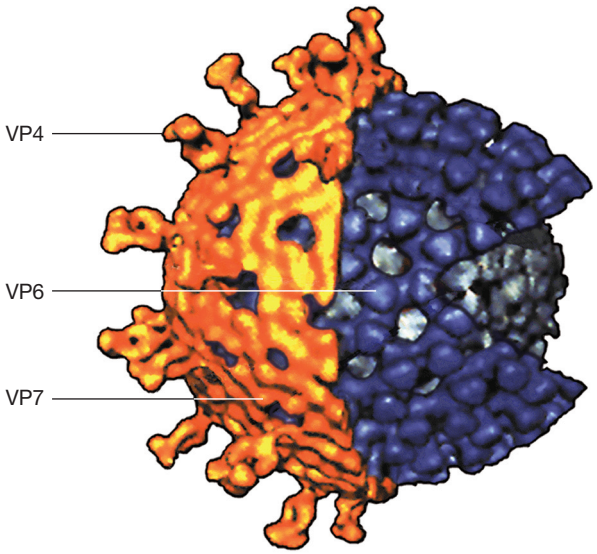

Figure 52.2. Three layers of a rotavirus particle: inner core, inner capsid, and outer capsid. Two surface proteins (VP4 and VP7) and one inner capsid protein (VP6) are shown.

circumstances, cross-reactive neutralizing antibodies.[40–46] The VP7 protein is glycosylated and serotypes determined by this protein are termed *G types*[26]; 27 rotavirus G serotypes have been identified. The VP4 protein is cleaved by the protease trypsin into VP5 and VP8; serotypes determined by the latter protein are termed *P types*.[26] The P protein presents in the form of 60 protein dimer spikes (the hemagglutinin) that extend beyond the VP7 surface of the virion while also penetrating through the outer capsid to interact with VP6 on the inner capsid.[47] Because of extensive cross-reactivity among different P types, it has not been possible to classify all P types by use of polyclonal hyperimmune antisera or monoclonal antibodies alone, although the major P serotypes have been established. This led to development of an additional system of P typing into genotypes identified by nucleic acid hybridization and nucleic acid sequencing studies.[48] Thirty-seven P genotypes have been identified.

Because of the above phenomena, a complex nomenclature has been developed. A complete rotavirus serotype is described using a number (or a number and letter) for the P serotype, followed by a number in brackets that represents the P genotype. This is followed or preceded by the G type designation (e.g., P1A[8]G1). Table 52.2 lists the most common human serotypes.

TABLE 52.2 Common Human Group A Rotavirus Serotypes Worldwide

VP4 Serotype (Genotypes)	Associated VP7 Types
P1A[8]	G1, G3, G4, G9, G12
P1B[4]	G2
P2[6]	G9, G12

PATHOGENESIS

Studies of rotavirus pathology and pathophysiology in animals and humans focus on four important questions:

1. In which intestinal and nonintestinal tissues do rotaviruses replicate and induce disease?
2. By what mechanism does rotavirus induce gastroenteritis?
3. Why is rotavirus-induced gastroenteritis primarily a disease of the young?
4. What factors determine why rotavirus disease is more severe in developing than in developed countries?

Studies of natural rotavirus infection indicate that rotavirus replication is restricted to mature villous epithelial cells in the mucosal surface of the small intestine.[49–54] Replication progresses from the proximal to the distal small intestine.[52,54] Rotaviruses do not appear to replicate in immature epithelial cells of the villous crypt or in M cells overlying Peyer patches.[55] Despite epidemiologic support for respiratory spread, there is no clear evidence that rotaviruses productively replicate in organs or tissues other than the intestine. Rotavirus antigen, RNA, and live virus have been identified in blood during rotavirus infection, and RNA has been identified in cerebrospinal fluid, but the significance of these observations is unknown[14,22,23,55a,55b,55c]; rotaviruses have never been shown to replicate productively in humans in sites distant to the intestine. Although simian rotaviruses have been shown to replicate in hepatocytes of inbred mice, often leading to biliary atresia,[56,57] the relevance of these findings to human infection remains unclear.

Rotavirus replication in intestinal epithelial cells causes several physiologic and morphologic changes. Infected animals have a decreased capacity to absorb sodium, glucose, and water and have decreased levels of intestinal lactase, alkaline phosphatase, and sucrase.[58,59] These findings are consistent with an absorptive abnormality associated with an accelerated migration of immature epithelial cells toward the villous tip. Because no inflammatory changes occur in the lamina propria, in Peyer patches, or at the intestinal mucosal surface,[49–54] it is unlikely that intestinal epithelial cell damage is mediated by the host immune response.

One of the rotavirus nonstructural proteins, NSP4, acts as a viral enterotoxin.[39] Exposure of intestinal epithelial cells to NSP4 induces diarrhea in suckling mice in an age-dependent, dose-dependent, and specific manner. Disease is caused by excess chloride secretion by a calcium-dependent signaling pathway that can be blocked by oral administration of human immunoglobulin.[60,61] This finding is consistent with animal studies using reassortant rotaviruses generated from pathogenic and nonpathogenic strains,[62] indicating that the genes that encode pathogenic VP3, VP4, VP7, and NSP4 of the pathogenic strain were all required to reconstitute virulence. Because virus replication is required for generation of nonstructural proteins, it is not surprising that attenuation of rotavirus virulence can occur without attenuation of NSP4.[63]

Rotavirus infections are more likely to be severe in children 3 to 24 months of age than in younger infants or older children and adults.[64–67] Several studies have offered possible explanations for these differences in age susceptibility. First, children of increasing age may be protected by a virus-specific immune response generated by repeated natural infections.[68] Protection of young infants may be mediated by passively transferred, transplacental, maternal antibodies. Breastfeeding clearly protects against rotavirus disease.[69] Second, infant mice have a larger percentage of intestinal epithelial cells with putative rotavirus-binding proteins on the surface than do older mice[70]—an observation that correlates directly with the age susceptibility to disease. Last, rotavirus entry into target cells is facilitated by cleavage of VP4,[71,72] which occurs in the presence of trypsin, elastase, or pancreatin.[73] Quantities of these exopeptidases are decreased in intestinal fluid secretions of newborn infants compared with older infants and young children.[74]

Children in developing countries are more susceptible to severe rotavirus disease than those in developed countries.[75] This is probably a consequence of poor access to hydration therapy and medical care, poor nutrition, concomitant infections with other viruses and enteropathogenic and toxin-producing bacteria, and possible differences in the gut microbiome.[76,77] Several studies in animals support the hypotheses that poor nutrition,[78,79] or associated bacterial infections, may enhance the severity of rotavirus-induced enteritis.[55,79,80]

IMMUNOLOGIC FACTORS ASSOCIATED WITH PROTECTION AGAINST DISEASE

Protection against reinfection, which has been reviewed,[81,82] focuses on two important questions:

1. Which effector function or functions of the immune response mediate protection?
2. What is the importance of including different rotavirus serotypes in an optimal vaccine?

In 1983, the role of immunity to rotavirus was demonstrated by studies of natural infection in neonates.[83] Neonates infected in the first month of life were not protected against rotavirus reinfection but were protected against moderate to severe disease on reinfection. Conversely, neonates not infected with rotavirus during the first month of life were fully susceptible to diarrheal disease associated with the first rotavirus infection. Since then, studies of natural infection in infants and young children indicate that prior infections protect against severe disease upon reinfection.[84,85] In birth cohort studies from Mexico,[68] Guinea Bissau,[86] and India,[86a] a primary rotavirus infection conferred 77%, 70%, and 43% protection, respectively, against subsequent rotavirus disease (any severity). In Mexico, two previous infections provided 100% protection against subsequent moderate or severe rotavirus disease, but in India, three previous infections provided only 79% protection against this outcome. Such cohort studies from various geographic areas have examined preexisting antirotavirus IgG and IgA levels and subsequent rotavirus infections and disease episodes, with differing estimates of association.[84,85,86b,86c] Protection is associated with the presence of virus-specific immunoglobulin (Ig) A at the intestinal mucosal surface[87,88] and therefore serum IgA responses are often measured to evaluate immune responses to vaccines. However serum IgA antibodies do not accurately predict rotavirus-specific IgA antibody levels at the intestinal surface of infants.

While IgG- or IgA-binding antibody responses to vaccine have not consistently correlated with protective efficacy,[88a,88b] a recent analysis found serum antirotavirus IgA titers, in

aggregate, correlated with vaccine efficacy based on clinical trials of the two vaccines currently in wide use.[88c] Serotype-specific serum neutralizing antibody responses are often also measured. This is based on the knowledge that maternal protection following rotavirus infection is at least partially serotype-specific and virus-neutralizing antibodies have most often correlated with protection in many other infectious diseases.

Although natural rotavirus infection protects against moderate to severe disease caused by reinfection, some children experience repeated episodes of diarrhea with the same serotype during the following rotavirus season,[83,89–99] and a small number of children develop symptomatic rotavirus infection twice within the same season.[87] These observations are consistent with the fact that effector functions at mucosal surfaces, such as production of virus-specific secretory IgA (sIgA), are usually short-lived and that rotavirus-specific sIgA often is not detected at the intestinal mucosal surface within 1 year of symptomatic infection.[83,87–100] Modification of the severity of rotavirus disease caused by reinfection is most likely mediated by production of virus-specific sIgA by memory rotavirus-specific B cells located in the intestinal lamina propria.[101]

The presence of rotavirus-specific sIgA at the intestinal mucosal surface (as reflected in the feces) and in serum is predictive of protection against disease in studies of natural infection but not in vaccine trials. Virus-specific IgA in feces or serum did not predict protection against disease after immunization of infants with simian-human reassortant rotaviruses.[102–104] Several explanations for this phenomenon have been posited. First, the absence of rotavirus-specific sIgA in feces does not necessarily predict the absence of rotavirus-specific memory B cells in the intestinal lamina propria.[101] The presence of rotavirus-specific memory B cells in the lamina propria can only be determined by intestinal biopsy. Second, protection against rotavirus disease after immunization with animal rotaviruses might be mediated in part by virus-specific cytotoxic T lymphocytes. Whereas the role of rotavirus-specific cytotoxic T lymphocytes in protection against human disease is unknown, some evidence supports their importance in protection against disease in animals.[105–108] Alternatively, after immunization, cytokines with antiviral activity that are produced by activated CD4-bearing T cells may be generated either earlier or in greater quantities than after primary infection. Studies have found that rotavirus-specific CD4-bearing T cells alone mediated protection against challenge in experimental animals.[109,110] Several cytokines have been found to block rotavirus replication in vitro.[111]

It has been reported in some instances that natural infection or immunization of children with one rotavirus serotype induced protection against challenge with a different serotype (heterotypic protection).[93,112] Heterotypic protection may be mediated by antibodies directed against cross-reactive epitopes on outer capsid proteins VP4 and VP7,[42] antigenically conserved inner capsid proteins that are actively transported through rotavirus-infected villous epithelial cells,[113] rotavirus-specific cytotoxic T lymphocytes that broadly cross-react with cells infected with different rotavirus serotypes,[114] or antiviral cytokines generated by activated CD4-bearing T cells.[109,110,115]

The relative importance of including all common human P and G types in a rotavirus vaccine remains undetermined. However, it is clear that after a primary, natural rotavirus infection infants develop virus-specific neutralizing antibodies in serum directed against the infecting G type at levels greater than those directed against other G types.[116–120] In a similar manner, it has been reported that children are more likely to be protected against disease after reinfection with a G type to which they have already been exposed.[89,93] Finally, protection against rotavirus disease in adults challenged with a virulent human rotavirus strain (G1P1A[8]) correlated with antibodies directed against homotypic VP4 and VP7.[121] This may explain, in part, why heterotypic protection following administration of vaccines is inconsistent (see below).

DIAGNOSIS

Electron microscopy, which once served as the reference standard for diagnosis of rotavirus infections, has now been replaced by enzyme-linked immunosorbent assay (ELISA). ELISA, which uses either polyclonal or monoclonal antibody preparations directed against the antigenically conserved inner capsid protein VP6, is as sensitive as electron microscopy but easier and less expensive to use.[122,123] However, false-positive ELISA results have been reported.[124]

The detection of rotavirus by polyacrylamide gel electrophoresis, although not commercially available, offers several advantages over ELISA. Assays that detect rotaviral genome, such as polyacrylamide gel electrophoresis and polymerase chain reaction, are absolutely specific for rotavirus. In addition, detection of migration patterns of segmented double-stranded RNA (electropherotypes) is of value in determining specific strains associated with community outbreaks or nosocomial infections, as is reverse transcriptase–polymerase chain reaction with partial sequencing of the gene coding VP7.[125] Indeed, because of difficulty in developing highly specific antisera against certain rotavirus P-serotypes, many have been classified only by characterization of their nucleic acid. Such strains are designated as *genotypes* with arbitrary numbered serotypes assigned based upon each P type newly identified by its genotype.

Reverse transcriptase–polymerase chain reaction is more sensitive than ELISA or electrophoresis in detecting small concentrations of rotavirus, particularly from clinical stool specimens.[126,127] A technique for VP7 typing of rotavirus in stool samples using partial genome product sequencing has proved consistently useful for characterizing specific serotype subtypes and allowing worldwide assessment of rotavirus strain relationships.[125]

EPIDEMIOLOGY

Rotavirus is a ubiquitous infection in young children.[2] In settings without rotavirus vaccines, nearly all children are exposed to rotavirus and acquire antibodies by 2 to 3 years of age and most rotavirus diarrhea occurs during the first 3 years. In the first 3 months, infections might be asymptomatic or less severe than those in older infants; this is most likely a result of the protective effect of passively transferred maternal antibodies or breastfeeding or both. Infections in neonatal nurseries are often asymptomatic.[83] First infections after 3 months of age are generally associated with diarrhea that can range from mild to severe, whereas subsequent exposures lead to milder illness or asymptomatic infections.[68,84,85,87,128] The observation that nearly all children throughout the world, regardless of socioeconomic status, were infected early in life suggests that rotavirus is not primarily transmitted through fecally contaminated water or food, as distinct from bacterial or parasitic pathogens. Therefore, improvements in water, sanitation, and hygiene are not likely to substantially alter the incidence of disease. The priority placed on prevention of rotavirus by vaccination is predicated on the great global disease burden of rotavirus, the recognition that natural immunity is protective, and the expectation that alternative public health measures, including the provision of clean food and water, are unlikely to fully prevent disease.[1,129] Also, although infants in developing countries experience many more episodes of gastroenteritis every year than those in developed countries, the percentage

of rotavirus disease in hospitalized infants with dehydration secondary to diarrhea (approximately 40%) was similar in developing and developed countries before vaccine introduction.[130] Clearly, rotavirus causes most of the life-threatening gastroenteritis, regardless of the economic status of a nation, if vaccine is not in use.

Little is known about the exact mode of transmission of rotavirus. Person-to-person contact or exposure to aerosolized respiratory droplets are the most likely modes of transmission. In a mouse model, airborne spread of epidemic diarrhea by a murine strain has been reported.[131] Furthermore, rotavirus disease has a distinct winter seasonality in temperate climates that is similar to that seen for viruses spread by the respiratory route, such as influenza, respiratory syncytial virus, and measles. Before implementation of rotavirus vaccination in the United States, annual rotavirus epidemics began in the Southwest and spread to the North and East. The reasons for this phenomenon are not clear, although a recent mathematical study correlated the earlier onset of rotavirus activity in the West with higher birth rates in Western U.S. states, possibly resulting in more rapid accumulation of susceptible infants through births in each rotavirus season.[132] Following implementation of rotavirus vaccination in 2006, postvaccine seasons have demonstrated a delayed onset and distortion of the geographic patterns seen in prevaccine seasons. A south-to-north migration of rotavirus activity has been documented in Europe, and has been correlated with variations in birth rates, temperature, and rainfall.[133]

Humans are believed to be the only reservoir of human rotaviruses and consistent transmission of animal rotavirus strains to humans seems unlikely. Nevertheless, although classical epidemiology has failed to identify transmission of virus from animals to humans, reassortant strains composed of genomic segments from both human and animal rotaviruses have been identified. The presence of wild-type animal–human reassortants indicates that some mixing of strains must occur in nature and that these reassortments might be important for virus evolution.[134–136]

Global surveillance has led to the characterization of at least 27 G types and 37 P types in humans, and because rotavirus has a segmented genome, gene reassortment could theoretically lead to almost 1000 different G and P combinations. Although more than 60 G-P combinations have been found in human beings, just five strains (P[8], G1; P[4], G2; P[8], G3; P[8], G4; and P[8], G9) cause 80% to 90% of childhood rotavirus disease globally (see Table 52.2). Certain histo–blood-group antigens expressed on enterocytes have recently been proposed as receptors or ligands for the P protein of rotaviruses and associations between a population's frequency of particular histo–blood-group antigens and disease (or lack of disease) from particular rotavirus P genotypes have been made.[137–141] The distribution of various rotavirus strains varies by region and over time within the same region[142]; these natural variations are important to keep in mind when monitoring ecologic changes in rotavirus strains following the implementation of rotavirus vaccination.

Certain clues about immunity and transmission of rotavirus can be gained from epidemic investigations and special studies. Whereas immunity is believed to protect adults from disease,[143–146] parents and caretakers of children with rotavirus diarrhea often get disease, perhaps because practices such as diaper changing expose them to a large infectious dose.[146–152] Outbreaks in childcare centers and hospitals can spread rapidly among nonimmune infants and young children, presumably because of person-to-person contact, airborne or droplet spread, or contact with contaminated toys.[150–152] In the elderly, outbreaks have been described that may be linked to waning immunity or institutional crowding or both. Of note, many of these outbreaks have been associated with G2 strains rather than other more common rotavirus serotypes.[153–155] In adults traveling from developed to developing countries (i.e., persons who would be expected to be immune to rotavirus), the virus has been identified as a cause of diarrhea, perhaps because the mode of transmission is different or the inoculum size is greater.[156] In addition, people immunocompromised by HIV infection,[157] hereditary immunodeficiency,[158,159] immunosuppression for organ transplantation,[160] or chemotherapy can develop rotavirus diarrhea with virus shedding that can persist for months.

Given the relatively high prevalence of HIV in some developing country settings, it is important to evaluate the safety of rotavirus vaccines in HIV-infected infants. It is anticipated that rotavirus vaccines will be well tolerated in HIV-infected infants, given that the vaccines are composed of highly attenuated viruses. In addition, wild-type rotavirus does not lead to more-severe disease in HIV-infected as compared with uninfected children. Studies conducted in the United States, Latin America, and several countries in Africa have shown that the presentation of rotavirus is similar in HIV-infected and uninfected infants.[161–166] The severity of symptoms, duration of hospitalization, and age at presentation does not appear to differ by HIV status. One study showed shedding of rotavirus up to 3 weeks after onset of symptoms in a higher proportion of HIV-infected than uninfected infants; however, the shedding was not associated with symptoms.[161] Furthermore, Rotarix (see below) was found to be safe in HIV-infected infants in South Africa.[167] Another factor that supports the safety of rotavirus vaccines in HIV-infected infants is the tolerability of oral polio vaccine (OPV) in this population. OPV is a live vaccine that replicates vigorously in the intestinal tract. There is no evidence of an increased risk of vaccine-associated paralytic poliomyelitis in HIV-infected infants.[168]

Several differences in the epidemiology of rotavirus diarrhea between developed and developing countries may affect future considerations concerning the use of vaccines. The distinct winter seasonality of rotavirus hospitalizations in temperate climates stands in contrast to the year-round disease seen in several tropical settings.[10] This means that a child born in a temperate climate immediately after the rotavirus season will have to wait many months before encountering the first possible natural infection during the following year's winter season. A child born in a tropical setting could be exposed any day of the year. Consequently, the average age at first infection is often younger in developing countries in tropical areas. In such tropical countries the first episode of rotavirus disease occurs most often during the first year of life, whereas frequently in developed countries the greatest prevalence of first rotavirus infections occurs in the second year of life. Therefore, an effective vaccine program in a developing country may require earlier and higher levels of coverage than a vaccine program in a developed country.[86a,168a] The Expanded Program on Immunization schedule, which is widely used throughout the developing world, calls for completion of the third vaccination visit by 14 weeks of age, which would provide such early coverage regardless of the rotavirus vaccine used. For unexplained reasons, fecal specimens from children from developed countries are typically infected with a single strain of virus of one of the common serotypes found globally,[155,169] while in developing countries, the rate of mixed infections with two or more strains can be as high as 30%. These mixed infections as well as single-virus infections in developing countries may include uncommon serotypes not found in other parts of the world.[171] Nevertheless G1 to G4 and G9 serotypes are still predominant (~80% of all strains); thus, a vaccine that provides protection against these strains would be expected to have broad coverage in the developing world.

TABLE 52.3 Burden of Rotavirus Disease in the United States and Worldwide Prevaccine

	United States		Worldwide	
Parameter	**Total**	**Risk Per Child**	**Total**	**Risk Per Child**
Births	3.9 million	—	130 million	—
Rotavirus gastroenteritis	2.7 million	1 in 1.4[a]	111 million	1 in 1.2
Physician, ED visits	600,000	1 in 6.5	2.5 million	1 in 52
Hospitalizations	55,000–70,000	1 in 70	2 million	1 in 65
Moderate to severe disease	—	—	16 million	1 in 8
Deaths	20–60	1 in 100,000	450,000–600,000	1 in 250
Medical costs	$400 million	—	—	—
Indirect and direct costs	$1 billion	—	—	—

[a]Meaning that 1 of every 1.4 children born in the United States will have at least one episode of symptomatic rotavirus infection.
ED, emergency department.

The burden of rotavirus diarrhea for children in developing countries became evident when the first diagnostic tests were used to study the etiology of diarrhea in hospitalized children (Table 52.3). In more than 100 studies conducted around the world among children younger than 5 years of age who were hospitalized for diarrhea, rotavirus was the most common cause of diarrhea (detected in 20–60% of cases). Prospective studies of children observed from birth to 2 years of age suggest that the incidence of rotavirus diarrhea varies directly with the intensity of surveillance. These studies indicate that 77% to 83% of children will have an episode of rotavirus diarrhea in their first 2 to 3 years of life and, depending somewhat on the locale,[172–174] seek medical attention or treatment.

In developed countries, rotavirus was originally considered to be a mild, inconsequential infection of children. This point of view was proved incorrect when early studies documented a clear winter peak of rotavirus-associated hospitalizations that accounted for as much as 80% of cases of winter diarrhea.[6,175,176] On the basis of these surveys, the Centers for Disease Control and Prevention (CDC) developed national estimates for rotavirus diarrhea. These estimates, prior to the use of rotavirus vaccines, indicated that by the end of the second or third year of life 60% to 80% of all children developed a rotaviral diarrheal illness (~2.7 million episodes per year), one in 6.5 sought medical attention, one in 70 (55,000–70,000 patients) were hospitalized, and one in 66,000 to one in 200,000 (20–60 children) died from rotavirus.[4,177] The estimated rate of hospitalizations for rotavirus gastroenteritis among U.S. children (~275 per 100,000 for children younger than 5 years of age) was lower than the estimated rates for the United Kingdom,[178] Australia,[179] Ireland,[180] Venezuela,[181] and Finland, which ranged from approximately 800 to 3000 per 100,000. The cost of medical care in the United States was estimated to be more than US$400 million; indirect costs were estimated to be more than US$1 billion.[7] However, because rotavirus can cause vomiting and fever in the absence of diarrhea,[182] estimates of disease burden from U.S. medical records that include a code for diarrhea alone may underestimate the actual incidence of disease.

PASSIVE IMMUNIZATION

Passive immunization with rotavirus-specific antibodies administered by the oral route ameliorates acute rotavirus infection in infants.[183–186] Sources of rotavirus-specific antibodies studied have included pooled commercial preparations of human serum immunoglobulin or colostrum from cows parenterally immunized with rotavirus. In both immunocompetent and immunocompromised children, oral inoculation with rotavirus-specific antibodies caused a decrease in the number of days with diarrhea as well as a decrease in the length of hospital stays. No commercial source of rotavirus antiserum for therapy is currently available.

ACTIVE IMMUNIZATION

Nonhuman Rotaviruses

Initially, researchers examined two bovine- and one simian-origin rotavirus as oral vaccines for humans. In each case, promising early clinical trials characterized by low pathogenicity and impressive protective efficacy were followed by more extensive trials yielding inconsistent results. They are described briefly below because many of their phenotypic characteristics are retained in reassortant vaccines. A single animal rotavirus strain of lamb origin is currently available in China.

Bovine Strain RIT4237

The first rotavirus vaccine to be evaluated in humans was the bovine strain Nebraska Calf Diarrhea Virus (P6[1]G6),[29] which was named RIT4237 for use in human trials.[187] This virus was highly attenuated by approximately 200 passages in bovine cell culture and most often was administered to infants at a dose of 10^8 median tissue culture-infective doses. Induction of immunity to the vaccine virus was associated with minimal replication and minimal shedding of vaccine virus in feces.[188] Between 50% and 70% of vaccine recipients had a humoral immune response measured by rotavirus-specific ELISA for serum IgG or IgA or by neutralization of the vaccine virus strain.[188–190] Adverse clinical events were not noted in infants as young as 2 weeks of age.

In two initial efficacy trials of RIT4237 in 6- to 12-month-old Finnish infants, 50% and 58% were protected against all rotavirus diarrhea and 88% and 82% were protected against clinically significant disease.[190,191] The natural challenge was serotype P1A[8]G1. In subsequent efficacy trials performed at other sites, little or no protection was observed.[192–194] As a result, RIT4237 was withdrawn from further development.

Several principles generally applicable to oral rotavirus vaccines in infants were established with RIT4237:

1. A live, attenuated oral vaccine could protect children against natural rotavirus challenge.

2. The highest rates of immune response were achieved in infants 5 to 12 months of age, a time when prevaccination serum antibody levels, which reflected passively transferred maternal antibodies, were minimal.[188,190,195]
3. The specificity of virus-neutralizing antibodies in serum was primarily restricted to the homologous (G6) serotype, but heterotypic immunity could protect children against human strains.[196,197]
4. Administration of infant formulas to buffer stomach acids given before the vaccine enhanced virus-specific immune responses.[198,199]
5. Coadministration of OPV with a bovine-origin rotavirus vaccine had the potential to inhibit rotavirus-specific immune responses.[200]
6. Protection against severe rotavirus disease was always more efficient than protection against all rotavirus disease.

Bovine Strain WC3

The parent rotavirus strain Wistar Calf 3 (WC3; P7[5]G6) was isolated from a calf with diarrhea in Pennsylvania in 1981 and passaged 12 times in African green monkey kidney cells.[201] Like RIT4237, WC3 vaccine was given at high titers (10^7 plaque-forming units [PFU] per child), was shed infrequently in feces, and was well tolerated.[201,202] Virus-specific neutralizing antibody responses in serum occurred in 71% to 100% of infants in trials in the United States and were primarily homotypic.[201]

In an initial double-blinded, placebo-controlled, efficacy trial in Philadelphia, WC3 vaccine caused a 76% reduction in rotavirus morbidity and 100% protection against moderate to severe rotavirus diarrhea when the natural challenge strain was P1A[8]G1.[112] Levels of virus-neutralizing antibodies did not correlate with protection from rotavirus illness. In a subsequent efficacy trial of WC3 conducted in Cincinnati, 100% of infant vaccine recipients developed WC3-specific neutralizing antibodies but none were protected against G1 rotavirus disease.[203] However, following immunization with WC3 vaccine, seropositive infants with evidence of prior infection exhibited booster responses of broad specificity (G1–G4).[204] In subsequent efficacy trials, WC3 gave little protection in the Central African Republic[205] and only 50% protection in Shanghai. Because protection against rotavirus disease was inconsistent, WC3 was eliminated as a potential vaccine candidate.

Simian Strain RRV

The third animal-origin rotavirus tested in infants was the rhesus rotavirus vaccine (RRV) (P5[3]G3), which was isolated from a young monkey with diarrhea[206] and tested as a vaccine candidate in the 16th cell-culture passage.[206] Although RRV is nominally type G3,[207] the G protein shares only moderate homology with human G3 strains.[208]

RRV was safe and immunogenic in children 2 to 12 years of age,[206] but in infants 5 to 20 months of age, a clustering of febrile responses was noted 3 to 4 days after inoculation.[209] In Finnish infants 6 to 8 months of age, postvaccine fevers (64%) and watery stools (20%) were associated with administration of RRV in quantities of 10^5 PFU.[210] In the same study, infants administered RIT4237 vaccine exhibited a lower rate of serum antibody responses but had no adverse reactions.[210]

The increased incidence of fevers was frequently absent in RRV vaccine recipients in developing countries[211] and in younger infants (4 months of age or younger) inoculated with a lower dose of vaccine. Immunogenicity was less at lower doses (i.e., 10^4 PFU) and in children who were breastfed or did not receive a buffer before vaccination.[211–213] RRV at a dose of 10^4 PFU was not reactogenic in newborn Venezuelan infants.[214] Coadministration of RRV and OPV did not appear to lead to significant inhibition of serum antibody responses to either vaccine.[214,215]

Results of clinical efficacy trials of RRV varied. Infants were given a single dose of 10^4 PFU between 2 and 12 months of age. Trials in Finland and Sweden identified modest protection (38% and 48%, respectively) against all cases of rotavirus diarrhea, but greater efficacy against severe rotavirus diarrhea (67% and 80%, respectively).[216,217] However, in three trials in the United States, much lower levels of protection were observed. In all these trials, the natural challenge viruses were predominantly G1.[194,218,219]

The greatest efficacy of RRV was observed in Venezuela. The vaccine protected 65% of children from all rotavirus disease and 100% of children from severe disease[220]; consistent with that observation, the natural challenge rotavirus strains were predominately serotype G3. Vaccine-associated reduction in cases identified as G1, G2, or G4 (67%) was similar to the efficacy against G3 (70%).[221] Because protection against rotavirus disease was inconsistent, RRV was not pursued as a vaccine candidate.

Lamb Strain Lanzhou Lamb Rotavirus Vaccine

The Lanzhou Lamb Rotavirus Vaccine (LLR), developed at the Lanzhou Institute of Biological Products, is licensed in China.[222] This live oral vaccine, which was derived from an ovine rotavirus isolated in 1985 and characterized as P[10]G12, was passaged 42 times in calf kidney cells. The vaccine is a liquid formulation with buffer containing $10^{5.5}$ infectious particles per dose in a volume of 3 mL and is given as a single dose between 2 and 24 months of age. In an efficacy trial, two cases of rotavirus diarrhea occurred among 1506 vaccine recipients and eight cases occurred among 1583 placebo recipients (73% efficacy). The rates of mild reactions were similar in the vaccine and placebo groups. The vaccine was licensed in China in 2000 and currently is being sold in several provinces. Postlicensure evaluations have found one dose, or one or more doses, of LLR to be 35.0% to 73.3% effective against rotavirus diarrhea requiring hospitalization.[223,224,224a]

Animal X Human Reassortant Rotaviruses

Because protection induced against rotavirus disease by animal rotavirus strains was inconsistent, vaccine researchers focused efforts on recombinant (reassortant) rotaviruses. Such reassortant strains were prepared by using simian (RRV) or bovine (WC3 or UK) rotaviruses. In vitro–derived reassortants were selected bearing a human VP7 protein (to evoke human G type-specific neutralizing antibodies) and the remaining genes from an animal rotavirus (to attenuate rotavirus virulence for infants).[62,225] One multivalent bovine (WC3) human reassortant vaccine (RotaTeq) also contains a reassortant strain containing human VP4 (to evoke human P serotype-specific neutralizing antibodies). In addition, naturally occurring bovine–human reassortants ("Indian strains") currently are being tested as vaccines.

The first generation of reassortants, including those in the first licensed vaccine (RotaShield), were designed to contain the gene coding for VP7 of a human virus and 10 genes of the animal virus. To prepare a reassortant, susceptible cell cultures, usually derived from African green monkeys, were coinfected with a human virus and an animal virus (Fig. 52.3). Reassortment of viral gene segments occurred by chance and a virus containing the desired human virus VP7 was selected, often by suppressing the VP7 of animal origin with a monotypic

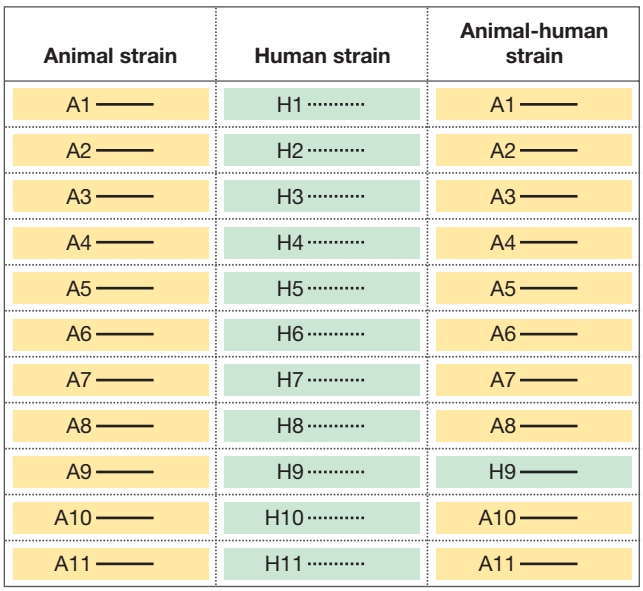

Figure 52.3. The rotavirus genome consists of 11 individual segments of double-stranded RNA (dsRNA). Segments can be distinguished by their pattern of migration following electrophoresis in polyacrylamide gels. Progeny virions resulting from coinfection of monkey kidney cells with an animal and a human rotavirus strain often contain gene segments from each parent. The animal-human reassortant rotavirus strain shown has 10 dsRNA segments from the animal strain and 1 segment (gene segment 9) from the human strain.

antiserum against that protein. Viruses with the human VP7 gene accompanied by 10 genes from the animal virus were selected by use of gels identifying all the genomic segments of the reassortants. In some cases, additional confirmation of the origin of each reassortant gene was obtained by sequencing the viral genome.

Simian (Strain RRV)–Human Reassortant Rotaviruses (RotaShield)

The first reassortant rotavirus vaccine candidates consisted of simian–human rotavirus reassortants that contained a single human gene (i.e., that coding for VP7) and the remaining 10 genes from RRV. These reassortant viruses were prepared at the Laboratory of Infectious Diseases at the National Institutes of Health.[226]

RotaShield was licensed for universal use for infants in the United States in August 1998. However, because the vaccine was later found to be a rare cause of intussusception, the recommendation to use RotaShield was withdrawn in October 1999.

Composition. The vaccine (RotaShield), produced by Wyeth-Lederle, contained RRV (P5[3]G3) and three simian–human reassortants of G types 1, 2, and 4, each in a virus containing all the other genes of RRV. The human virus genes were from strain D1 (RRV-G1), DS1 (RRV-G2), and ST-3 (RRV-G4). This quadrivalent combination of RRV with three simian–human reassortant rotavirus strains was called RotaShield.

Dosage and Route. Field trials of the quadrivalent RRV-human reassortant vaccine were initiated at an inoculum of 10^4 PFU of each of the four viruses (i.e., a total dose of 4×10^4 PFU) and completed at a dose of 1×10^5 PFU per strain (4×10^5 PFU total), the dose of the licensed vaccine.[226] In each of these trials, vaccine was administered orally in three doses, immunizations were separated by at least 3 weeks, and dosing was completed by the time a child was 6 to 7 months old. Protective outcomes were determined either by recording episodes of rotavirus diarrhea reported through active surveillance by field workers during the rotavirus season or passive catchment surveillance of children attending a clinic or hospital for diarrhea confirmed to be caused by rotavirus. In the United States, two separate but comparable multicenter trials using either the low (10^4 PFU per strain) or the high (10^5 PFU per strain) doses did not demonstrate a significant difference in efficacy.[103,227] However, in Latin America, two trials conducted in Peru[228] and Brazil[229] with the lower dose of vaccine each demonstrated a lower efficacy against severe disease than a trial with the same low dose in the United States and a trial with the higher dose conducted in Venezuela.[230]

Immunogenicity. RotaShield was developed with the hope that children would develop serotype-specific immunity to the four most common G types of rotavirus in global circulation at that time (G1, G2, G3, and G4). Whereas more than 90% of children developed an immune response, as measured by the appearance of virus-specific serum IgA or virus-neutralizing antibodies directed against RRV, few children (<50%) developed serotype-specific neutralizing antibodies to any of the four human G serotypes.[227] Nonetheless, studies of efficacy of RotaShield outperformed those using a single RRV-human reassortant (containing human G1) in seasons when strains other than G1 were circulating. This finding indicated that the strategy of using RotaShield to afford broad protection against several serotypes was correct even if there was not an adequate immunologic marker to predict protection against challenge or a complete understanding of the mechanism of this protection.[103,227,231] In a rare clinical trial in which the predominant natural challenge was not serotype G1 (but was G3), the quadrivalent RRV reassortant vaccine, which contained a strain (RRV) that was of G3 specificity, was clearly more protective than was a monotype G1 RRV reassortant, lending further evidence to the utility of multivalent vaccines.[232]

Efficacy. Seven efficacy trials of RRV-human vaccine were conducted, three using the vaccine in the lower dose and four using the vaccine in the higher dose. In all these trials, infants were enrolled for immunization between 6 weeks and 2 months of age and three doses were given by mouth. Efficacy was greater against severe disease than against mild disease and, in trials lasting 2 years, protection endured for both years.[232]

In general, the efficacy of the RRV-human reassortant vaccine was lower in developing countries. The protective efficacy of the low-dose vaccine was poorest in Peru,[228] intermediate in Brazil,[229] and best in the United States.[103] In a similar manner, the higher-dose preparations performed least well among Native Americans,[194] better among Venezuelans[230] and Americans,[232] and best among Finns.[233]

In trials using high-dose vaccine, efficacy ranged from 48% to 68% against any rotavirus disease and from 64% to 91% against severe disease. Of particular note, the efficacy reported in Venezuela (48% for mild disease and 88% for severe disease) was not significantly different from that reported in the multicenter trial in the United States using this higher dose (57% and 82%), suggesting that RotaShield might be well suited for use in developing countries. Furthermore, the observation that the higher dose worked well in Venezuela, when a lower dose did not work in Peru or Brazil, suggested that in developing countries vaccine dose might be critical.

Only two trials were large enough to examine protection against hospitalization. In the trial in Finland, all 22 children

hospitalized for rotavirus diarrhea were in the placebo group,[233] and, in Venezuela, efficacy against hospitalization was 70%.[230] A postlicensure effectiveness evaluation at three U.S. hospitals showed 100% protection against hospitalization for rotavirus disease.[234]

Adverse Reactions. A significant increase in mild fevers was observed 3 to 5 days after immunization with the RRV-human reassortant vaccine. Low-grade fevers (temperature >38°C and <39°C) were most common (up to 15%) after the first dose and a small group of children (1–2%) had higher temperatures (>39°C).[103,227,229,232,233] In the Finnish trial, fever was associated with diarrhea and abdominal cramping in approximately 3% of children.[235] No increase in the incidence of vomiting was associated with vaccination in the first 6 months of life. However, in earlier studies with RRV only, older children in Sweden did have an increased incidence of loose stools and fever, suggesting that replication of the virus in older children could lead to mild symptoms of diarrhea.[217] In Bangladesh, the RRV-human reassortant vaccine caused fever in 15% of vaccinees, compared with 2% in placebo recipients. In addition, vaccine strain virus was isolated from some of the latter, indicating contact spread from vaccinees.[236]

Prior to licensure, intussusception was reported in five of approximately 11,000 children who had received RRV-human reassortant rotaviruses compared with one of approximately 4500 children who had received placebo.[231] Intussusception was not found after the first dose in any child, but was observed within 7 days after receiving the second or third dose of vaccine in three of the five affected children. Differences in rates of intussusception between vaccine and placebo recipients were not found to be statistically significant and the incidence of intussusception in vaccine recipients was not greater than estimated background rates. However, both the CDC and the American Academy of Pediatrics warned in their recommendations for use of RRV-human reassortant vaccine that intussusception might be an adverse event associated with vaccination.[231,237] In addition, the possible relationship between the vaccine and intussusception was noted in the product insert.

In July 1999, after the RRV-human reassortant vaccine had been given to approximately 1 million children, 15 cases of intussusception following administration were reported to the Vaccine Adverse Event Reporting System (VAERS).[238,239] Although approximately 2000 cases of intussusception occur each year in the United States, these 15 cases were greater than what would have been predicted given the general underreporting to VAERS. Following these reports, RotaShield was temporarily suspended from use[238] pending results of a case-controlled analysis by the CDC.

In October 1999, the CDC completed its analysis and found that the relative risk 3 to 7 days after receipt of the first or second dose of RRV-human reassortant vaccine was 37 ($P < .001$) and 3.8 ($P < .05$), respectively.[233] Using case series and case-control analysis, the population-attributable risk was initially estimated to be approximately one case of intussusception per 10,000 children immunized.[240,241] The actual attributable risks were one in 4670 to one in 9474 for the case series and case-control studies, respectively. Following results of the CDC analysis, use of the vaccine was discontinued and the manufacturer ceased its production. Subsequent ecologic studies using hospital discharge diagnoses estimated that the attributable risk of intussusception following administration of RRV-human reassortant vaccine might have been much smaller than initial estimates.[242,243]

The cause of intussusception following RotaShield remains unknown. However, because the benefits of the vaccine likely outweigh its risks in the developing world, the vaccine was tested in Ghana, given as two doses administered in the first 2 months of life.[244] The two-dose efficacy against rotavirus gastroenteritis (any severity) to age 1 year was 64%.

Bovine (Strain WC3)–Human Reassortant Rotaviruses (RotaTeq)

RotaTeq (Merck and Co.) was licensed by the U.S. Food and Drug Administration (FDA) and recommended by the CDC and the American Academy of Pediatrics for universal use in U.S. infants in February 2006.[245] RotaTeq is also licensed in the European Union and many other countries.

Composition. RotaTeq is a live, oral vaccine that contains five reassortant rotaviruses developed from human and bovine parent rotavirus strains.[245,246] Four of the bovine (WC3)–human reassortant rotaviruses express human virus VP7 from serotypes G1, G2, G3, or G4 and VP4 (P7[5]) from bovine strain WC3. The fifth reassortant virus contains VP4 (P1A[8]) from a human rotavirus strain and VP7 (G6) from WC3. The human strains that provided surface proteins G1, G2, G3, G4, and P1A for the bovine–human reassortant vaccine were WI79, SC2, WI78, Bricout B, and WI79, respectively. The reassortants were propagated in Vero cells.

Each 2-mL vial of vaccine contains the following minimum concentration of each of the five reassortants: WC3-G1: 2.2×10^6 infectious units; WC3-G2: 2.8×10^6 infectious units; WC3-G3: 2.2×10^6 infectious units; WC3-G4: 2.0×10^6 infectious units; and WC3-P1A: 2.3×10^6 infectious units. Trace amounts of fetal bovine serum might be present. The vaccine does not contain thimerosal or other preservatives.

Buffer and Stability. WC3-human reassortant vaccine is suspended in a solution of buffer (sodium citrate and phosphate) and stabilizer (sucrose) that can be stored refrigerated at 2°C to 8°C for 24 months. The vaccine formulation contains sucrose, sodium citrate, sodium phosphate monobasic monohydrate, sodium hydroxide, polysorbate 80, and tissue culture media. This diluent was adapted following a bivalent (G1 and G2) WC3-reassortant experiment in which no loss of protective potency was observed in the reassortants suspended in the buffer-stabilizer formulation after 125 weeks.[247] The shelf life is 24 months at refrigeration temperature—6 months is reserved for packaging and shipping and 18 months for shelf life in the clinic. The vaccine does not require reconstitution into a liquid form; it requires only that the cap be removed from the squeezable plastic container and the contents then squirted into the infant's mouth.

Immunogenicity

Relative Capacity of VP4 and VP7 to Evoke Neutralizing Antibodies. Infants given one or two oral doses of the univalent G1 or G2 reassortant vaccine tended to have a more efficient neutralizing antibody response in serum to the bovine WC3 (the VP4 antigen in the reassortant) than to G1 or G2 (the human VP7 antigen in the reassortant).[248–252] This led to an early opinion that, unlike the response to parenterally inoculated rotavirus, the neutralizing antibody response to VP4 predominated following oral administration. This phenomenon also had been observed repeatedly in clinical trials with RRV-human reassortant rotaviruses.

However, when a WC3 reassortant was constructed with a human P1A (VP4) and administered orally to infants, the serum neutralizing antibody responses after two doses were predominately to the WC3 VP7 surface G6 component: 76% serum neutralizing antibody response to WC3 (VP7) and only 28% response to the P1A (VP4) surface component.[250,253] When two doses of a mixture of equal concentrations of the

G1 (VP7) and P1A (VP4) single-gene reassortants of WC3 were administered to infants, an excellent neutralizing antibody response in serum was obtained to both the P1AG1 parent (78%) and to the WC3 P7G6 parent (100%).[253] Conversely, less than 35% of infants developed neutralizing antibodies to either WC3 or the human P1AG1 parent after oral inoculation with two doses of one double reassortant (a single virus containing both P1A and G1 on a WC3 background).[250,253] These findings suggest that an animal rotavirus/human rotavirus reassortant (with regard to VP4 and VP7) may have the potential to induce certain antihuman rotavirus immune responses more efficiently than an entirely human rotavirus-origin vaccine; that is, one surface antigen of bovine virus origin in some manner enhances the immunogenicity of the reassortants in response to both surface antigens VP4 and VP7.

Importance of Dose. It was later determined in two separate clinical trials that, compared with two doses of the univalent G1 reassortant, three doses resulted in higher rates of neutralizing antibody responses in serum to both the WC3 (93% after two doses and 95% after three doses) and the P1AG1 (70% after two doses and 78% after three doses) parent viruses.[251] Most infants developed neutralizing antibodies to WC3 after the first dose, a few developed them after the second dose, and almost none developed them after the third dose. In contrast, a minority of infants responded to P1AG1 rotavirus after the first dose, but many more responded to the second and third doses. Infants with neutralizing antibodies to P1AG1 virus prior to the first dose were less likely to develop an antibody response of that specificity after the first dose, but, after three doses, they exhibited response rates similar to those of originally seronegative infants.[254] Therefore, it appears that one or two serial doses given to an infant who lost maternally acquired antibody gives a serum antibody response after the completion of the series that is equal to that of those who were seronegative prior to the first dose.

Efficacy. In a pilot efficacy trial of the WC3-G1 reassortant involving 77 infants given two doses, complete protection against rotavirus disease was observed. Cases of disease in the placebo cohort were caused by either serotype G1 or G3.[252] A subsequent efficacy trial employed three doses of the G1 reassortant administered to 312 infants in either New York or Philadelphia. The vaccine provided 64% protection against all episodes of rotavirus disease and 84% protection against moderate to severe rotavirus disease.[249] The predominant wild-type challenge rotavirus was serotype G1. No adverse effects followed administration of any dose of this vaccine.

Because of the success of the WC3-G1 reassortant vaccine in situations of primarily G1 challenge, additional WC3 reassortants of the other traditionally most common serotypes (i.e., G2, G3, and G4) were constructed, based on epidemiological evidence that protective immunity is at least partly G-serotype-specific. Each was individually evaluated in infants and found to be safe and immunogenic.

Prior to the availability of the G4 reassortant, the principle of using a multivalent WC3 reassortant vaccine was evaluated in an efficacy trial of a WC3–human reassortant vaccine containing human G1, G2, G3, and P1A.[255–258] Quadrivalent WC3–human reassortant vaccine containing G1, G2, G3, and P1A, given in three doses and containing 10^7 PFU of each reassortant, was safe, immunogenic, and protective in a trial involving 439 infants in 10 different U.S. sites. Rates of vaccine virus shedding in feces were less than 10%. There was no significant excess of fever, diarrhea, or vomiting in vaccine recipients. The vaccine provided 74.6% protection against all rotavirus disease and 100% protection against severe rotavirus disease.

In the clinical trial of quadrivalent WC3–human reassortant vaccine containing G1, G2, G3, and P1A, a rotavirus-specific serum IgA antibody response occurred in 88% of vaccine recipients and a fecal rotavirus-specific IgA antibody response occurred in 65% of vaccine recipients.[257,258] The proportion of children who developed virus neutralizing antibodies to serotype G1 was 57%. Similar rates of neutralizing antibody responses specific to types G3, G6, and P1A were observed; the neutralizing antibody response to G2 was slightly lower. The predominant wild-type rotavirus challenge strains as found in placebo cases of rotavirus disease were G1 (26 of 39 episodes) and G3 (10 of 39 episodes), while G2 and G4 were associated with two cases and one case, respectively. The breakthrough cases of rotavirus disease seen in quadrivalent rotavirus vaccine-immunized infants were predominately G1 (10 of 11 cases); the other breakthrough case was G2.

Because rotaviruses are highly acid labile, all the above-mentioned clinical trials involved prefeeding of vaccine recipients with breast milk, infant formula, or Maalox. These trials also involved a frozen product thawed immediately before use. Because prebuffering and use of a frozen product are impractical, a vaccine-diluent formulation was developed that contained both buffer and stabilizing components that permitted direct administration without reconstitution and storage of viable vaccine refrigerated in liquid form.[259,260] In a clinical trial of bivalent (types G1 and G2) reassortant vaccine, vaccine suspended in the buffer-stabilizer in varying volumes and concentrations, given without a previous oral buffer, was compared with traditionally prepared vaccine given after a separate administration of buffer.[247] Three doses were given and no adverse events were observed. Although the trial was not designed to demonstrate efficacy, immune responses in infants given vaccine in the new formulation without prebuffering were excellent and equal to those of the prebuffered vaccine cohort. For example, following administration of the vaccine in the buffer-stabilizer formulation, serum neutralizing antibody responses to G1 were 67% to 73% and rotavirus-specific IgA antibody responses were 84% to 91% in serum and 77% to 88% in feces.

Following the clinical success of a quadrivalent WC3–human reassortant vaccine containing G1, G2, G3, and P1A, a pentavalent reassortant rotavirus vaccine (RotaTeq) was developed by adding WC3-G4, to protect against the G4 serotype which, like G1, G2, and G3, was established to be of worldwide prevalence. In a multisite trial involving 1946 infants, the safety, immunogenicity, and efficacy of five different vaccine compositions (approximately 300 infants per group) were evaluated in comparison with placebo (Table 52.4). The test vaccines included three pentavalent vaccine combinations (G1, G2, G3, G4, and P1A) in concentrations of either 5×10^6, 1.6×10^6, or 5.5×10^5 PFU per reassortant. Also included were groups given the G1, G2, G3, and G4 reassortants alone and the P1A reassortant alone at concentrations of 5×10^6 PFU per reassortant.[260] In this trial, infants were prefed with infant formula for buffering before vaccine. The incidence of adverse events was comparable among vaccine and placebo recipients for all vaccines evaluated. All compositions were immunogenic and protective; however, the magnitude of the antibody responses varied with virus concentration. The immunogenicity and efficacy of the high and middle concentrations of the pentavalent vaccine and the quadrivalent vaccine (G1, G2, G3, and G4) were about equal and consistent with the efficacy of the previously evaluated quadrivalent vaccine (G1, G2, G3, and P1A). The low-concentration pentavalent rotavirus vaccine and the monovalent P1A vaccine were less effective. However, the approximate 50% efficacy of the P1A reassortant against rotavirus infection of any degree of severity suggested that P1A might provide protection against

TABLE 52.4 Effect of Dose and Composition of RotaTeq, Quadrivalent (G1, G2, G3, and G4) and Univalent (P1A) Bovine (WC3)–Human Reassortant Rotavirus Vaccine on Efficacy and Immunogenicity in Infants

Dose (PFU)	Strains	N	G1 SNA[a]	Serum IgA[b]	Efficacy (95% CI)
2.5×10^{7}[c]	G1–G4, P1A	375	86.2	98.7	68.0 (31.1–86.4)
8.0×10^{6}	G1–G4, P1A	328	73.3	97.3	74.3 (37.9–91.0)
2.5×10^{6}	G1–G4, P1A	324	61.7	93.4	57.6 (11.8–80.9)
2.0×10^{7}	G1–G4	270	84.4	98.2	74.0 (40.3–90.3)
5.0×10^{6}	P1A	327	3.6	68.7	43.4 (–1.7–69.2)
Placebo	—	322	1.1	13.5	—

prevalent rotaviruses (e.g., P1AG9) expressing the P1A antigen but none of the G specificities in the vaccine (see Table 52.4). This trial conclusively demonstrated that the G antigens of these vaccine strains are the dominant molecular components in inducing serum antibody and protection. As a result of these studies, 1.6×10^{6} PFU per reassortant or 8.0×10^{6} PFU for all five reassortants (G1, G2, G3, G4, and P1A) was selected for further development.[261] These quantities of vaccine viruses also served as the basis for selection of the lowest dose acceptable at expiration.

The efficacy of RotaTeq was confirmed in a placebo-controlled trial involving 1312 infants randomized to receive three doses of either approximately 1.1×10^{7} infectious units of RotaTeq in a buffer stabilizer solution or placebo.[247] The incidence of adverse events was comparable among vaccine and placebo recipients with the exception of a statistically significant 4.6% excess of fevers greater than 38.1°C among vaccinees during the week after the first dose. A high proportion (96%) of infants had a significant increase in serum antirotavirus IgA and 57% had a significant increase in serum neutralizing antibody response to serotype G1. Efficacy against all rotavirus disease was 72.5% (95% confidence interval [CI], 50.6 to 85.6); efficacy against severe rotavirus disease was 100% (95% CI, 13.0 to 100).[247]

Although all rotavirus reassortants based upon a bovine WC3 rotavirus had been generally well tolerated in all clinical trials, new concerns for RotaTeq safety arose when the RRV reassortant-based vaccine RotaShield was found to be a rare cause of intussusception. It became necessary to perform a large (70,000 infant) Rotavirus Efficacy and Safety Trial (REST) to determine whether RotaTeq was also a rare cause of intussusception.[262]

The large sample size provided an opportunity to evaluate the efficacy of the vaccine in preventing healthcare encounters for rotavirus gastroenteritis of all serotypes including hospitalizations, emergency visits, and physicians' office visits. In addition, efficacy against all cases of rotavirus gastroenteritis regardless of whether they resulted in a healthcare encounter were evaluated in a subset of 5673 vaccinated subjects in this nested placebo-controlled study.

The efficacy of RotaTeq against rotavirus gastroenteritis caused by major rotavirus serotypes was also evaluated in a nested placebo-controlled study within the large-scale clinical trial. RotaTeq protected against the serotypes included in the vaccine (i.e., G1, G2, G3, and G4) (Table 52.5).[262] RotaTeq also protected against natural challenge with P1AG9 rotaviruses, demonstrating the contribution of the WC3–human reassortant containing human P1A. Compared with placebo, efficacy against any severity of rotavirus disease caused by serotypes G1, G2, G3, and G4 was 74.0% (95% CI, 66.8–79.9%); efficacy against severe rotavirus disease was 98% (95% CI, 88.3–100%).[45] RotaTeq reduced the rate of rotavirus-associated hospitalizations by 95.8% (95% CI, 90.5–98.2%), emergency visits by 93.7% (95% CI, 88.8–96.5%), and office visits by 86.0% (95% CI, 73.9–92.5%). Efficacy against all-cause gastroenteritis hospitalizations was 58.9% (95% CI, 51.7–65.0%), demonstrating the importance of rotavirus as a cause of severe gastroenteritis in children. The efficacy of RotaTeq in the second rotavirus season postvaccination was 63% (95% CI, 44–75%) against rotavirus gastroenteritis of any severity, and 88% (95% CI, 49–99%) against severe rotavirus gastroenteritis. RotaTeq has also shown sustained protective efficacy against rotavirus hospitalizations and emergency department visits, regardless of rotavirus serotype, for up to 3.1 years after vaccination, with rate reductions (95% CI) in hospitalizations and emergency department visits during the first, second, and third years of life of 94.0% (90.0–96.5%), 94.7% (90.7–97.2%), and 85.9% (51.6–97.2%), respectively.[263]

TABLE 52.5 Reduction in Hospitalizations and Emergency Department Visits (by G Type) in the Phase III Efficacy Study of RotaTeq

Serotype	Number of Cases of Rotavirus Disease		
	Vaccine (N = 34,035)	Placebo (N = 34,003)	Rate Reduction (95% CI)
G1	16	328	95.1 (91.6–97.1)
G2	1	8	87.6 (–0.0 to 98.5)
G3	1	15	93.4 (49.4–99.1)
G4	2	18	89.1 (52.0–97.5)
G9	0	13	100.0 (67.4–100.0)

CI, confidence interval.

Data on the efficacy of a partial series of RotaTeq are primarily based on protection conferred between vaccine doses (i.e., between dose 1 and 2 and between dose 2 and 3) as most vaccine recipients in the REST study received the full vaccine series. In the trial, RotaTeq reduced the rates of combined hospitalizations and emergency department visits for G1 to G4 rotavirus gastroenteritis or rotavirus gastroenteritis regardless of serotype between doses 1 and 2 by 100% (95% CI, 72–100%) or 82% (95% CI, 39–97%), respectively. Between doses 2 and 3, RotaTeq reduced the rates of combined hospitalizations and emergency department visits for G1 to G4

TABLE 52.6 Efficacy of RotaTeq and Rotarix Against Severe Rotavirus Gastroenteritis in the First Year of Life in Africa and Asia

Country	Incidence Per 100 Person-Years		Vaccine Efficacy (95% CI)
	Vaccine	Placebo	
ROTARIX			
South Africa	0.8	3.3	76.9 (56.0–88.4)
Malawi	4.0	7.9	49.4 (19.2–68.3)
ROTATEQ			
Ghana	2.7	7.7	65.0 (35.5–81.9)
Kenya	0.7	4.0	83.4 (25.5–98.2)

rotavirus gastroenteritis or rotavirus gastroenteritis regardless of serotype by 91% (95% CI, 63–99%) or 84% (95% CI, 54–96%).[264]

In the Phase III prelicensure study of RotaTeq, protection against severe rotavirus-induced gastroenteritis was 100%, 95.4%, and 100% in children who were never breastfed, sometimes breastfed, or exclusively breastfed, respectively.[265]

Phase III trials of RotaTeq were completed in developing countries of Asia and Africa (Table 52.6).[266,267] In three African clinical trial sites in Kenya, Ghana, and Mali, a three-dose regimen of RotaTeq administered at 6, 10, and 14 weeks of age was overall 64% (95% CI, 40–79%) effective against severe rotavirus gastroenteritis during the first year of follow-up. During the first year of follow-up in the two Asian trial sites in Vietnam and Bangladesh, three doses of RotaTeq were overall 51% (95% CI, 13–73%) effective against severe rotavirus gastroenteritis.

Effectiveness and Impact. Recently summarized,[268–270] effectiveness studies in the United States using the case-control approach were conducted primarily by performing active surveillance for children presenting to the emergency department or admitted to the hospital for acute gastroenteritis; the largest network for these evaluations comprised seven pediatric hospitals. Children whose stools tested positive for rotavirus by enzyme immunoassay comprise the cases; control groups consisted of children with gastroenteritis who tested negative for rotavirus (test-negative controls), children with acute respiratory illness, or children selected from city or state immunization registries. Statistically significant vaccine effectiveness estimates for three doses of RotaTeq against emergency department visits or hospitalization (considered moderate to severe illness) for rotavirus ranged from 83% to 92%, with similar estimates in infants aged 8 to 12 months of age and those older; there was with no evidence of waning protection up to 4 years of age.[271–279] Similarly high vaccine effectiveness estimates were found against moderate to severe rotavirus disease from all specific genotypes thus reported: G1P[8], G2P[4], G3P[8], G9, and G12P[8]. The statistically significant point estimates for effectiveness after one dose ranged from 69% to 74% and after two doses from 78% to 88%, demonstrating good protection for the time between doses.

Based on examination of medical claims databases, other RotaTeq effectiveness estimates in the United States have ranged from 89% to 100%.[280–282] In reports from other high income locations in Australia, Finland, France, Spain, Portugal (≥1 dose) and Taiwan, the statistically significant point estimates for vaccine effectiveness of three doses of RotaTeq against hospitalization for rotavirus disease has ranged from 92% to 97%.[283–288]

In Nicaragua, one of the poorest countries in Latin America and an early adopter of RotaTeq in 2006 (through a manufacturer-sponsored donation program), lower vaccine effectiveness was observed than in industrialized settings. In one evaluation, a full series of RotaTeq was 52% to 63% effective in preventing severe (Vesikari score ≥11) rotavirus gastroenteritis. However, RotaTeq was more effective (73–86%) in preventing very severe (Vesikari score ≥15) rotavirus gastroenteritis.[289] Another evaluation in Nicaragua found three-dose vaccine effectiveness against severe disease of 64% and 87%, depending on the control group.[290]

Consistent with the high effectiveness results, the use of RotaTeq in the United States (used exclusively before Rotarix was licensed) resulted in marked reductions in rotavirus hospitalizations in young children younger than 5 years of age: reductions ranged from approximately 62% to 83%.[281,291–299] This reduction in rotavirus disease translated to reductions in all-cause hospitalizations for gastroenteritis among children younger than 5 years of age, ranging from approximately 25% to 50%. Studies in Australia in areas that used RotaTeq also reported reductions of 50% to 83% in rotavirus hospitalizations and of 20% to 48% in total gastroenteritis hospitalizations among young children.[286,300,301]

An additional and somewhat unexpected benefit following the use of RotaTeq was identified by investigators with the U.S. Vaccine Safety Datalink (VSD). Given earlier clinical reports of the association of rotavirus disease and seizures, they performed a retrospective cohort analysis and found that children who received the rotavirus vaccine series had an 18% to 20% reduction in risk of seizures requiring hospitalization or emergency department care, compared with children who did not receive a rotavirus vaccine.[302] A protective effect against hospital or emergency department care for febrile seizures was found in Australia.[302a]

Transmission of Vaccine Virus. Reassortants of G1, G2, G3, and G4 specificity have been administered individually to infants and demonstrated to be as safe as WC3 and, like WC3, to be shed in feces in low incidence (<10%) and at low concentration.[248–251] Therefore, WC3-containing vaccine is much-less-well adapted to growth at the infant intestinal mucosal surface than were RRV-containing vaccines. As a result, horizontal transmission of WC3-based vaccine from immunized infants would seem unlikely. (The initial Phase I study of WC3 rotavirus in infants revealed virus shedding in seven of 22 infants inoculated with $10^{7.5}$ PFU; no shedding rate of similar magnitude has been noted in any subsequent clinical trial of WC3 or WC3 reassortants.) A report in 2009 described detection of a RotaTeq vaccine-derived strain in a child with gastroenteritis whose sibling had been recently vaccinated with RotaTeq, and further investigation indicated that this strain was generated by further reassortment between two of the reassortant rotavirus strains present in RotaTeq.[303] Additional patients with acute-gastroenteritis and vaccine-derived double-reassortant rotavirus strains have been identified through active surveillance, although it has often been difficult to determine the extent that the rotavirus detected contributed to the patients' symptoms.[304–306]

Adverse Reactions

Intussusception. Because RotaShield was found to be associated with intussusception postlicensure, a large trial was necessary to determine whether intussusception was causally

or coincidentally associated with administration of RotaTeq.[262] In the large Phase III REST study, one case of intussusception occurred in the vaccine group and one in the placebo group within 14 days of inoculation; six cases in the vaccine group and five in the placebo group occurred within 42 days of inoculation; and 13 cases in the vaccine group and 15 in the placebo group occurred within 1 year of inoculation. No clustering of cases in the RotaTeq group occurred at any time after vaccination.[303] There were no other cases of intussusception reported in the other Phase III studies. Therefore, RotaTeq did not appear to be associated with intussusception.

