16 Cytomegalovirus Vaccines

Mark R. Schleiss and Stanley A. Plotkin

Cytomegalovirus (CMV) is a ubiquitous β-herpesvirus that only replicates in human cells.[1] CMV infections are generally asymptomatic in immunocompetent individuals, but may produce a heterophile-negative mononucleosis syndrome in approximately 10% of primary infections in older children and adults.[2–4] Like other herpesviruses, it becomes latent after primary infection, but may reactivate from latency, particularly in the setting of immune suppression, leading to disease. Infection typically requires intimate contact with body fluids (blood, urine, saliva, breast milk). There is no seasonality to infection. Patient populations with an increased incidence of primary infection include breastfeeding infants,[5] toddlers and care providers in group childcare settings,[6–8] and sexually active adolescents.[9–13] Seroprevalence is higher among nonwhites and among individuals of lower socioeconomic status.[14,15]

From a public health perspective, the most important medical impact of CMV is the damage caused to a fetus when infection occurs in utero. A recent metaanalysis of published studies concluded that the overall birth prevalence of congenital CMV infection was 0.64%, although this study also noted that rates varied considerably among different study populations.[16] Current estimates suggest that there are approximately 60,000 congenital infections annually in the United States and Europe (Table 16.1). Nonwhite race, low socioeconomic status, premature birth, and neonatal intensive care unit admittance are risk factors for congenital CMV infection. Congenital infections correlate directly with maternal CMV seroprevalence in the subpopulation assessed. Recent efforts to develop newborn screening programs for congenital CMV should provide more rigorous estimates regarding the overall prevalence of this infection in future studies.[17,18] Interestingly, the prevalence of congenital CMV infection in developing countries is even higher, ranging from 0.6% to 6.1%.[19,20] The risk of intrauterine transmission is highest when primary infection occurs during pregnancy, with a significantly increased risk of adverse fetal effects if infection occurs during the first half of pregnancy.[21] CMV infection of the placenta interferes with the maintenance and differentiation of trophoblast progenitor cells, possibly resulting in decreased transport of oxygen and substrate to the fetus and leading, through indirect mechanisms, to intrauterine growth retardation.[22,23] Among congenitally infected infants, approximately 10% have signs and symptoms of disease at birth, and these symptomatic infants are reported to have a 40% to 90% risk of subsequent neurologic sequelae, including mental retardation, microcephaly, development delay, seizure disorders, and cerebral palsy.[24–26] Although the remaining 90% of infants are asymptomatic at birth, between 7% and 20% of these children are reported to subsequently develop permanent sequelae, particularly sensorineural hearing loss.[27–30] Overall, it has been estimated that in a given cohort of 1000 infants with congenital CMV, 170 to 190 will have permanent sequelae, of whom one-third are from the symptomatic group and two-thirds are from the asymptomatic group (Fig. 16.1).[24]

The public health impact of congenital CMV infection is significant and underrecognized,[31–33] and carries with it substantial costs to society. In the early 1990s, the disease burden associated with congenital CMV infection was estimated to cost the U.S. healthcare system approximately $1.9 billion annually, with an estimated cost of more than $300,000 per child.[34] Although partially effective antiviral therapy is available,[35–37] development of a CMV vaccine is the most promising strategy for addressing the problem of congenital CMV. An effective vaccine could, by preventing neurological sequelae and other disabilities, provide a lifetime of benefit for newborns. A study modeling the financial impact of routine vaccination of adolescent females demonstrated that such a strategy would be highly cost-effective.[38] A report from the Institute of Medicine of the National Academy of Sciences categorized development of a CMV vaccine for adolescents as a "Level 1" (highest level) priority.[39] The optimal timing for administration of a CMV vaccine aimed at preventing congenital infections may depend on the age-dependent seroprevalence in the population being vaccinated.[40] Some models suggest that immunization of toddlers and young children may be preferable to vaccination of adolescents, as this strategy could protect young women of child-bearing age from exposure to CMV by decreasing or eliminating infectious virus in the urine and secretions of these children.[41,42]

In addition to young women of childbearing age, patient populations that could benefit from development of a CMV vaccine include immunocompromised patients, in particular solid organ transplant (SOT) patients and hematopoietic stem cell transplant (HSCT) recipients, who are at high risk for CMV disease (manifested variably as interstitial pneumonia, hepatitis, nephritis, encephalitis, bone marrow depression, and potentiation of bacterial and fungal infections).[43–50] CMV-seropositive HSCT recipients and seronegative recipients with a seropositive donor have an enhanced and persistent risk when compared with seronegative recipients of a seronegative donor.[47] SOT recipients are also at risk for CMV disease and graft rejection, particularly seronegative recipients of organs from seropositive donors.[43,44,46,48–50] Although the advent of highly active antiretroviral therapy has dramatically decreased the risk of CMV disease in HIV-infected patients in the developed world,[51,52] HIV-CMV interactions continue to be of substantial importance in the developing world, where HIV therapies may be less available. This may have particular importance in the context of vertical transmission, since maternal HIV infection confers a high risk of congenital CMV infection, even if the infant remains HIV uninfected.[53,54] CMV vaccines may ultimately also prove to be useful in this high-risk setting. In addition, an emerging body of evidence suggests that CMV infection may play a role in the pathogenesis of atherosclerosis, autoimmune diseases, and malignancies, in particular glioblastoma multiforme.[55] CMV serostatus may also impact the clinical course of burns, trauma, and sepsis.[56,57] CMV seropositivity has also been shown to affect B-, T-, and natural killer (NK)-cell responses to influenza vaccination.[58–60] Finally, studies have noted an intriguing association between CMV infection and immunosenescence.[61–67] In light of these observations, universal vaccination against CMV might confer benefits to *all* individuals over the course of a lifetime, and not just women of reproductive age and the special populations described above.

CORRELATES OF CYTOMEGALOVIRUS IMMUNITY: IMPLICATIONS FOR VACCINE DESIGN

Congenital CMV infection can occur as the result of a primary infection, reactivation of latent infection, or reinfection with a new strain, although the relative importance of reactivation versus reinfection has not been fully elucidated. The degree of effectiveness of natural immunity in preventing congenital CMV infection and its attendant sequelae is not established with certainty. A number of studies have described fetal CMV transmission in women with preconception immunity, a result of reinfection with new strains of CMV.[68–73] Such infections can produce sequelae identical to those observed in congenitally infected infants born to women with primary CMV infection during pregnancy. These observations complicate CMV vaccine design, and suggest that (a) for full protection, a CMV vaccine may need to stimulate responses superior to those conferred by natural immunity; and (b) there may be a strong rationale for vaccinating seropositive individuals, with the goal of increasing immunity and preventing reinfections.

TABLE 16.1 Annual Impact of Estimated Congenital Cytomegalovirus Infection and Disease in Europe and the United States

Category of Infants	Total
Total number of live births per year	8,600,000
Average rate of congenital CMV infection (%)	0.7
Total number of newborns with CMV infection	60,200
Number with symptomatic infection (12.7%)	7645
Number with fatal disease (~4%)	306
Number of survivors with sequelae (40–58%)	3058–4434
Number with asymptomatic infection (87.3%)	52,555
Number with sequelae (13.5%)	7095

CMV, cytomegalovirus.
From Dollard SC, Grosse SD, Ross DS. New estimates of the prevalence of neurological and sensory sequelae and mortality associated with congenital cytomegalovirus infection. Rev Med Virol. *2007;17:355–363, 2007.*

Although imperfect, several studies indicate that preconception immunity clearly does confer reduction in both the risk of congenital CMV transmission and the risk of sequelae if transmission occurs. Reported rates of transmission of CMV to the fetus in the setting of proven primary maternal infection are quite high, with ranges spanning 24% to 75%; an overall risk of transmission of approximately 30% was estimated in a 2007 metaanalysis.[16] Transmission rates are much lower (in the range of 1–2%) in women with preconception immunity who are reinfected during pregnancy,[68–71] compared to women with primary infection, although the relative contributions of secondary infection with novel strains and reactivation of latent strains remain incompletely defined.[72,73] At least two studies have compared transmission of CMV to the fetus from seronegative women and seropositive women, in an attempt to gauge the protective benefit of preconception immunity. Protection in seropositive women was 60% in one study and 91% in another.[74,75] In addition to decreasing the risk of infection, preconception immunity also reduces the risk of severe sequelae in those infants who acquire infection in utero. It has been reported that 25% of congenitally infected infants born to mothers with a primary CMV infection during pregnancy had at least one sequela, compared with only 8% in infants born to women with recurrent infection.[76]

A major hurdle encumbering CMV vaccine development is the lack of a clearly defined correlate of protective immunity. Considering that human CMV is a large and complex virus encoding at least 200 proteins, it is not surprising that immune control involves more than one arm of the immune system. Several lines of evidence suggest a key role for antibody in protection against congenital infection and disease. Antibodies to virally encoded envelope glycoproteins have also been shown to be protective against congenital guinea pig CMV

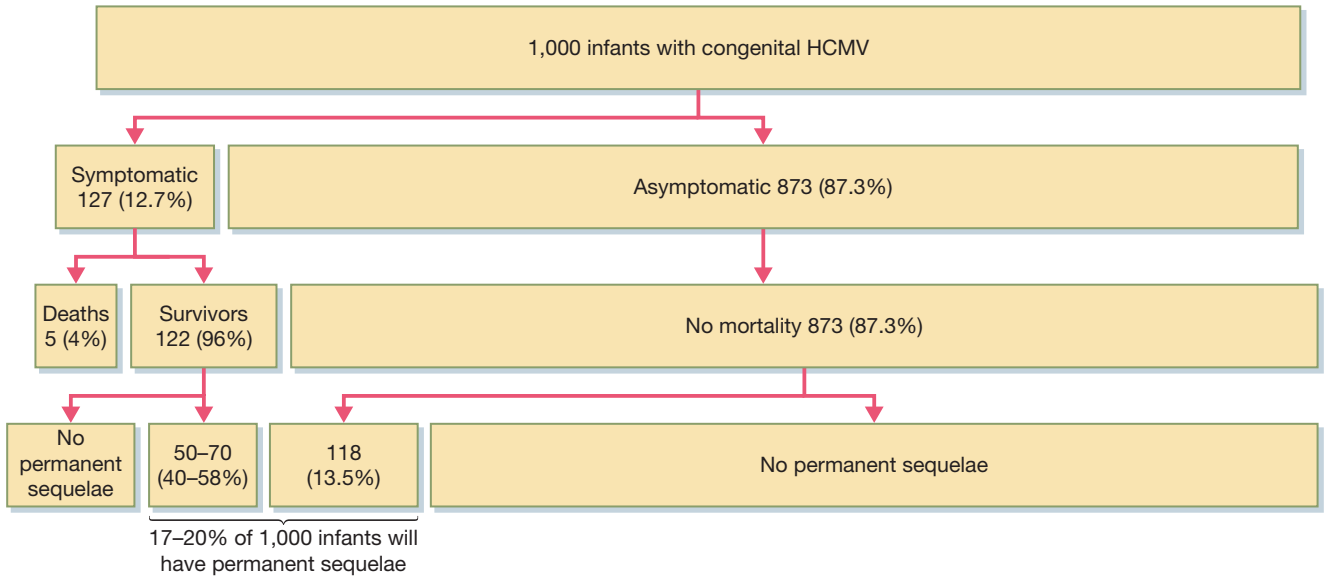

Figure 16.1. Current estimates of magnitude of long-term sequelae in infants with congenital cytomegalovirus (CMV) infection in the United States. In a given cohort of 1000 infants with congenital CMV infection, 170 to 190 will have permanent sequelae, with one-third from the symptomatic group and two-thirds from the asymptomatic group. HCMV, human cytomegalovirus. *(Data from Dollard SC, Grosse SD, Ross DS. New estimates of the prevalence of neurological and sensory sequelae and mortality associated with congenital cytomegalovirus infection.* Rev Med Virol. *2007;17:355–363.)*

infection.[77–79] Moreover, the use of human CMV immunoglobulin has proved to be useful in SOT recipients, in whom good evidence for approximately 50% prevention of CMV disease has been demonstrated.[80–87] In addition to modifying the risk of infection in transplant recipients, the importance of antibodies in protection of premature infants against postnatally acquired CMV infection is supported by the observations of clinical efficacy of passive maternal IgG against virus transmission via blood transfusion.[88,89] There may be some evidence for protection of the fetus conferred by passive administration of antibodies to pregnant women who are at high risk for transplacental transmission of virus.[90] In an uncontrolled study conducted by Nigro and colleagues, hyperimmune CMV immunoglobulin therapy was associated with significantly lower risks of congenital CMV infection and disease.[91] However, in a Phase IIB, randomized, double-blind study conducted by Revello and colleagues (CHIP study), CMV hyperimmunoglobulin, when compared to saline placebo, did not have a statistically significant impact on the rate of CMV transmission in pregnant women with primary CMV infection.[92,93] An National Institutes of Health (NIH)-supported multicenter trial is ongoing to resolve the question of the impact of passive CMV immunoglobulin therapy on congenital CMV transmission in pregnant women with primary CMV infections.[94] Putative beneficial effects of CMV hyperimmunoglobulin treatment for the infected fetus appear to be mediated in part at the placental-fetal interface.[95–97] In the Nigro study, hyperimmunoglobulin treatment was associated with maintenance of normal placental size and structure, as measured by ultrasound, and with normal placental histology, as compared to untreated CMV-infected controls.[98,99] Finally, as discussed below, glycoprotein B (gB) vaccine protected women and solid-organ transplant recipients against CMV infection in clinical trials, providing additional support for a key role for antibody in mediating protection.

Until recently, CMV-neutralizing antibodies were measured in the laboratory based upon their ability to prevent CMV infection of human fibroblast cells. In 2005, Wang and Shenk demonstrated that the ability of CMV to infect epithelial cells was dependent on the presence of intact CMV genes capable of encoding proteins UL128-131, genes that were routinely deleted or mutated in viral strains highly passaged in fibroblasts.[100] Moreover, these proteins formed a pentameric complex (PC) with the gH and gL glycoproteins of the virus. Although the gH/gL proteins are capable of inducing neutralizing antibodies, neutralization is improved by including the UL128-131 subunits in a vaccine formulation.[101–103] Studies in many laboratories indicate that viral neutralization at epithelial cell surfaces requires antibody to the CMV PC (described below; see Table 16.2). A recent analysis of the virus-neutralizing characteristics of CMV hyperimmunoglobulin performed by serial depletion of antibody to cell-surface expressed surface proteins indicated that the major neutralizing antibody response was directed to PC, suggesting that the contribution of anti-gB antibodies to the overall CMV neutralization profile may have been overestimated in earlier studies.[104] Studies by the group in Pavia, Italy, suggested that early appearance of antibodies against the PC correlated with protection against transplacental virus transmission in women with primary CMV infection, while development of gB antibodies was not protective.[105]

Although antibody is a vital component of protection, it is evident that cellular responses are also important in the control of CMV infection. In the setting of transplantation, the correlation between recovery of host cellular immunity and freedom from CMV disease has been apparent for many years.[106–111] $CD4^+$ cells sensitized to the virus appear to be necessary to resolve the persistent excretion of CMV by congenitally infected children,[112] and delayed development of a CMV-specific $CD4^+$ T-cell response has been observed in infected mothers who transmitted virus to the fetus.[113] $CD8^+$ cytotoxic T cells are also important in immunity to CMV, particularly those that target the immunodominant CMV tegument phosphoprotein, pp65. This has been confirmed by the demonstration of the therapeutic efficacy of adoptive transfer of both pp65-specific and mixed populations of cytotoxic T lymphocyte (CTL) cells to bone marrow transplant recipients in preventing development of CMV disease in the posttransplantation setting.[106,114,115] Interestingly, CMV-specific $CD8^+$ cells are also found in congenitally infected children who have infections that do not disseminate after birth,[116,117] although T-cell responses in these infants are reduced in both frequency and functionality when compared to adult subjects.[118] The targets of $CD8^+$ T cells that appear to be of paramount importance in protection are the immediate-early antigen 1 (IE1) and, as noted, the pp65 tegument protein.[119–121] T-cell epitopes encoded by additional CMV proteins may also be required for optimal T-cell–mediated protection, and may be employed in future subunit vaccines.[122–124]

Table 16.2 lists several of the CMV proteins thought to be responsible for the induction of neutralizing and nonneutralizing antibodies as well as cellular immune responses (particularly CTL responses) in the normal seropositive host. Many are currently being evaluated in the various clinical trials of candidate CMV vaccines that are described below.

TABLE 16.2 Cytomegalovirus-Encoded Proteins That Might Be Included in a Subunit Vaccine

CMV Gene Product	Host Immune Response
ENVELOPE GLYCOPROTEINS	
gB	Major target of neutralizing antibodies; target of CTLs
gH/gL	Important target of neutralizing antibodies; target of CTLs
gH, gL, UL128–131 (PC)	PC of gH/gL/UL128/UL130/UL131 on viral envelope; target of neutralizing antibodies; antibodies neutralize CMV infection at epithelial and endothelial cell surfaces
gM/gN	Targets of neutralizing antibody responses
STRUCTURAL PROTEINS	
pp65	Major target of CTLs; target of nonneutralizing antibody responses
pp150, pp28	Targets of CTLs and nonneutralizing antibody responses
pp50	Target of CTLs
pp71, pp52	Targets of nonneutralizing antibody responses
NONSTRUCTURAL PROTEINS	
IE1	Major target of CTLs; target of nonneutralizing antibody responses

CMV, cytomegalovirus; CTL, cytotoxic T lymphocyte; IE1, immediate-early antigen 1; PC, pentameric complex.

VACCINES IN CLINICAL TRIALS

Recent years have seen a notable increase in the number of candidate CMV vaccines that are undergoing testing in human trials. The history of efforts to develop a CMV vaccine has been reviewed.[125] The various vaccine candidates are listed in

TABLE 16.3 Status of Cytomegalovirus Vaccines Evaluated in Clinical Trials

LIVE ATTENUATED AND DISABLED VIRUS VACCINES	
AD169 vaccine	• Elicited CMV-specific antibodies in seronegative vaccine recipients • Significant injection-site and systemic reactogenicity
Towne vaccine (± rhIL12)	• Elicits humoral and cellular immune responses • Favorable safety profile; no evidence for latency or viral shedding in recipients • Reduced CMV disease but not infection in renal transplant recipients • Augmented immunogenicity when administered with recombinant IL-12 in Phase I studies
Towne/Toledo chimera vaccines	• Favorable safety profile; no evidence for latency or viral shedding in CMV seropositive subjects • Attenuated compared to Toledo strain of HCMV • No efficacy data available; studies in seronegatives in progress
V160–001 replication-defective vaccine	• AD169 backbone with restoration of UL128/130/131 PC components • Rendered replication-incompetent by inclusion of ddFKBP/Shld1 • Administered with alum-based adjuvant • Phase I studies ongoing
SUBUNIT VACCINE	
Glycoprotein B (CHO cell expression) MF59 (Sanofi)/AS01 (GSK) adjuvants	• Favorable safety profile • High-titer neutralizing antibody and strong cell-mediated immune responses; augments humoral immunity in seropositives (gB/MF59) • Demonstrated efficacy in young women against primary infection and against CMV disease in solid-organ transplant patients (gB/MF59) • Safety and immunogenicity demonstrated with gB/AS01 in Phase 1 (no efficacy data)
PADRE-pp65-CMV and Tet-pp65-CMV fusion peptide vaccines ± CpG DNA adjuvant	• Lipidated fusion peptides constructed from pp65 CTL epitopes • Linked to either a synthetically derived pan-DR or Tet epitope • Phase I studies ongoing
eVLP VACCINE	
eVLP gB vaccine (HEK cells) ± alum adjuvant	• eVLPs formed by cotransfection of MMLV gag and gB constructs • Extracellular domain fused with transmembrane and cytoplasmic domains of VSV G protein • Phase I studies currently in progress
VECTORED VACCINES	
Glycoprotein B/canarypox vector	• Favorable safety profile • Suboptimal immunogenicity • "Prime-boost" effect upon combined administration with Towne
pp65 (UL83)/canarypox vector	• Favorable safety profile • Strong antibody and cell-mediated immune responses
gB/pp65/IE1 trivalent DNA vaccine; gB/pp65 bivalent DNA vaccine	• DNA adjuvanted with poloxamer adjuvant and benzalkonium chloride • Phase II study with bivalent gB/pp65 vaccine in HSC transplant recipients demonstrates impact on CMV disease • Phase III study of bivalent vaccine ongoing in transplant patients • Trivalent vaccine (gB/pp65/IE1) was evaluated with Towne in prime-boost vaccination study
gB/pp65/IE1 alphavirus replicon trivalent vaccine	• Engineered using replication-deficient alphavirus technology • Generation of virus-like replicon particles • Phase I clinical trial recently reported • Virus-neutralizing antibody and cell-mediated immune responses
gB/pp65 LCMV bivalent vectored vaccine	• Vectored using LCMV backbone • LCMV GP gene replaced by gB, pp65 • Disabled, single round of replication • No antivector immunity (allows for boosting) • Virus-neutralizing antibody, cellular ($CD4^+$, $CD8^+$) responses

CMV, cytomegalovirus; CpG, cytosine phosphate guanine; CTL, cytotoxic T lymphocyte cell; HCMV, human cytomegalovirus; IE1, immediate-early antigen 1; IL, interleukin; LCMV, lymphocytic choriomeningitis virus; PC, pentameric complex; rhIL, recombinant human interleukin.

Table 16.3 and are discussed in detail below. They can be broadly grouped into three categories: *live attenuated vaccines*; *subunit vaccines* based on recombinant proteins and peptides; and *vectored vaccines* comprising combinations of key CMV immunogens in various expression systems. These categories are individually reviewed in the following sections.

Live Virus Vaccines

The first approach to CMV vaccine development employed live attenuated strains of virus passaged in tissue culture. Elek and Stern[126] initially used the AD-169 laboratory strain to immunize normal adults, but the strain was not further developed. Plotkin and colleagues[127] isolated a strain (Towne) from a congenitally infected infant and passaged it in human embryo fibroblasts until the 125th passage, in the process performing three clonings by plaque purification; pools were then prepared at the 128th passage for vaccine trials.[128–130] Initial clinical trials were performed in healthy adult volunteers.[131,132] In these studies when the vaccine was given subcutaneously or intramuscularly, seroconversion was seen in nearly 100% of volunteers (Fig. 16.2), but intranasal administration did not stimulate immunity. During the second week after immunization, a local reaction consisting of erythema

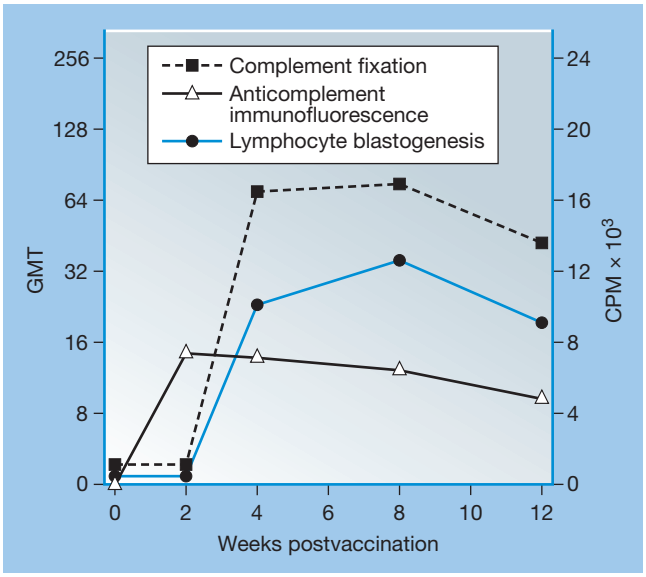

Figure 16.2. Typical immune responses to the Towne strain of live attenuated cytomegalovirus (CMV) vaccine showing the development of complement fixation antibodies, anticomplement immunofluorescence antibodies, and CMV-specific blastogenic responses. CPM, counts per minute; GMT, geometric mean antibody titer.

and induration appeared at the site of inoculation and lasted approximately 1 week, but systemic reactions were absent. Surprisingly, no virus was excreted in the pharynx or urine and virus was not recovered from the blood. Routine clinical laboratory tests also showed no abnormalities. Subsequent studies showed the persistence of antibodies for at least several years in adult female pediatric nurses who were vaccinated with the Towne strain.[133]

In the Towne vaccine studies, lymphocyte proliferation assays demonstrated sensitization to CMV antigens induced by vaccination. $CD8^+$ cell-mediated human leukocyte antigen (HLA)-restricted cytotoxicity of CMV-infected cells also was elicited in the Towne vaccinees.[134,135] Towne virus thus induced both cellular and humoral immunity to CMV.[136] However, tests of lymphocyte subsets after vaccination failed to show the increase in suppressor cells and decrease in the helper-to-suppressor cell ratio characteristic of acute CMV disease.[137] Studies of cellular immune responses in Towne vaccine recipients performed by Jacobson[138] confirmed that all vaccinees developed both $CD4^+$- and $CD8^+$-mediated responses, but over the course of 12 months those responses declined, particularly to the pp65 protein.

In related studies, sera of vaccinees were tested for antibodies to early antigens (EAs) and immediate early antigens (IEAs) of the virus.[139,140] These proteins are not present in the virus particle and are synthesized only during viral replication. Assessment of serologic, biopsy, and polymerase chain reaction (PCR) data led to the conclusion that Towne vaccine produced an abortive infection at the site of inoculation and stimulated a range of antibody and cellular responses similar to those noted after natural infection, including delayed-type hypersensitivity. However, immune responses were lower than after natural infection, perhaps because no virus excretion or systemic reaction occurred after vaccination.[141]

Vaccine Efficacy in Transplantation Patients

To evaluate efficacy of Towne vaccine, advantage was taken of the high morbidity and mortality that CMV causes in seronegative renal transplant recipients who receive a kidney from a seropositive donor.[142–144] After a pilot study to demonstrate tolerance of the vaccine, controlled, double-blind trials were conducted in prospective renal transplant recipients at academic hospitals at both the University of Pennsylvania and the University of Minnesota. The seronegative patients were randomized to receive vaccine or placebo subcutaneously prior to transplantation. Following transplantation, the patients were observed clinically, virologically, and serologically and scored for CMV-associated disease severity by individuals blind to the patients' vaccine status.[145–147] CMV disease scores were calculated based on assessment for fever; laboratory abnormalities including leukopenia and thrombocytopenia; hepatitis; pneumonia; gastrointestinal bleeding or ulceration; central nervous system changes including lethargy, stupor or coma; renal insufficiency; arthritis; secondary infection; and death.[147] Despite the induction of relatively poor antibody and cellular immune responses, the vaccine appeared to provide protection against severe CMV disease of a magnitude similar to that of prior natural infection. Two additional studies in renal transplantation patients, one of which was a multicenter study, reached the same conclusion.[148,149] In the double-blind, randomized, placebo-controlled multicenter trial, severe CMV disease was markedly reduced by vaccination, with an incidence of 17% in controls, versus 0% in vaccine recipients ($P < .03$).[148] Thus, Towne immunization rendered seronegative patients more resistant to the effects of CMV infection. Notably, no study has ever demonstrated evidence of shedding of Towne virus in any vaccine recipient; this has been confirmed by examination of viral strains in subjects in Towne vaccine studies that were later found to be shedding virus. In subjects shedding virus who received kidneys from seropositive donors, viral strains were shown by DNA restriction-endonuclease assays to be identical to strains that were latent in the donor kidneys that had been reactivated after transplantation, and not identical to the Towne strain.

TABLE 16.4 Doses of Subcutaneous Cytomegalovirus Challenge Required to Infect or Cause Disease

	Infection (PFU)	Disease (PFU)
Seronegative	≤10	≤10
Natural seropositive	~500	1000
Vacinees	100	≥100

Challenge Studies in Immunocompetent Towne Vaccinees

After this demonstration of safety and efficacy, volunteer Catholic priests who lived in a closed community and who were CMV-seronegative were vaccinated with Towne vaccine to determine whether they could be protected against a subsequent artificially administered challenge. One year later, in company with unvaccinated seronegative and naturally seropositive priests, they were challenged subcutaneously with varying doses of an unrelated and less attenuated wild-type CMV isolate called Toledo (see Fig. 16.3 for a comparison of the respective genome structures of Towne and Toledo virus). Table 16.4 shows the results. Although subsequent molecular studies demonstrated that the Toledo strain is not a fully authentic wild-type strain, since it contains both a genomic inversion and a mutation that abrogates synthesis of an intact UL128 (PC subunit),[150] a challenge dose of 1000

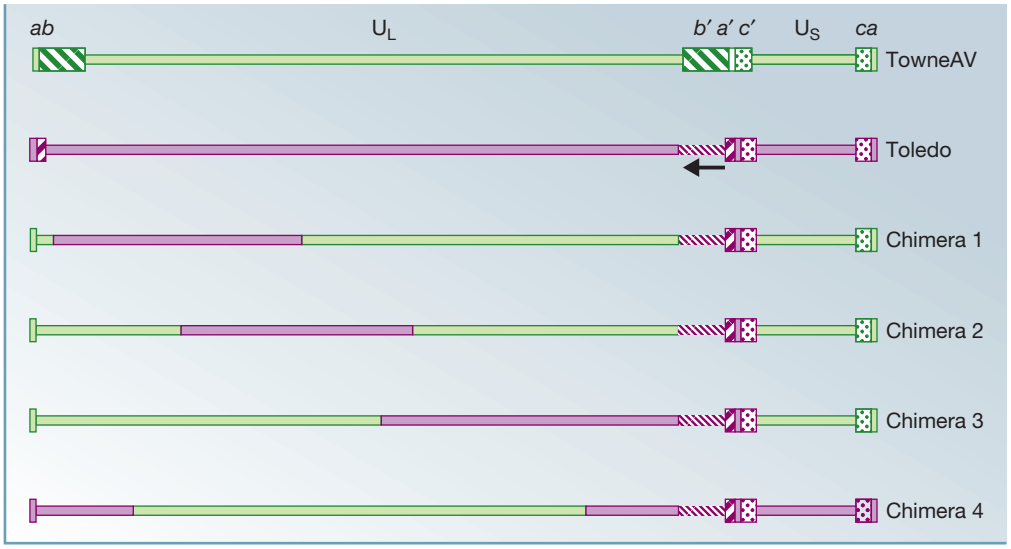

Figure 16.3. Genomic structures of cytomegalovirus Towne, Toledo, and four live attenuated "chimeric" vaccine candidates currently in clinical trials. The specific regions of each chimera's genome derived from Towne and Toledo are shown. The ULb′, unique long (U_L), unique short (U_S), and repeat (ab, b′a′c′, ca) regions of the genomes are shown. *(Modified from Heineman TC, Schleiss M, Bernstein DI, et al. A phase 1 study of 4 live, recombinant human cytomegalovirus Towne/Toledo chimeric vaccines*. J Infect Dis. *2006;193:1350–1360.)*

plaque-forming units (PFU) in this study nonetheless caused illness, even in those who were naturally seropositive; therefore, this dose was not given to other groups.[151] With a reduction to a 100-PFU dose, the challenge virus caused a mild infectious mononucleosis syndrome with virus excretion in seronegative individuals, but it was asymptomatic in naturally seropositive individuals.[152] Vaccinees also were protected against disease caused by 100 PFU, but about half transiently excreted virus asymptomatically. After injection of 10 PFU, CMV infection and symptoms were seen in the seronegative individuals, whereas both vaccinated and naturally seropositive individuals resisted the challenge. Thus, vaccination of normal individuals rendered them resistant to an artificial parenteral challenge, but with protection of lower magnitude than that conferred by natural immunity.

Despite the protection thus demonstrated against parenteral infection, in another study Towne vaccine failed to prevent infection of seronegative mothers in close contact with CMV-excreting children, although naturally seropositive women were protected.[75] This controlled trial showed no reduction in the infection rate of Towne-vaccinated mothers compared with placebo-inoculated seronegative mothers. The authors speculated that the 20-fold lower neutralizing antibody levels induced by Towne vaccine in comparison with those observed in the setting of natural seropositivity accounted for the vaccine's failure. Route of infection may have also played a role, since these young women presumably acquired CMV infection at mucosal surfaces following exposure to infectious body fluids (urine, saliva), in contrast to the parenteral route of inoculation carried out in the Toledo challenge studies.

Strategies to Improve Towne Immunogenicity

A number of strategies to improve the immunogenicity of the Towne vaccine are currently being explored. One approach is to coadminister Towne with recombinant human interleukin (IL)-12 (rhIL-12). The immunogenicity and safety of this approach was evaluated in a Phase I, dose-escalation, randomized clinical trial in CMV-seronegative healthy volunteers.[153] The adjuvant effect of rhIL-12 was associated with dose-related increases in peak anti-CMV antibody titers and improved $CD4^+$ T-cell proliferation responses. The vaccine with adjuvant rhIL-12 at doses up to 2 μg was well tolerated and did not lead to Towne persistence, confirmed by whole blood CMV DNA PCR and urine CMV culture.

In another approach aimed at improving the immunogenicity of the Towne vaccine, a CMV DNA vaccine (described in greater detail in the following section), designated as VCL-CT02, was used to prime for memory immune responses to subsequent Towne vaccination. The priming efficacy of VCL-CT02, containing the three CMV genes pp65, IE1, and gB cloned from AD169 strain, along with Towne vaccine challenge was evaluated in a series of Phase I clinical trials in healthy CMV-seronegative volunteers.[154] The median time to first pp65 T-cell response and gB antibody response after Towne vaccine was 14 days for DNA-primed subjects, and 28 days for controls who were administered Towne vaccine only, suggesting a more rapid induction of antigen-specific responses with the DNA vaccine-primed group. Vaccination with VCL-CT02 was found to safely prime for an anamnestic response following subsequent administration of Towne vaccine. Urine CMV cultures obtained after the Towne booster were negative in all subjects. Preclinical studies of DNA vaccine priming followed by boosting with Towne vaccine in mice demonstrated that priming significantly enhanced T-cell responses against gB, pp65, and IE1 as measured by interferon (IFN)-γ secretion.[155]

Towne/Toledo Chimeric Vaccine Approach

Scientists at MedImmune (formerly Aviron) discovered that some variants of the Towne vaccine strain had genetic deletions (~13.5 kb) in a particular part of its genome, designated as the ULb′ region.[156,157] This region, present in all low-passage clinical isolates, contains at least 17 genes not found in the Towne strain. Some of these gene products have emerged as important targets of host immune responses, latency, and pathogenicity.[158,159] Another difference in the genome of the Towne strain of CMV compared to clinical isolates is the discovery of a mutation in the Towne UL130 gene coding sequence that abrogates synthesis of a functional UL130 protein, a constituent of the PC[160]: this mutation may play a role in the attenuation of the Towne vaccine. In light of these observations, it was hypothesized that restoration of the

Toledo ULb′ sequences in the background of Towne virus might provide one or more genes coding for proteins that would increase the replication and immunogenicity of the Towne strain in vivo, resulting in a more efficacious vaccine. To address this possibility, four recombinant chimeric variants of Towne and the low-passage virulent Toledo strain have been made in which different segments of Towne have been replaced by the analogous sequences of Toledo (Fig. 16.3).[161] Phase I trials of safety and immunogenicity of these recombinant vaccines were initially conducted in seropositive subjects. These recombinants were well tolerated but not immunogenic in the seropositive volunteers. The lack of evidence of boosting of immune responses in seropositive subjects in this initial Phase I study may have implications for the prospects of vaccine-mediated protection against reinfection (and potential vertical transmission) in seropositive individuals. This theoretical shortcoming aside, subsequent studies of these chimeras in seronegatives focused on identifying distinctions in safety and immunogenicity among the recombinants, and correlating these findings with genetic markers that could elucidate the impact of viral gene variation on immune response as well as pathogenicity. A study of these chimeric vaccines in healthy, CMV-seronegative males conducted by Adler and colleagues at Virginia Commonwealth University has recently been published (NCT01195571, clinicaltrials.gov).[162] All these chimeras were safe, and none was shed by vaccinees, which is reassuring with respect to safety. Notably, all the chimeras were found to carry a mutation in *UL128* that presumably renders the vaccine viruses incapable of forming a functional PC. The impact of this mutation on immunogenicity and protection will require additional study.