Postmarketing evaluations designed to evaluate whether RotaTeq was associated with intussusception have been conducted in the United States and Australia (Table 52.7).[307–313] In the United States, through VSD, analyses of data from March 2006 through March 2013 found no increased risk of intussusception following any of the three doses compared to that expected based on historical rates, and no significant clustering of cases following RotaTeq was detected.[309,314] In the U.S. Post-Licensure Rapid Immunization Safety Monitoring (PRISM) program, an increased risk of intussusception following dose 1 was detected in both the self-controlled risk interval and cohort designs.[310] Although with inherent limitations of a passive reporting system, the clustering of intussusception cases in U.S. VAERS following dose 1 has suggested an increased risk.[311] In Australia, an increased risk was detected following dose 1 and dose 2 in the self-controlled case series (SCCS) design, and dose 1 only using case-control methodology.[312]

Other Adverse Events. Among RotaTeq and placebo recipients in the Phase III trials of RotaTeq, the incidence of serious adverse events (2.4% vs 2.6%, respectively), including deaths (~0.1% [$n = 25$] vs <0.1% [$n = 27$], respectively), was similar.[246] No deaths were attributed to vaccination by blinded investigators. Sudden infant death syndrome accounted for 17 of the 52 deaths; cases were equally distributed among RotaTeq and placebo recipients [$n = 8$ and $n = 9$, respectively].

TABLE 52.7 Attributable Risk Estimates of Intussusception Associated With RotaTeq or Rotarix Among Infants, by Study

	Country	Study Period	Attributable Risk Based on This Study Design[a]	Attributable Risk Based on These Doses and Intervals[a]	Attributable Risk (Per 100,000 Vaccinated Infants)[b]		Reference
					Point Estimate	95% CI

Modified from Rha B, Tate JE, Weintraub E, et al. Intussusception following rotavirus vaccination: an updated review of the available evidence. Expert Rev Vaccines. *2014;13(11):1339–1348.*

Approximately 11,700 children within the Phase III trials were studied in detail to assess other potential adverse experiences, such as fever, diarrhea, and vomiting.[246] Within 42 days of vaccination, vaccinees had a small but statistically significant greater rate of several symptoms than placebo recipients, including vomiting (15% vs 14%, respectively), diarrhea (24% vs 21%, respectively), nasopharyngitis (7% vs 6%, respectively), otitis media (15% vs 13%, respectively), and bronchospasm (1.1% vs 0.7%, respectively). Among RotaTeq and placebo recipients, the incidence of reported episodes of fever (43% vs 43%, respectively) and hematochezia (0.5% vs 0.3%, respectively) was similar. Although Kawasaki disease was reported in several children following RotaTeq in the Phase III trial, this association was not found postlicensure.[315]

In the 7-day period after vaccination, vaccinees had a statistically significantly greater rate of diarrhea after dose 1 (10% vs 9%, respectively), after dose 2 (9% vs 6%, respectively), and after any dose (18% vs 15%, respectively). Similarly, vaccinees had a statistically significantly greater rate of vomiting after dose 1 (7% vs 5%, respectively) and after any dose (12% and 10%, respectively). The incidence of fever and irritability during the 7-day period after any vaccine dose was similar among RotaTeq and placebo recipients.

Bovine (Strain UK)–Human Reassortant Rotaviruses

Bovine–human reassortant rotaviruses also have been generated incorporating the genes for VP7 of either G1, G2, G3, or G4 human serotypes and 10 genes from the bovine UK strain rotavirus, which (like strain WC3) is serotype P7[5]G6.[316–318] These reassortants are serotypically similar to the G1, G2, G3, and G4 reassortants of bovine rotavirus WC3. Phase I studies were performed on each of the four UK reassortants individually in small numbers of infants (11 to 20 per G serotype) at doses up to $10^{5.8}$ PFU per strain. The vaccine was well tolerated and was shed in feces at rates ranging from 10 to 64% per group. Serum neutralizing antibody responses to the human parent rotaviruses (representing G types 1, 2, 3, and 4) ranged from 0% to 30% per serotype, but the neutralizing antibody responses to the corresponding UK parent virus were higher (30–82%). Only 50% of a group of 14 infants given a G1 reassortant developed evidence of any immune response (serum neutralizing antibodies or serum IgA or IgG detected by ELISA) after the first dose of vaccine. However, following a second dose, all exhibited evidence of an immune response.[317]

Subsequently a quadrivalent vaccine containing G1, G2, G3, and G4 reassortants of UK was administered in three doses to 20 infants.[317] No adverse events occurred following vaccination. Nineteen (95%) of the infants developed neutralizing antibodies to UK bovine rotavirus; neutralizing antibody response rates to human rotaviruses of serotypes G1 through G4 ranged from 28% to 37%.[318,319]

The quadrivalent vaccine was tested for efficacy in a placebo-controlled trial involving 256 infants given two doses of 10^6 PFU (total) in Finland.[319] The first and second doses were given at mean ages of 95 days and 150 days, respectively. Efficacy in the first year postvaccination was 59% against all rotavirus gastroenteritis and 90% against severe gastroenteritis. The vaccine showed no protective efficacy in the second rotavirus season postimmunization. It has not been submitted for licensure in the United States. Despite limited information about the multivalent UK reassortant vaccine, the National Institutes of Health has now licensed it to seven non-U.S. research groups, including investigators located primarily in less-developed countries (including China, Brazil, and India). Both a quadrivalent (G1–G4) and pentavalent (G1–G4, G9) bovine–human reassortant vaccine have been shown to be safe and immunogenic in healthy Indian infants; efficacy testing is ongoing in India.[320,321] A recent randomized Phase III clinical trial of a pentavalent bovine-human reassortant vaccine (ROTASIIL) conducted in Niger found that the vaccine was not associated with any adverse events and had an efficacy of 66.7% (95% CI, 49.9–77.9%) against severe rotavirus gastroenteritis.[321a] Of note, the vaccine is reportedly thermostable for 24 months at 37°C and six months at 40°C, which may provide advantages for vaccine delivery in remote areas where cold chain capacity is limited.

Natural Human–Bovine Reassortant Rotaviruses (Rotavac)

Naturally occurring bovine–human reassortant rotaviruses were isolated in two sites in India—New Delhi (the 116E strain)[322] and Bangalore (the I321 strain).[323] Newborns infected with the 116E or I321 strains were found to be protected against severe disease on reinfection.[128,324] The 116E strain is a human G9 isolate with a single VP4 gene segment from a bovine strain (P[10]G9) while the I321 strain (P[11]G10) has a bovine backbone with two segments coding nonstructural proteins NSP1 and NSP3 from human strains. Both of these strains were developed for clinical trials. In Phase II trials, infants inoculated with strain 116E developed a more robust rotavirus-specific IgA response than those inoculated with I321.[325–327] Consequently, only the 116E candidate underwent further efficacy testing. In a multicenter Phase III trial that enrolled infants from three cities in India–New Delhi, Pune, and Vellore—the 116E vaccine (Rotavac) was administered in a three-dose schedule with doses given at 6, 10, and 14 weeks of age. The vaccine showed 56% efficacy (95% CI, 37–70%) against severe rotavirus gastroenteritis during the first year of life, with sustained efficacy in the second year of life (49%; 95% CI, 17–68%).[328,329] Rotavac provided protection against a wide variety of vaccine mismatch strains, including G1P[8], G2P[4], and G12P[6], which were the most common circulating strains during the trial. Rotavac was not associated with any serious adverse events, including intussusception, in the Phase III trial. Six (<1%) cases of intussusception were reported in the vaccine group and two (<1%) were reported in the placebo group (with a 2:1 allocation of vaccine and placebo recipients). All events took place after administration of dose 3. The minimum interval between dosing and intussusception was 112 days in the vaccine group and 36 days in the placebo group. However, since a relatively small number of infants (~4500) were vaccinated in the trial, a low risk of intussusception cannot be excluded. Rotavac was licensed for use in India in 2014 and was recommended for inclusion in the Universal Immunization Program of India.

Attenuated Human Rotaviruses

Newborn Rotavirus Strain M37

Rotavirus strains isolated from children in the first month of life have been studied as potential vaccines because infants in neonatal nurseries in several locales worldwide have been found to be infected with rotavirus with high prevalence but with little gastroenteritis; followed by resistance to subsequent episodes of severe disease.[83,330] Many of these newborn strains share a similar P gene.[41,330] These strains have been largely ineffective as vaccine candidates.[2,31,331–333] Only the Australian strain RV3 is currently in clinical testing.[88,334,335]

Attenuated Human Strain P1[8]AG1 (Rotarix)

The attenuated human rotavirus strain P1A[8]G1 (Rotarix) is now licensed in nearly 100 countries, including the European Union. The vaccine was licensed in the United States in April 2008, and recommended for use by ACIP in June 2008.

Origin. Symptomatic or asymptomatic infection of young children with a single circulating wild-type strain (serotype P1A[8]G1) in Cincinnati provided 100% protection against subsequent rotavirus disease caused primarily by the P1A[8]G1 serotype over a 2-year period.[84] A vaccine of this strain obtained from the stool of one of the study subjects (i.e., strain 89-12) was developed after 26 passages of the virus in primary African green monkey kidney cells and seven passages in serially passaged African green monkey kidney cells.[347] Initial safety and immunogenicity studies with this vaccine candidate indicated it was relatively safe and immunogenic in children less than 4 months of age.[336] Nearly every child developed an immune response to the vaccine virus after two doses.

Limited comparisons of the effects of dose on the immunogenicity of the 89-12 candidate vaccine have been conducted.[336] However, 19 of 20 infants inoculated with two doses of 10^5 fluorescent-focus units (FFU) of 89-12 developed rotavirus-specific antibodies and 16 did so after the first dose.

The strain 89-12 vaccine candidate was evaluated in an efficacy trial in healthy 10- to 16-week-old infants at four centers in the United States. Two doses of 10^5 FFU or placebo with a 4-week interval between doses were administered to 108 or 107 subjects, respectively.[337] Low-grade fever after the first dose was the only side effect more common in vaccine than placebo recipients (21 [19%] vs 5 [4.6%] subjects, respectively; $P < .001$). An immune response to rotavirus was detected in 94% of vaccinees and in only 4% of the placebo recipients. Rotavirus-specific serum IgA responses were detected in 91.6% and anti–89-12 serum neutralizing antibodies in 69.2% of vaccines.

During the first rotavirus season, rotavirus disease was detected in 18 placebo recipients and two vaccine recipients (efficacy of 89%). Vaccine episodes were scored for clinical severity using a 20-point system: in this system, cases scoring 8 or higher were considered "severe" and those scoring higher than 14 as "very severe." Ten placebo recipients but no vaccine recipients presented for medical care necessitated by rotavirus disease. In the second year, efficacy decreased to 59%, but only one case of severe rotavirus gastroenteritis occurred in vaccine recipients, while 10 severe cases occurred in placebo recipients. Vaccine efficacy for 2 years was 76% against any rotavirus gastroenteritis, 84% against severe disease, and 100% against very severe disease. As G1 rotaviruses predominated during both years, the efficacy against rotaviruses of other G or P types was not determinable.

To produce a homogeneous vaccine, strain 89-12 was purified by a series of three end point dilutions in Vero cells and passaged seven more times in these cells after it was sublicensed by GlaxoSmithKline in 1997. The final product, now at passage 43, was called RIX4414 and is being sold under the trademark name Rotarix.

Immunogenicity. Investigators orally inoculated 6- to 12-week-old infants in Finland with RIX4414 and found no increase in any elicited symptoms including fever.[338] Thus, it appeared that clonal selection and increased passage in tissue culture produced a more attenuated vaccine relative to its parental 89-12 strain. A dose range effect was seen for the immune response in Finnish infants with seroconversion detected in 73% to 96% after the second dose administered 4 weeks after the first dose (Table 52.8).[338]

Evaluation of RIX4414 began in Asia shortly thereafter, marking the initiation of what would become a global effort to evaluate this vaccine.[339,340] Unlike most vaccines, evaluation of RIX4414 was performed in developed and developing nations simultaneously (see Table 52.8). In a dose-ranging trial conducted in Singapore in 2464 infants, no increase in fever, diarrhea, vomiting, or irritability was detected—not even at the highest dose of $10^{6.1}$ FFU; seroconversion rates determined by rotavirus-specific serum IgA responses were 76% to 91% depending on the dose.[340] Interference with the other routine childhood vaccines administered concomitantly was not observed. In a multicenter study conducted in the United States, the vaccine appeared to be safe in infants 5 to 15 weeks of age, and did not interfere with the immune responses to concomitantly administered vaccines.[341] Concomitant use of Rotarix with OPV was reported to suppress the uptake of the rotavirus vaccine. This effect was eliminated following the second dose.[342] Vaccine-specific immune responses assessed by serum IgA response after two doses occurred in 81.5% to 88.0% of vaccinees, depending on the size of the dose.

TABLE 52.8 Clinical Studies of Rotarix in Infants

Site	N	Seroconversion[a]	Efficacy Against Severe Disease
Finland	92	73–96%	ND
Finland	405	80%	90%
Singapore	2464	76–91%	82%
United States	529	82–88%	ND
Latin America (Brazil, Mexico Venezuela)	2155	61–65%	66–86%
Latin America (11 countries) and Finland	63,225	ND	85%

[a]Percent of infants that developed an immune response after two doses as determined by rotavirus-specific IgA by ELISA.
IgA, immunoglobulin A; ELISA, enzyme-linked immunosorbent assay; ND, not determined.

Efficacy. The first efficacy study of RIX4414 was conducted in Finland during two rotavirus epidemic seasons following oral administration of two relatively low doses of the vaccine ($10^{4.7}$ FFU). In this trial of 405 infants, the vaccine was well tolerated with a seroconversion rate of 80% after the second dose (see Table 52.8).[343] Efficacy against any episode of rotavirus gastroenteritis was 73%, whereas efficacy against severe rotavirus disease was 90% in the first season and 85% after two seasons. Because 35 of the 38 cases of rotavirus gastroenteritis were associated with the same G1 serotype as the vaccine, this trial did not yield evidence about the potential of this vaccine to protect against heterotypic rotaviruses. In an initial placebo-controlled efficacy trial with RIX4414 in Latin America, seroconversion after two doses of either $10^{4.7}$, $10^{5.2}$, or $10^{5.8}$ FFU of vaccine virus based on serum rotavirus IgA responses, was a disappointing 61% to 65% and the dose administered had no significant effect on these responses.[344] Despite these low detectable serum antibody response rates, protection against severe rotavirus disease was 86% in vaccinees given the highest dose. Equally important was the observation that vaccine efficacy against non-G1 rotaviruses, most commonly P1AG9, was similar to that against G1 serotypes, confirming the hypothesis that a vaccine containing P1A could protect against P1A-containing viruses of a different G serotype from that of the vaccine.

A randomized, placebo-controlled safety, immunogenicity, and efficacy trial was next performed with the RIX4414 vaccine (now called by its commercial name Rotarix) in approximately 63,000 infants, primarily in 11 countries in Latin America (see Table 52.8).[345] The primary purposes of the study were to

determine if the rates of intussusception were equivalent in vaccinees and placebo recipients and, in a subset of 10,159 vaccinees and 10,010 placebo recipients, the efficacy of the vaccine against severe rotavirus disease and hospitalizations. The efficacy of Rotarix against hospitalizations resulting from rotavirus was 85% and reached 100% against the most-severe cases of rotavirus gastroenteritis. Overall efficacy against severe rotavirus disease was 91.8%. Efficacy against any severity of disease caused by non-G1 strains (G3, G4, and G9) that belonged to the same P1A[8] serotype and genotype as the vaccine was 87.3%. Although protection was only 41.0% against G2[P4] strains in this trial, a metaanalysis of the results of this trial combined with two previous trials of Rotarix[343,346] allowed the calculation of a protection rate against G2[P4] strain of 67%. Thus, although this vaccine appeared to be less protective against a rotavirus strain that differed serotypically in both its VP4 and VP7 neutralization proteins from that of the vaccine, it still provided protection. It is also important to note that protection against all cases of severe gastroenteritis or diarrhea-associated hospitalizations of any etiology in vaccinees in this trial was 40% and 42%, respectively, thus indicating that an effective rotavirus vaccine could dramatically reduce the numbers of cases of severe gastroenteritis in young children. In the other pivotal Phase III efficacy study, conducted among approximately 3800 infants from six European countries, the efficacy of two doses of Rotarix against rotavirus disease of any severity to age 1 year was 85%, with 100% efficacy against hospitalization for rotavirus diseases through the first rotavirus season.[347] The vaccine gave protection rates against severe gastroenteritis caused by G1, G2, G3, G4, and G9 strains of 96%, 86%, 94%, 95%, and 85%, respectively, through the second season. An efficacy trial was also conducted among approximately 10,700 infants in the high-income Asian locations of Hong Kong, Singapore, and Taiwan.[348] Two doses of Rotarix was 96% protective against severe rotavirus gastroenteritis (Vesikari score ≥11) to age 2 years. In the European, Latin American, and Asian trials, the efficacy of Rotarix was sustained in the second year of life.[349]

In the first Phase III trials of Rotarix in developing countries, Rotarix pooled efficacy for the 2- and 3-dose regimens ranged from 49% (95% CI, 19 to 68) in Malawi to 77% (95% CI, 56 to 88) in South Africa (see Table 51.6).[350] The number of severe rotavirus cases prevented per 100 infants vaccinated was substantial—seven cases per 100 vaccinated in Malawi and four cases per 100 vaccinated in South Africa—illustrating the large potential public health impact of even a moderately efficacious vaccine.

Effectiveness and Impact. The effectiveness of Rotarix has been evaluated in many countries.[268–270] Middle-income Latin American countries were among the first to introduce and evaluate the vaccine. Measured through case-control studies (described earlier), the overall effectiveness of two doses of Rotarix against hospitalization for rotavirus in Bolivia, Brazil, and El Salvador ranged from 40% to 77%, whereas an assessment from Columbia did not demonstrate effectiveness in all age groups combined, but did in infants 6 to 11 months of age (85%).[351–355] In a recent metaanalysis, the pooled estimate for effectiveness from these studies was 63% and 72%, with generally higher effectiveness in children 6 to 11 months of age (75% and 82%) than in those 12 months of age and older (56% and 66%).[356] The pooled estimate for one Rotarix dose was 50% and 55%, indicating moderately good protection in these countries at least during the period between doses.

The overall vaccine effectiveness of two doses of Rotarix against rotavirus hospitalization in the high-income countries of Belgium, Spain, Portugal, Taiwan, and the United States has ranged from 92% to 98% in case-control studies, with high effectiveness sustained in the second year of life in the two countries that reported results by separate age groups (i.e., Belgium and the United States).[274,276,284,285,357] In Central Australia with a large indigenous population, effectiveness estimate was 84% against hospitalization during a G9P[8] season, but was not statistically significant during a G2P[4] season—a genotype that is classified in a genogroup different from the vaccine strain.[358,359] However, in other middle- or in high-income settings where Rotarix effectiveness against hospitalization from genotype G2P[4] has been assessed, such as Belgium, Brazil, and the United States, the overall effectiveness against hospitalization has been 85% or greater, similar to that against P[8] strains; the Brazil study found the high effectiveness against G2P[4] challenge in infancy was not sustained in children 12 months of age or older.[276,353,357] In a metaanalysis, no differences were noted in Rotarix effectiveness against partly heterotypic or fully heterotypic strains, compared with homotypic strains, within country income levels.[360]

In the first evaluation of the effectiveness of Rotarix in the African region, two doses were found to be 57% effective against rotavirus hospitalization among South African children younger than 2 years of age, with similar results in the first and second year of life, and in HIV-exposed-uninfected and HIV-unexposed-uninfected children.[361] Importantly, in the low-income country of Malawi, two Rotarix doses were 64% effective against rotavirus hospitalization in young children.[362]

Several evaluations demonstrated marked reductions in hospitalizations for rotavirus among young children following the introduction of Rotarix into the immunization program, with reduction estimates ranging from 59% to 81% in Brazil and El Salvador, 68% to 88% in Australia, and 40% to 45% in S. Africa, including during early postintroduction periods when not all children younger than 5 years of age were age-eligible for vaccine.[363–367] In Blantyre, Malawi, the incidence of rotavirus hospitalizations among infants was reduced by 43% during the second season.[362] In the United States, in a retrospective cohort analysis based on a national insurance claims databases, a 96% rate reduction in the rotavirus-coded hospitalizations was observed in children who received Rotarix compared with children who were age-eligible but did not receive any rotavirus vaccine.[282]

Notably, Mexico was the first country to demonstrate a reduction in mortality from diarrheal disease following rotavirus vaccine introduction. Following the introduction of Rotarix, a sustained 46% decrease in overall diarrheal deaths has been detected among children younger than 5 years of age, with approximately 90% coverage in children younger than 2 years of age,[368,369] and similar diarrhea mortality rate reductions in high as well as low-income sectors.[370] Two studies in Brazil estimate diarrheal death rate reductions of 22%, and 33% to 39%, respectively, after Rotarix introduction.[371,372] In Panama, a reduction of 47% in diarrheal deaths was estimated, based on relatively small numbers.[373] Other studies from Latin America, some from single locations and others using regional or national data, estimated early annual reductions in overall diarrhea hospitalizations, generally among children younger than 5 years of age, with point estimates ranging from 17% to 55%.[367,371,372,374,375] In South Africa, diarrhea hospitalizations among children younger than 5 years of age were reduced by an estimated 33% in the first 2 years after Rotarix introduction.[364]

Transmission of Vaccine Virus. In Phase II or Phase III studies of Rotarix administered at $10^{6.5}$ to $10^{6.8}$ $CCID_{50}$ (median end point of the cell culture's infectious dose) per dose in various countries, after dose 1, rotavirus antigen shedding was detected by ELISA in 50% to 80% of infants at approximately day 7, 19.2% to 64.1% at approximately day 15, 0% to 24.3%

at approximately day 30, and 0% to 2.6% at approximately day 60.[376] Shedding was lower after dose 2, and was detected in 4.2% to 18.4% of infants at approximately day 7, 0% to 16.2% at approximately day 15, 0% to 1.2% at approximately day 30, and 0 at approximately day 45. Shedding of live rotavirus was assessed in two studies in which Rotarix was administered at $10^{6.5}$ $CCID_{50}$ per dose. In both studies, stool samples that were antigen-positive by ELISA at approximately day 7 after dose 1 were tested subsequently for live virus by focus forming unit assay. Live virus was detected in six (46.2%) of 13 and 15 (45.5%) of 33 rotavirus antigen-positive stools, for an estimated 26% of vaccinated infants shedding live virus at approximately day 7 after dose 1. The potential for transmission of vaccine virus to contacts was evaluated in a study of twin pairs conducted in the Dominican Republic. In this study, one twin from each pair received Rotarix and the other received placebo and fecal specimens were obtained thrice weekly for 6 consecutive weeks after vaccination. In 80 infants who received placebo, rotavirus vaccine strain was detected in at least one fecal specimen in 15 (19%) infants.[377] None of the transmission cases was associated with gastrointestinal symptoms.

Adverse Events. No excess of adverse effects in vaccinees compared with control infants was reported in any of the above-mentioned clinical trials.[378,379] However, the virus was shed in concentrations detectable by ELISA in 60% to 80% of infants[380,381] after dose 1 and often after dose 2, suggesting the possibility of horizontal transmission to nonvaccinees.

Intussusception. Because of the association of RotaShield with intussusception, a large Phase III safety trial was conducted with approximately 63,000 subjects randomized to receive either two doses of the Rotarix vaccine or placebo, as mentioned above. The primary end point of this large trial was the occurrence of intussusception within 31 days after each dose of vaccine.[345] A secondary objective was to assess the occurrence of serious adverse events, including intussusception, during the entire study period (i.e., a median of 100 days after the second dose). No increased risk for intussusception was observed after administration of Rotarix when compared with placebo. A total of 13 cases of intussusception were identified during the 31-day windows; six in Rotarix recipients and seven in placebo recipients. No clustering in the initial 1 to 2 weeks was identified after either dose. During the entire duration of the study, 16 cases of intussusception occurred in the placebo group compared with nine in the vaccine group.

Postmarketing studies to assess if Rotarix is associated with intussusception have been conducted in Mexico, Brazil, Australia, the United States, Singapore and the United Kingdom (see Table 52.7).[307–313,382,382a] An increased risk of intussusception was detected in a first study in Mexico, following dose 1 and dose 2 (SCCS and case-control methodology)[308]; a second study in Mexico, following dose 1 only (SCCS)[313]; in Brazil, following dose 2 but not dose 1 (SCCS and case-control)[308]; and in Australia, following dose 1 and dose 2 (SCCS) and dose 1 only (case-control).[312] In the United States, the VSD evaluation found an increased risk of intussusception following dose 2 compared with that expected based on historical rates; the statistical significance of the dose 1 relative risk could not be calculated.[309] The relative risk of intussusception within 7 days after Rotarix was greater than that following RotaTeq vaccination.[309] In the PRISM evaluation, the study of Rotarix was underpowered for the primary analysis (self-controlled risk interval design) but the secondary analysis (cohort design) suggested an increased risk following dose 2.[310] In Singapore, an increased risk of intussusception was detected following dose 1 (SCCS), and in the United Kingdom, following dose 1 and dose 2 (SCCS).[382,382a]

Inactivated Human Rotaviruses

Because administration of oral rotavirus vaccines in the developing world may induce a lesser response than in higher income countries—and because reduced immunogenicity and effectiveness in the developing world might be caused by antibodies in breast milk or interference by parasites or toxin-producing bacteria in the gut—parenteral rotavirus vaccines are being developed. A variety of approaches have been pursued, including inactivated whole rotavirus vaccine,[383] triple- and double-layered virus-like particle vaccines,[384,385] recombinant subunit VP6 protein vaccines,[386–388] and a truncated recombinant subunit VP8 protein vaccine candidate with P[8], P[4], or P[6] specificity expressed in *Escherichia coli*.[389] Preliminary studies in experimental animals show promise for some of these approaches[390]; further clinical development is ongoing.

Community Protection

Shortly after vaccine introduction in the U.S., declines in hospitalizations for rotavirus gastroenteritis were also observed among children under age 5 years that were not age-eligible for vaccination[268–270,281,291–294,297,299,391,392] suggesting indirect benefits from reduced transmission of rotavirus in the community. Similar observations were reported from Australia, countries in Europe and Latin America and in Israel, following national introduction of rotavirus vaccine.[286,301,363,367,393–398b] Interestingly, indirect protection from infant vaccination appears to extend to (unvaccinated) older children (United States, Australia, United Kingdom) and adults (United States, United Kingdom), revealing a previously unrecognized burden of moderate to severe rotavirus disease in these age groups.[398b,399–402] These indirect benefits were not anticipated prior to vaccine implementation and provide further encouragement for vaccine use, as do the early data on unanticipated benefits of rotavirus vaccination in protection against childhood seizures.[302,302a,402a]

Recommendations for Use of RotaTeq and Rotarix in the United States

Routine Administration. Recommendations for the use of rotavirus vaccines have been issued by several committees.[403–405] The ACIP recommends routine oral immunization of U.S. infants with either three doses of RotaTeq administered at 2, 4, and 6 months of age or two doses of Rotarix administered at 2 and 4 months of age.[404,405] The minimum age for the first dose is 6 weeks and the maximum age is 14 weeks and 6 days of age. Subsequent doses should be given with an interval of at least 4 weeks, and all doses of vaccine should be administered by age 8 months and 0 days. The first dose of vaccine was not recommended for infants more than 14 weeks and 6 days because of lack of safety data from the clinical trials in starting the series in infants older than this age and to avoid the peak age range at which idiopathic intussusception occurs. It was also recommended that no dose of vaccine be administered to infants more than 8 months and 0 days of age because of insufficient data on safety. It is unlikely that these age restrictions will be loosened any time soon.

Rotavirus vaccines can be administered together with diphtheria, tetanus, and acellular pertussis, *Haemophilus influenzae* type b, inactivated polio, hepatitis B, and pneumococcal conjugate vaccines. Rotavirus vaccine can be administered to infants with mild illness. Infants with moderate to severe illness should be vaccinated as soon as they recover from the acute phase of the illness.

The effect of simultaneous administration of both RotaTeq and Rotarix with OPV on the immune response to each of the

vaccines has been evaluated.[406–408] Neither RotaTeq nor Rotarix interferes with the immune response to any of the three antigens in OPV. OPV appears to interfere with the immune response of the first dose of rotavirus vaccine, but this interference is largely overcome after administration of the complete vaccine series. Bivalent and monovalent OPV also appear to interfere with the immune response to rotavirus vaccine.[408a,408b]

Breastfeeding. The efficacy of the vaccine is similar among breastfed and nonbreastfed infants. No restrictions are placed on the infant's feeding before or after receipt of rotavirus vaccine.

Premature Infants. Premature infants may be vaccinated if they are at least 6 weeks of age, have been discharged or are about to be discharged from the hospital nursery, and are clinically stable. The ACIP considers the benefits of rotavirus vaccination of premature infants to outweigh the theoretical risks.

Contraindications. Rotavirus vaccine should not be administered to persons who have severe hypersensitivity to any component of the vaccine or who have experienced a serious allergic reaction to a previous dose. Latex rubber is contained in the Rotarix oral applicator; consequently, infants with a severe (anaphylactic) allergy to latex should not receive Rotarix. The RotaTeq dosing tube is latex-free. Neither RotaTeq nor Rotarix should be administered to infants who have severe combined immunodeficiency disease; vaccine-acquired rotavirus infection and disease has been reported in infants with severe combined immunodeficiency disease following rotavirus vaccine administration.[409,410] RotaTeq and Rotarix are also contraindicated in infants that have had intussusception.[411]

Precautions. Practitioners should consider the potential risks and benefits when deciding whether to administer RotaTeq or Rotarix to the special populations listed below.

Altered Immunocompetence Other Than Severe Combined Immunodeficiency Disease. Children and adults who are immunocompromised because of congenital immunodeficiency, hematopoietic transplantation, or solid-organ transplantation sometimes experience severe, prolonged, and even fatal rotavirus gastroenteritis.[183–185] However, no safety or efficacy data are available for the administration of rotavirus vaccine to infants who are potentially immunocompromised.

Preexisting Chronic Gastrointestinal Disease. The safety and efficacy of RotaTeq or Rotarix have not been established for infants with chronic gastrointestinal diseases such as congenital malabsorption syndromes, Hirschsprung disease, short-gut syndrome, or persistent vomiting of unknown cause. However, the benefits of vaccination outweigh the theoretical risks in infants with preexisting chronic gastrointestinal conditions who are not undergoing immunosuppressive therapy.

Special Situations

Exposure of Immunocompromised Persons to Vaccinated Infants. Infants living in households with persons who have or are suspected of having an immunodeficiency disorder or impaired immune status may be vaccinated. Protection of the immunocompromised household member afforded by immunization of young children in the household likely outweighs the small risk of transmitting vaccine virus to the immunocompromised household member and any subsequent risk of vaccine virus-associated disease. To minimize potential virus transmission, all members of the household should employ measures such as good hand washing after contact with the feces of the vaccinated infant.

Exposure of Pregnant Women to Vaccinated Infants. Infants living in households with pregnant women should be vaccinated according to the same schedule as infants in households without pregnant women. Most women of childbearing age have preexisting immunity to rotavirus; therefore, the risk of infection and disease from potential exposure to the attenuated vaccine virus strains is low. In addition, immunization of young children would avoid potential exposure of pregnant women to wild-type virus if the unvaccinated infant suffers from rotavirus gastroenteritis.

Regurgitation of Vaccine. The practitioner should not readminister a dose of rotavirus vaccine to an infant who regurgitates, spits out, or vomits during or after administration of vaccine. The infant can receive the remaining recommended doses of rotavirus vaccine at appropriate intervals.

Hospitalization After Vaccination. If a recently vaccinated child is hospitalized for any reason, no precautions other than routine universal precautions need be taken to prevent the spread of vaccine virus in the hospital setting.

DETECTION OF PORCINE CIRCOVIRUSES IN ROTAVIRUS VACCINES

In 2010, Eric Delwart and colleagues at the University of California, San Francisco, using deep sequencing and microarray technologies, found nucleic acids from porcine circovirus (PCV) type 1 in Rotarix.[412] Subsequent studies performed by the U.S. Food and Drug Administration, Merck, and GlaxoSmithKline found evidence for live PCV type 1 in Rotarix and genetic fragments but not live PCV type 2 in RotaTeq.[412a,413,414] Neither PCV-1 nor PCV-2 has been found to cause an immune response or disease in humans.[415] Consistent with that observation, children inoculated with Rotarix or RotaTeq in Phase III trials were not found to have PCV-1 or PCV-2 antibodies in serum. The source of PCV in both vaccine preparations was probably the porcine trypsin used to grow rotaviruses in vitro. Although the presence of PCV does not pose a safety risk, both companies have committed to removing PCV from their vaccines.

PUBLIC HEALTH CONSIDERATIONS

After the withdrawal of RotaShield vaccine from the market, there was deep disappointment that, despite the licensing of an effective rotavirus vaccine, public health advocates were back at square one. A vaccine had been developed that had a rare flaw in its safety profile: intussusception in infants. The situation was made worse by the fact that the mechanism for the causation of intussusception was unknown and the incidence of intussusception attributed to the vaccine was extremely low (approximately one in 10,000). This meant that establishing apparent relative safety with a new and alternative vaccine could only be claimed by blindly vaccinating large numbers of infants and observing their health for an extended period, without the benefit of any biological markers known in the infant hosts to determine whether the vaccine trial in progress was safe (the numbers of infants tested by two companies that took up the challenge [GlaxoSmithKline and Merck] was more than 60,000 for each company). That two companies pursued this product at extraordinary cost and with absolutely no guarantee of success is just as remarkable as the fact that each created, produced, and licensed a new rotavirus vaccine, based on different biological approaches.

Many countries that have introduced rotavirus vaccines in their national childhood immunization programs have shown remarkable declines in severe rotavirus gastroenteritis post vaccine introduction.[268–270,415a] In the United States, for example, an estimated 177,000 hospitalizations, 242,000 emergency department visits, and more than 1,000,000 outpatient clinic visits for rotavirus gastroenteritis were averted during the 4-year period July 2007 through June 2011.[282] Data from a national network of sentinel clinical laboratories show the marked and sustained declines in U.S. rotavirus activity

after vaccine implementation and depict the biennial pattern of rotavirus activity that has emerged following vaccine introduction, with small peaks of rotavirus activity now alternating with years with very low levels (Fig. 52.4).[416]

Against these remarkable health benefits from vaccination, postlicensure evaluations have identified a safety issue, with a risk of intussusception following RotaTeq and Rotarix estimated between approximately one and six excess cases of intussusception per 100,000 vaccinated infants. Acknowledging the documented benefits as well as the small increased risk of intussusception from these vaccines (Table 52.9),[307,308,312,417] advisory bodies and health organizations continue to support the routine use of these vaccines. Evaluations based on ecological data do not demonstrate a consistent increase in the overall rate of intussusception in infants (younger than age 1 year) in early postintroduction data from the United States and Australia; however, ecological data have important inherent limitations for assessing possible changes in rate of such an uncommon condition.[417a,418,418a,418b] Given that three biologically different rotavirus vaccines are associated with intussusception, one could postulate that wild-type natural rotavirus infections might also be a rare cause of intussusception. If this is true, then one could argue that rotavirus vaccines, which prevent natural rotavirus infections, might also prevent intussusception caused by natural infection. U.S. investigators used VSD data to evaluate whether infants who received rotavirus vaccine have a lower intussusception risk in later infancy compared with infants who did not receive rotavirus vaccine; a statistically significant difference in rates in later infancy was not found.[419]

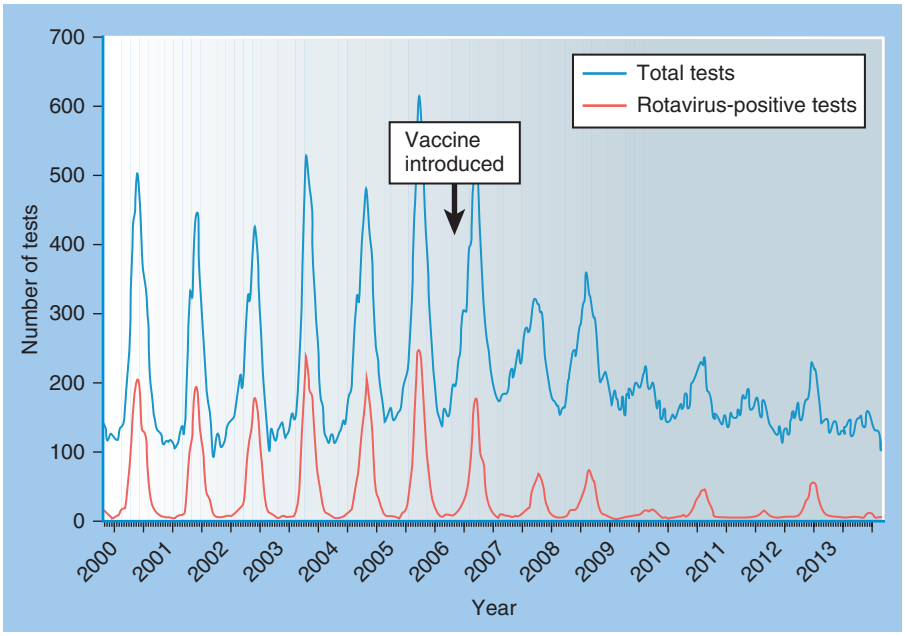

Figure 52.4. Number of total rotavirus enzyme immunoassay (EIA) tests performed and number of positive rotavirus EIA tests from 23 continuously reporting laboratories in the U.S. National Respiratory and Enteric Viruses Surveillance System (NREVSS), by week of year, July 2000–August 2014, 3-week moving average. *(Modified from Aliabadi N, Tate JE, Haynes AK, et al. Sustained decrease in laboratory detection of rotavirus after implementation of routine vaccination—United States, 2000–2014.* MMWR Morb Mortal Wkly Rep. *2015;64[13]: 337–342.)*

TABLE 52.9 Risk-to-Benefit Estimates of Rotavirus Disease vs. Intussusception Outcomes by Country[a]

Country		Rotavirus Outcome Averted	Intussusception Outcome Caused	Rotavirus Outcome Averted: Intussusception Outcome Caused	Reference
Mexico	Hospitalizations	11,551	41	282:1	308
	Deaths	663	2	331:1	
Brazil	Hospitalizations	69,572	55	1265:1	308
	Deaths	640	3	213:1	
Australia	Hospitalizations	6528	14	466:1	312
	Deaths	NR	NR	NR	
United States	Hospitalizations	53,444	35–166	322–1530:1[b] 251–1191:1[c]	417
	Deaths	14	0.1–0.5	28–134:1	

[a]Estimates based on one vaccinated birth cohort followed to age 5 years.

In 2010, results of Phase III trials of both RotaTeq and Rotarix conducted in developing countries of Africa and Asia were reported (see Table 52.6). The efficacy of both vaccines in these trials was moderate compared with that reported in earlier trials in affluent settings.[262,267,350,415a,419a,419b] However, because of the greater baseline burden of severe rotavirus in developing countries, the public health benefits of vaccination in terms of absolute number of cases of severe rotavirus disease prevented were substantial. While the exact reasons for the somewhat diminished performance of rotavirus vaccines in developing countries are unclear, other live oral vaccines such as those against polio, cholera, and typhoid have also not worked equally well in populations in developed and developing country settings. Many factors in infants in the developing world—levels of maternal antibody, micronutrient malnutrition, the presence of interfering microorganisms, and companion diseases such as HIV and malaria—can alter the ability of the infant to process a live oral vaccine, lower the effective dose, and interfere with virus replication and impede a good immune response.[420,420a] Alternate vaccine schedules have also been explored.[423a,423b,423c,423d] Antibodies and other factors present in breast milk have also been postulated as factors that could impair rotavirus vaccine performance.[421–423,423e] However, several newer studies have not shown any beneficial effect of temporarily withholding breastfeeding for 30 to 60 minutes before and after vaccine administration on the immune response to rotavirus vaccine.[424–426]

RECOMMENDATIONS FOR ROTAVIRUS VACCINE USE IN THE EXPANDED PROGRAMME ON IMMUNIZATION

WHO recommends that rotavirus vaccines be included in all national immunization programs and be considered a priority in countries with high rotavirus fatality rates.[427,428] Two vaccines are currently widely available. Rotarix is recommended to be given in a 2-dose schedule at the time of DTP1 and DTP2; RotaTeq is recommended to be given in a 3-dose schedule at the time of DTP1, DPT2, and DPT3. For both vaccines, a minimum interval of 4 weeks is recommended between doses.

WHO recommendations state that although early immunization is still favored, with the first dose of rotavirus vaccine administered as soon as possible after 6 weeks of age, immunization programs can allow children to receive rotavirus vaccine together with DTP regardless of the time of vaccination (to age 24 months). These updated recommendations were made following review of data on the potential impact of the manufacturers' conventional age restrictions on the first and last doses of the series[427]; in countries where rotavirus mortality is the highest, delays in immunization are common and hence strict limits on maximum ages for administration of rotavirus vaccine can substantially reduce the number of children who can receive rotavirus vaccine. A modeling study had assessed the potential benefits of mortality reduction from rotavirus versus the risk of fatal intussusception in low- and low/middle-income countries when the first dose of the vaccine is strictly administered by 15 weeks of age and the last dose is administered by 32 weeks of age, compared with a unrestricted age strategy with rotavirus vaccine administered at the time of DTP administration (up to age 3 years).[429] This analysis demonstrated that removing the age restrictions in these countries (which would allow an additional 21% to 25% of children to receive rotavirus vaccine) would avert an additional 47,200 rotavirus deaths and cause an additional 294 intussusception deaths, for an incremental benefit-to-risk ratio of 154 deaths averted for every death caused by vaccine. Postintroduction intussusception assessments are underway in Africa.

Future development and introduction of rotavirus vaccines will require substantial input from the international donor community, including the Vaccine Alliance, Gavi, and the Bill & Melinda Gates Foundation. Many local vaccine makers in China, India, Indonesia, and other settings have begun their own programs for rotavirus vaccine development and introduction, and these efforts could provide an additional supply of vaccine at an affordable cost to ensure that they reach the poorest children in the world who need them the most. In addition to other candidate oral rotavirus vaccines, approaches such as inactivated rotavirus vaccines are being pursued, especially since this could help overcome some of the challenges to diminished performance of oral rotavirus vaccines in developing countries and also potentially avoid a risk of intussusception.[383] Such new vaccines are unlikely to be proposed for international use for many years.

53 Rubella Vaccines

Susan E. Reef and Stanley A. Plotkin

RUBELLA

> *Just a dead comma of flesh where the ear should hang, a poxed hole mottled in bone, and she holds you, as you shiver curled against the muffled songs we sing as we pass by in our doctor's clothes and then leave you alone again, to redefine the white surgery waiting-room with glazed dum-dum eyes, not even warming the living gel of your pulped brain.*
>
> **Michael O'Reilly**[1]

First described in the late 18th century as a mild exanthematous disease of children and young adults, rubella became prominent in 1941 as a cause of congenital defects in the fetus after maternal infection during pregnancy. The development and use of a live attenuated vaccine has controlled rubella in developed countries during the last 40 years, even enabling elimination in Nordic countries and the Western Hemisphere, and more recently, use of the vaccine has been extended to large regions of the world. Nevertheless, congenital rubella continues to be an important problem in countries not using vaccine.

The first researchers to distinguish the disease from other exanthems were German physicians; hence, the common English language eponym *German measles*.[2] In 1841, a British physician reported an outbreak in a boys' school in India and coined the term *rubella*, a Latin diminutive meaning "little red."[3] For the next 100 years, rubella received scant attention, but in 1941, Norman McAlister Gregg,[4] an Australian ophthalmologist, linked congenital cataracts to maternal rubella. Gregg had noticed an unusual number of infants with cataracts coming to his practice, and he was curious enough to investigate. It is said that a crucial clue was a conversation he overheard in his waiting room between two mothers who were discussing the rubella they both had sustained in pregnancy during the Australian outbreak of 1940.[5] After several years of inattention and skepticism, Gregg's original observation was followed by reports of Australian,[6] Swedish,[7] American,[8] and British[9] epidemiologists and teratologists confirming the role of rubella in congenital cataracts and also noting the simultaneous association of heart disease and deafness in the infants. Thus, the characteristic congenital rubella triad was established.

During the next 20 years, efforts were made to isolate the causative agent and obtain statistics on the risk of fetal abnormality after maternal rubella. Various estimates of the risk were made, ranging from high to low. The disparity in estimates stemmed from the absence of a definitive diagnostic test and consequent misdiagnosis of rubella in the mother. In late 1962, a breakthrough came in the form of the first isolations of rubella virus by Weller and Neva[10] in Boston and by Parkman, Beuscher, and Artenstein[11] in Washington, DC. Weller and Neva detected the presence of rubella virus by cytopathic effect in human amnion cells, whereas Parkman, Beuscher, and Artenstein developed a technique dependent on interference with the growth of enteroviruses in African green monkey kidney (AGMK) cell culture.

Meanwhile, a pandemic of rubella started in Europe in the 1962 to 1963 season, with spread to the United States and pandemic disease in 1964 to 1965. As a result, from 1964 to 1966, thousands of pregnancies were affected by rubella, leaving behind a wake of medically induced abortions and abnormal infants.[12,13] The pandemic led to the recognition of an expanded congenital rubella syndrome (CRS), which added hepatitis, splenomegaly, thrombocytopenia, encephalitis, mental retardation, and numerous other anomalies to the already described deafness, cataracts, and heart disease.[2,3,14] The pandemic also made it obvious that a vaccine was needed, and many groups set to work.

Between 1965 and 1967, several attenuated rubella strains were developed and reached clinical trials.[15–17] In 1969 and 1970, rubella vaccine entered into commercial use in Europe and North America. Since the late 1970s, vaccination has had a major impact on the epidemiology of rubella and CRS.

BACKGROUND

Clinical Description

Acquired Rubella

Rubella is spread by large particle aerosols; primary implantation and replication occurs in the nasopharynx. The incubation period of rubella is 14 to 23 days, with most patients developing a rash 14 to 17 days after exposure.[18] During the first week after exposure, there are no symptoms, but in the second week, lymphadenopathy may be noted, particularly occipital and postauricular, and virus cultures reveal rubella virus in the nasopharynx. Later in the second week, virus appears in the blood. About this time, there may be a prodromal illness consisting of low-grade fever (<39.0°C), malaise, and mild conjunctivitis. If not already present, the aforementioned lymphadenopathy is likely to develop.

At the end of the incubation period, a maculopapular erythematous rash appears on the face and neck in about two thirds of cases, but the clinical to subclinical ratio is variable. The rash may be difficult to detect, particularly on pigmented skin, and is more prominent after hot showers or baths. During a course of 1 to 3 days, the rash spreads downward and begins to fade. Pharyngeal virus excretion is present in high titer up to 4 days after rash onset, and virus excretion in the pharynx and urine may continue for another 1 to 2 weeks, but viremia ends with the appearance of antibodies, which is more or less simultaneous with the onset of the rash.[19] Fig. 53.1 illustrates the evolution of acquired rubella.

Although acquired rubella is thought of as a benign disease, arthralgia and arthritis commonly are observed in adults, particularly women, associated with virus replication or latency in the synovia.[20,21] Chronic arthritis has been reported after rubella infection,[22] although the evidence is weak.[23,24] Other less-common complications are thrombocytopenia[23] and encephalitis, which may be fatal.[25,26] Encephalitis has been reported to occur in approximately one in 6000 cases and is of the postinfectious type, although the limited available pathologic data show little evidence of demyelination.[27] However, the incidence of encephalitis was one in 1600 cases of rubella in a Japanese outbreak,[28] and recently, in the South Pacific islands of Tonga and Samoa, the incidence was estimated as between one in 500 and one in 1000 cases (Ruben A: Rubella-associated encephalitis in Tonga, 2002; unpublished

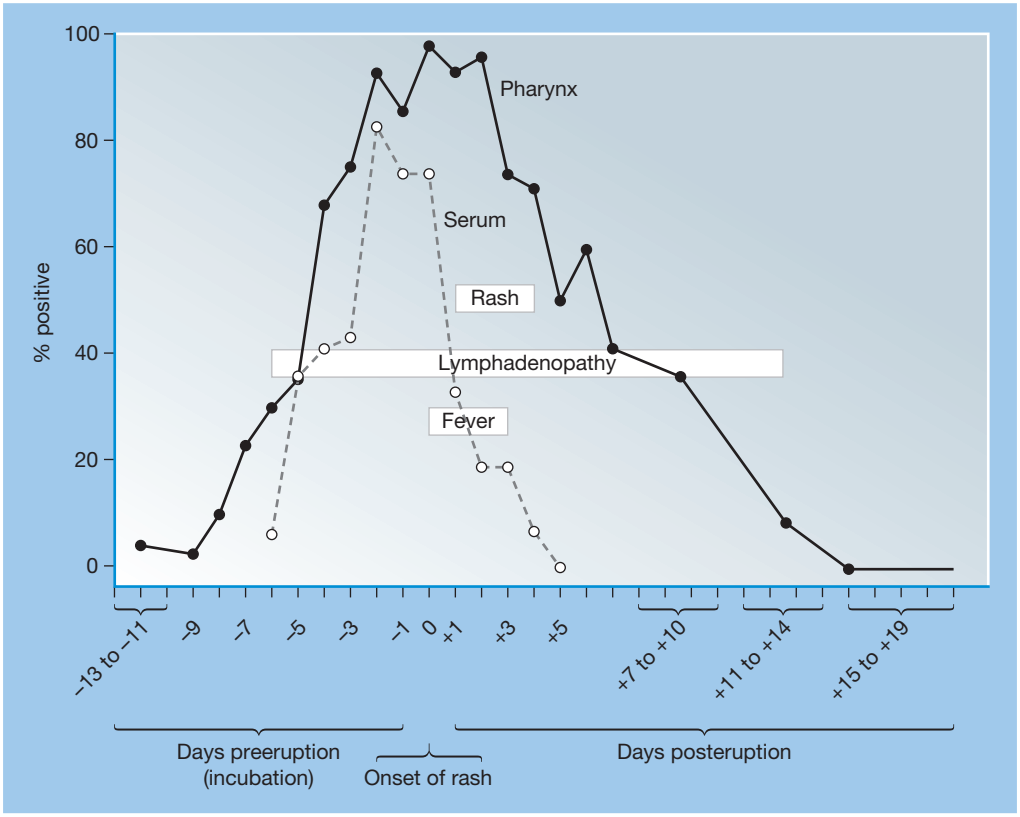

Figure 53.1. Sequence of events in acquired rubella infections, showing the relationship between onset of rash and other clinical symptoms and recovery of rubella virus from diagnostic specimens. Serum is noted by the dotted line; pharynx is noted by the solid line.

report, 2006). In 2011–12 in Tunisia, 280 cases of rubella were confirmed, including 39 cases of encephalitis that occurred mainly in adolescents and adults.[29] Another report described nine cases of encephalitis, most of which were in children.[30] A study done in China between 2010 and 2012 using a multiplex reverse transcription–polymerase chain reaction (PCR) showed that 3.3% of viral encephalitis was caused by rubella.[31] In addition, there is a rare late syndrome of progressive rubella panencephalitis that is inexorable and may also be seen in congenital infection.[32,33] By analogy to subacute sclerosing panencephalitis caused by measles, progressive rubella panencephalitis is thought to be related to persistence of viral antigens. Guillain-Barré syndrome after rubella has also been reported, although the causal relationship is uncertain.[34] Antibodies to rubella and measles structural proteins are elevated in autoimmune chronic active hepatitis, but there is no evidence for the presence of rubella virus in this disorder.[35]

Rubella virus may play a central role in the etiology of Fuchs heterochromatic anterior uveitis.[36,37] This condition is chronic and may lead to cataracts or glaucoma. Rubella virus RNA and high-titer antibodies have been demonstrated in intraocular fluid of patients with this condition.[38–40] Recently, intraocular rubella virus was detected in a 28-year-old survivor of congenital rubella syndrome, indicating the ability of the virus to persist and cause Fuchs uveitis.[40a] The prevalence of the syndrome has decreased in the United States since the introduction of vaccination.[41]

Congenital Rubella Syndrome

Rubella is the archetypical fetal infectious pathogen (see "Pathogenesis as It Relates to Prevention" later). Because all organs of the fetus are affected, it is not surprising that CRS comprises a lengthy list of abnormalities, including anatomic changes resulting from interference with organogenesis and inflammatory effects involving organs such as the liver and spleen (Table 53.1).[42] Histopathological study of several congenital rubella syndrome cases showed widespread presence of rubella antigen in fibroblasts lining the heart and blood vessels, alveolar macrophages, progenitor cells of the outer

granular layer of the brain, as well as capillary endothelium in the placenta.[42a] Rubella virus replicates in the nasopharynx of affected infants and presents a risk to others. In a Japanese study, 17% of infected infants were still excreting rubella virus 1 year after birth.[42b]

The time of infection during gestation is important in relation to the fetal outcome; infection in the first 3 months tends to result in serious ocular or cardiac disease, whereas infection late in the first half of pregnancy is more likely to result in isolated hearing impairment. However, the relationship between gestational age and abnormality can be overemphasized because fetal infection, once established, spreads to all organs, and damage may be progressive.

Table 53.2 demonstrates that organ specificity is only generally related to the stage of gestational infection with rubella virus. The most common congenital defects are sensorineural deafness, cataracts, pigmentary retinopathy, and patent ductus arteriosus; however, malformations of the pulmonary artery or its branches can be demonstrated in 78% of CRS patients in whom cardiac studies are done, and patent ductus arteriosus is found in 62%. In addition, myriad other abnormalities occur, including glaucoma, endocrinopathies such as diabetes, hyperimmunoglobulinemia M,[43] microcephaly, and mental disability. Ocular defects are particularly varied, including abnormalities of the cornea, the lens, the retina, and uveitis.[44–47] An analysis of prospective studies for distribution of clinical manifestations of CRS is summarized in Table 53.3.[48]

A comprehensive review of the retrospective and prospective studies estimated that hearing, cardiac, ocular, and intellectual manifestations were found, respectively, in 70%, 31%, 16%, and 6% of CRS infants. However, if mixed-cohort and infant-case series are included, the percentages of cardiac, ocular, and intellectual manifestations increase to 46%, 35%, and 40%, respectively.[49] Various other estimates have been made of the incidence of fetal abnormalities after maternal infection.[8,50–56] Many prospective studies of the incidence of fetal rubella have accepted clinical diagnosis of rubella in the mother for case inclusion, but if only virologically confirmed maternal rubella is considered, the rate of transmission to the fetus during the first 10 weeks of pregnancy is as high as 90%.[51,57–59] Table 53.4 tabulates data from the two most reliable studies, one from United States data[52] and the other from United Kingdom.[51] The first 12 weeks of pregnancy are clearly the most dangerous time for rubella infection in the mother. The incidence of fetal disease declines during the next 4 weeks, and in the 16th to the 20th weeks, only deafness has been reported as a complication. Preconceptional rubella rarely results in fetal infection, but rashes that occur within 12 days

TABLE 53.3 Frequencies of Selected Defects in Infants With Congenital Rubella Syndrome: Comparison of Data From Prospective Studies and Data Presented in a Standard Pediatric Infectious Disease Textbook

Clinical Manifestation	No. of Studies	Study Subjects (%)[a]	Previously Reported Studies (%)[b]
Hearing impairment	10	68/113 (60)	80–90
Heart defect	9	45/100 (45)	–

of the last menstrual period carry proven risk.[60,61] In an Irish epidemic, 71% of fetuses infected early in pregnancy were affected.[62] Although some Japanese workers[63] have claimed that rubella virus is less teratogenic in their country, these claims have not been supported.[28]

Damage caused by congenital rubella infection is not always evident at birth: glaucoma may become apparent and late cataracts are possible. Retinal detachments and esophageal problems are common later in life.[64] Of interest, autism is a feature of some late-onset neurologic disease in CRS patients. In addition, a variety of syndromes thought to be autoimmune are seen, including diabetes mellitus and thyroiditis.[64,65]

Diabetes develops in 12% to 20% of American, European, and Australian CRS survivors.[66,67] However, a 40-year follow-up of Japanese CRS patients showed that only 1.1% were diabetics.[68] Although autoimmunity is involved in ordinary diabetes mellitus, a thorough study of CRS patients showed no increase in autoantibodies to pancreatic proteins.[69]

Virology

The agent of rubella is a cubical, medium-sized (50 to 85 nm), lipid-enveloped virus with an RNA genome belonging to the Togaviridae family and the genus *Rubivirus*.[69a] Although the other togaviruses are arthropod-borne, there is no evidence for such transmission of rubella. Frey[70] has reviewed the virology of rubella. Apart from the complex lipid envelope derived from the host cell, rubella virus is composed of three proteins: two embedded in the envelope in the form of spikes (E1 and E2) and one (C) composing the capsid. E1 is a glycoprotein with neutralizing and hemagglutinating epitopes, while the function of the E2 glycoprotein is unclear.[71] The three proteins, which have molecular masses of 60,000 kDa (E1), 42,000 to 47,000 kDa (E2), and 30,000 kDa (C), are derived from a polypeptide of 110 kDa that is translated from a 245-kDa messenger RNA.[72–74]

The positive-sense RNA genome of rubella virus contains approximately 9800 nucleotides and is infectious.[75,76] The replication strategy of rubella virus is similar to that of the alphaviruses in that both full-length and subgenomic RNAs are produced, and it is from the subgenomic RNA that viral structural proteins are translated. Three other proteins are produced by the virus in infected cells but are not incorporated into the virion.[77] The structural capsid protein interferes with cellular mitochondrial function, inhibiting transport of proteins into the mitochondria and causing morphologic alterations of those organelles.[78] A receptor for the virus has not been definitely identified, but myelin oligodendrocyte glycoprotein may be involved in spread to the placenta and fetal brain.[69a]

There is only one serotype of rubella virus, and analyses of sequence variation among occidental isolates show high conservation of amino acid structure (0% to 3.3% differences), with less conservation of isolates from Asia (up to 7%).[79,80] However, there are two clades and at least three genotypes.[81,82] For rubella isolates collected before 2000, isolates from North America, Europe, and Japan are closely related to each other and form clade I, whereas clade II comprises some strains from China, Korea, and India.[81] However, in China, between 2001 and 2007, there was a shift of genotypes toward predominance of genotypes 1E and 1F.[83] Similarly, in France, genotype 1E has become predominant.[84] Isolation of virus from cataracts in Indian CRS cases revealed genotype 2B.[85] Of rubella isolates collected between 2005 and 2010, three genotypes (1E, 1G, and 2B) had wide geographic distribution, whereas others occurred sporadically or were geographically restricted.[82] More recent studies continue to identify the circulation of multiple genotypes, including in Africa, with 1B, 1E, 1G, and 2B being prominent.[85a,85b]

The genetic differences between clades do not appear to translate into antigenic differences, despite amino acid changes of 3% to 6% in viral proteins.[86] Moreover, isolates from CRS cases are not genetically distinct from isolates from acquired rubella.[87] No significant antigenic drift has occurred in recent years, and isolates from vaccinees showed little variation from vaccine strains. However, recent data show many intercontinental transfers of clades I and II.[88] Because clade II was clearly of Asian origin, and clade I isolates from Asia are highly variable, an Asian origin of rubella virus has been suggested.[89] Genetic analysis allowed the confirmation of the epidemiologic data that implicated spread of endemic rubella strains from Greece to the United Kingdom in 1999.[90] Table 53.5 shows the distribution of rubella virus clades.[91]

Rubella virus grows in many different primary, semicontinuous, and continuous cells of mammalian origin. In human amnion cells, it produces a subtle cytopathic effect. More pronounced cytopathic effects, sufficient to allow plaque formation, are produced in continuous cell lines, such as rabbit kidney (RK13) and baby hamster kidney (BHK-21).[19] Even in those cell lines, fresh isolates frequently are not cytopathogenic and require adaptation by serial passage. High passage generates defective interfering RNA and particles.[92]

Virus isolation is generally performed in primary AGMK cell culture in which virus growth is detected by "challenging" the cultures with a cytopathogenic agent such as echovirus 11. If rubella virus has infected the cultures, replication of echovirus 11 is blocked, probably by interferon induction; the presence of rubella virus is inferred by this interference. Confirmation is performed by another technique, such as neutralization or fluorescence with specific antirubella serum.[93]

Pathogenesis as It Relates to Prevention

The pathogenesis of acquired rubella infection provides two points at which immune intervention could have an effect. The first point is in the nasopharynx, where the virus first replicates and from which it spreads to local lymph nodes. Secretory immunoglobulin (Ig) A antibody in the nasopharynx, induced by prior disease or vaccination, can block mucosal replication. The second point begins about a week into the incubation period, at which time the viremia can be blocked by the presence of antibody, either passively or actively acquired.

During viremia in a pregnant woman, the virus often infects the placenta. Placental replication appears to precede fetal infections, leading to entrance of virus into the fetal circulation, from which it infects fetal organs.[94] In vitro experiments show that human embryonic cells of many different lineages are susceptible to viral replication and develop chronic noncytopathic infection.[95] The same phenomenon occurs in vivo, except that only a few cells are infected at any one time.[96] If the infected cells are stimulated to divide, either artificially in vitro or in the course of embryologic development in vivo, there is an inhibition of mitosis[95,97] that may be mediated in part by a soluble protein inhibitor[98] or by the induction of apoptosis.[99–102] Although low-passage strains produce more pronounced apoptosis, the effect is only moderate in human fibroblasts in culture.[103] In a few organs, including the lens, cochlea, and brain, the damage caused by the virus is more cytopathic.[104] Viral infection of the ciliary body may contribute to cataractogenesis[105] and wild virus destruction of endothelial cells may lead to vasculitis and ischemia.[106] Cytologic studies show that the cell skeleton and mitochondria both are damaged by rubella virus replication.[107] Atreya and coworkers[108] proposed that rubella virus replicase interacts with retinoblastoma tumor suppressor protein and the enzyme citron-K kinase, leading to cell-cycle arrest in S phase

and activation of apoptosis. Adamo and coworkers[109] emphasized the importance of the innate immune response to rubella infection, leading to interferon induction that causes apoptosis.

In summary, the action of rubella virus on organogenesis is mediated by varying combinations of intracellular pathology, inhibition of cellular replication, and apoptosis.[107,110]

Diagnosis

Methods for the diagnosis of acquired and congenital rubella have been reviewed[111] and are summarized in Table 53.6. Clinical diagnosis of acquired infection is so inaccurate as to be useless without laboratory support. When suspected measles cases are subjected to laboratory tests, rubella infection is often identified.[110a] Isolation of virus can be accomplished from the blood and nasopharynx during the prodromal period and from the nasopharynx for as long as 2 weeks after eruption, although the likelihood of virus recovery is sharply reduced by 4 days after the rash. The Vero cell line, primary AGMK cells, or the RK13 cell line are generally used for virus isolation; but because of the slow growth of the virus in tissue culture, virus isolation is often bypassed in favor of serologic diagnosis.

The PCR has been adapted to the detection of rubella RNA by reverse transcription and amplification.[112] The method appears to be 100% sensitive and approximately 90% specific[113–115] and is particularly useful for prenatal detection of rubella infection of the fetus (see below).[116] Reverse transcription–PCR was shown to permit diagnosis of rubella during the rash before appearance of IgM antibodies.[117] The Taq Man real-time PCR assay has been applied to rubella virus detection.[118]

Initially, serologic diagnosis became feasible because rubella virus hemagglutinates red blood cells, particularly of avian origin, permitting measurement of antibodies by hemagglutination-inhibition (HI) testing.[119] Because HI and neutralization tests are labor intensive, other serologic examinations that are amenable to mass testing have come into use, such as latex agglutination, indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), latex agglutination, single radial hemolysis, and fluorescence inhibition.[59,120] Any of these methods may be used to measure antibodies to rubella. Detection of antibodies in saliva or urine could simplify testing in developing countries, but commercial kits are not available.[121–125] Nevertheless, identification of IgM antibody in oral or crevicular fluid permitted efficient diagnosis of rubella in the United Kingdom over a 10-year period.[126]

Serologic diagnosis depends on the demonstration of a fourfold rise in IgG titer between acute and convalescent specimens or a demonstration of IgM antibody in the acute specimen.[120] For IgM testing, ELISA, in a capture format to avoid false positivity because of IgG antibody, is the predominant assay in use; results may be positive for up to 6 weeks after the acute infection.[127]

Susceptibility to rubella infection has been defined as an HI antibody titer of less than 1:8, a hemolysis-in-gel result of less than 10 IU, or an optical density by ELISA at less than the limit set by the manufacturer. Waning antibody may be restimulated on exposure, such that protection results, and epidemics have not occurred in well-vaccinated countries even when significant numbers of vaccinees no longer have antibodies at the 10 IU level. Titers at the borderline level are difficult to evaluate, but the consensus is that, although in the majority of cases they reflect immunity, the safest response is to vaccinate the individual with equivocal levels of antibody.[128,128a,128b]

Assays for antibody avidity and for responses to specific proteins or peptides have come into use for diagnosis of recent infection.[129,130] Low-avidity antibodies indicate recent infection, with maturation to high avidity by about 2 months postexanthem. A careful study of antibody responses to primary rubella infection found an initial low-avidity IgM response, followed by low-avidity IgG_3 and IgA responses, and then, finally, IgG_1 responses maturing from low to high avidity.[131] Liebert and coworkers[132] studied various serologic modalities and found that low levels of antibody to the major neutralizing epitope on the E1 protein, poor response to the E2 protein, and low IgG avidity for rubella virus were highly predictive of recent infection in both mother and infant.[116,133] Antibodies to E2 develop months after infection or vaccination.[134] Rules for diagnosis of rubella in pregnancy have been well summarized.[134a]

In contrast to the situation with acquired infection, the recognition of the combination of cataracts, heart disease, and deafness provides a clinical means of diagnosis of CRS that is reasonably accurate.[135] However, laboratory confirmation is always desirable, both because isolated abnormalities may occur and for public health reasons.

Congenital rubella infection in the infant is associated with the detection of virus, viral genome, IgM antibodies by capture techniques, low-avidity IgG antibodies, lack of antibodies to the E1 protein,[136] or antibodies persisting beyond the predicted decay of passively transmitted maternal antibodies. Virus often can be isolated from tissues obtained at biopsy or autopsy or during surgical procedures such as cataract extraction,[137] but more often nasopharyngeal swabs, urine specimens, or cerebrospinal fluid serve as the sources. Almost always, one or more of these sources are positive for virus at birth, gradually becoming negative during the first year of life.[138] In severe cases, virus excretion may persist for several years.[139] A negative result from PCR performed on fetal samples

TABLE 53.6 Laboratory Diagnosis of Acquired and Congenital Rubella

		When Positive	
Test	**Specimen**	**Acquired Rubella**	**Congenital Rubella**
Virus isolation	Throat, urine, blood	First week of illness	At birth, declining thereafter
RT-PCR	Amniotic fluid, placenta	NA	Throughout pregnancy
IgM antibody	Serum	Up to 2 mo postillness	At birth and first year of life
IgG antibody rise	Sera	Fourfold increase between acute and convalescent	NA
Low IgG antibody avidity	Serum	Up to 2 mo postillness	At birth and years later
IgG antibody persistence	Serum	NA	Beyond 6 mo of age, until exposure to infection or vaccination

IgG, immunoglobulin G; IgM, immunoglobulin M; NA, not applicable; RT-PCR, reverse transcription–polymerase chain reaction.

or amniotic fluid during pregnancy is good evidence against intrauterine rubella.[61]

IgM antibodies are present in the infant for as long as a year after birth; however, the IgM titers decline over 6 months, whereas low-avidity IgG antibodies may persist for longer periods. Persistence of IgG antibodies beyond 6 months of age can be detected in 95% of infants with CRS.[140] Salivary specimens are also useful in CRS for detection of antibodies.[141] An infant with seropositive results for rubella after 6 months of age and who has not received rubella vaccine is likely to have been congenitally infected. However, CRS patients may lose their antibodies over time: 60 years after fetal infection, 40% were seronegative.[142] Moreover, sensitization to proliferation of lymphocytes after stimulation with rubella antigens is often negative in CRS infants, even when they are seropositive,[143] and this test may be used for diagnosis in children younger than 3 years of age. Congenital rubella can also be diagnosed by PCR tests of lens aspirates in cases of congenital cataracts.[144]

Diagnosis of CRS has been focused on the first year of life when IgM antibody and viral shedding are likely to be present. However, a recent study of school-age children with CRS identified several serologic markers of fetal infection, including higher rubella-specific IgG, higher relative concentrations of antibodies to the core C and E2 proteins of the virus, but lower relative concentration of antibodies to the E1 protein when compared with normal children. Using those markers, CRS could be identified retrospectively with 65% sensitivity and 100% specificity.[145] Reinfection with rubella virus has been documented to rarely cause CRS, in which case IgG3 antibody is usually absent, in contrast to CRS after primary infection.[145a]

EPIDEMIOLOGY

Acquired Infection

Until 2009, rubella was a worldwide infection, as may be inferred from serologic surveys conducted in many different countries.[122,146] With the successful implementation of the rubella vaccination strategies in the Region of the Americas, endemic rubella and CRS in the Region of the Americas was eliminated in 2009 as verified in 2015 by the International Expert Committee on the Documentation of Elimination of Measles and Rubella.[147,148] Before 2009, the Global Measles and Rubella Laboratory Network found rubella to be the cause of 15% of rash disease for which they received specimens.[91] The factors that give rubella its epidemiologic characteristics are respiratory spread that is greater in crowded societies, different age at infection, and periodic disappearance from geographic areas, only to reappear in epidemic form when susceptibles accumulate. The recent prevalence of rubella antibodies has recently been reviewed.[148a]

As is true of other diseases, some individual rubella patients excrete large amounts of virus in respiratory secretions and are highly infectious "spreaders."[149] The basic reproductive rate, Ro, before vaccination was estimated to be 6 to 7 in developed and most developing countries but up to 12 in crowded developing countries.[150,151] In Europe, there was wide variation in the contagiousness of rubella infection between countries, with reproductive rates ranging from 3 to 8.[152] In Mexico before vaccination, Ro varied among districts from 3.4 to 9.6 and mean age of infection from 3 to 10 years.[153] In the World Health Organization (WHO) African Region there is wide variation in the contagiousness of infection between countries, ranging from 3.3 to 7.9[154] Many rubella infections in childhood are asymptomatic or without rash and therefore unrecognized. Daycare centers also promote early infection with rubella. In island countries and in countries that are less crowded, the average age at rubella infection is older, and many children reach puberty still in a seronegative state.[155] Under these circumstances, introduction of the virus into places where young persons congregate results in epidemic spread.[149] Thus schools, colleges, and military camps are all places where rubella is likely to become epidemic. Other sites where outbreaks have also been reported include African refugee camps.[156]

Outbreaks at the stock exchange on Wall Street illustrate the potential effect of bringing seronegative individuals together in close quarters. In fact, rubella is highly efficient at infecting susceptible persons in certain epidemiologic situations.[157–159]

In the United States, the epidemiology of rubella before vaccination was both endemic and epidemic.[12] Rubella tended to occur each spring, primarily in schoolchildren 6 to 10 years of age, but also in older individuals. Superimposed on this occurrence was a cycle of major epidemics at 7-year intervals. Susceptibility in young adults varied from 10% to 20%, with the lower figure being found after an epidemic. Similarly, in Israel, approximately 9% of women were infected during a 1972 rubella outbreak[160]; however, even after the epidemic, a significant pool of susceptible individuals remained. A seroprevalence study of healthcare workers in Japan found 9.6% without rubella antibodies.[161] Although vaccination has sharply reduced rubella in Japan, immunity is incomplete and epidemics still occur.[161a]

The epidemiology of rubella in developing countries can be deduced from the seroprevalence of rubella antibodies. The large variation seen in seroprevalence suggests that rubella occurs in sporadic epidemics except where population density is high. In the metropolis of Saõ Paulo, Brazil, nearly everyone is seropositive by 20 years of age,[162] whereas in rural Mexico, seropositivity varies from 29% to 76%.[163] Surveillance of rash disease in South America shows that rubella infection is ubiquitous. Cutts and colleagues[164] reviewed rubella susceptibility data from 45 developing countries and found remarkable differences among them, not correlated with geography. For example, Malaysia, Peru, and Nigeria were among the countries where more than 25% of women were found to be seronegative. Studies done in Lagos and Ibadan, Nigeria, in Thailand, and in Izmir, Turkey, confirm the low seroprevalence in women of childbearing age.[165–168] Studies of rubella outbreaks in Kenya and Zimbabwe showed that rubella is endemic in those countries, and a serological survey in Cambodia showed only 73% seropositivity in women.[169–171] Thus, even in countries where little has been done in the way of vaccination and where low socioeconomic levels would predict high seropositivity, 5% to 25% susceptibility may be seen in women of childbearing age.[172–181] Vietnam has had a recent rubella epidemic with a high incidence of CRS,[181a] and studies in various African countries have revealed ubiquitous rubella infection.[181b,181c,181d,181e] The median age of infection in Africa is 7 years.[181f]

Most information on the epidemiology of CRS is available from the United Kingdom and the United States. Table 53.7 presents the tally of fetal damage caused by rubella subsequent to the 1963 to 1964 outbreak.[13] At least 30,000 fetuses were damaged by intrauterine rubella, for an incidence rate of 100 per 10,000 pregnancies. In Philadelphia, the rate was also as high as 1% of pregnancies.[182] After that outbreak, CRS rates fell to four to eight per 10,000 pregnancies until 1970, when the first vaccines were licensed. Since then, CRS declined further to an incidence of less than 0.01 per 10,000 pregnancies, with no indigenous cases,[183,184] and endemic rubella virus is no longer believed to be circulating. Table 53.8 gives the current surveillance criteria for CRS in the United States.[48] In the prevaccine era, the epidemiology of CRS in the United Kingdom was similar to that in the United States, with rates of approximately

TABLE 53.7 Estimated Morbidity Associated With the 1963–1964 Rubella Epidemic

Clinical Events	Cases
Rubella cases	12,500,000
Arthritis-arthralgia	159,375

4.6 per 10,000 births.[185] In general, in Europe at present, CRS incidence is low, and surveillance is improving.[186,187]

Nevertheless, observations in Italy show that CRS was still a problem as of 2013, and a large outbreak of rubella occurred in Poland that same year.[188,189] As with other vaccine-preventable diseases, CRS in the United States has been associated with religious minorities that refuse vaccination. An epidemic of rubella among the Pennsylvania Amish resulted in a rate of more than 20 per 1000 live births.[190] An orthodox Protestant community in The Netherlands was the site of a large outbreak that spread to coreligionists in Canada, leading to 14 cases of CRS and two fetal deaths. Of the reported cases, 97% occurred in unvaccinated persons, but those vaccinated exhibited 99% protection.[191]

In recent years, the worldwide epidemiology of CRS is beginning to be known. Little published information is available for the countries in Africa, and most of Asia, although such data suggest that CRS is common even in the developing world.[192,193] In 2011–12, 279 CRS cases were identified in three Vietnamese hospitals.[194] CRS cases have been identified in Nigeria and in India it is estimated that CRS accounts for 10% to 15% of pediatric cataracts.[195,196] A thorough retrospective study done in the Maldives gave a CRS incidence of one to four per 1000 births during epidemics and 0.1 to 0.2 per 1000 births during endemic periods.[197] Observations made in Myanmar implied a CRS incidence of 0.1 per 1000 births.[198] Based on clinical virology studies, CRS seems to be common in Brazil.[199] In India, 26% of 90 infants investigated for congenital malformations had serologic evidence of CRS.[200] Several other Indian studies[201–205] showed that 6% to 25% of children with nontraumatic cataracts and 15% of infants

TABLE 53.8 Clinical Description and Criteria for Congenital Rubella Syndrome Case Definition for the United States

Definition	Case Classification
Clinical case definition: an illness, usually manifesting in infancy, resulting from rubella infection in utero and characterized by signs or symptoms from the following categories:	**Suspected:** a case with some compatible clinical findings but not meeting the criteria for a probable case **Probable:** a case that is not laboratory confirmed and that has any two complications listed in first paragraph of the clinical case definition or one complication from the first paragraph and one from the second paragraph, and lacks evidence of any other etiology **Confirmed:** a clinically consistent case that is laboratory confirmed **Infection only:** a case that demonstrates laboratory evidence of infection, but without any clinical symptoms or signs
• Cataracts and congenital glaucoma, congenital heart disease (most commonly patent ductus arteriosus or peripheral pulmonary artery stenosis), hearing impairment, pigmentary retinopathy	
• Purpura, hepatosplenomegaly, jaundice, microcephaly, developmental delay, meningoencephalitis, radiolucent bone disease	
Clinical description: presence of any defect(s) or laboratory data consistent with congenital rubella infection. Infants with CRS usually present with more than one sign or symptom consistent with congenital rubella infection. However, infants may present with a single defect. Hearing impairment is the most common single defect	
Laboratory criteria for diagnosis:	
• Isolation of rubella virus	
• Demonstration of rubella-specific IgM antibody	
• Infant rubella antibody level that persists at a higher level and for a longer period than expected from passive transfer of maternal antibody (i.e., rubella titer that does not drop at the expected rate of a twofold dilution per month)	
• Detection of rubella virus by RT-PCR	

CRS, congenital rubella syndrome; IgG, immunoglobulin G; IgM, immunoglobulin M; RT-PCR, reverse transcriptase–polymerase chain reaction.
Material from Reef SE, Plotkin S, Cordero JF, et al. Preparing for elimination of congenital rubella syndrome (CRS): summary of a workshop on CRS elimination in the United States. Clin Infect Dis. *2000;31:89.*

suspected of having congenital infection had rubella-specific antibodies. A history of maternal rash and fever was obtained in 40% of deaf Bangladeshi children.[202,206] Retrospective analysis of a recent epidemic in Kumasi, Ghana gave an incidence of 0.8 per 1000 live births.[207] An investigation in Nepal estimated a rate of CRS of 192 per 100,000 live births.[208] In Shenzhen, China, 22% of female migrant factory workers were seronegative.[209] After a rubella outbreak in Vietnam, several hundred congenital rubella infections and disease were confirmed in 2011–12.[194] Although not well described, rubella virus circulates widely in Africa, and serologic data suggest that 22,500 cases of CRS are estimated to occur yearly.[210]

An incidence of 0.1 per 1000 live births[198] was identified in Moroccco.[211] A review of worldwide data concerning CRS revealed rates in developing countries varying between 0.6 and 2.2 per 1000 live births, similar to rates seen in developed countries before universal vaccination.[151,211–214]

In the absence of systematic laboratory testing of newborns, detection of cataracts and of deafness with subsequent laboratory confirmation of rubella infection is the best method for estimating the incidence of CRS. As congenital cataracts occur in approximately 25% of CRS cases,[215] a rough estimate of incidence can be obtained by multiplying the number of patients with cataracts by four and dividing by the number of births.

A virulence factor has been postulated for rubella strains, and it has been argued from laboratory and clinical data that rubella virus is not teratogenic in Japan. Kono and colleagues[63] reported that Japanese strains had no effect on pregnant rabbits, whereas American strains were transmitted across the placenta from dams to fetal rabbits. In addition, they reported that on the main island of Honshu, no CRS was reported even though rubella outbreaks were evident.[216] However, by careful analysis of rubella on the southern Japanese island of Kyushu, Ueda and coworkers[217] showed that the rates of both rubella and CRS were high. They concluded that the apparently low rate of CRS on Honshu is the result of a high seropositivity rate in adult women and a low clinical reporting rate of CRS. More recently, in 2012–13 a large outbreak of rubella occurred in Japan involving thousands of cases and many CRS babies.[218]

CRS shows a predisposition to affect infants of young mothers, presumably because these women are more likely to enter pregnancy in a seronegative state. Women in contact with populations in which rubella outbreaks occur frequently, such as military recruits and school-age children, are more likely to be exposed. Military dependents and schoolteachers are thus at increased risk. Pregnant women with older children are also at greater risk.

Although rubella outbreaks may be explosive, they frequently do not exhaust all susceptible persons in large populations, and thus a history of having been exposed to a rubella outbreak does not necessarily indicate immunity to rubella. Even more important is the fact that 10% to 85% of infections in various outbreaks have been inapparent or at least have been without evidence of rash.[158] Infection without rash in pregnancy can still lead to fetal disease, although the risk may be lower than that after symptomatic infection with rash.[219]

Significance as a Public Health Problem

The seriousness of congenital rubella as a public health problem can be gauged by the results of the last major American epidemic in 1964 to 1965 (see Table 53.7). An estimated 12.5 million rubella cases occurred, including approximately 2000 cases of encephalitis. More than 30,000 pregnancies were affected by this epidemic. Of these pregnancies, approximately 5000 pregnant women chose to have surgical abortions, surely an underestimate, and approximately 6250 lost fetuses to spontaneous abortions. Another 2100 infants were stillborn or died soon after birth.[13] CRS occurred in 20,000 infants who survived pregnancy. Of these, 11,600 were deaf, 3580 blind, and approximately 1800 mentally disabled. The human misery imposed by such severe damage can well be imagined. The economic burden was estimated to be US$221,660 per child with CRS, and the total cost of the epidemic may have been US$1.5 billion in 1965 dollars.[13]

A more recent economic analysis of the impact of CRS calculated the disability-adjusted life-years and cost of care. For a CRS child in a low-income country, 29 disability-adjusted life-years and US$11,266 in cost of care would be incurred, whereas for a high-income country the figures are 19 disability-adjusted life-years and US$934,000 in cost of care.[220] Before the use of vaccine, rubella epidemics involved approximately 5% of the population, although only approximately 10% of these cases were reported to public health authorities.[221] In the years between epidemics, rates were about one-tenth of the epidemic peaks, but CRS continued at a low endemic rate even in those years.

Analysis of the age distribution of acquired rubella in the prevaccine era showed 60% of cases in children younger than 10 years of age and 23% in those older than 15 years of age.[222] As discussed subsequently, application of vaccine in children did not reduce the incidence in adolescents and adults by much, and CRS continued to occur for some years after the introduction of vaccination.

Lest it be thought that rubella infection in pregnancy has lost its danger, a more recent outbreak among unvaccinated Amish persons living in Pennsylvania serves as a corrective.[190] Young Amish women were 20% seronegative at the beginning of the outbreak, and infections in pregnancy were common. More than 8% of Amish infants gave laboratory evidence of infection, and more than 2% had CRS. Of infants born after first-trimester infection, 90% had confirmed or possible CRS.

In the United Kingdom, CRS estimates before the use of vaccine were only about 200 to 300 cases per year, but that figure was from a passive ascertainment system.[185] In Australia, about one baby with CRS per 2000 births was recorded before vaccine.[223] During an outbreak of rubella in Israel, there were 1441 confirmed infections in pregnant women, most of whom had abortions.[224] Projection of the experience to the United States would be equivalent to 75,000 pregnancies complicated by rubella. In France, 16% of congenital cataract cases were attributable to CRS.[225] A follow-up study of an epidemic in Poland showed that 15% of pregnant women had been infected. The rate of CRS after first, second, and third trimester infection was 78%, 33%, and 0%, respectively.[226] The picture of rubella in the developing world is complex.[151,227] Although a frequent seroepidemiologic finding has been a high rate of infection early in life,[159] there are many exceptions, including island populations,[228] several West African countries, the city of Calcutta, and Morocco.[229] Thus, the pattern is that of a disease that comes in epidemic waves, but that may be absent from an area for some time.

The epidemiology of CRS is known in detail for only a few countries of the world. Clusters of CRS have been reported in developing countries,[212,230,231] and there is little doubt that, wherever seronegative pregnant women are exposed to a rubella outbreak, CRS cases will follow. A study conducted in Chennai, India, confirmed the presence of rubella virus in 18% of congenital cataract cases, with serologic evidence of infection in 25%[232] (see "Epidemiology" earlier).

The most complete analysis of CRS globally was performed by Vynnycky and Adams (unpublished data, 2011). They

modeled the incidence of the disease in all WHO member states for the years 1996 and 2010 and derived the estimate of 103,068 annual cases of CRS globally, although the confidence limits were wide, ranging from 17,146 to 269,223 cases. Table 53.9 shows their estimates.

PASSIVE IMMUNIZATION

Immune Serum Globulin

Because most adults have had rubella, immune serum globulin (ISG) contains rubella antibody.[233] By the HI test, rubella antibody titers of approximately 1:16 are found in immunoglobulins.[234] Before the development of vaccine, ISG frequently was offered to pregnant women who had been exposed to rubella in the hope that it would prevent fetal infection. The results were equivocal, but if large doses (20 to 30 mL) of material were given, frank symptoms and viremia could be prevented.[235–239] Experimental studies confirmed the efficacy of passive antibody in preventing both viremia and clinical rubella,[240,241] but there were numerous failures of γ-globulin to prevent congenital fetal abnormality in actual practice.[237,241] In one study of CRS patients, 6% of mothers gave histories of receipt of γ-globulin after exposure.[140] Thus, whatever the real efficacy of ISG, it is unlikely to be complete.

The sole current indication for ISG is the exposure to rubella of a pregnant seronegative woman who will not accept abortion if infection is proved. If 1 week or less has elapsed since exposure and a serum specimen is taken first to confirm susceptibility, ISG in large amounts (20 mL) can be given intramuscularly. Convalescent specimens should be obtained 3 and 4 weeks later to search for IgM antibody and a rise in IgG titer. The absence of a rash in the exposed woman does not mean that viremia and fetal infection have been prevented. The newer intravenous γ-globulins do not have high concentrations of rubella antibodies, presumably because the antibodies are now the result of immunization rather than disease.[234]

Hyperimmune Rubella Globulin

To overcome the deficiencies of ISG, a hyperimmunoglobulin was prepared by Cutter Laboratories (Elkhart, IN) from the sera of normal individuals who had high rubella antibody titers. The titer of rubella virus-specific antibodies in this preparation was 1:8000 by HI. A controlled clinical trial of the preparation was performed with volunteers who were inoculated first with live unattenuated rubella virus and then given hyperimmune rubella globulin 24 to 96 hours later. With a challenge given intranasally, viremia was detected in two of five control subjects and in one of 10 subjects given γ-globulin. Pharyngeal excretion was similar in the two groups.[242] Although a previous experimental study with high-titered globulin had given better results,[240] the production of hyperimmunoglobulin was stopped, and it is not now commercially available.

ACTIVE IMMUNIZATION

Nonliving Vaccines

Advances in molecular biology allow consideration of a subunit-inactivated vaccine against rubella. The genome of the virus has been sequenced, in particular the genetic code for the E1 protein,[243,244] which carries multiple neutralizing epitopes located between amino acids 214 and 285 of the 481 amino acids contained in the polypeptide.[245–247] T-cell epitopes also were defined on the E1 protein, although no single epitope was recognized by a majority of individuals.[248–252] The E1 protein has been produced in quantity in baculovirus vectors and Chinese hamster ovary cells by truncating the C terminus to allow secretion.[253–257] The immunogenicity of bioengineered E1 has been moderate,[253] but strong adjuvants have produced good responses in animals.[258] Synthetic peptides also have generated neutralizing antibodies,[259] and virus-like particles containing the three main viral proteins have been produced from transfected cell lines, with retention of immunogenicity.[260,261] Other possible strategies for rubella vaccines include nucleic acid vaccine. Pougatcheva and coworkers[262] raised neutralizing antibodies in mice by injecting complementary DNA coding for the envelope glycoproteins. Although it is doubtful that an inactivated vaccine could provide protection from infancy throughout the childbearing period, it might be useful for immunizing adult women.

Live Virus Vaccine

Vaccine Strains: Origin and Development

Several vaccine strains were developed soon after the isolation of rubella virus in tissue culture.[263] Three vaccines were licensed in the United States in 1969 to 1970, as follows: HPV-77 (human papillomavirus 77; originally passaged 77 times in monkey kidney cells and then adapted to duck embryo),[264] HPV-77 (dog kidney),[15] and Cendehill (rabbit kidney).[16] In the same period, the RA27/3 human diploid fibroblast vaccine was licensed in Europe.[17] Between 1969 and 1979, the duck embryo derivative of HPV-77 was widely used in the United

States, in particular as part of the first measles-mumps-rubella (MMR) vaccine. The result was a sharp decline in rubella incidence commensurate with vaccine coverage in children of 60% to 70% by 1978.[265] HPV-77, in its original form and as a duck embryo–passaged virus, was immunogenic in more than 95% of subjects and, during outbreaks, gave protection to 65% to 94% of vaccinees.[15,266] Artificial challenge studies showed good protection against infection.[267] However, comparative studies of HPV-77 (duck embryo) versus RA27/3 conducted during the same period revealed lower antibody levels,[268,269] less persistent seropositivity,[270] less resistance to reinfection,[271,272] less herd immunity,[273] and more joint symptoms[274] in those vaccinated with the former strain, ultimately leading to replacement by RA27/3 in a new MMR vaccine (MMR-II). HPV-77 (dog kidney) and Cendehill had been previously withdrawn from American licensure when RA27/3 was licensed in the United States in 1979, and HPV-77 (duck embryo) was then withdrawn, leaving RA27/3 as the only American rubella vaccine. The RA27/3 strain is also the most widely used throughout the world, except in Japan and China (Table 53.10).[275] This strain was adopted because of its consistent immunogenicity, induction of resistance to reinfection, and low rate of side effects.[276] Accordingly, most of the information presented hereafter concerns the RA27/3 strain, with the addition of data on the other strains that can be extrapolated to the currently used vaccine.

RA27/3 was isolated from a fetus infected with rubella in early 1965.[263,277] Culture fluid from a tissue explant was passaged directly into WI-38 cells, and eight serial passages were made in WI-38 cultures incubated at 37°C. Additional passages then were done in cultures incubated at 30°C. After seven passages at 30°C, studies using human volunteers showed that the strain was attenuated. To reduce the pathogenicity even further, 10 additional passages were made.[278] The RA27/3 strain is produced as a vaccine strain between the 25th and 33rd passages in human diploid cells (WI-38 or MRC-5).[276] The relatively rapid attenuation by passage may be attributable to the use of cold adaptation, whereas the retention of high immunogenicity may be attributable to the low number of passages required to attenuate.[279] The nucleotide sequence of the envelope genes of RA27/3 has been sequenced, revealing 31 amino acid changes in the vaccine compared with the sequence of a wild strain.[280] In comparison, only five changes were noted in the HPV-77-DE strain.[281]

Strain-specific nucleotide sequences have been demonstrated in the RA27/3 strain, permitting specific identification.[282] Although some antigenic variations in rubella virus have been discerned with rabbit antibodies against *Escherichia coli*–expressed proteins,[283] studies employing a panel of monoclonal antibodies showed no significant differences (see "Virology" earlier).[284]

In Japan, five Japanese strains were attenuated by passage in the following substrates: Matsuba—AGMK, swine kidney, rabbit kidney; Matsuura—AGMK, chick embryo amniotic cavity, quail embryo fibroblasts; Takahashi—AGMK, rabbit testicle, rabbit kidney; TCRB19—AGMK, bovine kidney, rabbit kidney; and TO-336—AGMK, guinea pig kidney, rabbit kidney.[285] As of 2011, only three of these rubella vaccine strains (Takahashi, Matsuura, and TO-336) are still being administered.[286] One Japanese vaccine strain, TO-336, has been sequenced before and after attenuation.[287] Nucleotide mutations were discovered at 21 sites, 13 in the genes for nonstructural proteins, five in the genes for structural proteins, and three in noncoding regions. Although these mutations gave rise to 10 amino acid changes, none could be associated with attenuation. Moreover, the mutations were different from those of two other attenuated strains (RA27/3 and Cendehill). Two papers on Japanese strains attributed temperature sensitivity to mutations in the p150 nonstructural gene.[288,289] In China a strain called BRD-II is in use, but no details of attenuation are published in English.[290] The RA27/3 viruses being used by Merck (Whitehouse Station, NJ) and by GlaxoSmithKline (Research Triangle Park, NC) as part of their MMR combination have been shown to be identical by nucleotide sequencing.[291]

Dosage and Route of Administration

The vaccine dose of RA27/3 is required to be at least 1000 plaque-forming units (PFU) of virus delivered subcutaneously. However, titration studies in humans showed that, in keeping with its being a live vaccine, even small subcutaneous doses (<3 PFU) of RA27/3) are immunogenic.[292] A peculiar attribute of RA27/3, not so far demonstrated with any other rubella vaccine strain, is its immunogenicity when administered intranasally.[293–299] Some studies suggested that intranasal administration might confer an advantage on the vaccinees in terms of quality of the immune response.[300] However, the subcutaneous administration of vaccine gave similar humoral antibody with only slightly less secretory antibody.[277,300] Moreover, the intranasal dose of RA27/3 required for consistent immunization is high: 10,000 PFU.[295] Lower doses result in frequent failures,[301] particularly in children, possibly because of the mechanics of administration. Nevertheless, under careful conditions, some workers have been able to achieve 95% seroconversion rates, only slightly inferior to those rates achieved with subcutaneous injection of RA27/3.[298]

Mexican workers have attempted vaccination against measles, mumps, and rubella by a small-particle aerosol, and in preliminary studies have achieved seroconversion rates indistinguishable from those obtained with subcutaneous inoculation.[302,303] A trial was also done in young adults comparing a MMR vaccine given subcutaneously or by aerosol. Seroconversion of the small percentage of seronegative subjects and geometric mean titers in the two groups were quite similar after vaccination by either route.[304]

Aerosol administration may have public health advantages and is being explored further by the WHO.

Combination With Measles and Mumps

In most countries, rubella vaccination is accomplished with a triple vaccine that also contains measles and mumps vaccine viruses (MMR). The American triple formulation (MMR II; Merck Sharp & Dohme, Whitehouse Station, NJ) contains the

Moraten attenuated measles virus (1000 median tissue culture infective doses [$TCID_{50}$]), the Jeryl Lynn mumps virus (5000 $TCID_{50}$), and the RA27/3 rubella virus (1000 $TCID_{50}$). Three formulations are available in Europe and elsewhere. Pluserix (GlaxoSmithKline) contains the Schwarz measles virus (1000 $TCID_{50}$), the Jeryl Lynn–like mumps strain (20,000 $TCID_{50}$), and RA27/3 rubella virus (1000 $TCID_{50}$). Trimovax (Sanofi Pasteur, Swiftwater, PA) contains the Schwarz measles virus (1000 $TCID_{50}$), the Urabe mumps virus (20,000 $TCID_{50}$), and the RA27/3 rubella virus (1000 $TCID_{50}$). Morupar (Chiron, Emeryville, CA) contains the same three viruses, but the mumps virus concentration is given as at least 5000 $TCID_{50}$. For those who prefer not to vaccinate against mumps, a measles and rubella combination is produced by Sanofi Pasteur and the Serum Institute of India (Mumbai), which manufactures three different rubella-containing formulations: rubella-only vaccine (Wistar RA27/3; 1000 $TCID_{50}$), measles-rubella (MR) (with the addition of Edmonston Zagreb measles virus; 1000 $TCID_{50}$), and MMR (Tresivac, with the addition of L-Zagreb mumps strain; 5000 $TCID_{50}$).

Production and Constituents of Vaccine

RA27/3 is manufactured on a human diploid cell substrate, either WI-38 or MRC-5 fetal lung fibroblasts. Cell cultures inoculated with the seed virus are incubated at 30°C. After 4 to 7 days of initial incubation, there is sufficient virus in the supernatant medium to harvest. Fresh medium is added, and subsequent harvests can be made every 2 to 3 days for several weeks. Stabilizer is added to the harvest fluids, which are frozen for later safety testing and pooling before eventual lyophilization.[305,306] The final RA27/3 vaccine is essentially free of animal serum but does contain 0.4% human albumin, 25 to 50 µg/mL neomycin, and, in one case (Chiron), 50 µg/mL of kanamycin. However, human albumin is being replaced with recombinants-produced albumin. The lyophilization medium varies according to the manufacturer; however, it generally contains sucrose or sorbitol, glutamic acid and other amino acids, and buffering salts. When lyophilized, the vaccine is hypertonic. Reconstitution is accomplished with preservative-free sterile distilled water (0.5 to 1.0 mL) according to the manufacturer's directions, which restores the vaccine to a normal or slightly hypertonic state.

RA27/3 is produced in the United States, the United Kingdom, France, Belgium, Italy, Switzerland, Yugoslavia, and India by the manufacturers listed in Table 53.10. Despite minor differences in dose, antibiotic content, and other details among manufacturers, differences in vaccine efficacy or in the nature or severity of side effects have not been reported.

Stability of Vaccine

Rubella vaccine is highly stable in the frozen state at approximately −70°C or approximately 20°C. At 4°C, the viability of the virus and the potency of the vaccine also are maintained for at least 5 years. At room temperature, there is significant loss after 3 months; at 37°C, a 3-week period is sufficient to damage vaccine potency.[307] The vaccine should be stored at 2°C to 8°C and protected from light. The virus is labile after reconstitution and should be used within 8 hours.

Results of Vaccination

Immune Responses

Vaccination induces antibodies of both IgM and IgG classes and cellular immune responses. Secretory IgA responses are also induced.

Most studies of immunogenicity have been done by measuring HI responses, although the neutralizing responses may be more important biologically. By the HI technique, 95% to 100% of RA27/3 vaccinees experience seroconversion by 21 to 28 days after vaccination, with geometric mean antibody titers ranging from 1:30 to 1:300, depending on the method of titration.[17,278,308,309] Some of the apparent failures, at least in young adults, may be explained by preexisting low levels of antibody that neutralize the vaccine virus but are detectable only by sensitive tests.[310]

Several direct comparative immunogenicity studies have been done with different strains. A trial comparing the administration of the RA27/3 and Cendehill strains to Scottish schoolgirls resulted in a 98% seroconversion for the former and 90% for the latter.[311] In Sweden, Bottiger and Heller[312] found a 98% response after inoculation with RA27/3 and 96% after inoculation with Cendehill. In another Swedish trial, Grillner[313] tested neutralizing titers after vaccination, and 95% of RA27/3 vaccinees were seropositive compared with 56% of Cendehill vaccinees. Menser and colleagues[314] tested RA27/3 and Cendehill in Australian schoolgirls and adults; they found no differences in seroconversion but better boosting of seropositive individuals by RA27/3. Weibel and associates[315] conducted large comparative studies of RA27/3 and HPV-77DE that showed higher immunogenicity of the former strain. The Japanese TO-336 and the Chinese BRD-II strains compared favorably with RA27/3 in parallel studies.[316,317] A vaccination study conducted in India using MMRV showed 99% to 100% seroconversion to rubella after one dose.[318] RA27/3 elicits complement-fixing and precipitating antibody titers in nearly all vaccinees.[277] In a precipitin test system, RA27/3 was the only vaccine strain that evoked antibodies to the iota internal antigen of rubella virus.[319] Vaccination induces antibodies predominantly binding the E1 protein as detected by immunoblot, but those antibodies mature in avidity less rapidly than after natural infection and do not reach the same level.[320]

The induction of neutralizing antibody is particularly significant and is seen regularly and promptly after the administration of RA27/3. Fig. 53.2 and Table 53.11 present comparative data obtained in New Haven, Connecticut,[222] and in Sweden.[312] Immunoblot analysis confirmed the persistence of antibodies for at least 3 years to the E1 protein that bears neutralizing epitopes. Antibodies to the C protein also persisted, but antibodies to E2 were often absent.[321]

A crucial property of RA27/3 is its ability to induce secretory IgA antibody in the nasopharynx, which, as discussed subsequently, may prevent reinfection with wild virus. This property makes vaccination with RA27/3 similar to natural infection, which also induces local immunity. Although secretory IgA responses are higher after intranasal vaccination, they also are induced by subcutaneous vaccination with RA27/3

TABLE 53.11 Neutralizing Antibody Response in 114 Rubella-Vaccinated Women Who Demonstrated Seroconversion With Hemagglutination-Inhibiting Antibodies

Vaccine	Before Vaccination[a]	After Vaccination	
		8 Weeks	2 Years
Cendehill	1/45	24/43 (56%)	27/33 (82%)

because of replication of the virus in the nasopharynx.[322–324] IgA antibodies were detected 5 years after vaccination with RA27/3, when they had disappeared subsequent to other vaccine strains.[325]

Not surprisingly, vaccination, like disease, is followed by the early production of IgM-class antibodies. These antibodies reach a peak at 1 month after vaccination[287] and last approximately l month more but may persist longer at low levels.[325–327]

Cellular immune responses to vaccination have been studied, although they have no known significance to protection. A proliferation of lymphoblasts in response to rubella antigen appears 2 weeks after vaccination, without suppression of tuberculin hypersensitivity.[328] Relatively short-lived cellular responses also were seen in other studies.[329–332] Human leukocyte antigen (HLA)-restricted T-cell cytotoxicity was shown to increase after immunization.[333] Morag and coworkers[334] showed that cytotoxic T-lymphocyte activity was high in tonsillar lymphocytes after intranasal vaccination (with RA27/3) but was low after subcutaneous vaccination (with HPV-77DE). Unfortunately, subcutaneous administration of RA27/3 was not evaluated. An association of rubella antibody response with class II but not class I HLA antigens has been demonstrated.[335,336] Elevation of tumor necrosis factor-α (TNF-α), interleukin (IL)-4 (IL-4), and IL-10 after vaccination has been reported.[337] A study of second-dose MMR revealed effects on the distribution of lymphocyte classes, but no functional changes.[338]

A group from the Mayo Clinic has studied single nucleotide polymorphisms (SNPs) in relation to both antibody and cellular responses to rubella revaccination and have found numerous SNPs associated with higher or lower responses, although none that eliminated responses entirely. The SNPs were located in HLA genes and cytokine receptor genes.[339–343] These extensive studies have recently been summarized.[69a] Males may have somewhat higher immune responses than females.[344] Viremia has been documented between 7 and 11 days after RA27/3 inoculation.[345] However, the viremia is low and inconstant. Pharyngeal excretion of virus is more frequent, occurring from approximately 7 to 21 days after vaccination, in low titer of usually less than 10 PFU per swab. Excretion peaks on approximately the 11th day after vaccination; if properly tested, essentially all vaccinees will be shown to excrete virus from the nasopharynx.[346,347]

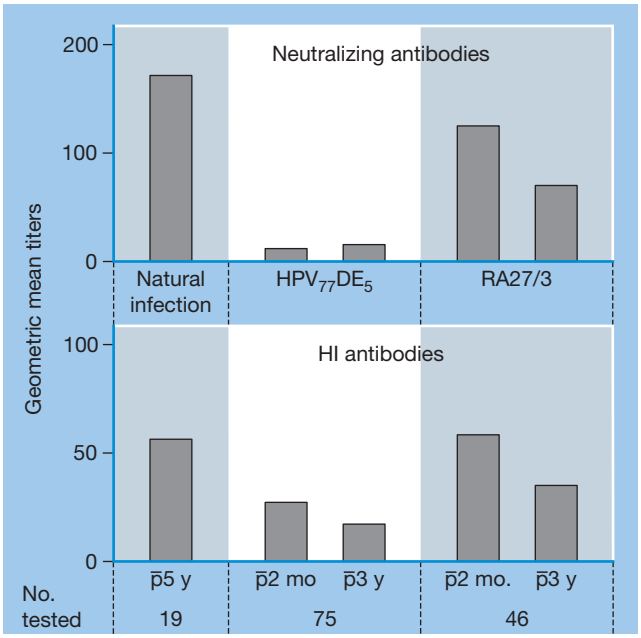

Figure 53.2. Comparison of neutralizing antibodies and hemagglutination-inhibiting (HI) antibodies in three groups of persons: naturally infected children, children given human papillomavirus 77 duck embryo ($HPV_{77}DE_5$) vaccine, and children given RA27/3 vaccine. *(From Horstmann DM. Viral vaccines and their ways.* Rev Infect Dis. *1979;1:502–516.)*

Contact Spread. In view of the excretion of rubella virus by vaccinees, considerable effort has been made to detect the spread of vaccine virus to susceptible contacts. Initially, contact studies were focused on children in institutions and on families, and no evidence for spread of vaccine virus was found.[16,17,275] For example, none of 393 seronegative family members was infected by contact with RA27/3 vaccinees.[17] Veronelli[348] studied 347 familial contacts of HPV-77DE vaccinees and also found no evidence of spread.

Experience in studies of contact spread produced largely negative results, with the rare asymptomatic seroconversion that could not be explained fully.[349,350] In the early 1970s, many studies were conducted in contacts of HPV-77DE or Cendehill strain vaccinees, including pregnant women, marital partners, school teachers, and the general population, with little or no evidence of spread.[351–357] The general lack of evidence for spread by vaccine virus may reflect the maintenance of attenuated markers by excreted virus, as demonstrated for RA27/3.[358]

Rubella in the Measles-Mumps-Rubella Combination. Responses to rubella as part of MMR combinations are equal to those seen after rubella vaccination as a single antigen. Table 53.12 is taken from a study by Weibel and colleagues[315] that compared MMR formulated with RA27/3 to RA27/3 alone. The excellent responses in both groups of vaccinees

From Weibel RE, Carlson AJ, Villarejos VM, et al. Clinical and laboratory studies of combined live measles, mumps, and rubella vaccines using the RA27/3 rubella virus. Proc Soc Exp Biol Med. *1980;165:323–326.*

have been confirmed by other investigators,[359,360] who also found RA27/3 to be superior to the earlier HPV-77DE component.[359] Seroconversion to rubella vaccination with any of the other triple combinations (see "Immune Responses" earlier) is usually 97% to 98%.[361,362] Bivalent measles-rubella and mumps-rubella vaccines also produce rubella antibody levels that are equivalent to those of the monovalent vaccine.[359,363] Comparative studies of the Merck and GlaxoSmithKline triple combinations showed excellent seroconversion to rubella after both vaccines.[364,365]

In summary, rubella vaccines induce immune responses that are similar in quality but lesser in quantity than those after natural disease.[366,367] The live virus produces viremia and pharyngeal excretion, but both are of low magnitude and are noncommunicable. IgG and IgM antibody responses follow vaccination. Natural infection elicits nasal secretory antibody that may be useful in the prevention of reinfection, and RA27/3 vaccine also has the same property.

Effect of Maternal Antibody. On average, maternal rubella antibody levels are detected only for approximately 2 months after birth in the infant, and thus rubella vaccine does not suffer the same problem as measles vaccination in early life, where maternal antibodies interfere with infant vaccination.[368] Studies have documented that the seroconversion rate in infants at 9 months of age is similar to that of children older than 12 months of age.[318,369,370]

Immunocompromised Subjects. Children who have recovered from chemotherapy for hematologic malignancies and solid tumors usually lose their rubella antibodies that were generated by prior vaccination. One year after chemotherapy a booster dose will restore their immunity.[371] Rubella revaccination of children with juvenile rheumatoid arthritis using MMR induced good responses despite the children being treated with methotrexate and antibody to TNF-α receptor.[372]

A study of children who had received bone marrow transplants also showed frequent loss of antibodies (33%), but revaccination 2 years later induced an anamnestic response with high-avidity antibodies.[373] Vaccination of children with the DiGeorge congenital immune deficiency was not followed by severe adverse reaction, and 93% of subjects seroconverted at titers equal to controls.[374] Patients with HIV infection are discussed later under "Contraindications."

Protective Effects

The protective efficacy of rubella vaccination has been assessed (a) by observation of vaccinees and control subjects during natural epidemics and (b) by intranasal challenge of vaccinated volunteers with unattenuated or attenuated viruses. No double-blind efficacy study has been done, but there is much evidence for effectiveness.

During an institutional outbreak of rubella, Davis and colleagues[267] were able to evaluate the effect of natural rubella exposure on persons who had been vaccinated with HPV-77DE. Clinical rubella occurred in 22 of 33 unvaccinated seronegative individuals but in none of 22 vaccinees and 66 naturally immune individuals. Asymptomatic reinfection without viremia was noted in five vaccinees (23.0%) and in one naturally immune subject (1.5%). Grayston and associates[375] compared the effect of three HPV-77 vaccines with a placebo during an epidemic on Taiwan. Rubella incidence began to drop in the vaccinated group within 2 to 3 weeks, and vaccine efficacy was estimated at 94%. In a separate study undertaken during the same outbreak, RA27/3 vaccine gave a 97% protection rate. A group of children in daycare was observed by Chang and colleagues[376] after some had been vaccinated with Cendehill. The vaccine afforded complete protection against disease, but 50% of the vaccinees were reinfected.

A dramatic example of protection by vaccine was reported from Japan.[377] An outbreak started in a school for apprentices at the Toyota automobile factory. RA27/3 vaccine was given randomly to a third of the boys. As shown in Fig. 53.3, the epidemic continued for 7 weeks, but rubella ceased to occur in vaccinees 2 weeks after they were vaccinated. Observation of an outbreak that occurred in Chinese school children allowed calculation of 99.5% efficacy of prior RA27/3 vaccination.[378]

An outbreak of rubella in a primary school in France during 1997 permitted a calculation of effectiveness because only approximately 75% of children had been vaccinated. Effectiveness of RA27/3 against clinical rubella was 95% (85% to 99% confidence interval) and almost 100% for laboratory-confirmed rubella.[379] An effectiveness study done with Italian military recruits gave a result of 94.5% for rubella vaccination.[380]

In Olmstead County, Minnesota, adolescent girls were vaccinated with Cendehill; unvaccinated boys were used as control subjects, which permitted a calculation of efficacy at 94% during a 1972 outbreak.[381] The introduction of rubella vaccination of recruits at Lackland Air Force Base resulted in a 95% reduction in rubella by 1979.[382] A 1980–81 outbreak in Sanford, Maine, allowed an assessment of vaccine efficacy 8 years after vaccination; it was 90%.[383]

In Finland, five cases of rubella encephalitis were seen at Helsinki Children's Hospital during a 15-year period, starting in the late 1960s, whereas none has been seen since the advent of MMR vaccination in 1982.[384] The Chinese BRD-II strain was shown to have high efficacy in an outbreak in Guangzho.[290] It is possible that rapid administration of rubella vaccine to contacts of a case would provide prophylaxis, but this possibility has not been tested in any controlled fashion.

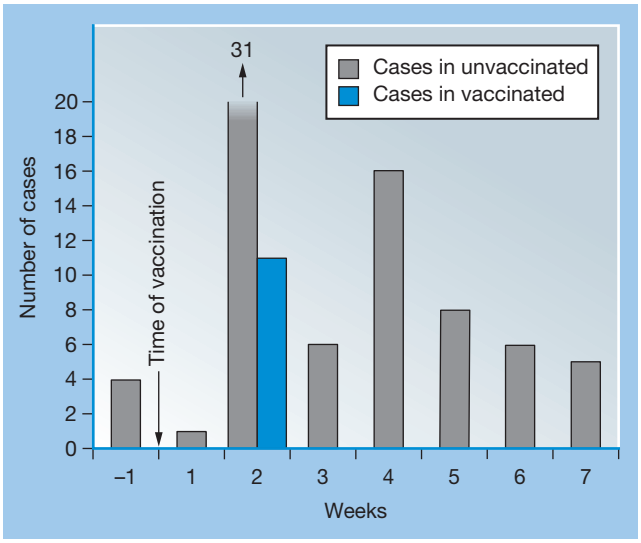

Figure 53.3. Demonstration of protection against rubella during an epidemic in a boys' school at the Toyota car factory near Nagoya, Japan. Boys were selected at random to receive RA27/3 vaccine at the time indicated, and about one-third received the vaccine. *(From Furukawa T, Miyata T, Kondo K, et al. Rubella vaccination during an epidemic.* JAMA. *1970;213:987–990. Copyright 1970, American Medical Association.)*

Correlates of Immunity

The immune response that correlates best with protection is neutralizing antibodies.[385] However, on the one hand, even vaccinees with low levels of serum antibodies are often protected,[386] while on the other hand, reinfection may take place in some individuals with measurable antibodies. Because measurement of neutralizing antibodies is not routinely available, 15 IU of antibodies measured by other methods has been proposed as a correlate of protection.[387] However, infants with CRS have been born to mothers who have antibody levels of 15 IU or greater. Review of epidemiologic data in the United States demonstrated protection at 10 IU, so the cutoff for protection was set at 10 IU in the United States.[128] Although there is some variation among countries in terms of the concentration of IgG antibodies considered to be protective, the presence of rubella IgG antibodies greater than or equal to 10 IU/mL is commonly considered to provide evidence of protection (WHO immunologic basis).[134]

Although cellular immunity seems to have little correlation with protection from replication, arrest of viral excretion by CRS patients correlates with the appearance of specific lymphoproliferation responses (Best J. Personal communication to SA Plotkin, 2001).

Reinfection and Herd Immunity

Early in rubella vaccine studies, it became evident that, under conditions of exposure to wild virus, reinfection of persons vaccinated with HPV-77 and Cendehill could occur with a frequency of 50% or greater.[271,272,388–390] Herd immunity was shown to be ineffective when rubella broke out in a company of military recruits.[391] Although most recruits had antibodies as a result of vaccination or prior infection at the start of the epidemic, 100% of the remaining susceptible individuals were infected. Moreover, 80% of the recruits vaccinated with HPV-77DE were reinfected. The same conclusion was reached in another study of recruits, in which rubella singled out the susceptible individuals despite high levels of immunity in the group.[392]

Bermuda experienced a rubella outbreak in 1971. A vaccination campaign with Cendehill resulted in prompt termination of the epidemic, and vaccine efficacy was estimated to be 94%.[393] However, a rubella epidemic in Casper, Wyoming, in the same year, showed that although the vaccine (HPV-77DE) prevented rubella in immunized elementary school children, spread to unimmunized adolescents and adults resulted in an attack rate that was 50% of that expected without vaccination.[394,395] Fogel and colleagues[242] used intranasal RA27/3 as a challenge to RA27/3, Cendehill, and HPV-77DE vaccinees. Their results showed a higher rate of reinfection in the last two groups compared with that in RA27/3 vaccinees (Table 53.13).

Among RA27/3 vaccinees, approximately 5% had low titers 6 to 16 years after vaccination.[396] A 9.8% incidence of asymptomatic reinfection was reported 5 years after vaccination.[397]

Harcourt and coworkers[388] concluded that reinfection is dependent on a number of immunologic factors, including, but not restricted to, the presence of nasopharyngeal IgA rubella antibody. When the RA27/3 virus itself was given intranasally as a challenge virus, O'Shea and coworkers[386] found that reinfection, as determined by titer rises, was infrequent in those who had significant titers (>15 IU) of rubella antibody from previous infection or vaccination, but was frequent in vaccinees who had low titers (<15 IU). However, reinfection was not associated with lack of neutralizing antibodies, and viremia as part of the reinfection was rare (Table 53.14).

In some studies, reinfection led only to an IgG booster response, without IgM,[398] whereas in others, the appearance of IgM antibody suggested significant viral replication.[399,400] The distinction between primary infection and reinfection can be more accurately assessed by avidity antibody testing than by IgM tests. In primary infection, low-avidity antibody is found, whereas in reinfection, antibody is of high avidity.[387,399,401]

Clinical rubella has been documented during reinfection of vaccinees[402,403] and naturally immune individuals.[404,405] Moreover, maternal reinfection during pregnancy has resulted in congenital rubella.[62,168,406–422] In a prospective study, Morgan-Capner and associates[423] found definite evidence of passage of virus from reinfected mothers to their fetuses in two of three cases in which exposure had occurred in the first trimester and fetal tissue was available. However, follow-up of seven live-born infants did not reveal CRS. O'Shea and colleagues[424] measured rubella immunity in reinfected women and reinfected seropositive volunteers undergoing a challenge with rubella virus. The presence or absence of serum neutralizing antibodies or cellular immunity did not correlate with the likelihood of reinfection. However, Matter and coworkers[387] suggested that reinfection may be more likely at low levels of antibody as measured by hemolysis in gel (10 to 15 IU), and Mitchell and colleagues[425] reported that reinfection was correlated with lack of prior antibodies to a peptide of the E1 protein.

The best conclusion at this time is that reinfection with fetal transmission of wild rubella virus is a fact in the presence of both natural and vaccine-induced immunity, but that the

risk of fetal transmission is probably less than 5% in the first trimester of pregnancy; however, the risk of CRS is even rarer.

Persistence of Immunity and Revaccination

Numerous data are available on persistence of antibody after vaccination. Liebhaber and colleagues[426] found antibodies in all 18 vaccinees 2 years after vaccination with RA27/3. In response to a challenge with unattenuated rubella virus, 16 of the 18 vaccinees showed resistance to reinfection. Amazonian Indians given RA27/3 by Black and coworkers[427] had persistent antibodies in the absence of any possible reexposure to the virus, although there was a twofold drop during 2.5 years. A 98% to 99% persistence of antibody was noted in schoolchildren 4 years after vaccination.[428] Zealley and Edmond[429] reported on a long-term study of Edinburgh schoolgirls, 97% of whom retained antibodies 6 to 7 years after vaccination with RA27/3. The longest observation periods after vaccination with RA27/3 thus far have been 12 to 17 years,[279] 15 years,[430] and 10 to 21 years.[431] In the latter study, 97% of subjects retained their positive antibody status. In one long-term study, 75 (96%) of 78 vaccinees retained measurable antibody (Fig. 53.4).[279] In a follow-up of Baltimore schoolchildren, there was a decline of less than fourfold in mean titer during a 15-year postvaccination period, and 97% remained seropositive.[432]

Miller and colleagues[433] studied 475 children 4 years after vaccination with MMR and found 97% to be positive for rubella antibodies. A Canadian study of a similar number of children tested 5 to 6 years after vaccination with MMR gave identical results.[434] Bottiger[435] observed 220 Swedish children given MMR at 18 months of age. At 12 years of age, 97% had rubella antibodies, although not at the same levels seen immediately after vaccination. A second dose given at 12 years of age raised the titer levels to those seen after primary vaccination. Christenson and Bottiger[436] also observed a cohort of almost 500 girls vaccinated at age 12 years. After 8 years, 96% were still seropositive, and 94% were still so at 16 years after vaccination, although the mean titers had dropped from 1:110 to 1:18 (Table 53.15). On a population level, between 1988 and 1994, 96% of 6- to 11-year-old children and 94% of adolescents in the United States were seropositive to rubella.[437]

Different results were reported by Johnson and coworkers,[438] who studied 95 children given MMR at 15 months of age. Children studied at age 4 to 6 years were 100% positive for rubella-neutralizing antibodies, but only 63% of children ages 11 to 13 years were positive. They suggested that immunity had waned. After a second dose of MMR, 100% of children became seropositive, with almost a threefold rise in the geometric mean titer of rubella antibodies. In Newfoundland, Ratnam and associates[439] found that 16.5% of children 8 to 17 years of age were seronegative after prior vaccination at 1 year of age. Elsewhere, in Canada, Mitchell and coworkers[440] found ELISA antibodies, "subprotective" neutralizing antibodies, and lymphocyte proliferation responses in 92%, 77%, and 74%, respectively, of adolescents 14 to 16 years after their first dose. Le Baron and coworkers[441] showed that 9% of vaccinated children were seronegative when given a second dose before admission to school, that almost all responded to the second dose, but that 12 years later 10% had become seronegative.

A Dutch seroprevalence study showed that 9 years after the introduction of universal rubella vaccination of infants more than 95% of vaccinees were still seropositive. Moreover, only 5% of reported rubella cases occurred in vaccinees.[442] Another Dutch study of 17- to 23-year-old subjects vaccinated as children showed antibodies in 71% of those who had one dose and 99% in those who had two.[443]

In Finland, titrations were done in children followed over 15 years. Five to 7 years after a single dose, 98% to 100% of the children were still seropositive. They were given a booster dose, after which seroprevalence continued to be 100%. However, at 15 years after a first rubella vaccination and 9 years after a second dose, 30% of children had low titers. Children given a second dose at 11 to 13 years still had elevated titers.[444] Twenty years postvaccination, 100% of children were seropositive.[445] Follow-up of Swedish adult women vaccinated as children showed 96% with rubella antibodies,[446] whereas follow-up of Saudi children in Saudi Arabia and residents in Luxembourg showed rather uniform persistence of antibodies after vaccination.[447,448] Also, in Saõ Paolo, Brazil, and in Korea, 15% to 20% loss of antibodies was seen 3 to 8 years postvaccination,[179,449] A follow-up study conducted in Luxembourg 15 to 20 years after first vaccination in infancy showed 94% seropositivity in those who had received one dose of rubella vaccine and 100% in those who had received two doses.[450]

Reports of persistence of antibody to Cendehill and HPV-77DE strain vaccines, no longer in use, were summarized in the fourth edition of this book, to which the reader is referred.

However, several observations are of continued interest. Best[451] summarized published studies of antibody persistence 9 to 21 years after vaccination and found a seronegativity rate of 1% for RA27/3 vaccinees, 2.7% for Cendehill vaccinees, and 7.3% for HPV-77DE vaccinees. An epidemic of rubella occurred during 1981 to 1982 among students at the University of California at Los Angeles. Strassburg and colleagues[452] performed a case-control study and found that prior immunization with unspecified rubella vaccines conferred 97% protection, even though some students had been immunized 10 years previously. Natural immunity to rubella lasts at least 26 years.[453]

A follow-up of women vaccinated prepubertally in Taiwan showed that after 20 years approximately 7% were seronegative and 9% weakly seropositive.[454] One study reported good persistence of antibody 10 years after inoculation with the Japanese TO-336 virus.[455] Persistent antibody and protection also followed the use of the Matsuba strain.[456] In a small group of vaccinees followed 23 years after receipt of the Matsuba strain, 15% were negative by HI, but reimmunization nevertheless induced secondary responses.[457] A follow-up study of subjects given the Matsuba strain also showed good persistence of antibodies and T-cell activation.[458]

Table 53.16 attempts to summarize most of the studies done on persistence after vaccination. It appears that antibodies wane after each of the two doses of rubella vaccine, although most vaccinees retain antibodies. Judging from the absence of outbreaks in well-vaccinated countries, such as the United States, persistence of protection may be the result of anamnestic responses that are protective. A recent small study showed good persistence of memory B cells in rubella-vaccinated adults.[459]

Reimmunization has been advocated by some of those who have studied the persistence of antibodies to HPV-77DE and Cendehill,[460,461] and subcutaneous RA27/3 could be given as a booster vaccine for those previously immunized.[462,463] However, ostensibly seronegative individuals usually show secondary immunologic responses after boosters, indicating that they had been immune.[464,465] A study of two doses of rubella vaccine (as part of MMR) showed persistent immunity in 95% of children 2 to 4 years after the first dose, with a boost in geometric mean titers from 41 IU to 72 IU after a second dose.[466] The authors commented that within 3 years of the booster, antibodies fell to prior levels. In any case, the question has now been rendered partially moot by the adoption in many countries of a routine second dose of measles vaccine, usually as a triple vaccine containing rubella. Revaccination is a suggested strategy to augment rubella immunity before the age of reproduction. Individuals who fail to seroconvert after rubella vaccination should be given a single repeated dose. Failure to respond to the second dose may be evidence for tolerance to rubella virus antigens,[136] which is seen in survivors of CRS.[467]

In summary, the need for a second dose of rubella vaccine is unproven. The rare cases of rubella occurring in the United States are in unvaccinated persons, without signs of spread to the general population and suggest that a second dose of rubella vaccine may not be needed. Although titers decrease with time, high rates of seropositivity are maintained. Indeed, considering the long incubation period of rubella (14 to 21 days) an anamnestic response in vaccinees after exposure may offer sufficient protection, making the presence of detectable antibodies at the time of exposure unnecessary. However, the routine indication for a second dose of a measles-containing vaccine, the general use of combination vaccines containing rubella for that purpose, the innocuousness of a second dose of rubella vaccine, the success of two-dose national strategies in eliminating rubella, and the need to maintain protection during the years of childbearing all argue for a two-dose schedule. Although a second dose of rubella vaccine would be preferable just before adolescence, measles control and convenience are better with a second dose at school entry.[468]

Combined and Associated Vaccines

As mentioned previously, when rubella vaccine is given to preschool-age children it is almost always given in combination with measles and mumps vaccines as MMR vaccine, or, more recently, in measles-mumps-rubella-varicella (MMRV) vaccines. Excellent results have been reported for both RA27/3 and Cendehill as components of triple vaccines.[315,469] There is no contraindication to giving MMR even in the presence of immunity to one or two of its components, and American

authorities prefer to use MMR exclusively in vaccination programs. Rubella or MMR vaccine can be given simultaneously (but separately) with diphtheria and tetanus toxoids and pertussis vaccine, *Haemophilus influenzae* type b vaccine, inactivated poliovirus vaccine, hepatitis B vaccine, oral poliovirus vaccine,[470] and varicella vaccine.[471]

Adverse Reactions

Common Side Effects

Vaccinees sometimes develop mild rubella, including rash, lymphadenopathy, fever, sore throat, and headache. The incidence of each side effect varies directly with age, being almost absent in infants but present in up to 50% of women, particularly in those older than age 30 years. Fortunately, the minor side effects are seldom severe enough to cause days to be lost from school or work.[312,314,472,473]

A double-blind study of vaccination with MMR in children gave a 1% incidence of arthropathy and little evidence of other reactions.[474] This study was conducted in twins, one of whom received vaccine and the other placebo. The results are given in Table 53.17, which shows that the differences in reactions between vaccinees and placebos were small. The twin study by the same Finnish workers was repeated in 6-year-old children receiving second doses of MMR. The only symptom appearing to be associated with vaccination was arthralgia.[475] Another controlled study revealed no significant differences in reactions of children receiving either MMR or measles vaccines.[476] Female children are more likely than males to have fever and rash after vaccination.[477] Reactions attributable to rubella after second doses of MMR or MMRV vaccines are much more uncommon.[478,479]

Serious Reactions

In 1991, the Institute of Medicine (IOM) of the National Academy of Sciences published a committee report on four possible adverse effects of rubella vaccine: acute arthritis, chronic arthritis, neuropathies, and thrombocytopenia.[480] The committee concluded that RA27/3 causes acute arthritis. With regard to chronic arthritis, the committee stated, "The evidence is consistent with a causal relation between the currently used rubella vaccine strain (RA27/3) and chronic arthritis in adult women, although the evidence is limited in scope and confined to reports from one institution." However, the committee found insufficient evidence to indicate a causal relationship between use of the vaccine and incidence of radiculoneuritis, other neuropathies, and thrombocytopenia. In 2011, the IOM published a committee report on the evidence of adverse health events associated with several vaccines including MMR.[481] As discussed in the following sections, some of these conclusions remain controversial.