Replication-Defective Virus Vaccine Approach

Recently, Tong-Ming Fu and colleagues at Merck have initiated a randomized, double-blind, placebo-controlled, dose escalation study of a candidate vaccine, V160, in healthy adult subjects.[162–165] This vaccine restored the UL128/UL130/UL131 proteins to the genome of the AD169 strain of CMV, in the process allowing a functional PC to be formed toward the goal of eliciting high-titer antibody capable of neutralizing virus infectivity at the epithelial-endothelial cell interface. In addition, it linked two CMV gene products, UL51 and IE1/2, to the destabilization domains of FK506 binding protein, ddFKBP, in the process rendering protein stability dependent on the presence of the small molecule Shield 1 (Shld 1). Accordingly, viral progeny can only form in cell culture when Shld 1 is provided by stable transfection, which allows production of a replication-defective candidate vaccine. Because Shld 1 is a synthetic ligand that does not exist in any natural biological system,[166] the resulting virus is safe for human use, as it can give only one cycle of replication in the human host, but as a vaccine it should be able to, in principle, confer the full breadth of immune responses to all relevant CMV antigens. In addition to eliciting high-titer antibody to the PC, preclinical animal testing indicates that this vaccine engenders cellular responses. This Phase I study is currently ongoing (NCT01986010, clinicaltrials.gov).

SUBUNIT VACCINE

Glycoprotein B Vaccines

The administration of purified protein subunit vaccine in CMV vaccine trials has chiefly focused, to date, on the glycoproteins in the envelope of the CMV virion that induce virus-neutralizing antibodies (see Table 16.2). Among the numerous glycoproteins present in the envelope, most attention has been directed toward the *gB protein* (so-called because of its analogy with the herpes simplex gB). All CMV-seropositive individuals have antibody to gB.[167,168] The glycoprotein analogous to gB has both been purified from guinea pig CMV-infected cell lysates and/or expressed via a number of recombinant methodologies, and when administered as a vaccine has been shown to protect pups born to mothers immunized before pregnancy and subsequently experimentally challenged with virus during gestation.[169–172] The gB protein initially was purified from the virus by immunoaffinity chromatography and inoculated into animals and then humans, with induction of neutralizing antibodies.[173–176] Subsequently, the gene for gB was inserted into several expression vectors for in vitro production and purification of the protein. Spaete and his colleagues at Chiron (Chiron was acquired by Novartis vaccines, which was subsequently acquired by Glaxo-Smith-Kline [GSK] vaccines) produced a truncated gB in Chinese hamster ovary cells, engineered to be secreted as a truncated, uncleaved polypeptide into cell supernatants.[177] Clinical trials have been performed using this purified protein (the gB vaccine was acquired from Chiron by Sanofi-Pasteur vaccines, prior to Chiron's acquisition by Novartis) combined with an oil-in-water emulsion adjuvant known as MF59. The initial report of the use of gB vaccine was a Phase I randomized, double-blind, placebo-controlled trial, in adults, in which gB was combined either with MF59, or alum, with vaccine administered at a 0-, 1-, and 6-month schedule.[178] Levels of gB-specific antibodies and total virus-neutralizing activity were determined 2 weeks after the third dose of vaccine, and were found to exceed those observed in CMV-seropositive control subjects. Formulation with MF59 was substantially more immunogenic than with alum. The optimal dose of vaccine appeared to be between 5 μg and 30 μg of gB. A fourth vaccine was given at 12 months to a subgroup in this study and neutralizing antibody increased from a geometric mean titer of 26 to 113, although 1 year later it fell to 57.[178] Antigen dose and immunization regimen were further evaluated in a Phase I study of 95 CMV-seronegative adult volunteers.[179] A 5-μg dose of gB/MF59 was compared with a 30-μg dose, at dose intervals of 0, 1, and 2 months; 0, 1, and 4 months; or 0, 1, and 6 months. There was no significant difference in antibody production between the two dose levels, but the vaccine induced the highest antibody titers when given as the 0-, 1-, and 6-month regimen. The immunogenicity and safety of recombinant gB were subsequently studied in toddlers.[180] A 20-μg dose was evaluated in 15 children (age range: 12–35 months) administered at 0, 1, and 6 months. After the third dose of vaccine, antibody responses of toddlers were greater than those of naturally infected adults and were notably higher than those of adults who had received three doses of the same vaccine in earlier trials. Interestingly, both mucosal immunoglobulin G and secretory immunoglobulin A antibodies were induced in many vaccinees studied in clinical trials of gB/MF59 vaccine. Presence of the former in vaccinees has been correlated with a serum neutralizing antibody titer of over 1 : 64.[181]

Because the immune responses engendered against gB/MF59 target the version of the gB sequence encoded by the "Towne" strain of CMV, there is a theoretical concern that antibodies elicited by this vaccine may fail to cross-neutralize clinical isolates of CMV, which may encode different amino acid sequences in key gB epitopes. This concern, however, does not appear warranted, as serum from vaccinees is capable of broad cross-neutralization of clinical isolates of CMV.[182] Moreover, the sequence and structural modifications introduced into the vaccine form of gB do not appear to have impaired the authenticity of the anti-gB response, as antibodies from subjects vaccinated with gB/MF59 recognize the major neutralizing domains of the protein.[183] Vaccinees exhibit high levels

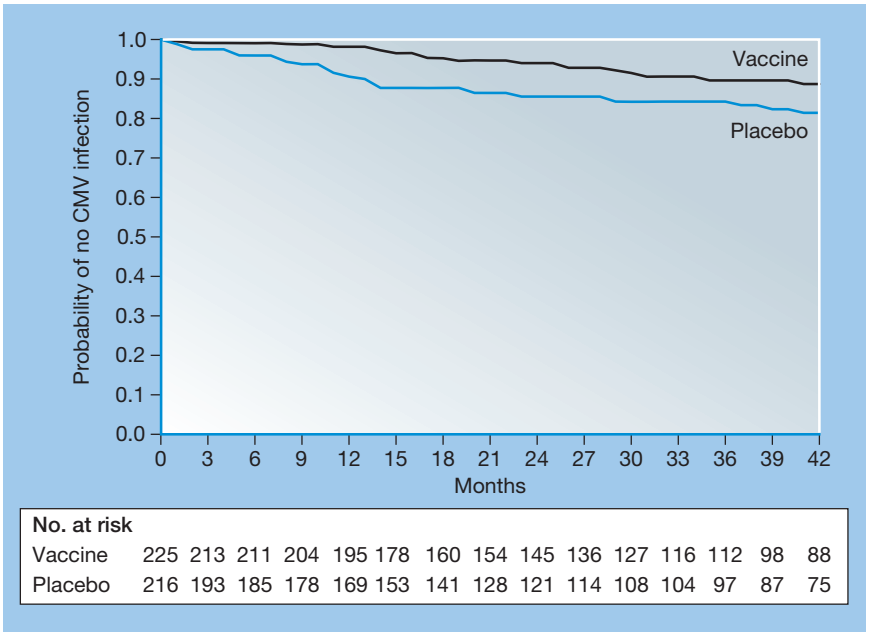

Figure 16.4. Efficacy of recombinant, adjuvanted cytomegalovirus (CMV) gB vaccine in seronegative women from a placebo-controlled study. Kaplan-Meier estimates of probability of remaining CMV-uninfected are shown. Up to 42 months after study enrollment, subjects in the vaccine group were more likely to remain free of CMV infection than were subjects in the placebo group ($P = .02$). In the vaccine group, 18 subjects were found to have CMV infection compared with 31 in the placebo group. *(Data from Pass RF, Zhang C, Evans A, et al. Vaccine prevention of maternal cytomegalovirus infection*. N Engl J Med. *2009;360:1191–1199.)*

of antibody avidity, comparable to those observed in natural infection.[184] Vaccine recipients also demonstrated an antibody response to the AD-2 epitope of gB, an important epitope in antibody-mediated neutralization, that was comparable to natural seropositives.[185] Recent insights into the postfusion conformation of gB should facilitate an improved understanding of the mechanisms of antibody-mediated neutralization.[186]

Pass and colleagues reported the results of a Phase II efficacy trial of the gB-MF59 vaccine conducted at the University of Alabama, Birmingham. This trial was undertaken in adolescent and young adult women who were at high risk for acquisition of CMV between pregnancies, with an annualized seroconversion rate of 7.8%.[74] The study was a randomized, double-blind, placebo-controlled clinical trial in seronegative women of childbearing age; 21% of the subjects had a toddler (age 13–36 months) at home. Vaccine (20 µg with MF59 adjuvant) or placebo was administered according to a 0-, 1-, and 6-month schedule.[187] The primary end point reported in this study was the time to primary CMV infection, documented by seroconversion using a gB-absorbed CMV immunoglobulin G assay.[188] Fig. 16.4 demonstrates the impact of gB vaccine on acquisition of CMV infection in this patient population. Primary CMV infection was confirmed by virus culture or immunoblotting in 18 of 225 (8%) in the vaccine group compared to 31 of 216 (14%) in the placebo group, an efficacy of 50% (95% confidence interval, 7–73%). The beneficial effect of vaccine appeared somewhat short-lived, being apparent for approximately 18 months, during the time window when vaccine-derived antibodies to gB were demonstrable. Limited information could be gleaned from this study about the impact of vaccine on congenital CMV infection. Congenital CMV infection occurred in 1 of 81 (1%) and 3 of 97 (3%) infants born to vaccine and placebo recipients, respectively. One infant in the placebo group had severe symptomatic congenital CMV infection. However, the sample size was too small to draw conclusions about efficacy against congenital infection. In another recently reported study of gB/MF59 vaccine in seronegative adolescent women, efficacy was somewhat lower than in the Pass study. In that study, adolescents completing the three-dose series (164 vaccine, 170 placebo) had 18 documented CMV infections in the placebo group and 11 in the vaccine group, with an efficacy of 38% (95% confidence interval, −31 to 72; $P = .20$) in the intent-to-treat analysis.[189]

In addition to studies in CMV seronegative individuals, gB-MF59 vaccine has also been evaluated for its potential to boost immune responses in individuals who are already CMV-seropositive. In a study of 120 seropositive women receiving a three-dose series of gB-MF59 vaccine (0-, 1-, and 6-month schedule), both CMV-specific antibody (enzyme-linked immunosorbent assay [ELISA] and neutralizing titer) and $CD4^+$ T-cell responses were significantly boosted.[190] This demonstration that antibody and T-cell responses could be augmented in an individual already infected with CMV may have implications for vaccination of seropositive women. Because approximately 75% of congenital CMV infections in the United States result from recurrent infections among pregnant women,[191] these data suggest an important potential strategy of immunizing seropositive individuals, toward the goal of preventing CMV reinfection and subsequent congenital transmission.

Further evidence of the potential usefulness of the gB-MF59 vaccine comes from a placebo-controlled Phase II study in solid-organ transplant recipients.[192] Seventy CMV seronegative and 70 CMV seropositive patients awaiting kidney or liver transplantation were randomized to receive either gB-MF59 adjuvant (20-µg dose, administered on a 0-, 1-, and 6-month schedule) or placebo. Anti-gB ELISA and neutralizing titers were stimulated in seronegative transplant recipients and were significantly boosted in seropositive subjects. Posttransplantation, the magnitude and duration of CMV viral DNA detection in blood (DNAemia), as well as the total number of days of antiviral (ganciclovir) therapy, were compared across groups. The results were striking, particularly for gB-MF59–vaccinated seronegative recipients of organs from seropositive donors, in

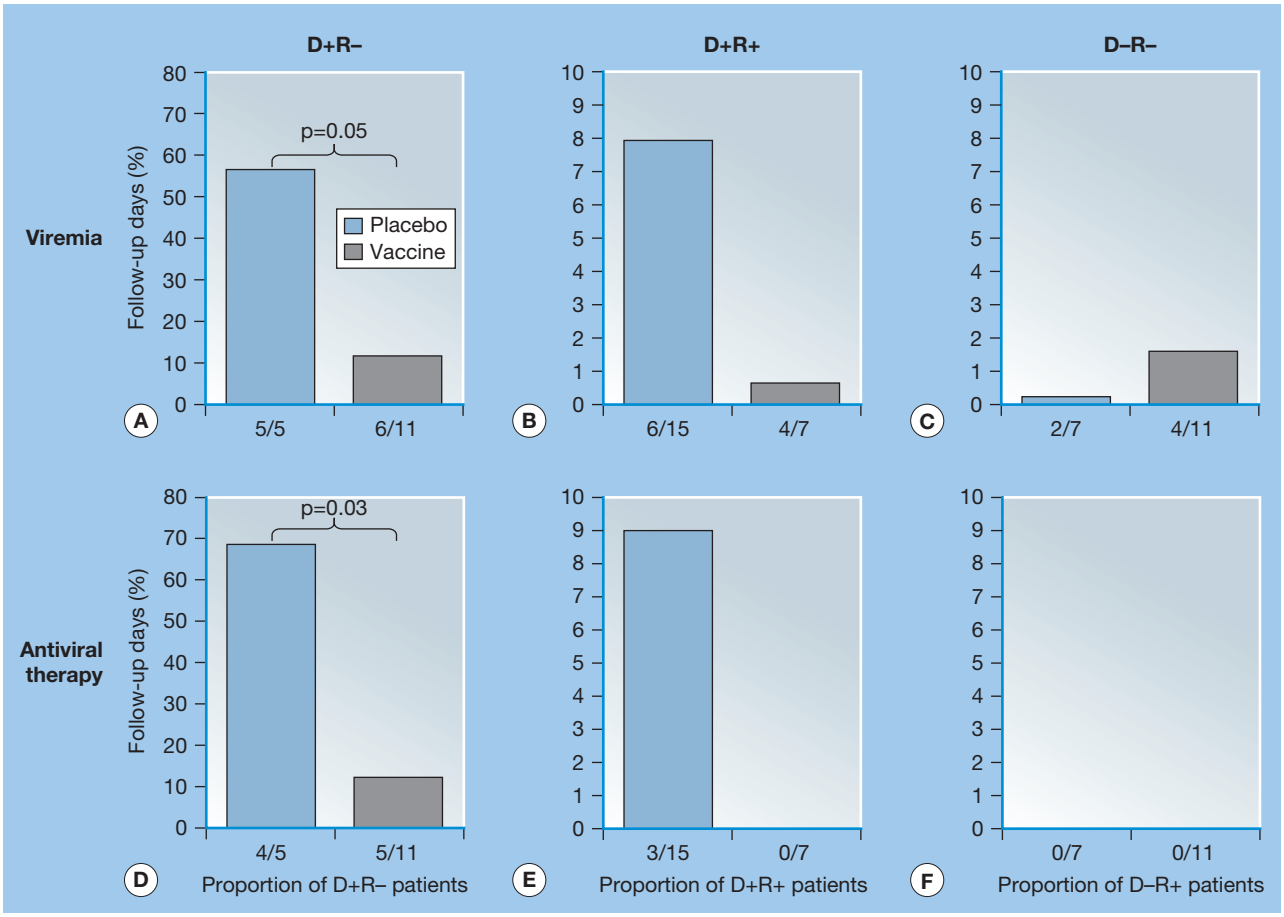

Figure 16.5. Impact of gB/MF59 vaccine in kidney or liver transplantation patients. The proportion of days that patients in the three subgroups at risk of CMV infection (D+R–, D+R+, or D–R+) experienced either viremia (panels **A** to **C**) or required antiviral therapy (panels **D** to **F**). The total number of patients with viremia or requiring antiviral therapy is indicated below each column. Recombinant gB vaccine had a statistically significant impact on both end points in the D+R– subgroup. D–, cytomegalovirus seronegative donor; D+, cytomegalovirus seropositive donor; R–, cytomegalovirus seronegative recipient; R+, cytomegalovirus seropositive recipient. *(Data from Griffiths PD, Stanton A, McCarrell E, et al. A randomised placebo controlled pharmacodynamic trial of cytomegalovirus glycoprotein B vaccine with MF59 adjuvant in transplant patients*. Lancet. *2011;377:1256–1263.)*

whom both the duration of DNAemia and the total number of days of ganciclovir administration were significantly reduced when compared to placebo recipients (Fig. 16.5). Only one patient (placebo recipient) was observed to have CMV end-organ disease, so no assessment of the efficacy of vaccination on the development of CMV disease could be made. Anti-gB antibody titer correlated directly with the virus-neutralizing capacity of serum, and there was an inverse correlation between antibody titer and the duration of DNAemia. These observations suggest that a gB subunit vaccine may ultimately prove useful in not only preventing or modifying congenital CMV infection, but also in reducing CMV disease following solid organ transplantation.

Other formulations of recombinant gB vaccine have been evaluated in early Phase I studies. A secreted, uncleaved form of CMV gB, fused to a portion of the herpes simplex virus-2 gD protein, was developed by GlaxoSmithKline vaccines, and has been evaluated with adjuvant AS01 for immunogenicity and safety (NCT00435396, clinicaltrials.gov). The gB/AS01 vaccine, designated as GSK1492903A, induced virus-neutralizing antibody responses and $CD4^+$ T-cell responses, and neutralizing responses following vaccination persisted longer than those noted by historical comparisons to gB adjuvanted with MF59.[125] Other adjuvants for recombinant gB based on synthetic Toll-like receptor (TLR) 4 agonists have also been evaluated in preclinical studies but have not yet entered human trials.[193]

Peptide Vaccines

Another type of subunit approach evaluated in clinical trials has been peptide-based vaccines, based on identification of key immunogenic sequences important for T-cell responses in the CMV proteome. A peptide vaccine to induce cytotoxic T-lymphocyte (CTL) cells has been developed by the Beckman Research Institute at the City of Hope (California) and is currently being evaluated in Phase I studies (NCT00712634, clinicaltrials.gov). Lipidated fusion peptides were constructed from multiple pp65 CTL epitopes, linked to either a synthetically derived pan-DR epitope peptide (PADRE) or one of several tetanus T(H) epitopes.[194,195] The epitopes cover the most prevalent HLA alleles in the Caucasian population, and induced robust cytotoxic cellular immune responses in HLA A*0201/K(b) transgenic mice. In preclinical testing the fusion peptides were immunogenic when administered in saline solution by either subcutaneous or intranasal routes.[196] CpG-containing single-stranded DNA (CpG7909; ss-oligodeoxynucleotide) added to the fusion peptides dramatically upregulated immune recognition by either route.[197] A Phase I trial of these PADRE-CMV fusion peptide vaccines, administered either with or

without the cytosine phosphate guanine (CpG) 7909 DNA adjuvant, was conducted in CMV seronegative and seropositive subjects ages 18 to 55 years.[197] This study demonstrated expansion of vaccine-elicited pp65-specific T cells, particularly in those subjects receiving vaccine in combination with adjuvant.[198] A recent Phase Ib study (NCT01588015, clinicaltrials.gov) demonstrated safety of the adjuvanted Tet-pp65 fusion peptide vaccine, with no evidence of an increase in adverse events related to HSCT in vaccine recipients.[199] City of Hope and Fortress Biotech have recently collaborated to form a new subsidiary company, DiaVax Biosciences, that will advance these candidate peptide vaccines into clinical trials. A Phase II study of the Tet-pp65 fusion peptide vaccine, CMVPepVax, is currently planned in HSCT patients (NCT02396134, clinicaltrials.gov). Outcome measures will include CMV-related events such as viremia, initiation and use of antivirals, and CMV end-organ disease.

VECTORED VACCINES

In general, vectored vaccines against CMV express, through a variety of techniques, the key immunogens described in Table 16.2, alone or in combination. The various expression techniques currently in clinical trials are outlined below.

Canarypox-Vectored gB and pp65 Vaccine

CMV proteins believed to be essential for an effective vaccine have been expressed using viral vectors suitable for clinical trials. In addition to inducing antibody, such vectors are particularly useful in inducing CTL responses to heterologous proteins encoded by inserted foreign genes. One such approach uses recombinant canarypox as the viral vector. Because avian poxviruses do not replicate in mammalian cells, canarypox virus vectors are safe for human use. Sanofi Pasteur developed canarypox gB and pp65 recombinants that were evaluated in a series of clinical trials.[200–202] Canarypox gB vaccine was not as immunogenic as subunit gB, but the pp65 recombinant gave excellent antibody responses. In addition, all 14 seronegative subjects given canarypox containing the gene for pp65 developed CTLs specific to CMV after two doses. The CTLs were $CD8^+$ cell–mediated and reached precursor frequencies similar to those found in naturally seropositive individuals.[201] Clinical trials have also explored the usefulness of ALVAC-gB employed in a "prime-boost" approach, in which ALVAC vaccine is administered to "prime" immune responses for subsequent "boost" with live attenuated vaccine or recombinant protein. In the first prime-boost study, ALVAC-gB was evaluated alone or in combination with Towne vaccine.[200] ALVAC-gB vaccine induced low neutralizing and ELISA antibodies in seronegative adults, but subjects primed with ALVAC-gB and then boosted with a single dose of Towne vaccine developed binding and neutralizing antibody titers comparable to naturally seropositive individuals. A subsequent study compared three immunization regimens: subunit gB/MF59; a "prime-boost" regimen in which ALVAC-gB was followed by gB/MF59; or a regimen in which both vaccines were administered concomitantly. All three approaches induced high-titer antibody and lymphoproliferative responses, but little benefit with priming was detected.[202]

Venezuelan Equine Encephalitis–Vectored gB, pp65, and IE1 Vaccine

Alphavirus replicon vector systems are being used as platforms for the development of many prophylactic and therapeutic vaccines for infectious diseases and cancer, and this vector technology has also been applied to CMV vaccines. One such vaccine developed by AlphaVax Vaccines, AVX601, is a two-component alphavirus replicon particle vaccine expressing CMV gB and an inframe fusion protein of pp65 and IE1[203,204]; thus, it contains both the immunodominant antibody and T-cell targets for CMV. This was evaluated in a randomized, double-blind, Phase I trial in healthy, CMV-seronegative adult volunteers.[205] This dose comparison study was performed in CMV-seronegative subjects; 40 subjects were randomized to either receive low-dose vaccine (1×10^7 infectious units) or high-dose vaccine (1×10^8 infectious units) by either subcutaneous or intramuscular route, or placebo, at 0, 8, and 24 weeks after enrollment. Local reactogenicity was more pronounced when vaccine was given by subcutaneous route, but immunizations were generally well tolerated. Four weeks after the third dose, 93% of the subjects in the low-dose and 100% of subjects in the high-dose groups developed neutralizing antibodies, as assessed by a microneutralization assay. T-cell responses to each of the CMV antigens measured by direct IFN-γ enzyme-linked immunospot (ELISPOT) assay were detected in 90% to 97% of vaccine recipients after the second dose, with similar rates of response in both low-dose and high-dose groups. The magnitude of the T-cell response was greatest for pp65, followed by gB and IE1. Polychromatic flow cytometry demonstrated that CMV antigen-specific $CD4^+$ and $CD8^+$ effector T cells producing multiple cytokines in response to peptide stimulation were induced in all subjects. The AlphaVax platform was acquired by Novartis Vaccines, who in turn (as noted) sold their vaccine portfolio to GSK. Therefore, the future development plan for AVX601 is unclear at this time. Similar Venezuelan equine encephalitis (VEE)-vectored vaccines have been developed targeting CMV gH and gL, and vaccine studies of the gH/gL complexes formed in vitro using the VRP platform have been performed in mice. These studies have demonstrated potent and cross-reactive neutralizing antibody responses.[206] No plans for clinical studies in humans of these vaccines have been reported to date, however.

Lymphocytic Choriomeningitis Virus-Vectored gB/pp65 Vaccine

A novel vector strategy that has recently entered phase I study utilizes an attenuated recombinant lymphocytic choriomeningitis virus (LCMV) platform. This vector employs producer cells that constitutively express the LCMV viral glycoprotein, allowing for replacement of this gene with the vaccine immunogen(s) of interest.[207] These vectors are replication defective, but elicit not only high-level antibody but also $CD4^+$ and $CD8^+$ T-cell responses, including cytotoxic responses. Hookipa Biotech AG (Vienna, Austria) has developed a replication-deficient LCMV-vectored CMV vaccine based on a truncated, membrane-anchored form of gB as well as pp65 (NCT02798692, clinicaltrials.gov). The combination of gB and pp65 in the LCMV-vectored vaccine platform has been shown in the guinea pig CMV system to confer additive protection in a model of congenital infection.[207] A phase I dose escalation study of this bivalent vaccination approach is currently ongoing with a bivalent vaccine, HB-101, which contains two vectored vaccines: one expressing pp65, and the other a truncated variant of gB. The primary study endpoint is safety, and the secondary endpoints include ELISA and virus-neutralizing antibody responses, cytokine responses, and T-cell responses.

DNA gB, pp65, and IE1 Vaccines

Vical (now Astellas) Corporation has developed two CMV DNA vaccines. VCL-CB01 (now ASP0113), a bivalent CMV DNA vaccine that contains two plasmids encoding CMV pp65 and gB, in combination with poloxamer CRL1005 and

benzalkonium chloride to increase immunogenicity,[208] was evaluated in a Phase I, open-label, dose-escalating trial in healthy CMV-seropositive and seronegative adults.[209] Through week 16 of the study, immunogenicity, defined by gB-binding ELISA antibody and/or ex vivo IFN-γ ELISPOT positive assay with pp65 or gB antigens, was documented in 45.5% of CMV-seronegative subjects and in 25% of CMV-seropositive subjects who received the full vaccine series. An additional assay, the cultured IFN-γ ELISPOT assay, was employed to evaluate whether the vaccine primed the memory T-cell response at week 32 or 16; this assay demonstrated a positive response to pp65 and/or gB in 68.2% (15/22) of CMV-seronegative subjects, including subjects who did not have detectable responses by ex vivo IFN-γ ELISPOT assay or ELISA. These results suggest that ASP0113 could prime antigen-specific T cells for the capacity to proliferate and secrete IFN-γ on restimulation with antigen.[209] A limitation of ASP0113 was the lack of gB antibody response in CMV-seropositive subjects, although the vaccine boosted existing pp65 T cell response. A Phase II, randomized, double-blind, placebo-controlled clinical trial to assess the safety and immunogenicity of ASP0113 was performed in donors and recipients undergoing allogeneic HSCT.[210,211] In immunogenicity analyses, higher frequencies of CMV-specific pp65 and gB T cells were observed at days 56 and 84 after transplantation in 33 CMV-seropositive recipients, who were immunized at 3 to 5 days prior to, and 3 to 6, 12, and 28 weeks after transplantation compared to placebo recipients. In the Phase II study of 80 HSCT recipients, ASP0113-vaccinated recipients demonstrated reductions in recurrence of CMV infection, duration of DNAemia, area under the curve (AUC) for cumulative viral load post-HSCT, and peak magnitude of DNAemia compared with recipients receiving placebo. Overall rates of CMV viremia were lower in the ASP0113 group when measured by a central laboratory, and time-to-first episode of viremia was longer in subjects receiving ASP0113.[210,211] These findings have set the stage for an ongoing placebo-controlled Phase III analysis aimed at enrolling 500 subjects who are undergoing allogeneic HSCT (NCT01877655, clinicaltrials.gov).

Another DNA vaccine, a trivalent formulation targeting gB, pp65, and IE1 (VCL-CT02), was evaluated in a Phase I trial involving a total of 40 healthy adult subjects (24 CMV-seronegative, 16 CMV-seropositive). Subjects received either a 1-mg or 5-mg dose of unadjuvanted trivalent vaccine in several multidose regimens, with modest immunogenicity; however, when participants received VCL-CT02 as a prime and the Towne vaccine as a boost, significantly enhanced pp65 T-cell and gB antibody responses were observed.[153] Efforts to improve the immunogenicity of DNA vaccines using cationic lipid-based adjuvants[212] and electroporation[213,214] are ongoing, although these approaches have not yet entered clinical trials.

Another group has approached CMV vaccine development for the transplantation setting by using messenger RNA (mRNA) to transfect dendritic cells, followed by adoptive transfer of these cells to stem cell transplant recipients.[215] Four CMV-seronegative healthy volunteers and three allogeneic HSCT recipients were immunized in this way, and CMV pp65-specific T cell responses were induced or expanded in a majority of recipients. Efforts to adapt these techniques to high-throughput good manufacturing practice (GMP) techniques are ongoing.[216,217]

NOVEL CYTOMEGALOVIRUS VACCINE APPROACHES ENTERING CLINICAL TRIALS OR IN PRECLINICAL DEVELOPMENT

Several novel vaccine approaches have been recently proposed for CMV; some have been evaluated to varying degrees in preclinical animal models.[218,219] Other new strategies are now beginning to be explored in Phase I studies. An interesting new approach to CMV vaccine development uses enveloped virus-like particles (eVLPs) that express gB in a strategy that delivers this antigen in a membrane-associated formulation that mimics that observed in viral particles. Preclinical evaluation of eVLPs expressing either full-length CMV gB (gB eVLPs) or the full extracellular domain of CMV gB fused with the transmembrane and cytoplasmic domains from vesicular stomatitis virus (VSV) G protein (gB-G eVLPs) demonstrated the superior immunogenicity of the gB-G form of the protein in mice.[220] Based on these findings, a candidate eVLP vaccine was generated by cotransfection of the Moloney murine leukemia virus (MLV) *gag* gene with the CMV gB gene. Following transcription and translation in human embryonic kidney (HEK) cells, the MLV matrix proteins and CMV gB form fully enveloped eVLPs which are then used as the candidate vaccine. This vaccine is designated as VBI-1501A, and has now entered a Phase I clinical trial. This study is being performed by VBI Vaccines, who generated the eVLP vaccine (NCT02826798, clinicaltrials.gov). The study is currently comparing the safety and immunogenicity of four dose formulations of vaccine, ranging from 0.5 to 2.0 μg of gB content with aluminum phosphate (alum) adjuvant or, in the case of one subgroup of vaccinees in the study, 1.0 μg of gB without alum. Another approach to generation of virus-like particles, originally developed using a baculovirus expression system by Redvax GmbH, a spin-off from Redbiotec AG,[221] was recently acquired by Pfizer Vaccines. RNA-based vaccines, in which "self-amplifying" RNAs are synthesized in vitro and then delivered as a vaccine, are currently being developed against CMV antigens by Novartis Vaccines (now GSK).[222] A recombinant vectored vaccine approach, expressing the murine cytomegalovirus (MCMV) gB in recombinant vesicular stomatitis virus, was effective when administered via a mucosal vaccine approach in a mouse challenge study.[223] A CMV "triplex" vaccine based on another attenuated poxvirus, modified vaccinia virus Ankara (MVA), has been developed by investigators at the City of Hope Research Institute (Duarte, California), expressing gB, pp65, and IE1.[224–226] A Phase II study is currently enrolling CMV-seropositive allogeneic HSCT transplant recipients (NCT02506933, clinicaltrials.gov), although no results have been reported at this time. The efficacy of the MVA vaccine approach has been established in challenge studies in a rhesus macaque model of CMV infection.[227,228] Recombinant adenovirus can also be engineered to express CMV proteins that elicit antibody and/or stimulate cellular targets. Like the recombinant vesicular stomatitis virus vectored vaccine, systemic and mucosal immunity can be induced by intranasal immunization using a replication-deficient adenoviral vector expressing MCMV gB or gH.[229,230] A novel replication-deficient adenoviral vectored vaccine, Ad-gBCMVpoly, has been developed by the Khanna Laboratory at the Queensland Institute of Medical Research to induce a broad repertoire of CMV-specific immune responses. Ad-gBCMVpoly encodes 46 CMV T-cell epitopes from multiple antigens such as IE1, IE2, pp50, pp65, pp150, gB, gH, and DNase, covalently linked to the extracellular domain of CMV gB antigen to allow the expression of the CMV polypeptide and gB proteins as a single fusion protein.[231–233] Recent evidence suggests that the immunogenicity of the polyepitope vaccine can be further augmented by the inclusion of TLR4 and/or TLR9 agonists.[234] An adenovirus-vectored vaccine using adenovirus serotype 4 is in early stage development by PaxVax Vaccines of Redwood City, California.[235]

Another novel approach to live, attenuated vaccine design is the targeted deletion of CMV genes modulating the host immune response through targeted mutagenesis of the viral genome maintained as a bacterial artificial chromosome

(BAC) in *Escherichia coli*. Such vaccines could, in principle, have enhanced safety profiles, as the genes responsible for immune evasion can be deleted, while retaining the broad repertoire of immune responses to multiple viral proteins intrinsic to live virus vaccines.[236] A BAC-derived MCMV recombinant vaccine lacking a total of 32 genes regulating immunoevasive functions in major histocompatibility complex (MHC)-1 presentation and NK cell response induced protective humoral and cellular immunes responses.[237] A recombinant live attenuated vaccine with a targeted deletion of a CMV protein kinase R antagonist was recently shown to be immunogenic and protective in the guinea pig model of congenital CMV infection, supporting the hypothesis that blocking viral immune evasion functions may improve the safety and immunogenicity of live virus vaccines.[238] The importance of genes promoting evasion of host $CD8^+$ T-cell responses, with subsequent reinfection of the previously immune host, was recently demonstrated convincingly in the rhesus CMV model,[239] underscoring the importance of developing vaccine strategies capable of overcoming these functions. An attenuated vaccine strategy was recently described based on a recombinant CMV that expresses the host ligand, ULBP2, for the natural killer cell receptor NKG2D. The vaccine strain was found to be susceptible to control by NK cells, but retained the ability to stimulate CMV-specific T cells.[240] Another novel, recently described vaccine strategy in a preclinical model elicits antibodies to CMV-encoded IL-10 mimics of the natural cytokine.[241]

Other new vaccine strategies are exploiting recent studies elucidating the mechanisms of attachment and entry of CMV into epithelial and endothelial cells. These studies have demonstrated that that a substantial component of the host neutralizing antibody response targets the PC protein complex, comprised of gH/gL/UL128/UL130/UL131.[100–105,242–244] The UL128, UL130, and UL131 gene products interact with the CMV gH and gL glycoproteins to form this multimeric complex and this complex has emerged as a major vaccine target (Fig. 16.6). Support for development of recombinant expression strategies for these proteins as potential vaccine candidates is strengthened by studies demonstrating that polyclonal and monoclonal antibodies targeting various components of the PC potently neutralize virus infectivity in cell culture.[245,246] Antibodies to the PC appear to be of particular importance in preventing transplacental transmission of CMV to the fetus.[103,105,247] Neither Towne vaccine nor the gB-MF59 vaccine appear to be as efficient at eliciting antibody responses that interfere with this pathway of infection.[248,249]

Another vaccine approach in preclinical development exploits the fact that CMV infection of human cells produces both infectious virus and noninfectious "dense bodies," which are particles that contain many of the proteins found in infectious virus, including both gB and pp65.[250] Since dense bodies do not contain viral DNA, they cannot replicate. However, these particles are immunogenic. Dense bodies exploited as vaccines could, in principle, elicit responses to the key CMV immunogens, without the attendant risk of inducing CMV infection. Moreover, other viral proteins (or, indeed, any protein of interest) can be incorporated into the dense bodies by genetic engineering.[251,252] In mice, neutralizing antibodies and cytotoxic T cells have been elicited with dense body vaccines without the use of adjuvant, but no human data are yet available.[253] It has been observed in mice that dense bodies derived from the Towne strain of CMV induce broad cellular immune responses and neutralizing antibodies that are capable of blocking infection of both fibroblasts and epithelial cells.[254]

In summary, the large (and increasing) number of candidate vaccines currently in preclinical development and clinical trials provides considerable hope that vaccines against both congenital and transplantation-associated CMV disease will be licensed imminently. Although the optimal age for implementation of a universal CMV vaccine remains uncertain,[40] it is most likely that once a licensed vaccine is available, the primary target population would initially include adolescent girls and boys, and women intending pregnancies. Immunization of both sexes during adolescence was assumed in the modeling of the potential impact of a CMV vaccine by the Institute of Medicine in a cost-benefit analysis of economic benefits of new vaccine development.[39] A secondary target for a licensed CMV vaccine would be HSCT and SOT patients. An ideal vaccine in this setting may need to be primarily focused on T-cell responses[255] rather than neutralizing antibody responses, although both arms of adaptive immunity are likely required for protection in all susceptible patient populations (including women of child-bearing age). Vaccine modeling has been performed based on the force of infection for CMV, which is the instantaneous per capita rate of acquisition of infection that approximates the incidence of infection