Arthritis and Arthralgia

A review of adverse events in Canada gave a reaction rate for rubella vaccine of 28.7 per 100,000 doses distributed, of which 0.3 per 100,000 was arthritis or arthralgia.[481] Acute arthropathy is part of the disease caused by rubella virus, at least in adults, and is also the most important side effect of vaccination.[482] Although the HPV-77 strains are no longer in use, much information on joint reactions was obtained by studying reactions to vaccination with this strain. The HPV-77 dog kidney vaccine was particularly likely to cause reactions in joints, even in children.[21,484] At times, the reactions included neuropathies, such as the "catcher's crouch" syndrome.[25,484–488] The HPV-77DE vaccine produced reactions that were age related; for example, in one study, 0% of girls younger than age 13 years, 2% of those 13 to 16 years old, 6% of those 17 to 19 years old, 25% of women 20 to 24 years old, and 50% of women older than 25 years of age developed reactions in the joints.[489,490] Symptoms could be prolonged.[491] In two different studies, Cendehill vaccine was reported to cause these reactions in 23% and 16%, respectively, of women.[492,493] RA27/3 produced infrequent reactions in children,[494] but approximately 25% of adults had temporary joint symptoms.[472]

Polk and associates[495] performed a comparative trial of rubella vaccines in adult women. Table 53.18 presents some of their comparative data. In addition, they reviewed other reports and concluded that the incidence of transient arthralgia or arthritis was 35% to 63% with the use of HPV-77 (dog kidney), 27% to 33% with HPV-77DE, 8% to 10% with Cendehill, and 13% to 15% with RA27/3. Although many different joints can be involved in the reaction to rubella vaccines, knees and fingers are the most common, whereas the hips are seldom involved. Conflicting evidence has been reported regarding the influence of the stage of the menstrual cycle on joint symptoms.[316,489,491]

The mechanism of joint inflammation appears to be direct infection of the synovial tissue by the virus, if one extrapolates from recoveries of the virus from joints of patients with arthritis after occurrence of natural rubella[496] and after inoculation with HPV-77 (dog) vaccine.[497] Laboratory studies suggesting that rubella RNA and rubella peptides might induce

autoimmunity also have been published.[498,499] Women who possess class II HLA DR2 or DR5 have elevated risk of acute joint reactions after rubella vaccine.[500] Human joint tissue infected in vitro by Miki and Chantler[501] supported high-titer replication of wild viruses and of HPV-77DE but 100- to 1000-fold less replication of RA27/3. The Cendehill strain grew hardly at all in joint tissue, and genetic mapping showed that the mutations giving restriction were mostly located in the 5′ noncoding region.[502] Although RA27/3 has not been recovered from joints, Tingle and associates[503] reported isolating vaccine virus from the peripheral blood mononuclear cells of two women who had prolonged arthritis after administration of the vaccine. Joint reactions were not associated with elevated IgG or prolonged IgM responses.[503] Bosma and coworkers[23] tested synovial fluids or biopsies from 79 patients with chronic inflammatory arthritis and detected rubella RNA in only two specimens, one from a patient who had rheumatoid arthritis and the other from an immunodeficient patient with arthritis caused by mycoplasma. They concluded that rubella was not etiologic for chronic arthritis, but viral antigens might rarely persist within the joints.

Tingle and coworkers[504] reported a prospective study conducted in British Columbia of arthritis after RA27/3 vaccination or natural disease. The incidence of acute arthritis was 52% in the disease group and 14% in the vaccinees. Recurrent arthropathy developed in 30% of women who had the disease and 5% of women who had been vaccinated. Symptoms were not associated with circulating immune complexes.[505]

In 1991, the IOM committee suggested the need for prospective, double-blind, controlled trials of rubella vaccine in adult women, associated with attempts to isolate rubella virus, to resolve the controversy.[506] Six studies touching on this issue have since been reported. Phillips and coworkers,[507] and subsequently Frenkel and coworkers[508] and Nielsen and coworkers,[509] were unable to confirm the presence of viremia in vaccinees complaining of chronic arthritis. Rubella genomic RNA was not demonstrated by Zhang and coworkers[510] in blood and synovial fluid from cases of rheumatoid arthritis. Slater and coworkers[511] observed two cohorts of Israeli women, one of which had received rubella vaccine. Five to 10 years later, the incidence of arthritis in vaccinees and control subjects was 3.9% and 3.2%, respectively, an insignificant difference. At the Kaiser Permanente Northern California Health Maintenance Organization, Ray and coworkers[512] linked rubella vaccination records with cases of chronic arthritis and found no association between the two.

Finally, a British Columbia group performed a placebo-controlled prospective study of approximately 500 women, half of whom were vaccinated and observed for 1 year.[513] Table 53.19 summarizes their results. Not surprisingly, acute arthralgia and arthritis were more common in vaccinees, although the excess attributable to vaccine was only 5%. In evaluating women with persistent arthropathy, they defined "Persistent arthropathy…as occurrence of arthralgia or arthritis at any time during the 12 months after vaccination in women who experienced acute arthropathy and for whom joint complaints could not be attributed to other causes." The frequency of chronic arthropathy was 15% in the placebo group and 22% in the vaccine arm. However, whereas 58 (72%) of 81 women in the vaccine group with acute arthropathy later developed chronic arthropathy, 41 (75%) of the 55 women in the placebo arm with acute arthropathy also developed chronic arthropathy. Thus, chronic arthropathy was associated with prior acute arthropathy but not with rubella vaccine. In addition, there was no description of the severity or frequency or duration of the symptoms of the women in either group. Moreover, by the authors' case definition, a woman who had an episode of acute arthralgia for 3 days and then one episode of arthralgia of any duration more than a month later, would meet the chronic or persistent arthropathy case definition. Thus, it is unclear what relationship these findings have to the chronic rubella arthropathy previously reported.

More recently, the British Columbia group retested the seronegative women in the original study with several additional tests for antibodies and found that 21.7% were positive.[514] The group then revised its hypothesis, arguing that low, nonfunctional responses to prior rubella infection predisposed women to joint complaints when vaccinated. However, the original placebo group apparently was not retested, and the statistical significance of the new conclusions remains doubtful. Moreover, the large vaccination campaigns conducted in millions of Latin Americans, including women of childbearing age, has not been accompanied by additional reports of chronic arthropathy (WHO rubella position paper).[515]

Thus, taking the evidence as a whole, one is left with the conclusion that although chronic arthropathy caused by RA27/3 is plausible biologically, it is unconfirmed by virology or epidemiology, and is rare, if it occurs at all. However, despite extensive use of RA27/3 vaccine in millions of subjects including many adults in Latin America, articles confirming the British Columbia reports have not been published. In their 2011 report, the IOM concluded that the evidence is inadequate to accept or reject the causal relationship between MMR vaccine and chronic arthralgia or arthritis in women.[481] Nevertheless, on the basis of the IOM report, the National Vaccine Injury Compensation Program has been accepting claims of chronic arthropathy resulting from rubella vaccination, and compensation has been awarded to 23 of 56 completed cases.[516]

Chiba and colleagues[517] reported a depression of rubella-specific cellular immune responses in children with arthritis. Circulating immune complexes containing rubella antigen were found in 11 of 33 vaccinees who developed arthralgia after vaccination but in only three of 19 who did not.[518]

Neurologic Adverse Events

Although few neurologic events after vaccination with RA27/3 have been reported, it is useful to review this type of information for all vaccine strains.[519] Polyneuropathy is part of natural rubella and is among the most frequent of the unusual complications of rubella vaccination. Schaffner and coworkers[520] reviewed the problem in 1974 and found 299 reports of polyneuropathy after vaccination. The cases they reviewed followed immunization with HPV-77DE, HPV-77DK, and, less frequently, Cendehill vaccines. The symptoms began about 40 days after vaccination, appearing in the form of two syndromes, one consisting of paresthesias and pain in the arms and the other involving pain in the knee and preference for a crouching position. The second syndrome tended to recur. Carpal tunnel syndrome and Horner syndrome also were seen. Children with polyneuropathy showed impairment of motor and sensory nerve conduction. Cusi and coworkers[521] studied a case of a young seronegative woman with mild peripheral neuropathy that began 4 weeks postvaccination. Antibodies to myelin basic protein were detected in the patient, and the authors induced antirubella binding antibodies in mice by immunization with a peptide derived from myelin that is homologous with a peptide in the rubella C protein. Attempts to demonstrate rubella virus or genome in the patient's white blood cells were negative.

Other possible adverse neurological events following vaccination have been reported. Two cases of optic neuritis after vaccination for rubella have been reported, the vaccine being HPV-77DE in one instance[522] and an unstated vaccine in the other.[523] Two cases of anterior uveitis after MMR vaccination were reported from Saudi Arabia.[524] Transverse myelitis has been reported on two occasions[525] and diffuse myelitis on three occasions after inoculation with RA27/3, Cendehill, and an unstated vaccine.[141,526] Six cases of transverse myelitis have been reported after vaccination with MMR or MR containing RA27/3, although other associated vaccines may have been the cause.[527–529] Facial paresthesias were reported after vaccination with RA27/3.[530] A case of disseminated encephalomyelitis was reported in Japan after vaccination with the Takahashi strain.[531] Two cases of Guillain-Barré syndrome have been noted after the use of HPV-77DE, but an etiologic association could not be confirmed.[525,532]

Guillain-Barré syndrome after rubella vaccination given in combination with other vaccines has been reported,[533] but an epidemiologic study in the United Kingdom after an MR vaccination campaign revealed rates of Guillain-Barré less than that expected by the background rate (1 per 100,000 children).[534] In addition, a large retrospective study of Guillain-Barré syndrome was conducted in Finland. No clustering of cases occurred after MMR vaccination, nor did subsequent MMR vaccination cause relapses in patients with the syndrome.[535] Another Finnish study showed no relationship of MMR vaccination to encephalitis, aseptic meningitis, or autism.[536] Chantler and associates[537] showed that rubella viruses grow well in human astrocytes but poorly in oligodendrocytes, suggesting that demyelinating disease is not likely to be associated with rubella virus replication.

Other Adverse Events

A study of transfusions from vaccinated persons gave no evidence of transmission of vaccine virus.[538]

A case of "bone changes" after rubella vaccination was reported,[539] but the negative virus isolation, absence of IgM antibodies, and lack of detail make the association dubious. One case of mild orchitis after the administration of rubella vaccine was reported.[540]

Thrombocytopenia has followed vaccination for rubella on several occasions[541–543] and has been reported frequently after the administration of triple vaccine.[544,545] A decrease in platelets may be seen in some asymptomatic vaccinees after vaccination, and symptomatic thrombocytopenia has been reported after natural rubella. A rate of one in 3000 is accepted for thrombocytopenia after wild-type rubella virus infection,[546] whereas rates 10 times lower have been reported after rubella vaccination.[544] It appears that either measles or rubella vaccines may be responsible for thrombocytopenia after MMR.[547] Platelet-binding antibodies to rubella were demonstrated in some cases of thrombocytopenia after vaccination with a Japanese strain.[548] In addition, exacerbation of chronic thrombocytopenia has been reported after MMR,[549] as has recurrent thrombocytopenia after repeated administration.[550] A British study concluded that the risk of thrombocytopenia within 6 weeks of MMR vaccination was one in 22,300 doses, but only two-thirds of cases were attributable to the vaccine, for a risk of one in 33,000 doses.[551] Another British study concluded that the rate of thrombocytopenia after MMR was one in 50,000 doses.[552] An American Vaccine Safety Datalink study of more than a million doses of MMR calculated a one per 40,000 rate of immune thrombocytopenia,[553] and a systematic review of reported cases calculated a similar rate.[554] Both the review and case reports[555] found no problem with vaccination of children with chronic thrombocytopenia.

Revaccination is not recommended by the Advisory Committee on Immunization Practices for children who suffered thrombocytopenic purpura after MMR,[556] but the balance of risk and benefit should be weighed, particularly because the British study found no recurrences after MMR in children with prior thrombocytopenia.[557]

A Swedish study examined autoantibodies to pancreatic islet cells and to thyroid cells before and after MMR

vaccination and found no increase, making it unlikely that vaccination contributes to diabetes or thyroiditis.[558]

Recently, a French group reported that rubella vaccine virus was a trigger for cutaneous granulomas in T-cell–deficient children. RA27/3 genome was recovered from those patients, whose biopsies revealed the presence of rubella virus by immunofluorescence.[559] This observation has been confirmed at the U.S. Centers for Disease Control and Prevention (CDC). The rubella vaccine was found to persist in keratinocytes and particularly in M2 macrophages.[559a] A second paper from France confirmed that this complication of vaccination is not rare.[559b] However, as with all live vaccines, immunodeficiency is a contraindication to vaccination.

Rubella vaccines have been noted to depress nonspecific cellular immunity transiently,[560] including the tuberculin reaction, cell-mediated immunity to *Candida*, phytohemagglutinin responses, and delayed-type hypersensitivity to recall antigens; they also increase suppressor T cells.[561–563] A decrease in lymphocytes was noted at 7 days postvaccination, followed at 30 days by increased production of TNF-α, IL-10, and IL-4 and decreased production of interferon-γ.[337] A follow-up study of RA27/3 vaccinees has shown no increase in cancer incidence.[564] A summary of findings from the U.S. Vaccine Adverse Events Reporting System (VAERS) for the 2003–13 period relative to adults who received MMR turned up no unusual safety signals. Pyrexia, rash, pain, and arthralgia were the most common complaints.[565]

Indications for Rubella Vaccine

Table 53.20 lists the targets of rubella vaccination.

Infants

Rubella vaccine is given to preschool-age children in the United States and many other developed countries in an effort to immunize them for the future and to protect their mothers through reduction of rubella virus circulation. In view of the lack of evidence of contagiousness of vaccinees, infants whose mothers are pregnant may be vaccinated.

Rubella vaccine is usually given at 12 to 15 months of age as part of the MMR or MMRV vaccine. Children who miss the vaccine at that time can receive it at any later age and, in most states, must receive it at the time of school entry. The age at first vaccination does not seem to be as critical for rubella as for measles vaccine. Although passive maternal antibodies are well transmitted to both term and preterm infants, they were lower in those born before 28 weeks of gestation. In general, rubella antibodies disappeared rapidly, being present in only 13% of infants at 6 to 12 months, 5% of infants from 9 to 12 months, and 2% from 12 to 15 months of age.[566–568] From 9 months of age on, vaccination is almost 100% successful,[361,569–574] and a study done in Brazil showed reliable seroconversion after rubella vaccine from about 6 months of age.[162] However, there is little need to prevent rubella in those younger than age 1 year.[575] Three separate studies showed that the presence of acute respiratory infection at the time of vaccination of infants 12 to 18 months of age was shown to have no influence on seroconversion.[576–578]

College students
Childcare personnel
Healthcare workers
Military personnel
Adult women before pregnancy
Adult seronegative women postpartum
Adult men in contact with pregnant women
All the above as part of a two-dose elimination strategy

Adolescents

Vaccination is recommended for all adolescents, male and female, who have not been previously vaccinated. In addition, revaccination with rubella vaccine as part of MMR is recommended in many countries, either at entry to primary school or at 11 to 13 years of age. The justification for this practice lies mainly in the prevention of measles outbreaks caused by accumulation of susceptibles resulting from primary vaccine failure, but it has been argued that revaccination also provides protection to adolescents who did not initially seroconvert to rubella and also boosts waning antibody in those who did. Although the evidence for the need to revaccinate against rubella is slim, two-dose regimens are now standard in the United States and other countries (see "Persistence of Immunity and Revaccination" earlier and "Epidemiologic Results of Vaccination" later).

In the United Kingdom, public health policy formerly emphasized vaccination of 11- to 14-year-old girls, with the idea that a cohort of immune women could be created during a period of 10 to 20 years. The success of this policy is considered subsequently (see "Epidemiologic Results of Vaccination"): in brief, its advantage was narrowing the target group to potential mothers, and its disadvantages were a high refusal rate and the lack of effect on the circulation of virus. However, Schiff and colleagues[579] succeeded in vaccinating 97% of the high school girls in a rural town in Wisconsin, with excellent results. Immunization of adolescent girls has been done with and without the addition of contraception, depending on the known sexual activity in the particular population.[580,581]

Adults

The most direct vaccination program, in the sense of having the most immediate impact on CRS, is vaccination of women. The principal problem with this approach is the possibility of unsuspected pregnancy, although, as described subsequently (see "Pregnancy" later), the observed risk to the fetus has been zero.

Identification of seronegative women cannot be done accurately on the basis of history because clinical diagnosis of prior rubella is unreliable.[582] Vaccination of women with negative histories of prior vaccination is advocated without confirmatory serologic testing.[575] However, a frequent practice has been to test women for immune status and then to vaccinate them while oral contraceptives or other forms of pregnancy precaution are taken.[583–586] Vaccination can be practiced as part of routine gynecologic care, premarital screening, and occupational healthcare or at other medical opportunities, as long as pregnancy can be avoided for 1 month. A frequently expressed concern is whether to vaccinate women with low titers, such as those with ELISA values just below the cutoff value, with hemolysis-in-gel values of 10 to 15 IU or with HI titers of 1:8. Current evidence suggests that those women usually are immune but may be at higher risk of reinfection,[587] and thus, one dose of vaccine should be offered (see "Reinfection and Herd Immunity" earlier). There is no evidence that vaccination of seropositive women is attended by increased risk of untoward reactions.

The use of rubella vaccine during the puerperium (postpartum vaccination) has been widely advocated.[492,588–594] For example, because 56% of CRS children in the United Kingdom were born to multiparae,[595] this practice should prevent a significant portion of CRS. Indeed, Edmond and Zealley[596] observed that CRS was prevented in Edinburgh by vaccination of girls and postpartum vaccination of women, with most of the failures occurring in women who had been screened but not vaccinated. However, pregnancy can occur even in the immediate postpartum period,[595,597] and contraceptive measures, such as the use of depot progestogen, have been advocated.[598] Administration of blood or blood products such as Rh_0(D) immunoglobulin before vaccination requires postvaccination tests for seroconversion because of the rubella antibodies in those products.

Although the postpartum genital tract is not susceptible to rubella vaccine virus,[599] vaccinated parturient women do excrete vaccine virus in their breast milk.[600] The vaccine virus then may be transmitted to their newborns, who remain asymptomatic and do not develop tolerance to subsequent vaccination.[601–603] Thus, breastfeeding is not a contraindication to vaccination.

Adult men not in high-risk groups are not generally targeted for vaccination, although they are also a reservoir of susceptibles and may serve as the source of infection of pregnant women.[604] An outbreak in Croatia showed that infection can propagate among men even if they do not live in a collectivity situation, despite routine vaccination of infants and women.[605]

In Latin America, rubella vaccination of both men and women has resulted in rapid control and elimination of the virus.

Military Recruits and College Students

Vaccination is routinely practiced in the armed forces of the United States, with the consequence being the virtual eradication of rubella.[382] Rubella also was eradicated in the armed forces of Singapore several years after commencement of routine vaccination.[606] The consequences of failure to vaccinate were illustrated by an epidemic in British troops in Bosnia.[607] The French army, which until recently has not practiced routine rubella vaccination of its recruits, has had perennial epidemics.[608] In view of the congregation of large numbers of susceptible young adults in colleges and universities, routine vaccination with MMR at matriculation also is advocated.[575] In principle, these vaccinations will be extra doses, but they are considered important to prevent outbreaks of measles and perhaps rubella on college campuses.

Hospital Employees

Outbreaks of rubella in hospitals,[609–612] with the resultant exposure of pregnant women, have led to the recommendation of compulsory rubella vaccination for both male and female hospital employees.[613] In one hospital outbreak,[614] those departments that had a compulsory vaccination policy escaped unscathed, whereas those departments that had a voluntary vaccination policy suffered numerous cases, including infections of pregnant women. A comprehensive evaluation reconfirmed the recommendation for vaccination of hospital personnel.[615]

International Travelers

Because the United States has eliminated endemic rubella and CRS, travelers should be immunized against rubella before they travel overseas if they have not been previously immunized; many imported cases result from U.S. residents returning from countries where rubella vaccination is not widespread. In particular, unimmunized women of childbearing age who travel overseas should be vaccinated to protect against the greater likelihood of exposure to the disease in countries that do not use rubella vaccine.

Contraindications

General Contraindications

Rubella vaccine can be given to patients with minor respiratory illnesses, whether febrile or afebrile (see "Indications for Rubella Vaccine" earlier). Those with congenital immune deficiencies should never receive a live virus vaccine, although family members should be vaccinated to protect the patients against rubella, measles, and mumps.[575] It also would be prudent to wait until systemic immunosuppressant drug therapy has been terminated for 3 months before vaccinating patients receiving such regimens. A 16-year-old boy with acute lymphoblastic leukemia who received RA27/3 rubella vaccine developed chronic infection of leukocytes and high antibody titers. Symptoms of arthritis required temporary interruption of immunosuppression, but fortunately, the patient recovered spontaneously.[616] Short-term (less than 2 weeks) corticosteroid therapy is not a contraindication to the administration of rubella vaccine. Patients whose immunity had been ablated during bone marrow transplantation 2 years previously were given rubella vaccine in MMR by Ljungman and coworkers.[617] They observed 75% seroconversion to the rubella component with no safety problems. King and colleagues[618] performed a similar study and found 91% seroconversion.

Children with chronic renal disease who are on hemodialysis can be immunized successfully before transplantation.[619]

Persons who have had anaphylactic reactions to neomycin should not receive rubella vaccines containing that antibiotic.[620] Whereas monovalent RA27/3 vaccine is grown in human diploid cells, MMR does contain other viruses grown in avian tissue, reactions in egg-sensitive persons may occur, but are very rare.

Concurrent Immunoglobulin G

Vaccination within 2 weeks before receipt of IgG or 3 months after receipt of IgG is inadvisable.[234,575] However, anti-Rh_0(D) globulin did not interfere with vaccination of postpartum women.[594] Women who are vaccinated after receiving anti-Rh_0(D) globulin should be tested 6 weeks later for rubella antibodies. Because most rubella vaccine is administered with measles vaccine (MR, MMR) in many countries, the precautions pertaining to measles-containing vaccine should be followed. Thus, the administration of immunoglobulins or other antibody-containing blood products may neutralize the effect of the measles component for 3 to 11 months, depending on the dose of measles antibody.

Human Immunodeficiency Virus Infection

There are not many data concerning the results of rubella immunization in HIV-seropositive children, but one study reported 80% seroconversion.[621] A similar result was obtained in another study, with a rise to 100% after revaccination.[622] A recent study of children with perinatal HIV infection given MMR showed a 65% seroconversion rate.[623] Although relatively asymptomatic HIV-positive children respond well to rubella vaccine, those in late stages may have a poor response.[624] Vaccination of HIV-seropositive women has been reported to be safe.[625,626]

HIV-infected children who are asymptomatic should receive rubella vaccine as part of MMR. Virologic study of 10 HIV-infected patients who received MMR failed to detect rubella virus.[627] MMR also should be considered for children with AIDS who are not severely immunosuppressed. However, in a small study, children with symptomatic infection had a significantly poorer response than asymptomatic children, who responded normally.[628] Older children and adults who were rubella seropositive before becoming infected with HIV maintain high-avidity rubella antibodies and do not need revaccination.[629]

Of interest is the report that rubella vaccination may give transiently positive ELISA tests for HIV antibodies.[630]

Juvenile Idiopathic Arthritis

A study of 314 patients with this condition revealed no exacerbations of disease after rubella vaccination.[631] Even treatment with methotrexate and etanercept was not associated with vaccine failure or reactions.[372] A relapse was reported in a single patient after vaccination with a Japanese rubella vaccine.[372,632]

Acute Lymphoblastic Leukemia

Children with acute lymphoblastic leukemia lose rubella antibodies after therapy but respond well to revaccination.[633]

Pregnancy

Although there is now abundant evidence for the safety of RA27/3 for the fetus, pregnancy remains a contraindication to rubella vaccination, and women are advised to take precautions against pregnancy for 1 month (28 days) after vaccination. On the basis of a case of wild virus transmission to a fetus conceived 7 weeks after vaccination,[629] a prior recommendation had been for a 3-month delay, but evidence for damage to the fetus by rubella vaccine strains is nonexistent.[634] Several summaries of the accumulated American, British, and German data have been published (Table 53.21).[635–637] Transplacental passage of vaccine virus is a rare event, having been documented four times in 708 pregnancies complicated by RA27/3 vaccination. More important, there was no CRS case demonstrated in more than 2750 pregnancies during which rubella vaccines were given. Hoffman and coworkers[638] reported the case of a woman vaccinated 3 weeks after conception who gave birth to an infant who excreted RA27/3 virus until 8 months of age. Nevertheless, the infant was free of abnormalities.[638]

Data from Germany and Latin America are particularly supportive of a lack of teratogenic effect of rubella vaccine given during pregnancy. In Germany, cord blood was positive for rubella IgM in only six of 126 (4.6%) infants born to rubella seronegative mothers, and none of those infants, plus 131 other infants from whom cord blood had not been obtained, had abnormalities compatible with CRS (Enders G. Personal communication to SA Plotkin, 2006). In the course of efforts to eliminate rubella from Latin America (see "Latin America and the Caribbean" later), women who were unknowingly pregnant at the time of vaccination were surveyed in Costa Rica, Brazil, Ecuador, El Salvador, Paraguay, Argentina, and Mexico.[639–641] Although cord blood was positive for rubella IgM antibodies in 3.6% of cases, no case of CRS was confirmed in either country, nor was there evidence for increased fetal loss.[642,643] A smaller study in Israel reached the same conclusion.[363] Iran performed a mass measles-rubella vaccination in December 2003. Infants born to 535 women who were inadvertently vaccinated during pregnancy were studied, including women known to be seronegative before vaccination and women who had not been tested. Only five newborns had IgM antibodies at birth, and none had evidence of abnormality on follow-up.[401]

The results of the studies conducted in six Latin American countries provide the largest collection of new evidence to support existing documentation of a negligible or absent risk for CRS after administration of rubella vaccine shortly before or during pregnancy. Of the 1980 susceptible pregnant women followed, 70 (3.6%) of the infants had congenital rubella infection, but none had congenital defects associated with CRS.[640] In the Brazilian study, one rubella IgM antibody–positive infant had clinical features of CRS but had wild-type

TABLE 53.21 Summary of Data on Vaccination of Unknowingly Pregnant Rubella-Susceptible Women

	Live Births to Women Receiving Rubella Immunization		
Country	Within 3 Months Before Conception or During Pregnancy	Evidence of Infection	Abnormalities Compatible With CRS
United States	324[a]	6/222 (2.7%)	0/324
Germany (West BRD)	280[a]	3/69 (4.3%)	0/279
Sweden	5[a]	NK	0/5

rubella virus identified by molecular genotyping of viral culture.[641] Badilla and coworkers[644] followed more than 3000 women who were vaccinated during a rubella campaign in Costa Rica, of whom 1191 were followed closely. Comparison of subgroups that were seronegative, seropositive, or of unknown serologic status before vaccination showed no differences in fetal outcome, no association with defects compatible with CRS, and no IgM seropositivity in newborns. In Iran, 106 pregnant women vaccinated with MR were followed, and again no infant had clinical or serologic evidence of infection.[645] Infants born to 60 Iranian women who received vaccine around the time of conception also showed no CRS.[646] Finally, a prospective study of 175 susceptible Mexican women studied show that all the 174 infants studied were IgM negative and had no CRS-compatible defects.[639]

On the basis of data in Table 53.21, the theoretical maximum risk for CRS after the administration of vaccine is 0.2%, considerably lower than the risk with wild rubella virus, or indeed the risk of non–CRS-induced congenital defects in pregnancy. If only the American women known to be seronegative and who received RA27/3 are considered in the calculation, the theoretical risk to the fetus still does not rise to more than 2.1%. The newer data recorded above substantially reduce the theoretical risk. Because the observed risk has been zero, rubella vaccination during pregnancy is no longer considered an indication for abortion.[647,648]

These data are reassuring because pregnant women continue to receive rubella-containing vaccines. In a review of the VAERS database between 2003 and 2013, there were 131 reports of pregnant women vaccinated with MMR alone or in combination with other vaccines. Of the pregnancies that went to delivery, no infant was born with CRS-associated manifestations.[565] Based on the information on pregnancies between 2002 and 2009 in the U.S. Vaccine Safety Link Database, pregnant women had received MMR or rubella monovalent vaccine at rates of 1.19 and 0.16 vaccinations per 1000 pregnancies, respectively.[649] In fact, there is little evidence for danger of vaccination in pregnancy for other live and killed vaccines.[650]

Concomitant Yellow Fever Vaccine. A report from Brazil recorded lower seroconversion to rubella, mumps, and yellow fever when the vaccines were given concomitantly then separately, although the rubella response may have been measured too early after simultaneous administration.[651]

Children With Congenital Rubella Syndrome

Children with CRS probably will not respond to parenteral rubella vaccine, even when they are seronegative.[652] The reason for resistance of CRS children is unknown, and probably involves immune factors other than antibodies, but immune tolerance is not responsible. In fact, 81.5% of CRS children were seropositive 5 years after birth, although the loss of antibody in 18.5% is faster than in normal children postinfection.[652] Even though they could be immunized with RA27/3 intranasally,[653] there is no official recommendation to vaccinate these children.

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Results of Vaccination

The goal of rubella vaccination programs is the prevention of the intrauterine infection that causes CRS, and, incidentally, the occasional complication of the disease in adults. Since the licensure of the rubella vaccine in 1969, the global epidemiology of rubella and CRS has changed dramatically. In 2000, the WHO convened a meeting to review the worldwide status of CRS and its prevention.[654,655] This meeting was prompted by the availability of more data on the CRS disease burden in developing countries, an increase in the number of countries with national rubella immunization programs, and advances in laboratory diagnosis since the last international meeting on CRS and rubella in 1984. In 1996, only 83 countries and territories used rubella vaccine in their national immunization programs. Since the 2000 meeting, additional countries have introduced rubella-containing vaccine, two WHO regions (Regions of the Americas and Europe) have established rubella elimination goals by 2010 and 2015, respectively, and one WHO region (Western Pacific) has established an elimination goal for rubella and CRS. As of September 2016, 149 (77%) this number had increased to 140 (72%) of the 194 reporting countries and territories. The proportion of countries using rubella vaccine varies markedly by WHO region (Fig. 53.5).[656] Much of the recent increase occurred in Asia and Africa. Even

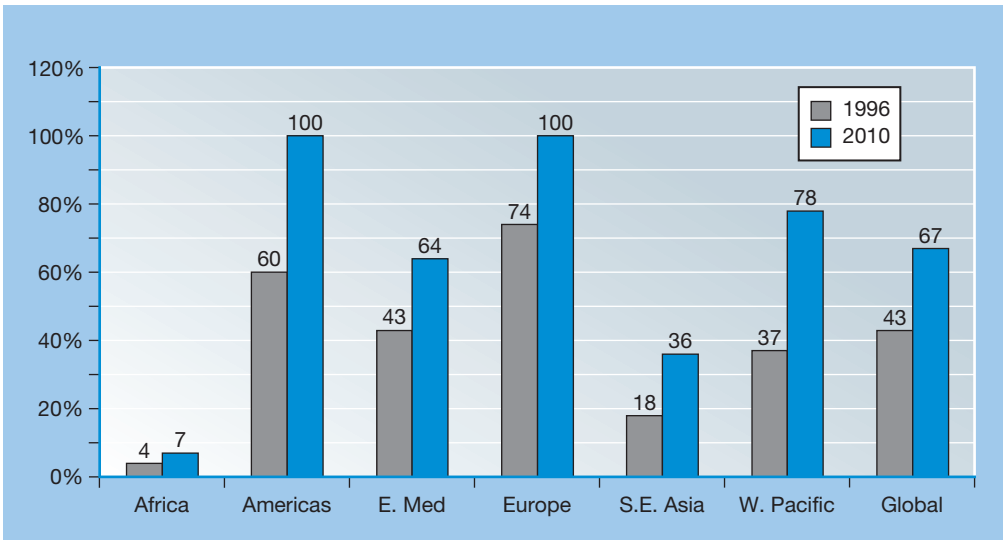

Figure 53.5. Percentage of member states by World Health Organization (WHO) region, with routine rubella vaccination, 2009. *(From Reef SE, Strebel P, Dabbagh A, et al. Progress toward control of rubella and prevention of congenital rubella syndrome: worldwide, 2009.* J Infect Dis. *2011;203:S24–S27.)*

though only one dose is required, most countries use a two-dose schedule because rubella vaccine is generally combined with measles vaccine, which is recommended as a two-dose schedule.[657]

United States

Rubella vaccine has had spectacular success in the United States, in terms of the number of persons vaccinated and the declining numbers of rubella cases reported. Since the licensing of the vaccine in 1969, no major epidemic of rubella has occurred, despite the previously observed 6- to 9-year cycle.

These impressive results were obtained initially by the vaccination of children, with a dependence on herd immunity to protect pregnant women. However, assessment in 1977–78 revealed that although the program was having a major impact on rubella in children, rubella rates in those older than 15 years were not substantially different from prevaccination rates.[234] Specific experiences in institutional or citywide outbreaks showed that herd immunity was limited, giving a protection of perhaps 50%.[394,658,659] Moreover, children were not the sole source of infection for their mothers.[660] Serologic surveys showed a persistence of 12% to 24% seronegativity in adolescents and adults. As a consequence, programs to expand vaccination of these groups were increased. Subsequently, the incidence of rubella dropped to less than one per 100,000 population, and the incidence of CRS dropped to less than 0.1 per 100,000 births (Fig. 53.6).[183]

In 1988, a nadir was reached in reported postnatal rubella, and only one case of CRS was registered in 1989. Large outbreaks of rubella occurred in unimmunized immigrants to California and among persons in religious communities that do not accept vaccination, which were followed by the expected cluster of CRS cases.[190,661] A serologic survey conducted between 1988 and 1994 showed 92% seropositivity in 6- to 11-year-old children, but only 85% in persons 20 to 29 years of age.[662]

In the mid-1990s, rubella occurred mainly among foreign-born Hispanic adults who were unvaccinated or whose vaccination status was unknown, with very limited spread and circulation among the U.S. resident population.[663] From 1997 to 1999, 20 (83%) of 24 infants with CRS were born to Hispanic mothers, of whom 91% were foreign-born.[180] Mothers' countries of birth include mainly Mexico, Central American countries, and countries of the Spanish-speaking Caribbean. Genomic sequencing confirmed that the strains circulating earlier were sporadic, while imported strains featured in remaining small outbreaks.[215] Finally, elimination of endemic rubella was achieved in 2001 and has been maintained, with rubella and CRS becoming an imported disease, as in a recent case of a mother immigrating from Liberia.[664,665]

Cost-benefit analyses showed that for every dollar spent on childhood rubella vaccination in the United States, US$7.70 was saved.[666]

Accumulating evidence that there was no more endemic circulation of rubella virus allowed the CDC and an expert committee to declare in 2004 that rubella had been eliminated from the United States.[401] Since the meeting in 2004, elimination of rubella and CRS has been maintained in the United States. As part of the verification of elimination of measles, rubella, and CRS in the Region of the Americas, the CDC convened an external expert panel in December 2011, which reviewed the evidence. The panel concluded that rubella and CRS had been eliminated from the United States.[667] Recent serologic data show that 95% of Americans have rubella antibodies.[668]

Meanwhile, the growing resurgence of measles resulted in a recommendation for a routine second dose of measles vaccine, usually in the form of MMR.[669,670] Thus, revaccination with rubella became standard, practiced at either entrance to primary school (4 to 6 years of age) or entrance to secondary school (11 to 12 years of age). Although there are theoretical arguments in favor of revaccinating older preadolescent children,[468] the United States has moved to uniform revaccination with MMR at 4 to 6 years of age. An economic analysis revealed a ratio of benefit to cost of 14.2 for direct costs and 26.0 for societal costs.[671]

Canada

The provinces of Canada adopted a policy either of mass vaccination of infants or of selective vaccination of preschool-age girls.[242,639] Total rubella incidence dropped in the provinces that adopted mass vaccination of infants but was not much changed in those adopting vaccination of preschool-age girls. However, reported CRS decreased throughout Canada. As of 1983, all provinces give vaccine to infants and also to 12-year-old girls who had not been immunized previously.[672] During 1996 to 1997, a nationwide two-dose MMR policy was implemented. As part of measles elimination strategy, several of the

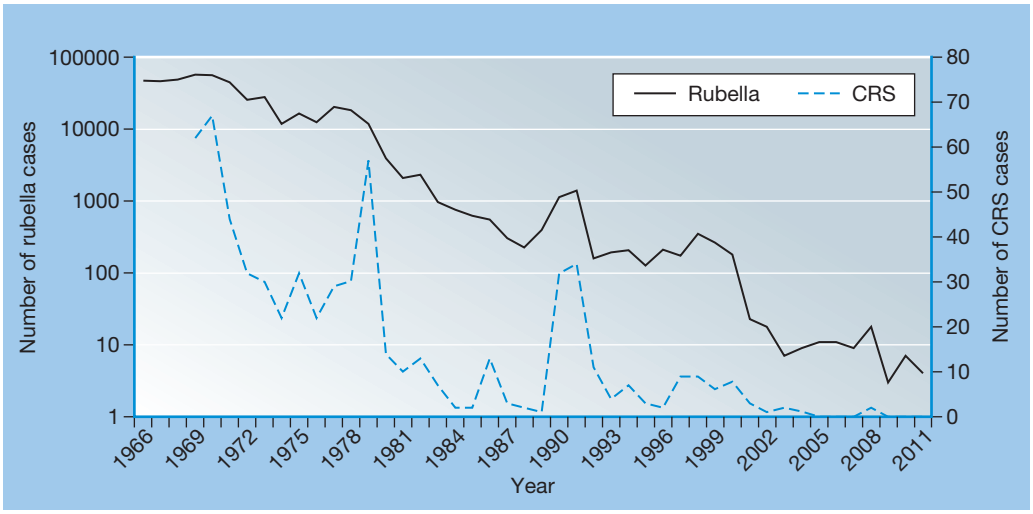

Figure 53.6. Reported rubella and congenital rubella syndrome (CRS) cases, United States, 1966–2009.

provinces conducted MR catch-up campaigns. With the success of the measles-rubella vaccination program, rubella incidence has been at an all-time low since 1999, except during 2005 when there was an outbreak among a religious community in Ontario. The review of epidemiologic and laboratory evidence indicates that endemic rubella transmission has been interrupted.[673]

Europe

The WHO European Region is composed of 53 member states, including Western and Eastern Europe, Russia, and the Newly Independent States. WHO-Europe had set a goal of eliminating rubella and thus reducing CRS incidence in the European Region to less than one per 100,000 births by 2010,[674] and by 2004, 90% of countries in the region were using rubella vaccine.[675] By 2009, all 53 member states had included rubella vaccination in routine childhood vaccination as part of MR/MMR.[676,678] Most countries using MMR recommend two doses. The Scandinavian countries have succeeded in eliminating rubella (see "Scandinavia" later). Not surprisingly, rubella incidence is relatively low in Western Europe, more frequent in Central and Eastern Europe, and very common in the Newly Independent States.[678,679] However, in 2010, vaccine coverage with MMR was low in Southern Europe and epidemics of measles and rubella occurred. Thus, the elimination goal had not been met. The goal for rubella elimination target date was changed to 2015.[680] The number of rubella cases in the European Region decreased from 621,039 in 41 countries in 2000 to 640 cases in 37 countries in 2014.[147] In November 2015, at the regional verification meeting, 23(43%) of the member states were verified to have interrupted endemic rubella transmission.[681]

United Kingdom. The policy of vaccinating schoolgirls was adopted by the British in 1970.[265,682] During subsequent years, the number of reported rubella cases decreased only slightly, although the reported cases of CRS decreased approximately 75%.[683] Approximately 15% of schoolgirls did not accept the vaccine,[684,685] which explained why 88% of women reporting for assessment for rash disease had not been immunized.[686] Although serologic studies showed that vaccination had reduced seronegativity of young women,[686–689] many susceptible persons still remained.[689,690]

After original hesitation, opinion in Britain changed to favor the inclusion of young children in rubella vaccination practice, as is now done in the United States.[682,691–694] Since October 1988, rubella vaccine as part of MMR has been recommended to all infants,[695] and in 1994, a large-scale vaccination campaign was conducted with MR combined vaccine. Congenital rubella and terminations of pregnancy for rubella decreased markedly in England and Wales,[696] with only one CRS case reported in 1995.[697,69] In 1996, however, the United Kingdom experienced a resurgence of rubella, primarily in adult and adolescent males who were unvaccinated.[698] As might be predicted, cases of CRS followed the outbreak. In response, during 1994 to 1995, a catch-up campaign was conducted in both boys and girls of 5 to 16 years of age, with considerable reduction in susceptible youths and in rubella infections.

Pregnant women immigrating into the United Kingdom from Asia and Africa are at increased risk of being seronegative.[699,700] Additional outbreaks in universities have resulted from imported rubella in Greek students.[701] In 2011, 7% of British women were seronegative; the figure for women born after 1986 was 18%,[702] possibly the result of public concern relating to allegations of a relationship between MMR vaccination and autism that reduced rubella coverage, but CRS remains rare.[703]

Scandinavia. In 1982, Sweden adopted a two-stage vaccination scheme involving the use of MMR at two ages: 18 months and 12 years.[704,705]

An acceptance rate of 88% was achieved among Swedish schoolgirls and an even higher rate among other children. Some problems with seroconversion for mumps and measles among the 12-year-old girls were reported, but rubella vaccine gave good results in both age groups.[706] Christenson and Bottiger[707] studied the rubella serology of 1343 susceptible 12-year-olds in the Swedish program and found that 100% seroconverted after vaccination. Before 1974, a yearly average of 14 CRS cases was recorded in Sweden; there were two cases per year between 1975 and 1985, and there have been no cases since 1985.[708]

Nevertheless, some resistance to vaccination has caused vaccination to be done later in life than infancy[709] and in 2012 an outbreak of rubella resulting in 50 cases occurred largely in an anthroposophic community.[710]

In Denmark, no case of rubella has been reported since 1996.[711] A survey of congenital cataracts identified 26 cases resulting from congenital rubella before rubella vaccination was introduced in 1987, but only one indigenous case subsequently.[712] A review of deafblind persons born in Denmark before 2008 revealed that those cases caused by congenital rubella was 32% in adults but only 3% in children.[713]

The Finns vaccinate with MMR at 14 to 18 months and at 6 years of age. The peak incidence has shifted to adults, whereas children appear to be protected.[714] The success of the MMR two-dose vaccination policy in Finland has been spectacular. Peltola and colleagues[715] summarized the results of the program that succeeded in eliminating indigenous cases of rubella, measles, and mumps. This program was supported by improved surveillance of disease and by ancillary studies demonstrating lack of significant reactions to vaccine and persistence of antibodies. Ukkonen[716] provided data on the disappearance of rubella and the state of rubella immunity in the Finnish population. As shown in Fig. 53.7, the two-dose policy has erased seronegativity in adolescents and caused rubella to disappear. Since 1986, no case of CRS has been reported. The last indigenous rubella case occurred in 1996. In 1997 and 1998, rubella was eliminated from Finland.[625,717] Only one case of rubella was reported between 2003 and 2007.[718]

France. Between 1982 and 1994, during which MMR was recommended for all 1-year-old French children, rubella infections in pregnancy dropped from 45 to nine cases per 100,000 births.[719] Vaccine coverage is now greater than 90% in children younger than 10 years, but considerably lower in adolescents.[720] Moreover, areas of low vaccine coverage persist, resulting in large numbers of measles cases and probably unreported rubella, as well. Although French authorities have instituted a second dose of MMR at 6 years of age, and much congenital rubella has been prevented, susceptibility remains high in adolescents and adults.[312,721,722]

The Netherlands. The Netherlands replaced selective vaccination of girls with mass vaccination of infants in 1987. Although serologic immunity to rubella is high in the Dutch population,[723] circulation of rubella virus persists and rare cases of CRS continue to occur, perhaps because some religious communities have low coverage and export infection (Van Doornum GJ. Personal communication, 2005).[724,725] A population-based serosurveillance study performed in The Netherlands in 2006–07 found that orthodox Protestants reached a seroprevalence above 85% only at 5 years of age, whereas in the nonorthodox community that level was reached at 2 years of age.[726] In 2013 an outbreak of rubella comprising

54 cases was linked to an orthodox Protestant primary school.[726]

Italy. Although adolescent girls have been targeted for rubella vaccination since 1972,[727] routine childhood vaccination began in 1990 with MMR vaccine being administered at 12 to 24 months. In 1999, Italy introduced a two-dose MMR schedule. However, measles-containing vaccine coverage was less than 80% until 2002. In 2002, MMR vaccine was provided free of charge. Recent efforts designed to eliminate CRS by 2007 have decreased the incidence of rubella in women of childbearing age from 14.1 to 2.8 cases per 100,000.[728] CRS continues to occur in Italy,[729,730] as substantial percentages of women are seronegative.[731]

Between 2005 and 2013 a total of 75 congenital rubella infections were reported, amounting to a national mean incidence of 1.5 per 100,000 live births. Two peaks occurred in 2008 and 2012, giving incidences of 5.0 and 3.6 per 100,000, respectively. Rubella and CRS continue to be a public health problem in Italy.[188,188a]

Spain. Serologic data show that 97% of children in Spain have rubella antibodies because of high vaccine coverage.[732] In the Basque region, there have been no rubella cases since 1997 and no CRS since 1984.[733] However, in 2003, there was an epidemic of rubella in Madrid, centering on women who had immigrated from Latin America.[734–736] Nevertheless, in Catalonia, MMR vaccination has achieved elimination of indigenous rubella, and only 6% of pregnant women are seronegative.[737,738]

Greece. Vaccination against rubella was introduced slowly into Greece through the private market in 1975. In 1989, MMR was introduced into the routine childhood program, with a second dose of MMR added in 1991. An outbreak in 1993 was attributed to the reductive effect of insufficient rubella vaccination in children on the circulation of rubella virus and thus greater susceptibility of adult women. Since then, high rates of coverage have been achieved in infants, but many adolescents are still susceptible.[739]

Other European Countries. Ninety-six percent of children and adolescents in Luxembourg are rubella seropositive.[447]

Coverage rates in Switzerland are uncertain, and Matter and colleagues[740] reported the persistence of rubella and CRS cases.

A large rubella outbreak in 2002–03 caused Romania to adopt MR vaccination of adolescent girls and subsequently MMR vaccination of infants in 2004.[741] Again, in 2011–12, Romania experienced an outbreak involving 24,727 cases, of which 98% were unvaccinated and more than 75% were in 14 to 19 year olds. The majority of cases occurred in those who had not been recommended to receive vaccine. In 2012, 119 pregnant women were infected by rubella, resulting in 55 cases of laboratory-confirmed CRS, nine infant deaths, and one stillborn CRS. Poland also experienced epidemics until 2008 but has now undertaken rubella elimination.[676] However, a report from 2013 recounted an epidemic of more than 21,000 cases centered in 15- to 29-year-old boys, who had not been vaccinated because Poland had previously vaccinated only adolescent girls. Since 2004, a universal two-dose combined MMR vaccination program has been implemented.[726] In Austria, vaccination of children has reduced rubella incidence in children, but unvaccinated adolescents are still being infected.[742]

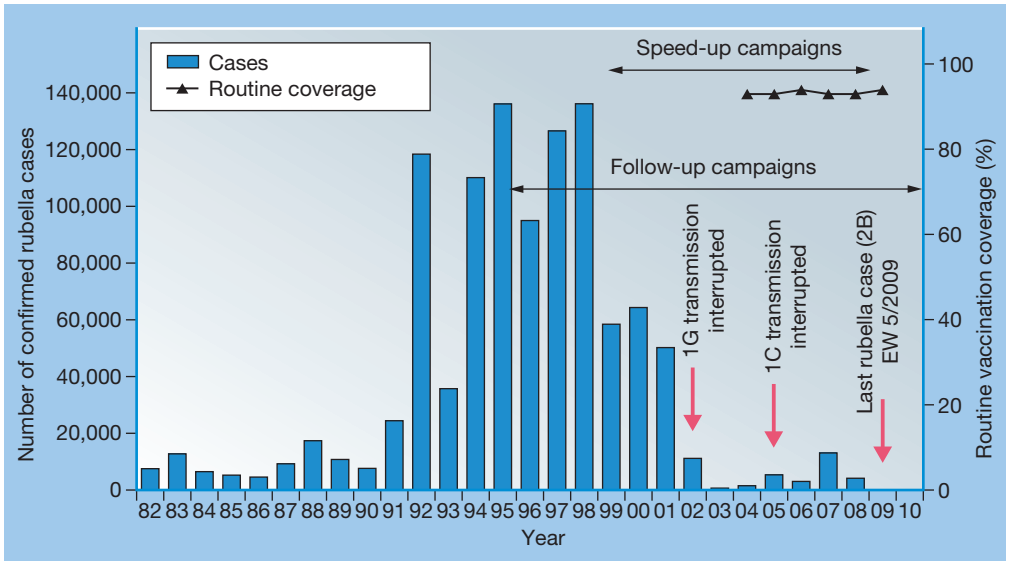
In Albania, a mass vaccination campaign was conducted in 2000, covering children 1 to 14 years of age. In 2001, women of childbearing age were targeted. Since then rubella and CRS have been rare.[743]

Israel

Israel at first adopted the British policy of vaccination of schoolgirls. Subsequent observations showed that although the youngest girls were being protected, epidemics could still infect large numbers of pregnant women. Accordingly, family health clinics, which most Israeli women attend, began to screen for rubella antibodies and to vaccinate seronegative women, and universal vaccination of children with MMR was started in 1989.[190] Economic analysis supported that step.[744] The problem of eliminating rubella in Israel has been exacerbated by the early emphasis on vaccination of women only, by immigration of unvaccinated populations, and by the existence of religious communities that do not accept vaccination. An epidemic of rubella in the Israeli Army led to an analysis that showed only 69% in seropositivity in male soldiers, probably because of insufficient catch-up vaccination.[745] The earlier vaccine policy is also reflected in a low rate of seropositivity in the civilian 13- to 17-year-old age group.[746] Nevertheless, since the occurrence in 1992 of five CRS cases, only one further CRS case has been reported, and that was in the baby of an immigrant woman (Slater P. Personal communication, 2006).[747,748]

Russia and the Newly Independent States

In 2000, a survey in the Perm region of Russia showed a 17% susceptibility rate in Russian women and a CRS rate of 3.5 per 1000 live births. An estimated 15% of all birth defects were attributed to rubella.[749] Since then, more rubella vaccination has been done in Russia, but coverage is far from complete, and epidemiologic information is scarce.



All the newly independent countries have introduced rubella-containing vaccine, with Tajikistan being the last country to do so in 2009. Kyrgyzstan served as the model. Early studies showed that rubella was endemic and epidemic in that country and that 13% of women 15 to 39 years of age were susceptible.[173,177] Subsequent vaccination campaigns were highly successful, and similar campaigns have been conducted in Belarus, and many of the other Newly Independent States.

Latin America and the Caribbean

The Technical Advisory Group (TAG) of the Pan-American Health Organization (PAHO) recommended routine rubella immunization throughout the Americas in 1997 after concluding that 20,000 infants with CRS are born each year in that region even in the absence of an epidemic.[750] In 1999, the PAHO TAG recommended an accelerated rubella control and CRS prevention initiative. Countries wishing to eliminate rubella and CRS rapidly were advised to conduct a one-time mass campaign that targeted adolescent and adult females and males with MR vaccine. Countries wishing to prevent and control CRS were advised to conduct a one-time campaign in females only, 5 to 39 years of age.

In 2003, the Directing Council for the Member States for the Americas established a goal for the elimination of rubella and CRS by 2010. Rubella and CRS elimination was defined as the interruption of endemic rubella virus transmission in all the countries of the Americas for a period greater than or equal to 12 months, without the occurrence of CRS cases associated with endemic transmission, in the presence of high-quality surveillance. In 2003, the TAG recommended that mass campaigns be conducted in both males and females. The target age group (5 to 39 years of age) was selected on the basis of year of vaccine introduction, previous campaigns conducted, epidemiology, and fertility rates in the countries. In 2007–09, the three countries (Chile, Argentina, and Brazil) that initially conducted female-only mass campaigns documented outbreaks in adult males.[751,752] All three countries subsequently conducted additional mass campaigns, two in males only (Argentina, Chile) and one in both males and females (Brazil).

With the successful implementation of the PAHO strategy for rubella vaccine, endemic transmission of rubella virus in the WHO Region of the Americas was interrupted in 2009 (Fig. 53.8).[148] Since 2010, countries in the Region of the Americas

*Data until EW 52/2010

Figure 53.8. Reported routine coverage (2004–2009), time frame of campaigns conducted, and reported rubella cases (1982–2010), Region of the Americas. PAHO, Pan American Health Organization; WHO, World Health Organization.

have started the documentation of elimination of measles, rubella, and CRS using standardized guidelines.[752] In addition to the United States, Costa Rica and Canada have published their evidence for the elimination of rubella and CRS.[753] In 2015, it was declared that rubella had been eliminated from the Region of the Americas.

Costa Rica has been a pioneer in the elimination of rubella, having introduced the vaccine as early as 1972. However, because of low coverage of infant vaccination for more than one decade, the epidemiology changed with a shift in the peak age of rubella toward adults. Serologic studies showed that coverage was incomplete, particularly in young adults. In 1999, a large rubella outbreak occurred, with 84% of cases in persons more than 15 years old. A mass vaccination campaign in adults with MR finally eliminated rubella in 2001.[754–756]

Brazil has also had an extensive experience with vaccination. A model immunization program for rubella was conducted in Saõ Paulo, Brazil in 1993 by Massad and coworkers.[757,758] All children 1 to 10 years old were included in a mass campaign with MMR, accompanied by routine MMR vaccination of infants at 15 months of age. Immunity to rubella in the population jumped from 40% to 97%, and, more importantly, the number of CRS cases dropped from 29 confirmed and suspected in 1992 to none in 1994. However, immigration of new children into Saõ Paulo and the absence of a vaccination program for older persons led to a subsequent increase in the overall incidence of rubella. Although the highest incidence in 1997 was still among children 1 to 9 years of age, by 1999 to 2000, the incidence in the older age groups (15 to 29 years) had risen from seven to 13 per 100,000 and exceeded that of the younger age groups. Serologic studies conducted 8 years later showed that previously vaccinated adolescents were 94% seropositive, and 100% if they had received two doses, but in general, the population older than 20 years was 30% seronegative.[449,754,758,759]

Accordingly, a two-phase vaccination plan for Brazil as a whole was developed to accelerate CRS prevention. In 2001–02, in a two-phase campaign, Brazil targeted women 12 to 29 years of age. During the first phase in 2001, a total population of 16,437,881 females in 13 states received MMR vaccine.[760,761] The incidence of rubella dropped to a low level; however, in 2006, a rubella outbreak occurred that spread to other major cities in 2007 and was concentrated among adolescent and adult males who had not been included in the previous vaccination strategy. In 2007, 8753 rubella cases were reported.[762] As a consequence, 47 CRS cases were reported between 2007 and 2008. To reach the 2010 elimination goal, in 2008 Brazil conducted a mass campaign targeting mainly adult males and females, but also included some adolescents. The estimated target population was greater than 70,000,000.[763]

Chile began MMR vaccination of infants in 1990 and booster vaccination of 6-year-old children in 1993. However, rubella outbreaks were observed in 1997 and 1998 involving adolescents and adults. The Chileans launched a mass vaccination program for women 10 to 29 years of age in 1999. Pregnant women were excluded from the mass vaccination, but were vaccinated postpartum.[754,764] Similar to Brazil, Chile experienced rubella outbreaks mainly among adolescent and adult males. During these epidemics, pregnant women were infected and infants with CRS were born. To achieve the rubella elimination goal, Chile conducted a mass campaign in adult males. After the completion of these mass campaigns, the last endemic rubella case in Argentina was in February 2009.[751,752,765]

Australia

Australia also adopted the policy of vaccinating schoolgirls. By 1983, 12 years after the program had started, 96% of pregnant women were seropositive, and in 2000, a serologic survey showed 97% seropositivity.[766] MMR vaccination of children began in 1988–89, followed by vaccination of adolescents of both sexes in 1994–96. A second dose of MMR at age 4 to 5 years has been recommended.[767] Vaccine coverage is 93%, and 97% of children with documented rubella immunization are seropositive.[768] Cases of reported CRS have fallen from approximately 120 per year (prevaccine) to two cases in 2003.[142] Vaccine-induced immunity is high,[769] and since then, there has been only 1 imported case (Burgess M. Personal communication, 2006). In the province of Victoria, rubella incidence fell by 90% between 1995 and 2000,[770] and overall, the incidence in 2001–02 had fallen to 1.3 per 100,000 population.[771]

Between 2008 and 2012 only two CRS cases were recorded, and rubella incidence has fallen so low that rubella may have been eliminated from Australia.[772]

Taiwan

Taiwan has made extensive efforts to vaccinate both girls and women of childbearing age. A serologic survey showed that only 4% of women covered by both programs were seronegative, but older women were still 23% seronegative, showing the need for more vaccination of adults.[773] A recent evaluation pointed out the need to immunize immigrants and to improve vaccination of women before pregnancy.[774]

Japan

An epidemiologic analysis showed that Japan had suffered rubella epidemics every 5 years and reported 1600 CRS cases between 1965 and 1985. Vaccination has been focused on young girls, because of the absence of an MMR vaccine in Japan. Because vaccination is voluntary, 27% of schoolgirls were found to be seronegative in 2003.[775] Nevertheless, a survey by Katow[87] in 2004 found that CRS cases in the past were typical of those found in other countries but that a decrease in CRS cases to one to three per year had occurred because of the application of vaccination in infancy with monovalent products. However, because rubella has not been eliminated from Japan and there has been a recent epidemic, the government launched campaigns with MR vaccine in young adolescents.

Developing Countries

The facts concerning rubella and CRS described earlier under "Epidemiology" suggest that many developing countries have a significant incidence of CRS and could benefit from rubella vaccination. Robertson and colleagues[776] have reviewed the use of rubella vaccine in developing countries.

Most developing countries with middle income, notably Malaysia, Thailand, Hong Kong, and the Middle Eastern states, are vaccinating against rubella. Singapore has made good progress and has not had recent CRS cases.[777] Malaysia has achieved high rubella vaccine coverage, including women of childbearing age.[778] However, in Korea, only vaccination of female infants has been practiced.[779] Large countries such as China and India are vaccinating few of their children against rubella; one estimate of CRS incidence in South India is 32 to 97 cases per 100,000 live births.[728] A recent review concluded that the burden of CRS in India is high but undefined.[780] Modeling analysis concluded that CRS will increase in China, but that routine vaccination of infants would eliminate rubella by 2051.[781] Iran undertook a mass vaccination program of the 5- to 25-year-old population in 2003 because of high levels of seronegativity, resulting in 98% seroconversion.[782] In Sri Lanka, multiple age cohorts of children and women

have been vaccinated.[728] Egypt has conducted a national MR vaccination campaign, achieving 95% coverage,[783] and Taiwan now has high seropositivity in pregnant women, except for immigrants.[784]

Africa has been moving slowly toward inclusion of rubella vaccine in measles campaigns. Nevertheless, only 46% of the world's birth cohort was vaccinated against rubella in 2014. In South Africa, the rubella component of an MMR vaccine elicited seroconversion in 94% of black African infants, and in Oman and Iran, vaccination resulted in 98% seropositivity.[95,571,785]

Rubella outbreaks have recently been reported in two Pacific island countries: Tonga and Samoa. In 2002, the Kingdom of Tonga experienced an outbreak of more than 1000 rubella cases, including 42 with encephalitis. In response to the outbreak, a mass rubella vaccination campaign was conducted, targeting all children from 1 to 14 years of age and women from 15 to 44 years of age. In 2003, Samoa had a similar outbreak, with more than 1000 cases, mainly in school-age children and, to a lesser extent, in younger children. Encephalitis also occurred in Samoa. Thus, encephalitis was much more common in the Pacific island outbreaks than previously reported elsewhere.[29]

Hinman and colleagues[786] reviewed 17 studies of cost-benefit and cost-effectiveness in both developed and developing countries. They found that the economic argument for rubella vaccination was as strong as for hepatitis B and *H. influenzae* type b vaccination, certainly in developed countries, Latin America, and the Caribbean, and, probably, in Asia and Africa, although more data are needed. Considerable progress is being made toward the worldwide prevention of CRS.[677]

In 2000, Babigumura et al.[787] reviewed the economics of rubella vaccination. Twenty-seven studies, 11 cost-benefit analyses, four cost-effectiveness analyses, and one cost-utility analysis were identified. Of these, 20 were conducted in high-income countries, five in middle-income countries, two in lower-middle-income countries, and none in low-income countries. CRS was estimated to cost (in 2012 U.S. dollars) between US$4300 and US$57,000 per case annually in middle-income countries and up to US$140,000 over a lifetime in high-income countries. Rubella vaccination programs, including the vaccination of health workers, children, and women, had favorable cost-effectiveness, cost-utility, and cost-benefit ratios in high- and middle-income countries.[787]

Strategies for Rubella Vaccination

Although many possible strategies for the prevention of CRS have been used, there are two basic approaches: CRS reduction and rubella/CRS elimination. CRS reduction focuses exclusively on immunizing adolescent girls or women of childbearing age, or both groups. This approach will provide direct protection to women of childbearing age; however, the impact of this strategy is limited by the coverage achieved and the range of age groups targeted. The second approach focuses on interruption of rubella virus circulation, thereby eliminating rubella and subsequently CRS. In principal, assuming high coverage, routine vaccination of infants alone would eliminate CRS in 25 to 30 years. Countries can shorten the time frame to elimination by vaccinating wider age ranges. Rubella and CRS will be eliminated within approximately 10 to 20 years when vaccination at high coverage is provided to young children and adolescents (e.g., children 1 to 14 years of age), and within 10 years when vaccination at high coverage is provided to young children, adolescents, and adults.

In 2011, the WHO rubella vaccine recommendations were updated.[515] The WHO recommends that countries that have not introduced rubella vaccination take the opportunity offered by accelerated measles control and elimination to introduce rubella vaccine. The measles vaccine strategy platform provides the opportunity to use combined vaccine and an integrated measles-rubella surveillance system. The preferred strategy for introduction of rubella vaccination is to begin with MR/MMR vaccine in a campaign targeting a wide range of ages together with immediate introduction of MR/MMR vaccine into the routine program.

Countries planning to introduce rubella vaccine into their routine programs should review the epidemiology of rubella/CRS. Depending on the burden of CRS and available resources, a country should define its goal and the time frame for achieving it. Considerable progress has been made on a global level.

By 2014, 140 countries were using rubella vaccine and elimination of rubella is now a goal. Rubella vaccination is being accomplished using combinations containing measles vaccine in 98% of those countries. Vaccine is being administered at 8 to 11 months of age in 11% of countries, at 12 to 18 months of age in 85% of countries, and at older than 18 months of age in 4% of countries.[147]

In the United States, a decision was made to eliminate rubella and CRS.[788] The strategies for elimination were essentially childhood vaccinations supplemented by vaccination of women and other groups as outlined in Table 53.20. As described above, this policy has been successful, and rubella has been eliminated. Nevertheless, some lacunae remain, as shown, for example, by a study of poultry-plant workers born in Mexico and American women coming for obstetrical care, of whom, respectively, 20% and 9% were rubella susceptible.[663,789]

In the United Kingdom, rubella control has emphasized surveillance of rash disease and serologic status of women. Voluntary vaccination of schoolgirls reached approximately 80%, and routine immunization of infants with MMR was continued, despite some defections of parents because of the false accusations of a connection with autism. These strategies have made CRS a rarity, but rubella virus continues to circulate, largely through importation from Asia.[790]

Of importance, Knox,[791] Anderson and May,[792] and Gay and coworkers[793] have shown by mathematical modeling that institution of infant vaccination with inadequate vaccine coverage will decrease rubella virus circulation sufficiently to augment the susceptibility of adult women and thus allow a paradoxic increase in CRS. Another calculation found that a private-sector coverage of less than 60% might increase the incidence of CRS in developing countries with a high force of infection.[794] Indeed, as described above, it appears that the phenomenon may have occurred in Greece, where low-level introduction of MMR in infants through vaccination in the private sector only was followed by increased seronegativity of Athenian women and a large cluster of CRS in 1993.[795] The same phenomenon may also have operated in Costa Rica. In both countries the shift to the older age group was gradual over a 10+-year period during the low-level routine programs. Certainly, as demonstrated in Brazil, vaccination of children only does not entirely eliminate the risk for women of having babies with CRS.[796] Fig. 53.9, based on the mathematical modeling of Nigel Gay, gives the relation between rubella vaccine coverage and the predicted incidence of CRS, and shows that 80% infant coverage is needed to prevent the paradoxic effect (Gay N. Modeling the Impact of Strategy Options. Unpublished document, 2002). From country experiences, incorporating rubella vaccine into the measles strategy has rapidly controlled rubella and reduced CRS. Mathematical modeling of this strategy has also highlighted the impact of this strategy. Using this strategy, countries can introduce rubella vaccine into their programs if they can achieve 80% or greater coverage either through the routine program or regular supplementary

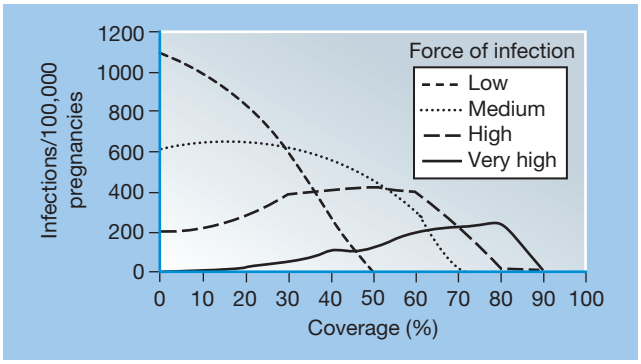

Figure 53.9. Predicted long-term effect of coverage by rubella vaccination of infants on the incidence of congenital rubella syndrome (CRS) according to the force of infection in a given population. *(Courtesy Nigel Gay, Consultant, Berkshire, UK.)*

immunization activities or both. If the force of infection is lower, the paradoxic effect can be avoided with lower coverage, as illustrated in Fig. 53.9.

Thus, to prevent the introduction of rubella vaccination in a country from temporarily increasing CRS, two options are possible: (a) rapid vaccination of all prepubertal children to quickly decrease rubella virus circulation or (b) vaccination of postpubertal females through routine vaccination to render them nonsusceptible. If a country conducts a campaign in postpubertal women, adult males must be included. However, the difficulty of adult vaccination should not act as a barrier to moving forward with elimination of rubella.[655] Measles elimination should be done with combined vaccines (MR or MMR) so as to take advantage of mass campaigns in infants that also deal with rubella. Of course, there must be a commitment to continue universal routine use of the same vaccines in infancy. In fact, many countries have been able to conduct campaigns both in children and in adults as demonstrated in the region of the Americas.[797]

The elements necessary for rubella and CRS elimination include virologic and epidemiologic surveillance for rubella and CRS,[798] high coverage of infants with MMR or MR vaccine, a second dose later in life, and a program for vaccination of adults, either at the time of routine visits for other reasons or in mass campaigns. The latter may include only young women or women up to 39 years of age, depending on resources, but for most complete control, men should also be vaccinated.

THE FUTURE

New manufacturers in developing countries such as the Serum Institute of India have made rubella vaccine more available in the form of MR or MMR. Aerosol administration may also help immunization programs.[304]

Although work continues on recombinant rubella E1 protein produced in Chinese hamster ovary cells transfected with the gene, and the protein is immunogenic in mice,[257] the live attenuated vaccine is likely to be the weapon for rubella control in the future.

Rubella virus and the congenital syndrome it causes are legitimate targets for eradication by vaccination for several reasons[799]: the virus is carried only by humans; the sole reservoir is chronically infected babies with CRS, who do eventually stop excreting; the vaccine is highly effective; and combination vaccination with measles or measles and mumps reduces the cost and avoids any additional expenses of administration.[800,801] There is a steady rise in the number of countries using rubella vaccine, with two WHO regions with rubella elimination goals. Using the measles elimination or control strategies, rubella vaccine can be rapidly introduced into the remaining countries.

In 2011, the Global Alliance for Vaccines and Immunizations (GAVI) board approved the decision to open the funding window for rubella vaccine. Of the remaining 63 countries that have not introduced rubella vaccine, 51 (81%) are GAVI eligible. GAVI will be supporting MR vaccine for catch-up campaigns targeting children 9 months to 14 years 11 months of age. Between 2013 and 2018, it is anticipated that all GAVI-eligible countries will introduce rubella vaccine. With GAVI support, the goal of rubella eradication may be within reach.[802] The implementation of universal immunization throughout the world would mean the end of CRS within 100 years of its description.[803,804]

54 Smallpox and Vaccinia

Richard B. Kennedy, J. Michael Lane, Donald A. Henderson,† and Gregory A. Poland

The World Health Assembly certified the eradication of smallpox on May 8, 1980,[1] an event that many hoped would consign smallpox to history. However, the former deputy director of the Soviet Union's BioPreparat activities has written that manufacturing facilities had been constructed that were capable of producing smallpox virus in ton quantities.[2] These claims also specified that the State Research Center of Virology and Biotechnology (the VECTOR Institute), in Novosibirsk, Russia, pursued the possible use of recombinant products of smallpox virus as biological weapons. The veracity of these claims is unclear. In addition, since the breakup of the former Soviet Union, there has been no documentation about the whereabouts of scientists previously involved with biowarfare involving smallpox. There have been no public statements by nation states or terrorist groups about plans to develop or use smallpox as a bioweapon, but there is no way to prove the lack of such motivation. Therefore, the United States and several other nations have rebuilt smallpox vaccine supplies and improved diagnostic laboratory capabilities.

Such actions are prudent because the release of an aerosol of smallpox virus and its subsequent spread could result in an international catastrophe. Accordingly, the United States and a number of other countries have developed and stored supplies of new vaccines and planned for an appropriate emergency response should smallpox recur. These countries are working with the World Health Organization (WHO) to devise means for coping with smallpox outbreaks wherever they might occur, recognizing that an outbreak anywhere threatens all countries. These efforts have been strengthened by the development of second- and third-generation vaccines,[3,4] improved antiviral agents,[5] more sophisticated laboratory and diagnostic techniques,[6–8] and a greater understanding of the biology and immunology of orthopoxviruses in general.[9]

HISTORY OF DISEASE

Smallpox is an exanthematous viral disease that was once prevalent throughout the world, existing as an endemic infection wherever population concentrations were sufficient to sustain transmission. Outbreaks of variola major, the only known variety until the end of the 19th century, resulted in case-fatality rates of 30% or more among unvaccinated persons. Most people who survived had distinctive residual facial pockmarks, blindness, or other residua. A less-severe variety, variola minor (known also as alastrim), produced a milder illness with case-fatality rates of 1% or less. Variola minor was first described in South Africa late in the 19th century by de Korte[10] and in the United States in 1897 by Chapin.[11] Variola minor eventually became the prevalent variety throughout the United States, parts of South America, Europe, and some areas of eastern and southern Africa.[12]

Fortunately, there is no animal reservoir of smallpox and no long-term human carrier state; thus, the virus must spread continuously from human to human to survive. Historians and virologists speculate that smallpox emerged sometime after the first agricultural settlements, about 10,000 BC.[12,13] The first certain evidence of smallpox in the ancient world comes from mummified remains of the 18th Egyptian dynasty (1580–1350 BC), evident in the characteristic skin pustules still visible in the mummified remains of Ramses V (1157 BC).[14] Possible epidemics of disease are described in the Bible and in Greek and Roman literature, but descriptions of clinical signs are sparse. More specific written descriptions of the disease did not appear until the 4th century AD in China, the 7th century in Egypt, and the 10th century in southwestern Asia and the Middle East.[12,15–17] Smallpox seems to have progressively spread from the populated endemic areas of Asia and Africa into less-populous areas of these continents and into Europe, becoming established as an endemic infection when populations increased sufficiently in size.[16] Smallpox began to be imported into the Western Hemisphere in the early 16th century by explorers. Catastrophic epidemics followed that seem to have decimated the Amerindian peoples and likely contributed to the collapse of the Aztec and Incan empires.[13] It is likely that smallpox in central and southern Africa probably became endemic about this time or soon thereafter. The impact of smallpox on history and human affairs has been profound.[17] Deities to smallpox became a part of the cultures of India, China, and parts of Africa. In Europe, by the end of the 18th century, an estimated 400,000 persons died annually of smallpox, and survivors accounted for one-third of all cases of blindness. During the 18th century, five reigning European monarchs died of smallpox, and the Austrian Hapsburg line of succession shifted four times in four generations.

The name *variola* was first used during the sixth century by Bishop Marius of Avenches (Switzerland).[18] The term is derived from the Latin *varius* (spotted) or *varus* (pimple). In the Anglo-Saxon world, by the 10th century, the word *poc* or *pocca*, a bag or pouch, described an exanthematous disease, possibly smallpox, and English accounts began to use the word *pockes.* When syphilis appeared in Europe in the late 15th century, writers began to use the prefix "small" to distinguish variola, the "smallpox," from syphilis, the "great pox."[19]

In Europe in the late 18th century, the notion that people who contracted cowpox were thereafter protected from smallpox was fairly common, especially in dairy communities in England and Germany.[20] There is evidence that physicians in these communities were aware, decades before Jenner's work, of the protective effect that prior cowpox infection provided patients, but these physicians did not follow through on the observations or disseminate the findings. A prominent farmer in Dorset county, Benjamin Jesty, inoculated his wife and two sons with material from cowpox lesions in 1774.[21] These persons remained free of smallpox despite local epidemics. In fact, Jesty's sons were variolated 15 years later without any signs of infection. Jesty, however, made no attempt to publicize these observations.[22] Two decades later, in 1796, Edward Jenner (Fig. 54.1) conclusively demonstrated that material could be taken from a human pustular lesion caused by cowpox virus and inoculated into the skin of another person, producing a similar localized and limited infection.[23] He showed that an inoculated person was protected from infection with smallpox after recovery. He called the material vaccine, from the Latin *vacca*, meaning cow, and the process vaccination. Pasteur, in recognition of Jenner's discovery, later

†Deceased.

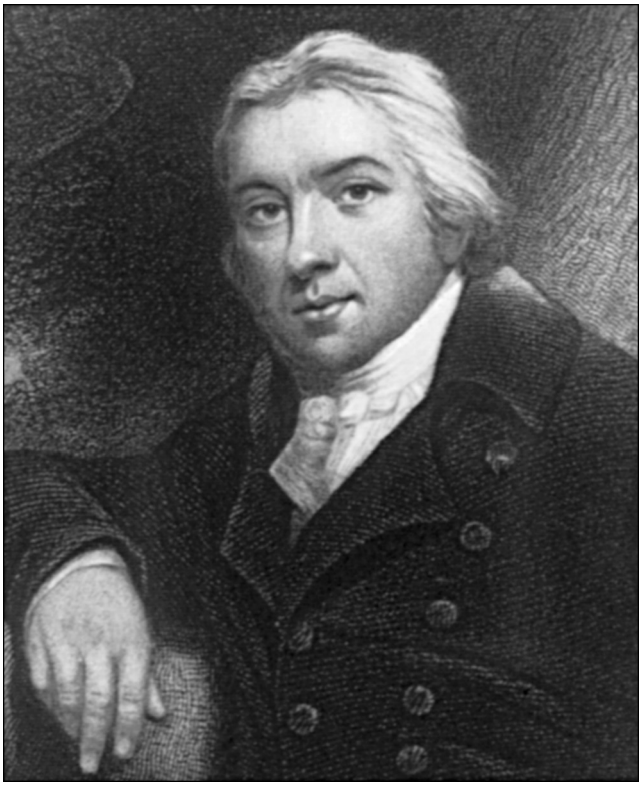

Figure 54.1. Edward Jenner (1749–1823) demonstrated that a person inoculated and infected with cowpox was protected against smallpox. The procedure, which he called vaccination, represented the first use of a vaccine in the prevention of disease. *(Courtesy the Institute of the History of Medicine. The Johns Hopkins University, Baltimore, MD.)*

Figure 54.2. Document signed on December 9, 1979, by members of the World Health Organization and Global Commission, certifying that smallpox had been eradicated. *(From Fenner F, Henderson DA, Arita I, et al.* Smallpox and its Eradication. *Geneva, Switzerland: World Health Organization; 1988, frontispiece, with permission.)*

broadened the term to denote preventive inoculation with other agents.[24] Jenner may not have been the first to observe that cowpox protected against smallpox, but he was the one to follow through on the observations, conduct experiments, and publish his findings.

Toward the end of the 19th century in the United States, vaccinia virus began to be propagated on the flanks of calves, making vaccine more readily and widely available. By 1897, the numbers of smallpox cases had decreased sharply as a result of vaccination and outbreak control.[25] That summer, however, an outbreak of variola minor occurred in Pensacola, Florida. Within 4 years, this variety of smallpox had spread across the country.[26] Routine childhood vaccination continued in the United States until 1972 as a protection in case smallpox was imported and was enforced in most states by compelling vaccination for school entry.

Through the 1800s, other industrialized countries had experiences with vaccination similar to that in the United States. After the initial surge of enthusiasm for vaccination in the early 1800s, vaccination was less uniformly and extensively practiced in most countries until near the close of the century, when the vaccinia virus began to be propagated on calves. By 1900, a number of countries in northern Europe had become smallpox free. By 1914, the incidence in most countries had decreased to comparatively low levels. Even so, during the period from 1910 to 1914, Russia reported 200,000 deaths, and nearly 25,000 deaths were recorded in other European countries.[27,28] World War I led to a resurgence of smallpox in Russia, and it spread from there to many other countries. During the 1920s, vaccination programs again led to the interruption of smallpox transmission in many European countries. By the mid-1930s, smallpox occurred only after importations except in Spain and Portugal, where endemic smallpox persisted until 1948 and 1953, respectively.

In the mid-1900s a concerted effort on part of the WHO and national governments worldwide led to the Smallpox Eradication Program (1966–80) culminating in the eradication of this disease in 1980.

Why Smallpox Is Important

Smallpox was widespread and had a relatively high mortality rate, making it one of the most deadly of all infectious diseases. Its impact on human civilization cannot be overstated. It also represents the only, hopefully the first, human disease to be eradicated (Fig. 54.2). This was made possible by the availability of a heat-stable vaccine, a vaccination technique that was simple and effective, intensive surveillance and containment procedures, and a united, global effort.[29] Although it has been 40 years since the last naturally occurring case of smallpox, the disease and vaccine remain relevant due to outbreaks of zoonotic orthopox viruses and concerns about the use of variola major in bioterrorism.

BACKGROUND

Clinical Description

Smallpox is caused by either of two closely related viruses, variola major or variola minor, that can be distinguished by polymerase chain reaction (PCR) analysis. Clinically they are similar, but variola minor cases are associated with fewer systemic symptoms, less-extensive rash, little persistent scarring, and far fewer deaths. The disease has an incubation period of approximately 12 days, with a range of 7 to 17 days. A 2- to

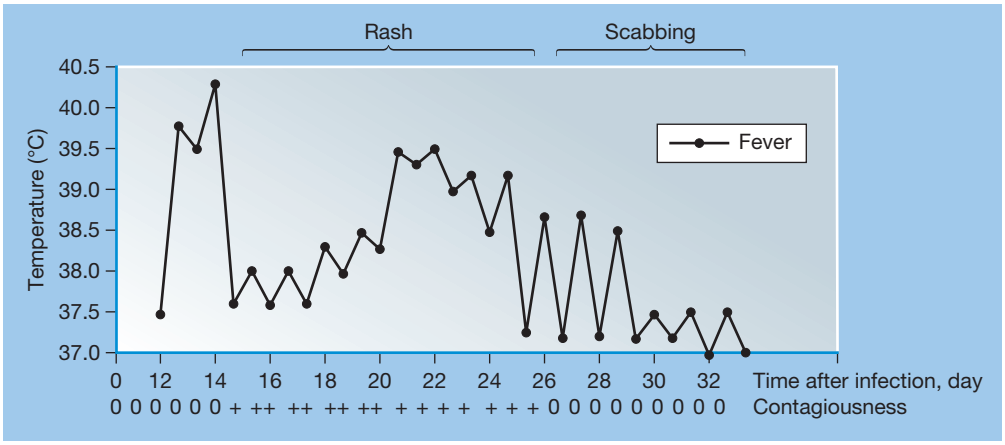

Figure 54.3. Typical temperature chart of a patient with smallpox infection showing the approximate time of appearance and evolution of the rash and the period in which the patient is contagious after acquisition of infection. *(Modified from Henderson DA, Inglesby TV, Bartlett JG, et al. Smallpox as a biological weapon: medical and public health, management.* JAMA. *1999;281:2427–2137.)*

3-day prodrome of high fever (Fig. 54.3), malaise, and prostration with headache and backache is followed by the development of a maculopapular rash (Fig. 54.4). The rash appears first on the mucosa of the mouth and pharynx, then the face and the forearms, and then spreads centrifugally to the legs and trunk. There is a slow evolution over approximately 6 or more days as the rash becomes vesicular and then pustular. The pustules are characteristically round, tense, and deeply embedded in the dermis. Crusts begin to form about the eighth or ninth day. When they separate, they leave pigment-free skin and frequently pitted scars. The eruption is characteristically more extensive on the cooler parts of the body, perhaps because the virus grows better at 35°C than 37°C. Lesions are most numerous on the face, arms, and legs (Fig. 54.4) and are often found on the palms and soles. Death usually occurs late in the first week or during the second week of the illness, and although the cause of death is not definitively known, evidence suggests that it is not the result of bacterial sepsis[30]; rather it is probably from the effects of an overwhelming viremia, the formation of immune complexes, and the associated immunopathology or "cytokine storm."[30,31]

The WHO classification scheme for smallpox[32] describes five types: (a) ordinary, (b) flat (also known as "malignant"), (c) hemorrhagic, (d) vaccine modified, and (e) variola sine eruptione. Rao[33] used this classification scheme to analyze the frequency and case-fatality rates of vaccinated and unvaccinated cases in Madras, India. Among persons not previously vaccinated, the vast majority of variola major cases (approximately 89%) were of the ordinary type and had a fatality rate of approximately 30%. Flat smallpox accounted for 6.7% of cases and had an associated mortality of 96%. The hemorrhagic type accounted for 2.4% of cases and was more common in pregnant women; 96% died, with nearly 100% fetal wastage. Extensive bleeding into the skin and the gastrointestinal tract preceded death; in retrospect, hemorrhagic cases almost certainly represented disseminated intravascular coagulation. Cases "modified" by prior vaccination had many fewer lesions and, in the series by Rao,[33] accounted for 2.1% of the cases and resulted in no deaths. The rash in such cases was usually more scant and atypical, and the evolution of lesions more rapid. Variola sine eruptione (without rash) was rare and occurred in highly immune persons who had laboratory evidence of infection but were not infectious to others.

Complications

Complications of smallpox include bacterial infections of the skin and other organs, pneumonia, generalized sepsis, destructive arthritis in young children and arthropathies, corneal ulceration resulting in blindness (most frequent in patients with trachoma), keratitis, osteomyelitis, and encephalitis. The latter, present in approximately one in 500 cases,[33] is indistinguishable from the acute postinfectious perivascular demyelination observed as a complication of infection with vaccinia, measles, and varicella.[34] Cases of smallpox among pregnant women usually result in spontaneous abortion or, occasionally, a stillborn infant with evidence of lesions on the skin.[12]

The most common sequelae among survivors are facial pockmarks, blindness, and limb deformities.[35] The scars (Fig. 54.5), present in 65% to 80% of survivors, are usually depigmented and most evident on the face and result from the destruction of sebaceous glands followed by shrinking of granulation tissue and fibrosis.[12]

Virology

Variola virus belongs to the genus *Orthopoxvirus*, family Poxviridae, which includes vaccinia, monkeypox, cowpox, camelpox, and ectromelia (mousepox).[36] All species exhibit extensive serologic cross-reactivity in vitro and in experimental animals. The poxvirus genome, the largest of all virions that infect humans, is an ovoid brick-shaped structure with a diameter of approximately 200 nm, consisting of a single molecule of a double-stranded DNA (Fig. 54.6). It differs from most other DNA viruses in that it multiplies in the cytoplasm rather than in the nucleus of susceptible cells.

The orthopoxviruses grow and produce a cytopathic effect in cultured cells derived from many species,[37,38] although they generally grow best in cells from humans and other primates. The four that infect humans (variola, vaccinia, cowpox, and monkeypox viruses) cannot be differentiated readily from one another in most cell cultures. For diagnostic purposes, therefore, they are customarily grown on the chorioallantoic membrane of 10- to 12-day-old chick embryos, on which they produce pocks characteristic of their species.[39] Newer PCR techniques have been developed that permit their differentiation (see "Diagnosis" later).

Although inactivated fairly rapidly by direct sunlight, especially under hot or humid conditions, Variola virus exhibits

considerable durability in lesion scabs (hundreds of days, and in one case up to 13 years)[40,41] or embedded in cotton (months to years).[42] A variety of historical artifacts (Egyptian mummies from 1200–1100 BC, 17th to 19th century corpses exhumed from permafrost, corpses exhumed from crypts or coffins from the 1500s to 1800s, a museum exhibit containing a scab from a child infected in 1876) have also been tested for the presence of variola virus.[43–46] Although in some cases viral particles have been identified by electron microscopy and viral DNA isolated by PCR, none of these relics has yielded infectious virus.[47]

Pathogenesis as It Relates to Prevention

Smallpox generally follows the progression in the host described by Fenner and colleagues[12] for ectromelia. Smallpox infection occurs by implantation of variola virus on the respiratory mucosa. The virus is usually transmitted as virions in droplets expressed from nasal and oropharyngeal secretions. Higher concentrations of virus are believed to be expelled by patients with the hemorrhagic and malignant forms of the disease. When cough is present, the virus can be expelled as a fine-particle aerosol,[48] but cough is not a typical symptom of ordinary smallpox. After migration to and multiplication in regional lymph nodes, asymptomatic viremia develops about the third or fourth day, followed by multiplication of virus in the spleen, bone marrow, and lymph nodes. A secondary viremia occurs some 8 to 10 days later, accompanied by high temperature, toxemia, and prostration. The virus, contained in leukocytes, then localizes in small blood vessels of the dermis and beneath the oral and pharyngeal mucosa, where it subsequently infects adjacent cells. In the skin, this process causes the characteristic maculopapular lesions that

then evolve into vesicular and pustular lesions. Lesions are more extensive on the face and extremities, perhaps because the virus grows most readily at temperatures slightly below 37°C. Lesions in the mouth and pharynx ulcerate quickly because of the absence of a stratum corneum, releasing large amounts of virus into the saliva about the time the cutaneous rash first becomes visible. Virus titers in saliva are highest during the first week of rash, corresponding with the period during which patients are most contagious.

Rudimentary immunologic studies of smallpox were done during the eradication era, but little is known about the immune response to variola major in modern terms. Hemagglutinin-inhibiting (HI) and neutralizing antibodies can be detected beginning about the sixth day of illness or, on average, about 18 days after infection, and complement-fixing (CF) antibodies, approximately 2 days later.[49,50] Neutralizing antibodies are long lasting. The HI antibodies decline to low levels within 5 years, and the CF antibodies rarely persist for longer than 6 months. Little is known about the development of cell-mediated immunity following smallpox, but it likely has a significant part in immunity. Modern studies of the immune response to vaccinia and other orthopoxviruses show a complex array of humoral and cellular immune responses, many with manifestations detectable in the first 3 or 4 days after infection.[51–55]

Except for the lesions in the skin and mucous membranes, other organs are seldom significantly involved in variola transmission. Secondary bacterial infection is not common. Death, when it occurs, probably results from the toxemia associated with circulating immune complexes and soluble variola antigens.[56]

Modes of Transmission

Transmission of variola virus, with few exceptions, results from droplets expressed from the oral, nasal, or pharyngeal mucosa of an overtly ill patient that are inhaled by susceptible persons in close contact with the patient. Such transmission is possible from the time of the end of the prodrome and onset of rash and was most frequent during the first week of the exanthem. Spread is generally through large droplets and, thus, was not widely dispersed.[12,57] Virus also was present in scabs that had separated from the skin lesions of convalescing patients,[58] but epidemiologic evidence shows that infected scabs had a negligible role in transmission of infection, presumably because the virus was tightly bound in its fibrin matrix.

Airborne infection over distances of more than a few meters was uncommon, although two outbreaks within hospitals demonstrated this to be possible as they probably resulted from an aerosol dispersal.[48,59] In the outbreak that occurred in a hospital in Meschede, Germany, in 1970, a patient initially presumed to have typhoid fever (and cared for under contact isolation precautions) gave rise to 19 other cases of smallpox in patients who had not been in close contact with the index patient.[48] Dissemination in this outbreak was favored by low relative humidity, prevailing air currents within the hospital

TABLE 54.1 Comparison of Common Conditions and Distinguishing Features of Smallpox

Conditions That Might Be Confused With Smallpox	Clinical Clues
Varicella (primary infection with varicella-zoster virus)	Most common in children <10 y; children usually do not have a viral prodrome
Disseminated herpes zoster	Immunocompromised or elderly persons; rash looks like varicella, usually begins in dermatomal distribution
Impetigo *(Streptococcus pyogenes, Staphylococcus aureus)*	Honey-colored crusted plaques with bullae are classic but may begin as vesicles; regional not disseminated rash; patients generally not ill
Drug eruptions	Exposure to medications; rash often generalized
Contact dermatitis	Itching; contact with possible allergens; rash often localized in pattern suggesting external contact
Erythema multiforme minor	Target, bull's eye, or iris lesions; often follows recurrent herpes simplex virus infections; may involve hands and feet (including palms and soles)
Erythema multiforme (including Stevens-Johnson syndrome)	Major form involves mucous membranes and conjunctivae; may be target lesions or vesicles
Enteroviral infection, especially hand, foot, and mouth disease	Summer and fall; fever and mild pharyngitis 1–2 days before rash onset; lesions initially maculopapular but evolve into whitish gray, tender, flat, often oval vesicles; peripheral distribution (hands, feet, mouth, or disseminated)
Disseminated herpes simplex	Lesions indistinguishable from varicella; immunocompromised host
Scabies; insect bites (including fleas)	Itching is a major symptom; patient not febrile and otherwise well
Molluscum contagiosum	May disseminate in immunosuppressed persons

building, and the presence of cough in the patient. Although cough is not a typical finding of ordinary smallpox, in this case, it would have facilitated viral aerosolization.

There have been instances in which a patient spread the disease to large numbers of contacts, but these were infrequent. In an outbreak in Yugoslavia in 1972, a patient with hemorrhagic smallpox was misdiagnosed as having a severe allergic reaction to penicillin. He was hospitalized because of the development of hemorrhagic disease. In all, he infected 38 healthcare workers and patients before dying.[60] In another patient in the same Yugoslavian outbreak, a woman who had vaccine-modified smallpox spread disease to 16 others. She was a neighborhood matriarch who was visited by many friends and neighbors in her community during her illness and had prolonged face-to-face conversations with many.[12]

Infection of persons such as mortuary workers who handled dead bodies and laundry workers who handled linen from patients has also been repeatedly documented.[60] However, various older accounts that purport to document transmission over great distances on other fomites, such as carpets, letters, and cotton rags, are suspect because the virus does not survive for long periods at customary ambient temperatures or with exposure to ultraviolet sunlight.[61]

Another method of transmission, the ancient practice of variolation (inoculation into the skin of material from pustules or scabs from patients), continued in a number of remote areas until August 1976 and was responsible for many cases in Afghanistan and Ethiopia. In persons inoculated by these methods, extensive rash sometimes developed, and they transmitted infection to susceptible contacts by respiratory droplet infection.[12]

Diagnosis

In endemic areas or when smallpox was known to be circulating, most cases could be readily clinically diagnosed by a history of direct contact with a patient with smallpox, the presence of a prodromal febrile illness, the appearance of a typical deep-seated rash, the centrifugal distribution of lesions, and the fact that all lesions were at the same stage of development on any given area of the body (unlike varicella infection). The infrequent hemorrhagic cases were often initially misdiagnosed as meningococcemia, acute leukemia, or drug toxicity. The diagnosis often was assisted by examination of patients who were the source of their infection or to whom they had transmitted disease. Varicella was by far the most frequent disease confused with the ordinary cases of smallpox (Table 54.1).

Patients with smallpox who had previously been vaccinated and patients with variola minor sometimes had a sparse and atypical rash with minimal systemic symptoms that resembled varicella. In contrast with smallpox, in varicella, the prodromal illness is typically mild or absent, lesions are superficial, appear first on the face or trunk, evolve rapidly and appear to be in different stages of development, and only rarely involve the palms and soles. Severe cases of varicella in adults with extensive rash were also sometimes mistaken for smallpox.[62] For this reason, the Centers for Disease Control and Prevention (CDC) has produced and distributed a chart with an algorithm to assist in the differential diagnosis of acute febrile illness associated with rash.[63] Patients are classified as having a low, moderate, or high likelihood of smallpox based on the presence or absence of a febrile prodrome, the appearance of skin lesions, and other clinical criteria, such as whether the patient appears "toxic." Only patients reporting a febrile prodrome and who have classic smallpox lesions in the same stage of development are classified in the high likelihood category.

A suspected case of smallpox must be reported immediately to the appropriate local, state, or territorial health department and, through them, to the CDC and the WHO. Electron microscopic examination of vesicular or pustular fluid or scabs will reveal the characteristic, brick-shaped orthopox virions.

The presence of poxvirus DNA can be rapidly established by PCR testing. Differentiation among variola, vaccinia, and monkeypox is usually apparent from the patient's history of possible exposure and the growth characteristics of the virus on the chorioallantoic membrane of chick embryos. PCR techniques for rapid identification and differentiation of orthopoxviruses have been developed,[64,65] and continue to be updated, as new poxvirus strains are sequenced, to provide rapid and reliable disease confirmation for public health responses to outbreaks.[66] These methods are available at the CDC and designated member laboratories of the national Laboratory Response Network. Specimens that are required include vesicular or pustular material (scraped or swabbed from the base of a lesion), punch biopsies, scabs, or venous blood. Detailed specimen collection guidelines are available from the CDC.[67] According to the emergency smallpox response plan available on the CDC website,[67] only personnel immunized against smallpox within the past 3 years or personnel wearing appropriate respiratory and barrier protective equipment should obtain specimens from patients suspected of having smallpox.

Treatment and Prevention With Antivirals

There has been considerable progress in development of antiviral drugs effective against orthopoxviruses in recent years.[5] Cidofovir and its more bioavailable analog, CMX001, are nucleoside analogs that are active against viral DNA polymerase. They are effective against vaccinia and variola in vitro.[68] Cidofovir is licensed for treatment of cytomegalovirus retinitis, but the administration of cidofovir is complicated by the fact that it is available only for intravenous administration, requires prehydration with saline and probenecid to minimize nephrotoxicity, and requires close monitoring of renal function.[69] CMX001 seems considerably less toxic, but is currently available for human use only as an investigational new drug. Brincidofovir, a lipid conjugate of cidofovir, has been coadministered with both ACAM2000 and ACAM3000 in a mouse model and found to reduce the severity of vaccination-association lesions with only a slight attenuation in immune response.[70]

ST-246 (tecovirimat) is a small-molecule compound that targets a gene that produces p37, a major envelope protein required for the production of extracellular virus.[71,72] Early evidence suggests it is safe for humans, with minimal manifestations of toxicity even at very high doses. It has proved efficacious against several orthopoxviruses in a variety of animal models as a prophylactic agent and in substantially reducing the pathology of established infections.[72–76] There are animal data that suggest ST-246 can curtail the replication and spread of vaccinia without diminishing the immune response, which would make it ideal for simultaneous treatment and vaccination of close contacts of patients with smallpox (Dennis Hruby, PhD, Oregon State University, Corvallis, personal communication, 2011).[77,78] Currently, ST-246 is available only as an investigational new drug.

Three human patients with immunologic abnormalities and severe life-threatening vaccinia infections have been treated with CMX001 and ST-246. The patients recovered, but were treated with such a wide array of therapies that it is difficult to isolate the specific role of the antivirals used.[79,80] Ribavirin, another antiviral that has some in vitro activity against vaccinia and variola,[5] was used in a patient with progressive vaccinia along with high doses of vaccinia immunoglobulin (VIG).[81] The role of ribavirin in this patient's recovery is uncertain. Animal studies using ribavirin to treat cowpox or vaccinia infections have not shown great promise.[82,83]

EPIDEMIOLOGY

Incidence and Prevalence Data

Smallpox is among the most lethal of all diseases. Unlike malaria and other infections that claim millions of lives annually, smallpox occurred globally when it was endemic (i.e., it affected the world's entire population). In the century before its eradication, it is estimated to have claimed 300 million lives and maimed countless more.[12] As late as the beginning of the smallpox program in 1967, it is estimated that there were 10 to 15 million cases and 2 million deaths in that year alone.[12] Routine childhood vaccination ceased in 1972 in the United States,[84,85] and by 1983, most of the rest of the world had followed suit. As a result, vaccine production facilities closed, and although many countries retained their smallpox vaccine stockpiles, those have been gradually depleted. Now, decades after the eradication of smallpox, a large proportion of the world's population has never been vaccinated or was vaccinated so long ago that immunity has likely waned; thus, the global population is extremely vulnerable to the disease should it reoccur.

The seasonal pattern of smallpox is similar to that of varicella, measles, and other epidemic respiratory diseases. Its incidence was highest during winter and spring. This seasonal peak was consonant with the observation that the duration of survival of an orthopoxvirus in the aerosolized form is inversely proportional to temperature and humidity.[86] Seasonal variation undoubtedly was amplified in many countries by social events, such as the congregation of large numbers of people at festivals and marriage parties during the dry season, and the seasonal movement of nomads.

The age distribution of smallpox cases depended on the immunity of the population, whether the immunity was acquired by vaccination or by infection. Because the disease is less infectious than other childhood diseases such as measles, cases regularly occurred among adults. As recently as 1974 to 1975 in India, where vaccination was widely practiced and smallpox was endemic, adults constituted 21% of a carefully documented series of 23,546 patients; approximately 2% (or 412) of the patients were older than 50 years. In western Africa between 1967 and 1969, most cases occurred in rural villages, and the age distribution of cases approximated the age profile of the population.[87] Men and women were equally affected in all endemic countries.

The severe Asian form of variola major customarily had overall case-fatality rates that ranged from 40% to 50% for persons younger than 1 year of age and approximately 30% among unvaccinated persons. Variola major in Africa and Indonesia was a somewhat milder disease, with age-standardized case-fatality rates of approximately 10% to 15%. Variola minor, which after 1967 was present only in Brazil and southern and eastern Africa, resulted in case-fatality rates of 1% or less (Table 54.2).[12]

Most estimates for the R_0 (the average number of secondary cases infected by each primary case) of smallpox are between 3 and 6,[12,88–90] but have ranged as high as 10.[91] Newer reports indicate that vaccine coverage of at least 66% to 70% is necessary to reach herd immunity levels that will prevent outbreaks,[90,92] and the Smallpox Eradication Program's initial goal was to obtain 80% vaccination coverage.[93,94] However, outbreaks have occurred in populations with high (>90%) vaccine coverage[12,95] and the first WHO Expert Committee on Smallpox recommended 100% vaccine coverage.[96]

Within the household, smallpox was as infectious as varicella but less infectious than measles.[97–99] With few exceptions, however, smallpox spread less widely and rapidly than these diseases. This finding can be accounted for by the fact that transmission of variola virus does not occur until 2 or 3 days

TABLE 54.2 Mortality of Smallpox Infections by Geographic Location

Strain	Country	Case-Fatality Rate (%)[a]
Variola major	Bangladesh	18.5
	India (Tamil Nadu)	26.0
	Burma	17.0
	Afghanistan	16.0
	India (Punjab)	15.0
	Indonesia (Jakarta)	13.0
	Indonesia (West Java)	8.0
	West Africa	13.0
	Togo	8.0
	Pakistan (Sind Province)	9.4
	Pakistan (Karachi)	23.9
	Tanzania	9.2
	Uganda	5.2
Variola Minor	Brazil	0.8
	Ethiopia	1.5
	Sudan	1.2
	Somalia	0.4
	Botswana	0.2

[a]Case-fatality rates for all age groups. These numbers include vaccinated and unvaccinated cases because precise proportions between the two groups are unobtainable. However, vaccinated persons generally have less-severe disease and survive. Fatality rates among unvaccinated persons would be substantially higher.
Data from Fenner F, Henderson DA, Arita I, et al. Smallpox and Its Eradication. *Geneva, Switzerland: World Health Organization; 1998.*

after the onset of the prodromal fever, as attested to by numerous epidemiologic observations. By then, most patients already were confined to bed because of the high fever and malaise, and, thus, secondary cases usually were restricted to the few who came in contact with patients in the household or hospital. For this reason, smallpox outbreaks tended to be clustered in a segment of a town or village and in localized areas of a province or district.[100–103]

High-Risk Groups

With routine immunization being stopped in nearly every country by 1983, nearly all children and the majority of adults have little or no protection against smallpox. If smallpox were to be released today, vaccination would be indicated for all people considered to be at immediate risk of exposure. The people at highest risk would be healthcare providers who might have contact with patients before the disease has been diagnosed and laboratory workers.

Reservoirs of Infection

Variola virus is a uniquely human pathogen and since its eradication in 1980, there are no reservoirs of infection. Today, there is concern that smallpox virus could be released accidentally from a laboratory or deliberately as a biological weapon. Although the risk of these events is not quantifiable, they are generally acknowledged as possible. There are also concerns regarding outbreaks of other zoonotic orthopoxviruses such as monkeypox, and, indeed, a monkeypox outbreak occurred in the midwestern United States in 2003 as a result of exotic small pet mammal trade.[104–106] Fortunately, it was quickly recognized and dealt with appropriately.

SIGNIFICANCE AS A PUBLIC HEALTH PROBLEM

Smallpox as a Biological Weapon

There are anecdotal reports that Spanish explorers gave Amerindians contaminated clothing, leading to devastating epidemics among the Aztecs and Incas, among others.[107] During the French and Indian Wars (1754–67) the British General Lord Jeffery Amherst suggested to his staff that they distribute smallpox-infected blankets to Amerindians.[107] It is not certain that they were successful, however, as smallpox was already raging among some tribes in the Hudson and St. Lawrence River valleys at the time.[108] During the Revolutionary War, smallpox became a serious problem for the Continental Army, forcing George Washington to institute the mandatory variolation for all American soldiers.

The media have raised concern about the risk of a terrorist biological attack using smallpox. Such risks are unknown but probably quite low. Much of the concern stems from a book written by the former deputy director of the Soviet Union's BioPreparat[2] that states that during the height of the Cold War there existed manufacturing facilities capable of producing tons of smallpox virus and that the State Research Center of Virology and Biotechnology (the VECTOR Institute), Novosibirsk, Russia, pursued the possible use of recombinant products of smallpox virus as biological weapons. There have been no public statements by nation states or terrorist groups about development of smallpox as a bioweapon. The United States did not find evidence that smallpox virus existed in Iraq, despite the claims of the aforementioned book's author that Saddam Hussein had the means and plans to use smallpox as a weapon of mass destruction. No published evidence suggests that smallpox is being illegally grown or produced anywhere else. Furthermore, efforts to recover virus from bodies buried in the tundra or from mummified corpses have been unsuccessful.[44–46,109]

In terms of weaponization, variola virus may be lyophilized and is relatively stable as an aerosol.[86] The infectious dose, as suggested from the epidemiology of a hospital outbreak in which aerosol spread was documented,[48] may be only a few virions and may be effectively disseminated through aerosolization. The resulting disease has high mortality and morbidity rates. The current world population is immunologically naïve or has waning levels of protection. There is no effective treatment for the disease. Even a small outbreak would cause global panic and disruption.

Since the terrorist events of September 11, 2001, and the anthrax attacks of fall 2001, the U.S. federal government has procured a large stock of vaccine to meet the needs of the nation in case of an outbreak of smallpox.[110] As of 2015, the U.S. Strategic National Stockpile contained three smallpox vaccines: (1) sufficient doses of ACAM2000 to vaccinate the entire U.S. population, (2) 85 million remaining doses of Aventis Pasteur Smallpox Vaccine (APSV, or "wetvax," a liquid calf-lymph product), and (3) more than 20 million doses of Imvamune (a modified vaccinia virus Ankara [MVA]-based vaccine) to be used in populations for whom live vaccinia vaccines are contraindicated.[110a] Studies indicate that both APSV and Imvamune can be diluted up to fivefold and retain immunogenicity.[110b] In 2002, the CDC released a guidance plan to public health agencies detailing the necessary steps to be taken to contain an outbreak of smallpox, including vigorous surveillance for cases, rigorous isolation of cases, and identification and vaccination of close contacts.[111] Nevertheless, most experts believe that a deliberate release of smallpox remains a low-likelihood but high-consequence event.

PASSIVE IMMUNIZATION (VACCINIA IMMUNOGLOBULIN)

In 1960, Kempe[112] introduced the use of VIG for treatment of severe infections with vaccinia. There have been no formal controlled trials of VIG for treatment of smallpox or vaccinia.[113] In 1961, Kempe and colleagues[114] claimed a reduction of the incidence of smallpox in close contacts of index patients

to approximately one quarter that of a comparison group, although there was no randomization and the trial would not stand up to scrutiny by modern standards. Among 326 contacts receiving VIG, there were five cases of smallpox; among 379 control subjects, there were 21 cases of smallpox. Vaccination or revaccination of all contacts was also performed at various intervals after exposure. Marennikova[115] also conducted a small and poorly controlled trial. These trials suggested there might be some reduction in the incidence and severity of smallpox, but they were too small and inadequately controlled to draw firm conclusions.[12] With the development of more effective antivirals, VIG seems to have no place in the prophylaxis or treatment of smallpox.

Despite the absence of controlled trials of efficacy, VIG has continued to be used to treat adverse events following vaccinia. Historical controls and the opinion of expert clinicians suggest that VIG is effective, however, in the treatment of eczema vaccinatum and some forms of progressive vaccinia, but not in accidental implantation or benign maculopapular rashes. Progressive vaccinia was universally fatal before the introduction of VIG.[112] After VIG was introduced, the case-fatality rate for progressive vaccinia dropped to approximately 25% to 50%, although data may be confounded in that other interventions were often simultaneously used, such as antiviral agents, transfusions of blood from recently vaccinated donors, and surgical debridement.[116] Severe eczema vaccinatum in the pre-VIG era had a case-fatality rate of 8% to 30%.[112,117] After the institution of VIG, the case-fatality rate fell to 1% or less.[118] Note that VIG is contraindicated in patients whose ocular vaccinia is complicated by keratitis; in rabbits, such therapy causes corneal scarring presumably from precipitation of antigen–antibody complexes.[119]

In 2005, the U.S. Food and Drug Administration (FDA) licensed an intravenous form of VIG manufactured by Cangene Corporation.[110] The recommended dose is 6000 U/kg of body weight; severely ill patients may require repeated doses.[120] In addition, the CDC holds investigational new drug protocols for the use of cidofovir and ST-246 in the treatment of adverse effects after smallpox vaccination that fails to respond to treatment with VIG,[121] although there are no animal studies to support their use or benefit in treating adverse vaccine reactions.

ACTIVE IMMUNIZATION

History of Vaccine Development

Although early smallpox vaccines were cowpox virus, a virus from a disease called horsepox was sometimes used. Eventually, however, vaccinia virus became the poxvirus of choice in most major vaccines. Although its exact origins are unclear,[122] vaccinia is not a mutant of variola virus; rather, it may have arisen as a hybrid of cowpox and another orthopoxvirus or through thousands of serial passages under artificial conditions of culture. It is also possible that the species represents a laboratory survivor of a now naturally extinct species of orthopoxvirus.[123] Characterization of strains is further complicated by the fact that a seed lot system for vaccine production was not used widely until the 1960s. Thus, even the strains with common names and ancestors have different passage histories, having been passed sequentially through a variety of vaccinifers, such as cows, sheep, and water buffalo, with periodic passages through rabbits, horses, and even humans. Indicative of the scientific ignorance of vaccine technology until recent decades is a statement of the Ministry of Health of Great Britain, which, in 1928, advised that seed lymph could be obtained from (a) "smallpox direct"; (b) cowpox; (c) horsepox, sheep pox, or goatpox; and (d) vaccinia in the human body.[123]

At various times, attempts were made to create vaccine products based on inactivated virus.[124] Inactivated vaccines elicited high titers of neutralizing antibodies but were ineffective at preventing disease in animal models and human populations.[125–127] Inactivated vaccines consist almost entirely of a single type of poxvirus virion: mature virus (MV) particles, which lack an additional membrane, and associated proteins found on the other major type of poxvirus virion, extracellular virus (EV) particles. Consequently, these vaccines are unable to induce responses to EV proteins, a defect that likely accounts for their lack of protective efficacy.[128–130]

Attenuated strains of vaccinia were created in an effort to diminish the incidence of serious adverse events.[12] Several of these strains based on the New York City Board of Health (NYCBOH) strain (Rivers, CVI-78) produced less-severe reactions but also had reduced immunogenicity, calling into question the level of protection provided against smallpox.[131–136] Another attenuated vaccine, the MVA strain, was produced by a German research group[137] through more than 500 passages in chick embryo fibroblast cells.[138,139] During passage, multiple genetic deletions occurred (approximately 15% of its genome), and it became much more narrowly restricted in its host range. Laboratory studies demonstrated unimpaired MVA gene expression in human cells and a block in virion morphogenesis.[140] The ability to achieve high expression of recombinant genes despite abortive replication is a significant characteristic of this mutant virus.[140] MVA was only developed during the latter part of the eradication effort and, consequently, was never used in a smallpox-infected area. Nevertheless, the potentially improved safety profile of MVA and other attenuated vaccinia strains has led to renewed development of attenuated smallpox vaccine candidates and their clinical testing (see "Future Vaccines" later).

Development of the Smallpox Vaccine

A method for protection against naturally acquired smallpox infection seems to have been discovered in India sometime before 1000 AD, although there is evidence for its use in China as well.[141–144] There it became the practice to deliberately inoculate, into the skin or by nasal insufflation, scabs or pustular material from lesions of patients. This practice (now called variolation) resulted in an illness usually less severe than that acquired naturally by inhalation of droplets. From India, variolation spread to China, western Asia, Africa, and finally, in the early 18th century, to Europe and North America.[145] Case-fatality rates associated with variolation were considerably lower than fatality rates with naturally acquired infection, but infected persons were still capable of transmitting smallpox to others.[146] After cowpox (an orthopoxvirus closely related to variola virus) began to be used as a protective vaccine, the practice of variolation diminished, but continued to be practiced in Ethiopia, western Africa, Afghanistan, China, and Pakistan as recently as the 1960s and 1970s.[12]

Variolation was gradually replaced with vaccination. In fact, within 5 years of publication, Jenner's seminal paper had been translated into six other languages[147] and vaccination was widely used in many countries of Europe. Within a decade, this process began to be used in countries throughout the world. Historically, the chronicles of the de Balmis expedition of 1803 to 1806 vividly describe the transport of the vaccine by sea to Spanish colonies in the Americas and Asia by serial arm-to-arm vaccination of orphaned children.[148,149]

As the 19th century progressed, the initial wave of enthusiasm for vaccination subsided. Occasionally, syphilis, hepatitis, and other infections were transmitted in the process of arm-to-arm vaccination.[150,151] In some areas, significant opposition occurred among religious and governmental leaders and antivaccinationist societies that opposed the principle of

infecting humans with an animal disease, especially under civil mandate.[152–156] Despite Jenner's claims of lifelong immunity, smallpox can and did occur in patients who had previously been successfully vaccinated, and the need for revaccination was demonstrated early in the 19th century.[157] Other issues included difficulty obtaining fresh vaccination material and difficulty transporting vaccine over long distances. These problems were eventually solved by growing vaccinia on the flanks of calves or other animals, providing an adequate and safer supply of vaccine material. This approach was initially used in Italy as early as 1805[158] but did not become widespread until the mid-1800s.[159,160] In the 18th century an English physician, John Haygarth, carefully studied local outbreaks and disease transmission, then published simple rules for the prevention of smallpox. These rules (avoid entering homes of infected individuals, quarantine yourself when sick, clean everything that comes into contact with the patient, do not allow patient to approach susceptible people) proved to be highly effective when followed.[161]

Vaccine Use and Disease Occurrence in the United States

In the United States, variolation was promoted by a prominent minister, Cotton Mather, in collaboration with a Boston physician, Zabdiel Boylston.[17,152] General George Washington instituted variolation among the Continental Army in 1777 in an effort to minimize the drastic effect smallpox outbreaks were having on soldiers' combat readiness.[16] Thomas Jefferson and his family underwent variolation in 1782.[162] Benjamin Franklin lost a 4-year-old son to smallpox in 1736 and later became an outspoken proponent of variolation, even setting up an organization to provide free variolation to poor people.[163,164]

Benjamin Waterhouse performed the first vaccinations in Boston, Massachusetts, in July 1800 using material provided by Jenner[165] and is widely credited with introducing vaccination to the United States.[12,16,165,166] President Thomas Jefferson actively promoted vaccination,[167] although its routine use did not occur until the 1900s owing to difficulties sustaining the virus through arm-to-arm inoculation. Epidemics of variola major continued to occur at intervals, depending on population density and frequency of importations.

Although outbreaks of variola major continued to occur until about 1927, most 20th-century cases of smallpox in the United States were caused by variola minor. The origin of this strain is unknown. However, a similarly mild strain of smallpox, called Kaffir pox, had begun to circulate widely in South Africa in the early 1890s. What, if any, connection there was between these two foci of variola minor infections is unknown. Because the disease was mild and the case-fatality rate was less than 1%, interest in vaccination waned and smallpox incidence increased sharply. To control the disease, public health authorities sought to compel vaccination as a requirement for school entry, an action upheld by the U.S. Supreme Court.[168] However, antivaccinationist sentiment and antipathy toward compulsory measures prevailed in many states, most of which did not support the legislation or actually prohibited compulsory vaccination. Reported cases of smallpox declined from 108,487 in 1921 to 30,151 in 1931. Between 1932 and 1939, 5,000 to 15,000 cases were reported annually, with 21 to 52 deaths. During the following decade, reported U.S. cases steadily diminished, with the last occurring in 1949. This progress occurred in the absence of a nationally coordinated smallpox control effort. Leake attributed improved smallpox control and its eventual elimination to the wider availability of refrigeration and, consequently, better preservation of the vaccine.[169] Routine childhood vaccination continued in the United States until 1972 as a protection in case smallpox was imported and was enforced in most states by compelling vaccination for school entry. In the early 1960s, many importations of smallpox occurred in Europe; almost half of all subsequent cases occurred as a result of contact in hospitals. Accordingly, beginning in the 1960s, the CDC urged the routine vaccination of hospital staff, but few hospitals complied. After the global eradication of smallpox, distribution of vaccine was restricted to the military and to the few laboratories working with orthopoxviruses.

Vaccine Use and Disease Occurrence in the Industrialized World

Of the other major industrialized countries, Canada interrupted transmission of smallpox in the early 1940s, and Japan about 1950. Vaccination continued in all industrialized countries, as it did in the United States, until the mid to late 1970s, as a protective preventive measure in case smallpox was reintroduced. Australia and New Zealand were notable exceptions. These countries, protected by distance and strict quarantine measures, never vaccinated widely but also never became endemic for smallpox.

In 1958, a WHO study group first recommended that a seed lot system be used in vaccine manufacture.[170] Beginning in 1967, an increasing number of vaccine producers began to use one of two strains. Most common was the Lister strain from the Lister Institute in England, which was propagated as seed virus by the National Public Health Institute of The Netherlands for distribution by the WHO. The second strain was the NYCBOH strain, propagated by Wyeth Laboratories, Radnor, PA, using the trade name Dryvax. Three of the largest countries, Russia, China, and India, used other strains: EM-63 in the Soviet Union, the Temple of Heaven strain in China, and the Patwadanger strain in India.

Vaccine Use and Disease Occurrence in the Developing World

With an assured source of vaccinia, the numbers of vaccinations in Europe increased and smallpox was largely controlled in Europe and North America by the end of World War II. Unfortunately, the disease remained endemic throughout tropical and semitropical countries, in part because the vaccine was heat-labile and difficult to keep viable in tropical areas. It had long been noted that dried vaccines were more stable than liquid formulations. Two of the more common methods involved (a) placing vaccine lymph with sulfuric acid under vacuum conditions and allowing it to dry at room temperature and (b) mixing vaccine lymph with stabilizing and antibacterial agents such as peptone and phenol, followed by centrifugal freeze-drying techniques originally pioneered for human plasma.[12] In the 1940s, techniques were developed for large-scale and commercially feasible processes for the manufacture of stable, freeze-dried smallpox vaccine,[171] leading to increased success with vaccination and eradication programs in Indonesia and parts of Africa.

CONSTITUENTS OF CURRENT VACCINES

In the United States, two smallpox vaccines are available for use in an emergency. ACAM2000, developed by Acambis and manufactured by Sanofi Pasteur, is a second-generation lyophilized preparation of purified virus (grown in Vero cell line) in HEPES (hydroxyethylpiperazine ethanesulfonic acid)-buffered saline, pH 7.4, containing 1% to 4% human serum albumin USP, 5% mannitol, and trace amounts of antibiotics

(100 U/mL polymyxin B and 100 µg/mL neomycin) (John Becher, RPh, CDC, personal communication, 2006). It must be reconstituted before use by the addition of a diluent.

A second preparation, nicknamed "wetvax," manufactured by a predecessor company of Sanofi Pasteur in the 1950s, is a liquid preparation, unlike the lyophilized ACAM2000 vaccine. There are no plans to license wetvax owing to lack of availability of complete documentation of manufacture and storage over the years; it would be used only under an investigational protocol and only in an emergency at a 1:5 dilution.

The United States originally intended to stockpile at least 20 million doses of IMVAMUNE, an MVA-based vaccine developed by Bavarian Nordic.[172] This vaccine has gained fast-track status at the FDA for licensure and is available for government use under national emergency rules (see "Future Vaccines" later).[173] The vaccine is currently available as a frozen liquid suspension containing no less than 5×10^7 $TCID_{50}$ (tissue culture infectious dose) with the following excipients: trometanol, sodium chloride, and water. A freeze-dried version with potentially longer shelf life is under development.

Bavarian Nordic is also producing a vaccine in tissue cell culture based on the Lister strain. In The Netherlands, the National Institute of Public Health and the Environment is producing a vaccine in calves based on the Lister strain. In Japan, Kaketsuken has opened a large manufacturing facility in Kumamoto to produce LC16m8 vaccine.[174] There are also indications that the Russians are producing smallpox vaccine, but no official report has been issued.

PROCESS OF VACCINE MANUFACTURE

Classical Vaccine Manufacture

Most vaccine was grown on the skin of a calf, sheep, or water buffalo and harvested after the animal was humanely killed (Fig. 54.7). The vaccine usually was purified by the addition of fluorocarbon and differential centrifugation, and its bacterial content was reduced by the addition of phenol. Peptone was added as a stabilizing agent, and the vaccine was freeze dried. Because of its source, calfskin vaccine inevitably contained some bacteria but, when properly prepared, the number of bacteria was 10 organisms per milliliter or fewer. Microbiologic examination was required to confirm the absence of staphylococci, streptococci, bovine tuberculosis, *Clostridium perfringens,* and *Clostridium tetani*. For reconstitution of the vaccine for multiple puncture vaccination, a solution of 50% (volume/volume) glycerin in McIlvaine solution was used. The vaccine in its freeze-dried form was required to retain a potency of not less than 10^8 pock-forming units per milliliter after incubation at 37°C for 1 month.

Figure 54.7. Inoculation: lymph from calf. *(Courtesy National Library of Medicine, created by C.J. Staniland, 1883.)*

During the 1960s and 1970s, laboratories in Brazil, New Zealand, Sweden, and the United States (Texas State Health Department) harvested vaccinia membranes of chick embryos, a simple process that permits production of a bacteria-free vaccine. However, vaccine from this source proved difficult to produce in a satisfactory thermostable, freeze-dried form, and, as far as is known, only Sweden produced vaccine in eggs that were free of avian leukosis virus.[12,175]

Vaccinia virus grown in tissue culture initially proved difficult to produce as a thermostable, freeze-dried product but, in the 1970s, Hekker and colleagues[176] eventually achieved good results using Lister-strain vaccinia virus grown primarily in rabbit kidney cells. In field trials, the vaccine was comparable to vaccine grown on calf skin,[177] but because of the impending conclusion of the smallpox eradication program, no further use was made of it.

Current Vaccine Manufacture

Because of the eradication of smallpox and the cessation of routine immunization, smallpox vaccine production eventually ceased, and national stockpiles were used for laboratory workers and military personnel. However, increasing concern about the possible use of smallpox as a biological weapon caused the United States, in 2001, to contract with a United Kingdom–based company, Acambis, for a joint effort with Baxter Laboratory in Austria to develop and produce a freeze-dried, plaque-purified, bacteria-free, tissue-culture vaccine using the NYCBOH strain.[178] The United States has also contracted with Bavarian Nordic to produce 20 million doses of an MVA-based smallpox vaccine for use in immunocompromised persons.[179] In all, 200 to 300 million doses of the Acambis vaccine have been delivered to the U.S. national stockpile. Several vaccine manufacturers have begun development and production of next-generation smallpox vaccines (see "Future Vaccines" later). In 2004, the U.S. government passed the Project Bioshield Act (Public Law 108–276) to acquire countermeasures against chemical, biological, radiological, and nuclear terrorism agents. As of 2014, Project Bioshield has spent $1,100,000,000 on smallpox countermeasures. This includes: $625 million for 24 million doses of IMVAMUNE and $433 million for 1.7 million doses of the antiviral Arestvyer (ST-246).[180,181]

Producers and Trade Names

Although some doses of first-generation vaccines may still exist, the currently available vaccines are all second- and third-generation vaccines. In the United States, the following formulation is FDA approved: ACAM2000 (Sanofi Pasteur Biologics Co.). The MVA-based vaccine, IMVAMUNE (Bavarian Nordic; also known as IMVANEX) has been approved in the European Union and Canada. In the United States, IMVAMUNE recently completed Phase II and Phase III clinical trials.

Dosage and Route

Jenner realized that the skin had to be abraded to produce a successful vaccination. Over the years, a number of methods were developed to break open the skin and introduce the virus. Early vaccine preparations undoubtedly had variable titers, and fairly vigorous techniques sometimes were used to enhance the chance of successful vaccination. A variety of knives, needles, and scalpels were used to scarify the skin.

Some techniques, most notably the rotary lancets used in India, Pakistan, and Bangladesh, were painful and caused significant lesions even in the absence of viral replication. In the United States, during the 1920s, Leake[169] vigorously promoted a multiple pressure technique in which virus was pressed into the skin by multiple firm pressures with the tip of a needle held flat against the skin surface.

In the early days of the worldwide eradication campaign, specially adapted jet-injector guns were used to accelerate mass vaccination efforts, particularly in West Africa and Brazil. The guns proved to be cumbersome and expensive to maintain and not well adapted for use in sparsely populated areas. They were abandoned in favor of the bifurcated needle, which was invented in 1965 by Dr. Benjamin Rubin of Wyeth Laboratories.

Presently, first- and second-generation vaccines and the attenuated but replication-competent LC16m8 vaccine are inoculated intradermally with a bifurcated needle. If alcohol, acetone, or other skin preparation is used, it must be allowed to evaporate fully, or it may inactivate the live virus. The vaccine should have a titer of not less than 10^8 pock-forming units per milliliter by assay on the chorioallantoic membranes of 12-day-old chick embryos. Approximately 0.0025 mL of vaccine adheres by capillarity action between the tines of the bifurcated needle when it is dipped into the vaccine. The needle is positioned vertically to the skin surface, usually the lateral surface of the upper arm (Fig. 54.8), with the heel of the hand resting on the arm. Three (for primary vaccination) or 15 (for revaccination) rapid strokes are made sufficiently forcefully so that a trace of blood appears at the vaccination site within 20 to 30 seconds. Good technique produces more than 95% "takes" in vaccinia-naïve persons. The process of scarification with the bifurcated needle has been shown to elicit a strong, local, non-specific, innate immune response that boosts vaccinia-specific immunity and contributes to protection.[182]

Following terrorist attacks in the early 21st century, the limited availability of smallpox vaccine doses spurred a number of vaccine dilution studies.[183–190] Most of these efforts indicated that live virus vaccine doses of first-generation vaccines could be diluted 1:10 with little effect on take rate, seroconversion, immunoglobulin (Ig) G titer, or T-cell response.

Availability in Combinations

Smallpox vaccine is not available as a combination vaccine; however, it can be administered at the same time as a number of other antigens, usually at a different site, with levels of safety and efficacy comparable to those observed when the vaccines are given separately. Simultaneous administration of oral poliovirus, measles, and diphtheria-tetanus-pertussis (DTP) vaccines became a routine practice in many countries beginning in the 1970s.[191,192] Smallpox and bacille Calmette-Guérin (BCG) vaccines began to be administered to newborns in Hong Kong in the 1960s.[191] This became a common practice in many African countries in the late 1960s. Yellow fever and smallpox vaccines were mixed and administered successfully in many French-speaking areas of West Africa,[193] and measles and smallpox vaccines were simultaneously administered throughout western Africa from 1967 to 1972.[194] Mixing of smallpox, yellow fever, and measles vaccines for inoculation by jet injection resulted in a diminished immune response to yellow fever vaccine,[195] but responses were satisfactory when different sites of inoculation were used. Ruben and colleagues[196] extended the studies to the simultaneous administration by jet injection, but at different sites, of smallpox, yellow fever, measles, and DTP vaccines. They found that systemic reactions were no more frequent or severe than those that occur after measles or smallpox vaccination alone, although there was a diminished immune response to measles vaccine. However, this last observation was not confirmed in subsequent studies. From these and other observations, Foege and Foster[197] concluded in 1974 that it was safe and efficacious to administer simultaneously all vaccines (oral poliovirus, DTP, measles, and BCG) then used in the WHO Expanded Programme on Immunization, as well as smallpox and yellow fever vaccines. The Advisory Committee on Immunization Practices (ACIP) recommends that varicella and smallpox vaccines be administered at least 4 weeks apart[198] because if post-vaccination skin lesions occur following the concomitant administration of these two vaccines, it may not be possible to determine which vaccine was responsible and to provide appropriate care.

Vaccine Stability

Freeze-dried smallpox vaccine has proved to be the most stable of the currently available vaccines. The vaccine can be preserved indefinitely at −20°C, and most batches can be preserved for many months to years at 2°C to 8°C. International standards require that the vaccine in its freeze-dried form maintain full potency when it is incubated at 37°C for 1 month. Studies of vaccine produced at the Lister Institute demonstrated that it retained full potency for 64 weeks when incubated at temperatures of up to 45°C and for 104 weeks at 37°C.[199] Not all vaccines are this stable: during the eradication campaign, assay of vaccines produced in India and the former Union of Soviet Socialist Republics (USSR) and retrieved from the field revealed batches of vaccine that met potency standards after 6 to 9 months of exposure at high ambient summer temperatures.[12]

After reconstitution, the vaccine is much more sensitive to temperature and exposure to direct ultraviolet light. During the eradication program, unused reconstituted vaccine was routinely discarded at the end of each day, but, in fact, it will remain potent for a much longer time. Studies on the stability

of undiluted and diluted (1 : 5 and 1 : 10) reconstituted Dryvax showed that vaccine retained satisfactory potency at room temperature (<24 °C) for 1 month with a minimal decrease in viral titer[200] and that vaccine retained satisfactory potency for 2 weeks when subjected to alternate 12-hour cycles of 4 °C and 25 °C temperatures, much like temperature conditions to which the vaccine might be subjected in an immunization campaign.[201] However, the vaccine must be kept out of any extended period of direct ultraviolet light exposure.