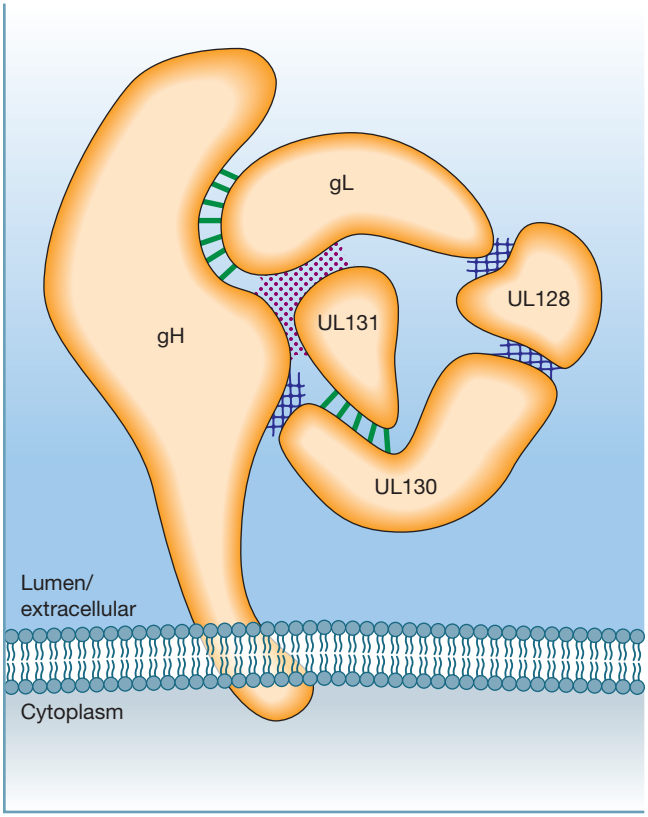

Figure 16.6. Novel cytomegalovirus (CMV) vaccine candidates aimed to elicit immune responses that block virus entry into epithelial/endothelial cells. Model demonstrating putative protein-protein interactions that make up a CMV protein complex consisting of glycoprotein H (gH)/glycoprotein L (gL)/UL128/UL130/UL131 complex. CMV gH protein is predicted to be inserted in the virion envelope and interacts with gL through disulfide linkage(s) (indicated by straight green lines). Interactions between UL130 and UL131 also involve a disulfide bond(s). UL128 interacts with both UL130 and gL through noncovalent interactions (indicated by crosshatching), and a surface created by both gH and gL is required for UL131 binding (indicated by red dots). *(From Ryckman BJ, Rainish BL, Chase MC, et al. Characterization of the human cytomegalovirus gH/gL/UL128–131 complex that mediates entry into epithelial and endothelial cells.* J Virol. *2008;82:60–70.)*

in the seronegative population. This modeling suggests that the force of CMV infection is quite low (1.6 infections per 100 susceptible persons per year), meaning that, on average, an infected person transmits CMV to just under two susceptible people annually.[256] Thus, even a modestly effective vaccine and moderate rates of vaccination could potentially have a significant impact on CMV transmission and lead to reductions in congenital CMV infection. A 2013 U.S. Food and Drug Administration workshop explored the clinical path toward licensure of a CMV vaccine, based on the assumption that prevention of congenital CMV infection would be the primary desired efficacy end point.[257] Analytic vaccinology approaches aimed at detailed dissection of the B-cell repertoire engendered in response to CMV infection may provide insights that inform and direct future subunit vaccine research.[258] Other future uses of a CMV vaccine, aside from HSCT and SOT recipients, remain speculative and dependent on further elucidation of the biology of the virus. Intriguingly, the use of the CMV virus itself as a possible vector for novel vaccines against other pathogens, including as a vectored vaccine against HIV infection, is an area of active investigation.[259] The very paradox of CMV immunity—the lack of long-term protection against reinfection observed in seropositives—could be exploited in the design of CMV-vectored vaccines for other pathogens, since preexisting immunity to CMV would not, in theory, be a barrier to effective immunization against the agent of interest. CMV-vectored vaccines for heterologous pathogens would ideally be modified to delete CMV genes involved in pathogenesis and, importantly, genes that increased the risk of transplacental transmission. Given the adverse health consequences of CMV infection that accrue over the life course for all individuals, CMV eradication effected by universal vaccination could become an eventual goal of large-scale immunization programs.[260]

17 Dengue Vaccines

*Scott B. Halstead and Stephen J. Thomas**

Since World War II, the four dengue viruses (DENVs) have spread throughout tropical and many subtropical areas, achieving pandemic status. They are estimated to have caused 390 million infections and 96 million overt disease occurrences in 2010. Of these, perhaps 1 to 2 million persons are hospitalized with severe illnesses, including dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS), and 0.1% to 5% die.[1–3] Dengue exacts a high socioeconomic toll on inhabitants of more than 120 tropical countries (Fig. 17.1). In addition, visitors to dengue-endemic countries are infected. In 2012, 91.7 million tourists arrived in dengue-affected areas in Asia.[4] Dengue illnesses exact a severe impact on quality of life.[5,6] In Asia and the Americas, the economic burden of dengue on the poor has been estimated at 1289 disability-adjusted life years per million population, similar to the burden imposed by the childhood and tropical disease clusters and tuberculosis.[7–10] An eight-country survey found costs for both outpatient and inpatient dengue illnesses to be substantial, ranging from 8 to 56 days of gross domestic product (GDP) per capita, costing the studied countries an estimated $587 million (in 2005 dollars) per year.[11] The global burden of dengue is both significant and underestimated.[12,13]

DENGUE VIRUSES AND DENGUE DISEASE

DENV-1 through DENV-4 are members of the *Flavivirus* group of the virus family Flaviviridae. The flavivirus genome consists of approximately RNA 11,000 base pairs (bp), which translate into three structural and seven nonstructural proteins (see "Chimeric Virus Vaccines" later). The four distinct DENVs all evolved from a common sylvatic ancestor, with separate introductions into the urban cycle of transmission—humans to *Aedes* mosquitoes to humans.[14,15] The basic virology of the four DENVs is similar to that of yellow fever (see Chapter 63) and Japanese encephalitis (see Chapter 33). The structural arrangement of DENV surface proteins controls how antibodies neutralize viruses. Dengue is an enveloped, positive-strand RNA spherical viral particle with a diameter of approximately 500 Å. RNA, when complexed with capsid proteins, forms the inside of the virus particle. It is surrounded by a bilayer lipid membrane. Anchored on the outside of the membrane are the M and E proteins. The M protein is a small protein that is hidden under the E protein but that projects to the surface in its immature state. The major protein that stimulates antibody response is the E protein. Each virus particle has 180 monomers of E that are organized into 90 tightly packed dimers that lie flat on the surface of the viral membrane. Each E protein monomer has three domains: DI, DII, and DIII.[16–19] DIII is thought to be involved in receptor binding. DII contains the fusion loop, which interacts with the endosomal membrane to facilitate fusion of the virus permitting entry into the cell.[19] The hinge that connects DI to DII is very flexible and is used to flex DII in the low pH environment of the endosome, leading to the exposure of its fusion loop.[18] The viral envelope contains two integral membrane proteins designated envelope (E) and premembrane (prM). E protein binds to cellular receptors and mediates fusion of viral and cellular membranes during viral entry into cells and is the main target of neutralizing antibodies. Individual subunits of E protein consist of three β-barrel domains designated domains I (EDI), II (EDII), and III (EDIII), with the native protein forming a head-to-tail homodimer. The hydrophobic viral fusion peptide is located at the tip of domain II and is shielded by domain III of the adjacent subunit. Domain III appears to be responsible for binding to cellular receptors as several mutations that affect receptor binding are located in this domain.[20]

Infection of humans follows the bite of an infected *Aedes* mosquito (primarily *Aedes aegypti, Aedes albopictus,* or *Aedes polynesiensis*). Infection with DENV-1 (five genotypes), DENV-2 (six genotypes), DENV-3 (five genotypes), or DENV-4 (four genotypes) may be asymptomatic, or it may result in a mild febrile illness, dengue fever (DF), or severe dengue, including DHF/DSS.[21,22] DF is a self-limited febrile illness, with an average incubation period of 5 days, characterized by acute onset of fever, and, variously, headache, myalgia/arthralgia, poor appetite, prostration, nausea, vomiting, abdominal pain, and rash. The continuum from DF to severe dengue is differentiated physiologically by the onset of the dengue vascular permeability syndrome (DVPS) which culminates around the time of defervescence, when virus-infected cells are being immunologically eliminated (Table 17.1). DVPS is the central component of DHF/DSS as described in many published observations over the past 50 years.[23–26] Hemorrhage, mild or severe, may be a component of either DF or DHF. Recent evidence shows that the nonstructural protein 1 (NS1) that is excreted from infected cells circulating at high concentrations, activates toll-receptor 4 (TLR4), directly damages endothelial cells, contributes to the damage of liver cells, activates complement, and stimulates the release of cytokines that are known to accompany the onset of the DVPS.[27,28]

Diagnosis

Dengue illnesses are documented either by detection of the etiologic agent or viral protein in blood or by documenting a specific antibody response after infection. Determination of etiology during the acute phase centers on isolating virus in any of several host systems or detecting circulating dengue RNA. An alternative method, recently commercialized, is the detection of NS1, which circulates in the blood in the acute and early convalescent phases.[29–32] Many tests, some commercialized, can be used to measure antibody responses to dengue

TABLE 17.1 Dengue Vascular Permeability Syndrome

Dengue vascular permeability syndrome is a syndrome that occurs late in the course of an acute dengue illness (on or near defervescence) and consists of:

- Thrombocytopenia (<100,000/mm^3)
- Altered hemostasis: most commonly prolonged bleeding time, elevated activated partial thromboplastin time, and reduced fibrinogen levels
- Activated complement, by classical and alternative pathways
- Elevated liver transaminase enzyme levels usually accompanied by enlarged liver
- Vascular permeability with clinically significant loss of fluid and small macromolecules (e.g., albumin) into interstitial spaces, commonly serosal cavities

Data from Halstead SB: Dengue haemorrhagic fever-a public health problem and a field for research. Bull World Health Organ. *1980;58:1–21.*

infection. The most common is the detection of DENV immunoglobulin (Ig) M antibodies in late acute or early convalescent sera using the enzyme-linked immunosorbent assay (ELISA).[33,34] In the United States, the Food and Drug Administration (FDA) regulates the marketing of several commercial tests to detect dengue (IgM Capture ELISA). Tests may be used to distinguish primary dengue infections from infections that occur in persons immune to another dengue virus or to other flaviviruses (secondary infections). During a primary DENV infection, there should be no DENV IgG ELISA antibodies in acute-phase sera, and there should be a high ratio of IgM to IgG DENV antibodies in early convalescent sera. IgG DENV antibodies accompany secondary infection with a heterotypic DENV, accompanied in some instances by low levels of IgM DENV ELISA antibodies.

Classical DHF/DSS also accompanies first DENV infections in 5- to 11-month-old infants born to dengue-immune mothers[35]; but overall, 90+% of cases occur during second (occasionally third) heterotypic DENV infections in individuals older than 1 year.[24,36,37] These two epidemiologic settings have in common a single immune factor—IgG_1 DENV antibodies. Numerous studies show that DENV antibodies at subneutralizing concentrations enhance DENV infections in Fc-receptor–bearing cells, a process referred to as antibody-dependent enhancement (ADE).[38,39] In studies on humans, peak viremia titers during secondary DENV infections correlate with subsequent occurrence of DHF/DSS.[40] The DHF/DSS response is rare, seen in only 2% to 4% of second DENV infections.[41] Although supportive intensive care and careful fluid management can be lifesaving, specific antiviral medications are not available.[42] The single preventive measure, comprehensive mosquito control, has conspicuously failed.[43]

CORRELATES OF PROTECTION

Early studies to understand how antibodies neutralize or enhance DENV were performed using mouse monoclonal antibodies (mAbs). Many of these mice had been immunized with E proteins. Neutralizing mouse mAbs have been mapped to all three domains (ED). The strongest serotype specific neutralizing antibodies bind to domain III. Two partially overlapping epitopes on EDIII designated the lateral ridge and A strand are the main targets of mouse mAbs that neutralize DENV. The lateral ridge epitope interacts with serotype-specific strongly neutralizing antibodies. Mouse mAbs that bind to the A strand epitope cross react with more than one serotype of DENV and are designated dengue subcomplex neutralizing mAbs. It is also becoming clear that the hypothetical structure of the mature flavivirus particle generated by cryoelectron microscopy and molecular fitting does not always predict epitope exposure. Binding of some E-reactive antibodies depends on the dynamic movement of protein molecules ("breathing") in the virion particle leading to transient exposure of hidden epitopes.[44,45]

Recently, studies on dengue antibodies have shifted to those raised by DENV infections of humans. Technological developments now enable the rapid generation of human mAbs. Polyclonal human monotypic dengue-immune sera contain mostly weakly neutralizing, cross-reactive and enhancing antibodies.[46,47] DIII antibodies, although highly neutralizing, are only present in human sera at low levels. Only a small fraction of antibodies is serotype specific and highly neutralizing and these recognize a quaternary structure on the intact virion.[46,48] A similar DENV-1 mAb has been studied by cryoelectron microscopy.[49] Presumably, live attenuated tetravalent DENV vaccines should raise neutralizing antibodies directed at each of the four type-specific quaternary structures.

This has been confirmed to be the case for the attenuated DENV-1 developed by the National Institutes of Health (NIH).[50]

As discussed below, the Sanofi Pasteur Phase IIb and Phase III clinical trials have demonstrated that vaccine-induced neutralizing antibodies measured in epithelial cell monolayers are not correlates of protection against DENV infection and disease. However, when the infection experience of humans has been a single wild-type DENV, homotypic neutralizing antibodies are a protection correlate as demonstrated in challenge experiments conducted by Sabin.[51] Following an initial wild-type DENV infection in humans, the development of heterospecific neutralizing antibodies correlates with protection against developing severe disease during a heterotypic DENV infection.[52] While these predictive correlates may extend to live attenuated viruses, as discussed below, full protection may require infection by a complete dengue virus, not a chimera, as protective T-cell immunity may depend on presentation of DENV nonstructural antigens.[53,54] Of interest, administration of the monovalent or tetravalent NIH vaccine elicits type-specific and broadly reactive human T-cell responses.[55]

DEVELOPING DENGUE VACCINES

The numerous challenges that face the dengue vaccinologist have made the goal of developing a safe and efficacious dengue vaccine elusive for more than 4 decades.[56] Each DENV type is capable of causing disease and death, and many dengue-endemic areas have concomitant cocirculation of multiple types, mandating development of a vaccine that protects against all four DENV. After natural infection of human volunteers with DENV-1, a few months of cross-protection against infection with DENV-2 was observed, after which heterotypic infection often resulted in overt illness.[51] It is now well established that heterotypic protective immunity following infection with any first DENV reduces the risk that severe disease will accompany a second heterotypic DENV infection when the two infections occur within a period of 2 years. As the interval between first and second DENV infections lengthens so does the risk of severe disease.[57,58] Because classical DHF has been documented in adults with secondary DENV-2 or DENV-3 infections 20 years after infection with DENV-1, it must be assumed that immunologically primed persons are at risk for enhanced disease essentially for a lifetime.[59,60] The mechanism of early heterotypic protection is not established. Studies on DENV-immune humans and experimental studies using mouse models of severe disease suggest a role for T cells.[53,61] But, there is also evidence that antibodies contribute to protection.[62]

The suboptimal efficacy of the Sanofi Pasteur tetravalent yellow fever chimeric dengue vaccine against infection and disease caused by each of the four DENV, especially DENV-2 in large clinical trials (reviewed below) underscores the lack of understanding of the mechanisms of protection in DENV.[63]

Dengue vaccine development is still an empirical process. All attempts to combine the four live attenuated DENV into a final candidate vaccine have been plagued by an interference phenomenon. Because of the uncertainty of preclinical efficacy testing in animal models, it is prudent to demonstrate monotypic and tetravalent protective immunity by challenging vaccinated individuals using attenuated or partially attenuated DENV before proceeding to expensive and time-consuming large field efficacy studies.[63] Future DENV vaccine developers are well advised to follow the model pioneered by the NIH group, where reactogenicity and immunogenicity of each of four monotypic vaccines were separately evaluated in susceptible human volunteers before tetravalent vaccine candidates were tested. In several instances, vaccine protection was demonstrated by challenge using monovalent live DENV vaccine candidates.[64] Whatever the composition of dengue vaccines, as recommended by the World Health Organization, prolonged Phase IV clinical observation and testing will be required to monitor effectiveness and safety of dengue vaccines once deployed.[65] Progress toward developing a human DENV challenge model is described in greater detail below.

VACCINES IN DEVELOPMENT

The development of dengue vaccines began in 1929 using virus inactivated with phenol, formalin, or bile.[66,67] During World War II, live attenuated virus vaccines were developed independently by passaging DENV-1 serially in suckling mouse brain.[68,69] DENV-2 was similarly attenuated.[70] These early live virus approaches were abandoned because of concerns about the safety of inoculating mouse tissues into humans.[71] Since the 1970s, numerous new dengue vaccine constructs have entered preclinical and clinical development. Currently, six different vaccine approaches have been tested in human clinical trials, and a single candidate has now finished Phase III clinical testing. The Sanofi Pasteur chimeric vaccine was licensed in several countries in 2015. It is feasible that the NIH and Takeda vaccines will be licensed within 5 years (Table 17.2).

A large number of useful reviews on dengue vaccine development provide supplementary information.[56,72–86]

TABLE 17.2 Dengue Fever Vaccines in Clinical Testing

Type of Vaccine	Dengue Virus Genes (No.)	Stage of Development
Live attenuated virus (traditional)	10 (all)	Phase II tetravalent (Walter Reed Army Institute of Research and GlaxoSmithKline Biologicals)
Live attenuated virus (molecular)	10	Phase II tetravalent (Butantan, U.S. National Institutes of Health)
Yellow fever chimera	Chimera, 2 (PrM, E) + 8 (yellow fever virus)	Phases IIb and III tetravalent (Sanofi Pasteur); licensed in 2015
Dengue chimera	Chimera, 2 (PrM, E) + 8 (DENV-2)	Phase II tetravalent (Takeda)
Purified inactivated	3 (c, PrM, E)	Phase I tetravalent (GlaxoSmithKline, Fiocruz, Walter Reed Army Institute of Research)
Recombinant subunit	<1	Phase I tetravalent (Merck Inc.)
DNA	2+ (PrM, E)	Phase I monovalent DENV-1 (Naval Medical Research Center and Maxygen)

DENV, dengue virus.

LIVE ATTENUATED VIRUS VACCINES IN CLINICAL TESTING

Selection of Viral Mutants

Historically, flaviviral live attenuated virus vaccines have proved to be safe and durably efficacious. Examples include the 17D yellow fever vaccine[87,88] and the SA 14-2-2 Japanese encephalitis vaccine.[89,90] Live attenuated viral vaccines replicate in the recipient and in so doing present all viral antigens in a manner analogous to that of wild viruses eliciting both antibody and T-cell responses. A tetravalent vaccine approach is designed to induce primary-type immune responses to each of the four DENVs simultaneously, a phenomenon demonstrated to be protective in susceptible rhesus monkeys.[91,92] In dengue endemic countries most adults during their lifetimes have experienced three to four DENV infections sequentially, resulting in the circulation of neutralizing antibodies to all four DENV types, and are demonstrably protected against severe dengue disease.

Hawaii-Mahidol Universities/Aventis Vaccine

A major effort at live attenuated dengue vaccine development was initiated at the University of Hawaii and transferred to Mahidol University in Bangkok by investigators who used the classical method of serial passage of virus in a nonhuman host. Virus strains DENV-1 16007, DENV-2 16681, and DENV-4 1036 were passaged 15 to 50 times in primary dog kidney (PDK) cells in Hawaii and in Thailand where candidate vaccines were developed and Phase I testing completed.[93] Studies in flavivirus-susceptible Thai adult volunteers identified strains with acceptable reactogenicity and immunogenicity for DENV-1, DENV-2, and DENV-4 viruses at PDK13, PDK53, and PDK48 passage levels, respectively.[94–96] DENV-3 viruses did not replicate in PDK cells and were attenuated by 48 passages in primary African green monkey kidney cells (DENV-3 16562), and three final passages in fetal rhesus lung cells. All 10 U.S. Army soldiers inoculated with DENV-2 PDK53 developed neutralizing antibodies in the absence of dengue-like symptoms.[97] The vaccine was licensed to Aventis Pasteur for further development.

In subsequent studies, the four monovalent candidates elicited neutralizing antibody seroconversions in 3/5, 5/5, 5/5, and 5/5 American volunteers, respectively, after a single dose of 10^3 to 10^4 plaque-forming units (PFU).[98] Bivalent and trivalent formulations using DENV-1, DENV-2, and DENV-4 vaccine candidates elicited balanced seroconversions.[99] However, when all four serotypes were combined into a tetravalent vaccine, the predominant response was to the DENV-3 component.[98] The vaccine was reformulated using lower viral concentrations of DENV-3 and resulted in more balanced tetravalent seroconversion.[100,101] Vaccinated children living in Thailand were followed for intercurrent dengue infections for 8 years without occurrence of severe disease.[102] Despite these promising results, all 10 adult Australian volunteers given tetravalent vaccine had DENV-3–related systemic reactions, including fever, headache, arthralgia/myalgia, eye pain, and rash—essentially, mild DF.[103] Similar results occurred in adult Asian volunteers inoculated with a molecularly rederived DENV-3 strain, which had been selected to reduce reactogenicity but had the reverse effect.[104,105] Further testing and development of the Mahidol/Aventis live attenuated vaccine has now stopped.

Walter Reed Army Institute of Research Vaccine

A second tissue culture–passaged vaccine developed at the Walter Reed Army Institute of Research (WRAIR) was derived by serial passage of all four DENVs in PDK cells with final passages in fetal rhesus lung cells. Ten monovalent candidates were tested in 65 flavivirus-naïve volunteers between 1987 and 1996.[97–101] Vaccine candidates (specific virus strains, viral concentrations, and PDK cell passage levels) were evaluated. Candidates DENV-1, 45AZ5 PDK-20; DENV-2, 16803 PDK-50; DENV-3, CH53489 PDK-20; and DENV-4, 341750 PDK-20 with single-dose seroconversion rates of 100%, 67%, 50%, and 63%, respectively, and acceptable reactogenicity were selected for continued development.

In a follow up study, 49 flavivirus-naïve adult volunteers were administered the monovalent candidates.[102] Neutralizing antibody seroconversion rates for DENV-1, DENV-2, DENV-3, and DENV-4 were 100%, 92%, 46%, and 58%, respectively. A second dose administered 1 to 3 months later failed to improve immunogenicity—an observation reminiscent of Sabin's observed period of cross-protection after primary challenge.[40,103] There were no serious adverse reactions. The DENV-1 candidate was the most reactogenic, with a 42% rate of fever (>38°C) after a single dose, and reactogenicity was uniformly less after dose 2.

The monovalent candidates were combined into a tetravalent preparation and administered to 10 volunteers.[102] Seroconversion rates after a single dose of tetravalent vaccine by DENV type were 70%, 60%, 50%, and 30%, respectively. Dose 2 failed to improve antibody response but dose 3 improved seroconversion rates—100%, 75%, 100%, and 50%, respectively. There were no serious safety concerns.

Tetravalent vaccines made using combinations of high ($10^{5,6}$ PFU/dose) or low ($10^{3.5–4.5}$ PFU/dose) viral concentration formulations of each of the four DENVs were inoculated in 64 flavivirus naïve adult volunteers.[104] Formulations 1 to 15 were administered to 54 volunteers, three to four volunteers per formulation, on days 0 and 28. Formulation 16 was tested in 10 volunteers, five volunteers inoculated on days 0 and 30, one volunteer on days 0 and 120, and four volunteers on days 0, 30, and 120. Reactogenicity was variable across the formulations and positively correlated with immunogenicity. Similar proportions of volunteers seroconverted to DENV-1, DENV-2, and DENV-3 (69%, 78%, and 69%, respectively), but significantly fewer volunteers seroconverted to DENV-4 (38%). Seven formulations were found to be serologically superior and three of these sufficiently nonreactogenic to justify further testing.

New tetravalent dengue vaccine (TDEN) lots were produced to try to reduce the theoretical risk of transmissible spongiform encephalopathy arising from use of animal products of incompletely documented origin in the vaccine seeds or during decades of cell culture. TDEN lots were prepared from rederived vaccine strains using the same manufacturing process, except that each strain has three additional passages in fetal rhesus lung (FRhL) cells, monovalent bulks were formulated with a carbohydrate stabilizer rather than human serum albumin, and the final vaccine was lyophilized as a tetravalent product. TDEN formulations had an acceptable safety profile in primed and unprimed volunteers with antibody response rates superior in primed compared to unprimed vaccine recipients.[106] The WRAIR entered a codevelopment partnership with GlaxoSmithKline Biologicals to further develop tetravalent vaccine candidates and conducted extensive additional tests in humans.[107–110a] The future of the WRAIR/GlaxoSmithKline TDEN vaccine in its current form is in question because of manufacturing complexities and the desire by both organizations to shorten the time to protection by altering the dosage schedule or to explore other vaccine approaches.

Directed Mutagenesis

National Institutes of Health Vaccine

Workers at the National Institute of Allergy and Infectious Diseases at the NIH introduced a new era of dengue vaccine research when they constructed viable complementary DNA (cDNA) clones of DENV-4 (WRAIR 814669, Dominica, 1981).[111,112] A DENV-4 mutant virus (rDENV-4 Δ30) with a 30-nucleotide deletion in the 3′ untranslated region (10478–10507) produced lower viremia levels than parental DENV-4, but the neutralizing antibody responses were comparable to those of parental DENV-4 when inoculated in susceptible rhesus monkeys.[113] Phase I trials in flavivirus-naïve volunteers showed low-level viremia; frequent mild, largely rashes without other symptoms or signs; infrequent elevations in alanine transferase blood levels; occasional depression of absolute neutrophil count; and high levels of neutralizing antibodies at dosages of 10^1 to 10^5 PFU/0.5 mL.[74,114] *A. aegypti* mosquitoes fed on vaccinees did not become infected.[115] By screening mutants, a DENV-4 with paired amino acid substitutions at positions 200 and 201 of NS5 was obtained.[116] This virus showed reduced replication in severe combined immunodeficiency mouse, human hepatoma, and rhesus monkey models.[74,117] In flavivirus-naïve humans, inoculation of this virus abrogated hepatotoxicity and viremia but retained full immunogenicity.[118] Introduction of Δ30 into DENV-1 resulted in a successful vaccine virus.[119] Successful human vaccines for DENV-2 were obtained only by use of chimeras with rDENV-4 Δ30.[117,120,121] A DENV-3 human vaccine candidate was obtained by substituting the entire 3′ untranslated region (UTR) with that of rDENV-4 Δ30.[122]

Tetravalent formulations containing these viruses along with rDENV-1 Δ30 and rDENV-4 Δ30 have been tested in monkeys and shown to be attenuated, and they elicit balanced antibody responses.[123] In total, eight monovalent vaccine candidates were tested in 15 Phase I clinical trials to identify optimal candidates for tetravalent preparations. A subcutaneous injection of 10^3 PFU induced neutralizing antibody seroconversions to the vaccine parent virus in 80% to 100% of vaccine recipients.[64] Subsequently, it was observed that most of the candidate vaccines raised high seroconversion rates in susceptible adults even at doses as low as 10 PFU. Each of the four vaccines resulted a light maculopapular, nonitchy rash on the trunk usually unobserved by the vaccinated individual.[124]

Four different tetravalent vaccine candidates (TetraVax-DV) were tested in a randomized, placebo-controlled study in 113 flavivirus-naïve adults. A single dose of each TetraVax-DV admixture induced a trivalent or better neutralizing antibody response in 75% to 90% of vaccinees. Black volunteers had a significantly reduced incidence of rash and vaccine viremia. TV003, a vaccine comprised of 1000 PFU each of rDENV-1 Δ30, rDENV-2/4 Δ30, rDENV-3 Δ30/31, and rDENV-4 Δ30, raised a trivalent or greater antibody response in 90% of flavivirus-naïve vaccinees.[125] To improve the DENV-2 seroconversion rate and raise the neutralizing antibody titer, another formulation, TV005, containing 10,000 PFU of DENV-2 vaccine was tested in 84 susceptible volunteers while TV003 was given to another 84 volunteers.[126] TV005 outperformed TV003 with a 90% neutralizing antibody seroconversion to all four DENV at 3 months. Vaccinees failed to develop rash, viremia, or a boost in neutralizing antibodies when revaccinated at 6 months. TV003 produced solid protective immunity to DENV-2 challenge and was selected for Phase II and Phase III testing.[126a] These vaccine trials are ongoing in Brazil.

The NIH has licensed vaccine candidates to Butantan Institute, Sao Paolo, Brazil; Biological E Ltd, Hyderabad, India; Panacea Biotech, Ltd, New Delhi, India; Vabiotech, Hanoi, Vietnam; and to Merck & Co.

Chimeric Virus Vaccines

Chimera of Yellow Fever and Dengue (CYD)

Insertion of a flavivirus *preM* and *E* genes into the cDNA backbone of yellow fever (YF) 17D was pioneered at the St. Louis University Health Sciences Center.[127,128] Using this technology, DENV chimeras were developed by Acambis, Inc., and licensed for manufacture to Sanofi Pasteur.[98,129] For the purpose of manufacture, it was expected that these vaccines would benefit from the high fidelity of YF 17D polymerase.[130] Studies to date suggest that chimeric structure of dengue and West Nile viruses provides attenuation.[128,129,131–133] Contrary to the case with DENV, when wild-type *prM-E* genes of Japanese encephalitis (JE), tickborne, and St. Louis encephalitis viruses were inserted into YF 17D, they retained encephalitic properties and required additional attenuation of the *prM-E* genes to produce vaccine viruses.[128,131,134–136] Vero cells serve as the substrate for vaccine virus production.

Chimeras of dengue and YF viruses have been developed using the *PrM-E* genes from DENV-1, PUO-359; DENV-2, PUO-218; DENV-3, PaH881; and DENV-4, 1228 viruses. The results of extensive preclinical and Phase I and Phase II tests in flavivirus-susceptible and flavivirus-immune individuals were described at length in the sixth edition of this book.

Phase IIb and Phase III clinical trials have been completed in 35,146 children. In NCT00842530, 4002 Thai schoolchildren, ages 4 to 11 years, were randomly assigned (2:1) to receive three injections of dengue vaccine or control (rabies vaccine or saline) at months 0, 6, and 12.[137] On entering the trial, in a serologically sampled subset, 90% of children had circulating antibodies against DENV or JE virus. Dengue etiology of acute febrile illnesses in vaccinees and controls was investigated to month 25 after initial vaccination by detecting serotype-specific reverse-transcription polymerase chain reaction (RT-PCR) and/or NS1 in acute phase blood. Of 3673 children included in the primary analysis (2452 vaccine, 1221 controls), there were 45 cases of virologically confirmed dengue disease among vaccinees and 32 among controls, respectively. The overall vaccine efficacy at 2 years was 30.2%, with marked individual differences in protection against disease caused by the four DENV (Table 17.3).

*Person-years of observation.[138,139]

In a separate trial conducted in the Philippines, Vietnam, Thailand, Malaysia, and Indonesia (NCT01373281), 6710 children, ages 2 to 14 years, received three doses of vaccine while 3350 received placebo; 79% of a sample from both groups circulated DENV or JE antibodies.[138] In this trial, 117 dengue cases were recorded in the vaccine group and 133 in the control group, respectively, with an overall protective efficacy of 56·5% (95% confidence interval [CI], 43·8–66·4). Again, there was differential protection against disease caused by each of the four serotypes, although DENV 2 protection rates were higher than in the Thailand trial (Table 17.3).

A second Phase III trial was performed in Puerto Rico, Mexico, Honduras, Colombia, and Brazil (NCT01374516). Among vaccinated children, ages 9 to 16 years, 68% to 75% of 1334 in a random subgroup circulated DENV-1 to DENV-4 neutralizing antibodies prior to vaccination.[139] There were 176 dengue cases (11,793 person-years at risk) in the vaccine group and 221 cases (5809 person-years at risk) in the control group, for a vaccine efficacy of 60.8% (95% CI, 52.0 to 68.0). Modest differences in DENV type-specific protective efficacy were observed (Table 17.3).

Vaccine protection among Asian and American children identified as seronegative from prebleeds was poor, while among seropositives efficacy was high (Table 17.4). The poor protection of seronegatives is mirrored by a rapid decline in neutralizing antibodies reported 5 years after immunization of seronegative adults in Singapore.[139a] Many of the "seropositives" have had one lifetime DENV infection, and this is the seropositive group who are at risk for disease accompanying a dengue infection. Individuals who have two or more lifetime DENV infections are at low risk of hospitalized disease.[140] An additional observation was that chimeric yellow fever-dengue vaccine (CYD) protected against hospitalized disease better than protection against mild disease (Table 17.5). This protective efficacy was mirrored by high protection rates against the occurrence of plasma leakage (Table 17.6), DHF or "severe" disease (Table 17.7).

In July 2015, Sanofi published surveillance data from years 3 and/or 4 postvaccination for the three efficacy trials.[141,142] During this period, surveillance shifted from intense fever case finding to virological studies on hospitalized vaccine cohort members. Shown in Tables 17.8 and 17.9 are an increased frequency in hospitalization for dengue illness among vaccinated children younger than 5 years of age compared with controls over a 6-year period.

Table 17.10 provides more stark evidence that it was dengue infections with increased vascular permeability that occurred more frequently in vaccinated than in control young children. Despite the occurrence of two children with DSS among vaccinated children, the investigators expressed doubt that the excess of severe dengue in young children suggested enhancement by the vaccine because of the absence of prolonged viremia and cytokine secretion typical of enhanced disease.[141] However, the possibility that this observation does reflect enhanced disease owing to waning immunity from the vaccine in previously seronegative children is concerning and not

disproven. Hospitalized disease among placebos may be due to secondary DENV infections, while hospitalizations of vaccinated children may accompany primary DENV infections, invalidating classical efficacy calculations.[142a] In April 2016, the WHO Strategic Advisory Group of Experts on Immunization (SAGE) recommended that developing country regulatory authorities release CYD vaccine for use in populations with a dengue antibody seroprevalence of at least 70%.[142b] To date, CYD has been licensed in six countries with large-scale immunizations initiated for 9-year-olds based on mathematical models predicting that immunization of 80% of 9-year-olds over a prolonged period would result in 10% to 30% reduction of hospitalizations.[142b] If enhancement is the reason for the excess of disease several years after vaccination this may also have an implication for vaccinated older individuals not previously exposed to natural infection. However, according to the trial sponsors, among children age 9 years or older in all three trials there was evidence of modest vaccine efficacy.

To allay concerns about dengue-naïve individuals careful follow up studies both in children and in adults are needed.

Comment on the Safety and Protection by CYD Dengue Vaccine

For live attenuated DENVs two safety issues have been identified: (a) preexisting dengue or nondengue flavivirus antibodies in the vaccinated person may increase reactogenicity to vaccine virus, and (b) in the event of primary or secondary vaccine failure or waning neutralizing antibody, enhanced infection and disease may accompany breakthrough wild-type DENV infections. A safety signal, an increased relative risk of hospitalizations of vaccinated children ages 2 to 5 years, has been recognized by WHO in the Phase III clinical trials of the SanofiPasteur CYD vaccine.[142b,142c] Others have suggested dengue infections of vaccine-sensitized children resulted in these hospitalizations.[142d]

The CYD dengue vaccine was designed to raise type specific antibodies to structural antigens for each of the four dengue-like viruses and, in addition, with successive doses to raise dengue group reactive cross protective neutralizing antibodies in flavivirus-immunes. Whether CYD raises type-specific neutralizing antibody responses as defined by the deSilva group to any of the four DENV either in susceptibles or partially-immune persons (immune to a single wild-type DENV) is not known.[46] Whatever the mix of immune responses that follows administration of one or more doses of CYD, these have failed to prevent symptomatic primary DENV infections. There is an urgent need to solve this problem at a fundamental level.[142a] In addition, based upon data from children 5 years of age or younger, one or more doses of CYD vaccine has resulted in an immune response that when followed by a wild-type DENV infection resulted in hospitalization because of increased vascular permeability. It has been recommended that before testing tetravalent DENV vaccine mixtures, each of the four monotypic CYD viruses should have been inoculated into susceptible humans who should then be challenged at an interval no earlier than 6 months with a suitable homotypic vaccine virus (see "Dengue Human Infection Model" later).[63] In the Sanofi vaccine clinical trials, vaccination of seropositives provided moderate to good protection against severe DENV disease. Presumably, this reflects a booster effect that removes children who have had one single DENV infection from being hospitalized with enhanced vascular permeability disease during a second heterotypic DENV infection.

There are a number of intriguing but as yet unestablished explanations for the poorer protection observed in seronegatives compared with seropositives. First, CYD vaccines do not present DENV nonstructural proteins to the immune system. This is likely to result in suboptimal protective CD8+ T-cell responses. In humans, nonstructural DENV antigens may contribute importantly to T-cell protection against DENV-2 infections and disease.[55] The observed protection against severe disease obtained by vaccinating partially immune humans is good news, but it is troubling that CYD vaccines do not present DENV NS1 antigens to the immune system. As described above, new evidence strongly suggests that NS1 is a viral toxin and the direct cause of the DVPS.[27,28]

Some vaccinologists have published concerns that CYD, when given to seronegative children ages 2 to 5 years, has resulted in enhanced disease during the third year postvaccination, and that this same phenomenon can be expected to occur in seronegatives of all ages.[139a,142a] Testing sera for dengue antibodies to identify those who will receive optimal benefit from vaccine has been advised.[142a,142d,143,143a] The Pan American Health Organization does not recommend integration of CYD vaccine into routine immunizations at this time.[143b] In contrast, the SAGE committee of WHO has taken the position that there is no empiric evidence supporting safety concerns in the target population,[142b,142c] and that testing to eliminate seronegatives from vaccination is impractical on a large scale. SAGE further noted that in populations with a high prevalence of prior dengue infection, vaccine will prevent considerable serious disease and hospitalization, a view also expressed by Wilder-Smith and colleagues[143c] and by the manufacturer.[143d,143e,143f] See Gailhardou et al.[143g] for more extensive safety data. Since the CYD vaccine has been licensed in five countries, it is likely there will soon be evidence from Phase IV studies to determine which view is correct.

Dengue-Dengue Chimera

The Centers for Disease Control and Prevention (CDC), Vector-borne Diseases Branch developed a tetravalent chimeric dengue vaccine by introducing DENV-1, DENV-3, and DENV-4 *prM* and *E* genes into cDNA derived from the successfully attenuated DENV-2 component of the Mahidol University–Aventis Pasteur live attenuated virus vaccine (DENV-2, 16681 PDK-53) (see above).[97,144–146] Attenuating mutations of the DENV-2 vaccine are located in the nonstructural genes and reportedly are stable.[146–148] DENV-1–DENV-2 chimeras have been produced using DENV-1 PDK-13 and parental DENV-1 16007 structural genes.[147] DENV-3–DENV-2 and DENV-4–DENV-2 chimeras using parental virus structural genes are stable in cell culture, and when all constructs were inoculated in cynomolgus monkeys, monomeric and tetravalent formulations resulted in neutralizing antibody responses, low viremia titers, but some evidence of interference.[146,149]

Dengue-dengue chimeras were formulated as a DENV-1/DENV-2, DENV-2, DENV-3/DENV-2, and DENV-4/DENV-2 tetravalent vaccine candidate and licensed to Inviragen, Inc., and subsequently to Takeda Pharmaceuticals, Inc. The vaccine candidate (DENVax) has undergone preclinical testing in mice and nonhuman primates, comparing intradermal and subcutaneous deliveries.[150] The intradermal delivery of DENVax (10^5 PFU per DENV type) produced superior immune responses in cynomolgus macaques; viremia was not detected after challenge with 10^5 PFU of DENV-1 West Pacific or DENV-2 New Guinea C viruses.[151,152]

In a Phase I clinical trial, high and low doses of tetravalent vaccine and placebo were given by the subcutaneous and intradermal routes to 96 adult residents of an area of Colombia without *A. aegypti*.[153] Both formulations were well tolerated with mostly mild and transient local or systemic reactions. Both high-dose and low-dose DENVax formulations induced neutralizing antibody responses to four dengue virus serotypes in two-thirds of recipients 30 days after a second dose with the lowest response to the DENV-4 component. Immune responses following intradermal inoculation were somewhat higher than responses following subcutaneous delivery.[153] The vaccine has been shown to have acceptable thermal stability.[154]

Additional Phase I and Phase II clinical trials are in progress. Phase III clinical trials are in advanced planning.

VECTORED VACCINES

Recombinant poxviruses and adenoviruses expressing foreign proteins have been demonstrated to induce strong humoral and cellular responses in humans against various pathogens.[155–157] These viruses can infect cells and express their proteins de novo in the cell. The antigens are then naturally processed, glycosylated, and associated with the cell membrane. Major histocompatibility complex (MHC)

class I–dependent immune responses are induced as a result of intracellular translation and processing of the gene products.

Vaccinia Virus Vector

Use of recombinant *Vaccinia* viruses to express the structural proteins of DENV-2 or DENV-4 have been disappointing.[158,159] These constructs, expressing prM and a full-length E protein, failed to induce neutralizing antibodies or to protect monkeys from wild-type challenge. Recombinants expressing truncated DENV E proteins did raise neutralizing antibody in mice and in rhesus macaques, providing some protection against wild-type challenge in both models.[160,161]

Adenovirus Vector

Replication-defective adenovirus vectors have been used to construct flavivirus vaccine candidates.[162,163] Many vaccine candidates have been created by inserting the EDIII with or without prM of one or more DENV into an adenovirus vector. These include DENV-2 New Guinea C (NGC) with adeno 5,[164] other constructs tested in a prime-boost format,[165,166] bivalent vaccines,[167,168] or tetravalent mixtures of monovalent vaccines,[169] or a tetravalent single antigen.[169] Subsequently, to ensure that the prM and E antigens are expressed at similarly high levels, the genes from each DENV were placed into identical, immediate-early cytomegalovirus (CMV)–bovine growth hormone polyadenylation cassettes and inserted into either end of the adenovirus (cAdVax) vector. DENV-1 and DENV-3 were injected into one arm and DENV-2 and DENV-4 into the other.[168,170] A two-dose tetravalent vaccine was shown to partially protect monkeys against challenge viremia.[171] Subsequently, it was shown that small interfering RNA (siRNA) of the nontranslated region of the dengue genome can be presented using an adenovirus vector to achieve the blocking of DENV infection.[172]

Venezuelan Equine Encephalitis Virus Vector

Nonpropagating Venezuelan equine encephalitis (VEE) virus replicon particles (VRPs) permit translation and expression of inserted genes during a single round of replication.[173–175] Monotypic DENV-1 and DENV-2 vaccines have been constructed using VEE VRPs.[176,177] In a prime-boost regimen, after two doses of a DNA vaccine, a single dose of VEE VRP resulted in complete protection of cynomolgus macaques.[177] It has been possible to use VEE VRPs to overcome maternal-antibody interference in a mouse model[176] and raise tetravalent neutralizing antibodies in vaccinated mice.[178] Antibodies raised are type-specific.[179]

Measles Virus Vector

Genes for the dengue virus EDIII protein of DENV-1 were fused to those of the ectodomain of the measles virus attachment protein (ectoM) and inserted into the Schwarz measles vaccine (MV) strain.[180] Measles-susceptible mice inoculated intraperitoneally with two doses of this construct produced DENV-1 neutralizing antibodies. Mice were challenged with live DENV-1 6 months after the initial immunization. The presence of ectoM was critical to the immunogenicity of inserted EDIII. The adjuvant capacity of ectoM correlated with its ability to promote the maturation of dendritic cells and the secretion of proinflammatory and antiviral cytokines and chemokines involved in adaptive immunity. Subsequently, a recombinant MV vector containing genes for all four DENV EDIII fused with ectoM was prepared. After two injections in mice susceptible to MV infection, the recombinant vector induced antibodies that when passively transferred to mice failed to protect mice from death resulting from intracerebral challenge with any of the four DENV types.[181]

REPLICATION-DEFECTIVE VACCINES

Capsid-Gene Deletion

Several flavivirus vaccines have been made by deleting the capsid gene (C) and propagating the virus in cells that express high levels of C.[182] Such a virus undergoes only a single cycle of infection in vaccinated hosts. A DENV-2 RepliVAX, produced by replacing the *prM/E* genes of RepliVAX West Nile virus with the same genes of DENV-2, resulted in partial protection of AG 129 mice challenged with a mouse-adapted DENV-2.[183]

Recombinant Immune Complexes

A consensus DENV domain III gene was fused to the binding epitope of the 6D8 anti-Ebola mAb resulting in a hybrid dengue-Ebola recombinant immune complex (DERIC). Human and mouse versions of these molecules were expressed in tobacco plants using a geminivirus-based expression system. Following purification from the plant extracts by protein G affinity chromatography, three doses of DERIC were used to immunize mice inducing neutralizing antibodies against DENV-4 but not DENV-2.[184]

Inactivated or Subunit Vaccines

The simplest approach to produce viral vaccines is the use of inactivated whole virus or viral subunits. Such vaccines have potential advantages; for example, they cannot revert to a more pathogenic phenotype, and when combined they are unlikely to produce immune interference. Thus, they may be suitable for a wider age range than live vaccines, immunosuppression would not be a contraindication to immunization, an accelerated immunization schedule may be possible, and, theoretically, there could be fewer safety issues. Cell-mediated as well as humoral immune responses have been demonstrated with an inactivated flavivirus vaccine.[185] It should be noted that inactivated virions do not present nonstructural antigens to the immune system. This is likely to cripple protective T-cell immunity as described above. Furthermore, killed or subunit vaccines raise antibodies to only a portion of the structural proteins and not to normal virion-based structural conformations. Other disadvantages include the requirement for high concentrations of antigens, the need for multiple doses and the expected waning of immunity with the passage of time. Inactivated flaviviral vaccines have been licensed and are in wide use to prevent JE[186,187] and tickborne encephalitis.[188] Inactivated vaccines against flaviviral encephalitis may succeed because immune enhancement is not part of the disease process. Whether inactivated or subunit dengue vaccines can be used as standalone products is debatable. They may be useful for relatively short-term protection or in a prime-boost strategy. Augmentation of inactivated vaccines with new proprietary adjuvants may improve manufacturing and performance parameters.[189] Recent studies on respiratory syncytial and measles viruses show that formalin not only alters the structure of viral proteins, resulting in poor B-cell and T-cell antigen processing by dendritic cells.[190,191] This result suggests that other, less-stressful mechanisms of inactivating DENV should be sought. Psoralen-inactivated DENV-1 was used to immunize *Aotus* monkeys but with only equivocal protection on challenge.[192,193]

Cell Culture–Based Inactivated Vaccines

The WRAIR developed a purified inactivated virus (PIV) dengue vaccine candidate by inactivation of each of the DENV types with formalin.[194–196] A Phase I proof-of-concept trial of a monovalent DENV-1 PIV vaccine candidate adjuvanted with aluminum hydroxide (AlOH) was completed in the United States in a small number of flavivirus-naïve volunteers. Two doses administered 28 days apart had an acceptable safety profile with low to moderate immunogenicity.[197] The WRAIR granted an exclusive license to GlaxoSmithKline Vaccines and the two are codeveloping, with the Oswaldo Cruz Foundation (FioCruz), a tetravalent PIV formulation (DPIV) adjuvanted with AlOH or a GlaxoSmithKline proprietary Adjuvant System, shown to be protective in rhesus monkeys.[198] For nonflavivirus vaccines, adjuvants, particularly newer complex adjuvant systems (AS), have been shown to mediate long-lasting antibody responses.

Two Phase I trials of this vaccine are near completion, one in the United States and the other in Puerto Rico. Each is exploring the safety and immunogenicity of two doses (administered day 0 and 28) of DPIV candidates adjuvanted with AlOH, AS01E, or AS03B in DENV unprimed (U.S.) and primed (Puerto Rico) adults. Publicly available data indicate an acceptable safety profile for all vaccine formulations through study day 56 and greater than 90% tetravalent antibody seroconversions in DPIV formulations adjuvanted with higher doses of AlOH and both AS01E and AS03B. There was a trend toward higher GMTs in the AS03B adjuvanted formulation (Thomas SJ, unpublished data).

Recombinant Subunit Vaccines

T-cell and B-cell epitopes have been mapped on DENV structural and nonstructural proteins.[55,199,200] The right combination of epitopes expressed in protein subunit vaccines might be the basis for an effective vaccine produced at moderate cost.[201] Structural and nonstructural DENV proteins can be produced in large quantities in many expression systems including *Escherichia coli*,[202,203] baculovirus in *Spodoptera frugiperda* insect cells,[204–206] yeast,[207] Vaccinia virus,[159,161,208] and *Drosophila* cells.[209,210] The last approach, which resulted in 80% *E* gene expression in *Drosophila* cells, is being developed by the Hawaii Biotech Inc/Merck & Co. (see Table 17.2).

A tetravalent vaccine has been developed consisting of 80% E proteins of each of the four DENVs. Efficacy expectations are based on experiments showing that 1 μg of DENV-2 E protein with the proprietary GlaxoSmithKline adjuvant, SBAS5, protected rhesus monkeys from viremia after challenge with wild-type virus.[210] Early development included a DENV-2 vaccine candidate with 80% E + nonstructural protein 1 (NS1), but the NS1 added little to performance and this candidate has been sidelined. Various formulations have been tested in rhesus macaques producing high-titer neutralizing antibodies to all four DENVs and protecting animals from viremia after wild-type viral challenge.[210] A Phase I, single-center, double-blind, randomized study to assess the safety and tolerability of a DENV-1 to DENV-4 candidate in healthy U.S. adults was recently completed. Vaccine was tested at three escalating dosage levels and three different adjuvant formulations against in 98 subjects including 18 placebo controls. Results are pending (B.A. Coller-Griswold, personal communication, May 21, 2015).

Cuban investigators have produced candidate dengue vaccines using recombinant proteins. DENV-3 DIII protein fused with a P64k *Neisseria meningitidis* carrier protein, administered with Freund's complete adjuvant, protected nonhuman primates after challenge.[211] However, only partial protection was obtained using AlOH as the adjuvant, and this required use of the *Neisseria* serogroup A polysaccharide.[212] The authors have also expressed a domain III capsid chimeric protein of the four DENV in *E. coli* and are testing this construct as a vaccine.[213] The authors suggest priming with dengue protein and boosting with live attenuated virus.[214] This group has also tested a tetravalent vaccine formulation using AlOH as adjuvant in mice. After three doses, neutralizing antibody titers were detected against the four viral serotypes, the lowest seroconversion rate being against DENV-4. One month after the last dose, immunized animals were challenged with the four wild-type DENV with partial protection.[215]

NUCLEIC ACID–BASED VACCINES

DNA vaccines consist of a plasmid (or plasmids) containing DENV genes reproduced to high copy number in bacteria such as *E. coli*. The plasmid contains a eukaryotic promoter and termination sequence to drive transcription in the vaccine recipient. The transcribed RNA is translated to produce proteins to be processed and presented to the immune system in the context of MHC molecules. Additional genes such as intracellular trafficking and immunostimulatory sequences can be added to the plasmid. Expressed antigens lead to B- and T-cell responses. DNA vaccines afford numerous theoretical advantages over conventional vaccines, including ease of production, stability and ability to be transported at room temperature, ability to add new genes to the vaccine, ability to immunize with or without adjuvant systems against multiple pathogens with a single construct, and reduced reactogenicity.[216]

PrM-E DNA Vaccines

Workers at the Naval Medical Research Center evaluated two eukaryotic plasmid expression vectors (pkCMVint-Polyli and pVR1012; Vical, Inc., San Diego, CA) expressing the PrM protein and 92% of the E protein for DENV-1 and DENV-2 virus (see Table 17.2). These constructs induced neutralizing antibody in mice,[217] and they were subsequently improved by adding immunostimulatory CpG motifs, and the full-length *E* gene with *PrM*.[217–220] In recent studies, a DENV-1 DNA vaccine protected a portion of challenged monkeys from viremia for varying lengths of time.[221] With the recognition that dendritic cells are the percutaneous portal for dengue virus replication,[222] efforts are being made to target DNA vaccines to these cells.[223] A DENV-1 DNA vaccine was administered intramuscularly to 22 flavivirus-negative volunteers, half of whom received high and low dosages, respectively, in a three-dose series (at day 0, and at 1 and 5 months). At the completion of this series, none of the low-dosage recipients and only five of 11 high-dosage recipients developed neutralizing antibodies.[224] More recently, protection has been achieved in a rhesus monkey model by boosting tetravalent DNA vaccination with a tetravalent live attenuated virus vaccine.[215,225]

TDENs have been created by shuffling the envelope genes from the four DENVs. Selected shuffled DNA was transfected into human cells, subjected to flow cytometry, and reacted with type-specific dengue antibodies. Antibody markers permitted rapid screening of libraries and identification of novel expressed chimeric antigens. A panel of chimeric clones expressing C-terminal truncated antigens that combined envelope and prM epitopes from all four DENV types when inoculated in mice and monkeys successfully raised neutralizing antibodies. Monkeys resisted challenge with DENV-1 but not challenge with DENV-2.[226,227] Plans for testing TDENs in humans have been discussed.[223]

DENGUE HUMAN INFECTION MODEL

Because of the requirement to achieve solid protective immunity against each of the four DENV following the administration of a combination of antigens the absence of a validated dengue animal model, the absence of immune protection correlates and/or the lack of understanding protective immunity have crippled dengue vaccine development. Obviously, early tests of candidate vaccine protective immunity would be useful. To that end, the NIH group has used monovalent attenuated DENV as challenge viruses (described above). Remarkably, there has been a huge experience with experimental infections of humans using wild-type DENVs beginning in the early 1900s with no adverse outcomes.[51,66,68,69,228–235] In view of this experience, a group of investigators at the WRAIR proposed to reestablish a dengue human infection model (DHIM) and use partially attenuated DENV to test vaccine-induced protective immunity.[236,237] Human safety studies on DENV candidates are in progress at State University of New York (SUNY) Upstate School of Medicine, Syracuse, with a goal of selecting strains that induce mild dengue-like illness. Human infections with these strains should contribute immeasurably to a better understanding of clinical and immunological correlates of disease responses, to candidate drug evaluation, to studies on vector-human interactions, and to simplifying, speeding-up, and reducing the cost of dengue vaccine development. A crucial benefit of early tests of candidate vaccines by the DHIM is the early identification of vaccines that do not protect humans against dengue virus infection or disease.[238,239]

CONCLUSIONS

Dengue virus infections inflict significant morbidity and mortality on nearly 4 billion residents of tropical and subtropical countries. In addition, dengue infections are consistently among the leading causes of febrile diseases in tourists and expatriate residents of tropical countries and among military personnel assigned to combat or peacekeeping roles in tropical countries. In view of the widespread failure of national mosquito-control programs, the social and clinical impacts of disease create a significant market for dengue vaccines as evidenced by the interest shown by major vaccine manufacturers. One vaccine is currently licensed in several dengue endemic countries and is currently being employed. Several other promising dengue vaccine candidates are nearing Phase III testing. If safety concerns about Dengvaxia can be solved by the manufacturer, WHO, and regulatory agencies, market forces should continue to support the introduction of new, improved vaccines. Important deficiencies in basic understanding of protective immunity to dengue remain. These may be addressed via a newly developed human dengue infection model as well as by careful Phase III and Phase IV clinical trials. Huge requirements for dengue vaccination will require heavy financial investments in vaccine production and in strategic methods to achieve optimal reductions in virus transmission and in disease burden.

18 Diarrhea Caused by Bacteria

Jan Holmgren and Anna Lundgren

Diarrheal infections are estimated to cause 1.7 billion disease episodes and 700,000 deaths each year, mainly in children in low- and middle-income countries.[1] Travelers to endemic areas are also at high risk for being infected. However, today there are only licensed vaccines against two bacterial enteric pathogens, *Salmonella enterica* serovar Typhi (*S.* Typhi) and *Vibrio cholerae.* There are intense efforts under way to develop vaccines against additional important agents, in particular enterotoxigenic *Escherichia coli* (ETEC) and *Shigella*. This chapter focuses on vaccine development efforts for these two groups of pathogens and also briefly discusses the development of vaccines against *Campylobacter*, Shiga toxin–producing *E. coli* (STEC), and nontyphoidal *Salmonella* (NTS). While ETEC and *Shigella* have exclusively human reservoirs, *Campylobacter*, STEC, and NTS are also zoonotic pathogens with known animal reservoirs (chicken, cattle, etc). Our discussion here is limited to vaccines for human use, but it should be noted that there are also ongoing efforts to develop veterinary vaccines aimed at indirectly reducing the spread to human populations.

PATHOGENESIS AND PROTECTIVE IMMUNE MECHANISMS

Enteric pathogens differ in the way they cause infection and disease and this influences what type of immune responses they elicit and how vaccination may protect against infection and disease.[2] The different bacterial enteropathogens can cause disease by: (a) colonizing the intestinal mucosa without invasion or morphological damage but eliciting diarrhea by means of powerful secreted enterotoxins (e.g., *V. cholerae* and ETEC); (b) adhering to the mucosa and inducing enterocyte effacement by "injecting" bacterial proteins into the epithelial cells (e.g., enteropathogenic *E. coli*); (c) inducing enterocyte killing by producing powerful exotoxins that block cellular protein synthesis (e.g., enterohemorrhagic *E. coli* [EHEC/STEC]); (d) locally invading and destroying the mucosa (e.g., *Shigella*); (e) locally invading the mucosa and inducing inflammation (e.g., NTS); and (f) translocating across the mucosa, invading the bloodstream and spreading to distal organs (e.g., *S.* Typhi and *S.* Paratyphi A and B).

Secretory immunoglobulin A (SIgA) produced by plasma cells in the intestinal lamina propria provides an important first line of defense against enteric infections.[3] Immunoglobulin (Ig) A is actively transported over the epithelial barrier into the lumen, where it is released in the form of SIgA, which is resistant to degradation and can neutralize bacterial enterotoxins (and viruses) and inhibit epithelial attachment, thereby preventing colonization and cell invasion. Low levels of IgG may also be present in gastrointestinal secretions.[3] However, the small intestine (at least in individuals from industrialized country settings) is essentially nonpermeable to blood proteins if uninflamed. This is in contrast to the lower respiratory tract and the female genital tract, which are relatively permeable to transudated IgG antibodies. Consistent with this observation, the noninflammatory cholera and ETEC infections of the small intestine represent examples where vaccine protection is mediated by locally produced SIgA antibodies and probably requires vaccination via the oral route. Many young children in developing countries manifest environmental enteropathy, a syndrome that includes a chronic state of inflammation of the proximal small intestine, small bowel bacterial overgrowth and excitation of the innate immune system.[4] In such children, circulating IgG antibodies may transudate to the mucosal surface of the gut where they may play some a role in protection. However, IgG is rapidly degraded by intestinal proteases and, together with the normally low levels and lack of function of complement in intestinal secretions, limits the protective significance of IgG in the gut. Long-lasting immunological memory, mainly through the generation of long-lived memory B cells in intestinal Peyer patches and lymphoid follicles, can mediate persistent protection after the acute SIgA antibody response has vanished. The memory B cells can rapidly evolve into IgA-secreting plasma cells upon reexposure to antigen; the anamnestic SIgA antibody response may then control infection before it causes disease.[5] Mucosal memory B cells can be very long lived; for example, functional antigen-specific B-cell memory has been demonstrated for longer than 10 years after primary oral cholera vaccination.[6]

Cell-mediated protection against pathogens that enter the host via mucosal surfaces can be mediated by intraepithelial and lamina propria $CD4^+$ helper and $CD8^+$ cytotoxic T lymphocytes. These cell-mediated responses are believed to explain the durable protection that has been observed in subjects immunized with Ty21a live oral typhoid vaccine.[7] Numerous T-helper cells producing interferon-γ (Th1) and cells producing interleukin (IL)-17A (Th17) are often found in the lamina propria throughout the gastrointestinal tract.[8] Although believed to be major effector T cells against *Helicobacter pylori* and intracellular organisms such as *S.* Typhi and *S.* Paratyphi, their role in the gut mucosa is not fully understood. There are also data suggesting an important role for IL-17A in promoting intestinal IgA production and secretion.[9,10] T-follicular helper cells support antibody production and affinity maturation to protein antigens in mucosal germinal centers,[11] thereby having an important indirect role in forming protective antibody responses in the gut. However, the roles of different T-cell subsets in immune responses to oral vaccines remain to be fully elucidated.

MUCOSAL VERSUS PARENTERAL VACCINATION

Traditional injected vaccines primarily induce systemic immune responses and are generally poor in inducing mucosal immunity. In contrast, mucosal vaccines, administered via oral, nasal, or sublingual routes, generally give rise to both mucosal and systemic immune responses.[12] The mucosal response is anatomically compartmentalized reflecting the migratory properties of lymphocytes activated at different mucosal inductive sites, thus imposing distinct constraints on the choice of mucosal route for vaccine administration.[13] In general, the strongest immune response is obtained at the site

of vaccine application and next after that in anatomically adjacent or evolutionarily linked sites. An example of the latter is the intestine–mammary gland link in lactating women which ensures that the breastfeeding baby receives epidemiologically relevant breast milk SIgA antibodies from the mother, which result from the current microbial exposure in the mother's intestine.

While vaccination via the oral route has potential to prevent clinical illness by all enteric pathogens, parenteral vaccination may work against those enteric infections in which the pathogen is first translocated across the intestinal epithelium. An example is shigellosis (bacillary dysentery) in which translocated *Shigella* infect other enterocytes from the basolateral side. At this point the organisms can readily be attacked by serum-derived antibodies in concert with complement and phagocytic neutrophils. Likewise, serum antibodies can effectively attack pathogens that cause disease by inducing inflammation in the submucosal lymphoid tissues (e.g., NTS serovars and *Campylobacter jejuni*) or after entering the bloodstream (such as *S.* Typhi or *S.* Paratyphi).[14] Previous exposure to the pathogen leading to mucosal immunological priming also increases the ability of parenteral vaccination to protect against mucosal infections. A general rule seems to be that parenteral vaccines may provide some degree of boosting in already primed individuals, but they are unable to induce an effective mucosal response in individuals who have not been primed by previous mucosal exposure to the pathogen or by oral vaccination.[12] As described below, ongoing efforts to develop vaccines against ETEC are mainly focused on oral administration, while both oral and parenteral vaccination is considered for *Shigella*, *Campylobacter*, STEC, and NTS.

SPECIFIC VACCINES

Enterotoxigenic *Escherichia coli*

Epidemiology

ETEC is among the most common bacterial causes of diarrhea-associated morbidity and mortality in children younger than age 5 years in developing countries. The peak incidence occurs in children 6 to 36 months of age, where ETEC together with rotavirus and *Shigella* are the most common pathogens.[15] ETEC is also the number one cause of travelers' diarrhea,[16] reportedly accounting for 20% to 60% of all travelers' diarrhea globally with at least 20% of affected travelers being bedridden for part of their trip and 40% changing their itinerary because of diarrhea (reviewed in Reference 17). Travelers' diarrhea, primarily caused by ETEC, is also the most common medical problem for military personnel from industrialized countries deployed in less-developed areas of Asia or Africa, with an average incidence of 29% per month and up to 60% per month in hyperendemic regions.[18]

Clinical Manifestations and Mechanisms of Disease and Immunity

Disease caused by ETEC is characterized by profuse watery diarrhea lasting for several days. Infection is usually self-limited but may lead to dehydration and malnutrition in young children. ETEC causes disease after ingestion of contaminated food or water by attachment to the small bowel mucosa by so-called colonization factor (CF) antigens, mostly fimbriae, followed by bacterial multiplication and production of heat-labile toxin (LT) and/or a heat-stabile toxin (ST).[19] More than 20 types of CF antigens have been identified on human ETEC isolates, with a few types occurring most frequently, including CFA/I and "coli surface" antigens CS1 through CS6. Another important CF antigen is CS6, which is an outer membrane antigen rather than a fimbrial protein. Mucosal SIgA antibody responses against these CFs are believed to be protective by inhibiting epithelial binding of bacteria.[19] Importantly, although there are some cross-reactions between selected fimbriae, immune responses against one CF type are in general not cross-protective against several other types. Therefore, a broadly effective vaccine would require inclusion of multiple CF antigens.

Once attached to the intestinal epithelium, ETEC produces LT and/or ST enterotoxins, which induce the characteristic watery diarrhea. LT, which is highly homologous to cholera toxin (CT), is composed of a single catalytic A subunit and five identical B subunits, comprising the cell-binding domain. The A subunit mediates activation of adenylate cyclase, leading to increased production of cyclic adenosine monophosphate (cAMP), which activates ion channels and causes massive fluid secretion. Short-term protection against ETEC disease has been documented in persons immunized with a CT B subunit containing cholera vaccine because of immunologic cross-reactivity between B subunits of CT and LT.[20–22] ST is a small peptide toxin (18 to 19 amino acids) that stimulates guanylate cyclase in target cells. Efforts to use ST as a vaccine antigen have been hindered because of the low immunogenicity of this small toxin and other considerations discussed later.

Several lines of evidence support the feasibility of an efficacious ETEC vaccine. Epidemiologic as well as volunteer studies have demonstrated homologous protection against ETEC reinfection. In animal models, antibodies to LT and CF antigens have been shown to cooperate synergistically for protection.[17,23] Intestinal antibodies protected against ETEC challenge with ETEC strain H10407 that expresses CFA/I fimbriae, LT and ST in 90% of volunteers who had received passive oral milk-derived immunoglobulin from cows hyperimmunized with several fimbriated ETEC strains and LT.[24]

Enterotoxigenic *Escherichia coli* Vaccine Candidates

Although the diversity of ETEC, with more than 100 O serogroups and more than 25 recognized CF antigens, represents a major challenge for vaccine development, several ETEC vaccine candidates are under development. Most vaccines are intended for oral administration and based on toxin-derived antigens alone or combined with CFs, the latter being either purified or expressed on the bacterial surface. These vaccines are in different stages of preclinical and clinical (Table 18.1) development. The oral cholera vaccine Dukoral is licensed in several countries for prevention of ETEC travelers' diarrhea based on its demonstrated 50% to 70% short-term cross-protective effect through the B subunit component against LT-mediated ETEC diarrhea.[20–22]

Toxoid and Fusion Protein Vaccines. To develop an ETEC vaccine based solely on toxin-derived antigens may seem to be a rational strategy, as all ETEC strains produce either LT or ST or both. However, because the low-molecular ST is not immunogenic, chemical conjugates or gene fusion proteins between ST or ST-derived peptides and various carrier proteins have been studied—for example, LT (or mutated versions thereof), CT B subunit, and CFs. This approach has usually resulted in only modestly immunogenic conjugates with regard to the ST component. Immunization of animals with such preparations have typically yielded immune sera with only low-titer ST neutralizing activity even when strong adjuvants were used, and notably, the immunogenic preparations have also retained ST toxic activity.[25] A special problem for antibody-mediated protection directed against ST would

also be that the low molecular size of ST in comparison with a SIgA antibody would require a large amount of locally produced anti-ST SIgA to effectively neutralize ST. Another obstacle to vaccine development is the structural similarity between ST and human guanylin and uroguanylin, which might cause anti-ST antibodies to cross-react with endogenous ligands. Surprisingly, successful preliminary results have been reported by parenteral immunization of sows with ST-LT fusion proteins in protecting suckling piglets against challenge with a porcine ST-producing ETEC strain.[26,27] However, the capacity of these fusion proteins to induce intestinal antibodies is still unknown. Furthermore, residual ST or LT toxicity may be less of a problem in animals than in young infants and children; thus it remains to be seen if this approach, however appealing, will succeed for vaccination in humans.

Vaccines Containing Killed Whole-Cell Bacteria Plus B Subunit. A more complex, but arguably more realistic, strategy to protect against both LT-mediated and ST-mediated ETEC diarrhea is to develop a vaccine that is capable of inhibiting the intestinal attachment and colonization of ETEC and thereby diminishing the production of enterotoxins, especially by ST-producing ETEC. For additional protection against LT-induced diarrhea, the vaccine would preferably be combined with an LT "toxoid" component such as LT or CT B subunit in addition to ST. Based on this strategy, a first-generation oral ETEC vaccine consisting of both formalin-inactivated ETEC bacteria expressing various prevalent CF antigens and recombinant CT B subunit (rCTB) was developed by researchers at the University of Gothenburg and extensively tested in Phase I and Phase II trials.[17,28–30] This vaccine, given orally with a buffer in a two- or three-dose regimen, was safe and induced intestinal mucosal immune responses in 70% to 90% of Swedish, Bangladeshi, and Egyptian vaccinees of different ages. However, when tested in two Phase III trials in North American travelers to Mexico and Guatemala and one Phase III study in 6- to 18-month-old children in Egypt, the vaccine failed to significantly reduce overall (usually mild) ETEC diarrhea[17,31] (also L. Bourgeois, personal communication, 2012). Nevertheless, in both of the traveler studies in adults the vaccine reduced more severe ETEC diarrhea by almost 80%. Thus, vaccine protection against ETEC appears to be in line with observations for already licensed enteric vaccines against cholera and rotavirus disease, which have greater impact on more severe than on milder disease.[12]

A second-generation oral killed ETEC vaccine based on the same approach has recently been developed, in which several improvements have been made compared to the first-generation vaccine[32,33]: (a) vaccine strains are engineered to express four- to 15-fold increased amounts of CFA/I, CS3, and CS5 antigens, and to express high levels of the CS6 antigen in an immunogenic form (which was missing in the previous vaccine); (b) the rCTB is replaced by a hybrid rCTB/LTB*subunit* protein (LCTB*A*) eliciting a stronger anti-LT immune response; and (c) the double-mutant LT (dmLT), being a combined mucosal adjuvant and LT antigen, is optionally included in the vaccine. The dmLT molecule (R192G/L211A), which has two mutations in the enzymatic A subunit compared to the

native LT toxin, is nontoxic, and has shown potent adjuvant activity when tested in combination with various vaccines in mice and in vitro with human cells.[34–36] When the improved ETEC vaccine was given to mice, strong intestinal-mucosal IgA antibody responses were induced (as well as serum IgG and IgA responses) to each of the vaccine CFs as well as to LTB, and responses to the vaccine were further enhanced by the dmLT adjuvant.[32] Based on these data, a Phase I study was undertaken in Swedish adult volunteers (30 to 35 subjects per group) given either the vaccine alone, the vaccine together with 10 or 25 μg of dmLT adjuvant, or placebo.[37] Adverse reactions were few and mild with no differences between subjects receiving vaccine with or without dmLT or placebo. The majority of the vaccinated subjects (74% of all vaccine recipients and 83% of those receiving vaccine plus low-dose dmLT) showed significant mucosal IgA responses to all five of the primary vaccine antigens. The mucosal IgA antibodies were measured from cultured gut-derived blood lymphocytes (the antibody in lymphocyte supernatants method) and/or as specific SIgA antibodies in stool samples. Addition of low-dose dmLT to the vaccine significantly enhanced antibody in lymphocyte supernatants responses to the CS6 antigen, which was the CF present in lowest amounts in the vaccine. It is possible that the already excellent immunogenicity of the vaccine alone in this adult population explains why dmLT did not have any major effect on responses to the other vaccine antigens. Studies are in progress to examine the safety and immunogenicity of the improved oral inactivated ETEC vaccine with and without dmLT adjuvant when given to children living in areas endemic for ETEC as well as the protective efficacy in travelers.