IMMUNOGENICITY OF VACCINE

Successful primary vaccination results in virus proliferation in the basal cells of the epidermis, producing a typical lesion known as a Jennerian vesicle (Fig. 54.9). A papule with surrounding erythema develops in 3 to 5 days, rapidly becoming a vesicle, and by day 7, a pustule. It reaches its maximum size after 8 to 10 days. A scab forms that traditionally was expected to separate after 14 to 21 days, leaving a typical vaccination scar. Recent experience showed that the scab sometimes stays attached somewhat longer if the site is bandaged much of the time.[202] A low-grade fever may accompany the development of the pustule, and swelling and tenderness of the draining lymph nodes is often observed. When certain European vaccine strains were used, viremia occasionally occurred between the 3rd and 10th days,[203] and the virus was sometimes isolated from tonsillar swabs.[204] Recent efforts to grow virus from the blood or the oropharynx of NYCBOH strain vaccine recipients postvaccination were unsuccessful.[205,206]

A person's response to revaccination depends on the person's prior degree of immunity. In highly immune persons, erythema typically develops within 24 to 48 hours as a classical delayed hypersensitivity reaction. This reaction can be elicited with both live and inactivated vaccine in previously vaccinated patients.[207] Persons with some residual humoral or cell-mediated immunity, but not enough to inhibit viral replication, develop erythema and sometimes a pustule at the site that evolves more rapidly than a primary vaccination reaction. If erythema or induration is present at 6 to 8 days, it is considered evidence of virus proliferation and is termed a "major reaction." It should be noted that persons with substantial immunity may experience no more than a delayed hypersensitivity reaction. It is impossible at day 5 or earlier after vaccination to distinguish clinically between a delayed hypersensitivity reaction resulting from the use of impotent vaccine or poor vaccination technique and a similar reaction resulting from a high level of immunity. Therefore, the WHO Expert Committee on Smallpox recommended that such a response be termed an "equivocal reaction."[32] Persons with equivocal reactions should be revaccinated with vaccine of known high potency using a vigorous technique.

Vaccinia-induced antibody responses are slightly more rapid than those following smallpox. They can be detected as early as the 10th day after primary vaccination and even more quickly with anamnestic response following revaccination.[208] Evidence of cell-mediated immunity also occurs about the fifth or sixth day.[12,209–211] This accelerated response is associated with complete or partial protection from smallpox infection in persons vaccinated within 3 or 4 days after exposure.[212–215] A considerable body of animal work shows that exogenous antibodies may be effective in treating vaccinia, monkeypox, and ectromelia.[216–219]

Contemporary studies in human vaccine recipients and animal models have found that cellular and humoral immune responses fulfill important roles in protection (Fig. 54.10).[52,130,220] Cytotoxic T-cell activity has a predominant role in the control of primary infection (i.e., clearance of the virus after infection), while antibody and memory B-cell responses are critical to protection during secondary infection.[221–223] Poxvirus immunology research is also focused on determining the genetic basis for variations in smallpox vaccine response or susceptibility to adverse events,[224–229] gene expression studies to determine host–pathogen interactions and the key drivers of immune responses,[230–236] and exploring animal models of infection, disease, immunity, and therapeutic interventions.[230,237–245]

Humoral Responses

After primary vaccination, neutralizing and HI antibodies develop about the 10th day and are present in almost all persons by the end of 2 weeks; CF antibodies develop in fewer than half of vaccinees.[208] The HI and CF antibodies are usually not detectable beyond 6 months. Antibody response after revaccination is more rapid, usually within 7 days, and antibody titers are generally higher. However, some persons who exhibit a substantial rise in neutralizing antibody titer after revaccination do not have a rise in HI or CF antibody levels.

The immunology of smallpox vaccines.* Curr Opin Immunol. *2009;21:314–320.)*

Poxviruses have two major forms: MV, the intracellular mature virion, and EV, the extracellular virion containing one additional membrane and several unique proteins.[128] Humoral responses induced by the smallpox vaccine target MV and EV proteins. Antibodies to either form can be protective, but it is thought that optimal protection and disease resistance require antibodies to both forms of the virus.[246] As EV is difficult to neutralize, protection against this form of the virus may be mediated by other, isotype-dependent antibody functions such as opsonization, or antibody-dependent, cell-mediated cytotoxicity.[247] One study shows that an early, neutralizing IgM response appears by day 4 postvaccination.[51] This early response is dependent on T-cell help, is capable of neutralizing the EV and MV virions, and may be important in controlling poxvirus infections.[248–250]

Neutralizing antibodies develop in almost all primary vaccinees by day 4 and can persist for 30 years or more.[51,129,251–255] Titers of neutralizing antibodies measured in primary vaccinees at 1 year were only 23.7% of the titers measured on day 28 after vaccination.[256] Neutralizing antibody titers to EV continue to decrease over time; in fact, 25 years postvaccination, 20% of vaccinees have little to no EV neutralizing activity.[246] In contrast, titers to MV decrease slightly within 5 years of vaccination and then remain stable for up to 75 years postvaccination.[246,254] Revaccination increases total serum antibody titer in most subjects but has little effect on neutralizing antibody titer.[253] Revaccination every 10 years is the current recommendation,[257] but longitudinal studies indicate that protection may last far longer than 10 years.[253,258,259] In the absence of endemic smallpox,

the question of how long after vaccination one remains protected may never be answered.

Cellular Responses

Although Jenner first noticed cellular immunity in the form of the delayed-type hypersensitivity reaction and pock formation at the site of vaccination, T-cell immunity was largely ignored during the eradication efforts. This was because of several factors, including the ease of measuring antibody titer and vaccine take and the lack of proper scientific tools to dissect cellular immune responses. In the last decade, T-cell immunity to smallpox vaccination has received far more attention. Following vaccination, sequential waves of cytokines can be detected in recipient's serum including: granulocyte colony-stimulating factor at days 6 and 7; tumor necrosis factor α, interferon γ, interferon-inducible protein 10, and interleukin 6 on days 8 and 9; soluble tumor necrosis factor receptor 2 and CXCL9 on days 10 and 11; and granulocyte-macrophage colony-stimulating factor on days 12 and 13.[260] Cell-mediated immunity to vaccinia may develop as early as 2 days after primary immunization,[207] peaks approximately 1 month after vaccination,[252,261] and correlates with vesicle formation.[256] In animal models, T-cell help is crucial for optimal formation of antibody responses.[211] Immunization induces extremely robust $CD4^+$ and $CD8^+$ T-cell responses, with up to 3% of circulating T cells being vaccinia-specific.[252] This T-cell population then gradually declines over decades, with $CD4^+$ T lymphocytes exhibiting greater longevity than their $CD8^+$ counterparts.[262–267] Newer work also indicates that the quantity of pathogen-specific T cells matters less than the functional capabilities of those T cells.[268] Although some studies found that antibodies are sufficient for protection against subsequent poxvirus infection,[222,269,270] other studies purport to show efficacy of cellular immunity alone in combating orthopoxvirus infections,[211,271–273] but an insufficient database makes it too preliminary to make strong statements about the comparative efficacy of the two main modes of immunity.

Viral Targets of Immune Responses

Advances in antigen prediction algorithms, pathogen proteome arrays, mass spectrometry, computational modeling, and other techniques allow researchers to comprehensively examine humoral and cellular immune responses to complex pathogens such as poxviruses. The ability to determine which of the many viral proteins are targeted by immune responses and which of these myriad responses provide clinical protection is critical to the development of next-generation, subunit-based smallpox vaccines (see "Future Vaccines later").

Unlike humoral responses to some viruses, smallpox vaccine–induced antibodies target a broad spectrum of viral proteins, with no clear immunodominant pattern. Antibody responses can be found to early and late proteins and predominantly target structural (membrane and core) proteins but can recognize secreted proteins as well (Fig. 54.11).[54,274–278] Convalescent serum samples from smallpox victims and from vaccine recipients show considerable overlap, further evidence of the immune cross-reactivity between vaccinia and variola.[278]

Despite the large genome size and complexity of poxviruses, T-cell epitope identification efforts by a number of laboratories have resulted in the characterization of hundreds of human leukocyte antigen (HLA) class I and class II epitopes.[53,271,272,279–306] The National Institute of Allergy and Infectious Diseases supports a public online epitope database and associated tools that can be found at http://www.iedb.org.[307] As with humoral responses, T cells recognize a wide variety of viral proteins, with $CD8^+$ T cells targeting proteins expressed early in infection[303] and $CD4^+$ T cells recognizing predominantly late antigens and structural proteins.[300] In mice, T-cell responses exhibit clear patterns of immunodominance that can be altered by the route of immunization.[308,309]

Consistent with the T-helper–dependent nature of poxvirus humoral responses, there is a strong correlation between CD4 T-cell epitopes and antibody targets.[302,303] Although it has been reported that there is a deterministic linkage between T-helper and antibody antigens (antigen-specific T cells were found to provide help to B cells specific to the same viral protein),[304] not all studies support this linkage.[310]

Correlates of Protection

During a primary infection, B cells, $CD4^+$ T cells, and $CD8^+$ T cells all play complementary roles in viral clearance and recovery. Upon secondary exposure following vaccination antibody responses are likely to neutralize viral particles before infection, whereas T cells control viral replication after infection by eliminating the infected cells before they can produce additional viral particles. Animal studies in vaccinated mice and nonhuman primates (challenged with mousepox and monkeypox, respectively) clearly show protection in the absence of $CD8^+$ T cells, but not in the absence of B cells and antibody responses.[211,302,303,311] However, vaccine-induced protection wanes at about the same rate as cellular immunity wanes and multiple studies show that $CD8^+$ T-cell peptide-based vaccines can induce protective immunity,[271–273] raising the question of what role T-cell responses fulfill in protection against infection.

The level of humoral antibody necessary to provide protection against smallpox or the development of a major reaction following revaccination is unknown.[312] The best estimate that we have comes from small studies performed during the eradication effort indicating that a neutralizing antibody titer of more than 1 : 20 or more than 1 : 32 conferred some protection against disease.[313,314] Studies of immune responses in vaccine recipients demonstrate a wide range of humoral and cell-mediated immunity.[189,252,256,265,315]

There are even fewer data concerning protection and T-cell immunity. Animal studies involving peptide immunization with a single T-cell epitope range from no protection to complete resistance to disease, with no discernible mechanism behind the differences in protection.[273]

These data and epidemiologic observations suggest the following about the probable protection provided against acquiring smallpox and fatal outcomes:

1. Patients who survive smallpox are fully protected for life from experiencing the disease a second time.[12,16,17,33,316]
2. Persons who responded to primary vaccination and who later experienced a subclinical smallpox infection (variola sine eruptione) are likewise protected for life.[12,16]
3. Persons who responded to primary vaccination and one or more successful revaccinations, even if more than 30 years ago, probably sustain substantial protection against a fatal outcome and some protection against acquiring the disease.[12] Repeated immunizations temporarily boost humoral and cellular immunity.[251,265] Even though total vaccinia-specific antibody levels remain elevated in recipients of multiple vaccinations, neither neutralizing antibody titers nor cellular immune measures appear significantly higher.[252,253] It must be noted, however, that a "successful" revaccination requires that the vaccination has been properly performed

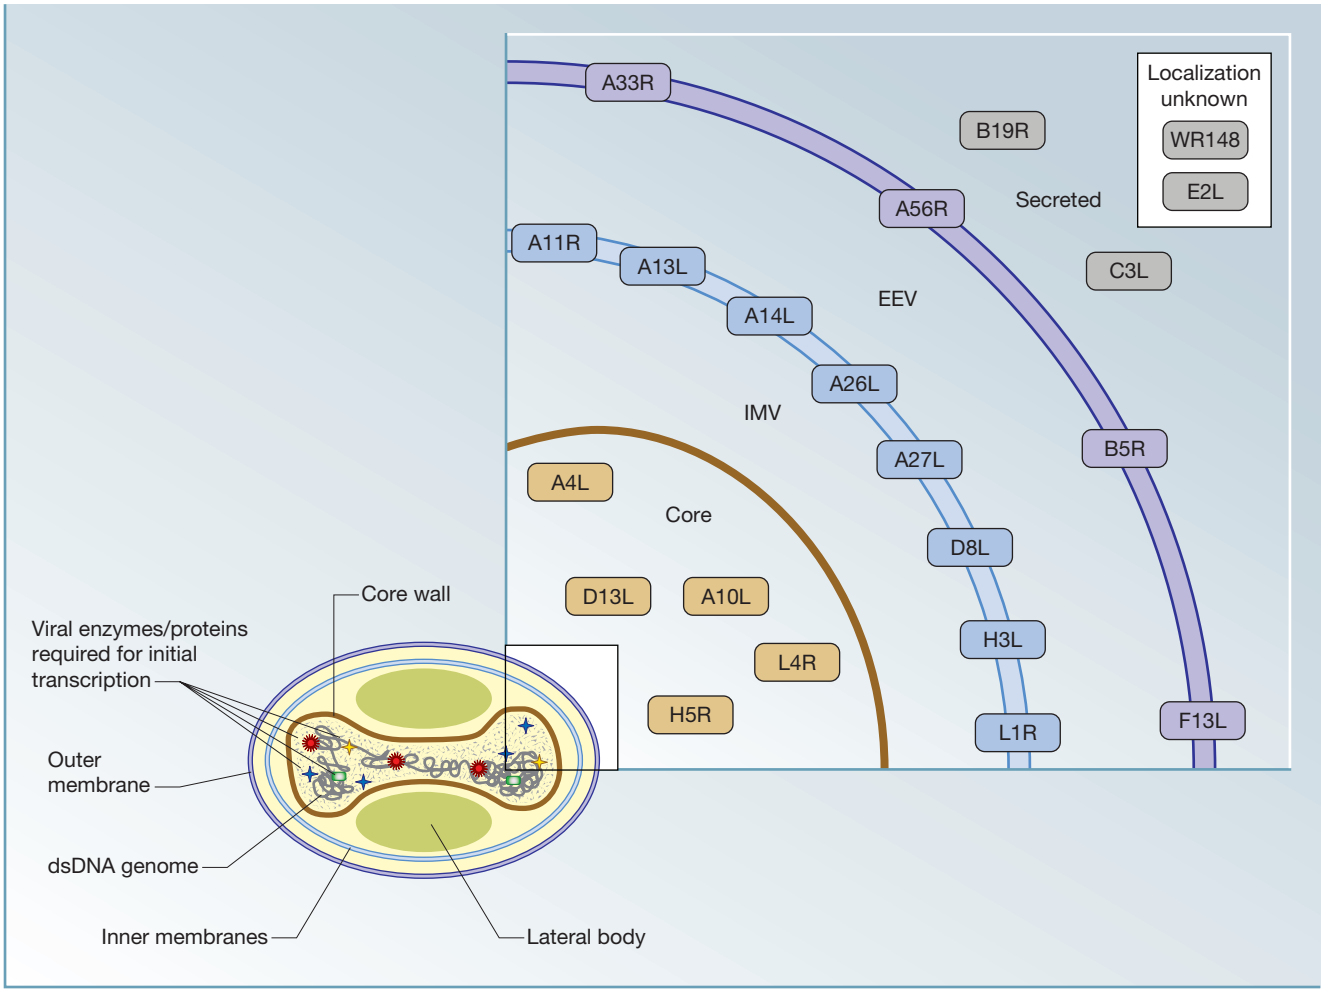

Figure 54.11. Schematic of poxvirus virion showing viral core and double membrane. *Inset* at upper right denotes the location of viral proteins targeted by humoral immune responses. dsDNA, double-stranded DNA.

so that the person has experienced a "major" reaction (see "Immunogenicity of Vaccine"). Because of the past practice in the United States of vaccinating very carefully so as not to draw blood, many revaccinations failed to result in virus proliferation and vaccinees did not have major reactions. It is possible that many of the revaccinations administered in the United States during that period were not successful. In the contemporary military and civilian vaccination programs, high take rates among revaccinees have been documented.[317–319]

4. Persons who have a primary vaccination only will have reasonably complete protection against acquiring smallpox for perhaps as long as 10 years, but protection against symptomatic infection steadily wanes and is probably minimal to nil after 30 years.[12,16] Protection against a fatal outcome of smallpox, however, may persist for a longer time and may, indeed, for some, extend beyond 30 years.[253,258,259,320,321]

In Special Groups (Infants, Immunocompromised)

Vaccination is contraindicated in premature infants and in immunocompromised individuals because of the high risk for adverse reactions (see "Safety [Adverse Events)]" later).

EFFICACY AND EFFECTIVENESS

For the Individual Vaccine

First-generation smallpox vaccine efficacy was typically measured by the development of the characteristic blister (or vaccine take) at the site of immunization. The vast majority (>97%) of individuals developed this take following vaccination. Because it was easily visible and required no special training to document, vaccine take was used as an indicator of successful vaccination, a policy that was successfully used during the eradication campaign. However, this blister is an indicator of local viral replication and not the development of humoral immunity. Preexisting humoral immunity can attenuate or even block the development of this skin lesion upon immunization.[322] Individual immune responses vary widely, and this variability is partly a result of genetic differences between individuals.[224–227,323–326]

For the Community

During the early eradication efforts, mass vaccination campaigns endeavored to reach 80% or more of the population. It was believed that herd immunity levels of 80% to 85% are necessary to stop smallpox transmission.[327] Later, it was found that surveillance and targeted vaccination of primary

contacts for each case was equally effective at containing outbreaks.

EXCRETION OF VACCINE VIRUS, IF ANY

The CDC ACIP recommends that recently vaccinated non–healthcare workers cover the site with a loose gauze bandage and adhere to strict hand hygiene after contact with the vaccinated site during the 2 to 3 weeks in which virus is shed.[198,328] Coverage can delay scab formation, drying, and separation,[202] but reduces the chance of vaccinial transmission, prevents clothing from being soiled, and prevents accidental abrasion of the lesion. More occlusive dressings, even if semipermeable, may cause maceration of the skin and the development of satellite lesions. Studies of site care options to prevent the spread of vaccinia and to avoid excessive local reaction (such as skin maceration) have been published.[329–331] The application of povidone iodine ointment on day 7 after vaccination has been shown to reduce viral shedding without altering the immune response.[332] Bathing is acceptable, but the site should be kept dry otherwise. A separate towel should be used to dry the vaccinated site until a scab forms.

For recently vaccinated healthcare workers, the ACIP recommends avoidance of contact with high-risk patients, if possible, until the scab separates. If contact is unavoidable, meticulous hand hygiene and a dressing comprising gauze (or a similar absorbent material) covered with a semiocclusive dressing or a product that combines an absorbent base with an overlying semipermeable layer are recommended during direct patient care until the scab separates.[198] The ACIP does not believe that healthcare workers need to be placed on administrative leave after being vaccinated unless extensive skin lesions develop, which would preclude adherence with the aforementioned infection control precautions. The contemporary experience of the U.S. military vaccination program supports this conclusion.[257,333–335]

Contact Vaccinia

Contact vaccinia may occur from the accidental mechanical transfer of vaccinia virus from a recently vaccinated person to close contacts. Primary vaccination lesions shed vaccinia from about the third day until a scab forms.[336] Several population-wide studies of contact vaccinia have been performed; they have been reviewed by Neff and colleagues.[337] Two of the studies dealt with the incidence of contact transmission during the course of emergency vaccination campaigns in the United States and Great Britain. During the 1947 New York City outbreak of smallpox, 5 to 6 million persons were vaccinated using the NYCBOH strain. In all, 28 persons developed eczema vaccinatum as a result of close contact with a vaccine recipient, and two of them died.[338] During the 1962 smallpox outbreak in Great Britain, at least 3,250,000 persons were vaccinated using the Lister strain vaccine. There were 185 cases of eczema vaccinatum, of which 89 resulted from contact with a vaccine recipient; seven with contact vaccinia died.[117] Note that compared with contemporary programs, screening to identify persons at risk and the covering and care of the inoculation site are likely to have been much less sophisticated.

National surveys to assess the frequency of complications were conducted in 1963 and 1968 by, respectively, Neff and colleagues[118] and Lane and colleagues.[339] Both used several methods to detect possible cases, but most reports included data for persons who had received VIG for the treatment of complications. The two surveys yielded similar results: the rates for the respective years were 8.7 and 10.7 cases of contact eczema vaccinatum per 1 million primary vaccinees. The incidence of accidental infection resulting from contact was somewhat lower than that for eczema vaccinatum. In all, three deaths were recorded among 114 persons with eczema vaccinatum acquired by contact. There were no cases of progressive vaccinia or postvaccinial encephalitis resulting from transfer of vaccinia virus to contacts (Table 54.3). In statewide surveys

From Lane JM, Ruben FL, Neff JM, et al. Complications of smallpox vaccination, 1968. N Engl J Med. *1969;281:1201–1208.*

in 1963 and 1968,[337,340] physicians were individually contacted and asked to report cases. The rates for contact eczema vaccinatum were approximately double those derived from the national surveys. It was thought that the higher rates reflected more complete reporting, especially of less severe complications.

In their review, Neff and colleagues[330] noted that contact vaccinia required very close contact, seldom occurred outside the home, and rarely occurred as a result of hospital contact. Persons transmitting vaccinia were predominantly children. During the 1960s, it occurred comparatively infrequently, at the rate of only two to six per 100,000 primary vaccinations.[330]

Data from the 1960s are informative but provide only limited insight as to what might be anticipated as a result of large-scale vaccination today, especially of adults. During the 1960s, most persons were vaccinated at about 1 year of age or before school entry. Not surprisingly, most cases of contact vaccinia resulted from transfer of vaccinia from young children to others in the household. Most adults who received the vaccine had previously been vaccinated, with a correspondingly smaller vaccine take and diminished viral shedding. Today, in contrast, a proportionately larger number of persons are at higher risk of complications, and yet the complication rates observed in intense surveillance systems detected adverse events that were largely at or below historic rates.[317,341,342] There were a few exceptions to this rule, as a 2002 study found that the autoinoculation rate for ACAM2000 was 20.6 per 100,000 vaccinations and the contact transmission rate was 4.4 per 100,000 vaccinations.[343] Furthermore, these rates were similar between ACAM2000 and Dryvax. The prevalence of atopic dermatitis in the current population is considerably higher,[344–346] as is the prevalence of serious immunodeficiency in the population because of HIV,[347] organ transplantation,[348] cancer chemotherapy,[349] and the availability of corticosteroid and immunomodulatory therapy for a range of prevalent inflammatory and musculoskeletal diseases.[350] That few cases of contact transfer occurred after 2 million vaccinations of U.S. military personnel who used simple bandages, not semipermeable dressings, suggests the primacy of human factors and postvaccination discipline on infection control and the relative difficulty of transferring this virus in nonintimate settings.

DURATION OF IMMUNITY AND PROTECTION

Reliable data about the protection provided by vaccination are sparse. Furthermore, the degree of protection among a population is difficult to quantify with the passage of decades. Before 1967, revaccination every 3 to 10 years was considered essential to ensure protection. This practice was based on early data largely from the United Kingdom, such as those provided by Hanna and Baxby[213] and on newer data from India.[33] These studies compared the frequency of smallpox cases among persons with and without vaccination scars. However, the vaccine in use in the populations studied had a far lower titer than that used after 1967, and most of the vaccine was heavily contaminated with bacteria. In India, the vaccination instrument used was the rotary lancet, which frequently produced localized sepsis and an apparent scar even when only the diluent was applied. The estimates of protection after successful vaccination in these studies are probably understated.

From studies conducted since 1967, it is probable that vaccinial immunity is more durable than most investigators believed. The evidence is indirect, however, because there are no proven serologic correlates of protection. Unfortunately, resistance to intradermal inoculation with vaccinia virus has been mistakenly equated by some with resistance to variola virus acquired by droplet inhalation. With the available higher titer vaccines, studies show that major reactions can be induced in persons successfully vaccinated as recently as 3 to 6 months before and, indeed, in more than 10% of persons who experienced smallpox only 1 year previously.[351] Because natural infection confers permanent immunity, the ability of vaccinia virus to proliferate in the basal cells of the dermis is not known to correlate well with the level of protection provided against natural infection.

In most countries, 90% or more of smallpox cases occurred among persons without vaccination scars. This finding led to surveys in endemic countries that disclosed vaccine efficacy ratios of 80% or more among persons vaccinated 20 years previously. Heiner and colleagues[99] showed that this protection could not be attributed solely to the vaccine. They discovered that previously vaccinated persons often developed noncontagious inapparent infections (termed variola sine eruptione) with substantial increases in antibody levels. Immunity in the endemic countries was, thus, a composite of past experiences with vaccinia and variola infections.

Data from countries where smallpox was introduced after an absence of many years provide insufficient information to permit a calculation of duration of vaccine protection, but they suggest that vaccinia provides long-term protection against a fatal outcome.[352] Among 680 cases of variola major occurring after importations of smallpox into Europe, the case-fatality rate was 52% among persons who had never been vaccinated, 1.4% among persons vaccinated up to 10 years before exposure, 7% among persons vaccinated 10 to 20 years before exposure, and 11.1% among persons vaccinated more than 20 years before.[352] Other studies show a similar trend of decreasing protection resulting from waning immunity over time.[33,213,353]

As mentioned, studies on smallpox vaccine–induced immunity have found detectable antibody titer and memory B-cell and memory T-cell populations for decades after vaccination. These measures of immune function wane at differing rates,[251–253,255,258,264,354] with antibody responses exhibiting greater longevity. A similar situation occurs in persons who recover from smallpox infection.[264] According to these studies, only 30% to 50% of vaccine recipients maintain neutralizing antibody titers more than 1:32 for 20 years after vaccination. Without established correlates of protection (for either humoral or cellular immunity), it is not known precisely how much protection remains at a given time after vaccination. Complete protection against infection and clinical illness is likely short-lived, lasting for perhaps 5 to 10 years after vaccination, followed by 10 to 20 years of diminishing partial protection (exposure to smallpox then resulting in mild illness such as variola sine eruptione), with protection against fatal disease lasting much longer, possibly for life.[258,259,320,355]

POSTEXPOSURE PROPHYLAXIS AND THERAPEUTIC VACCINATION

Antibody response after primary vaccination usually occurs 4 to 8 days earlier than the response after naturally acquired smallpox infection[356]; thus, primary vaccination, even after exposure, can modify or abort the wild virus disease. The available data indicate the likelihood of substantial protection against disease even when vaccination takes place as long as 3 to 4 days after infection and at least partial protection against a fatal outcome when administered as late as 4 to 5 days after infection occurs.[161,212–215]

SAFETY (ADVERSE EVENTS)

Common Adverse Events

The most frequent symptoms after receipt of the smallpox vaccine are similar to those experienced with other vaccines: pain at the vaccination site, muscle aches, and fatigue, with the addition of pruritus at the vaccination site. Slight temperature elevations are also common, with overt fever occurring in a minority of subjects. Historically, for every 1 million primary vaccine recipients, there would be approximately five to 10 persons with adverse reactions serious enough to require hospitalization and one or two deaths. In the absence of smallpox (or other poxvirus) exposure, these risks are unnecessary. However, they pale in comparison with those encountered during a smallpox epidemic. In fact, a smallpox outbreak with 1 million cases among an unvaccinated population would result in hundreds of thousands of deaths and long-term sequelae (blindness, limb deformities, facial scarring, and depigmentation) among the majority of the survivors.

The frequency of the minor but common adverse events in four contemporary trials of Dryvax and Lister vaccines are shown in Table 54.4. These studies are smaller than the large-scale data available from the 1970s but are more applicable to the current U.S. population. Rates of adverse events are generally similar, and disparities in adverse event rates between these studies likely reflect differences in study design and reporting. For example, the National Institutes of Health Vaccine and Treatment Evaluation Units and the CDC study defined fever as a temperature of 37.7°C or higher, but reported different rates of fever (2.3% and 21.5%, respectively) in different time frames (0 to 6 days and 0 to 20 days postvaccination, respectively). An important note from the data in Table 54.4 is the fact that "repeat" vaccinees had far fewer adverse events than did primary vaccinees. Fever (temperature >38.3°C) occurred in 3.3% to 20% of subjects. In all, 14% of subjects had minor rashes at other than the vaccination site, usually maculopapular or vesicular, affecting the chest and back, with spontaneous resolution in all. A total of 36% of subjects were sufficiently affected by the vaccine to have trouble sleeping or miss at least 1 day of work, school, or recreational activities.[190] In military cohorts, 2.4% reported diminished work activities, 0.4% missed work, and 0.1% were hospitalized.[317,357] Of some concern are generalized vaccinia, erythema multiforme, vaccinia keratitis, and accidental implantation of vaccinia in distal sites. More serious and occasionally life-threatening are eczema vaccinatum, progressive vaccinia, congenital vaccinia, and postvaccinial encephalitis. Estimates of the frequency for these reactions are shown in Table 54.3 (U.S. historical data from the 1960s) and in Table 54.5 (data from the recent U.S. Department of Defense

[a]The data provide examples of the frequency of common adverse effects of smallpox vaccination. For some of the trials the numbers are very low. Furthermore, much of the data are for Dryvax, which is no longer available. The frequency of side effects from the ACAM2000 replacement may differ. Dashes mean that the specific adverse event was not monitored in the study and no data are available for that adverse event.

[a]Data are for the Department of Defense Smallpox Vaccination Program, Smallpox Vaccine Adverse Events, December 2002 to January 2011. Population details: 2,253,771 screened, 89% primary vaccinees, 88% male, and 70% white. Adverse event numbers include cases defined as confirmed, probable, possible, and suspected (based on surveillance definitions).
[b]Total includes active duty service members, beneficiaries, and nonbeneficiaries.
AEFI, adverse events following immunization; EV, eczema vaccinatum; PV, progressive vaccinia; VIG, vaccinia immunoglobulin.

Smallpox Vaccination Program, 2002–11). Note that during the 1960s, far more vaccinations were given; however, it was a routine vaccination with no subject screening, whereas the data from the 2000s reflect somewhat smaller cohorts that underwent prevaccination screening and include data on Dryvax and ACAM2000. Furthermore, note that Table 54.5 shows a similar frequency of adverse events with ACAM2000 and Dryvax; all recent smallpox vaccine recipients are healthy adults, and we do not have any contemporary data regarding adverse reaction rates among children or the general U.S. population.

Rare Adverse Events (By Organ System)

Skin Reactions

Vaccinees may have a variety of skin rashes after vaccination. Most are benign, but two can be life threatening: eczema vaccinatum and progressive vaccinia (see Tables 54.3 and 54.5).

Eczema vaccinatum (Fig. 54.12A) follows vaccination (or accidental implantation from vaccinated contacts) of persons with active or quiescent atopic dermatitis (including eczema). Concurrently with or shortly after the development of the local vaccinial lesion, or after an incubation period of about 5 days in an unvaccinated eczematous contact, a vaccinial eruption occurs at sites that are eczematous or that had previously been so. The areas become intensely inflamed, and the eruption can spread to involve normal skin. Constitutional symptoms can be severe, with high fever and generalized lymphadenopathy. Subjects may lose fluid and electrolytes through exudation. Deaths are uncommon if the condition is properly treated with VIG and supportive care. The deaths that occur are usually in young children with severe eczema who have acquired vaccinia through contact.

Progressive vaccinia (sometimes called vaccinia necrosum, vaccinia gangrenosa, or disseminated vaccinia) (see Fig. 54.12B) is the most severe complication of vaccination and solely affects immunodeficient persons. These include, among others, persons with agammaglobulinemia, defective cell-mediated immunity, and immune deficiency associated with tumors of the reticuloendothelial system or from the use of immunosuppressive drugs. In the 1960s, this population was composed mostly of persons with agammaglobulinemia or chronic lymphocytic leukemia, and rates were extremely low (≈1 per 1 million vaccinees). Today, patients with serious immunosuppression from HIV, organ transplantation, cancer chemotherapy, or the use of a variety of immune-modifying drugs would constitute most of this at-risk population. In patients with these conditions, the vaccinia lesion fails to heal and usually does not show the cardinal signs of inflammation. Secondary lesions sometimes appear elsewhere on the body and then gradually spread. VIG and methisazone (*N*-methylisatin β-thiosemicarbazone) are reported to have been partially effective in treatment during the 1960s.[358] Data are sparse, however, and methisazone is no longer available for use. Cidofovir, an antiviral agent licensed in 1996 for the treatment of cytomegalovirus retinitis in people with AIDS, shows in vitro activity against orthopoxviruses and may prevent disease in animal models when given shortly before or at the time of vaccinia infection,[359] but it has not been shown to have therapeutic value in treating an established infection of any orthopoxvirus. Likewise, ST-246, another antiviral agent, has shown promise of therapeutic value in the treatment of orthopoxviruses and may be made available for emergency use.

Generalized vaccinia (see Fig. 54.12C) occurs in immunocompetent persons from the systemic spread of vaccinia from the vaccination site. It is a benign reaction in which one to multiple lesions develop within 6 to 9 days after vaccination at locations other than the vaccination site. The evolution of these lesions follows the same temporal course as that of the vaccination lesion itself. Although occasionally patients may experience high temperature and malaise, an uneventful recovery without the need for specific therapy is the norm. Contemporary surveillance suggests that clinicians may be inclined to casually describe a variety of benign maculopapular rashes after smallpox vaccination as generalized vaccinia, but the incidence rate using a strict case definition is far lower than historical reports of about 25 per 1 million vaccinees.[317,341]

Accidental implantation (or autoinoculation) of vaccinia virus occurs when virus from the primary site is transferred to other parts of the body (or to other persons). Accidental implantation is the most common adverse event following vaccination and occurs most frequently in young children who cannot refrain from scratching the pruritic vaccination site and scratching other areas of the body. The most common sites for implantation are the vulva, perineum, and eyelids (see Fig. 54.12D). Lesions resulting from accidental implantation usually heal without therapy at the same time as the primary site lesion. Occasionally, implantation on the eyelids leads to vaccinia keratitis. In the only large series available, 6% of patients with ocular implantation had corneal involvement.[360] Although VIG frequently was given to patients with ocular vaccinia in the hope that it would reduce inflammation, VIG is contraindicated in patients with corneal lesions because antibody–antigen precipitates could cause corneal scars and blindness.[119]

Erythema multiforme (see Fig. 54.12E) is the term used to identify several types of skin rashes that require symptomatic therapy. Rarely, bullous lesions of Stevens-Johnson syndrome develop, requiring aggressive supportive, and even steroid,

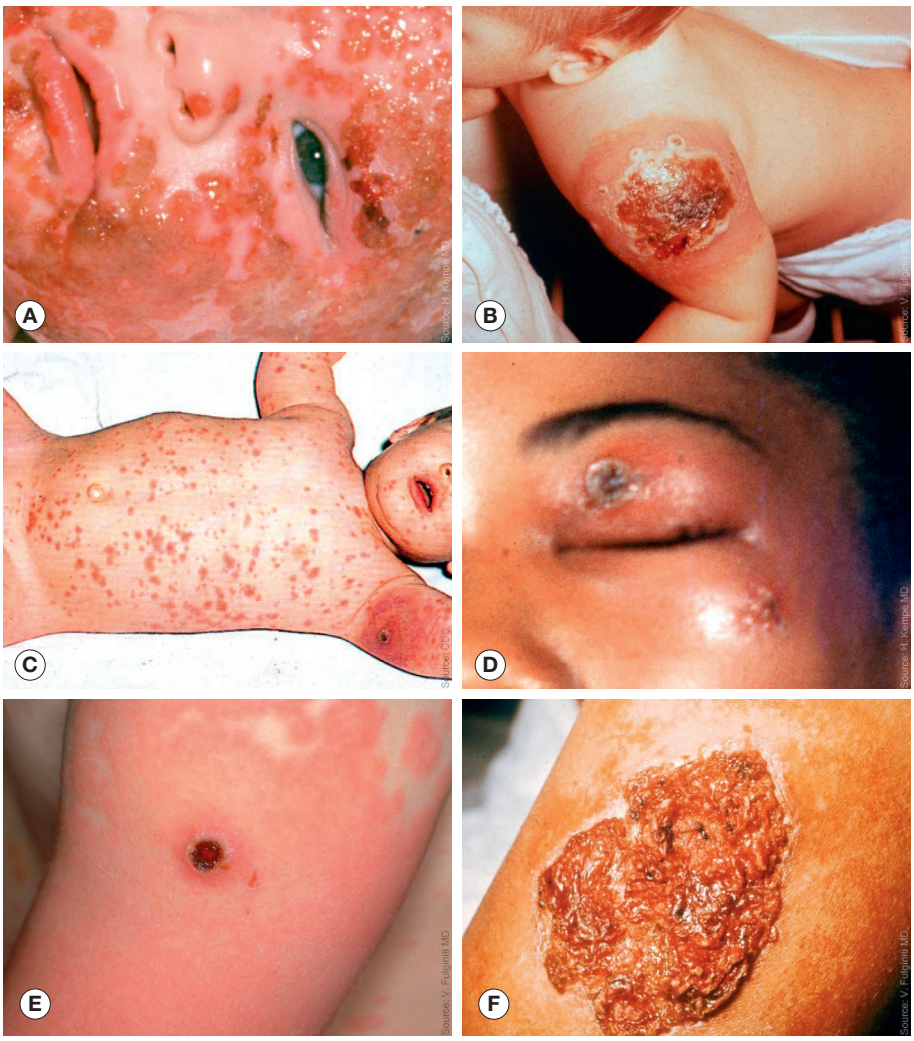

Figure 54.12. Complications of smallpox vaccination. Kempe; B, E, and F, courtesy Dr. V. Fulginiti; C, courtesy Centers for Disease Control and Prevention.)*

therapy. Pyogenic infections (see Fig. 54.12F) sometimes occur and may be difficult to distinguish from normal but vigorous primary takes. With improved methods, such infections have ceased to occur. True bacterial infections may require antimicrobial therapy for resolution.

Postvaccinial Encephalopathy and Encephalitis

Among persons without known contraindications to vaccination, postvaccinial encephalopathy and encephalitis are the most serious adverse events, although these were quite rare in the civilian and Department of Defense contemporary programs.[361] The incidence of these complications was substantially higher in Europe, where especially reactogenic strains were in common use in most countries before the 1960s.[362] DeVries[363] distinguished two pathologic forms: encephalopathy primarily in children younger than 2 years of age, and encephalitis or encephalomyelitis in individuals older than 2 years.

Postvaccinial encephalopathy is characterized by general hyperemia of the brain, lymphocytic infiltration of the meninges, widespread degenerative changes in ganglion cells, and perivascular hemorrhage. Symptoms are severe and begin abruptly within 6 to 10 days after vaccination,[364] with fever and seizures, usually followed by hemiplegia and aphasia. Death, when it occurs, follows within a few days. Recovery is seldom complete; the patient is left with mental impairment and some degree of paralysis.

Postvaccinial encephalitis is characterized by perivenous demyelination and microglial proliferation and primarily afflicts persons older than 2 years. It is similar to the form of postviral encephalitis observed after some vaccinations against rabies or after measles infection. Illness usually begins between 8 and 15 days after vaccination and is accompanied by fever, vomiting, headache, malaise, and anorexia followed by disorientation and drowsiness and sometimes seizures and coma. Death occurs in 10% to 35% of cases, usually within a week. Survivors may have residual paralysis or mental impairment. Paralysis, when it is present, tends to be of the upper motor neuron type. Among patients who recover fully, symptoms and signs resolve within 2 weeks.[365–371]

Many reports give the frequency of cases of postvaccinial encephalopathy and encephalitis in Europe and the United States. The rates are difficult to compare because of differing criteria for diagnosis and variability in the completeness of reporting (Table 54.6). The rest of the chapter does not

[a]Number of cases includes postvaccinial encephalopathy and encephalomyelitis (see text for description of each).
Data from Fenner F, Henderson DA, Arita I, et al. Smallpox and Its Eradication. Geneva, Switzerland: World Health Organization; 1988.

distinguish between the two events. The incidence rates reported from The Netherlands, Germany, and Austria were much higher than those in the United Kingdom, which, in turn, seemed to be somewhat higher than those found in the United States.[118,339,340] Whatever the criteria and methods, differences between the rates seemed to be real. This fact caused a number of countries, during the 1960s, to begin using the Lister strain, then in use in the United Kingdom. A dramatic reduction in the incidence of postvaccinial encephalitis subsequently occurred.[367,373] Only five cases of postvaccinial neurologic adverse events were identified among the 2,057,388 U.S. military personnel vaccinated between 2002 and 2011. Analysis of other neurologic events such as vertigo, meningitis, Bell palsy, and seizures in military and civilian recipients of the smallpox vaccine between 2002 and 2004 found incidence rates of less than two per 100,000 vaccinations for each event. None of the neurologic syndromes were reported at rates above baseline estimates in nonvaccinated populations.[361]

No single laboratory test correlates with strain virulence, but Marennikova and colleagues,[374] using the results of a series of studies in mice and rats, provided a broad classification of a number of strains as follows: (a) least pathogenic: NYCBOH and EM-63 (a derivative of this strain); (b) moderately pathogenic: Lister, Berne, and Patwadanger (from India); and (c) highly pathogenic: Denmark, Tashkent (an older Russian strain), and Ikeda (an older Japanese strain).

Myopericarditis

Occasional cases of myopericarditis (dyspnea, palpitations, and/or chest pain of probably cardiac origin in the absence of any other likely cause of symptoms) after smallpox vaccination were reported through the 1970s when routine vaccination ceased, but whether they were associated causally or temporally was often unclear as myopericarditis has been recognized to occur in association with a number of viral infections.[375] The terrorist attacks in New York and Maryland in September 2001, spurred renewed interest in smallpox vaccination and a reevaluation of adverse event risks in a contemporary population (with higher numbers of individuals with contraindications).

Multiple investigations led by the Department of Health and Human Services identified a causal relationship between myopericarditis and smallpox vaccination in both military and civilian cohorts.[376–380] By May 2006, following the reinstitution of smallpox vaccination of U.S. military personnel, 113 cases of myopericarditis had been reported among approximately 710,000 persons who had received primary vaccinations, whereas four cases occurred among 300,000 revaccinees. These events occurred disproportionately among young adult male white primary vaccinees, clustered in the second week after vaccination, and were associated largely with full recovery of cardiac function as assessed by electrocardiography, echocardiography, and exercise stress tests.[379,381,382] Affected persons experienced fever, fatigue, and myalgia, accompanied by chest pain, beginning between 7 and 12 days postvaccination. Electrocardiograms showed ST-segment changes and an increase in circulating cardiac enzymes (troponin), consistent with myopericarditis. Except for one person in whom severe heart failure developed, patients were generally able to be discharged back to active duty within 7 to 10 days. In more than 2 million vaccine recipients, 241 cases of myopericarditis or pericarditis were noted. This rate is similar to the rate (1.3 per 1000) observed in the recent Department of Health and Human Services civilian program that vaccinated some 40,000 persons.[341] Newer studies benefited from a larger data set that included more vaccinees, and were able to examine the new ACAM2000 vaccine. A study published in 2015 found that 10.6% of new ACAM2000 recipients experienced new-onset cardiac symptoms, compared to only 2.6% of the control group receiving trivalent inactivated influenza vaccine.[383] Using active surveillance, the incidence rate for myopericarditis was estimated to be 463 per 100,000 for smallpox vaccine recipients, 0 per 100,000 for trivalent inactivated influenza vaccine recipients, and 2.2 per 100,000 for unvaccinated, healthy controls. Subclinical myopericarditis rates (defined as elevated cardiac troponin T levels) were estimated to be 2868 per 100,000 for smallpox vaccine recipients and 0 per 100,000 for trivalent inactivated influenza vaccine recipients. These estimates are far higher than the studies performed in the early 2000s and likely reflect the active, prospective nature of the study compared to the earlier, passive surveillance efforts.

Another study, published in 2014, reviewed 1149 reports submitted to the Vaccine Adverse Event Reporting System after ACAM2000 vaccination over the 5-year period between 2008 and 2013.[384] This study found that 54.4% of the serious adverse events and 31% of the nonserious events reported were for cardiac issues. The authors identified 16 cases of myopericarditis and 15 acute ischemic cardiac events.

At least two studies examining cardiac events in subjects receiving MVA-based vaccines did not find any evidence of vaccine-linked myopericarditis.[385,386] A study involving 125 recipients of the LC16m8 vaccine did not identify any cardiac events related to this vaccine.[387] Because of the limited number of subjects in these studies, one cannot rule out a potential risk for myopericarditis. The bottom line is that the first- and second-generation smallpox vaccines do carry a risk of cardiac adverse reactions, which typically occur within 30 days of immunization. Most cases are mild and self-limited. Because individuals with cardiac risk factors were excluded from the clinical trials, safety information on ACAM2000 in persons with heart disease is not available. Persons with known heart disease or cardiac risk factors who are at high risk of infection or with known exposure should be vaccinated because the risk of smallpox is greater than the risk of cardiac reactions.[388]

Other Types of Heart Disease

Among healthcare workers who were vaccinated in the United States, several ischemic incidents (e.g., angina, myocardial infarction) occurred after vaccination.[341,389] These events were detected by a sensitive system designed to monitor adverse events of all types. Many of the afflicted persons had known heart disease or significant risk factors. However, the incidence of ischemic cardiac events identified in civilian vaccinees, including the incidence of sudden death, does not seem to be greater than that expected in a comparable nonvaccinated population.[341] In analyses of several military cohorts, including more than 62,000 vaccinees age 35 years or older, the risk of ischemic cardiac events was comparable among smallpox-vaccinated and unvaccinated groups (Dr. Eric Shry, U.S. Army Medical Department, personal communication, 2006).

While awaiting definitive analyses of the risk of cardiac events postvaccination, the CDC, on the advice of the ACIP, recommended that people with known heart disease or with three or more risk factors for heart disease (such as hypertension, hyperlipidemia, diabetes mellitus, tobacco use, or a first-degree relative with premature cardiac disease) defer being vaccinated.[198] It is now apparent that these contraindications were not warranted based on actual experience.[390]

Unusual Adverse Events

Congenital vaccinia is rare, having been documented on approximately 50 occasions.[391,392] Vaccination during pregnancy does not seem to result in an increase in the incidence of abortions or stillbirths.[393–395] No study has implicated vaccinia virus as a teratogen.[396] The development of a malignant skin tumor, such as a melanoma, in the vaccination scar many years later is a rare occurrence and likely represents coincidence.[397] Vaccinial osteomyelitis occasionally has been recorded and sometimes confirmed by recovery of vaccinia virus.[398]

INDICATIONS FOR VACCINE—WHO AND WHY

In endemic countries, which consisted of most of the world until after World War I, vaccination was recommended for everyone, with revaccination every 3 to 10 years. The only exceptions were infants, for whom primary vaccination customarily was delayed until they were 3 to 12 months old, mainly because frequent vaccination failures occurred at an earlier age. As higher-titer vaccines became available in the 1920s, French, then German, physicians showed that a high proportion of successful vaccinations could be achieved at birth and, in some hospitals, this became routine practice.[399] At least one city in the United States—Detroit, Michigan—mandated neonatal vaccination in the mid-1920s.[400]

As time passed and smallpox incidence declined, smallpox-free countries began to delay primary vaccination until children were older. This resulted in part from the demonstration that maternal antibody inhibited virus proliferation[401] and in part from the belief that older children could better handle the fever and systemic symptoms of vaccinia inoculation. Vaccination at a later age was also less likely to be mistakenly associated with other events, such as sudden infant death syndrome, which might be temporally, but not causally, related. Some European countries recommended that vaccination be delayed until the second year of life to avoid the possible erroneous attribution to vaccinia of cases of encephalopathy resulting from other causes.[367] The United States started vaccinating infants at 12 months of age when studies suggested a higher frequency of postvaccinial encephalitis among infants vaccinated at 9 to 12 months than among children vaccinated between 1 and 4 years of age.[339] No studies were subsequently performed to show that complications became less frequent after these changes in policy.

Vaccination practices in developing countries tended to parallel those in Europe and North America. By 1967, most countries, even those with endemic smallpox, delayed vaccination until the child was 3 to 9 months old. Notable exceptions included Hong Kong,[402] where neonatal vaccination had been traditional at least since World War II, and Madras, India,[33] where neonatal vaccination had been introduced in the late 1950s. During the late 1960s, vaccines that met international standards of potency consistently produced high levels of vaccination takes in newborns. Newborn vaccination became widely recommended, although not all countries followed the practice. There are no adequate studies that compare the efficacy and durability of immunity provided at birth with that provided at older ages, nor are there data that permit a comparison of the relative frequency of vaccination complications at infancy and older ages.

Primary vaccination was provided for adults if required, although there were concerns that adults might have a higher incidence of postvaccinial encephalitis and other serious complications. Earlier European data suggested this to be the case,[362] although studies conducted in the United States, where primary vaccination of adults was rare, did not confirm it.[118,339] A review of U.S. military medical records between 1946 and 1962, conducted by the CDC, found no cases of central nervous system complications among an estimated 2 million basic trainees given primary vaccinations. Data from U.S. military personnel who were vaccinated between 2002 and 2011 indicate that there were five cases in more than 2 million vaccine recipients. The differences between European and U.S. studies probably reflect differences in the pathogenicity of different strains and/or different diagnostic criteria.

Routine vaccination ceased in all countries in the early 1980s, although a number of countries continued to provide vaccination to military forces in case variola virus was to be used as a biological warfare agent. U.S. military vaccination was restricted to trainees in 1984 and discontinued in 1990, until reintroduced in late 2002 for forces being deployed for duty in certain high-risk geographic areas.[317] Otherwise, vaccination, until recently, has been recommended only for persons working in laboratories and animal handlers working in facilities where orthopoxviruses are used.[198]

Recommendations for wider use of the vaccine are under review in some countries because of the threat of use of smallpox as a biological weapon. By the end of 2002, the United States had acquired sufficient vaccine to permit, if necessary, vaccination of the entire country. Because of the substantial risks associated with vaccination, this was not considered desirable unless the risk of release of smallpox virus was substantial. As additional vaccine has become available, it has been possible to consider several options for its use. In a preevent setting (zoonotic orthopox outbreak, bioterrorism act involving variola or another orthopoxvirus), normal contraindications should be followed and the vaccine is only currently recommended for laboratory workers handling orthopoxviruses and for military personnel deployed to southeast Asia. In a postevent setting, everyone except severely immunocompromised individuals should be vaccinated with a replication-competent vaccine while individuals with immune deficiencies should receive an attenuated vaccine (IMVAMUNE) unless effective antivirals are immediately available.[388] The ACIP recommends that vaccination be undertaken to protect persons deemed to be at highest risk should an outbreak occur.[198] These would include smallpox public health response teams at federal and state levels who would be expected to investigate cases and smallpox healthcare teams composed of healthcare workers in acute care hospitals who would be expected to provide 24-hour care for acutely ill patients with smallpox in hospitals. In this plan, every acute care hospital would have the opportunity to establish smallpox healthcare teams, comprising emergency department, intensive care unit, and general medical unit staff; selected medical house staff from a variety of disciplines; medical subspecialists; infection control professionals; respiratory therapists; radiology technicians; security personnel; and housekeeping staff.

As a result, a national smallpox vaccination program was established.[333] It was initially hampered by concerns about possible risks of vaccination and workmen's compensation issues should vaccine-induced medical complications arise. Eventually, almost 40,000 civilian U.S. workers were vaccinated,[341] and some states continue to provide vaccine to select personnel, but this policy is no longer actively pursued. By vaccinating these groups, experience in vaccination was gained by those who would be responsible for vaccinating larger numbers should an outbreak occur and for caring for persons with complications of vaccination.[403] Similarly, this program allowed for the development of surveillance and review procedures to track adverse events related to smallpox vaccination.[404,405] At the same time, several million U.S. military personnel considered at elevated risk have been vaccinated since late 2002.[317,333]

The current risk of natural exposure to smallpox is zero and the risk of exposure from intentional release of variola as a biological weapon is considered to be low; therefore, current ACIP recommendations are to limit preexposure vaccination to selected groups with work-related contact with poxviruses. In case of a smallpox release, ACIP recommends vaccination of the following groups: (a) persons exposed at the site of initial release; (b) persons who come into face-to-face contact with, proximity of, or household contact of persons exposed at the site of initial release; (c) personnel involved in the medical care, public health evaluation, or transport of patients with known or suspected smallpox; (d) persons involved in the collecting or processing of tissues, fluids, or other samples from patients with known or suspected smallpox; (e) any persons with an increased risk of contact with potentially infectious materials from a patient with smallpox (medical waste disposal, laundry services responsible for linen disinfection or disposal, janitorial services responsible for room cleaning and disinfection); and (f) other groups deemed necessary for appropriate response activities (military personnel, law enforcement, and emergency response). Insofar as possible, vaccination of persons in group 6 should be limited to those with no contraindications to vaccination.[198] Contraindications for administration of the smallpox vaccines (including immune deficiencies, cancer, use of immunosuppression drugs, skin disorders, and heart conditions) are discussed later in this chapter. In case of known exposure to smallpox, there are *no* contraindications, although individuals with a significant immunodeficiency might be better treated with VIG and antiviral medications rather than a vaccine to which they will likely not respond.

Meanwhile, some countries in Europe, Asia, and Latin America are contracting for supplies of vaccine, and a few vaccine production facilities are being prepared. The WHO is exploring mechanisms and resources to deal with an outbreak of smallpox wherever it might occur and is establishing a modest stockpile of second-generation vaccines. Constant vigilance and the availability of vaccine will be requirements far into the distant future.

CONTRAINDICATIONS AND PRECAUTIONS

The WHO recognized no contraindications to vaccination in areas that were endemic for smallpox for two reasons. First, the risk associated with smallpox infection was significantly greater than the risk of complications. Second, most vaccinations were performed by persons without medical training who could not be expected to recognize conditions such as eczema or to identify patients with immune deficiency syndromes. The WHO recommended that only patients who were extremely sick not be vaccinated because their subsequent death might be attributed mistakenly to vaccination.

In nonendemic areas, several conditions were and currently are accepted as contraindications. The major conditions include immune deficiency, atopic dermatitis and other skin conditions with open lesions or abraded dermis, pregnancy, and certain hypersensitivities.[257,389]

Immune Deficiency Disorders

Primary or acquired immune deficiency disorders include agammaglobulinemia, hypogammaglobulinemia, a variety of neoplasms, organ transplantation, certain autoimmune diseases, and AIDS. Persons with such disorders may be at risk for development of the sometimes fatal progressive vaccinia and should not be vaccinated. The ACIP does not require mandatory HIV testing before smallpox vaccination but recommends that HIV testing be readily available to persons who want to be tested or who have risk factors for HIV infection.[198] It is not known whether persons infected with HIV with higher CD4 cell counts could be safely immunized, although this is probable. Ten HIV-infected military personnel with median CD4 lymphocyte counts of 483 cells/mm^3 who were inadvertently vaccinated developed Jennerian lesions that healed without sequelae.[406] First- and second-generation vaccines are also contraindicated for persons receiving immunosuppressive drugs for the treatment of cancer or for organ transplant maintenance or receiving systemic steroid therapy (≥2 mg/kg per day or ≥20 mg per day for longer than 14 days).[198] The recent increase in the number and use of immune-modifying drugs also raises concern about vaccinia vaccination in such cases. No data are available on the safety of this vaccine in such cases, although substantial trials of MVA vaccine have been completed in atopic adults and patients with HIV with CD4 counts of more than 250 cells/mm^3, with no cases of eczema vaccinatum or progressive vaccinia.[179,407,408] In terms of immune response, at least one study found that vaccination

with MVA elicits similar antibody titers in HIV-infected subjects and uninfected controls.[409] Animal models show that vaccination with MVA also elicits robust, long-lasting $CD8^+$ T-cell memory.[410–413] These findings are supported by similar results in human vaccine studies.[268,414]

Eczema, Atopic Dermatitis, and Other Skin Disorders

Persons with a history of or active eczema or atopic dermatitis, irrespective of disease severity, are at special risk for the development of eczema vaccinatum after they or their close contacts are vaccinated.[198] Family members with eczema are at risk from contact spread of vaccinia virus, so the healthy vaccinee or the eczematous family member should live apart, if possible, until the lesion has fully scabbed over. Otherwise, strict infection control precautions, as described earlier (see "Excretion of Virus"), should be observed. Other skin conditions that may be of concern, if extensive, include acne, burns, impetigo, varicella zoster, herpes, psoriasis, open or surgical incision wounds, Darier disease, and contact dermatitis. It is best for vaccination to be deferred until the condition is resolved. If vaccine is administered, patients should be counseled in ways to prevent the transfer of vaccinia from the primary site to the affected area.[198] In a mouse model of eczema vaccinatum, MVA immunization did not cause satellite lesions and protected greater than 83% of animals against a lethal intranasal challenge.[415] These promising results indicate that third-generation attenuated vaccines may provide protective immunity for those individuals with contraindications for the conventional live virus smallpox vaccines.

Disorders of the Central Nervous System

Some countries considered disorders of the central nervous system in potential vaccinees to be contraindications to vaccination. It was hoped that this might decrease the risk of postvaccinial encephalitis, but there is no evidence that this diminishes the risk.

Pregnancy

Pregnant women are not vaccinated on the general principle that live viral immunizations should be avoided during pregnancy and because of the very low risk of fetal vaccinia. The ACIP does not recommend routine pregnancy testing of women of childbearing age before smallpox vaccination (other than verbal screening), but recommends the exclusion of women who are pregnant or intend to become pregnant within a 4-week period following vaccination.[198] Because fetal vaccinia seems to be an extraordinarily rare complication, inadvertent vaccination of a pregnant woman is not a reason to terminate pregnancy. Pregnant women who have direct contact with a patient with smallpox should be vaccinated.

Other Contraindications

Vaccine is contraindicated in persons with a history of acute hypersensitivity to vaccine components such as polymyxin B sulfate, streptomycin sulfate, chlortetracycline hydrochloride, and neomycin sulfate.[416] Because persons with certain inflammatory eye disorders (that predispose to itching or rubbing the eye) might be more likely to autoinoculate their eyes following vaccination, it may be best to avoid vaccinating them.

Some authorities recommended withholding vaccination from patients with various serious acute or chronic illnesses, hypothesizing that the response to vaccination might be abnormal. There is no evidence for this occurrence except that people with leprosy sometimes developed erythema nodosum leprosum or neuritis after primary vaccination.[417,418] In endemic areas, however, people with leprosy were vaccinated because the risk of smallpox substantially outweighed the risk of adverse events.

As mentioned, exemptions based on cardiac risk factors were adopted by the CDC in spring 2003, after several ischemic events occurred among recent vaccinees. Further assessment has not identified any elevated risk among vaccinees in the contemporary program or in retrospective evaluations of a mass vaccination program in New York City in 1947.[419,420]

PUBLIC HEALTH CONSIDERATIONS

Epidemiological Effects of Vaccination

Disease Control Strategies

As a consequence of the eradication of smallpox, disease control strategies are no longer needed. These efforts have been replaced with sensitive diagnostic assays and regular training for first responders to quickly and accurately identify, diagnose, and contain potential outbreaks.

Cost-to-Benefit Information

In the years preceding the eradication program, all countries were expending substantial funds to control smallpox and care for its victims or to vaccinate and operate quarantine programs to prevent the importation of disease. In India alone, the estimated cost of smallpox in 1967 was US$722 million (US$10 million used to control smallpox through vaccination, US$12 million to care for sick patients, and US$700 million in lost economic productivity). Even in the absence of endemic disease, the costs were tremendous. In the United States, the estimated cost associated with smallpox protection in 1968 was US$150.2 million (US$93.5 million to vaccinate and treat complications, US$42.2 million in lost productivity, and US$14.5 million for international traffic surveillance and related to delays in clearance of vessels).[12] Other countries, such as the United Kingdom and the Federal Republic of Germany, maintained special hospitals to be opened to receive patients when imported cases of smallpox occurred.

For the entire global eradication program, the overall cost was estimated at approximately US$300 million, of which US$100 million represented international assistance. The savings, as a result of cessation of vaccination and quarantine measures, has been estimated to be more than $1 billion annually.[12] The United States is estimated to realize in savings the total of all its contributions to the eradication program every 26 days.[421]

Smallpox Eradication

The first commitment to smallpox eradication was made in 1950 by the Pan American Sanitary Organization, which decided that year on a hemisphere-wide effort.[422] Freeze-dried vaccine was used in mass vaccination campaigns that, during the succeeding decade, eliminated smallpox from all countries except Argentina, Brazil, Colombia, and Ecuador.

The World Health Assembly considered smallpox eradication programs in 1950, 1952, 1954, and 1955. The first resolution for smallpox eradication, introduced by Dr. Brock Chisholm (WHO Director General), was rejected. In 1958, Dr. Victor Zhdanov, Vice Minister of Health of the Union of Soviet Socialist Republics (USSR), proposed to the World Health Assembly that a global smallpox eradication program be undertaken.[423] This second resolution was approved the

following year at the 12th World Health Assembly in May 1959.[424] During the succeeding 7 years, a number of countries embarked on mass vaccination campaigns, and several, including China, eliminated the disease. Overall, however, progress was disappointing, especially in Africa and the Indian subcontinent. Few countries voluntarily contributed resources, and the WHO, then preoccupied with a costly and disappointing global malaria eradication program, provided few of its own resources and little support.

Frustrated by lack of progress in the program, although skeptical about the feasibility of the concept of eradication itself, the World Health Assembly in 1966 decided to provide to the WHO a special allocation of $2.4 million annually for an intensified global smallpox eradication effort.[425] It expressed hope that the task might be accomplished within a 10-year period, that is, by December 1976.[426]

During the first year of this program, an estimated 10 to 15 million smallpox cases occurred in the 31 countries in which the disease remained endemic.[1] The eradication campaign was based on a twofold strategy: (a) vaccination campaigns in each country, using vaccine of ensured potency and stability, that would reach at least 80% of the population (a coverage level that would be assessed by independent teams); and (b) special programs to detect and isolate cases, and contain outbreaks,[427,428] called "surveillance and containment." Progress was not to be measured in terms of the number of vaccinations performed, as had been the practice, but in terms of a declining incidence of smallpox. This principle required the development of an effective case notification system and focused attention on measures to reduce incidence.

The strategy of surveillance and containment proved highly effective in controlling the spread of smallpox throughout the global eradication program, whether in villages or major cities.[152] It is the strategy that is given priority for the control of an outbreak should one occur in the United States, whether or not large-scale vaccination is also undertaken. The reason for this concept is straightforward—to detect cases as quickly as possible, to isolate them, and to vaccinate all persons who have been in contact with any cases since the time they became ill and the persons to whom the contacts might transmit infection if they become ill. The method originally was called "ring vaccination" by Dixon,[16] a term that some have erroneously interpreted to mean a geographic ring when, in fact, it means erecting a barrier of immune persons around the case and his or her contacts (following onset of symptoms) as quickly as possible.