Live Attenuated Vaccines. Several observations established the feasibility of immunoprophylaxis against ETEC using live oral vaccines. In a challenge model of ETEC diarrhea in adult volunteers, an initial clinical diarrheal infection caused by a fimbriated LT/ST ETEC strain conferred approximately 80% protection against clinical illness upon subsequent homologous rechallenge.[38] Immunization with a single 5×10^{10} colony-forming unit (CFU) dose of an ETEC strain (serotype O6:H16 expressing CS1 and CS3) that had lost the genes encoding LT and ST stimulated significant intestinal SIgA anti-CF antibody responses and conferred 75% protection against challenge with a heterologous ETEC serotype (O139:H28) expressing CS1 and CS3 and LT and ST.[39] More recently, the ACE527 live vaccine was developed containing three attenuated ETEC strains with deletions in *aroC*, *ompC*, and *ompF*, which collectively express CFA/I, CS1, CS2, CS3, CS5, and CS6, as well as LTB.[40] In a Phase I trial, two doses of ACE527 (10^{10} and 10^{11} CFUs) were well tolerated, and the higher vaccine dosage induced a high frequency of gut-derived IgA antibody in lymphocyte supernatants responses against LTB as well as CFA/I, CS6, and to a lesser extent CS3.[41] Irrespective of dose, immune responses to other antigens were low and infrequent. These observations were extended in a Phase IIb study in subjects who received two 10^{11} CFU doses and were then challenged with ETEC strain H10407 (O78, CFA/I, LT/ST).[42] In this study, 19% of vaccinees, but none of the placebo recipients, vomited upon immunization, and other gastrointestinal symptoms also tended to be more common in the vaccine group. A nonsignificant 27% reduction was seen in moderate to severe diarrhea, the primary end point, although the vaccine decreased the intestinal colonization by the challenge strain. Efforts are underway to further improve the immunogenicity of this vaccine by addition of dmLT adjuvant.

Labile Toxin Administered Transcutaneously. The safety and immunogenicity as well as protective efficacy of transcutaneously administered *E. coli* LT via skin patches have been extensively tested in human volunteers.[43,44] The patches, which did not give rise to any significant systemic side effects and only mild local skin reactions, induced significant anti-LT serum IgA and IgG, as well as IgA antibody-secreting cell responses in most vaccinees. However, two transcutaneous immunizations with LT did not protect against challenge with LT-producing ETEC.[44] In a placebo-controlled Phase II study in adult travelers to Mexico or Guatemala who were given two transcutaneous immunizations with LT there was also no significant protection against ETEC disease, although, quite surprisingly, significant protection against travelers' diarrhea of any origin was observed.[45] However, a subsequent Phase III trial did not show significant protection against travelers' diarrhea caused by either ETEC or other pathogens.[46] In a subgroup analysis by ETEC enterotoxin type, the vaccine seemed to be somewhat protective against diarrhea caused by LT-only–positive ETEC, but not against ST-positive or LT/ST-positive ETEC.[46] The manufacturer has ceased further development of LT skin patches as a human ETEC vaccine.

Fimbrial Tip Adhesion Vaccines. Another approach to develop an ETEC vaccine that provides combined anticolonization and antitoxic immunity is to produce chimeric proteins between ETEC CF antigens and LTB subunit by linking the tip protein of the CFA/I fimbriae (CfaE) to LTB. Recent Phase I clinical trials have been undertaken with a complex CfaE adhesin-toxoid chimera in which CfaE replaces the A1 domain of CT A subunit and is noncovalently assembled with LTB pentamer (CfaE-sCTA2/LTB chimera). Escalating doses of these prototype ETEC adhesin vaccines, admixed with single mutant LT (LTR192G) as adjuvant and antigen, were given by transcutaneous patch (CfaE only) and intradermal (CfaE chimera) vaccination. Although local skin reactions were common, there were no serious adverse reactions. Preliminary immunogenicity results also indicated anti-LTB as well as anti-CfaE IgG and IgA responses were seen after either route of immunization.[47] Studies to determine efficacy against ETEC challenge are in progress.

Shigella

Epidemiology

Shigella spp. are the most common cause of acute, bloody diarrhea (dysentery) and are responsible for a significant proportion of morbidity and mortality associated with diarrheal disease. Shigellosis only affects humans, and even though all age groups are susceptible, most cases occur in children younger than 5 years of age. The *Shigella* genus comprises four pathogenic species: *Shigella dysenteriae*, *Shigella flexneri*, *Shigella sonnei*, and *Shigella boydii*, including 50 serotypes and subserotypes; however, *S. dysenteriae* 1, which caused severe outbreaks up to the 1990s, has now almost disappeared. *S. flexneri* is endemic in developing countries, whereas *S. sonnei* is the most common cause of shigellosis in highly industrialized countries. *Shigella* (mostly *S. flexneri*) was found to be one of the top four attributable pathogens overall in children younger than 5 years of age with moderate to severe diarrhea in four sites in sub-Saharan Africa and in three sites in South Asia, and was the most common diarrhea pathogen in the 2- to 5-year-old age group.[15]

Clinical Manifestations and Mechanisms of Disease and Immunity

Symptoms of *Shigella* infection vary from mild, watery diarrhea to severe inflammatory bacillary dysentery with fever,

severe abdominal pain, and blood and mucus in the stools. *Shigella* bacteria cause disease by invading the human lower intestine and causing intense inflammation and epithelial destruction.[48] When the orally ingested organism reaches the terminal ileum and colon, it traverses the follicle-associated epithelium, is taken up by phagocytic cells, and can then invade neighboring epithelial cells at the basolateral pole, spreading from cell to cell. Apoptosis of infected macrophages releases proinflammatory cytokines and elicits a strong inflammatory response with accumulation of large numbers of neutrophils and destruction of the intestinal epithelium. Depending on serotype, *Shigella* can also produce one or more toxins that contribute to virulence, including Shiga toxin (*S. dysenteriae* 1); *Shigella* enterotoxin 1 ("ShET1"; *S. flexneri* 2a and some *S. flexneri* 2b strains); and *Shigella* enterotoxin 2 ("ShET2"; all *Shigella* serotypes). ShET1 and ShET2 are thought to be responsible for the watery diarrhea phase of clinical shigellosis that often precedes the dysenteric phase.[48]

There are still no licensed vaccines against shigellosis. Because *Shigella* is antigenically diverse, a *Shigella* vaccine should protect against all 15 *S. flexneri* serotypes plus *S. sonnei* (which is a single serotype) and ideally also *S. dysenteriae* 1. It is believed that a vaccine comprising four to five *Shigella* strains (*S. sonnei*, *S. flexneri* 2a, 3a, and 6, and possibly *S. dysenteriae* 1) could protect not only against the serotypes contained in the vaccine but also against the other 11 *S. flexneri* serotypes because of shared antigens.[48]

Studies in healthy adult volunteers have shown that an initial episode of clinical shigellosis confers significant (approximately 75%) protection against illness upon rechallenge a few months later with the homologous virulent serotype.[49,50] A similar level of protection against homologous reinfection was observed in Chilean children.[51] Serum and/or mucosal antibodies directed against the O antigen appear to play a major role in protection.[48] Both oral and parenteral prototype *Shigella* vaccines have induced significant protection against clinical shigellosis, and the presence of gut-derived O-antigen–specific IgA antibody-secreting cells in blood 7 to 10 days after oral vaccination have correlated with vaccine efficacy. Cell-mediated immunity, including interferon-γ production, may also contribute.[48]

Shigella Vaccine Candidates

Two main strategies have been pursued to develop effective vaccines against shigellosis: (a) primarily orally administered live or killed whole-cell vaccines and (b) parenterally injected conjugate vaccines containing purified O-antigen polysaccharide (PS) coupled to a carrier protein. The main challenge for the oral live attenuated vaccine candidates has been how to achieve adequate attenuation while retaining the ability of the vaccine strain to multiply and stimulate immunity in the gut. For oral killed whole-cell or parenterally injected conjugate vaccines reactogenicity is much less of a problem and instead the main challenge has been to stimulate the right type and magnitude of immune response. These vaccines may need to be combined with an effective adjuvant. Some of the *Shigella* vaccine candidates and those that have been tested in humans are summarized below and in Table 18.2.

Live Oral *Shigella* Vaccines. In the 1960s, Mel and others evaluated in Phase I to Phase III trials a first generation of live oral attenuated *Shigella* vaccines. One type consisted of streptomycin-dependent (SmD) *Shigella* bacteria of different serotypes that had lost the ability to invade epithelial cells. A second type was a spontaneous mutant *S. flexneri* 2a strain (T32) which was noninvasive because of a large deletion in the invasiveness plasmid. Overall, these vaccines were well tolerated and protective in both adults and children in randomized, controlled field trials in Romania and China.[52,53] These early live oral *Shigella* vaccines were later superseded by better defined genetically engineered *Shigella* bacteria, and a multitude of strains have been tested in humans (see Table 18.2).

The SC602 vaccine was constructed by researchers at the Institut Pasteur by creating in a *S. flexneri 2a* strain deletion mutations in the *icsA (virG)* gene, which encodes a protein involved in intracellular motility and cell-to-cell spread of *Shigella*, and in *iuc*, which encodes the iron-scavenging protein aerobactin. A dosage of 10^6 CFUs was strongly immunogenic but unacceptably reactogenic in North American volunteers, whereas 10^4 CFUs was well tolerated and still significantly immunogenic. When vaccinated volunteers were challenged with virulent *S. flexneri* 2a, significant protection was observed 2 months later.[54] SC602 was also tested in a Phase II trial in adults and children in Bangladesh. All dose levels (10^4, 10^5, or 10^6 CFUs) were well tolerated but in this population even the highest dose was minimally shed and poorly immunogenic.[55]

The SC599 vaccine is another live *S. dysenteriae* type 1 strain attenuated by deletions of *icsA* (inhibiting invasion), *ent* and *fep* (inhibiting iron chelation), and *stxA* (blocking Shiga toxin A subunit synthesis) genes. In Phase I and Phase II trials, this vaccine was well tolerated and immunogenic at dosage of 10^5 to more than 10^8 CFUs, but induced only modest IgA antibody responses.[56,57] The clinical development of this vaccine has not been pursued further.

Investigators at Walter Reed Army Institute of Research constructed strain WRSS1 by deleting the *icsA* gene in a virulent strain of *S. sonnei*.[58] Safety and immunogenicity trials in North American volunteers,[59] and subsequently in Israeli adults,[60] indicated that the vaccine strain was well tolerated in dosages up to 10^4 CFUs. At this dosage all subjects examined had detectable IgA anti-O antigen antibody-secreting cell responses. An analogous *S. dysenteriae* 1 vaccine candidate, WRSd1, with a mutation in *icsA* and a chromosomal deletion in *stxAB*, which encodes Shiga toxin, was constructed[61] and doses of 10^3 to 10^7 CFUs were given to North American volunteers. However, approximately 20% developed diarrhea and 60% developed a detectable IgA response.[62] The adverse reactions seen with WRSs1 and WRSd1 led to efforts to introduce additional mutations to try to decrease the reactogenicity without compromising the immunogenicity. Several new vaccine strains have been developed, but none has yet been tested in humans.

Investigators at the Center for Vaccine Development (CVD) have constructed and clinically tested a number of live attenuated *Shigella* vaccine candidate strains. Their work with two early vaccine strains, CVD 1204 and CVD 1208, established the attenuating effects of deletion of the *guaBA* (leading to inhibition of the ability to biosynthesize guanine nucleotides) and of the *sen* chromosomal and plasmid genes encoding ShET1 and ShET2, respectively.[63] Based on this, the CVD 1208S *S. flexneri* 2a vaccine strain having deletion mutations in *guaBA* as well as in both *sen* genes was developed. When CVD 1208S was tested in North American adults (10^7 or 10^8 CFUs) it was well tolerated and immunogenic.[64] Analogous strains of other serotypes have now also been constructed to combine with CVD 1208S in a pentavalent live oral vaccine (CVD 1213 *S. flexneri* 3a, CVD 121 *S. flexneri* 6, CVD 1233S *S. sonnei*, and CVD 1254 *S. dysenteriae* 1) which remains to be tested in humans.

Killed Whole-Cell Vaccines. This strategy aims to develop a safe multivalent oral vaccine comprising the bacterial components needed for achieving broad protection against *Shigella*

Heat-killed *S. dysenteriae* 1 bacteria	Several efficacy trials	65
Formalin-killed *S. sonnei*	Phase I trial in U.S.	66
PARENTERAL CONJUGATE VACCINES		
S. sonnei O polysaccharide (PS) conjugated to rEPA carrier protein	Phase III trial in Israel	71
S. sonnei O PS-rEPA + *S. flexneri*-rEPA conjugates	Phase III trial in Israel	74
S. dysenteriae O PS-EPA biosynthetic conjugate	Phase I trial in Switzerland	75
Flexyn2a		
S. flexneri 2a O PS-EPA biosynthetic conjugate	Phase I trial in U.S.	76
INTRANASAL PROTEIN VACCINE		
Invaplex		
Invasion complex vaccine; *IpaA, IpaC, IpaD* + LPS	Phase I and Phase II trials in U.S.	77, 78

EPA, *Pseudomonas aeruginosa* exotoxin A; LPS, lipopolysaccharide; rEPA, recombinant *P. aeruginosa* exotoxin A; SmD, streptomycin dependent.

infections. Heat-killed *S. dysenteriae* 1 bacteria administered orally were used in many places in the 1920s to control outbreaks of dysentery.[65] These trials were neither blinded nor placebo-controlled but the results clearly suggest that the vaccines were effective, reducing dysentery incidence among vaccinated when compared to unvaccinated subjects by 50% to 70%. More recently, a formalin-killed *S. sonnei* vaccine was evaluated in a Phase I clinical study in North American volunteers.[66] This vaccine was well tolerated and induced an immune response to *Shigella* antigens in most individuals. A trivalent formalin-killed vaccine comprising *S. flexneri* 2a and 3a components in addition to the *S. sonnei* component has been produced and will undergo clinical testing.[67]

Parenteral Conjugate Vaccines. A strategy that has been demonstrated to confer protection in adults and older children living in endemic settings is the parenteral conjugate *Shigella* vaccine approach. Early parenterally administered killed whole-cell vaccines stimulated high levels of serum antibodies but failed to protect monkeys against challenge[68] or children from natural infection in field trials,[69] leading many to conclude that serum antibodies alone could not protect against shigellosis. This notion was contested by studies of parenteral conjugate vaccines consisting of lipopolysaccharide (LPS)-derived O PSs of relevant *Shigella* serotypes covalently linked to a carrier protein (recombinant *Pseudomonas aeruginosa* exotoxin A [rEPA]). A single dose of *S. sonnei* O PS conjugated to rEPA was well tolerated and induced high levels of serum IgG anti-PS antibodies in Israeli soldiers.[70,71] In a randomized, controlled, double-blind Phase III efficacy trial in Israeli soldiers, the vaccine conferred 74% protection against *S. sonnei* diarrhea.[71] These results were followed by Phase II trials in Israeli children, ages 4 to 7 years and 1 to 4 years,[72,73] and, subsequently, a Phase III trial in children 1 to 4 years of

age,[74] where children were given two injections of a combination of *S. sonnei* PS conjugated to rEPA and *S. flexneri* 2a PS conjugated to succinylated rEPA 6 weeks apart. While the Phase II studies showed promising immunogenicity to both serotypes in the pediatric age groups, the Phase III trial did not provide significant protection against *S. sonnei* disease, the overall efficacy being 27%; protection against *S. flexneri* could not be determined because of too few cases for analysis. Efficacy against *S. sonnei* in children ages 3 to 4 years was 71% (95% confidence interval [CI] −4.4, 92.0; $P = .04$), whereas it was 36% (95% CI −56.4, 73.4; $P = .36$) in children 2 to 3 years of age and 4% (95% CI −101.1, 46.5; $P = .91$) in children 1 to 2 years of age. This was associated with an age-related increase in serum IgG antibody levels. It is not clear if the apparent protection in the oldest children was a consequence of higher serum IgG antibody levels allowing more antibodies to transudate into the intestine or, whether the older children were immunologically primed from prior exposure to *S. sonnei* and therefore able to produce mucosal SIgA that mediated the protection.

Investigators at GlycoVaxyn have developed conjugate vaccines to various enteric pathogens using a genetic system for low-cost production of glycosylated proteins in *E. coli*. A *S. dysenteriae* 1 O PS-EPA (*P. aeruginosa* exotoxin A) conjugate was administered intramuscularly in a Phase I trial, with or without adjuvant (aluminium hydroxide), in Swiss adults. It was well tolerated and highly immunogenic irrespective of dose or formulation.[75] An analogous bioconjugate vaccine of *S. flexneri* 2a O PS-EPA (Flexyn2a) was also found to be safe and highly immunogenic when administered intramuscularly with and without aluminum hydroxide to healthy adult volunteers.[76] Plans to prepare and test a multivalent bioconjugate *Shigella* vaccine are in progress.

Additional *Shigella* Vaccine Strategies. All four species of *Shigella* produce identical type III secretion proteins (Ipa invasion proteins). Based on this concept, a *Shigella* invasion protein complex vaccine (Invaplex) containing IpaB, IpaC, and IpaD and LPS has been prepared. Administered intranasally, Invaplex was well tolerated and elicited relevant anti-*Shigella* immune responses in Phase I and Phase II trials.[77,78] Other approaches in preclinical testing include injectable or intranasal vaccines based on outer membrane vesicles being developed by Novartis in Italy,[79] vaccines based on recombinant shared *Shigella* outer membrane proteins such as PSSP-1 developed at the International Vaccine Institute in South Korea,[80] and various combined *Shigella*-ETEC vaccines based on oral live or killed *Shigella* bacteria expressing ETEC CFs and LTB developed at CVD, USA[48] or University of Gothenburg, Sweden.

Campylobacter jejuni

C. jejuni is a major cause of diarrheal disease in both industrialized and developing countries. The pathogen is the most common bacterial cause of diarrhea in the United States and the second most common cause in United Kingdom.[81] In many developing countries, almost all children are infected during early childhood, and asymptomatic reinfection and prolonged carriage are common.[82] *Campylobacter* is one of the most common causes of travelers' diarrhea[16] and also of diarrheal outbreaks during military exercises.[83] Importantly, the infection is associated with many life-threatening cases of Guillain-Barré syndrome (GBS), a form of symmetric ascending paralysis with autoimmune etiology.[81,84] *Campylobacter* species have also been associated with a range of gastrointestinal conditions, including inflammatory bowel disease (IBD), Barrett esophagus, and colorectal cancer, as well as some extragastrointestinal manifestations.[81] *Campylobacter* spp. are frequent commensals in the intestinal tracts of chickens and are commonly implicated in foodborne diarrheal illness.[85] In developing countries, *Campylobacter*, because of the heterogeneous antigenic properties of clinical isolates, may cause several infections per year per child and has been identified as an important cause of moderate to severe diarrhea in infants and young children.[15,82,86] On the other hand, *Campylobacter* infections are often asymptomatic in children older than 5 years of age and in adults in endemic areas.[87]

Campylobacter infection typically begins with a watery diarrhea phase. The infection commonly manifests with signs of inflammation, fever, abdominal pain, and bloody diarrhea.[85] Infection in developing countries is more commonly watery in nature without frank blood.[82] Untreated infection may subside after 3 to 7 days, but persistent disease is not uncommon. GBS following *Campylobacter* infection is usually self-limiting, but death may occur, especially if clinical management is not optimal.[84] The pathophysiology of *Campylobacter*-associated GBS is not fully elucidated, but antibodies to some *C. jejuni* lipooligosaccharide serotypes cross-react with human neural sheath gangliosides.[88,89]

Campylobacter Vaccine Candidates

Vaccine approaches to protect against *Campylobacter* infection are complicated by the organism's antigenic heterogeneity and by the threat of GBS. Two antigenic typing systems are in use: the Lior system and the Penner system. The Lior typing scheme includes 108 serotypes and is based on a heat-labile surface antigen that is still not characterized. The Penner system recognizes more than 60 serotypes and is based on LPS and lipooligosaccharide antigens.[90,91] Immunity to *Campylobacter* appears to be strain specific, but the antigens conferring immunity are unknown. Human challenge studies have demonstrated homologous strain-specific immunity against rechallenge with some but not all strains. The well-characterized outbreak strain, *C. jejuni* 81-176, gave complete protection against homologous rechallenge 1.5 months after the initial infection, which had decreased to 57% against rechallenge after one year.[92] *Campylobacter*-specific production of interferon-γ by peripheral blood mononuclear cells has been strongly associated with protection from illness. In contrast, there was a lack of homologous protection against *C. jejuni* CG8421 in a human challenge model.[93]

Because of the uncertainty regarding the mechanism of GBS, *Campylobacter* whole-cell vaccines, either viable or killed, must be generated and evaluated with extreme caution. The most intensively studied *Campylobacter* vaccine candidate comprises a mixture of heat-killed and formalin-killed whole bacteria derived from prototype strain 81-176, combined with *E. coli* LT as a mucosal adjuvant.[94] In mice, a single dose provided homologous protection against intestinal colonization. Initial Phase I trials indicated that the vaccine is safe and immunogenic in humans,[95] but the vaccine was unsuccessful in a Phase IIb challenge study with the same strain.[96]

Other vaccine strategies against *Campylobacter* are also being considered. A conjugate vaccine composed of capsular PS from strain 81-176 linked to CRM197 (mutated diphtheria toxin) administered subcutaneously conferred 100% protection against diarrhea in nonhuman primates after homologous challenge,[97] and Phase I trials of this vaccine are being planned.[98] The flagellin antigen is an attractive vaccine candidate because of its relatively high antigenic conservation and the expectation that this molecule will not elicit GBS. A truncated recombinant flagellin subunit vaccine administered intranasally together with single mutant LT (R192G) has provided more than 80% protection against disease symptoms

and colonization after intranasal challenge with a heterologous *C. jejuni* strain in mice.[99] Other proteins secreted through the *Campylobacter* flagellum have also been evaluated as vaccine candidates,[100] but to our knowledge none has been tested in humans.

Enterohemorrhagic *Escherichia coli*/Shiga Toxin–Producing *Escherichia coli*

EHEC was first described in 1983 after having been isolated from patients with hemorrhagic diarrhea in two diarrheal outbreaks associated with eating poorly cooked hamburgers in restaurants.[101] The *E. coli* strain isolated was O157:H7 serotype and produced the same cytotoxins (Verotoxins or Shiga toxins) as those described in cases of hemolytic uremic syndrome (HUS),[102] also caused by *E. c*oli O157:H7 bacteria. EHEC is considered as a subgroup of STEC. Approximately 450 serotypes of STEC have been isolated from humans with disease, and in most countries EHEC O157:H7 is the most common serotype causing outbreaks. EHEC is endemic in the United States with an estimated incidence of one case per 100,000 individuals. In Europe the incidence rate is lower but increasing. Many EHEC outbreaks have also been reported from low- and middle-income countries, although the importance of the pathogen in these environments is likely to be underestimated because of lack of proper diagnosis.[103]

STEC infection is acquired by ingestion of contaminated food or water or by person-to-person spread. A natural reservoir for the pathogen exists in the intestines of cattle.[104] The difficulty in eliminating the organism from bovine populations presents significant challenges to control that may be best addressed by vaccination. Whether this is best achieved by vaccination of cattle or of risk group humans or both remains an open question. Currently, two parenteral vaccines for control of EHEC in livestock have been licensed (Econiche in Canada and Epitopix in the United States). Both of these vaccines significantly decrease colonization and stool contents of O157:H7, but do not eliminate this organism completely.[105,106] It is not known whether either of these vaccines have any effect on other STEC serogroups that also cause HUS in young children and elderly people.

STEC infection is accompanied by watery diarrhea, frequently progressing to hemorrhagic colitis.[104,107] Systemic absorption of Shiga toxin (Stx), an oligomeric toxin related to the toxin produced by *S. dysenteriae* 1,[108] leads to serious sequelae, including HUS, which develops in up to 20% of pediatric patients infected with *E. coli* O157:H7. Other potentially fatal complications include intestinal perforation and cerebrovascular accident. In addition, non-O157:H7 STEC strains are increasingly being recognized as causes of HUS, bloody diarrhea, and other gastrointestinal illnesses.[109,110] Similar to CT and *E. coli* LT, Stx is composed of a single catalytic toxic—active A subunit and five cell-binding B subunits.[108] The B subunit binds to the cell by the glycolipid globotriaosylceramide (Gb3). The A subunit catalyzes the depurination of a single residue in the 28S eukaryotic ribosomal RNA, thereby inhibiting protein synthesis and leading to target cell death.

Shiga Toxin–Producing *Escherichia coli* Vaccine Candidates

The most advanced vaccine candidate appears to be a conjugate vaccine based on O157 O-specific PS conjugated to rEPA. A Phase I trial in adults indicated that a single parenteral dose was safe and stimulated strong O-antigen–specific responses.[111] All children ages 2 to 5 years participating in a Phase II study responded with anti-O157 IgG titers with high bactericidal activity, but efficacy was not reported.[112] An alternative approach is to link the O157 PS to the StxB1 subunit, to elicit both antitoxic and anticapsular antibody responses. In young mice, this formulation induced bactericidal antibodies to *E. coli* O157 as well as neutralizing antibodies to Stx.[113]

The importance of Stx in STEC disease has made it a natural target for immunization. Antibodies against the B subunit have been shown to prevent binding of the toxin to target cells[114] and immunization with the Stx2B subunit conjugated to keyhole limpet hemocyanin protected mice from a lethal dose of Stx2 holotoxin.[115] However, the A-B complex is more immunogenic than the B subunit alone, and thus both B and A-B toxoids have been examined as candidate vaccines. Vaccine approaches have been summarized[116] and include both parenteral and mucosal vaccination with inactivated holotoxin, toxoids generated by site-directed mutagenesis, genetically detoxified hybrid toxoids and fusion proteins carrying both Stx1 and Stx2 B subunits. However, the toxoid approach will likely be tested first as a vaccine for *S. dysenteriae*, which is a more important pathogen than STEC worldwide.

Several attenuated vector vaccines have been modified to express STEC antigens,[117,118] but none of these strains is being seriously considered as a vaccine candidate. Orally administered *Salmonella landau*, a *Salmonella* strain that naturally expresses the O157 antigen, is able to elicit protection of mice from colonization by *E. coli* O157.[119] These results suggest that local exposure to the O157 antigen may induce resistance when delivered by live *Salmonella*, although humans exposed to STEC do not generate highly protective O157 responses after natural infection. Proteins translocated through the type III secretion system, such as Tir, and the outer membrane protein intimin, have also been investigated as vaccine candidates, sometimes in the form of fusion proteins, also including Stx subunits.[116] There is also a continued search for novel vaccine antigens which may induce broad-based protection. Studies using comparative genomics[120] or immunoproteomics[121] have described a number of antigens expressed by STEC strains which are absent in commensal *E. coli* strains and may be potential candidates for vaccine development.

Nontyphoidal *Salmonella*

Salmonellae causing human disease are divided into thousands of NTS serotypes with a broad host range and a small number of invasive typhoidal serotypes (e.g., *S. enterica* var Typhi and *S. enterica* var Paratyphi A). NTS infection can occur by consumption of both animal and nonanimal food products, contaminated water, or by contact with animals. In healthy individuals in high-income countries, NTS predominantly causes localized and self-limited gastroenteritis, which is very distinct from the severe systemic disease caused by *S. enterica* serovars Typhi and Paratyphi, which are primarily seen in developing countries. However, invasive NTS disease can cause severe clinical disease, meningitis, and death in young infants, the elderly, and immunocompromised hosts in developed countries.[122,123] A large proportion of the episodes of invasive NTS disease, as well as of gastroenteritis in North Americans and Europeans, are caused by *Salmonella enteritidis*, *Salmonella typhimurium* or a monophasic variant of the latter that does not produce Phase II flagella. Importantly, NTS has also been identified as a major cause of invasive bacterial infections in infants and toddlers in sub-Saharan Africa.[124] These strains are often multiply antibiotic resistant and have high case fatality rates (typically 20% to 25%). In addition in this region unusual strains of *S. typhimurium* and *S. enteritidis* are circulating that cause severe, often fatal invasive disease, usually without a history of gastroenteritis.[124]

Nontyphoidal *Salmonella* Vaccine Candidates

Vaccine efforts targeting NTS include live attenuated and conjugate vaccine strategies. The live oral vaccines include one vaccine candidate, *S. typhimurium* WT05, which has deletions in the *ssaV* gene, which encodes a structural protein in the Type III secretion system, and in *aroC* gene, encoding chorismate synthase which is critical for the synthesis of aromatic amino acids and for bacterial growth. In human volunteers, oral administration of 10^7 to 10^9 CFUs of WT05 was reported to be well tolerated, but only the highest dose gave rise to a detectable immune response.[125] A number of additional *S. typhimurium* vaccine candidate strains harboring additional or alternative mutations have been generated as has also two attenuated *S. enteritidis* strains. These vaccines (reviewed in reference 126) have all shown promising safety and immunogenicity profiles in mice and the *S. typhimurium* strains have also been found to be highly protective in the mouse model. None of these vaccine candidates have yet been tested in humans.

The conjugate vaccines consist of the O PS extracted from *S. enteritidis* (group D) and *S. typhimurium* (group B) linked to carrier proteins. For *S. typhimurium* PS the carrier proteins used include, for example, tetanus toxoid[127] and bacterial porin,[128] or in a more recent conjugate using CRM_{197}.[129] These conjugate vaccines were reported to be well tolerated, highly immunogenic, and protective against challenge in mice or rabbits. A conjugate between the O PS and Phase I flagellin subunits of *S. enteritidis* stimulated high titers of opsonizing and bactericidal IgG antibodies, and the conjugates were also highly protective in the mouse model.[130] Phase I and Phase II clinical trials are being planned.

PUBLIC HEALTH PERSPECTIVES, INDICATIONS, AND CHALLENGES FOR VACCINATION

Since the first licensure of the Sabin oral polio vaccine more than 50 years ago, only a few vaccines have been licensed for enteric infections. As discussed above, there are currently intense efforts to develop vaccines against additional major diarrheal pathogens. There are strong indications to use vaccines once available for the control of ETEC diarrhea and shigellosis, which are both major causes of enteric infection and disease worldwide. Weanling infants and young children in ETEC and *Shigella* endemic countries—that is, practically all low- and middle-income countries in tropical and subtropical settings—are prime target populations for ETEC and *Shigella* vaccination. Travelers to and military personnel deployed to endemic areas are additional important target groups for such vaccines.

Likewise, *Campylobacter* vaccination is a priority in developing countries, where infants experience a high burden of life-threatening diarrhea. Travelers to developing nations may also benefit from *Campylobacter* vaccination, especially those traveling for prolonged periods such as soldiers. Although *Campylobacter* infection is less common than *E. coli* and *Shigella*, the risk of GBS increases the importance of *Campylobacter* infection. At the same time, GBS presents a particular concern in relation to vaccination, since strong safe-guards will obviously be required against triggering rather than protecting against GBS by vaccination.

There is a growing interest in the development of safe and effective EHEC/STEC vaccines both for veterinary and human use. At the same time, there are significant policy issues regarding STEC vaccination of humans. Given the low incidence of serious infection and HUS, a vaccine would need to be highly effective and extraordinarily safe. Vaccination of cattle would not pose the same requirement for safety, however practical effectiveness of available vaccines is not fully defined. Vaccines against NTS are also under development and may become particularly important for control of invasive disease. However, the development of these vaccines are complicated by the immunocompromised nature of susceptible individuals.

Despite the strong indications for vaccination, especially against ETEC and *Shigella*, no vaccines for human use against these pathogens are available. There are several reasons for this situation, some being pathogen-specific and others being more generic. Pathogen-related challenges for vaccine development include the wide antigen diversity of different strains of the infecting organisms, problems in achieving adequate safety especially in live-attenuated vaccines while retaining protective immunogenicity and for some bacteria important animal reservoirs or risks of inducing neuro-inflammatory conditions. The more generic challenges are largely related to our still limited knowledge about the gut mucosal immune system. Mucosally administered vaccines are probably essential for inducing immune protection in subjects that have not been immunologically primed by previous natural exposure, and in those with noninvasive infections not readily reached by serum antibodies. They are also inherently safer and easier to deploy than injectable vaccines. However, development of mucosally administered vaccines have been hampered by several factors including, for example, (a) a lack of reliable animal models for predicting vaccine-induced immune protection in humans together with limitations in available adult human challenge models to predict practical vaccine efficacy in developing countries and in children; (b) a general lack of immunological correlates of mucosal immune protection; (c) a lack of safe yet effective mucosal adjuvants, limiting mucosal vaccine development to date to live-attenuated or inactivated whole virus and bacterial vaccines; (d) a limited knowledge of the factors responsible for the underperformance of (especially live) oral vaccines in children in developing countries; and (e) until recently a lacking recognition of the importance of herd protection as a means to increase the public health impact of oral enteric vaccines (for a further discussion of these factors and possible means to overcome them the reader is referred to a recent review[131]). There are reasons to believe that the development of promising safe and effective mucosal adjuvants and programmatically improved intervention strategies could enhance the efficacy of both current and next generation enteric vaccines. As emphasized throughout this chapter, this would be of special importance in low- and middle-income countries, which are often co-endemic for enteric infections, environmental enteropathy ("tropical sprue") and malnutrition.

Acknowledgments

We thank Drs. James P. Nataro and Eileen M. Barry, who contributed to earlier editions of the chapter on the subject of this book and whose treatise on the sections of *Campylobacter*, STEC, and NTS we have largely updated rather than rewritten.

19 Diphtheria Toxoid

Tejpratap S.P. Tiwari and Melinda Wharton

Respiratory diphtheria is an acute communicable upper respiratory illness caused by toxigenic strains of *Corynebacterium diphtheriae*, a Gram-positive bacillus. The illness is characterized by a membranous inflammation of the upper respiratory tract, usually of the pharynx but sometimes of the posterior nasal passages, larynx, and trachea, and by widespread damage to other organs, primarily the myocardium and peripheral nerves. Extensive membrane production and organ damage are caused by local and systemic actions of a potent exotoxin produced by toxigenic strains of *C. diphtheriae*. A cutaneous form of diphtheria commonly occurs in warmer climates or tropical countries.

HISTORY OF THE DISEASE

Historical descriptions of diphtheria-like illness (throat membrane, neck swelling, frequent suffocation) first appeared in ancient Egyptian writings from the second millennium BC[1] with increasingly detailed descriptions by Greek writers, including Hippocrates (fifth century BC), Aretaeus (second century AD), and Aëtius (sixth century AD).[2–4] Only isolated reports of the disease appeared until the 17th century, when devastating outbreaks occurred in Spain.[3] Indeed, in Spanish history, 1613 is known as the Year of Diphtheria (Año de los Garrotillos).[2] Successive outbreaks occurred in southwestern Europe approximately every 12 years through the 18th century. The earliest definitive description of diphtheria in America was that of Samuel Bard in New York in 1771, although outbreaks had previously been noted in the American colonies.[2,3,5] In the early 19th century, Bretonneau clearly delineated the clinical picture of diphtheria, convincingly argued for its communicability, successfully pioneered tracheostomy as a method of treatment, and gave the disease its name, derived from the Greek word for leather or tanned skin.[2,3]

In the second half of the 19th century, increasingly severe epidemics swept many parts of Europe and the large cities of the United States, and vigorous efforts were made by researchers in the new field of bacteriology to identify the causative agent.[4] In 1883, Klebs first described the characteristic organisms in stained preparations of diphtheritic membranes, and Löffler reported the successful growth of these organisms in culture a year later.[3] Other investigators soon confirmed the pathogenicity of the organism for guinea pigs, and in 1888, Roux and Yersin demonstrated the presence of a potent exotoxin (see "Passive Immunization," later). Over the next decade, antisera produced in animals by injection of sublethal or inactivated cultures were first shown to prevent death in nonimmune animals that were challenged with virulent organisms, and then to prevent death in children with clinical diphtheria.[2,3]

The concept of active immunization began with Theobald Smith in 1907, who noted that long-lasting immunity to diphtheria could be produced in guinea pigs by the injection of mixtures of diphtheria toxin and antitoxin and suggested that these mixtures might do the same for humans. After successful immunization of children by von Behring with toxin–antitoxin mixtures, immunization programs began in selected European and American cities. However, these immunizations, although usually effective, were not free of adverse reactions. In 1913, Schick introduced a skin test for immunity that consisted of the injection of a small, measured amount of diphtheria toxin; in immune persons, circulating antibody neutralized the toxin, and no local lesion was observed.[2] The Schick skin test was widely used to distinguish immune individuals and target immunization to those susceptible. In the early 1920s, Ramon showed that diphtheria toxin, when treated with heat and formalin, lost its toxic properties but retained its ability to produce serologic protection against the disease. Thus the current immunizing preparation, diphtheria toxoid, came into being.[6]

WHY THE DISEASE IS IMPORTANT

Before the introduction of diphtheria immunization, diphtheria was a major cause of childhood mortality, and it remains endemic in many developing countries. A large outbreak of diphtheria in the newly independent states of the former Soviet Union in the 1990s highlighted the potential for this ancient scourge to reemerge in countries that fail to maintain high levels of population immunity through immunization.[7]

BACKGROUND

Clinical Description

Classic diphtheria has an insidious onset after an incubation period of 1 to 5 days (rarely longer). The gradual onset of diphtheria is in contrast to the usually sudden, almost explosive manifestations of streptococcal pharyngitis. Symptoms of diphtheria are initially nonspecific and mild; throughout the course of the disease, the patient's temperature usually does not exceed 38.5°C. Other early symptoms in children include diminished activity and some irritability. At the very onset of symptoms, the pharynx is inspected on examination but no membrane is present. About a day after onset, small patches of exudate appear in the pharynx. Within 2 or 3 days, the patches of exudate spread and become confluent and may form a membrane that covers the entire pharynx, including the tonsillar areas, soft palate, and uvula. This membrane becomes grayish, thick, and firmly adherent to the underlying mucosa. Efforts to dislodge the membrane result in bleeding. Anterior cervical lymph nodes become markedly enlarged and tender. In a proportion of patients, the lymph node swelling is associated with considerable inflammation and edema of the surrounding soft tissues, giving rise to the so-called bull-neck appearance, which is associated with a higher morbidity and mortality. Although fever is rarely high, the patient characteristically appears toxic and displays a rapid, thready pulse. In untreated patients, the membrane begins to soften about a week after onset and gradually sloughs off, usually in pieces but sometimes as a single unit. As the membrane detaches, acute systemic symptoms, such as fever, begin to disappear.

Although pharyngeal diphtheria is by far the most common form of disease seen in unimmunized populations, other skin or mucosal sites may be involved. Laryngeal diphtheria occurs in 25% of cases; in 75% of these instances, the pharynx is also involved. Isolated nasal diphtheria is uncommon (approximately 2% of cases). Cutaneous, aural, vaginal, and conjunctival diphtheria together account for only approximately 2%

of cases and are often secondary to nasopharyngeal infection. Laryngeal diphtheria may occur at any age, but is particularly likely to occur in children younger than 4 years. It is marked by an insidious onset with gradually increasing hoarseness and stridor. Fever is usually slight. The diagnosis is often missed or delayed when the pharynx is not simultaneously involved. Laryngeal diphtheria is associated with greater morbidity and mortality as a result of airway obstruction and the greater degree of toxin absorption from the extensive membrane.

Cutaneous diphtheria is an indolent skin infection that often occurs at sites of burns or other wounds and may act as a source of respiratory infection in others.[8–12] It is more common in warmer climates and in poor social conditions.[8–11] Although sufficient diphtheria toxin is absorbed from skin lesions to frequently produce immunity, systemic complications are uncommon with cutaneous diphtheria. In warmer climates, the high incidence of cutaneous diphtheria appears to have played a major role in producing immunity in the population in the absence of high rates of respiratory diphtheria.

Invasive disease caused by *C. diphtheriae* occurs rarely, most commonly as a result of nontoxigenic strains. Bacteremia, endocarditis, osteomyelitis, and arthritis have been reported.[13–17] Molecular epidemiology studies show that several of the reported clusters of invasive disease were associated with clonally related organisms.[18–20]

Complications

The impact of diphtheria is largely measured by complications attributable to the local disease and to the effect of absorbed toxin on other organs. The major threat from laryngeal diphtheria is respiratory obstruction. Life-endangering obstruction is generally managed by tracheostomy. Even with a tracheostomy tube in place, fatal acute respiratory obstruction occasionally occurs when a portion of a laryngeal membrane is dislodged and aspirated. The membrane may extend down into the tracheobronchial tree, resulting in pneumonia and expiratory respiratory obstruction. Because of edema of the upper respiratory tract, pharyngeal and nasal diphtheria are frequently associated with secondary otitis media and sinusitis.

The majority of deaths from diphtheria result from the effects of absorbed diphtheria toxin on various organs; severe complications from toxin absorption include acute systemic toxicity, myocarditis, and neurologic complications, primarily peripheral neuritis. The risk for complications is directly proportional to the extent of local disease, presumably because of increased production and absorption of the toxin in larger membranes. In addition, the frequency of these various complications appears to vary considerably between epidemics, for which no clear explanation is available. In the past, it was erroneously believed that the severity of the disease could be related to strains of the organism that were morphologically different on culture, being designated gravis, intermedius, and mitis.[21,22] A possible explanation for variation in reported frequency of complications is variability in the timeliness of therapy with diphtheria antitoxin, as well as differences in susceptibility among affected populations.

Severe acute systemic toxicity with myocardial involvement usually occurs between the third and seventh day of the illness; many investigators classify this complication as early myocarditis.[23] Others, however, believe that the effects on the myocardium are only part of diffuse systemic toxicity, including fever, purpura, peripheral circulatory collapse, restlessness, somnolence, and disturbances of carbohydrate metabolism.[24,25] This so-called early myocarditis is usually fatal. Late myocarditis usually appears in the second or third week of illness, when the local symptoms of diphtheria in the respiratory tract are resolving and the patient is otherwise improving.

In either early or late myocarditis, a wide variety of clinical and electrocardiographic findings may be noted.[24] Tachycardia, distant heart sounds, and a weak pulse may be observed. Electrocardiography most often shows conduction changes and alterations in T waves. Supraventricular and ventricular ectopic rhythms are common in severe diphtheria, even in the absence of evidence of heart failure.[26] The earlier electrocardiographic changes appear, the worse is the prognosis. Complete heart block frequently occurs and is usually fatal; ventricular pacing may not improve survival.[27–30] Echocardiograms show decreased contractility and ventricular dilation proportional to the severity of the clinical carditis; a left ventricular ejection fraction of less than 35% is associated with an increased risk for death.[31,32] Although electrocardiograms and echocardiograms return to normal in most survivors, residual changes are seen in some survivors of severe carditis for up to several years after illness.[26,31,33] Left bundle-branch block at hospital discharge has a poor prognosis.[34]

Neurologic complications of diphtheria are primarily toxic peripheral neuropathies, and they occur in approximately 15% to 20% of cases.[35,36] The manifestations are more motor than sensory and usually begin 2 to 8 weeks after onset of the illness. In severe cases, palatal paralysis with consequent nasal voice and nasal regurgitation of ingested fluids may occur during the acute membranous phase, particularly with extensive pharyngeal disease, and are believed to be attributable to local effects of the toxin. With milder disease, palatal paralysis is common as late as the third week. Symmetric peripheral neuritis of the lower extremities is a frequent neurologic complication, usually occurring 3 to 10 weeks after onset of the infection. Diaphragmatic paralysis occasionally occurs, usually a month or more after onset, and may require mechanical respiratory support. Ocular paralysis, involving either the extraocular muscles or those of accommodation, sometimes appears, usually 5 or 6 weeks after onset. Fortunately, functional recovery from these neuropathies is the rule, even in severe disease.[37] An association between diphtheria and delayed-onset hearing loss has also been reported.[38]

BACTERIOLOGY

Corynebacterium diphtheriae is a slender, Gram-positive bacillus, usually with one end being wider, thus giving the often-described club-shaped appearance. On culture, particularly under suboptimal conditions, characteristic bands or granules appear. On smear, the organisms often have a "pick-up sticks" relationship, assuming parallel (palisade-like), or V- or L-type patterns. The organisms are resistant to environmental changes, such as freezing and drying. There are four biotypes of *C. diphtheriae* (gravis, mitis, belfanti, and intermedius), which historically were identified by colonial morphology and biochemical differences; however, in practice, only the intermedius biotype can be distinguished reliably by colonial morphology.[39] No consistent differences are found in severity of disease caused by different biotypes. Biotype differentiation is not supported by phylogenetic analyses.[40]

PATHOGENESIS AS IT RELATES TO PREVENTION

The exotoxin produced by *C. diphtheriae* is by far the most important pathogenic factor associated with the organism. The extensive study of the biology of diphtheria toxin has pioneered many biomedical developments over the past century. The basic biology of diphtheria toxin, including its production and actions, has become reasonably well understood, although some gaps remain.[41,42]

The ability of strains *C. diphtheriae* to produce toxin results from a nonlytic infection by one of a series of related bacteriophages that contain a genetic sequence encoding the toxin. The phage integrates into specific sites present in *C. diphtheriae* and other *Corynebacterium* species. The presence of the phage is thought to confer a survival advantage to the bacterium by increasing the probability of transmission in a susceptible population; transmission may be facilitated by local tissue damage resulting from the toxin.[43,44] The sequence of diphtheria toxin has been demonstrated to be highly conserved in *C. diphtheriae* strains, suggesting that immunologically important differences among the toxins produced by different strains are unlikely to occur.[45] Once integrated, the *tox* gene is part of a multiple bacterial gene operon; other bacterial gene products in this operon are involved in the liberation and uptake of host iron.[46] The entire operon is under the control of a repressor gene, *dtxR*, which in the presence of iron binds to and inhibits the *tox* gene; toxin is produced only under low-iron conditions.[47]

Diphtheria toxin is a polypeptide with a molecular weight of approximately 58,000 Da. The toxin is secreted as a proenzyme, requiring enzymatic cleavage into two fragments (fragments A and B) to become active. Fragment B is responsible for attachment to and penetration of the host cell. Although nontoxic by itself, fragment B appears to be the antigen responsible for clinical immunity. The receptor domain of fragment B binds to a cell surface receptor, heparin-binding epidermal growth factor precursor,[48] with CD9 as a coreceptor.[49] After receptor-mediated endocytosis and penetration of the cell, fragments A and B are detached.[50] The released fragment A is the toxic moiety, and it acts by inhibiting protein synthesis, resulting in cell death.[44] Unless cell penetration occurs, fragment A is inactive. Differences in the tissue distribution of the receptor and coreceptors may account for the differential effects of diphtheria toxin on different organs.[51,52]

The ability of *tox* gene–containing bacteriophages to infect nontoxigenic strains of *C. diphtheriae* provides a potential explanation for the fact that, during outbreaks of diphtheria, both toxin-producing and non–toxin-producing strains of the organism may be isolated on culture surveys. Some evidence suggests that the introduction of a toxin-producing strain of *C. diphtheriae* into a community may occasionally initiate an outbreak by transfer of phage to nontoxigenic strains of the organism carried in the respiratory tracts of community inhabitants, rather than a new strain being the responsible agent.[53]

On mucous membranes, the toxin causes local cellular destruction, and the accumulated debris and fibrin result in the characteristic membrane. More important, absorbed toxin is responsible for remote manifestations affecting various organs, including, for example, the myocardium, nervous system, and kidneys. Because the lethality of diphtheria is almost entirely determined by the organism's toxin, clinical immunity depends primarily on the presence of antibodies to the toxin. In the presence of small amounts of formaldehyde, diphtheria toxin loses its attachment and enzymatic activities while retaining its immunogenicity, thus becoming a toxoid. This process is the basis of active immunization against diphtheria.

Certain cell wall antigens of *C. diphtheriae* are also thought to contribute to the pathogenesis of the disease in humans. The cell wall contains a heat-stable O antigen, which is found in all corynebacteria. The cell wall also contains K antigens, which are heat-labile proteins that differ among strains of *C. diphtheriae* and therefore permit categorization of the organism into a number of types.[54] The K antigens play two roles in relation to humans: first, they appear to be important in the establishment of infection, and second, they produce local type-specific immunity. Lack of immunity to K antigens appears to be responsible for the fact that local upper respiratory tract diphtheria can occur with non–toxin-producing organisms, and toxin-producing organisms may infect persons with ample serum antitoxin levels, but neither of these instances is associated with systemic manifestations, even though a faucial membrane is produced.[55] Another factor responsible for the local invasiveness of the organism is the so-called cord factor, which is a toxic glycolipid. This glycolipid has been shown to disrupt mitochondria, depress cell respiration, and interfere with oxidative phosphorylation.[56] The term *cord factor* is derived from a similar substance found in *Mycobacterium tuberculosis* that results in the growth of the organism in serpentine coils. Undoubtedly, there are other factors as well that help *C. diphtheriae* establish residence and provide nutritional substrates.

Some strains of two other closely related *Corynebacterium* species, *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis*, have been demonstrated to produce diphtheria toxin,[57] and nontoxigenic strains can be converted to toxigenic strains by infection with β-corynebacteriophage.[58] Sequencing studies demonstrate that both the base-pair sequence of the *tox* genes and the amino acid sequence of the diphtheria toxins from *C. diphtheriae* and *C. ulcerans* differ by approximately 5%.[59] Disease indistinguishable from that caused by toxigenic strains of *C. diphtheriae* is associated with *C. ulcerans* infection.[60–63]

DIAGNOSIS

Diphtheria is rare in the United States. However, physicians need to be aware of the signs and symptoms that suggest diphtheria. Some developing countries continue to have high levels of circulation of toxigenic strains of *C. diphtheriae*. Some circulation persists in a few countries of the former Soviet Union after a large epidemic in the 1990s,[64,65] and until recently limited persisting foci were reported in some highly developed countries.[66,67]

In countries where the disease is endemic, a patient with confluent pharyngeal exudate should be suspected of having diphtheria until proven otherwise. The onset is usually gradual over the course of 1 to 2 days and is associated with low-grade fever. The hallmark of respiratory diphtheria is the presence of pseudomembrane in the pharynx. Although certain clinical characteristics of membranous pharyngitis caused by diphtheria, such as the color, adherence, and odor of the membrane, can be recognized as being different from other forms of exudative pharyngitis by experienced clinicians, very few physicians in industrialized countries currently have the experience required to base a differential diagnosis on the clinical appearance of the lesion.

Because laryngeal diphtheria usually occurs concomitantly with pharyngeal involvement, membranous pharyngitis with stridor should be considered to be diphtheria until proved otherwise. However, about a quarter of all cases of laryngeal diphtheria do not display a pharyngeal lesion and therefore may often be misdiagnosed. The differential diagnosis includes epiglottitis caused by *Haemophilus influenzae* type b (Hib), although uncommon in immunized populations, spasmodic croup, the presence of a foreign body, or viral laryngotracheobronchitis. There should be little confusion regarding the first three because the onset and clinical characteristics of each are well known and are different from diphtheritic croup, which is ordinarily associated with gradual onset and steady progression through hoarseness to stridor during a period of 2 or 3 days. Viral laryngotracheobronchitis may be more difficult to differentiate, and, if diphtheria is suspected for epidemiologic or other reasons, laryngoscopy is indicated.

Nasal diphtheria may be difficult to distinguish from many other causes of nasal discharge and accordingly is most likely to be suspected if the patient has been exposed to diphtheria, such as during an outbreak. Suspicion should be heightened if a serosanguineous discharge is present and if the upper lip is ulcerated. However, the latter also occurs with streptococcal infections. Any cutaneous or mucous membrane lesions at other sites should be considered suspicious if a membrane is noted.

The risk of complications and mortality from diphtheria are inversely related to the promptness of diagnosis and treatment. Thus, it is critical that the diagnosis be considered, appropriate clinical specimens be obtained, and a decision made regarding administration of antitoxin as early as possible in the course of illness. When diphtheria is suspected, treatment for the disease should be initiated immediately after bacteriologic specimens are obtained, without waiting for results. Delay, even for a few hours, may increase the risk of complications and death.

Swabs for culture should be obtained under direct visualization, preferably from the edge or beneath the edge of the membrane. Directly stained smears are usually grossly misleading even in experienced hands and should not be used. Swabs should be inoculated promptly onto tellurite-containing media and onto blood agar.[68] Cultures should be incubated promptly and interpreted by an experienced microbiologist. Because not all *C. diphtheriae* recovered on culture are toxigenic, testing for toxin production must be performed. The modified Elek immunoprecipitation test for detection of toxin is the standard assay, but it generally requires 24 to 48 hours, and more rapid approaches to toxin detection have been described.[69] Many laboratories now use a polymerase chain reaction (PCR) assay for the detection of the *tox* gene.[70–73] Although this assay can provide a rapid indication that an isolate may be toxigenic, in some isolates the *tox* gene is detected but is nonfunctional.[74] For this reason, toxin production in PCR-positive isolates should be confirmed by an immunoprecipitation test. PCR can also be performed directly on clinical specimens.[75] Real-time PCR assays that detect toxin genes associated with both *C. diphtheriae* and *C. ulcerans* have been developed.[76,77]

Several approaches to typing of strains of *C. diphtheriae* as an adjunct to epidemiologic investigations have been developed. During the 1960s, Saragea and Maximescu[78] developed a system of phage typing and demonstrated considerable diversity of circulating strains in different countries. Subsequently, the usefulness of molecular typing methods was demonstrated in analysis of outbreak-related strains in Sweden[79] and the United States.[80] Since then, ribotyping,[81] pulsed-field gel electrophoresis,[81] and multilocus enzyme electrophoresis[82] have been used for molecular subtyping, as has PCR–single-strand conformation polymorphism (SSCP) analysis.[83] A rapid ribotyping method using PCR-SSCP has been described.[84] Ribotyping has been used most extensively and standard nomenclature has been developed.[85] Multilocus sequence typing also has been used and appears useful for discriminating reliably among strains of *C. diphtheriae*.[86] Molecular methods have been used to characterize the dominant strains of *C. diphtheriae* associated with the outbreak in the former Soviet Union,[81] and to document ongoing endemic circulation in certain communities in the United States and Canada.[66,87,88] However, these tests are only available in research laboratories.

TREATMENT AND PREVENTION WITH ANTIMICROBIALS

Although diphtheria antitoxin is the mainstay of diphtheria therapy, penicillin or, alternatively, erythromycin should be given to hasten clearance of the organism, prevent transmission, and cease further production of diphtheria toxin.[89] Before the availability of antibiotic therapy, convalescent carriage of toxigenic organisms was a major problem. Up to 50% and 25% of patients continued to harbor the organism 2 and 4 weeks after onset, respectively. As late as 2 months after onset, reported carriage rates varied between 1% and 8%.[3] Long-term convalescent carriers were often subjected to tonsillectomy, probably with some effect.[90]

Treatment with penicillin or erythromycin should be continued for 2 weeks. On completion of treatment, patients should be cultured twice at least 24 hours apart to confirm elimination *C. diphtheriae*. Patients who continue to harbor the organism after treatment with either penicillin or erythromycin should receive an additional 10-day course of oral erythromycin, and specimens for follow-up cultures should be obtained on completion of the course.[89] Although treatment with penicillin or erythromycin has no apparent effect on the clinical course of the disease, in most instances the organism can no longer be recovered on culture within a week of therapy and subsequent convalescent carriage is thus uncommon.

EPIDEMIOLOGY

Incidence and Prevalence Data

Active immunization of children with diphtheria toxoid has markedly altered the epidemiology of diphtheria, reducing diphtheria to extremely low levels in both developed countries and developing countries that have sustainable and well-implemented vaccination programs. However, diphtheria continues to produce substantial childhood morbidity and mortality in developing countries with incompletely implemented childhood immunization programs.[91,92]

From 1980 to 2014, only 57 cases of respiratory diphtheria were reported in the United States.[93–101] The last case in the United States was reported in 2014 in a 17-year-old white female resident of Ohio.[101] However, the isolated organism *C. diphtheriae* was nontoxigenic. The patient was fully immunized. No other family member or close contact was ill.

The decline of reported cases in the United States was abrupt partially because cutaneous diphtheria ceased to be nationally notifiable in 1980 (Fig. 19.1). However, improved childhood immunization in Mexico and other developing countries as part of the World Health Organization (WHO) Expanded Programme on Immunization (EPI) beginning in the late 1970s is likely to have contributed to improved diphtheria control in the United States by reducing importations of toxigenic strains. In the mid-1990s, with so little disease reported in the United States, it seemed likely that toxigenic strains of *C. diphtheriae* were no longer circulating in this country.[93] However, in 1996, surveillance revealed widespread circulation of the organism in one American Indian community in the Northern Plains.[102] Similarly, although recognized cases of diphtheria remain rare, endemic transmission of *C. diphtheriae* has been documented in some native communities in Canada.[103–105] Strains from the United States and Canada were assayed by ribotyping and multilocus enzyme electrophoresis and found to be closely related to strains that circulated in the same areas during the 1970s and 1980s, suggesting ongoing endemic circulation.[66,88] Circulation has also been reported among the aboriginal population in central Australia.[106] The common denominator in these communities is likely to be poverty and crowding.

In temperate climates, respiratory diphtheria occurs year-round but most often during colder months, probably because of the close contact of children indoors. In tropical climates,

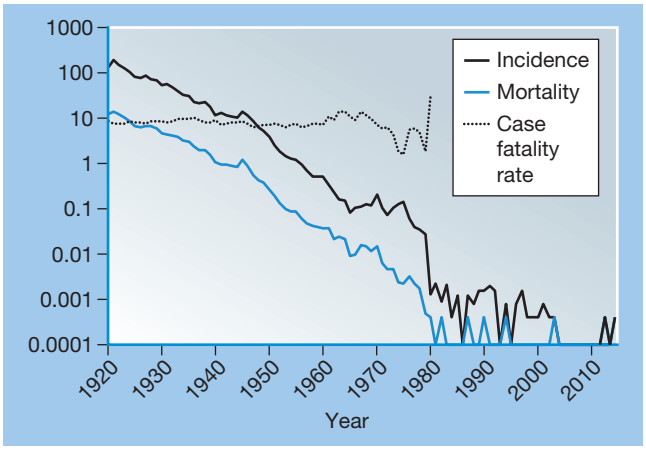

Figure 19.1. Diphtheria incidence in the United States, 1920–2014, and mortality rates, 1920–1980. Years in which no case was reported are plotted with an incidence rate of 0.0001 per 100,000 population. Because of the small number of diphtheria deaths since 1980, case fatality rates (CFRs) are unstable and are not shown on this graph. CFRs have varied widely since 1980 because of the small number of cases, but the overall CFR from 1980 to 2010 was 16%. *(Data from the Centers for Disease Control and Prevention, Atlanta, GA.)*

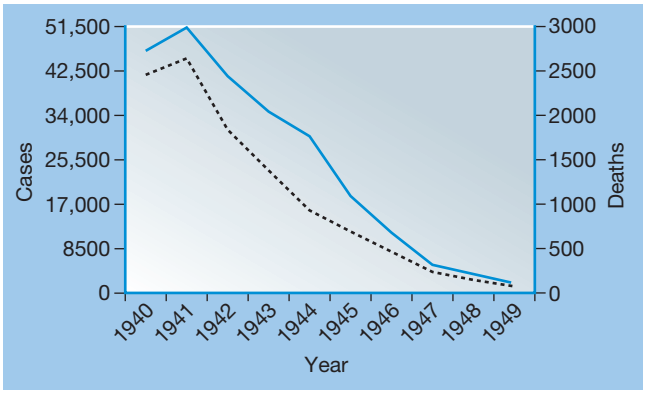

Figure 19.2. Diphtheria cases (solid line) and deaths (dashed line) in England and Wales, 1940–1949. *(From Mortimer PP. The diphtheria vaccine debacle of 1940 that ushered in comprehensive childhood immunization in the United Kingdom.* Epidemiol Infect. *2011;139: 487–493.)*

cutaneous diphtheria is more common and is unrelated to season.

Risk Groups

Unvaccinated or inadequately vaccinated preschool and school-age children are most often affected by respiratory diphtheria. Diphtheria is rare in infants younger than 6 months of age, presumably because of the presence of maternal antibody, and rare among adults, especially those living in urban areas, as a result of acquired immunity. Although no differences in diphtheria incidence were noted by sex in the prevaccine era, an increased risk of diphtheria among women was reported in several outbreaks among adults in the 1940s and subsequently; an increase in risk of diphtheria among women was observed in Russia and some of the other countries of the former Soviet Union during the outbreaks that occurred there in the 1990s.[64,107–111]

Reservoirs of Infection and Modes of Transmission

Humans are the only natural host for *C. diphtheriae*. Transmission is from person to person, most likely by intimate respiratory and physical contact. The organism is reasonably hardy and has been isolated from the environment of persons infected with *C. diphtheriae*.[112–115] Nonetheless, the occurrence of indirect transmission by airborne droplet nuclei, dust, or fomites has not been established. Evidence of outbreaks caused by contaminated milk and milk products has been reported.[23,115,116] Cutaneous lesions appear to be important in transmission under poor social conditions.[9,10,117]

The precise microbial events responsible for the transmission of diphtheria remain unclear. However, the molecular epidemiologic data showing clonal identity of bacteria in large numbers of infected people in the outbreaks in Seattle,[80] Sweden,[79] and Russia[87] strongly suggest that direct spread of toxigenic bacteria from one individual to another is a major factor in large epidemics.

Significance as a Public Health Problem

In the past, in the absence of immunization, most people acquired immunity to diphtheria as measured by the Schick test without experiencing clinical diphtheria. Transplacental antibody to diphtheria toxin is present at birth in most infants but declines to nonprotective levels during the second 6 months of life. Thereafter, the proportion of immune children (Schick-negative) in unimmunized populations gradually increases to 75% or more, presumably as a result of repeated subclinical infection with the organism.[118]

In the 21st century, it is difficult to comprehend what a major cause of morbidity and mortality diphtheria was in the past. Before 1900, the best data for the United States were from Massachusetts. From 1860 to 1897, death rates from diphtheria ranged between 46 and 196 per 100,000 population annually, with a median of 78, with the proportion of total deaths attributable to diphtheria ranging from 3% and 10% annually.[119] By 1900, a considerable fall in the death rate had occurred and continued to decline from 40 to 15 per 100,000 over the next 20 years, presumably because of the therapeutic use of diphtheria antitoxin and, perhaps, other measures such as intubation. However, even in 1900, more than half as many deaths from diphtheria were recorded in the United States as from cancer.[119] Several interesting and readable histories of diphtheria in the late 19th and early 20th centuries have been published.[120–122]

Excellent data on morbidity, mortality, and case-fatality rates for diphtheria were available for the Province of Ontario for 1880 to 1940 and for several Canadian cities for some of those years.[123] Mortality from diphtheria exceeded 50 per 100,000 population in most years before the advent of diphtheria antitoxin. Mortality subsequently declined to approximately 15 per 100,000 by World War I, although morbidity rates did not decline. With the widespread use of diphtheria toxoid vaccine beginning in the late 1920s in Canada, the disease nearly disappeared.[124]

At the beginning of the 20th century, diphtheria was a major cause of death of children in the United Kingdom. In 1934, the diphtheria mortality rate among children was 38.5 per 100,000. Widespread diphtheria immunization programs began there in 1940 and by 1944, it was reduced to 9.2 per 100,000, and by 1949 both morbidity and mortality were reduced more than 10-fold compared with the period from 1940 to 1941 (Fig. 19.2).[125]

Since the introduction of vaccination with diphtheria toxoid, a number of diphtheria outbreaks have occurred in

industrial countries. During World War II, a major outbreak spread throughout western Europe with well over 1 million cases reported.[126,127] The outbreaks spread from Europe to North America. A major outbreak affecting nearly 1% of the population of Halifax, Nova Scotia, during the winter of 1940–1941 was linked to disease imported by Norwegian sailors.[128] Another outbreak occurred in Alabama in 1943 among German prisoners of war.[129]

By the late 1950s, the incidence of diphtheria was markedly reduced in the United States, but disease continued to occur in some other areas. From 1959 to 1970, 5048 cases of diphtheria were reported in the United States, with the highest incidence rates reported in the southeast, south central, and northern plains states. Incidence rates were 20-fold higher for Native Americans and sevenfold higher for blacks than for whites.[130]

Diphtheria incidence continued to decline (see Fig. 19.1), and from 1971 to 1981, 853 noncutaneous and 435 cutaneous cases were reported in the United States.[131] Incidence rates exceeded 1 per million population in South Dakota, New Mexico, Alaska, Washington, Arizona, and Montana, and incidence rates were 100-fold greater for Native Americans than for whites and blacks.[131] During this period, there were seven outbreaks with 15 or more cases in the United States.[131] From 1972 to 1982, a large outbreak of predominantly cutaneous diphtheria occurred among residents of Skid Road in Seattle, Washington.[10,80] The Seattle outbreak and most of the other outbreaks from 1969 to 1980 were caused by toxigenic strains of the intermedius biotype, which had previously been uncommon; clonality of these strains was suggested by molecular epidemiologic studies of strains from outbreaks in Seattle[80] and the southwestern states.[132]

Although diphtheria has become a rare disease in most developed countries, a major epidemic of it began in the Russian Federation in 1990 and subsequently spread throughout the countries of the former Soviet Union (Fig. 19.3), with more than 157,000 cases and 5000 deaths reported between 1990 and 1998.[111] A compendium summarizing the knowledge gained from this outbreak has been published.[133] Although the cause of the epidemic was uncertain, it was multifactorial. Contributing factors included decline in childhood vaccination acceptance and coverage, exaggerated physicians fears about adverse events, the use of three doses of Td (diphtheria and tetanus toxoids–adult) instead of DTP (diphtheria, tetanus, pertussis) in the childhood immunization schedule, and the absence of an adult Td immunization program resulted in inadequate population immunity among children and adults. In addition, delayed recognition of cases and public health response, and changing social conditions facilitated spread once the outbreak began.[111] In the Russian Federation, the emergence of an epidemic clone of *C. diphtheriae* biotype gravis was demonstrated.[82] The epidemic clone was present in Russia as early as 1985, and strains of this clonal group have been retrospectively identified in different geographic areas of Russia from 1985 to 1987.[134] Many cases were also caused by biotype mitis strains as well, especially in the newly independent states of Central Asia, suggesting that microbial factors alone did not account for the epidemic.[135] The Russian epidemic peaked between 1994 and 1995 and subsequently was brought under control by increasing immunization coverage with diphtheria toxoid among both children and adults (see later).[64,111]

Figure 19.3. Reported cases of diphtheria, by year, in the Soviet Union (1965–1990) and in the newly independent states of the former Soviet Union (1991–2013).

Diphtheria toxoid has been included in the WHO's EPI since its inception in 1974. In developing countries, the implementation of the EPI has led to dramatic falls in the global number of reported cases of diphtheria since 1980; however, marked disparities remain in reported rates between countries. Some countries have achieved control of diphtheria comparable to that seen in highly developed countries. In others, disease rates have fallen dramatically but sporadic outbreaks still occur, for example, Thailand,[136] India,[137–139] Brazil,[140] Indonesia,[141] and Laos,[142] which have recent evidence of widespread circulation of toxigenic strains. Low vaccination coverage rates and population immunity were reported in the affected areas in these countries.

Before the WHO EPI began, it was estimated that close to a million cases of diphtheria occurred annually in the Third World, with 50,000 to 60,000 deaths.[143] From 1980 to 2013, reported cases of diphtheria globally decreased from 97,774 to 4680 in 2013 with control of the outbreak in the former Soviet Union. Approximately 87% of cases worldwide in 2013 were reported from the WHO Southeast Asian region (Fig. 19.4); 77% of cases in this region were reported from India.[144]

Under the EPI, the goal was to achieve 90% or higher immunization rates in 1-year-old children by the year 2000. By this time, it was estimated that the proportion who had received three doses of DTP vaccine (DTP3) had risen from negligible levels in the early 1970s to 81% worldwide, with Africa being the lowest at approximately 55%.[145] By 2013, global coverage improved to 84% while 79% of the countries of the African region reported DTP3 coverage of 80% or more by 1 year of age.[144] Some of the regional differences in these data no doubt reflect differences in either the capacity or quality of surveillance in member countries.

PASSIVE IMMUNIZATION

The history of the development of diphtheria antitoxin was reviewed in detail by Andrewes and colleagues.[3] In brief, in 1888 Roux and Yersin reported their observation that bacteria-free filtrates of broth cultures of *C. diphtheriae*, when injected into animals, produced all the manifestations of diphtheria except for the membranous local lesions.[146] In rapid succession, other advances followed. von Behring showed that inactivated cultures of the organism injected into animals subsequently rendered them protected against living cultures.[147] Ultimately, von Behring demonstrated the transfer of protection from an immunized animal to another unimmunized one by serum, which he named antitoxin. Diphtheria antitoxin was first given to a child in 1891, and antitoxin was

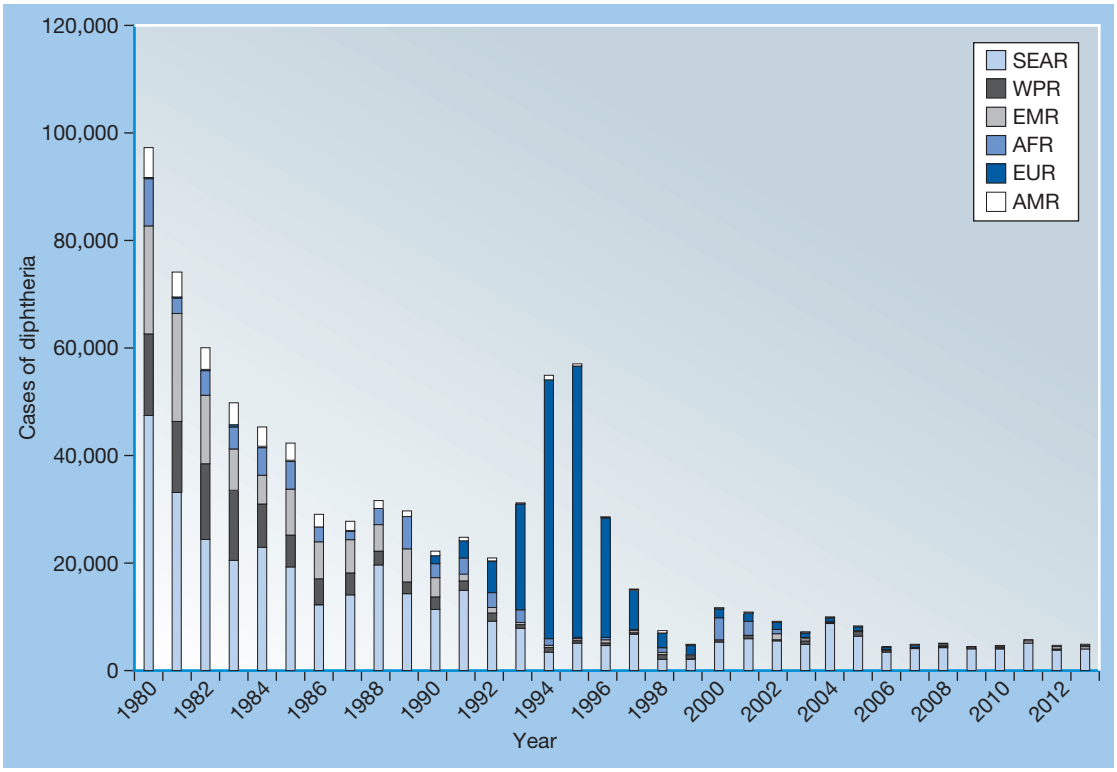

Figure 19.4. Reported cases of diphtheria, by year and region, 1980–2013. commercially produced in Germany in 1892. The use of horses for the production of antitoxin began in 1894 and was widespread within a few years. The lack of regulated standards for the production of equine diphtheria antitoxin resulted in the release of contaminated or counterfeit antisera and contributed to the development of the predecessors of the present Center for Biologics Evaluation and Research of the U.S. Food and Drug Administration (FDA).[148–150]

Equine diphtheria antitoxin continues to be used to date. The product is prepared by hyperimmunizing horses with diphtheria toxoid and toxin.[149] To diminish reactivity from horse serum, current preparations are semipurified by techniques that concentrate immunoglobulin G and remove as much extraneous protein as possible. There must be at least 500 units of antitoxin per milliliter, and sterility is attained by microfiltration. A cresol derivative is added as a preservative.