The surveillance-containment strategy worked as well as it did because of a number of unique clinical and epidemiologic features of smallpox. First is the fact that smallpox virus, to sustain itself, must pass from one person to another, each of whom experiences a clinically obvious infection with rash. There are no persons with subclinical infection who can spread the disease unnoticed, and there is no animal reservoir. Thus, it is a simple matter to identify where smallpox is at any time and to know how and by whom it has been spread. An outbreak may be envisaged as a continuing chain of cases with control measures being directed at breaking the chain. Second is the fact that the person is able to transmit infection only from the time of onset of rash until scabs form. Although a patient normally experiences a 10- to 12-day asymptomatic incubation period after the patient is infected, the patient cannot transmit virus during this period. Thus, although an infected patient may contact many persons during the incubation period, the patient will not infect them. Next, the infected patient experiences a 2- to 3-day prodromal period before rash develops. With variola major, the Asian form of smallpox and the one of most concern, patients during the prodromal phase experience a very high temperature and serious systemic symptoms and generally take to bed. Even though they are very ill, they still cannot transmit infection to others until oropharyngeal and skin lesions begin to develop and the virus begins to be shed into the oropharynx. Not surprisingly, most patients are successful in transmitting smallpox only to household members and to persons with whom they have contact in the hospital.

The strategy of containment, therefore, is to identify contacts of a patient since the patient first became ill and to vaccinate the persons to whom an infected patient is most likely to transmit the disease. This strategy works because vaccination after exposure provides protection to the contact even when given 4 to 5 days after infection has been transmitted. Usually, the numbers of such contacts are comparatively few and include members of the infected person's household but not persons such as fellow passengers on trains or subways or fellow workers in an office complex. Hospital contacts are likewise of major importance. They include not only hospital staff, but also other patients and visitors. Most person-to-person contact results from droplets expressed by the patient from the mouth during speaking or coughing. The patients and visitors most likely to become infected are those who come within 6 feet of the patient. Such persons must be identified as soon as possible and vaccinated.

Patients who are severely ill with malignant or hemorrhagic smallpox and who may be coughing pose a special risk. Patients in such condition constitute only a small percentage of patients in whom smallpox develops, but they can generate fine-particle aerosols that can drift over very long distances within a building. Should such cases be admitted to a hospital without special infection control precautions, large numbers throughout the hospital might need to be vaccinated.

Provision of adequate supplies of fully potent vaccine was a critical initial problem.[429,430] Early surveys revealed that 90% of the vaccine produced in or provided to endemic countries failed to meet accepted international standards. Laboratories in Canada and The Netherlands agreed to test samples of all vaccine to be used in the program. Manufacturers collaborated in developing a detailed production manual, and consultants and equipment were provided to vaccine production laboratories in endemic countries. Donations of vaccine, primarily from the Soviet Union and the United States, partially met initial needs. By 1973, more than 80% of all vaccine for the program was produced in the developing countries.

During 1967, the first year of the program, 44 countries, 31 of which had endemic disease, reported 217,218 cases of smallpox. The endemic countries were Brazil, most countries of Africa south of the Sahara, and five countries in Asia: Afghanistan, India, Indonesia, Nepal, and Pakistan (which then included Bangladesh). Later surveys revealed that only approximately 1% of all cases were being reported. Thus, it is estimated that probably 10 to 15 million cases occurred that initial year in countries with a total population of about 1.2 billion.

Vaccination technique also improved, and, thus, results improved.[431] The WHO encouraged abandonment of traditional methods of vaccination by scarification or rotary lancet. Jet injectors were introduced in 1967 for programs in Brazil and western and central Africa, but they proved cumbersome, expensive to maintain, and not well adapted for use in sparsely populated areas. One year later, the bifurcated needle, developed by Wyeth Laboratories, proved extremely effective in multiple-puncture vaccinations, inexpensive, and easy to use.[432] By 1969, bifurcated needles were in use in all countries. Vaccination with the bifurcated needle required only one-fourth as much vaccine, and even illiterate village volunteers required less than an hour's training in proper use, and workers could vaccinate, on average, 500 persons per day.

Vaccination programs were developed or strengthened in all endemic and neighboring countries, the last of them beginning in 1971. Although the strategy also called for the improvement of national reporting systems and containment of outbreaks by special teams, such activities were slow to begin. It quickly became apparent, however, that these activities, referred to as the surveillance-containment strategy, could interrupt smallpox transmission more easily and quickly than anyone had imagined, even where vaccinial immunity was low.[100,212,428]

With increasingly greater emphasis on surveillance-containment activities, endemic smallpox steadily receded. It was eliminated from 20 countries of western and central Africa by 1970,[87] from Brazil in 1971, from Indonesia in 1972, and from the entire continent of Asia in 1975. Ethiopia halted transmission in 1976 and Somalia in 1977. The last naturally occurring case of smallpox developed less than 1 year after the originally projected 10-year target date, on October 26, 1977, in Merka, Somalia.[433] Two further cases occurred in 1978 as a result of a laboratory infection in Birmingham, England[434] and were the last known cases. Subsequently, many rumors of other cases have been investigated but found not to be smallpox.

To confirm eradication, WHO-organized international commissions visited each of the endemic countries and areas 2 years or more after the last recorded smallpox cases. In May 1980, the World Health Assembly, acting on the recommendation of a WHO global commission, announced that worldwide eradication had been achieved (see Fig. 54.2) and recommended that routine smallpox vaccination be discontinued.[1] The WHO established an international stockpile of vaccine should it ever be required and encouraged laboratories to destroy their stocks of variola virus or transfer them to one of two designated reference laboratories (WHO Collaborating Centres on Smallpox and Other Poxvirus Infections), at the CDC, Atlanta, Georgia, or the Research Institute of Viral Preparations, Moscow, Russian Federation.[435] All countries reported voluntary compliance with the WHO recommendations.[436] The last country to destroy its stocks was South Africa, in 1983.[12] By 1984, only the CDC and the Research Institute of Viral Preparations were known to have retained variola virus isolates. In 1994, the Russian isolates were moved to the State Research Center of Virology and Biotechnology (the VECTOR Institute), Novosibirsk, Russia.

For a more complete and detailed discussion of the history of smallpox and the eradication effort readers are encouraged to review this chapter in the sixth edition of *Vaccines* and are directed to several additional sources: *Smallpox and Its Eradication*,[12] which provides a detailed account of the eradication campaign, *The Greatest Killer: Smallpox in History*, by Hopkins (originally issued in 1983 under the title *Princes and Peasants*),[17] recent books by epidemiologists DA Henderson and William Foege who were intimately involved in the eradication campaign,[437,438] and detailed accounts of national eradication programs,[20,84,421,439–443] including a 2011 special supplement in the journal *Vaccine* to commemorate the 30th anniversary of the eradication of smallpox.[220]

FUTURE VACCINES

Smallpox vaccine use has seen an evolution over time because of disease eradication, changes in public perception of risk, concerns about bioterrorism, increasing outbreaks of zoonotic poxviruses, and increases in understanding of poxvirus immunity. Table 54.7 depicts the main categories of smallpox vaccines, each of which is described in subsequent paragraphs. In the absence of endemic smallpox, all new vaccines are routinely compared against products such as Dryvax or Lister that are known to induce protective immunity. Approval for clinical trials and eventual production are dependent on noninferiority to the previously licensed products and on test results from multiple animal models according to guidelines from the FDA's "animal rule."[444]

First-Generation Vaccines

The relative risks and benefits of vaccination have changed with the eradication of smallpox. The most successful vaccines contained live vaccinia virus and were crude products. Vaccinia virus was applied to the shaved and abraded skin on the flank of a calf or sheep; the animal was killed after 7 to 8 days, and the crude vaccinia pulp was scraped off; the pulp was purified; and the product was freeze-dried. Inevitably, the vaccine contained some bacteria, but the number was minimized through use of carefully cleansed animal facilities, and the final product was always tested for possible pathogens. Most smallpox vaccines that were produced from the late 1800 s through 1980 are called first-generation vaccines.

After smallpox was eradicated, vaccination ceased and vaccine production facilities were dismantled because they were of no use for producing other vaccines. Such limited quantities of vaccine as were required were drawn from stockpiles stored at −20°C. With the recognition that smallpox might be used as a biological weapon, the United States decided that a large supply of vaccine should be produced to avert a potential catastrophe should smallpox virus be released. It was decided that a contemporary vaccine should be produced using tissue cell culture production. The product, called ACAM2000, is referred to as a second-generation smallpox vaccine.

Second-Generation Vaccines

As the perceived threat of smallpox as a biological weapon grew, there were efforts to replace dwindling old vaccine stocks to protect largely naïve populations. They are tissue culture–based products containing the same viral strains used in earlier smallpox vaccines. The most prominent of these new formulations is ACAM2000. This vaccine was derived from the original NYCBOH strain[445] and subsequently underwent safety testing in small animal models.[178,446] Vaccines based on tissue culture production methods are better characterized, free of adventitious agents, and possibly somewhat safer than lymph-based preparations. These products contain live vaccinia virus, so it is not surprising that immunogenicity testing and clinical trials have shown take rates, resulting antibody titers, and induction of cellular immunity similar to those of first-generation vaccines.[179,316,447] However, these vaccines also induce a similar spectrum of immediate (fever, headache, lymphadenopathy, malaise) and cutaneous reactions,[448] and can result in the same more serious adverse events discussed earlier. The majority of the present U.S. national strategic stockpile of smallpox vaccine consists of ACAM2000.[449]

Several additional second-generation vaccines have shown promise in clinical trials. Dynport has developed a cell-culture smallpox vaccine grown in MRC-5 human diploid fibroblasts. In a clinical trial directly comparing cell-culture smallpox vaccine with Dryvax, both vaccines induced similar levels of neutralizing antibody titer and similar quantities of interferon-γ–producing T cells and had similar rates of local adverse events.[450] Another cell-culture–derived product, CJ-50300, developed in South Korea,[210] was highly immunogenic, with the vaccine take rate and the rate of induction of high-titer antibody responses at 99%. Cellular immunity developed in 89% of vaccinees. Although this study did not directly compare CJ-50300 and a first-generation vaccine,

TABLE 54.7 Historical and Modern Smallpox Vaccines[a]

Name	Strain/Antigen Source	Production Method	Description
First-Generation (Classical, Live Virus Vaccines Used During Eradication Efforts)			
Dryvax	NYCBOH	Freeze-dried, lymph	Live vaccine used in United States
SPSV	NYCBOH	Frozen liquid, lymph	Live vaccine used in United States
Lister	Lister/Elstree	Chick chorioallantoic membranes	Live vaccine used worldwide
Lancy-Vaxina	Lister	Freeze-dried, lymph	Live vaccine used worldwide
EM-63	NYCBOH	Freeze-dried, lymph	Live vaccine used in Russia
Temple of Heaven	Tian Tian	Freeze-dried, lymph	Live vaccine used in China, greater percentage of adverse events than NYCBOH or Lister vaccines
Second-Generation (Live Virus, Cell Line–Produced Vaccines Based on First-Generation Vaccine Strains)			
ACAM1000	NYCBOH	MRC-5 cells	Interim Acambis product no longer in production
ACAM2000	NYCBOH	Vero cells	Acambis product with similar immunogenicity as Dryvax
Elstree BN	Lister/Elstree	Chick embryo fibroblasts	Bavarian Nordic product based on Lister strain
CCSV	NYCBOH	MRC-5 cells	Dynport cell-cultured smallpox vaccine
CJ-50300	NYCBOH	MRC-5 cells	Korean vaccine with similar reactogenicity and immunogenicity as Lancy-Vaxina
Third-Generation (Live Attenuated Virus Vaccines)			
MVA	Ankara	CEF	Lost 15% of genome during passage; limited use during eradication efforts
LC16m8	Lister	Cell line	B5R deletion mutant, used in Japan, improved safety over live vaccines
NYVAC	Copenhagen	Cell line	Missing 18 immunomodulatory genes
dVVL	NYCBOH	Cell line with UDG activity	Missing UDG; nonreplicating
ACAM3000	Ankara	Cell line	MVA-based formulation developed by Acambis
IMVAMUNE	Ankara	Cell line	Bavarian Nordic MVA-based vaccine
TBC-MVA	Ankara	Cell line	MVA-based vaccine in development at Therion
Fourth-Generation (Subunit Vaccines, Including Protein, Peptide, DNA Based)			
Protein-vaccine	A33, B5, L1, A27 proteins	Recombinant protein	Quadrivalent, alum-adjuvanted protein vaccine
4pox-VRP	A33, B5, A27, L1 genes	Alphavirus replicon vectors	Viral-like particle vaccine encoding for four poxvirus membrane proteins
VennVax	Multiepitope	DNA vector	T-cell peptide vaccine based on 25 HLA class II epitopes
Others	Various	Expression vector or cell line	Vaccine candidates are in various stages of research and development

[a]This table describes the different types of smallpox vaccines, the source of antigen or parental viral strain, the production method, and a brief description. Several of these vaccines represent temporary products no longer being pursued (e.g., ACAM1000), and others are at very early stages, requiring several years to a decade of additional research and development.

CEF, chicken embryo fibroblast; HLA, human leukocyte antigen: MVA, modified vaccinia virus Ankara; NYCBOH, New York City Board of Health; UDG, uracil-DNA-glycosylase.

measures of humoral and cellular immunity in vaccine recipients were similar to those elicited in subjects receiving Dryvax.[451]

Third-Generation Vaccines

Attenuated vaccinia strains form the basis for the third-generation vaccines. These include replication-competent (LC16m8) and replication-defective (MVA) vaccinia viruses. Attenuated vaccines would be particularly suited for use in persons who are immunocompromised and thus, at special risk of developing progressive vaccinia, and in persons with severe eczema or exfoliative skin conditions. A modern understanding of the genetics of vaccinia and the ability to manipulate the genome have led to the development of additional vaccine strains to complement the products based on the earlier strains.

LC16m8 was produced by Hashizume in the 1970s by repeated passage of Lister-strain vaccinia at low temperature in rabbit kidney cells.[452–454] The attenuated vaccine virus replicates in the skin but is replication-deficient at human body core temperatures and is thus expected to have less potential for inducing adverse events in humans. This strain produced HI and neutralizing antibodies in humans and, in a field trial of 50,000 children, produced markedly less-severe cutaneous reactions and less fever than other strains.[455] Studies in immunocompromised animals show that LC16m8 is much safer than unattenuated vaccinia strains.[456] A clinical trial

involving the administration of LC16m8 to several thousand participants was recently conducted in Japan and showed similar immunogenicity to Lister strains, no serious adverse events, and lower frequencies of minor adverse events (fever, swelling, itching, and headache) than seen with first-generation vaccines.[457] Mice, rabbits, and monkeys vaccinated with LC16m8 have been protected against challenge with, respectively, ectromelia, rabbitpox, and monkeypox.[458–460] This strain has been licensed for use by Japanese government authorities, who have purchased some 56 million doses for Japan's national stockpile.

Progress is also being made in developing nonreplicating third-generation vaccines such as MVA.[138,461] A modern understanding of the genetics of vaccinia and the ability to manipulate the genome have led to the development of additional vaccine strains to complement the products based on the earlier strains. There are concerns that these attenuated vaccines induce lower levels of humoral and cellular immunity that may not last as long as the responses elicited by replication-competent vaccines.[462,463] On the other hand, nonhuman primate studies have shown protection against lethal challenge with monkeypox.[462,464] These vaccines would likely be used in a multidose regimen: the first dose of attenuated vaccine used to induce partial immunity and reduce the frequency and severity of side effects upon receipt of a subsequent dose of live virus vaccine (such as ACAM2000). Because 6 weeks would be required for full immunity to develop, such vaccines would be of limited use in coping with epidemic smallpox.

MVA is a live, nonreplicating form of vaccinia virus developed in Germany in the 1950s and 1960s.[12,465] The virus originates from a Turkish vaccine strain (Ankara) that had been used for routine vaccination for many years and was propagated at the Ankara Vaccination Station. The MVA form was derived by more than 500 serial passages of the Ankara strain in primary chick embryo fibroblasts resulting in the loss of approximately 15% of its genome and the ability to replicate in most mammalian cell types.[466,467] It was originally intended to be administered as a prevaccination intradermal injection to be followed by scarification with the replicating Lister vaccinia virus 1 to 2 weeks later. Published German reports from the 1960s indicate that some 120,000 persons had been given MVA vaccine without known complications.[12] However, the titer of the MVA vaccine used in the German studies was some 100 times less than is now intended, and the MVA vaccinia strain, since the 1960s,[138] has undergone multiple additional passages. Newer studies (see next paragraph) also indicate that the vaccine is safe, but it is probable that not more than 20,000 have been vaccinated in the course of these studies, far too few to examine the rates of serious adverse events.

Several companies have MVA-based products in development, including IMVAMUNE,[463] TBC-MVA,[414] and ACAM3000.[468] IMVAMUNE has been found to be safe, well tolerated, and immunogenic in Phase I clinical trials[138] and has completed Phase II clinical testing[469] during which it was determined that two doses are necessary to elicit immune responses similar to those of Dryvax or ACAM2000.[470] Animal studies supported the need for a prime-boost vaccination schedule.[471] Further work is being performed to ascertain the usefulness of IMVAMUNE as a priming vaccine preparatory to immunization with the second-generation ACAM2000 vaccine in the hope that priming would reduce local and systemic reactivity to the live virus vaccine.[472] Phase I/Ib trials of TBC-MVA have shown that vaccination with MVA reduces the severity of local symptoms and lesions on subsequent Dryvax immunization.[414] A recent clinical trial testing increasing doses and different immunization routes with ACAM3000 found that all doses and routes were well tolerated.[473] No serious adverse events occurred, while self-limiting, local and systemic reactions (headache, local swelling and discomfort, fever, malaise, nausea) occurred in half of the subjects. A separate study found that doses above 2×10^8 plaque-forming units [PFU] resulted in a significant increase in malaise, nausea, and "flu-like" symptoms.[474] Neutralizing antibody response and cellular immunity (interferon-γ enzyme-linked immunosorbent spot [ELISPOT]) were detectable at least 180 days after vaccination. A companion trial examining the effect of ACAM3000 priming on subsequent Dryvax inoculation found similar results as the TBC-MVA study discussed previously, providing further support for the prime-boost vaccination strategy.[414] If an outbreak of smallpox does occur, (a) there will be relatively few contraindications for the live virus vaccines (e.g., severe immune deficiency), and (b) rapid containment is critical and IMVAMUNE does not provide protection until approximately 2 weeks after the second dose. These conditions, as well as cost considerations, make it difficult to determine the utility of widespread use of the stockpiled MVA-based vaccines in a biological attack or outbreak scenario.

Additional attenuated vaccinia strains are also under investigation as potential vaccines. NYVAC, was developed in the United States in the 1980s. It stemmed from the observation that 50 or more of the nearly 200 genes of vaccinia virus are dispensable for replication in tissue culture cells and that deletion of some of these genes reduced virulence in animal models.[475–477] In all, 18 genes were deleted from the Copenhagen strain of vaccinia virus to produce this strain.[478] Several studies indicate that NYVAC has potential for a human vaccine, perhaps to be used as would the nonreplicating MVA strain.[479,480] dVV-L is a Lister derivative missing the uracil-DNA-glycosylase gene.[481] This strain can grow only in cell lines complementing the deleted enzyme. As with other attenuated strains, it too requires high doses and multiple vaccinations to induce the same levels of immunity seen with first- and second-generation vaccines.[482,483] Selective combination of these vaccines with appropriate adjuvants may serve to boost immunogenicity to the levels seen with second- and third-generation vaccines.[484]

A significant problem in developing attenuated strains is that a definitive assessment of their efficacy is now impossible. Because of the absence of human smallpox cases, a determination of efficacy under the conditions of a natural challenge is not possible; in addition, there is no suitable animal model of variola virus infection, and surrogate serologic measures of protection are unknown. The evaluation of efficacy thus will have to rely on comparison of serologic responses with those induced by the NYCBOH (ACAM2000) or Lister strains and challenge of vaccinated monkeys with aerosols of monkeypox virus.

Fourth-Generation Vaccines

Increased understanding of poxvirus immunology, the identification of T- and B-cell epitopes, and advances in reverse immunology approaches have made feasible the development of fourth-generation subunit smallpox vaccines. Numerous vaccine candidates are in various stages of research and development. Among the most promising candidates are combinations of MV and EV proteins (most notably, A27, A33, B5, and L1) that, when injected as DNA or protein formulations, elicit strong, protective immune responses to a number of poxviruses, including vaccinia, ectromelia, and monkeypox.[485–489] Other subunit vaccine examples include a multiepitope, peptide-based DNA vaccine,[490] a B5R protein–based vaccine produced in plants,[491] and an inactivated, mucosal vaccine.[492] Peptide vaccines based on HLA supertype motifs capable of inducing immune responses in large portions of the

population are also being considered.[272,273,289,290,292,493] These subunit vaccines have several notable advantages: well-defined composition, lack of viral/bacterial contaminants, easy adaptability to multivalent applications, rapid and cost-effective production, and increased safety profiles.

Despite the eradication of smallpox, poxviruses remain a public health threat as an agent of bioterrorism and because of an increasing number of zoonotic outbreaks such as those involving monkeypox in Africa and the United States,[104,494–496] vaccinia viruses in South America,[497–499] buffalopox in India and Pakistan,[500] and cowpox in Germany.[501,502] Furthermore, previously uncharacterized poxviruses are being seen for the first time as they cause human infections.[503–506] Thus, these new vaccine candidates (and antiviral compounds) may be used in biodefense and to protect against and contain natural disease outbreaks.[507] The current consensus view is that of a need for a vaccine with fewer complications, that is more antigenic (preferably requiring a single dose), is cost-effective, has a long shelf life, and can be readily stockpiled. As we move forward with research and product development in this area, it will be important to align global and local public health objectives with various national security goals and realistic financial considerations given the immense costs involved.

DESTRUCTION OF THE VIRUS

After 1980, when the World Health Assembly declared that eradication had been achieved, many countries questioned whether it would be prudent to destroy the known remaining laboratory stocks of variola virus to provide added assurance that the virus might not accidentally or deliberately be released into an unprotected world. The first official recommendation to destroy the known stockpiles of variola virus was made in 1994 by the WHO Expert Committee on Smallpox.[508] This recommendation was made after almost 10 years of scientific review and expert consultations. This recommendation was then discussed at multiple World Health Assemblies as arguments were advanced supporting[509] and objecting to[510] destruction of the virus stocks. Arguments against destruction stemmed from concerns that it would prohibit significant advances in understanding the pathogenesis of variola virus and that destruction of the two known repositories would not guarantee that forgotten or hidden stocks of virus were not preserved elsewhere.[511] This point was brought into focus in July 2014, as researchers at the National Institutes of Health discovered several vials containing viable smallpox virus in a freezer on their Maryland campus.[512] Arguments for destruction of the virus stemmed from concerns that an unintentional release of virus in an increasingly susceptible global population would lead to a serious outbreak, that all should be done to ensure that smallpox never again would afflict humankind, and that the available cloned DNA fragments and sequence information of several strains of variola were sufficient to allow scientific inquiry into the virus and an understanding of its properties.

Since that original recommendation, the destruction of the viral stocks has been postponed multiple times to complete specific research projects requiring variola virus.[513–516] Dissatisfaction by a number of countries with the progress of these research programs resulted in further debate at the World Health Assemblies of 2006 and 2007. The WHO Director General then arranged for the publication of a comprehensive report documenting published and unpublished research involving variola virus during 1999 to 2010.[9,517,518] Subsequently, a separate advisory group of independent experts from outside the variola virus field reviewed this material and reported to the 2011 World Health Assembly.[516,519,520] This Assembly reaffirmed the need to destroy the remaining stocks of smallpox on completion of crucial variola virus research. Progress in this regard was reviewed in 2014 at the 67th World Health Assembly but the decision was delayed yet again.[521] We agree that the elimination of the last remaining stocks of variola virus will reduce (but not necessarily eliminate) the risk of a smallpox virus release; nevertheless we believe that this outweighs the potential benefits of further research requiring live variola virus and are in favor of destroying the official virus stocks.[522,523]

55 *Staphylococcus aureus* Vaccines

Robert S. Daum

More than a century ago, the Scottish surgeon Alexander Ogston first noticed an association between skin abscesses and an organism that formed structures resembling clusters of grapes when seen by light microscopy.[1] The organism he saw, *Staphylococcus aureus*, is now known to be a commensal that is also responsible for many serious community and nosocomially acquired infections and several more recently recognized toxin-mediated diseases. It is also the most frequently isolated bacterial pathogen from patients with hospital-acquired infections.[2] Among staphylococci, the defining characteristics of this species are the production of the extracellular enzyme coagulase and protein A. Staphylococci lacking coagulase are grouped under the designation coagulase-negative staphylococci (CoNS). Once thought to be nonpathogenic constituents of human bacterial flora, the approximately 16 species of CoNS isolated from humans are now also known to cause nosocomial infections and urinary tract infections in children, catheter-related infections, prosthetic joint infections, endocarditis, and septic episodes in premature infants and other immunocompromised hosts.[3] Although CoNS can be important pathogens in certain settings, vaccine development has been focused primarily on *S. aureus*, the subject of this chapter. CoNS isolates also colonize human skin universally,[4] and multiple strains may be isolated from the same person.

ECOLOGY

Staphylococci usually have a symbiotic relationship with their human hosts. The traditional view is that asymptomatic *S. aureus* colonization occurs intermittently in between 10% and 40% of children and adults, with children having somewhat higher colonization rates than adults.[5–9] Nasal carriage is widely believed to be a risk factor for invasive disease.[10,11] In addition, the skin, hair, nails, axillae, perineum, rectum, and vagina (in approximately 10% of menstruating women) may be colonized.[12–14] Three patterns of colonization by *S. aureus* have been reported: approximately 20% of the population is persistently colonized, 60% is intermittently colonized, and approximately 20% is never colonized.[15] Hospital personnel, persons with chronic skin conditions, individuals with implanted medical devices, people who indulge in intravenous substance abuse,[16] patients with type 1 diabetes, patients undergoing hemodialysis, and patients with AIDS have higher rates of asymptomatic *S. aureus* colonization than do persons in the general community.[5]

As a result of using new methodology for detection, higher rates of asymptomatic colonization have been reported, even among healthy people. A rate of 65% to 75% has been documented,[13] and some believe that colonization may even be universal, depending on the method used for sampling. Most of these strains associated with asymptomatic colonization are bacteria from genetic backgrounds that have not been isolated from infectious material. Thus, *S. aureus* is a commensal that is occasionally responsible for active infection.[17]

Conversely, most methicillin-resistant *S. aureus* (MRSA) strains that asymptomatically colonize are from genetically pathogenic backgrounds; the explanation is unclear. Moreover, the nose is not the commonest site of asymptomatic colonization of any *S. aureus* strain and colonization of a single individual by multiple *S. aureus* strains is common.[18–28]

An epidemic of *S. aureus* infections in the United States, with onset in the mid- to late-1990s intensified interest regarding this important pathogen. The emergence of several *S. aureus* genetic backgrounds, mainly USA300 MRSA, circulating in the community as methicillin-resistant clones, so-called community-acquired MRSA (CA-MRSA), exponentially increased the burden of disease in many areas.[29] *S. aureus* is now the most frequent pathogen isolated from children.[30] The rate of asymptomatic colonization with methicillin-resistant strains has increased and was reported to be as high as 22% in children in Texas.[31] Virulence determinants in these CA-MRSA strains have been recognized that are apparently new to the species, such as the ACME element with its attendant gene[32]; increased in frequency, such as the Panton-Valentine leukocidin; or increased in expression, such as alpha toxin.[33] This increase in the clinical burden of *S. aureus* disease associated with this epidemic has initiated discussions about the possible need for a universal immunization strategy.

CLINICAL SPECTRUM

When not acting as a commensal, *S. aureus* is a major cause of morbidity and mortality. It is the most virulent member of the genus *Staphylococcus.* Unlike other members of the genus, *S. aureus* is well endowed with a variety of virulence factors (Fig. 55.1).

Superficial and invasive *S. aureus* infections occur in previously healthy persons. Infections of the skin range from impetigo to abscess formation, cellulitis, or lymphadenitis, particularly of the cervical lymph nodes in children or adjacent to an infectious focus. *S. aureus* also may cause several important ocular infections, including conjunctivitis, preseptal cellulitis, and endophthalmitis. *S. aureus* is an important cause of endocarditis and is the leading cause in many regions of the world.[34] The infected heart valves may have been previously normal, especially when the mitral or aortic valves are involved and the clinical manifestations may be particularly severe. Pericarditis may be an isolated syndrome or may accompany endocarditis.

Hematogenous seeding of a bone or joint may result in osteomyelitis, septic arthritis, or even bursitis. *S. aureus* is a cause of several respiratory tract infections, including an occasional otitis media and pneumonia. The latter may be a severe, necrotizing process with high mortality. Central nervous system infections are infrequent and usually involve an assisted portal of entry for the organism, such as extension from an infected sinus, a dermal sinus, or a meningomyelocele. Central nervous system infectious syndromes also include subdural and epidural empyemas and even meningitis.[35] A spinal epidural abscess adjacent to the dura also may be caused by *S. aureus*. *S. aureus* may rarely infect the urinary tract or be recovered from the urine of a patient with high-grade bacteremia or a renal abscess.

S. aureus frequently complicates surgical procedures in which the integument was breached and indwelling foreign bodies are left in place.[36] The insertion of plastic, metal, or Gore-Tex devices provides an opportunity for *S. aureus* to

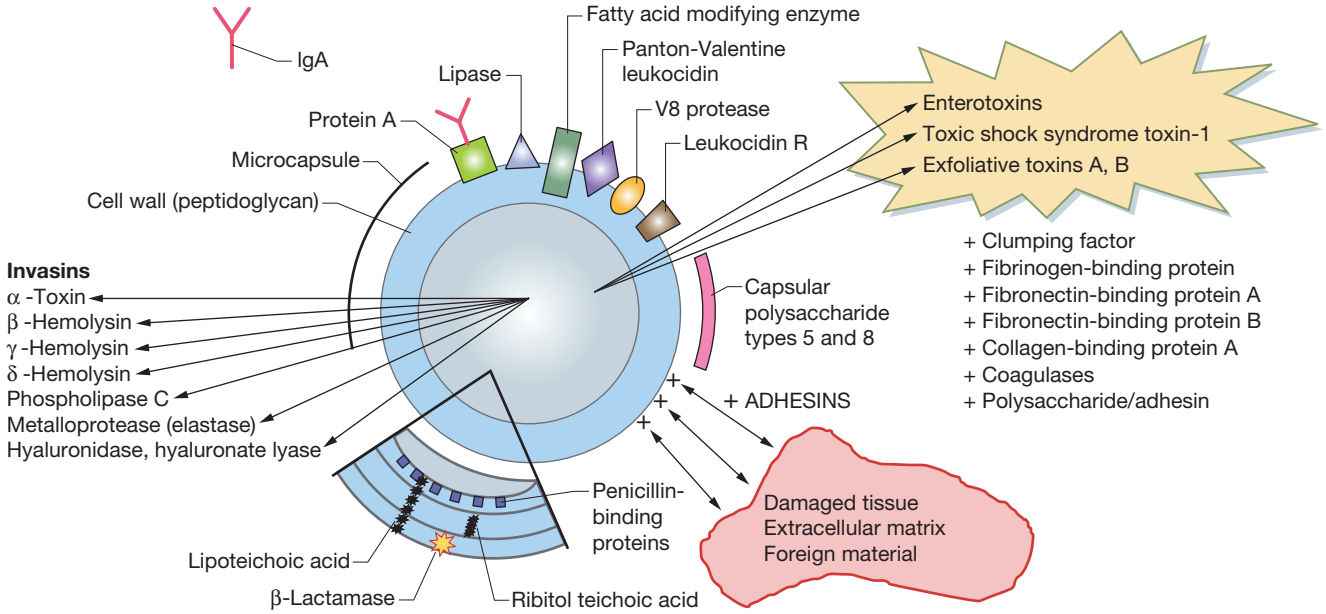

Figure 55.1. Virulence factors of *Staphylococcus aureus*. IgA, immunoglobulin A. *(Modified from Lowy FD. Medical progress:* Staphylococcus aureus *infections.* N Engl J Med. *1998;339:520–532.)*

adhere, causing persistent infection. Success in eradicating the organisms from the inserted device often poses major challenges, even when the isolate is susceptible to the antibiotic used. Thus, certain patients, such as those needing hemodialysis, those with indwelling venous catheterization, indwelling intravascular Gore-Tex patches, artificial prostheses, or cerebrospinal fluid flow diversionary devices, are at high risk for *S. aureus* infections.

A variety of veterinary infections are also caused by *S. aureus*. For example, mastitis in cows is an economically important disease. Horses, chickens, dogs, and cats are among the animals known to be colonized or infected with *S. aureus*, with documented transmission to humans from horses.[37] Mounting evidence suggests that pigs may represent a new important reservoir for CA-MRSA strains. ST398 is the most commonly reported sequence type among livestock in Europe and the United States. Transmission to pig-farm workers has occurred, although invasive disease has rarely been documented.[38–41]

Although veterinary vaccines have been developed for *S. aureus*, particularly in cows,[42,43] they are not discussed in this chapter.

S. aureus is also the cause of a number of toxinoses with clinical manifestations that reflect the effects of one or more elaborated and released exotoxins. Examples include toxic shock syndrome (TSS), scalded skin syndrome, and food poisoning.

Attention has been called to septic illnesses caused by *S. aureus* with multiorgan failure that likely reflect the activity of one or more *S. aureus* toxins. Examples include so-called severe sepsis,[44] an illness with a sometimes fulminant course, purpura fulminans,[45] and the Waterhouse-Friderichsen syndrome.[46]

PROBLEM OF ANTIMICROBIAL RESISTANCE IN *STAPHYLOCOCCUS AUREUS:* EPIDEMIC COMMUNITY-ACQUIRED METHICILLIN-RESISTANT DISEASE

Before the introduction of antimicrobials in the early 1940s, the mortality rate of invasive *S. aureus* infections was approximately 90%; this rate decreased markedly following the introduction of penicillin G into clinical practice.[47] Almost immediately, however, a few *S. aureus* isolates were noted to be resistant to penicillin.[48–50] By the end of the 1940s, most strains isolated from hospitalized patients were penicillin-resistant[51]; currently, resistance rates exceed 90%, rendering penicillin virtually ineffective in treating *S. aureus* infections. The mechanism of resistance is the elaboration of a β-lactamase, usually encoded by a transposon borne on a plasmid; there is also cross-resistance with other β-lactams that are susceptible to β-lactamase hydrolysis.

In the early 1960s, methicillin, representative of a new class of semisynthetic β-lactam antibiotics that are relatively resistant to hydrolysis by staphylococcal β-lactamases, was marketed. However, resistance to it was immediately recognized.[52,53] Such resistance is still referred to as MRSA, although methicillin is uncommonly used in clinical practice. MRSA isolates survive β-lactam exposure by elaborating a peptidoglycan-synthesizing enzyme called penicillin-binding protein (PBP) 2a that, in concert with native PBP2, allows peptidoglycan synthesis to occur despite the presence of a β-lactam compound. This resistance mechanism conveys cross-resistance to all β-lactam antibiotics, including cephalosporins except for ceftaroline.[54] Since their recognition, the prevalence of MRSA isolates has been slowly but steadily increasing,[55–57] but has now probably plateaued and may be declining. Institutional prevalence rates exceeding 45% are not uncommon.[58] One development has been the recognition of epidemic CA-MRSA infections in children and adults in many regions of the United States, elsewhere in North America, Western Europe, Asia, Australia, and South America who lack traditional MRSA risk factors such as frequent contact with healthcare facilities.[59] The MRSA isolates responsible for these community-acquired infections are less resistant to multiple antibiotics than their hospital counterparts; the genetic backgrounds of these isolates differ from their hospital counterparts, and the isolates usually contain novel, smaller chromosomal elements called staphylococcal cassette chromosome mec (SCC*mec*) IV or V[60,61] that may be more transferable to other staphylococcal organisms than the larger SCC*mec* elements found in hospital MRSA isolates. CA-MRSA isolates have been associated with

dramatic upsurges in the prevalence of *S. aureus* infections in general and rates of MRSA infections in particular.[62,63]

Vancomycin, a glycopeptide antibiotic, until recently had been the only agent to which MRSA isolates had remained uniformly susceptible. In the late 1990s, this susceptibility changed with the recognition of glycopeptide intermediate-resistant *S. aureus* (minimal inhibitory concentration of vancomycin, >2 and <16 μg/mL) isolates in Japan,[64] the United States,[65–68] and several other countries.[69–74] Often, patients with glycopeptide intermediate-resistant *S. aureus* isolates have been receiving dialysis and, therefore, have prolonged low-level serum vancomycin levels, an in vivo environment similar to that used to select for vancomycin-intermediate resistant mutants in the laboratory,[75,76] and have failed vancomycin treatment. More recently, higher level vancomycin-resistant *S. aureus* isolates have also been isolated from patients in the United States[77] with minimal inhibitory concentrations of vancomycin of more than 16 μg/mL. These isolates bear genes from vancomycin-resistant enterococcal strains that produce a structurally altered peptidoglycan precursor that does not bind vancomycin.[77] The occurrence of these isolates represents an important event that will greatly impact healthcare throughout the world.[78–80] The ever-evolving resistance mechanisms in *S. aureus* suggest that any antimicrobial therapy for this agent will be met with a resistance mechanism by the staphylococcus species. The situation with antibiotic resistance in *S. aureus* is certainly one issue that has spurred vaccine development.

Resistance to other antimicrobials active against *S. aureus*, such as linezolid,[81,82] tedizolid, daptomycin,[83] dalbavancin,[84] oritavancin,[85] and mupirocin,[86] has also been identified and is a source of clinical concern. This continuing saga of antimicrobial resistance in *S. aureus* and the slowing of the development of new antimicrobials is reminiscent of the clinical alarms sounded by resistance of *Haemophilus influenzae* type b to ampicillin and chloramphenicol, and resistance of *Streptococcus pneumoniae* to penicillin,[87] which suggested that infections caused by these important pathogens had become increasingly difficult to treat. In both instances, the deployment of an effective vaccine decreased these concerns. Effective prevention outpaced new concerns about therapy.

MICROBIOLOGY AND PATHOGENESIS

Staphylococci are hardy aerobic or facultatively anaerobic gram-positive bacteria that can persist in distressed environments such as acidic conditions, high sodium concentrations, and wide temperature variations; they can survive on fomites, in dust, and on clothing from several days to more than a week. Once *S. aureus* infection is established, local and systemic effects result from direct invasion, hematogenous dissemination, and/or toxin release.

Initially the organisms were thought to be nonencapsulated, but it is now clear that many clinical *S. aureus* isolates, and some CoNS isolates, have a polysaccharide capsule, sometimes called a microcapsule because of its thinness and adherence to the bacterial cell surface.[88] The prevalence of two capsular polysaccharide types (5 and 8)[89] in most collections of clinically important human and veterinary isolates suggests an important role for these polysaccharides in pathogenesis, although, to date, its nature is uncertain. These capsular antigens were targeted in a staphylococcal vaccine to be described subsequently.

The cell wall of *S. aureus* is composed of capsular polysaccharide, peptidoglycan, lipoteichoic acid (LTA), ribitol wall teichoic acid, and numerous surface proteins. Protein A, also an important surface protein, binds the Fc region of the immunoglobulin (Ig) G molecule[90–93] and decreases the efficiency of antibody binding to *S. aureus* isolates, reducing opsonization and phagocytosis.[94–97]

The virulence of *S. aureus* is the result of a combination of many elaborated virulence proteins that include extracellular products, such as α-,[98] β-,[99] γ-,[100] and δ-[101] hemolysins (or toxins); leukocidins[102]; proteases[103]; lipase[104]; deoxyribonuclease, a fatty acid-modifying enzyme[105]; and hyaluronidase.[106] Coagulase is an extracellular protein that binds host prothrombin to form staphylothrombin; this, in turn, activates thrombin and results in the formation of fibrin from fibrinogen.[107] A small amount of coagulase remains cell-bound. Clumping factors are distinct cell surface proteins that bind fibrinogen, thereby producing the typical clusters of staphylococci when mixed with plasma.[108] The pathogenic roles of coagulase and the clumping factors[109] have been uncertain; they may protect against host defenses by causing localized clotting, and clumping factors may aid in adherence to traumatized skin, endothelial structures, and foreign surfaces. Recognition of this role for *S. aureus* clumping factors has prompted investigation into their use as potential vaccine antigens, as reviewed subsequently.

α-Hemolysin, the best studied of the staphylococcal exotoxins, hemolyzes erythrocytes, leads to skin necrosis, and triggers the release of cytokines and eicosanoids that can produce shock. It is lethal when injected into animals,[110] and mutants lacking α-toxin are less virulent.[111] However, pathogenic *S. aureus* isolates that do not produce α-hemolysin have been identified. β-Toxin is a sphingomyelinase that damages membranes rich in this lipid, but its role in disease pathogenesis is uncertain. Although most human isolates do not express β-toxin, its elaboration by a majority of isolates associated with mastitis in cows suggests a potentially important pathogenic role, at least in that species.[112] δ-Toxin and leukocidins are synergohymenotropic toxins that damage membranes of certain cells as a result of in-concert action by several elaborated proteins. Interestingly, the transcription of the individual protein components is separate.[100,113] The high percentage of γ-leukocidin-producing isolates from necrotizing skin infections suggests the importance of this toxin in dermonecrosis. Another leukocidin, the Panton-Valentine leukocidin, has been found in cases of severe community-acquired pneumonia in children; the majority of those cases were fatal, and all were marked by hemorrhagic necrosis of the lung.[114] Controversy persists as to the role of this toxin in pathogenesis.

Other toxins, produced by specific *S. aureus* isolates, mediate specific clinical syndromes. For example, epidermolytic (exfoliative) toxins A and B cause sloughing of skin that occurs in staphylococcal scalded skin syndrome.[115] The mechanism of epidermal splitting is unknown, although the toxins have esterase and, possibly, protease activity.[116] The clinical characteristics of TSS can be attributed to the actions of two different types of toxins: TSS toxin-1 (TSST-1) and certain enterotoxins. TSST-1 can be elaborated by *S. aureus* and is responsible for most TSS cases and nearly all of cases associated with menses; antibody to TSST-1 is protective,[117] but patients with TSS often do not make antibody during convalescence from TSS. The family of *S. aureus* enterotoxins may cause vomiting and diarrhea when ingested and is responsible for staphylococcal food poisoning; these enterotoxins also may cause TSS when their entry is via a nongastrointestinal route. Enterotoxins B and C account for about half the TSS cases not associated with menses. The enterotoxins and TSST-1 can have superantigen activity, that is, they can stimulate T cells nonspecifically.[118] This nonspecific antigen T-cell stimulation results in release of immunomodulators, particularly cytokines, an event that produces the clinical picture of TSS. Superantigens bind to class II major histocompatibility complex receptors but recognize

only the V_β element of the receptor, resulting in nonspecific polyclonal T-cell activation.[119]

Locally, *S. aureus* organisms may invade or necrose tissue and evoke a potent inflammatory response that largely affects the interaction of bacteria and polymorphonuclear leukocytes. Abscess formation is common, with a necrotic center consisting of pus and a fibrin wall that makes penetration by antibiotics difficult. The infection may spread locally by the formation of sinus tracts and secondary abscesses. Hematogenous dissemination and infection of distant bones, joints, cardiac valves, or other tissues may result.

CoNS strains readily adhere to foreign bodies and cause infections that are difficult to eradicate without removal of the prosthetic material. Like *S. aureus*, CoNS have a cell wall composed of peptidoglycan and teichoic acid but with a glycerol backbone. The teichoic acid and surface proteins have a role in adhering to plastic and other foreign material.[120] In addition, secretion of material commonly called "slime" is thought to be important in the pathogenesis of infection because it coats foreign bodies, thereby insulating the organism; this, in turn, makes penetration by antibiotics and phagocytosis by host cells difficult. It has been surmised that *Staphylococcus epidermidis* isolates may be more likely than isolates of other CoNS species to produce slime.[121]

DO WE NEED A STAPHYLOCOCCAL VACCINE?

Available epidemiologic data suggest that *S. aureus* infections now constitute a public health imperative. MRSA infections have been the subject of recent population-based epidemiologic studies. Klevens and colleagues[122] estimated that there were 94,360 invasive MRSA infections in the United States in 2005 and 80,461 in 2011.[123] Liu and colleagues[124] found that one in 316 people in San Francisco sought medical care for a MRSA skin and soft tissue infection in 2004–05. At Fort Benning, Georgia, it was recently estimated that the attack rate for medically attended MRSA infections peaked at 42 per 1000 soldiers per year and exceeded 35 per 1000 soldiers per year in the two subsequent years that the study encompassed.[125] In 2008–10, the rate remained high at 27 per 1000 soldiers annually.[126] These data suggest an urgent need for improved strategies for control and prevention of *S. aureus* infections.

Although all would agree that *S. aureus* is an important pathogen with protean clinical manifestations, substantial controversy exists about whether *S. aureus* infections can be prevented by vaccination and, if so, who should be targeted to receive this preventive strategy. Various vaccine approaches have been used with varying levels of promise and success. Interpretation of the data should be done with an understanding of whether the chosen vaccine antigen was relevant, what immune response was measured, what clinical end point was sought, if the work was performed with the use of an animal model, and whether the pathophysiology in the animal model was relevant to the pathogenesis of human disease. With these thoughts in mind, the available data regarding vaccine development in *S. aureus* are reviewed.

VACCINE DEVELOPMENT

Live Whole-Cell Vaccines

Several investigators have used whole-cell vaccines with varying success at preventing certain *S. aureus* syndromes. A live attenuated vaccine strain has been derived from a *S. aureus* isolate from bovine mastitis mutated with nitrosoguanidine. The mutant was selected for its ability to grow well at low temperatures, such as those found in breast tissue, and to replicate poorly at 37°C. The vaccine was injected into the mammary gland of pregnant or lactating mice and produced IgA and IgG antibody responses in milk and serum as measured by an enzyme-linked immunosorbent assay using killed *S. aureus* as the coating antigen. This vaccine also primed CD4 and CD8 lymphocyte populations capable of responding to staphylococcal antigens in vitro and in vivo challenge.[127] Immunized mice had a 2-$\log_{10}$ decrease in the quantity of *S. aureus* recovered from milk after challenge. A similar decrease was not observed when the vaccine was given parenterally.[128] Thus, this whole-cell vaccine, injected locally, provided some protection against an infection with pathogenesis that involves access by the microorganism to the breast from the exterior. It is unlikely that a live bacterial vaccine, even if efficacious, would receive serious consideration today.

Killed Whole-Cell Vaccines

There was no vaccine efficacy when a formalin-killed whole-cell vaccine prepared clinical *S. aureus* isolate[129,130] was given parenterally to rabbits before *S. aureus* challenge in a model of experimental endocarditis. Following immunization, antibodies to *S. aureus* protein A and bacterial agglutination titers were detectable in serum at high levels. However, after intravenous challenge, the incidence of endocarditis, the concentration of *S. aureus* in infective vegetations, incidence of renal abscess, and the concentration of bacteria in infected kidneys[130] were not significantly different in the immunized animals and the unimmunized controls. Thus, systemic immunity against an invasive bacteremic disease syndrome was not achieved by systemic immunization with this killed whole-cell vaccine.

A similar vaccine, called Staphypan, consisting of a killed suspension of *S. aureus* cells combined with a "toxoided" α-hemolysin (α-toxin) was developed. After a complex immunization schedule consisting of 10 injections, the effectiveness of Staphypan was assessed in patients undergoing continuous ambulatory peritoneal dialysis. Among vaccine recipients, Staphypan was immunogenic stimulating a robust serum antibody response to α-hemolysin and to *S. aureus* cells in the dialysate of vaccine recipients. However, vaccine recipients had rates of peritonitis, catheter-associated infection, and *S. aureus* asymptomatic carriage that did not differ significantly from the unimmunized control group.[131] Although this patient population may have posed challenges for the demonstration of vaccine efficacy, and there were issues regarding choice of outcome parameters, the failure of this vaccine reinforces the difficulties faced in the choice of vaccine components. Put simply, if the whole-cell vaccine had poor efficacy, how does one proceed to selection of components for a component vaccine? Also, given this experience, it is unlikely that a killed whole cell vaccine would be evaluated for possible licensure.

Component Protein Vaccine Antigens

The choice of a relevant *S. aureus* protein in a component vaccine has obvious advantages over a whole-cell vaccine, particularly in an era of enhanced concern about vaccine safety. Investigators have attempted to identify one or more protective antigens among the many toxins or "virulence factors" elaborated by *S. aureus* as targets for vaccine development (Table 55.1). Substantial effort spanning many years has suggested that a fully efficacious single protective antigen is not likely to be the ideal vaccine candidate. Thus, efficacy of a candidate vaccine antigen often is measured by a decrease in disease severity without preventing infection per se. For example, immunization with either purified α-toxoid or β-toxoid in experimental model of mastitis in lactating rabbits,[132] demonstrated that both vaccines were immunogenic. In this model, mastitis, typified by abscesses at or near

TABLE 55.1 Virulence Factors as Potential Targets for Vaccine Development

Factor	Gene
VIRULENCE FACTORS INVOLVED IN ATTACHMENT	
Clumping factors	*clfA*, *clfB*
Fibrinogen-binding protein	*fbpA*
Fibronectin-binding protein A	*fnbA*
Fibronectin-binding protein B	*fnbB*
Collagen-binding protein	*can*
Coagulase	*Coa*
Polysaccharide/adhesin	*ica* locus
VIRULENCE FACTORS INVOLVED IN EVASION OF HOST DEFENSES	
Enterotoxins A, B, C1–C3, D, E, H, etc.	*sea-set* or *entA-T*
Toxic shock syndrome toxin-1	*tst*
Exfoliative toxins A, B	*eta*, *etb*
Protein A	*Spa*
Lipase	*Geh*
V8 protease	*sasP*
Fatty acid-modifying enzyme (FAME)	
Panton-Valentine leukocidin	*lukF-PV*, *lukS-PV*
Leukocidin R	*luk-F-R*, *lukS-R*
Capsular polysaccharide type 5	*cap5* locus
Capsular polysaccharide type 8	*cap8* locus
Staphylokinase	*Sak*
VIRULENCE FACTORS INVOLVED IN INVASION/TISSUE PENETRATION	
α-Toxin	*Hla*
β-Hemolysin	*Hlb*
γ-Hemolysin	*hlgA*, *hlgB*, *hlgC*
δ-Hemolysin	*Hld*
Phospholipase C	*Plc*
Metalloprotease (elastase)	*sepA*
Hyaluronidase, hyaluronate lyase	hysA

one or more teats, occasionally was complicated by a rapidly fatal, edematous, hemorrhagic mastitis with systemic manifestations termed "blue breast." Three clinically relevant *S. aureus* isolates were used for challenge of immunized animals. However, for two of the three isolates, α-toxoid prevented blue breast but not mastitis. The β-toxoid vaccine had no apparent efficacy against either clinical outcome.[132]

Protein A, a 40- to 60-kDa *S. aureus* cell wall protein encoded by the *spa* gene, is produced by nearly all *S. aureus* isolates. It binds to the Fc region of human IgG_1 and IgG_2 to mouse IgG_{2a} and IgG_{2b} with high affinity. It also binds with moderate affinity to human IgM, IgA, and IgE, and to mouse IgG_3 and IgG_1, but not to human IgG_3 or IgD or to mouse IgM, IgA, or IgE. The binding of protein A to the Fcγ region of the immunoglobulin molecule through interaction with the heavy chain results in improper orientation (when compared to normal antibody binding) and, thus, disrupts the role of the antibody in opsonization and phagocytosis. Protein A can therefore be considered a protective mechanism for the species shielding it from antibody "attack." Protein A has also been termed a B-cell superantigen[133] because it also binds to V_H3 B-cell receptors and limits their antibody production. Furthermore, marginal zone B cells and B-1 cells undergo, preferentially, induced cell death with supraclonal depletion and immune tolerance on exposure to protein A.

Thus, protein A likely impedes development of a vaccine that depends on the traditional approach of finding the protective antigen(s), demonstrating that it is immunogenic and generating opsonophagocytic antibody. It may also decrease antibody production by virtue of B-cell binding with resulting diminution in antibody production and B-cell apoptosis. Kim and colleagues[134] engineered a mutant protein A molecule that had mutations targeted to the immunoglobulin binding site and the V_H3 B-cell binding site and this mutant protein A SpA_{KKAA} did not bind the Fc fragment of immunoglobulins or trigger B-cell apoptosis. Immunization of mice with SpA_{KKAA} elicited antibodies that neutralized immunoglobulin binding activities of protein A, augmented the immunogenicity of unrelated antigens, and provided some protection in a mouse model of bacteremic *S. aureus* infection.[134]

Another approach for staphylococcal vaccine development has been targeting the bacteria–host cell adhesion. In the 1980s, the results of several studies indicated that *S. aureus* adhered to certain components of the host extracellular matrix.[135–138] Substantial effort has been invested in identifying these externally expressed bacterial proteins that mediate bacterial binding to host extracellular matrix. The proteins are collectively referred to as microbial surface components recognizing adhesive matrix molecules (MSCRAMMs), and they mediate *S. aureus* binding to host proteins including fibronectin, fibrinogen/fibrin, elastin, vitronectin, collagen, laminin, decorin, and heparan sulfate–containing proteoglycans.[139]

A recombinant collagen adhesin fragment was used to immunize mice, the animals were challenged with intravenous *S. aureus*, and the mortality in the immunized animals was decreased from 87% to 13%.[140] Immunization with another MSCRAMM, fibronectin-binding protein, effected a 2-log (99%) decrease in bacterial density in heart valve vegetations in experimental endocarditis.[141] Similarly, a fusion protein vaccine consisting of the fibrinogen-binding domain of fibronectin-binding protein A effected a 99.9% decrease in *S. aureus* density in the mammary glands of experimentally challenged mice after immunization.[142]

Another MSCRAMM, clumping factor A (ClfA), a surface protein that binds fibrinogen and fibrin, has been evaluated as a vaccine candidate.[143,144] ClfA differs from coagulase, which also binds fibrinogen, in that it promotes clumping of bacterial cells (the defining staphylococcal morphology of clusters) and bacterial adherence to blood clots and to plasma-conditioned biomaterials and catheter-damaged heart valves. In a mouse model of *S. aureus* arthritis, mice immunized with purified recombinant ClfA and subsequently challenged with *S. aureus* developed less-severe arthritis. In addition, passive administration of anti-ClfA antibodies was protective against experimental septic arthritis and death.[145] A DNA vaccine directed against ClfA with genetic adjuvants elicited IgG_2 anti-ClfA antibody and decreased *S. aureus* adherence to mammary gland epithelial cells.[146] Thus, ClfA is an important MSCRAMM that has induced partial or complete protection against invasive *S. aureus* infections in experimental animals. In human studies, a polyclonal anti-ClfA antibody administered to premature infants delayed the onset of naturally occurring *S. aureus* infections. However, this observation could not be confirmed in a prospective, randomized trial (S. Hetherington, personal communication, May 2006).

Perhaps a multiple MSCRAMM-containing vaccine would hold more promise. DNA vaccine directed against both ClfA and fibronectin-binding protein provided modest protection against experimental mastitis in dairy cows.[147]

Efforts are underway to identify other protective antigens. Merck has identified the iron-scavenging, cell wall–anchored protein isdB as a potential vaccine candidate.[148] Patients with *S. aureus* infections were shown to have a brisk antibody response to this protein during convalescence. The protein also was immunogenic in mice and rhesus monkeys.[148] A Phase I dose-range study[149] of the Merck adjuvanted isdB vaccine in 124 healthy adults demonstrated that a single 30- or 90-μg dose was more immunogenic than a 5-μg dose and that the immune response appeared by 10 to 14 days after vaccination and persisted through day 84.[149]

A Phase IIb/III double-blind, randomized, placebo-controlled, event-driven trial was conducted with a novel vaccine candidate called V710 that contained the unadjuvanted isdB. This trial, conducted between December 2007 and August 2011, enrolled 8031 patients 18 years of age or older who were scheduled to undergo a median sternotomy for heart surgery within 14 to 60 days after vaccination. It was an international trial conducted at 165 sites in 26 countries. However, the Data and Safety Monitoring Board recommended termination of the study in 2011 after concerns about safety and low efficacy. Although V710 vaccination induced a significant but modest and transient increase in functional antibodies, it was not significantly more efficacious than placebo in preventing *S. aureus* bacteremia or mediastinitis through postoperative day 90. In addition, the mortality rate and the occurrence of multiorgan failure was higher among the vaccinees, a finding that has not been explained.

Interfering with Nasal Colonization: A Valid Vaccine End Point?

Because the nares are believed to be the principal site of *S. aureus* colonization and because colonization appears to be a risk factor for invasive disease, several investigators have focused on novel immunization strategies aimed at decreasing nasal colonization as a method of decreasing invasive disease. ClfB is an *S. aureus* MSCRAMM that binds to fibrinogen and type 1 cytokeratin molecule K10 on the surface of desquamated human epithelial cells.[150,151] In mice, *S. aureus* mutants deficient in ClfB had decreased nasal colonization compared with controls,[152] suggesting that ClfB might be an attractive vaccine component to decrease nasal colonization. However, it is not clear whether ClfB decreases asymptomatic colonization at other body sites or if it selectively decreases nasal colonization of the more pathogenic *S. aureus* strains.

Carbohydrate Surface Molecules as Vaccine Candidates

Two lines of investigation have suggested that polysaccharides elaborated by *S. aureus* may be important protective antigens. The first concerns an in vivo–expressed[153] polysaccharide formerly called poly-*N*-succinyl-β-1-6-glucosamine, or PNSG, now termed poly-*N*-acetylglucosamine (PNAG). This intercellular adhesin was first recognized among strains of CoNS.[153] However, *S. aureus* isolates obtained from the lungs and sputum of patients with cystic fibrosis reacted with antirabbit anti-PNAG antibody as well. Additional study revealed that eight examined isolates all had the *ica*ADBC locus whose gene products synthesized PNAG among CoNS isolates. It was also appreciated that *S. aureus* strains elaborated PNAG in vivo, whereas in vitro, expression was minimal or undetectable. Rabbits immunized with purified PNAG produced high-titer anti-PNAG IgG antibody and passive administration of rabbit anti-PNAG antibody to mice significantly decreased or eliminated organisms after experimentally induced *S. aureus* kidney infection.[153] Active PNAG immunization of mice produced similar results.[154]

PNAG is structurally distinct from types 5 and 8 *S. aureus* capsular polysaccharides, studied in earlier vaccine studies. Interestingly, the elaboration of the type 5 or 8 capsules was found to be inversely related to the expression of PNAG, suggesting that staphylococci may choose to preferentially express PNAG in vivo. Moreover, cultivation of the *S. aureus* isolates in aerobic trypticase soy broth resulted in high capsular polysaccharide expression with an associated decreased PNAG expression. Although most clinical strains of *S. aureus* did not express PNAG in vitro,[153,154] subsequent data revealed that PNAG expression could be induced in vitro by growing the bacteria in a brain–heart infusion broth supplemented by glucose.[154]

Deletion of the *ica* locus resulted in decreased virulence of several *S. aureus* isolates in a murine model of *S. aureus* infection.[155] Human monoclonal antibodies directed against deacetylated or backbone PNAG epitopes (dPNAG) were shown to be opsonophagocytic and were modestly protective in a mouse model (high inoculum, intraperitoneal challenge, lethality end point).[156]

Thus, dPNAG, but not PNAG, is an immunogen that may be a protective antigen against *S. aureus* invasive disease. Both a monoclonal antibody prepared against dPNAG and a dPNAG vaccine will be evaluated in a planned clinical trial in 2016. Evaluation will be by human challenge experiments among bacterial infections that will not include *S. aureus*.

Recognition of the crucial role of the polysaccharide capsule in the virulence of *S. pneumoniae* and *H. influenzae* type b led to the development and deployment of highly successful preventive vaccine strategies currently in use in the United States and other countries. These vaccines rely on the notion that antibody to the capsular polysaccharide is opsonic and, thus, counters the antiphagocytic properties imparted by the capsular polysaccharide. The possibility that the *S. aureus* capsular polysaccharide is a similarly protective antigen and that a vaccine directed against capsule can greatly decrease the incidence of invasive staphylococcal disease has created enthusiasm for this approach, but the available data raise doubts about this concept.

Many *S. aureus* isolates are said to produce capsular polysaccharide. Four polysaccharide types—1, 2, 5, and 8—have been chemically characterized. Isolates elaborating the type 1 and type 2 polysaccharides are heavily encapsulated with mucoid colony morphology, but they rarely cause clinical disease. However, most clinical isolates do not elaborate a mucoid capsule like *H. influenzae* type b and *S. pneumoniae*, which shed capsular polysaccharide into the surrounding environment. In contrast, *S. aureus* capsular polysaccharide is shed only minimally if at all. Two types, 5 and 8, account for approximately 85% of encapsulated isolates from clinical sources. Because it was shown that antibody to the type 5 and type 8 capsular polysaccharides provided type-specific opsonophagocytosis[157] and conferred protection in animals,[158,159] although conflicting data exist,[160] a vaccine was prepared consisting of the type 5 and type 8 capsular polysaccharides, each bound to detoxified recombinant *Pseudomonas aeruginosa* exotoxin A expressed in *Escherichia coli*. This vaccine was evaluated in two clinical trials.[161]

The initial trial enrolled adults undergoing hemodialysis, a population at high risk for invasive *S. aureus* infections, and was conducted in 1998–99 among 73 hemodialysis centers. A total of 1804 subjects were randomized to receive either an *S. aureus* capsular polysaccharide–protein conjugate vaccine (100

μg of the types 5 and 8 polysaccharides) or placebo. Of the participants, 22% were asymptomatic *S. aureus* carriers. The primary end point for the study was the occurrence of *S. aureus* bacteremia at any time in the first year after immunization beginning 2 or more weeks after immunization.[161]

Although the vaccine was well tolerated, there was no significant efficacy observed from 2 to 20 weeks after immunization; 28 episodes of *S. aureus* bacteremia occurred (10 episodes in vaccine recipients and 18 in placebo recipients). However, at the 30- and 40-week postimmunization time points modest efficacy was noted (63%; 95% confidence interval, 14% to 86%, and 57%; 95% confidence interval, 10% to 81%, respectively). Furthermore, efficacy dissipated when observed at the 50-, 54-, and 91-week postimmunization time points, and was not significantly different in the vaccine recipients and controls. The investigators interpreted these data to indicate that the vaccine had provided some protection for about 40 weeks after immunization.

First, analysis of anticapsular antibody responses following immunization in the vaccine recipients was 80 μg/mL, a value vastly exceeding concentrations believed to be protective against other encapsulated bacteria, such as *H. influenzae* type b and *S. pneumoniae*. Second, there were no significant differences between the peak antibody levels achieved in the vaccinees who became bacteremic and those who did not. Third, the antibody concentrations peaked 6 weeks after immunization and declined thereafter, although significant protection was not observed until sometime later. Finally, approximately 20% of the isolates obtained from study subjects had neither the type 5 nor type 8 capsule, suggesting that other *S. aureus* antigens will have to be targeted in addition to types 5 and 8 for a successful vaccination program.

A second randomized, placebo-controlled clinical trial with this same bivalent capsular polysaccharide–protein conjugate vaccine was conducted in adult patients receiving dialysis at 200 sites in the United States. Efficacy was evaluated 3 to 35 weeks after immunization. A booster dose was administered, and participants were followed for 6 more months. This trial produced a clearer result in that there was no decrease in types 5 and 8 *S. aureus* bacteremia among vaccinees when compared with controls.[161]

Why did the types 5 and 8 conjugated capsular polysaccharide vaccine prove unsuccessful? There are several possible explanations. First, and most simply, the capsule may not be the protective antigen. Unlike the case with *H. influenzae* type b, *S. pneumonia* and *N meningitidis* in which it was clear that circulating anticapsular antibody was protective, no such demonstration has been made for *S. aureus*. Second, a relatively high frequency of isolates lacking the type 5 and type 8 capsule was found in the clinical trial.[162] It should be noted that USA300, the genetic background most responsible for the CA-MRSA outbreak currently affecting the United States, also does not elaborate either type 5 or type 8 capsule.[163,164] Third, it is possible, although less likely, that people undergoing dialysis were too immunocompromised to generate a protective antibody titer against *S. aureus* bacteremia.