Diphtheria antitoxin is used for the treatment of diphtheria and occasionally for prevention in exposed persons. Its therapeutic efficacy is well established, although it is in no way a substitute for prior active immunization with diphtheria toxoid. No antiserum or hyperimmunoglobulin of human origin is currently available.

Globally, the production and supply of equine antitoxin for human therapeutic use has become increasingly problematic. Almost all industrialized countries that traditionally manufactured and supplied antitoxin have ceased production. Unavailability of an antitoxin supply increases the likelihood of mortality, as highlighted by shortages during the epidemic in the newly independent states of the former Soviet Union. With low demand for the product, many manufacturers have left the market, so only a few manufacturers supply diphtheria antitoxin to other countries, many of which have reported difficulty in identifying a supplier and maintaining a supply for domestic use.[151,152] As of January 6, 1997, licensed diphtheria antitoxin with a valid expiration date was no longer available in the United States, and there was no manufacturer proposed to produce it. However, for treatment of the disease in the United States, the Centers for Disease Control and Prevention has a supply of antitoxin that can be distributed for treatment under an investigational new drug protocol.[153] This antitoxin is comparable to the prior U.S. product and may be requested by calling 770-488-7100.

Novel approaches to passive immunity could include the commercial development of human monoclonal antibodies to diphtheria toxin or the development of recombinant modified diphtheria toxin receptor molecules to bind diphtheria toxin.[154,155] A neutralizing monoclonal antibody of human origin has been developed which completely protected guinea pigs from lethal challenge in an in vivo assay. The monoclonal antibody binds to the receptor-binding domain of diphtheria toxin and blocks the toxin from binding the receptor.[156]

Postexposure Use of Antitoxin and Toxoid

The value of antitoxin in postexposure prophylaxis is dubious. Theoretically, it should be useful in preventing the establishment of infection in exposed, susceptible people because the toxin plays a role in local invasiveness. However, there is no acceptable clinical evidence of prophylactic efficacy; all that exist are anecdotes and small, uncontrolled series of experiments.[3] Even if it were effective, antitoxin would be of little use in controlling community outbreaks, because asymptomatic carriers, rather than persons with overt disease, are usually the major source of transmission.[157] For these reasons,

antitoxin is not recommended for exposed, susceptible persons, particularly in view of the high rates of subsequent serum sickness and occasional anaphylaxis. The preferred treatment for exposed, unimmunized, asymptomatic persons is to obtain a throat culture, begin immunization with a preparation containing diphtheria toxoid that is appropriate for age, and institute prophylaxis with erythromycin or penicillin for 7 days, during which time the patient must be kept under surveillance for development of symptoms.[89]

USE OF ANTITOXIN FOR TREATMENT OF DIPHTHERIA

Many studies have demonstrated that therapy with antitoxin is efficacious in reducing mortality from diphtheria primarily by preventing cardiovascular toxicity.[4,158] However, only a single controlled therapeutic trial is discussed in the literature.[159,160] This nonblinded trial consisted of treating all patients admitted on alternate days with antitoxin and comparing their outcomes with those of patients admitted on nontreatment days. Eight (3.3%) of 242 patients treated with antitoxin died, compared with 30 (12.2%) of 245 control subjects.

In addition, many observations of the direct relationship between mortality and the day of disease when antitoxin was administered provide ample evidence of its efficacy. For example, among 3558 patients observed by Ker,[158] 320 cases of paralysis occurred. There was a strong direct relationship between the frequency of postdiphtheritic paralysis and the number of days between onset of illness and administration of antitoxin. Only 4.8% of 1168 patients developed paralysis when antitoxin was administered no later than the second day of illness, in contrast to 12.1% of 1375 patients who received antitoxin on the fourth day of the disease or later.

Antitoxin is given intramuscularly or intravenously; many authorities prefer the intravenous route for at least part of the dose because a therapeutic blood level can be reached more rapidly.[161] The entire therapeutic dose should be administered at one time, and the amount of antitoxin recommended varies between 20,000 and 100,000 units. Larger amounts are recommended for persons with extensive local lesions, because the amount of toxin produced depends on the size of the membrane. Furthermore, the longer the interval since onset, the higher should be the dose of antitoxin. Toxin that has already entered host cells is unaffected by antitoxin.

ACTIVE IMMUNIZATION

History of Vaccine Development

After the discovery of diphtheria toxin and the development of antitoxin in the 19th century, the first successful approach to active immunization was the use of balanced mixtures of toxin and antitoxin, which successfully immunized both animals and humans after injection.[162,163] The combination preparation, toxin-antitoxin, was rapidly accepted as an active immunizing agent. It was widely used in the United States beginning in 1914, and was found to protect approximately 85% of recipients.[164] There is little question that the toxin-antitoxin preparation developed by von Behring created active immunity against diphtheria, on the basis of the results of Schick testing and clinical observation, despite the absence of well-controlled studies.[3]

In the early 1920s, Ramon treated diphtheria toxin with small amounts of formalin and found that the product retained most of its immunizing capacity while losing its toxic properties.[6] Ramon dubbed this preparation anatoxine; this name has since been replaced in English usage with the term toxoid. For primary immunization, the toxin-antitoxin preparation was gradually replaced by toxoid in the United States and Canada during the next 15 years, and elsewhere thereafter. In 1926, Glenny and coworkers[165] found that alum-precipitated toxoid was more immunogenic, and by the mid-1940s, diphtheria toxoid was combined with tetanus toxoid and pertussis vaccine as diphtheria and tetanus toxoids and whole-cell pertussis vaccine. Adsorption of all three onto an aluminum salt followed shortly thereafter. It is clear that the immunogenicity of diphtheria toxoid, as well as that of tetanus toxoid, is enhanced by the adjuvant effects of both pertussis vaccine and the aluminum salt.[166–168] In recent years, diphtheria and tetanus toxoids with acellular pertussis components (DTaP) have been licensed, and various other combinations of DTaP with Hib vaccine, inactivated poliovirus vaccine, and hepatitis B vaccine have been developed.[169] Combination vaccines have been shown to be as comparably immunogenic as the monovalent preparations.

Vaccine Constituents

A preservative to prevent antimicrobial growth is required when diphtheria toxoid is dispensed in multidose vials. Thimerosal, a preservative containing ethyl mercury, has been used in vaccines and biologics for this purpose since the 1930s.[170] Some diphtheria toxoid–containing vaccines containing only trace (<1 μg of mercury) or no thimerosal are available in single-dose preparations (single-dose vials or prefilled syringes). Diphtheria toxoid is adsorbed onto an adjuvant (most commonly aluminum hydroxide or aluminum phosphate) to improve the immunogenicity of the vaccine. Only adjuvanted diphtheria toxoids are available in the United States.

Manufacture of Vaccine

Diphtheria toxoid is produced worldwide in a standard fashion; in the United States, production and testing procedures are specified in the Code of Federal Regulations. Specifically, a strain of *C. diphtheriae* that is known to produce large amounts of toxin (such as the Park Williams 8 strain) is grown in a liquid medium conducive to toxin production. After appropriate incubation, sterilization is achieved by centrifugation and filtration. After ascertainment of potency, the filtrate is incubated with formalin for conversion to toxoid. The product is then further purified and concentrated to achieve the necessary dosage. It is adsorbed onto an aluminum salt, usually aluminum hydroxide or aluminum phosphate. After each step, appropriate tests for potency and sterility are conducted. Toxoid concentration is ascertained by determining the content of flocculating units (Lf) in established fashion; 1 Lf is the amount of toxoid that flocculates 1 unit of a standard reference diphtheria antitoxin. The purity of diphtheria toxoids in vaccines currently licensed in the United States is usually at least 1500 Lf/mg nondialyzable nitrogen; WHO recommends a similar standard. Toxoid potency is determined by assays, with different tests currently required by WHO, the European Pharmacopoeia, and the FDA.[148,171,172] Although there are ongoing efforts to harmonize potency testing requirements globally, no single approach has yet been universally adopted.

Producers

Diphtheria toxoid is produced both by large multinational vaccine companies and by developing country manufacturers, many of which produce vaccine only for domestic use. A 1995

assessment of global DTP manufacturing capacity reported DTP production by 63 manufacturers in 46 countries. At that time, it was estimated that approximately two-thirds of children received DTP that was manufactured in their own country, and that more than one-half of the global DTP supply came from developing country manufacturers.[173] In 2006, it was estimated that more than 500 million doses of DTP were produced globally, with many manufacturers producing vaccine for domestic use only. More than 100 million doses of DTaP are produced as well, with major production by Sanofi Pasteur and GlaxoSmithKline.

Preparations Available, Including Combinations

Currently in the United States, diphtheria toxoid is available in combination with tetanus toxoid (DT [diphtheria and tetanus toxoids–pediatric], Td) and in combination with tetanus toxoid and acellular pertussis vaccine (DTaP), as well as in other combination vaccines including DTaP; additional combination vaccines are available in Europe, Canada, and Australia that are not licensed for use in the United States. Globally, diphtheria toxoid continues to be used in combination with tetanus toxoid and whole-cell pertussis vaccine (DTP) as well as in other combinations including DTP. The product is available only in adsorbed form in the United States.

Since September 2011, DTaP vaccines from two manufacturers are marketed for use in infants in the United States: Infanrix (manufactured by GlaxoSmithKline Biologicals and distributed by GlaxoSmithKline) and Daptacel (manufactured by Aventis Pasteur Ltd., and distributed by Sanofi Pasteur). Two pentavalent combination vaccines—a combined DTaP (Infanrix), hepatitis B vaccine, and inactivated polio vaccine (GlaxoSmithKline) and a combined DTaP, Hib conjugate vaccine, and inactivated polio vaccine (Pentacel, Sanofi Pasteur, Ltd.)—are available for use at 2, 4, and 6 months of age; Pentacel is also licensed for use for the fourth dose of the series. A DTaP-inactivated polio vaccine combination, KINRIX, is licensed and marketed by GlaxoSmithKline Biologicals for use as the fifth dose of the DTaP series at 4 to 6 years of age. Another DTaP-inactivated polio vaccine combination, Quadracel, was licensed and marketed by Sanofi Pasteur Limited for active immunization against DTP and poliomyelitis in the United States. A single dose of Quadracel is licensed for use in children 4 through 6 years of age as a fifth dose in the DTaP vaccination series, and as a fourth or fifth dose in the inactivated poliovirus vaccination (IPV) series, in children who have received 4 doses of Pentacel and/or Daptacel vaccine.

The amounts of diphtheria toxoid in the DTaP vaccines currently licensed in the United States range from 6.7 to 25 Lf/0.5-mL dose. They provide levels of serum antitoxin that are considerably lower than those seen after receipt of whole-cell DTP, probably reflecting the adjuvant effect of the whole-cell pertussis component.[174,175] However, the lower antitoxin levels induced by vaccination with DTaP are probably of no clinical consequence, being manyfold higher than protective levels.[169] For routine immunization of children, five doses are recommended (at 2, 4, 6, and 15 to 18 months of age and at school entry before the seventh birthday).[176] The fourth dose should be administered at least 6 months after the third dose.[177]

Combined adult formulation tetanus and diphtheria toxoids (Td) are licensed in the United States for use in persons 7 years of age and older. These vaccines are licensed for primary vaccination as a three-dose series in previously unvaccinated persons 7 years of age and older, and as a decennial booster for use in adolescents and adults. These products contain reduced amounts of diphtheria toxoid (<2 Lf). Since 2005, formulations of tetanus and diphtheria toxoids with acellular pertussis vaccine (Tdap) have been licensed in the United States for use in adolescents and adults. Boostrix (GlaxoSmithKline) is currently licensed for use in persons 10 years of age and older, and Adacel (Sanofi Pasteur) is licensed for use in persons 11 to 64 years of age. These vaccines are licensed for use as a single booster vaccination in persons who have previously received a primary series of DTP or DTaP. A single dose of Tdap is recommended by the ACIP in the United States for persons aged 11 years and older, with the preferred timing at 11 to 12 years of age.[178] A dose of Tdap is recommended for women during each pregnancy to provide maternal antibodies to their newborn for added protection against pertussis until they are eligible to receive their first dose of DTaP.[179]

Dosage and Route

All products currently in use in the United States are administered as a 0.5-mL dose. Preparations containing diphtheria toxoid should always be injected intramuscularly, not subcutaneously.

Vaccine Stability

Expiration dates for diphtheria toxoid are established through the licensing process for each vaccine by national authorities. Preparations containing diphtheria toxoid should be stored at refrigerator temperatures (2°C to 8°C) but not frozen. If vaccine has been frozen, it should be discarded.

Immunogenicity of Vaccine

Several laboratory assays for diphtheria antitoxin are available. Vero cell neutralization assays are highly accurate but technically cumbersome and are available in only a few research laboratories.[180] Standard enzyme immunoassays are widely available and technically less demanding; these assays generally correlate with results from neutralization assays at concentrations greater than 0.01 IU/mL.[181] Double-antigen enzyme-linked immunosorbent assay (ELISA), double-antigen delayed time-resolved fluorescence immunoassays, and toxin-binding inhibition tests, which are more accurate than standard enzyme immunoassays but technically less demanding than Vero cell neutralization, have been developed.[182,183]

Maternal antitoxin levels do affect the immune response of infants. Diphtheria antitoxin levels greater than 0.1 IU/mL inhibit the response to active immunization, but no effect is seen at levels of less than 0.02 IU/mL.[184,185] This is more likely to be of significance in areas where *C. diphtheriae* continues to circulate, resulting in high levels of antibody in mothers and their infants. However, it appears that high maternal antibody titers suppress, but do not prevent, adequate responses of infants to two doses of vaccine, and after the third dose the suppressive effect is gone.[186,187] The half-life of diphtheria antitoxin has been estimated to be 30 days.[188]

After three doses of diphtheria toxoid, nearly all infants develop diphtheria titers greater than 0.01 IU/mL.[189] Geometric mean titers vary among vaccine preparations, with some DTaP products producing significantly lower geometric mean titers than those observed after vaccination with DTP[174]; however, these differences are unlikely to be clinically significant. When the toxoid is used for primary immunization of adults, data suggest that nearly all adults develop diphtheria antitoxin titers greater than 0.01 IU/mL after administration of three doses of diphtheria toxoid, and that most develop titers greater than 0.1 IU/mL.[190]

Vaccination with protein conjugate vaccines containing diphtheria toxoid may result in a booster response to the

carrier protein in persons who have previously received diphtheria toxoid.[191] One of the tetravalent meningococcal polysaccharide diphtheria toxoid conjugate vaccines currently licensed in the United States (Menactra, Sanofi Pasteur) contains approximately six times as much diphtheria toxoid as is contained in the adult formulations of Td vaccine. Simultaneous administration of Td and Menactra resulted in much higher geometric mean titers of diphtheria antitoxin than did Td (120.0 IU/mL compared with 8.4 IU/mL); consistent with the increase in diphtheria toxoid content, Menactra alone was also substantially more immunogenic than Td alone (46.5 IU/mL compared with 8.4 IU/mL).[192] There is also cross-reactivity between diphtheria toxoid and CRM_{197} in protein conjugate vaccines; the other tetravalent meningococcal polysaccharide conjugate vaccine licensed in the United States, Menveo (Novartis Vaccines and Diagnostics), uses CRM_{197} as the protein carrier. Children receiving meningococcal serogroup C-CRM_{197} vaccines develop higher diphtheria antitoxin levels than are seen in children who did not receive the vaccine.[193,194] Lack of baseline immunity to diphtheria may result in poor antibody responses to vaccines conjugated to CRM_{197}.[195] Although immunologic interference is a potential concern with simultaneous administration of diphtheria toxoid with diphtheria toxoid or CRM_{197}-containing protein conjugate vaccines,[196–198] experience to date does not suggest that the immunogenicity of diphtheria toxoid is adversely affected by simultaneous administration with these vaccines.

Correlates of Protection

Several lines of evidence suggest that persons with diphtheria antitoxin levels of less than 0.01 IU/mL should be considered susceptible. Ipsen reported results of studies in which rabbits were administered antitoxin and then challenged with intravenously administered diphtheria toxin; rabbits with a serum level of 0.01 IU/mL were almost completely protected from death with the standard lethal dose.[199] However, higher doses of toxin required higher serum antitoxin levels for equivalent protection. On the basis of studies of diphtheria antitoxin levels early in the course of disease, persons with diphtheria antitoxin levels of less than 0.01 IU/mL appear to be highly susceptible to disease, and higher levels are generally associated with progressively less-severe symptoms.[199–202] Probably no level of circulating antitoxin confers absolute protection; Ipsen reported two cases of fatal diphtheria in patients with antitoxin levels above 30 IU/mL the day after onset of symptoms.[199] Historically, clinical diphtheria was rare among persons with a negative Schick test; the minimal serum antitoxin level associated with a negative Schick test was approximately 0.005 IU/mL.[203] Overall, the data allow some general conclusions regarding protective levels in most circumstances. An antitoxin level of 0.01 IU/mL is the lowest level providing some degree of protection, and 0.1 IU/mL is considered a protective level of circulating antitoxin. Levels of 1.0 IU/mL and greater are associated with long-term protection.[204]

Efficacy and Effectiveness of Vaccine

No controlled clinical trial of the efficacy of the toxoid in preventing diphtheria has ever been conducted. There is, however, strong evidence from observational studies to support the effectiveness of vaccination. Some evidence of the protective efficacy of diphtheria toxoid is provided by observations during the Halifax epidemic.[128] During the course of this outbreak, an intense effort was made to administer diphtheria toxoid to previously unimmunized individuals, and the subsequent incidence of diphtheria in these children was compared with the incidence in the unimmunized population during the next few months. Among those immunized, the monthly incidence of diphtheria fell to 24.5 per 100,000 population, about one-seventh of the rate in the unimmunized children during that same period (168.9 per 100,000). In Britain in 1943, the rate of clinical diphtheria among the unimmunized was 3.5 times that among the immunized, and mortality was 25-fold greater.[127] In an outbreak in Elgin, Texas, in 1970, only two of 205 fully immunized, exposed elementary schoolchildren acquired the disease.[205] In contrast, among 97 children who had received inadequate or no immunization, a 13% attack rate occurred.

In a household study during a diphtheria outbreak in San Antonio, Texas, in 1970, vaccine efficacy was estimated at only 54%.[206] However, because index cases were included and denominators of exposed individuals were unknown, the data are difficult to interpret. Furthermore, any differences in attack rates between immunized and nonimmunized persons might have been blunted by the institution of antibiotic therapy in all members of the household on recognition of a case. Thus, the apparent efficacy of 54% is probably low. In an outbreak in Yemen, the protective efficacy of diphtheria toxoid was determined to be 87% by the case-control method.[116]

The effectiveness of Russian-manufactured diphtheria toxoid was evaluated in several case-control studies during the epidemic in the former Soviet Union. Three or more doses of diphtheria toxoid were demonstrated to be highly effective in prevention of diphtheria among children younger than 15 years in a preliminary study in Ukraine in 1992 and a subsequent study performed in Moscow in 1993. In Ukraine, the effectiveness of three or more doses was 98.2% (95% confidence interval [CI], 90.3% to 99.9%).[207] In Moscow, the effectiveness of three or more doses was 96.9% (95% CI, 94.3% to 98.4%), increasing to 99.0% for five or more doses (95% CI, 97.7% to 99.6%).[208] In addition, administration of a booster dose of diphtheria toxoid within 2 years was shown to decrease risk of diphtheria among children 6 to 8 years of age compared with those who had received the last dose 3 to 4, or 5 to 7 years previously.[209] Among adults in the Russian Federation, the effectiveness of three or more doses compared with no doses was 70% (95% CI, 10% to 90%).[210] Similarly, recent vaccination also was found to be highly effective among adults in Ukraine.[211]

Thus, it appears that the effectiveness of diphtheria toxoid is high but not 100%. However, most reports indicate that the disease in previously immunized individuals is milder and less likely to be fatal.[130,131,205,212–214] In Britain in 1943, case-fatality rates in unimmunized children were more than sevenfold greater than rates in those who had been immunized (6.4% versus 0.9%).[127] The failure to protect 100% of individuals on exposure indicates the importance of herd immunity in the disappearance of diphtheria from developed countries.[215]

Duration of Immunity and Protection

Both the diphtheria toxoid formulation and the schedule of administration affect the level of diphtheria antitoxin achieved and the duration of protection. Globally, various schedules for primary immunization of infants are used, but after three doses of diphtheria toxoid, most children achieve antitoxin titers greater than the minimally protective level.[216] However, in the absence of ongoing exposure, immunity wanes over time, requiring booster doses of diphtheria toxoid to maintain protective antitoxin levels. Longitudinal studies indicate that after a period of rapid decline of antitoxin levels, there is a prolonged, slower decline, presumably reflecting the initially activated immune system and half-life of immunoglobulin, followed by a sustained period of less active production of

immunoglobulin.[217,218] Both the four-dose schedule used in the United States, with 15 Lf doses at 2, 4, 6, and 15 months of age, and the three-dose schedule used in Sweden, Denmark, and Norway, administering 25 Lf doses at 3, 5, and 12 months of age, resulted in geometric mean levels well in excess of the minimally protective level at 48 months of age.[219] Similar geometric mean levels were found 23 months after dose three was administered as DT (pediatric diphtheria and tetanus toxoids), DTP, or DTaP, with varying diphtheria toxoid contents in a two-, four-, and six-dose schedule.[218] In 1990, the United Kingdom moved to an accelerated schedule, administering DTP at 2, 3, and 4 months instead of at 3, 5, and 9 months of age. Although postvaccination geometric mean concentrations of diphtheria antitoxin were lower among children vaccinated on the accelerated schedule, geometric mean antitoxin levels did not differ at age 4 years among children who completed the series at 8 to 13 months, 6 to 7 months, or before 6 months of age, suggesting that adequate protection would be maintained until administration of the preschool booster dose.[220–222]

Although various schedules for primary immunization appear to provide adequate protection from diphtheria in the early years of life, in the absence of a booster dose at 4 to 6 years, protection may not be maintained throughout the school-age years. In Sweden, the first booster dose after the primary series is not administered until age 10 years, resulting in lower levels of antitoxin among children 5 to 9 years of age than is observed in countries administering a preschool-age booster.[223] In one study, 12% of 10-year-old children had diphtheria antitoxin levels below 0.01 IU/mL before receipt of a booster dose.[224] In the Soviet Union, the immunization schedule was changed in 1986, delaying the age 6 (years) booster dose to age 9 years. During the diphtheria outbreak in Russia in the 1990s, receipt of the booster dose at 6 to 8 years of age was found to decrease the risk of diphtheria in this age group.[209] In countries with longstanding childhood immunization programs, adults who have neither been exposed to diphtheria nor received booster doses of diphtheria toxoid may become susceptible to diphtheria as a result of waning immunity.[216] During the outbreak in the former Soviet Union, waning of immunity was thought to contribute to the high incidence rate observed among adults. A large proportion of the population of adults, although seronegative, were previously primed by prior immunization or infection with toxigenic *C. diphtheriae*, as evidenced by development of protective titers after a single booster dose of toxoid.[225–228] Although the immunization histories of the adult patients were difficult to ascertain, the overall population data suggested that many probably had been immune but lost immunity over time. With implementation of booster vaccination for all age groups, the outbreak came under control.

The experience of this massive epidemic strongly suggests that sustaining high immunization coverage with a primary series of diphtheria toxoid among infants and administering booster doses at school entry and subsequently throughout life are important for maintenance of population immunity.[114] WHO now recommends that people living in low-endemic or nonendemic areas should receive booster doses of diphtheria and tetanus toxoids approximately 10 years after completing the primary series, and subsequently every 10 years throughout life.[229]

Postexposure Prophylaxis and Therapeutic Vaccination

The immunization status of close contacts of diphtheria cases should be assessed, and any contacts found to not be fully up to date with diphtheria toxoid immunization should be vaccinated.[90] Diphtheria patients should be immunized in the convalescent phase of illness because clinical infection does not always induce adequate levels of diphtheria antitoxin. However, vaccination after onset of disease has no role in treatment of diphtheria; diphtheria patients should be promptly treated with diphtheria antitoxin (see "Treatment and prevention with Antimicrobials" earlier).

Safety

Common Adverse Reactions. Extensive data on adverse reactions after administration of currently available preparations of diphtheria toxoid, adsorbed, are not available because the toxoid is usually administered in combination with tetanus toxoid and, in children, with pertussis vaccine as well. When it is given in combination with pertussis vaccine, local reactions often are ascribed to the pertussis-containing component. In several large clinical trials, the reactogenicity of DT was compared with that of DTaP for primary vaccination of infants. In general, the frequencies of reported common systemic symptoms (temperature of 38°C or higher, crying for 1 hour or longer, irritability, drowsiness, loss of appetite, vomiting) and local reactions (redness, swelling, tenderness) after vaccination with DT or DTaP were comparable.[230–232] In clinical trials in Sweden and Italy, DT vaccines containing 15 or 25 Lf of diphtheria toxoid and 3.75 or 10 Lf of tetanus toxoid, respectively, were given to more than 7000 infants. The frequency of temperature of 38°C or higher after any vaccine dose was 35% in the Swedish trial and 9% in the Italian study. Other common systemic symptoms occurred with similar frequencies in the two studies: crying for 1 hour or longer in 5% and 6% of infants, irritability in 67% and 55% of infants, drowsiness in 54% and 43% of infants, loss of appetite in 22% and 26% of infants, and vomiting in 15% and 9% of infants. Redness and tenderness after any vaccine dose were reported in 42% and 22% of infants in the Swedish trial, respectively, and in 19% and 9% of infants in the Italian study, respectively. The frequencies of marked redness or swelling were substantially lower in both studies, with redness and swelling of 2 cm or more reported in only 4% and 6% of infants in the Swedish trial, respectively.[230,231,233] The frequency of adverse reactions after DT increased with increasing dose number.[232,234]

Available data suggest that both diphtheria and tetanus toxoids contribute to the reactogenicity of Td and DT. Among Swedish medical personnel with a history of receipt of previous primary immunization in childhood, adverse events (local tenderness and swelling >5 cm, or general discomfort) were reported by 11% of those who received 2.5 Lf of diphtheria toxoid, compared with 20% of those who received 2.5 Lf of diphtheria toxoid combined with 0.75 Lf of tetanus toxoid, documenting the additive effects of the two toxoids.[235] Data from several controlled studies suggest that fever and local reactions are more common after administration of Td than after tetanus toxoid alone.[236,237]

In some populations, large numbers of previously primed persons develop local reactions and fever in response to diphtheria toxoid, even at low dosages. In a small study of Israeli military recruits who had been previously vaccinated in childhood, mild to moderate pain at the injection site was reported by 38% and severe pain by 20% after receipt of a booster dose of 2 Lf diphtheria toxoid without tetanus toxoid; limitation of abduction was reported by 8%. Systemic symptoms of mild to moderate or severe weakness were reported by 24% and 9%, respectively, and a temperature of 38°C or higher was reported by a single subject (<1%).[238] Similarly, a booster dose of 1.5 Lf was administered to 215 university students with prevaccination diphtheria antitoxin levels of less than 0.1 IU/mL. Eight percent reported tenderness at the injection site, and 13% reported pain with abduction, which

was marked in 2% of subjects; none had erythema or swelling noted on examination.[239]

With current formulations of diphtheria toxoid, the frequency of reported adverse events varies by prior vaccination history, prevaccination diphtheria antitoxin level, and dosage of diphtheria toxoid administered. Among 123 persons 30 to 70 years of age with diphtheria antitoxin levels of 0.05 IU/mL or less, adverse events after vaccination were more severe among those who received 12 Lf of diphtheria toxoid without tetanus toxoid as a booster than among those who received dosages of 5 Lf or 2 Lf of diphtheria toxoid without tetanus toxoid, supporting the recommendation to administer reduced dosages of diphtheria toxoid to adults.[240] A second study in military recruits 18 to 25 years of age, most of whom had documentation of receipt of a complete primary vaccination series in childhood, also showed no differences in adverse events between dosages of 5 Lf and 2 Lf of diphtheria toxoid when combined with tetanus toxoid.[241] A newer study in 180 adults evaluated the reactogenicity of DTaP (9 Lf) with Td (2 IU) and monovalent diphtheria toxoid (2 IU). Although the proportion of vaccinees with local reactions (e.g., erythema, induration, warmth, tenderness) was generally lower among recipients of the monovalent diphtheria toxoid than was observed in the other two groups, there was no consistent pattern of increased reactogenicity among recipients of DTaP compared with Td.[242]

Lower diphtheria toxoid content generally results in decreased reactogenicity of booster doses among children. Among children who had previously received three doses of DTaP containing 25 Lf of diphtheria toxoid at 3, 4, and 5 months of age, booster doses containing varying amounts of antigen and adjuvant were administered as a fourth dose at 15 to 27 months of age. Among 117 children who received vaccine containing a reduced amount of diphtheria toxoid (7.5 Lf) and tetanus toxoid (7.5 Lf compared with 10 Lf), there were significant reductions in the proportion of children with redness (27% vs 50%), swelling (18% vs 39%), or pain (17% vs 30%) compared with the frequency in 859 children who received the 25 Lf-containing preparation. A temperature higher than 38°C was also significantly more common in the group receiving vaccine with higher diphtheria toxoid content (27% compared with 18%). A third group of 117 children received vaccine containing 1.5 Lf of diphtheria toxoid, 10 Lf of tetanus toxoid, and reduced aluminum adjuvant (0.3 mg, compared with 0.5 mg); the proportion of children experiencing local reactions was lower than those seen with the 25 Lf vaccine and similar to that seen with 7.5 Lf (28% redness, 25% swelling, 14% pain), but there was no decrease in the proportion with temperature greater than 38°C (28%).[243] Diphtheria toxoid content of one-fifth the dosage at 4 to 6 years of age was evaluated in a study of 593 children in Canada, in which the licensed DTaP-IPV combination (Quadracel, Sanofi Pasteur) (15 Lf) was compared with Tdap (Adacel, Sanofi Pasteur) (2 Lf). The proportions of children developing erythema, swelling, pain, and fever were significantly reduced in the group receiving Tdap with 2 Lf of diphtheria toxoid.[244] In the United Kingdom, among children who had previously received meningococcal conjugate vaccine containing CRM_{197}, there were similar rates of local reactions and fever among children receiving 30 Lf- and 2 Lf-containing vaccines at ages 3.5 to 5 years.[245]

Use of adsorbed vaccine for primary immunization has been reported to result in higher rates of local adverse reactions after subsequent booster vaccination. A higher incidence of local reactions after booster vaccination with DT was observed among Swedish schoolchildren who received adsorbed DT for primary immunization in infancy compared with those who had received nonadsorbed fluid DTP. Seventy-three percent of children who had been primed with DT reported redness, 56% reported swelling, and 47% reported itching, compared with 23%, 15%, and 21%, respectively, among those who had received DTP.[246] In contrast, local reactions did not differ among children who had received adsorbed DT for the primary series when they were boosted with either adsorbed or nonadsorbed DT.[247,248]

Although local injection site reactions are common, only a small proportion of these reactions are clinically significant. A study in the Vaccine Safety Datalink found a rate of medically attended local reactions after Td of 3.6 per 10,000 among persons 9 to 25 years of age. Although infection is an unlikely cause of injection site swelling after vaccination, persons with medically attended local reactions were frequently prescribed antibiotics for cellulitis.[249] A similar rate of medically attended local reactions has been reported after Tdap.[250] Because administration of the U.S.-licensed tetravalent meningococcal conjugate vaccine Menactra (Sanofi Pasteur) contains a relatively large amount of diphtheria toxoid and may produce a high level of diphtheria antitoxin in persons who have previously received childhood immunization with diphtheria toxoid–containing vaccines, there are at least theoretical concerns about administration of Td or Tdap after Menactra.[192] Prelicensure data were not available on adverse events after Td or Tdap administered nonsimultaneously after Menactra; postlicensure data are limited but do not suggest that significant adverse events result from sequential administration of diphtheria toxoid–containing vaccines, including Menactra.[250] Similarly, a second U.S.-licensed tetravalent meningococcal vaccine, Menveo (Novartis Vaccines and Diagnostics) contains CRM_{197} as the protein carrier; prelicensure evaluation of this vaccine found a similarly high proportion of vaccinees reporting injection site pain associated with administration of Tdap, regardless of whether it was given before, simultaneously, or after Menveo.[251]

Rare Adverse Events

The potential for anaphylaxis exists with any protein antigen, but has not been attributed to diphtheria toxoid. A recent case series from a food allergy clinic identified eight cases of anaphylaxis after DTaP or Tdap among children with severe milk allergy; the authors hypothesized that the reaction could have been caused by residual casein.[252] This observation has not been replicated in other patient populations. The British National Childhood Encephalopathy Study, designed to examine the incidence of brain damage after the administration of pertussis vaccine, showed a slight but statistically insignificant excess of acute encephalopathy in the first 7 days after a dose of DT.[253] It is likely, however, that this excess is attributable to the induction of inevitable manifestations of preexisting central nervous system disorders by the systemic effects of DT, as was observed with infantile spasms.[254] Newer studies suggest that many cases of encephalopathy after DTP are among children with severe myoclonic epilepsy of infants (Dravet syndrome), a disorder associated with mutations of the gene encoding the sodium channel.[255,256]

In 1994, the Institute of Medicine (IOM) reviewed the possible association between tetanus and diphtheria toxoids and Guillain-Barré syndrome (GBS) or polyneuritis. Of 29 reports identified in the medical literature, most cases were in adults who had received tetanus toxoids alone (21 cases) or tetanus toxoid and tetanus antitoxin (four cases). Few cases of GBS or polyneuritis after diphtheria toxoid–containing vaccines have been reported. In 1994, the IOM concluded that the evidence favored a causal relationship between tetanus toxoid and GBS,[257] but a more recent report concluded that the evidence was inadequate to either accept or reject a causal relationship

between diphtheria toxoid, tetanus toxoid, or acellular pertussis–containing vaccines and GBS.[258] Although there is little evidence to support an independent association between receipt of diphtheria toxoid and GBS, cases of GBS have been reported in the United States among recipients of a tetravalent meningococcal conjugate vaccine, in which the meningococcal polysaccharides are conjugated to diphtheria toxoid (Menactra, Sanofi Pasteur).[259] A causal relationship between receipt of Menactra and GBS has not been established.

Indications for Vaccine. DTaP is ordinarily not given to infants who are younger than 6 weeks of age because responses to pertussis vaccine in the young infant are suboptimal; responses to tetanus and diphtheria toxoids, however, are satisfactory in such young infants regardless of the presence of maternally derived serum antibody and without induction of immunologic tolerance.[260] The optimal age for immunization of premature infants cannot be stated with confidence, although available data suggest that satisfactory responses are achieved by initiating the usual DTP series according to the routine immunization schedule regardless of pregnancy duration.[261–264] Follow-up of a small group of children born at less than 29 weeks' gestation suggests lower diphtheria antibody levels at age 7 years, after a five-dose series, than in children born at term.[265] There is evidence that high titers of transplacental antibody to diphtheria toxin inhibit serologic responses to the first two doses of diphtheria toxoid in infants, but after the third dose (administered in the Swedish schedule at 12 months of age), the effect is no longer evident.[186]

Diphtheria and tetanus toxoids, adsorbed, for pediatric use (DT) is recommended for the primary immunization of children younger than 7 years in whom pertussis vaccine is contraindicated. DT contains 10 to 12 Lf of diphtheria toxoid; infants who begin the series before 1 year of age should receive DT at 2, 4, 6, and 15 to 18 months of age. Satisfactory responses are obtained even in the absence of the adjuvant effect of pertussis vaccine.[266,267] For unimmunized children 1 to 7 years of age, two doses 2 months apart and a third dose 6 to 12 months later constitute primary immunization.[268]

Tetanus and diphtheria toxoids, adsorbed, for adult use (Td) contains approximately the same amount of tetanus toxoid as do DTP and DT, but the amount of diphtheria toxoid is reduced to no more than 2 Lf per dose. This reduction minimizes reactivity in persons who may have been sensitized previously to diphtheria toxoid, and it is sufficient to provoke satisfactory anamnestic responses in previously immunized persons.[216] In addition, in previously unimmunized older children and adults, Td is satisfactory for primary immunization[190,269] when administered as a three-dose series, with the second dose given 4 to 8 weeks after the first dose, and the third dose 6 to 12 months after the second dose.[262] Td should be administered approximately every 10 years after the completion of childhood immunization, with the first booster dose given as Tdap. Although Td is slightly more reactive than tetanus toxoid alone,[235] it is preferable to monovalent tetanus toxoid for prophylaxis of tetanus after wounds to maintain satisfactory population immunity against diphtheria. In the United States, DT and Td are distributed by Sanofi Pasteur, Inc. Monovalent diphtheria toxoid is no longer available in the United States.