OTHER POTENTIAL VACCINE TARGETS

The notion that LTA may be a protective antigen to prevent *S. aureus* sepsis has been evaluated. Initial efforts have focused on an anti-LTA monoclonal antibody, pagibaximab, that underwent clinical trials in neonates.[165] However, protection against *S. aureus* sepsis did not occur.

Antibody against PBP2a surprisingly protected against infection of the kidney after intravenous challenge with a MRSA strain. No protection occurred after challenge with a methicillin-susceptible isolate.[166] Immunization with a chimera-like heteropolymer consisting of an antibody conjugate targeting *S. aureus* and the type 1 complement receptor found on erythrocytes protected mice from death after intravenous *S. aureus* challenge by both of two challenge isolates.[167]

The role of T cells, a new chapter in *S. aureus* vaccine development, was recently opened by the recognition that lymphocyte-mediated pathways have a role in immunity to *S. aureus* infections. Spellberg and colleagues[168] and Lin and colleagues[169,170] found that interferon-γ–deficient mice were very susceptible to *S. aureus* infection after intravenous inoculation. Others found that mice deficient in interleukin (IL)-17A and IL-17F developed spontaneous *S. aureus* skin infections.[171,172] Hence, it may be possible to induce memory T cells that are capable of increasing phagocyte recruitment to sites of infection and facilitate clearance of *S. aureus* from tissues. In support of this concept, a novel recombinant N-terminus vaccine molecule containing the candidal adhesion, rAls3p, is being evaluated (Table 55.2).[168–170] This vaccine induced high antibody concentrations, but they were not protective when used to passively protect animals against *S. aureus* intravenous challenge[168] and the antibody titers did not correlate with protection against lethal *S. aureus* infection.[170] Furthermore, the vaccine was equally effective in B-cell–deficient and wild-type mice but had no efficacy in T-cell–deficient mice.[168] Adoptive transfer of immune $B220^+$ B cells did not transfer protection, but transfer of $CD4^+$ T cells did. The vaccine was ineffective in interferon-γ– and IL-17A–deficient mice and in $gp91^{phox-/-}$ mice that are unable to produce superoxide.[170] Cross-adoptive transfer experiments confirmed that functional phagocytes were operative in vaccine-mediated protection at the downstream effector stage. Finally, vaccination increased the recruitment and activation of phagocytes at sites of tissue infection in mice, and cytokines produced by vaccine-primed lymphocytes improved the ability of phagocytes to kill *S. aureus*. Hence, the rAls3p-N vaccine demonstrates that it is feasible to induce a protective immune response in mice against *S. aureus* in the absence of induction of protective antibodies, and by inducing a protective T-helper (Th) 1/Th17 response.[173–175]

These observations do not preclude development of a humoral-based vaccine against *S. aureus*. Rather, they suggest that cell-mediated vaccines merit additional study and raise the possibility of combining antigens that stimulate both humoral and cellular responses against *S. aureus*. Indeed, this

TABLE 55.2 *Staphylococcus aureus* Vaccines Receiving Clinical Evaluation as of December 2015

Manufacturer	Vaccine	Type of Study	Composition of Vaccine
Novartis	4 Components	Safety and immunogenicity–COMPLETE	Not publicly disclosed; components are all proteins
Pfizer	4 Components	Safety and immunogenicity–COMPLETE. Efficacy after spinal surgery trial ongoing	Conjugated capsular polysaccharides, types 5 and 8; clumping factor A; manganese transporter C
Novadigm	Recombinant protein	Safety and immunogenicity–COMPLETE	rAls3p-N
GlaxoSmithKline	4 Components	Safety and immunogenicity–COMPLETE	Capsular polysaccharides conjugated to tetanus toxin, α-toxoid, clumping factor A

strategy may be the most likely to result in a protective vaccine against *S. aureus*.

EPILOGUE

Table 55.2 summarizes clinical trials in progress or recently completed. However, many questions remain. Is the *S. aureus* disease burden sufficient in the general population to justify development of a universal vaccine? Recent data suggest that the answer is yes. Administration of an *S. aureus* vaccine to young children during the time when they are receiving other vaccines (first year of life) would be most convenient, and, perhaps, appropriate, as the attack rate is so high at that time. Can one vaccine formulation protect against the three major clinical scenarios, skin and soft tissue infection, pneumonia, and invasive disease? This is a difficult question for which the answer is not fully known. Can an antibody eliciting vaccine protect against any *S. aureus* clinical syndrome? Antigens that have elicited opsonophagocytic antibody have not elicited protection against *S. aureus* disease. The reason has remained a mystery. If it is possible to elicit protective antibody(ies), what is (are) the protective antigen(s)? Is protein A a barrier to this approach? If so, how can this conundrum be dealt with? Can any active immunization strategy protect immunocompromised persons at high risk for *S. aureus* disease? If not, can a passive vaccination approach be delivered with sufficient regularity to be helpful to persons with such conditions with reasonable ease and at a reasonable cost? What is the role of the polysaccharide capsule? Its presence suggests that it is important, but defining its place in the pathophysiologic cascade has not been easy. Its absence from USA300, the epidemic genetic background of the last decade in the United States, does not lend confidence to believing that this antigen is crucial for protection against currently circulating invasive strains. The recent identification of important T-cell pathways, particularly the Th17/IL-17 pathway in *S. aureus* immunity, suggests that they might have a role in eliciting protection. An additional problem is understanding immunity to *S. aureus*, a commensal organism that causes disease in a small subset. Is there an immunologic gap in persons who acquire disease that can be traversed with a vaccine? Despite extensive investigation, we do not know the answers to many of these questions, and *S. aureus* remains a complex enigmatic pathogen. Understanding the answers will be necessary to the development of a rational vaccine formulation.[176]

56 *Streptococcus* Group A Vaccines

Karen L. Kotloff

Streptococcus pyogenes (group A β-hemolytic *Streptococcus* [GAS]) has challenged scientists and clinicians throughout modern medical history. Descriptions of epidemics of fulminant illnesses in previously healthy individuals date back to the 1600s.[1,2] Until the early 1900s, scarlet fever and acute rheumatic fever (ARF) were a major cause of child death in the United States and Europe. Thereafter, the incidence and severity of GAS-related diseases declined. In the United States, the case-fatality rate from scarlet fever fell from nearly 30% to less than 2%, well before the advent of antibiotics, for reasons that are not fully understood.[3] Institution of antibiotic therapy of GAS pharyngitis produced further improvements. In the 1980s, amid discussion about the vanishing threat of GAS pharyngitis,[4] outbreaks of severe invasive disease and ARF and a newly described streptococcal toxic shock syndrome (STSS) emerged around the world.[5] These invasive infections carried a high mortality, even in the face of appropriate antibiotic therapy.

In addition to its unpredictable epidemiology, GAS has presented a diagnostic dilemma requiring a series of incisive observations to link its manifold manifestations with a single etiology. Circa 1880, Pasteur identified the microbe in specimens from puerperal fever victims.[6] In 1898, Cheadle linked the major features of ARF that comprise the five major criteria that we know today (i.e., carditis, polyarteritis, chorea, erythema marginatum, and subcutaneous nodules).[3,7] In 1903, Brown established that complete (β) hemolysis on blood agar could distinguish streptococci that were pathogenic for humans.[8] Although β-hemolytic streptococci were among suspected etiologic agents of ARF, it was the landmark studies of Coburn in 1930 that firmly established the direct link between GAS pharyngitis and the "rheumatic state."[9] Lancefield pioneered the serologic classification of β-hemolytic streptococci according to the group-specific polysaccharide. She determined that most human pathogens belonged to group A, and further categorized group A strains according to the trypsin-sensitive surface-exposed M protein[10,11] and a trypsin-resistant T antigen.[12] The ability to classify streptococci serologically provided the foundation for studies to characterize the clinical features, epidemiology, and protective immunity, and to devise strategies for vaccine development.

BACKGROUND

Clinical and Epidemiologic Features

Pharyngitis and impetigo are the most common uncomplicated manifestations of GAS infection. Serious infections result when the organism spreads to contiguous sites or disseminates to normally sterile spaces or deep tissues, which may be accompanied by necrotizing fasciitis or STSS or both. Major nonsuppurative complications of GAS infections are ARF and poststreptococcal glomerulonephritis (PSGN), both considered immune-mediated.[13,14] In industrialized countries, the burden of uncomplicated infections is high; an estimated 2% to 6% of U.S. schoolchildren visit a physician for GAS pharyngitis annually.[15] Despite their benign nature, these illnesses incur substantial costs related to missed school and work and use of healthcare resources. The incidence and mortality from invasive infection has remained stable in the United States for more than a decade, causing approximately 15,360 cases (4.8 per 100,000 population) and 1640 deaths (case fatality: 10.7%) in 2014.[16] Localized, episodic increases of invasive infection are seen, as has been the case in Utah.[17] Exceptionally high rates occur in northern Australia among nonindigenous (8.8 per 100,000 population) and indigenous populations (69.7 per 100,000 population).

Cases of ARF continue to occur in some U.S. communities,[17] but the overall incidence is less than 0.5 per 100,000 population.[4,18] In contrast, ARF persists in causing substantial morbidity and mortality in many developing countries and in indigenous populations within developed countries. The incidence of ARF reaches 650 per 100,000 population in some remote Aboriginal communities.[19] The prevalence of rheumatic heart disease reported from South Asia and sub-Saharan Africa ranges from 130 to 640 per 100,000 children 5 to 14 years old.[20]

PSGN has received less attention than ARF because of its generally benign outcome, even in those who develop renal insufficiency during the acute episode.[21] However, in areas where nephritogenic strains are prevalent, PSGN can follow 10% to 15% of episodes of GAS pharyngitis or pyoderma.[22]

Epidemic waves that characterize the epidemiology of severe GAS infection have been attributed both to the host and the organism. Circulating strains produce herd immunity, resulting in decreased transmission and disease severity. GAS acquires virulence factors via transmissible agents, such as bacteriophages,[23] or via genetic mutations.[24] The upsurge of severe GAS disease in the 1980s occurred during a time when the incidence of uncomplicated disease remained constant, suggesting that highly virulent organisms created by genetic alterations in critical regulatory and virulence genes emerged in an immunologically susceptible population.[5,25] One virulence factor that has been strongly associated with these hypervirulent invasive strains (regardless of M type) is the extracellular enzyme nicotinamide adenine dinucleotidase, which has chemotactic, cytotoxic, and vasoactive properties.[26] Accordingly, genome sequencing of population-based M1 strains demonstrated the acquisition of the chromosomal region containing the gene for nicotinamide adenine dinucleotidase just before the pandemic surged.[27]

Bacteriology, Virulence Factors, and Pathogenic Mechanisms

An assortment of secreted and surface-expressed molecules mediate the four pathogenic processes that characterize acute infection: adhesion, immune evasion, inflammation, and tissue invasion (Fig. 56.1). The virulence factors that are being explored as possible vaccine antigens are highlighted.

Group A β-hemolytic streptococci adhere to epithelial cells in the pharynx, cervix, or skin by binding to plasma and matrix proteins,[28] forming microbial aggregates and producing a biofilm that protects against host defenses and nutrient deprivation.[29] Among the best described adhesins are M protein,[30] hyaluronic acid capsule,[31] and fibronectin binding proteins such as SfbI[32] and FBP54.[33] R28 is found in GAS

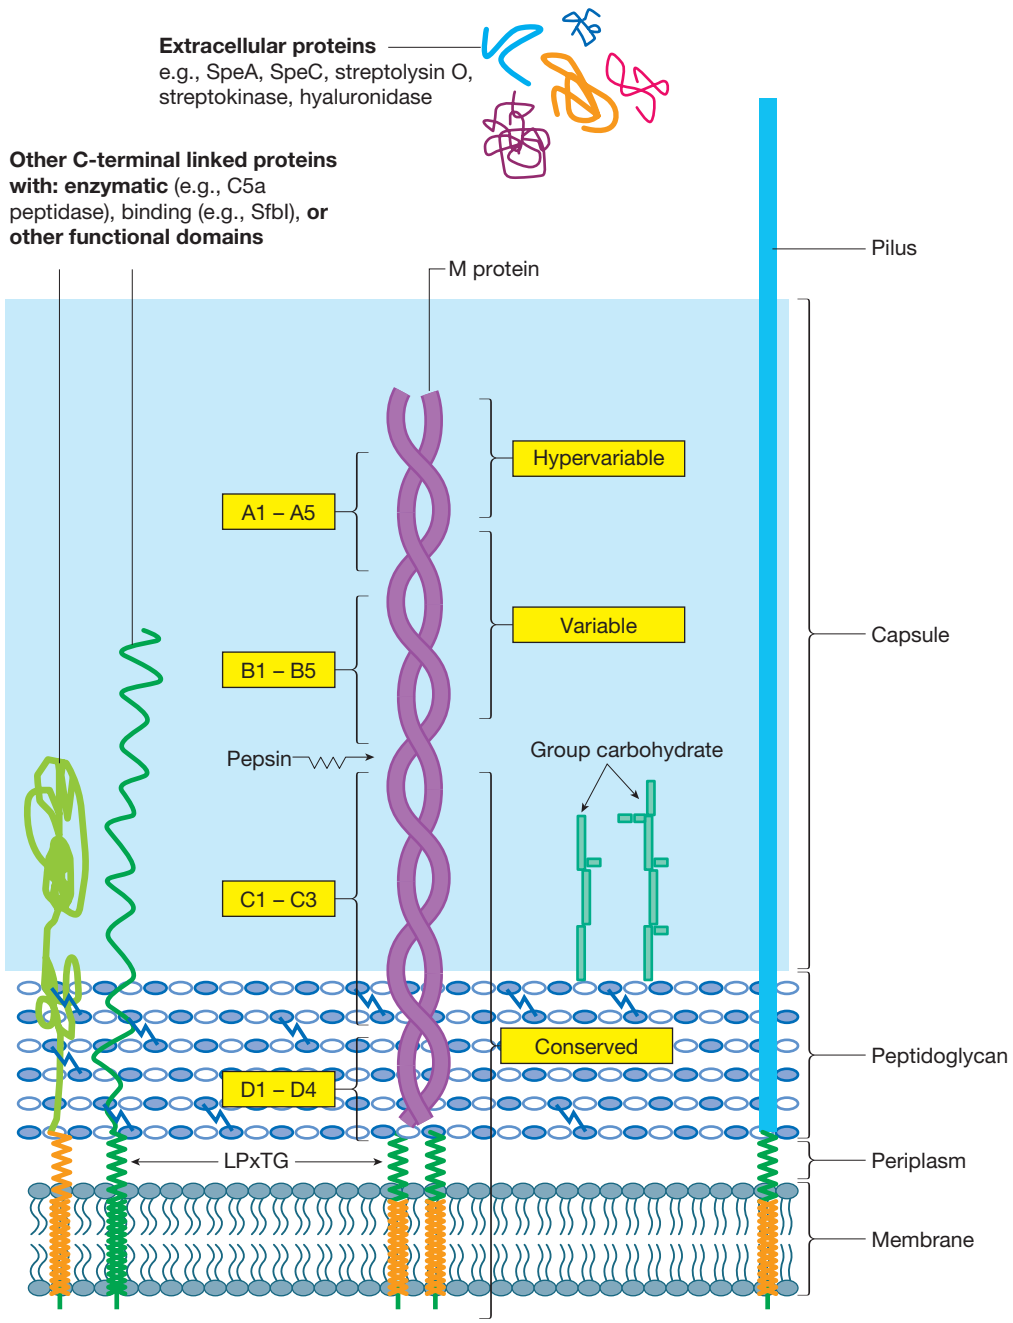

Figure 56.1. Major surface structures of group A β-hemolytic *Streptococcus*. The main categories of proteins that have been exploited in vaccine development are shown. Most proteins are anchored at the C terminus via a highly conserved LPxTP consensus motif followed by a hydrophobic region that spans the cell membrane and terminates with a short charged tail within the cytoplasm. After translocation to the surface, the LPxTP motif is cleaved and the mature molecule is anchored into peptidoglycan. The majority of proteins are multifunctional, usually with domains that bind molecules found in extracellular matrix, such as fibronectin (SfbI), but also domains that exhibit enzymatic activity, such as C5a peptidase, or have other functions. In the case of proteins with multiple repeats, such as M protein, each repeat domain (designated as A, B, C, and D) has a different function. The pepsin cleavage site of M protein is marked with a crooked arrow. Extracellular proteins that exhibit toxin and/or superantigen properties include streptococcal pyrogenic exotoxin (Spe) A and SpeC, which have been targeted for vaccine development, as well as anti–streptolysin *O*, streptokinase, and hyaluronidase.

strains associated with puerperal fever and is thought to promote binding to cervical epithelium.[34]

GAS pilus, identified in 2005, contributes to adhesion and biofilm formation.[29,35] Interestingly, these filamentous structures protruding from the cell surface bear the T antigens described by Lancefield and thus present a potential avenue for vaccine development. All GAS isolates tested thus far carry and express the *bp/tee* pilus genetic locus.[29]

After colonization, GAS persists in the host by deploying a multi-pronged approach to disarm the innate immune response. C5a peptidase (also called SCPA, or surface-bound C5a peptidase) inactivates a chemokine of the complement

system,[36,37] while SpyCEP (also called ScpC or Spy 0416), a cell envelope serine protease, cleaves the neutrophil attractant interleukin-8,[38] both contributing to inhibition of neutrophil recruitment. Extracellular DNAases degrade chromatin webs produced by neutrophils to entrap GAS bacteria.[39] The secreted serine esterase (SsE, or Spy 1718) inhibits neutrophil recruitment and contributes to skin invasion and systemic dissemination.[40] The hyaluronic capsule promotes resistance to host defense peptides and to phagocyte killing within the extracellular neutrophil traps,[41,42] and streptococcal inhibitor of complement, found only in M1 and M57, inhibits complement-mediated lysis.[43] M protein, encoded by *emm*, impedes neutrophil phagocytosis in the absence of type-specific antibody by binding plasma proteins and inhibiting opsonization via the alternate complement pathway.[44–48] Antigenic heterogeneity of the amino terminus of M protein further enables GAS to escape recognition by specific antibody.

GAS elaborate several extracellular products, including streptolysin *O*, deoxyribonuclease B, streptokinase, and hyaluronidase, that induce tissue liquefaction and facilitate invasion.[49] Streptolysin *O* kills eukaryotic cells by forming membrane pores.[50]

M protein and the streptococcal pyrogenic exotoxins (SPEs) have potent proinflammatory properties.[51,52] The SPEs form a family of superantigens that induce profound immunologic changes[53,54] as well as fever, tissue damage, and clinical manifestations of endotoxic shock.[55–57] SPE A and SPE C, formerly known as erythrogenic toxins because of their association with the rash of scarlet fever, are bacteriophage-encoded and contain distinct T-cell receptor and class II major histocompatibility complex binding sites.[58] Severe scarlet fever and STSS has been associated with SPE A– and SPE B–producing strains.

The pathogenesis of the nonsuppurative postinfectious sequelae of GAS is not well understood. ARF follows approximately 3% of episodes of untreated GAS pharyngitis under epidemic conditions[59] but is considerably less frequent in endemic situations.[60] Observations of Aboriginal populations experiencing high rates of ARF have led some investigators to suggest that skin infections lead to ARF in these communities.[61] Strains causing pharyngitis and ARF were long thought to bear different M types and other antigenic and virulence properties than those that cause impetigo/pyoderma, although some overlap exists.[62,63] Proof that skin strains are responsible for a substantial burden of ARF would alter the necessary composition of M protein–based vaccines.

Appreciation of the structure of M protein helps explain its function as the major virulence factor of GAS and also the major protective antigen (see Fig. 56.1).[64] These α-helical coiled–coil fibrillar rods consist of two polypeptide chains anchored in the cell wall peptidoglycan by a C-terminus LP×TG motif.[65] Each polypeptide contains up to four segments of repeating amino acids (labeled A to D). The C repeats contain epitopes that are exposed on the surface of the cell wall and are largely conserved among different M types.[66] During infection, opsonic antibodies that confer protection are directed predominantly at the N-terminus,[67] a highly variable region that constitutes the basis for Lancefield's serotyping classification of GAS into approximately 100 M serotypes. Currently, group A β-hemolytic streptococci are classified based on sequence analysis of the portion of the *emm* gene that encodes M serospecificity. The more than 220 distinct *emm* types have been further classified into 48 distinct *emm* clusters based on phylogenetic, structural, and binding properties of M protein.[68,69] Epitopes found within the B repeats and adjacent segments of the A and C repeats cross-react with human antigens and have been proposed as a mechanism in the pathogenesis of ARF. Moreover, a segment within the B-repeat region bears homology with known superantigens.[70]

The concept of molecular mimicry has been invoked to explain the pathogenesis of ARF and PSGN. M protein bears antigenic similarities with human fibrillar proteins, such as cardiac muscle myosin and molecules of the extracellular matrix of joints and kidneys.[71–74] A mechanism for carditis is postulated whereby GAS infection stimulates cross-reactive antibodies that bind to the valvular endothelium resulting in inflammation[74] and infiltration by $CD4^+$ T cells that recognize GAS M protein and cardiac antigens.[75,76] Antibodies evoked by the immunodominant epitope of group A carbohydrate, *N*-acetylglucosamine, cross-react with GM_1 gangliosides on the surface of neuronal and valvular endothelial cells and have been proposed in the pathogenesis of Sydenham chorea[77] and carditis,[74] respectively. Seroreactivity with components of the cell membrane, SPE B, and other GAS antigens has been suggested in the etiology of PSGN.[49,78] It is important to note that antibodies that cross-react with human tissues and somatic components of GAS are found in many healthy children, so their presence alone does not explain the nonsuppurative sequelae of GAS.[79,80] Further elucidation of the pathogenesis of nonsuppurative sequelae will facilitate rational development of a safe GAS vaccine.

Treatment and Prevention With Antimicrobials

In the 1950s, Denny and colleagues demonstrated that a course of penicillin prevents more than 90% of ARF episodes (primary prevention) if initiated within 9 days of the onset of GAS phayryngitis.[81] Furthermore, the observation that nearly 30% of patients with rheumatic carditis experience additional valvular injury when reinfected with GAS[82] prompted recommendations to administer prophylactic penicillin during the years when the risk of exposure to GAS is greatest (secondary prevention). In contrast, although antibiotics speed recovery of skin lesions, they do not appear to prevent glomerulonephritis following either pharyngitis or impetigo. Severe invasive infections are treated with a combination of penicillin and an antibiotic that inhibits protein synthesis such as clindamycin plus surgical debridement of necrotic tissue.[83] Intravenous immunoglobulin therapy has been advocated as ancillary therapy for STSS based on its ability to neutralize superantigen toxins, but its efficacy remains inconclusive.[84]

There are well-recognized limitations to the treatment of GAS disease. Nearly one-third of episodes of ARF are preceded by a GAS infection that does not receive medical attention.[85] In many parts of the world, resources are not available for effective primary and secondary prevention. Even in the face of adequate therapy, the outcome of invasive disease may be poor.[86,87] Development of a safe, effective, and affordable GAS vaccine has the potential to overcome many of these barriers.

ACTIVE IMMUNIZATION

Feasibility of Developing a Safe and Efficacious Group A β-Hemolytic *Streptococcus* Vaccine

The feasibility of developing a GAS vaccine depends on adequate resolution of several safety and immunogenicity concerns. The principal safety concern is the theoretical risk that a GAS vaccine, like natural infection, might trigger an immunopathological event such as ARF. Thus an important advance for the development of M-protein–based vaccines was the discovery in the 1980s that type-specific aminoterminal regions of the M protein elicited the strongest bactericidal immune responses and could be separated from the potentially harmful cross-reactive epitopes.[88–92]

Evidence suggests that there is immunity to GAS, so it is reasonable to expect that a vaccine could be constructed to do the same. The declining incidence of GAS pharyngitis with age implies the acquisition of immunity following natural exposure.[93] Lancefield established the role of type-specific immunity in preventing experimental infections in animals[94] and later showed that humans develop long-lasting type-specific immunity following natural infection.[95] Beachey and colleagues protected mice against M24 infection using serum from human volunteers immunized with a type-specific peptide fragment of type 24 M protein.[96] The most direct evidence comes from clinical trials performed by Fox and colleagues (described below), which demonstrated that vaccinated volunteers were significantly protected against challenge with virulent GAS bearing the homologous M protein.[97–99]

Correlates of Protection

Knowledge of the precise immune responses that mediate clinical protection could be exploited in vaccine development, but these remain incompletely elucidated. The findings of Lancefield and Fox bespeak type-specific immunity recognizing the N-terminal region of M protein,[97–99] presumed to be mediated by bactericidal antibodies. Nonetheless, a direct correlation between bactericidal antibodies and clinical immunity has not been observed consistently.[97] Type-specific mucosal immunity may confer protection against colonization.[98,100,101] Natural infection in children and adults induces strong antibody and cellular responses that may contribute to protective immunity. T-helper type 1 $CD4^+$ cells produce cytokines (e.g., interferon-γ) that stimulate complement-fixing, bactericidal immunoglobulin G_3 antibodies as well as cells of the innate immune system (macrophages) that are able to limit bacterial dissemination.[102] On the other hand, some investigators argue that immune responses evoked by repeated exposure to GAS antigens that are shared among different M types would be required to account for the observed age-related decreases in GAS pharyngitis, given the large number of M types in circulation.[103] Antibodies to the conserved regions of M protein and to a variety of surface expressed or secreted antigens have been shown to elicit protection in animals.[101,104,105]

Even if a safe and effective vaccine were developed, the feasibility of introduction and uptake will be driven by factors such as cost-to-benefit analysis, cost-effectiveness analysis, public perception, and market forces in a given country. The Institute of Medicine performed a cost-to-benefit analysis of GAS vaccination in the United States in which it was estimated that the annual healthcare costs for GAS in the United States reach US$493 million.[106] If a vaccine were provided to 95% of infants and conferred 75% efficacy, the committee predicted a net cost savings of US$314 million. Although similar cost-to-benefit analyses are not yet available for developing countries, the World Health Organization estimated that rheumatic heart disease accounted for 5.9 million disability-adjusted life-years during 2002.[107]

Historical Perspective: Clinical Group A β-Hemolytic *Streptococcus* Vaccine Trials

The history of modern GAS vaccine development dates back to the 1940s, when approximately 4000 young adults were injected with whole-cell vaccines inactivated by heat or ultraviolet light.[108] These vaccines produced reactions, some severe, but did not prevent GAS disease. In the 1960s, clinical trials involving children and adults were initiated using parenteral vaccines consisting of partially purified M protein or cell wall preparations containing high M protein content.[97,99,109–114] The crude preparations of whole cell or cell wall were unacceptably reactogenic and inconsistently immunogenic, presumably because the toxicity limited the total amount of protein that could be administered. However, when injected with mineral oil adjuvant, partially purified M protein induced bactericidal antibodies in some subjects.[109] These findings suggested that a vaccine based on M protein may be an effective strategy if a safe and reliable delivery system could be identified.

The 1960s saw an unfortunate turn of events. Investigators conducting a clinical trial involving a partially purified M3 protein reported an apparent increase in the attack rate of ARF among vaccinated children compared with historical controls.[115,116] The vaccine regimen consisted of increasing doses (up to 1 mg) generally administered subcutaneously at weekly intervals for 18 to 33 weeks. Recipients were siblings of ARF patients. The ARF episodes appeared 37 days to 23 months after the previous vaccination and occurred among subjects who were experiencing high rates of intercurrent GAS pharyngitis. Whether these cases were triggered by vaccination remains uncertain. Nevertheless, a federal regulation prohibiting licensure of GAS organisms or their derivatives for human administration was issued in 1979 and endured until 2006.[117]

Meanwhile, the sentinel studies conducted by Fox and colleagues clearly demonstrated that a vaccine could induce protective immunity. These investigators immunized seronegative volunteers with three monthly injections of purified M1, M3, or M12 protein[97–99] given either subcutaneously with alum or via aerosol to the nose and pharynx. One to 2 months after immunization, a cohort of vaccinated and unvaccinated subjects was challenged by painting virulent GAS bearing the homologous M type onto their tonsils and pharynx. Volunteers were evaluated clinically and microbiologically for 6 days and then treated with penicillin. Both parenteral and mucosal vaccines prevented GAS pharyngitis, although the level of protection achieved statistical significance only for M1 vaccine. Furthermore, mucosal vaccination significantly prevented acquisition of throat infection.

Around this same time Beachey and colleagues discovered techniques for creating highly purified M protein fragments as vaccine antigens[96] and demonstrated that M24 peptide adsorbed to alum was well-tolerated and elicited bactericidal antibodies in volunteers. None of the sera contained antibodies that cross-reacted with myocardial tissue. This trial provided further proof that the use of well-defined M protein epitopes could be safe and elicit type-specific immunity.

Current Prospects for a Group A β-Hemolytic *Streptococcus* Vaccine

M-Type–Specific Vaccines

The advent of molecular biology techniques enabled a new generation of GAS vaccines with rational, well-defined components and allowed clinical trials to resume after a hiatus of nearly 30 years (Table 56.1). Dale and colleagues constructed a recombinant fusion protein containing N-terminus fragments from six GAS M types of clinical and epidemiologic importance (1, 3, 5, 6, 19, and 24) and excluding tissue cross-reactive epitopes.[118] A Phase I, proof-of-principle trial was conducted to evaluate three dosage levels (50 μg, 100 μg, and 200 μg), with 10 subjects per group.[119] This intramuscular vaccine appeared safe, well-tolerated, and did not induce antibodies that cross-reacted with human tissues. Three spaced doses of 200 μg (at 0, 4, and 16 weeks) elicited a fourfold or greater rise in antibody by enzyme-linked immunosorbent assay (ELISA) in 57 (95%) of 60 possible assays (i.e., six antigens times 10 subjects). Postvaccination rises in functional (bactericidal or opsonophagocytic) antibody were common.

TABLE 56.1 Group A Streptococcal Candidate Vaccine Antigens That Evoke Immune Responses in Humans After Natural Infection and Demonstrate Efficacy in Animal Models

Antigen	Function in GAS Virulence
M PROTEIN-BASED VACCINES	
Type-specific M peptides[a,118–120,123,128]	Adhesion; inhibits opsonization by the alternate complement pathway
Conserved M protein epitopes Mucosal synthetic peptide vaccine[126] *Streptococcus gordonii* vector[127,135,184] J8-DT B-cell epitope[a,136–138] with SpyCEP[139,185] StreptInCor[140]	Inhibits opsonization SpyCEP inhibits neutrophil chemotaxis
NON-M PROTEIN ANTIGENS	
Fibronectin-binding proteins	
SfbI,[143–146,186–188] FBP54[147]	Adhesion to pharyngeal epithelium
R28[34]	Adhesion to cervical epithelium
Spy 1536 (and 8 other common antigens identified via antigenomics)[105]	Binding to extracellular matrix proteins
C5a peptidase (SCPA)[105,150,151]	Adhesion; inactivates a chemokine of the complement system
Serine protease (SpyCEP or ScpC)[153,154,168]	Cleaves interleukin-8
Serine carboxylic esterase (Sse)[156]	Tissue invasion
Streptococcal pyrogenic exotoxins (SPE)[157–160]	Superantigens, tissue damage, shock
Group A carbohydrate[79]; synthetic oligosaccharide conjugates[161]	Impedes phagocytosis
Pilus (T serotype antigens)[35]	Adhesion and biofilm formation
Spy 1536 (and 8 other common antigens identified via antigenomics)[105]	Binding to extracellular matrix proteins
Multi High-Throughput Approach identified 6 antigens: Spy0167, Spy2010, Spy0146 (SpyCEP), Spy0269 (mediates cell division, among the 9 strains identified by antigenome analysis and reported to be protective[105]), Spy0019, and Spy1361[168]	Spy0167: streptolysin *O* precursor (kills eukaryotic cells by forming membrane pores) Spy2010 (C5a peptidase precursor) Spy0416 (SpyCEP) (above) Spy0269 (mediates cell division) Spy0019 (unknown) Spy1361 (internalin A precursor)

[a]Only these candidates have been tested in clinical trials.
GAS, group A β-hemolytic *Streptococcus*.

TABLE 56.2 Response of 30 Volunteers to Immunization With a 200-µg Dose of 26-Valent GAS Vaccine at 0, 4, and 16 Weeks[123]

M Epitope or Antigen	Percent of Subjects With Fourfold Rise in Antibody by ELISA After Immunization
3, 12, 24, 75, 76, 89, 92, Spa	90–100%
1, 1.2, 11, 19, 28, 29, 59, 94, 101, 114	80–89%
2, 22, 77	70–79%
5, 14, 43	60–69%
6, 18, 33	<50%

ELISA, enzyme-linked immunosorbent assay; GAS, group A β-hemolytic *Streptococcus*.

In an effort to develop a broadly protective vaccine, Dale and colleagues next constructed fusion proteins containing aminoterminal peptides of 26 M types[120] that account for 79% to 90% of cases of pharyngitis and invasive disease from various populations in the United States, Canada, Mexico, and Israel (Table 56.2)[120–126]; serotype coverage in low-resource countries is estimated to be 32% to 68%.[127] Thirty subjects received a 200-µg dose at 0, 4, and 16 weeks. Local and systemic reactions were common but tended to be mild. No evidence of ARF was seen. Seventeen of the 26 M antigens (65%) elicited a fourfold or greater antibody response by ELISA in at least 80% of subjects, many of whom exhibited bactericidal activity (see Table 56.2). The proportion of subjects responding to M types responsible for the most severe infections in the United States in recent history (1, 3, 5, 6, and 18)[18] varied (see Table 56.2). A 30-valent vaccine has also been constructed; it targets 98% of pharyngitis cases in the United States and Canada, 90% of invasive disease in the United States, and 78% of invasive disease in Europe, but has far less homology with the broad spectrum of *emm* types seen in many developing countries.[128] However, evidence that the vaccine evokes cross-opsonic bactericidal antibodies against a significant percentage of nonvaccine M serotypes tested to date may further enhance the vaccine's spectrum of efficacy.[129] Clinical trials with the 30-valent vaccine have begun in Canada. To assess whether M peptides might be immunoprotective when delivered mucosally, a prototype vaccine comprising food-grade *Lactococcus lactis* expressing an aminoterminal peptide of M9 GAS was administered intranasally to mice. The vaccine appeared immunogenic and prevented colonization with a homologous wild-type intranasal challenge strain.[130]

Vaccines Using Conserved M Antigens

Several investigators have constructed vaccines from the conserved region of M protein with the hope of identifying antigens with broad protection. Antibodies to epitopes in this region have been found among persons from highly endemic communities[131] and exhibit opsonic potential.[132] In animal models, mucosal vaccines comprising the C-terminal region of the M6 strain induced serum and mucosal antibodies that did not cross-react with human heart tissue and conferred protection against challenge with both homologous and heterologous GAS M types.[133] The oral commensal bacteria *Streptococcus gordonii* was evaluated in animals as a mucosal vector for surface expression of the conserved fragment of M protein.[134] A *S. gordonii* vector strain bearing no GAS antigens was shown to be well-tolerated and able to achieve short-term colonization when delivered orally and nasally to healthy adults.[135] These studies were conducted to guide the design of future Phase I trials to evaluate a *S. gordonii* live vector vaccine expressing the conserved region of GAS M protein. However, the GAS antigen-bearing strain has not been constructed.

Good and colleagues identified the 12-amino-acid synthetic J8 peptide as a vaccine candidate; it contains a minimal conserved murine protective B-cell epitope in the C-repeat region within a non–M protein helix-forming sequence (to maintain conformational integrity), and lacks cross-reactive T-cell epitopes on valvular endothelium. Parenteral immunization with J8 conjugated to diphtheria toxoid (DT) in concert with adjuvant (alum or SBAS2) produced opsonic antibodies and memory B cells that protected mice against systemic challenge.[136,137] Intranasal administration of J8-DT plus cholera toxin B subunit protected mice against mucosal challenge.[138] The J8-DT vaccine was evaluated in a Phase I clinical trial in humans and a publication is in preparation (M.F. Good, personal communication, 2015). This group further combined J8-DT with a recombinant fragment of the antineutrophilic protease SpyCEP.[139] Whereas J8-DT alone was protective against multiple GAS strains, it was minimally protective against challenge with epidemic CovR/S mutants (which overproduce SpyCEP and thus avoid neutrophilic killing) in a mouse pyoderma/bacteremia model; however, the addition of SpyCEP to J8-DT resulted in significant enhancement of efficacy against these hypervirulent strains. The bivalent vaccine produced a synergism by allowing both neutrophil killing and opsonization.[140] These investigators are also exploring a strategy of presenting peptide vaccine antigens in a synthetic lipopeptide delivery system that is self-adjuvanting.[141,142]

By searching 79 overlapping synthetic peptides from the C-terminus of M5 protein for reactivity to a large library of human sera and peripheral blood mononuclear cells, researchers have identified a 55-amino-acid peptide designated StreptInCor that contains both T- and B-cell immunodominant epitopes. Subcutaneous delivery of StreptInCor with alum protects mice against intraperitoneal challenge.[140]

Non–M-Protein Vaccine Candidates

Several virulence antigens not borne by the M protein that are surface expressed or secreted among M types have undergone preclinical testing but have not yet reached clinical trials. Those discussed here in general are immunodominant (i.e., composed of antigens that elicit immune responses following natural infection), shared by multiple M types, evoke both homologous and heterologous protective immunity in animal models, and have no known epitopes that cross-react with human tissues. It is likely that a broadly protective GAS vaccine based on this approach would require a combination of these antigens.

One strategy for preventing GAS infection is to block GAS attachment to epithelial surfaces with the use of adhesins such as fibronectin-binding proteins. The most investigated of these is SfbI,[143,144] an antigen that possesses intrinsic adjuvanticity.[145] Intranasal immunization with either purified recombinant SfbI or DT conjugated polypeptides encompassing linear T- and B-cell epitopes of the SfbI protein, along with cholera toxin B subunit or the (TLR)2/6 agonist MALP-2 as mucosal adjuvants, protect mice against lethal challenge with homologous and heterologous GAS strains.[146] Recombinant FBP54 also induces heterologous protection in mice when delivered subcutaneously with Freund's complete adjuvant, and homologous protection when administered by the mucosal route with cholera toxin adjuvant.[147] The putative cervical epithelial cell adhesion R28 was protective in passive immunization murine experiments[34] and thus has potential as an immunogen for prevention of puerperal fever.

C5a peptidase, long considered an attractive vaccine candidate, exemplifies a vaccine approach intended to disarm the ability of GAS to evade immune surveillance.[148,149] In mice, intranasal immunization with recombinant enzymatically inactive protein without adjuvant prevented colonization following intranasal challenge in a serotype-independent fashion[150] and enhanced clearance of GAS from the nasopharynx of infected mice,[141] while a subcutaneous formulation adjuvanted with alum and monophosphoryl lipid A promoted clearance from both nasopharynx and lung.[151,152] The antiphagocytic protease SpyCEP also appears very promising as a vaccine antigen[153,154]; mice immunized with recombinant CEP protein plus Freunds' incomplete adjuvant had reduced bacterial dissemination after intramuscular and intranasal challenge.[155]

The secreted esterase SsE has two antigenic variants, together encompassing at least 10 M serotypes. The M types comprising each SsE variant share greater than 98% amino acid homology. Accordingly, subcutaneous vaccination with recombinant SsE plus alum protected mice against lethal subcutaneous infection with virulent M1 and M3 strains and inhibited GAS invasion of mouse skin tissue.[156]

Vaccine-mediated prevention of STSS and severe invasive disease has focused on SPEs as antigens. Vaccination with SPE A protects rabbits not only from STSS, but also from necrotizing fasciitis-myositis.[157] SPE A and SPE C toxoids and recombinant antigens lacking regions thought to mediate T-cell receptor or major histocompatibility complex class II interaction, given subcutaneously with adjuvant (either Freund's incomplete adjuvant or unspecified), lost their superantigenic properties yet protected against lethal challenge.[158–160]

The GAS cell wall polysaccharide is surface-exposed, conserved, immunoreactive, abundantly expressed in most GAS M serotypes, and forms the basis of the group A antigen used in rapid tests to diagnose GAS pharyngitis.[79] Several parenteral formulations of alum-adjuvanted synthetic oligosaccharide vaccines conjugated to CRM_{197}, when compared to purified native polysaccharide glycoconjugates, elicited comparable opsonophagocytic antibody and similar protection against lethal injection of wild-type GAS in mice.[161] Nonetheless, potential safety issues related to possible cross-reactivity of these antigens with valvular endothelial and neuronal tissues will have to be addressed.[74,77] A potential alternative approach is to use purified polyrhamnose backbone lacking the immunodominant (and potentially autoimmune) *N*-acetylglucosamine side chain.[162]

More recent searches for novel vaccine candidates have utilized proteomic techniques, reverse vaccinology, and genome-wide selection of surface-expressed antigens.[105,163,164] The discovery of the GAS pilus is one example. Recombinant pilus proteins administered intraperitoneally with Freund's

adjuvant conferred protection against lethal mucosal GAS challenge in mice.[35] Because there are only 21 known Lancefield T serotypes (based on pilus antigens), broader strain coverage with fewer vaccine antigens might be possible compared with M-protein–based vaccines. A subset would be needed for a vaccine to protect against greater than 90% of GAS strains from the United States, Europe,[165] and New Zealand,[166] but genetic diversity elsewhere remains unknown.[167]

Nine promising candidates for a GAS vaccine were identified by antigenomics. Potential antigens were selected from genome libraries that are surface expressed, conserved, reactive with convalescent human serum, confer virulence, and induce protection in at least one of several murine models. These modes varied by challenge route (intravenous or intranasal), challenge strain, and vaccination regimen (subcutaneous injection with either Freund's or alum adjuvant or intranasal inoculation with either IC31 or MALP-2 adjuvant).[105] Bioinformatic analysis excluded homology with human proteins. Sequence conservation was assessed with published GAS strain sequences and an international collection of clinical isolates. Spy 1536, which binds extracellular matrix proteins, emerged as a promising candidate, as did SpyCEP.[153,154]

A combination of three high-throughput technologies (mass spectrometry–based proteomics, protein array, and flow cytometry) identified six vaccine candidates that were well-expressed in a high number of strains, surface-associated or secreted, immunogenic during natural infection, and efficacious in murine models when administered with monophosphoryl lipid A–synthetic trehalose dicorynomycolate adjuvant. These include Spy0167 (streptolysin *O* precursor), Spy2010 (C5a peptidase precursor), Spy0146 (SpyCEP), Spy0269 (mediates cell division, among the nine immunoprotective strains identified by antigenome analysis),[105] Spy0019, and Spy1361.[168] The progress in clinical development of these promising antigens is eagerly awaited.

Indirect Effects

Viral infections, in particular varicella and influenza, may predispose to invasive GAS infection. The ability of vaccines that prevent viral infections to diminish the occurrence of severe GAS disease should not be underestimated.[169–171]

Future Challenges

Although promising, M type-specific vaccines must address the antigenic variability posed by the numerous distinct *emm* types. Less-developed and transitional countries show a much higher diversity and a different hierarchy of circulating *emm* types compared to the Americas (excepting Hawaii,[172] Europe, and Japan), limiting coverage rates for the proposed 30-valent vaccine. Moreover, *emm*-type distributions can change over time.[173–177] Careful analyses will be required to determine the overall level of efficacy and serotype coverage that would make a type-specific GAS vaccine desirable for public health use.

Challenges face each stage of the clinical development of a GAS vaccine, many resulting from the need to exclude the theoretical risk of a vaccine triggering ARF.[178,179] Preclinical assessments are handicapped by the lack of a reliable animal model for ARF but should at least provide assurance that the candidate does not contain B- and T-cell epitopes that cross-react with host tissues and does not possess superantigenic properties. Recent clinical trials provide a template for intensive safety evaluations but more expedient tools would be useful for larger Phase II and Phase III trials. Whether Phase III trials must be designed to exclude a potential rare occurrence of ARF remains to be determined.

The choice of primary clinical end points for Phase III trials has engendered debate; considerations such as all pharyngitis, medically attended pharyngitis, impetigo (in Aboriginal populations), invasive infections, primary ARF, and recurrent ARF each have merits. Other considerations for Phase III study design include potential confounding effects of herd immunity and high asymptomatic colonization rates. Implementation of vaccine programs will face issues such as emergence of newly characterized *emm* types[180,181] and the possibility that nonvaccine serotypes may replace those in the vaccine via so-called immune escape.[182,183] Finally, it will be critical to determine a level of vaccine efficacy that would sufficiently assure practitioners that they can safely abandon the practice of culturing throats, empirically treating pharyngitis with antibiotics, or recommending secondary antibiotic prophylaxis in individuals with ARF.

57 *Streptococcus* Group B Vaccines

C. Mary Healy and Carol J. Baker

In 1938, Fry[1] reported three cases of fatal puerperal sepsis caused by group B β-hemolytic streptococci. Sporadic reports appeared until the 1970s, when group B β-hemolytic *Streptococcus* (GBS) sepsis and meningitis in young infants increased dramatically,[2–4] followed by recognition of invasive GBS infections in pregnant women and in nonpregnant adults; the latter infections occasionally were severe and fatal.[5,6] Explanations for the emergence of GBS as a prominent human pathogen have been traced to bovine origin through a series of elegant genomic studies.[7] Despite implementation of intrapartum antibiotic prophylaxis (IAP) to prevent peripartum maternal morbidity and early-onset neonatal disease,[8] GBS infections continue to occur, albeit at a reduced incidence.[9,10] Among infants 7 to 89 days old, incidence, case-fatality rates, and short-term and long-term neurodevelopmental sequelae have remained stable for decades.[10–13] Finally, invasive GBS disease increasingly impacts adults with underlying medical conditions and elderly people.[14–16]

BACKGROUND

Clinical Description and Complications

Invasive GBS disease in infants is characterized by age at onset. Early-onset GBS (EOGBS) occurs before age 7 days (≈90% have signs of infection within 12 hours of birth), frequently manifesting as sepsis without a focus (80% to 95%), pneumonia (10% to 15%), or meningitis (5% to 10%). Clinical findings are nonspecific. Severity of illness ranges from fatal multiorgan failure to healthy-appearing infants who are evaluated because of maternal GBS colonization and inadequate duration of IAP before delivery. Focal findings, except pneumonia or meningitis, are rare. In contrast, late-onset GBS (LOGBS) occurs in infants 7 to 89 days of age, and more often manifests with fever, poor feeding, and lethargy and less commonly with overwhelming sepsis. Meningitis is more frequent with LOGBS (21% to 35%), and approximately 30% to 40% of cases have permanent neurological sequelae (e.g., vision or hearing loss, cerebral palsy, developmental delay).[11–13] Other focal manifestations include septic arthritis, osteomyelitis, cellulitis, and adenitis.[17–19] Late–LOGBS occurs in infants older than 89 days (typically very preterm infants whose corrected gestational age is younger than 3 months) and accounts for approximately 20% of LOGBS cases.[19,20] Recurrent GBS is reported in an estimated 0.5% to 3% of GBS cases.[19,21] Invasive GBS is rare after age 6 months unless an underlying immunodeficiency is present.[22]

Lower vaginal and/or rectal colonization with GBS in pregnant women is a prelude to maternal invasive disease and EOGBS in the infant. The risk of invasion of amniotic fluid or the neonatal bloodstream is related directly to the density of maternal colonization and virulence of the organism.[23–25] Maternal GBS infection manifests during pregnancy as asymptomatic bacteriuria, urinary tract infection, or pyelonephritis and during the peripartum period as bacteremia, chorioamnionitis, or postpartum endometritis; these infections can result in spontaneous abortion, preterm delivery, and stillbirth.[26] Two-thirds of GBS disease cases in adults are not associated with pregnancy; rates in nonpregnant adults have increased twofold to fourfold during the last 25 years.[16] Skin and soft-tissue infections are the most common manifestations of GBS infection in this population, but urinary tract infection, pneumonia, bacteremia, bone and joint infection, endocarditis, meningitis, peritonitis, and catheter-associated infections are described. The incidence of GBS is directly related to increasing age and coexistent morbid conditions.[14–16,25,27]

Bacteriology and Diagnosis

Group B β-hemolytic streptococci are aerobic gram-positive diplococci that are divided into 10 serotypes (Ia, Ib, and II though IX) based on their capsular polysaccharides (CPSs); types VI, VII, and VIII, however, rarely cause human infection. Many strains have surface proteins (e.g., α- and β-C, R1–R4, rib, alpl-3, Sip, pilus islands 1, 2a, and 2b) that allow further characterization for epidemiologic and virulence studies. They form gray-white, mucoid, 3- to 4-mm diameter colonies on sheep blood agar medium, and produce a narrow zone of β hemolysis. Infection is diagnosed by isolation of GBS from a normally sterile site.[19]

Pathogenesis

Virulence factors characterized as important for attachment and invasion in human infection are CPS, β-hemolysin, C proteins, and pilus-like proteins. Experimental models of infection have demonstrated that antibodies to these surface structures are protective.[28–31] Alpha- and β-C proteins and pili allow epithelial cell adherence, and β-hemolysin and other factors lyse epithelial and endothelial cells, leading to direct tissue damage to and spread through host tissues. Immune clearance of GBS is resisted by CPS and other virulence factor–mediated effects at the cellular and molecular levels, leading to inhibition of neutrophil recruitment, inhibition of opsonophagocytosis and impairment of phagocytosis, and oxidative burst killing. Finally, cell wall lipoteichoic acid, cell wall peptidoglycan, and β-hemolysin/cytolysin trigger cytokine activation and release.[19] High-virulence clonal complexes, such as ST-17 of type III GBS, are also described; the latter has a tropism for meninges and is typically found only among invasive cells.[32,33]

Treatment

Penicillin is the drug of choice for treatment of systemic infection.[34,35] GBS also is susceptible to other β-lactam antibiotics and to vancomycin. GBS isolates with point mutations in penicillin-binding proteins and reduced β-lactam susceptibility have been reported from the United States and Japan; the clinical significance of these is unclear.[36–39] Resistance to erythromycin and clindamycin is reported in approximately 32% and 20% of isolates, respectively, although higher rates of clindamycin resistance in serotype IV (up to 80%) and V recently have been described.[40] While typically resistant to aminoglycosides, synergistic killing of GBS occurs in vitro and in vivo when gentamicin is combined with penicillin or ampicillin.[19] Treatment duration depends on the severity of illness and site involved, but a minimum of 10 and 14 days is

recommended for bacteremia and meningitis, respectively, and longer for more complicated infections.[14,35] Despite advances in intensive care and prompt initiation of antimicrobials, GBS infant disease overall mortality (5%) and morbidity exceeds that of *Haemophilus influenzae* type b before the use of routine infant immunization to prevent this infection in infants.[41,42]

Prevention

Current preventive strategies target neonatal EOGBS disease. IAP was adopted in the United States in 1996 following randomized trials demonstrating that intravenous ampicillin or penicillin G given intrapartum to GBS carriers prevented EOGBS. Two methods, based on culture screening of pregnant women or presence of one or more risk factors predisposing to neonatal EOGBS disease were recommended.[43–45] In 2002, the Centers for Disease Control and Prevention revised the recommendations because universal culture-based IAP had superior efficacy (relative risk of EOGBS, 0.46 [95% confidence interval, 0.36–0.6]) compared with the risk-factor strategy.[46] These recommendations were updated in 2010 (Table 57.1) to incorporate additional diagnostic methods to detect GBS colonization and revised algorithms for screening and prophylaxis of women and management of newborns.[47] IAP remains an interim strategy while vaccine development proceeds.[8]

EPIDEMIOLOGY

Incidence and Prevalence

Group B β-hemolytic streptococci colonize mucous membranes, leading to intermittent or chronic carriage. The most common sites of colonization in adults are the rectum, lower vagina, and urethra (men). Isolation rates increase 10% to 15% in pregnant women if rectal cultures are assessed in addition to lower vaginal specimens, although two-thirds of colonized women are positive at both sites. Differences between ascertainment techniques make direct comparisons of reported prevalence impossible, but group B β-hemolytic streptococci carriage rates are approximately 10% in prepubertal children, 30% in women of childbearing age regardless of trimester of gestation, and 22% and 25%, respectively, in men and healthy elderly.[19,48]

The incidence of EOGBS in the United States decreased dramatically following the introduction of IAP, from 1.7 per 1000 live births in 1993 to 0.24 to 0.26 per 1000 live births between 2009 and 2013.[49] The incidence of LOGBS has remained unchanged at 0.25 to 0.32 per 1000 live births between 2009 and 2013. Late-late onset disease numbers are increasing in association with increased survival of preterm infants.[10,49] IAP has reduced invasive infection in pregnant women to 0.12 per 1000 deliveries.[16] A recent systemic review of the literature, largely prior to 2000, showed that GBS-related stillbirth rates varied from 0.04 to 0.9 per 1000 births, accounting for 0 to 12% of all stillbirths.[26] Invasive GBS infections are increasing in nonpregnant adults (4.1 to 7.2 per 100,000 population), especially in elderly people (25.4 per 100,000).[14,15] GBS infections in all age groups are overrepresented in black populations.[11,16,49] Europe, where national surveillance and IAP are not uniform, reported neonatal EOGBS rates of 0.3 to 0.4 per 1000 live births.[50–56] There was a fivefold reduction in Australasian rates for EOGBS (from 1.43 to 0.25 cases per 1000 births) as a result of IAP during the 1990s,[57] but recent reports show that EOGBS in Australia has increased to 0.38 per 1000 births, possibly a consequence of uneven compliance with prevention through IAP.[58] Data from low-income countries are lacking, precluding a reliable estimation of the GBS-associated global burden on rates of pregnancy loss, as well as EOGBS and LOGBS.[26,59]

In the United States and Europe, invasive disease in pregnant women and infants is caused predominately by five CPS types: III, Ia, V, Ib, and II, in decreasing order of prevalence (Table 57.2).[16,51,54,55,60–62] More recently, there has been a 10-fold increase in the proportion of serotype IV in carriage studies of nonpregnant American women; serotype IV also has emerged as a cause of EOGBS and LOGBS in Minnesota, suggesting that this serotype may be emerging.[40,63] In adults and elderly people, serotype data from the United States and Canada demonstrate that the same five CPS types cause more than 95% of disease, although type V has replaced type III as most common, and type IV is causing an increasing proportion.[14,16,25,62,64]

TABLE 57.1 Recommendations for IAP[a] to Prevent Perinatal GBS Disease

IAP Recommended	IAP Not Recommended

• Previous infant with invasive GBS disease
• GBS bacteriuria in the current pregnancy
• Positive GBS screening culture in current pregnancy (unless planned cesarean delivery performed without labor or rupture of membranes)
• GBS culture status not known and any of the following:
  ◦ Delivery at <37 wk gestation
  ◦ Rupture of membranes ≥18 h
  ◦ Intrapartum fever ≥38°C
  ◦ Intrapartum NAAT[b] positive for GBS
	• Previous pregnancy with GBS colonization
	• Previous pregnancy with GBS bacteriuria
	• Planned cesarean delivery in the absence of labor or rupture of membranes, regardless of GBS colonization
	• Negative vaginal and rectal GBS screening cultures at 35–37 wk gestation

[a]Vaginal and rectal GBS cultures are recommended at 35–37 wk gestation for all pregnant women (unless there is a history of GBS bacteriuria in the current pregnancy or a previous infant with GBS disease). For IAP, intravenous penicillin G is preferred and ampicillin is acceptable at onset of labor or rupture of membranes and every 4 h until the infant is delivered. For penicillin-allergic women at low risk for anaphylaxis, intravenous cefazolin every 8 h is preferred.

[b]If intrapartum nucleic acid amplification test (NAAT) is negative but any other intrapartum risk factor is present, IAP is indicated.

GBS, group B *Streptococcus*; IAP, intrapartum antibiotic prophylaxis.

Groups With Additional Risk of Group B β-Hemolytic *Streptococcus* Infection

In the United States, the incidence of EOGBS and LOGBS infection in African American infants is two to three times higher than in white infants.[11,16,47,49] Infants of Hispanic ethnicity also have somewhat higher incidence rates.[65] This may be a result of reduced access to prenatal care, higher rates of preterm birth, or higher colonization rates attributable to vaginal hygiene practices. Among adults, blacks have twice the rate of invasive GBS infection as whites, and disease rates rise in elderly people.[15,16,66] Nursing-home residents have a greater risk than do community-dwelling persons (72.3 vs 17.5 per 100,000 population).[67] After controlling for age, diabetes mellitus, cirrhosis, stroke, breast cancer, decubitus ulcer, and neurogenic bladder, all increase risk for invasive GBS infection.[15,16,68]

Disease Burden

Case-fatality rates of 3% and 20% are reported for term and preterm infants with EOGBS, respectively. Case-fatality rates for LOGBS are lower (2% and 6%), but LOGBS more often is accompanied by meningitis, which results in permanent neurologic sequelae in up to 30% of survivors.[11–13,16] In adults, invasive GBS infection is associated with a 15% case-fatality rate, but this rate approaches 25% or higher in elderly people and people with underlying medical conditions.[15] In most countries, including the United States, CPS types Ia, Ib, II, III, and V account for approximately 85% to 95% of invasive disease isolates.[60]

ACTIVE IMMUNIZATION

History of Vaccine Development

Lancefield's observations demonstrated protection against lethal GBS infection in a mouse model by antibodies to the CPS of GBS. In the 1970s, Baker and Kasper[69] reported that mothers of infants with GBS type III disease had significantly lower serum III CPS-specific antibodies at delivery than mothers of healthy infants, a finding confirmed and extended for serotypes Ia and Ib.[70,71] Human serum containing sufficient concentrations of Ia, Ib, II, III, and V CPS-specific immunoglobulin (Ig) G promotes efficient opsonization and phagocytosis of homologous strain in vitro and provides protection from lethal experimental infection in mice. Once the CPSs of Ia, II, and III GBS were purified and immunochemically defined, an effective polysaccharide vaccine seemed imminent. It was hoped that active immunization of pregnant women would elicit protective levels of antibodies that would prevent maternal disease and, through placental transport, protect their infants from EOGBS and LOGBS. However, studies of unconjugated GBS polysaccharide vaccines in healthy adults were disappointing. The first purified CPS (type III) was tested in 1978 and was followed by types Ia and II. Although well tolerated, CPS Ia, II, and III elicited variable immune responses: 40%, 88%, and 60%, respectively.[72] Nearly 90% of subjects had low preimmunization CPS-specific antibodies, reflecting immunological naïveté, and this predicted no or less robust immune responses to CPS vaccines. In the few subjects with higher initial CPS-specific IgG, brisk, reliable booster responses occurred.

The single maternal immunization study performed using type III CPS vaccine demonstrated that it was well tolerated and had comparable immunogenicity to that in nonpregnant adults (63% immune response).[73] Among infants of maternal vaccine responders, 90% had presumed protective levels of CPS-specific IgG in their serum samples at 2 months of age that promoted opsonophagocytosis and killing of type III GBS in vitro. Furthermore, these functionally active specific antibodies persisted in the majority of infants through age 3 months. Although disappointing, these early studies demonstrated that vaccine prevention of GBS disease was feasible but that improved immunogens were needed.

The success of polysaccharide–protein conjugate vaccine technology heralded more hope to control GBS through maternal immunization.[74,75] In addition, GBS glycoconjugates could generate T-cell–dependent responses and potentially long-term protection. Theoretically, a GBS CPS-protein glycoconjugate also would induce higher maternal CPS-specific IgG concentrations, favor an IgG_1 subclass response, thereby improving placental transport, and increase likelihood of protection of mother and infant.

Constituents of Candidate Conjugate Vaccines

Most candidate GBS conjugate vaccines for clinical trials were developed at the Channing Laboratory, Harvard Medical School (Boston, Massachusetts). The first glycoconjugate was type III CPS covalently linked to monomeric tetanus toxoid (TT) using reductive amination coupling chemistry.[76,77] Monovalent types Ia, Ib, II, and V CPS and one bivalent type II/III CPS were produced using the same method with TT as the carrier protein for all but one type V CPS conjugate lot in which diphtheria mutant cross-reactive material 197 (CRM_{197}) was used.[78–81] The preclinical studies defined optimal size, percentage of oxidation, and degree of crosslinking to retain epitope specificity for each CPS-TT conjugate and to optimize immunogenicity. They also established the relationship between binding antibody to CPS by quantitative enzyme-linked immunosorbent assay (ELISA) and protection in the maternal-neonatal mouse model. Each vaccine then was evaluated in healthy adults (Table 57.3).[60,78,79,81–83] In a Phase I study of type III CPS-TT conjugate, adding aluminum hydroxide adjuvant to type III CPS-TT conjugate did not enhance immunogenicity.[82]

Dosage and Route of Administration

Phase I and Phase II trials used decreasing doses of type-specific CPS to define the optimal immune responses (see Table 57.3). Candidate vaccines were administered as a single intramuscular injection in a volume of 0.5 mL, using

TABLE 57.3 Summary of Adverse Events and Immunogenicity of GBS Conjugate Vaccine in Healthy Adults[a]

IMMUNOGENICITY

Immune Response

Clinical trials measured CPS-specific antibodies before and 2, 4, 8, 26, and 52 weeks after immunization. Antibodies were measured by ELISA with type-specific CPS covalently linked to human serum albumin as the coating antigen.[84] Although another investigator group questioned the epitope specificity of the type III CPS-specific IgG ELISA, both investigator groups agreed that sialic acid is critical for conformational epitope specificity, that opsonophagocytosis of type III GBS in vitro is a functional correlate of protective activity, that "protective" antibodies are directed at this sialic acid–dependent epitope, and that a sufficient quantity of type III CPS-specific IgG in human serum is protective against infant GBS disease.[85,86] No controversy arose over the specificity of the types Ia, Ib, II, and V CPS-specific IgG ELISAs, but assay sensitivity varied substantially.

The first clinical evaluation of a GBS conjugate was in 100 women, 18 to 40 years old, who were randomized to receive III-TT at one of three doses, unconjugated type III CPS, or placebo.[77] This trial and those evaluating types Ia, Ib, and II CPS-TT conjugates demonstrated significantly higher geometric mean concentrations (GMCs) of CPS-specific IgG in serum samples from conjugate vaccine recipients compared with recipients of unconjugated CPS or placebo.[78,81] Immune responses were dose-dependent for each conjugate except for type V CPS-TT. Dose–response studies defined total amount of polysaccharide needed to optimize immune response (quantitative ELISA and opsonophagocytosis in vitro) while minimizing local and systemic symptoms. Fourfold or greater increases in CPS-specific IgG were demonstrated in a majority of recipients (see Table 57.2).[60] In addition, vaccine-induced IgG in adults promoted opsonization of homologous GBS strains by human neutrophils in the presence of endogenous human complement and correlated with the concentration of vaccine-induced CPS-specific IgG. When type III CPS-TT conjugate was administered to women at 30 to 32 weeks' gestation, the GMC III CPS-specific IgG rose from 0.18 μg/mL before to 9.98 μg/mL at delivery; 77% of maternal levels were

transported to infant cord sera, and maternally acquired CPS-specific IgG and endogenous infant complement in sera at age 2 months promoted opsonophagocytosis and killing of type III GBS. Furthermore, the type III CPS-specific IgG_1 subclass predominated in infant cord serum samples.[87] These data proved that conjugation results in T-cell–dependent responses.

Duration of Immunity and Protection