Tdap contains a reduced dose of acellular pertussis vaccine and adult formulation diphtheria and tetanus toxoids. Two Tdap vaccines are licensed for use in the United States, with different age indications (see "Preparations Available, Including Combinations" earlier). Both Tdap products are currently licensed for use as a single booster dose. After 10 years of follow-up from receiving Tdap, 97% to 100% of participants had protective levels of tetanus antibodies (>0.01 IU/mL) and 73.5% to 85.9% had protective antibody levels for diphtheria antibodies (>0.01 IU/mL) even when the booster dose was combined or given coadministered with other vaccines such as IPV or hepatitis B (HepB).[270–272] For added protection against pertussis, a dose of Tdap is recommended to replace one decennial dose Td in persons who have not received a prior dose of Tdap previously. In some industrialized countries like the United States, United Kingdom, Canada, New Zealand, and Belgium, Tdap is recommended during every pregnancy to protect the newborn against pertussis.[273–277] In Latin America, Tdap is recommended for use during pregnancy situations of high risk such as outbreaks.[278]

Limited data regarding simultaneous administration of the first three doses of DTaP with other childhood vaccines indicate no interference with response to the diphtheria toxoid component. Data are available regarding administration of DTaP with other vaccines recommended at the same time as the fourth and fifth doses of the diphtheria, tetanus, and pertussis series (i.e., Hib conjugate vaccine, measles-mumps-rubella vaccine, and varicella vaccine) and regarding administration of whole-cell DTP (all doses in the series) with these vaccines.[177,279] DTaP may be administered simultaneously with other routinely recommended childhood vaccines, including HepB vaccine, Hib vaccine, inactivated poliovirus vaccine, pneumococcal conjugate vaccine, and rotavirus vaccine, to infants at ages 2, 4, or 6 months.

As with tetanus toxoid and pertussis vaccine, prolonging the interval between doses does not require restarting the series; indeed, immune responses achieved after longer intervals between doses than those recommended are often higher than after the regular schedule, although the subject may be left unprotected in the interim.

In other countries, DTP is administered according to alternative schedules (see Chapters 72 and 74). According to the recommended schedule for the WHO's EPI, DTP is administered at 6, 10, and 14 weeks. In a number of European countries, two doses of DTP or DTaP are administered early in the first year of life, followed by a third dose late in the first year or early in the second year of life. Recommendations regarding subsequent boosters vary by country. In response to the epidemic of diphtheria in the former Soviet Union, booster doses have been recommended or reinstated in a number of countries outside the former Soviet Union. WHO now recommends that the primary vaccination series of three doses starting as early as 6 weeks of age and with a minimum interval of 4 weeks between doses. Where resources are available, additional doses can be given after completion of the primary series. In some countries, additional booster doses are given in the second year of life and a second booster is given at 4 to 7 years of age. WHO recommends that people living in low-endemic or nonendemic areas should receive a booster dose of diphtheria toxoid approximately 10 years after the primary series and subsequently every 10 years throughout life to sustain immunity, and that particular attention should be given to revaccination of healthcare workers.[229]

In some countries, booster doses are administered as adult formulations of Tdap to some age groups.

Contraindications and Precautions

There are few contraindications to the use of diphtheria toxoid. Severe hypersensitivity reactions after a previous dose are considered contraindications to further doses.[268] Even though causation by pertussis vaccine is not established, children who experienced encephalopathy within seven days after administration of a previous dose of DTaP or Tdap vaccine and not attributable to another cause should not receive additional

doses of a combination vaccine that contains pertussis antigens. Local side effects alone do not preclude continued use. Vaccination of persons with severe, febrile illness generally should be deferred until recovery, but mild illnesses with or without fever should not preclude vaccination.

Some diphtheria toxoid products are packaged in containers (vials or syringes) containing latex rubber. If a person reports a severe anaphylactic allergy to latex, vaccines supplied in vials or syringes that contain natural rubber should not be administered, unless the benefit of vaccination outweighs the risk of an allergic reaction to the vaccine. For latex allergies other than anaphylactic allergies (e.g., a history of contact allergy to latex gloves), vaccines supplied in vials or syringes that contain natural rubber or natural rubber latex can be administered.[280]

Persons with a bleeding disorder or receiving anticoagulant therapy may receive indicated vaccinations by the intramuscular route if, in the opinion of a physician familiar with the patient's bleeding risk, the vaccine can be administered with reasonable safety by this route. A fine needle (23 gauge or smaller) should be used for the injection and firm pressure applied to the site, without rubbing, for 2 or more minutes. The patient or family should be instructed concerning the risk for hematoma from the injection.[281]

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Effects of Vaccination

Despite the relatively low levels of immunity among adults in many countries, diphtheria has remained well controlled in most countries with effective childhood immunization programs. Historically, it has been thought that 70% or more of a childhood population must be immune to diphtheria to prevent major community outbreaks[281]; the herd immunity threshold has been estimated to be 80% to 85%, based on the average age of infection in the prevaccine era.[282] Whether an epidemic of a given infectious disease occurs is influenced by a number of factors other than the proportion of susceptible persons in the population, including the age distribution of immune and susceptible persons, the extent of mixing of individuals and subgroups in the community, and the infectivity and routes of transmission of the organism.[215] In countries with high rates of childhood immunization against diphtheria, it may well be that epidemics do not occur among adults, up to half of whom may be susceptible, because the reservoir of disease in the childhood population has been eliminated and because the strains of *C. diphtheriae* circulating in the community are less likely to be toxigenic.

Serologic studies in Europe and the United States demonstrate that many adults in these countries remain susceptible to diphtheria.[223,283–289] Differences in seroprevalence among countries reflect the varied immunization schedules and vaccination coverage among countries, the effect of immunization during military service, and the unknown effects of natural exposure to toxigenic *C. diphtheriae*.[141,142,223] Although there is some variability among countries, studies of diphtheria seroprevalence frequently have demonstrated low levels of immunity among older adults. In 1996, a serologic study in England and Wales showed that only 29% of adults age 60 years and older had diphtheria antitoxin titers of 0.01 IU/mL or greater.[290] A similar pattern of susceptibility is seen among elderly persons in other countries of Western Europe.[223] Some studies also demonstrated less susceptibility among males; in some countries, this may reflect immunization during military service.[223]

These concerns have been heightened by the epidemic of diphtheria in the former Soviet Union. A striking feature of this epidemic was the proportion of cases occurring among adults, varying from 38% in Azerbaijan to 82% in Latvia and Lithuania in 1994.[290] Before 1986, the last dose of diphtheria toxoid was routinely administered at 14 to 16 years of age in the Soviet Union; in response to an increase in reported cases of diphtheria in the early 1980s, targeted vaccination of certain occupational groups was initiated, but routine use of booster vaccinations among adults was not recommended. Immunogenicity studies in Russia, Ukraine, the Baltic States, and Georgia demonstrated that some adults failed to develop a booster response to a single dose of diphtheria toxoid, suggesting that they may never have received an effective primary series in childhood.[225–228,291] Childhood immunization coverage was low in some regions in the late 1980s and early 1990s, in part because of an extensive list of contraindications to vaccination,[292] which undoubtedly contributed to the epidemic.[293] For control of the epidemic, the WHO recommended identification, isolation, and appropriate treatment of all cases; prevention of secondary cases by optimum management of close contacts of cases; and rapidly increasing population immunity by sustaining high coverage among children with four doses of DTP in all districts and administering a single dose of an age-appropriate formulation of diphtheria toxoid to the entire population.[290] By 1997, all countries had made significant progress in immunization of children and adults; the declines in disease incidence were most dramatic in countries that had achieved high coverage.[64] Diphtheria incidence has continued to decrease. During the period 2000–2009, 7032 cases of diphtheria were reported in the WHO European Region, with more than 60% of the cases reported from the Russian Federation. During the decade, diphtheria incidence decreased by more than 95% in the region. By 2009, only Latvia reported an incidence of greater than 1 case per million population.[64] During the period 2001–2013, a total of 65,226 cases of diphtheria were reported from the WHO South East Asia Region; approximately 84% were from India.[65,140]

Disease Control Strategies: United States and Others

The primary control strategy for prevention of diphtheria globally is routine childhood vaccination with diphtheria toxoid as DTP or DTaP. In countries rendered nonepidemic through high immunization coverage, WHO recommends that the primary vaccination series of three doses be extended by at least one booster dose, and acknowledges that revaccination of adults against diphtheria every 10 years may be necessary to sustain immunity.

In the United States, DTaP, is administered as a five-dose series in childhood followed by decennial booster doses of Td beginning at age 11 to 12 years. For added protection against pertussis, Tdap is now recommended for the booster dose at age 11 to 12 years. Td, rather than monovalent tetanus toxoid, should be used in emergency departments, physicians' offices, and other situations in which tetanus-prone wounds are treated.[294–296] There are essentially no indications for monovalent tetanus toxoid at present in the United States or elsewhere.

Epidemiological surveillance to ensure the early detection of cases should be in place in all countries, and all countries should have access to laboratory facilities that can provide reliable identification of toxigenic *C. diphtheriae*. Rapid public health response to a suspected case of diphtheria, with case investigation to identify the source of infection and other persons who may have been exposed, can help limit spread of diphtheria.

Cost-to-Benefit Information

The costs and benefits of diphtheria toxoid as a component of DTP or DTaP, administered as part of the routine immunization series have been evaluated on several occasions. In 1997, it was estimated that diphtheria vaccination prevented almost all the 276,750 diphtheria cases and 27,675 diphtheria deaths that were estimated to occur in the absence of vaccination among a simulated birth cohort of 4.1 million children during the first 15 years of life; both were cost-saving from the societal and healthcare system perspectives.[297] A similar analysis evaluated DTaP as part of the 2001 recommended childhood immunization schedule, which also included Hib vaccine, IPV, measles-mumps-rubella vaccine, HepB vaccine, and varicella vaccine. Vaccination of a hypothetical U.S. birth cohort was estimated to result in savings of more than $2 billion in direct costs and $24 billion in total costs for cases of diphtheria prevented and was cost saving both in terms of direct costs (benefit-to-cost ratio: 5.3) and from the societal perspective (benefit-to-cost ratio: 16.5).[298]

ERADICATION

Although no animal reservoir exists for *C. diphtheriae*, *C. ulcerans* may carry the β-corynebacteriophage that encodes diphtheria toxin,[299] and an animal reservoir does exist for this organism[300,301] and thus for the bacteriophage. Given the worldwide ubiquity of carriage of *C. diphtheriae* and the bacteriophages implicated in toxin production, prospects for eradication of diphtheria currently seem remote. Continuing active immunization with diphtheria toxoid is the key to the control of diphtheria.

FUTURE VACCINES

New combination vaccines for use in young children built on both the DTaP and DTP backbone are under development.[302] Alternative approaches to diphtheria immunization in the future may include vaccination by the oral[303,304] or nasal[305] routes or use of a highly purified, less-reactive antigen[306–308] or carrier systems[309,310] for diphtheria toxoid that would require fewer injections. Such products would be particularly useful in the developing world, where severe limitations in healthcare personnel and financial resources are major barriers.

20 Ebola Vaccines

Aurélie Ploquin, Kendra Leigh, and Nancy J. Sullivan

Named for the site of the first outbreak in the Ebola River valley in 1977, Ebola virus and the closely related filovirus, Marburg virus, represent a family of pathogens that cause hemorrhagic fever with a high associated mortality. The potential significance of these viruses was first appreciated with the occurrence of a series of Ebola virus outbreaks in the 1970s. After a hiatus in the 1980s, the disease reemerged with greater frequency in the mid-1990s, likely as a consequence of zoonotic transmission from nonhuman primates (NHPs) to humans in equatorial Africa. In the past decade, Ebola virus outbreaks have occurred at regular, almost yearly intervals, typically during the latter part of the year and localized to the same regions of Central Africa; however, in 2014 an unprecedented outbreak in terms of scale and mortality began in Guinea (West Africa), an area where Ebola virus previously had little impact. From Guinea, the outbreak spread to several countries, requiring an international response to bring disease spread under control.[1,2] This most recent outbreak highlights the serious public health threat that natural transmission of Ebola virus represents, above and beyond its potential use as a bioterror agent. Because of its unusual pathogenesis, and the concern over its dissemination into the population through natural or deliberate means, an understanding of Ebola virus infectivity, molecular pathogenesis, and transmission, as well as the development of vaccines and therapies, have become high priorities.

BACKGROUND

Clinical Description

The initial clinical manifestations of Ebola virus begin 2 to 21 days after infection (average: 8 to 10 days) with "flu-like" symptoms including fever, fatigue, and myalgia. Within days, abnormalities related to liver function and clotting appear, with nausea, abdominal pain, rash, petechiae, diarrhea, and vomiting. As the disease progresses, in addition to the occasional development of respiratory disorders, the gastrointestinal tract becomes involved, leading to signs of bleeding from mucosal sites, including melena and hematochezia. In the terminal phases, typically within 1 to 2 weeks after infection, there is progression to disseminated infection, with abnormal clotting parameters, hepatic parenchymal damage, disseminated bleeding through various sites including but not limited to venipuncture sites and the conjunctiva, and cardiac distress resulting in terminal hypovolemic shock or septic shock in the absence of bacterial superinfection.[3–7] The mortality rate ranges from 36% to 90% in those with recognizable infection.

Complications

Clinical complications of Ebola virus infection stem from the nature of the cells targeted during the viral life cycle. In early infection, the virus replicates in reticuloendothelial cells, monocytes, macrophages, and dendritic-like cells.[8] Damage to these cell types results in the release of cytokines that likely contribute to early symptoms of infection, including fever. Subsequent damage to the liver and vasculature as the disease progresses results in impaired blood vessel integrity and gives rise to a bleeding diathesis accompanied by hypotension.[3] Ebola virus infection of the adrenal gland (at later stages of disease) may also contribute to hypotension.[9] The inability to maintain blood pressure in the setting of fever, blood loss, profuse vomiting and diarrhea, and shock leads to a high mortality rate, particularly in the absence of effective supportive care. Some case reports from the 2014 outbreak suggest that a rapid clinic visit and carefully monitored resuscitation improved patient outcomes.[3,10,11]

Virology

Ebola virus and the closely related Marburg virus (MARV) are members of the *Filoviridae* family, named for the filamentous morphology of virions that appear by electron microscopy to be a consistent diameter of approximately 80 nm, but nonuniform in length.[12] There are five species in the genus *Ebolavirus: Zaire ebolavirus* (Ebola virus/EBOV), *Sudan ebolavirus* (Sudan virus/SUDV), *Taï Forest ebolavirus* previously named Côte d'Ivoire (Taï Forest virus/TAFV), *Reston ebolavirus* (Reston virus/RESTV), and the most recent *Bundibugyo ebolavirus* (Bundibugyo virus/BDBV) discovered in 2007.[13] Of these species, RESTV is the only member that has not caused any reported human fatalities.[14]

The 19-kb nonsegmented negative-strand RNA genome of Ebola virus contains a linear array of seven genes, six of which each encode a single protein product. The seventh gene contains two open reading frames: the major transcript, secreted glycoprotein (sGP), is a secreted dimer, while trimeric glycoprotein (GP) is synthesized only after addition of a nontemplated adenosine by the viral polymerase, yielding the only virion surface protein.[15] Several cellular surface proteins, such as phosphatidylserine binding proteins, C-type lectins, DC-SIGN, and TIM-1, facilitate Ebola virus particle attachment. The virions are then taken up by macropinocytosis into intracellular compartments.[16–22] Cathepsin cleavage of GP within these acidified internal compartments exposes an occluded receptor binding site, allowing binding of GP to the endosomal/lysosomal cholesterol transporter Niemann-Pick C1 (NPC1), the cellular receptor for filoviruses.[23–27] A 3.4 Å x-ray structure of GP trimer lacking several regions was solved after cocrystallization with neutralizing antibody KZ52, isolated from an Ebola virus survivor.[28] The determination of several subsequent structures and the mapping of the cathepsin cleavage site, in combination with previous work on enzymatic processing during entry and identification of the cellular receptor, have contributed to a greater molecular understanding of GP function.[25,29]

Among the other viral proteins (VPs), VP40/VP24 form the inner matrix while the nucleoprotein (NP), VP30, VP35, and the RNA-dependent RNA polymerase, L, comprise the ribonucleoprotein complex (Fig. 20.1). Nucleocapsid-like filamentous structures can be formed by overexpression of NP, VP24, and VP35 in the absence of other VPs.[30,31] A T7-polymerase-based minireplicon system demonstrated that the minimal replication machinery for Ebola virus requires the cooperative activity of NP, VP30, VP35, and L,[32] whereas VP40 and GP are sufficient to form virus-like particles.[33] The structure of the

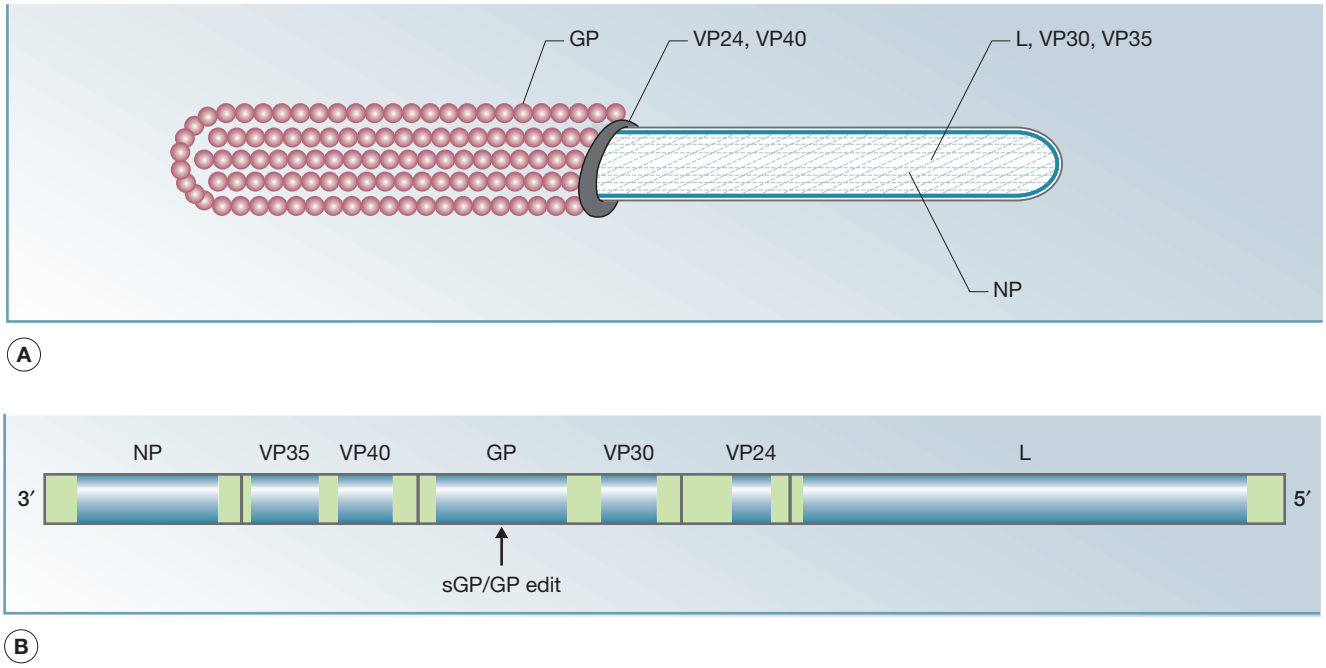

Figure 20.1. Schematic of Ebola virus components and its genomic organization. A, Model structure of Ebola virus. Among the virion proteins (VPs), VP40/VP24 and the glycoprotein (GP) are present in the membrane matrix and outer envelope, respectively, while the nucleoprotein (NP), VP30, VP35, and the RNA-dependent RNA polymerase, L, comprise the ribonucleoprotein complex. **B,** Ebola virus genomic organization. The 19-kb nonsegmented negative strand RNA genome contains a linear array of seven genes. Open reading frames (ORFs) are shown in *blue* and noncoding bases at gene termini, in the genome leader (3′) and trailer (5′), regions are *gray*. The presence of additional sequence, also known as intergenic regions, between the stop and start signals of sequential ORFs is also indicated *(dark blue lines)*. Each gene encodes a single protein except for the GP gene that contains two ORFs. The major transcript is secreted (sGP) and the minor transcript, GP, is synthesized only after addition of a nontemplated adenosine by the viral polymerase.

carboxyterminal domain of Ebola virus VP35, which possesses both its double-stranded ribonucleic acid (dsRNA) binding and interferon inhibitory activity, was determined to atomic resolution by x-ray crystallography.[34] In addition to its role in viral RNA replication and in virion assembly, VP35 plays a crucial role in Ebola virus infectivity and inhibition of host innate immune responses including suppression of type I interferon responses,[35] inhibition of RNA interference (RNAi),[36,37] and impairment of dendritic cell functions.[27,38] Another member of the replication machinery, VP30, also suppresses host cell silencing of viral genes through interaction with the RNAi pathway.[36] Advances in our molecular understanding of Ebola virus proteins strengthen the basis for future structure-function-guided identification of susceptible targets for therapeutic intervention.

Pathogenesis as It Relates to Prevention

Ebola virus enters the body through abrasions in the skin or exposure to mucosal surfaces, either by contact with bodily fluids or blood from an infected individual (Fig. 20.2).[39] It is thought that the virus traffics rapidly from these sites, possibly by transport on dendritic or other cells bearing DC-SIGN or related lectins, which bind the virus through their recognition of glycans on GP.[40] Cells of the reticuloendothelial system in the liver, lung, and spleen are the initial targets of infection, which then spreads to the endothelium.[9] In effective immune-mediated prevention, viral recognition would most likely have to occur early after infection by cells of the innate and adaptive immune system, as both $CD8^+$ T-cell and humoral responses are detected in Ebola survivors.[41–43] The mechanism of viral clearance is not fully understood but seems to require cellular immune responses.[27,185]

Diagnosis and Prevention

A diagnosis of Ebola virus disease (EVD) is suggested when a patient with high-risk epidemiological factors presents with symptoms of fever, flu-like illness, petechial rash, diarrhea, vomiting, abdominal pain, and unexplained hemorrhage.[44] Definitive diagnosis is best made using a reverse transcription polymerase chain reaction (RT-PCR) detection assay and can be confirmed by detection of viral replication in Vero cells. Additional diagnostic support can be made through the measurement of immunoglobulin (Ig) M antibodies to VPs and various more specialized research assays. During the recent outbreak in West Africa, mobile laboratories were organized to analyze suspected case samples more expeditiously. In addition, rapid Ebola virus in vitro diagnostics were approved for emergency use by the World Health Organization (WHO) and the U.S. Food and Drug Administration (FDA) as a first line of screening.[45,46,46a] The majority of those rapid assays are based on RT-PCR using whole blood (venipuncture or fingerstick), plasma, serum, or urine from patients starting to develop signs of disease. Most methods were developed for the hospital environment and not for mass population screening. Genome amplification targets different genes with NP, VP40, L, and GP used alone or in combination depending upon the kit used. EBOV is the principal target, but in some assays, detection of SUDV, BDBV, and MARV is also possible using degenerate primers. However, those assays lack species distinction if the result shows a positive signal, reinforcing the need for a follow-up species-specific test. In addition to genomic detection, a few diagnostic methods have focused on antigenic protein detection. For example, a rapid test kit reveals the presence of VP40 from any variant of EBOV in blood and plasma within 15 to 25 minutes, although results

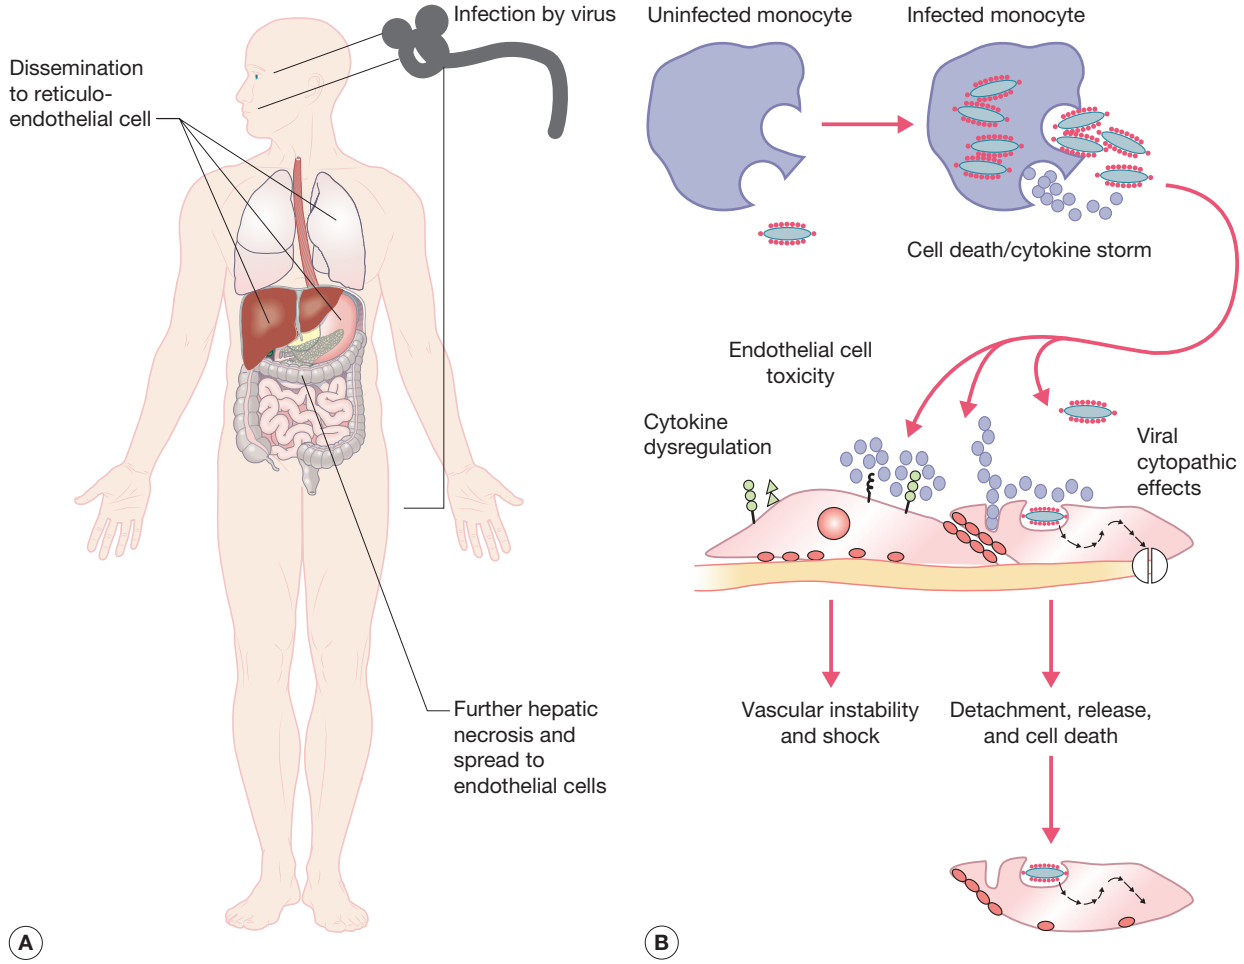

Figure 20.2. Pathophysiology of Ebola virus infection. A, After initial infection through mucosal sites or through cuts or abrasions in the skin, Ebola virus is thought to disseminate first to reticuloendothelial cells of the liver, lung, and spleen. **B,** Further replication at these sites is postulated to cause damage to these cells that result in the release of cytokines that may precipitate fever and alter vascular permeability/tone. Additional replication in the liver and endothelial cells further compromises thrombosis and hemostasis, as well as vascular integrity, leading to hemorrhage and the ultimate circulatory collapse responsible for its high mortality.

should be followed-up with the more rigorous RT-PCR detection assay.[45,46] With the emergence of new species of *Ebolavirus* like BDBV[47] increasing the number of possibilities that have to be considered with any new outbreak and the sequence diversity between *Ebolavirus* species, more than one diagnostic assay should be used to prevent false negatives. This testing redundancy is particularly critical in the early stages of an outbreak where the circulating variant has not yet been definitively identified.

In an outbreak situation, contact tracing is essential to halt spread of the disease through the population.[48,49] When an index case is identified, strict public health measures should be implemented, including use of adequate personal protective equipment (PPE), cleaning and decontamination of all equipment, isolation and quarantine to reduce transmission, and identification and testing of all contacts of the index case followed by immediate quarantine of any contacts that also develop signs of illness. Collaboration between healthcare workers and local community representatives is crucial to improve communication with the population and ensure dissemination and understanding of public health directives. To provide efficient basic healthcare during an outbreak, the number of treatment centers needs to be in accordance with the size of the susceptible population.[11] The Centers for Disease Control and Prevention (CDC) and WHO established guideline declares a country to be considered free of Ebola virus if during a 42-day window (twice the length of the maximum incubation period) no patients are diagnosed Ebola positive.[50]

EPIDEMIOLOGY

Incidence and Prevalence

Historically, outbreaks of Ebola virus infection have occurred sporadically, primarily in the countries of sub-Saharan Africa, including the Democratic Republic of Congo (DRC), the Republic of Congo (Brazzaville), Côte d'Ivoire, Sudan, and Uganda.[51] Depending on the proximity to larger population centers and the virulence of the *Ebolavirus* variant involved, outbreaks have ranged in size from dozens to hundreds of fatalities, resulting in cumulative mortality numbers of less than 1200 over the past 2 decades. Outbreaks have mainly centered in the rain forest regions of northern Congo and the DRC, particularly, but not exclusively, at the beginning of the rainy season in October or November. Fortunately, all these outbreaks remained localized and were contained quickly.

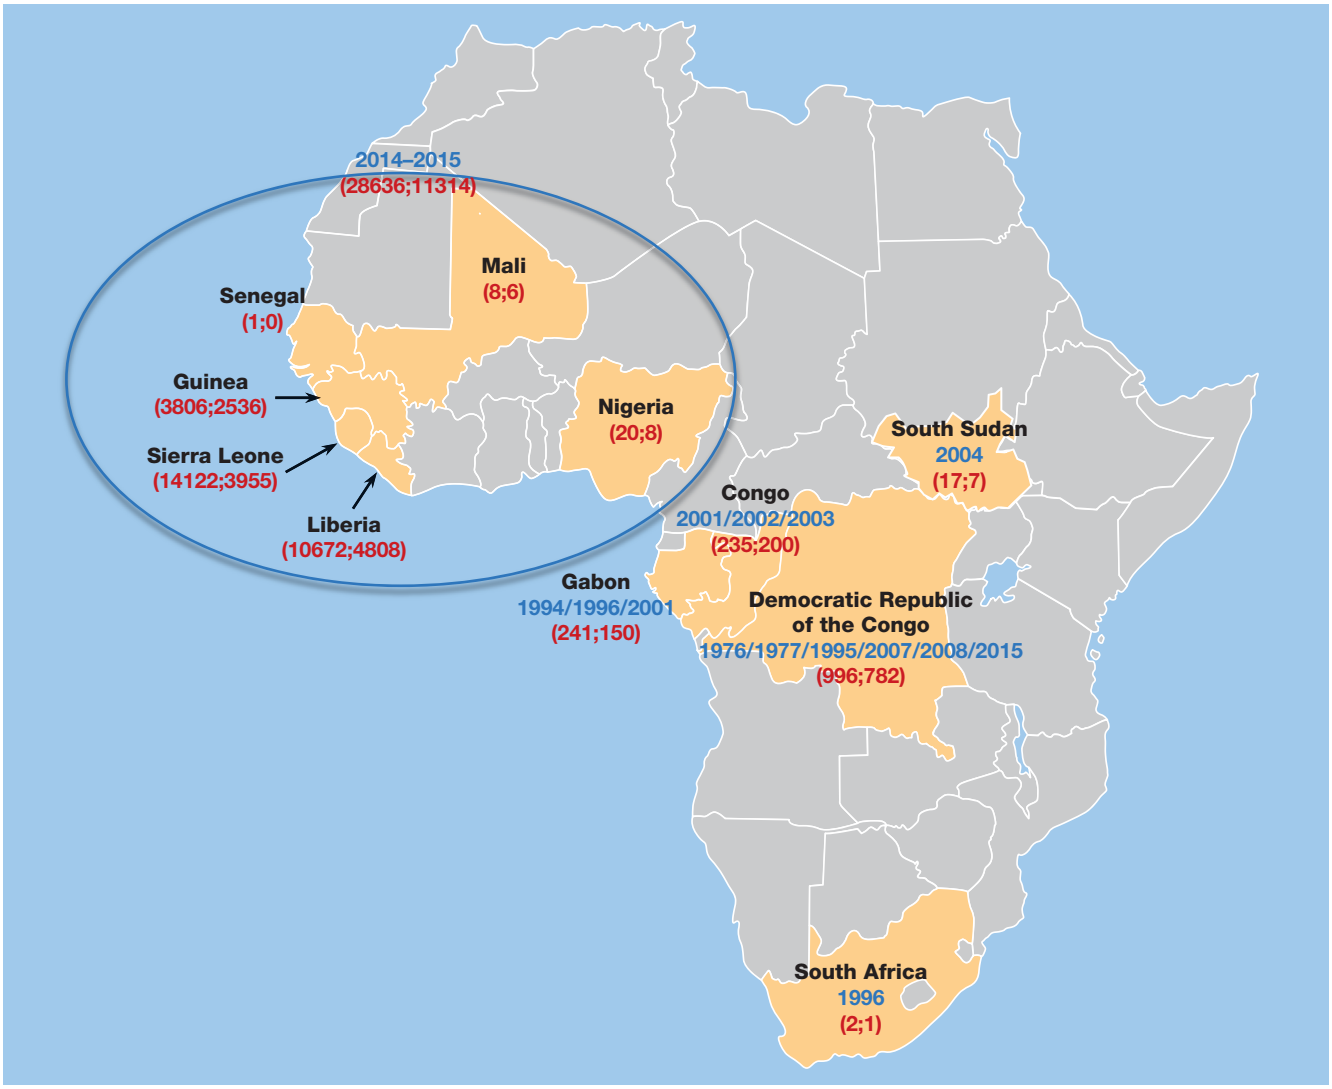

Figure 20.3. Ebola virus disease case reports in Africa between 1976 and 2015. Geographic schematic view of Africa representing in orange color countries affected by an Ebola virus disease outbreak (*Zaire ebolavirus*). Under the name of each country, the number of cases (suspected/probable/confirmed; death) is indicated in *red* and the date for each outbreak is reported in *blue*. The *blue circle* surrounding West Africa represents the spacial localization of the 2014–2015 outbreak. The case counts shown are accurate as of November 7, 2015. *(Data from Centers for Disease Control and Prevention. Outbreaks chronology: Ebola virus disease. 2015. Available at www.cdc.gov/vhf/ebola/outbreaks/history/chronology.html.)*

The 2014 outbreak stands apart from previous outbreaks, as the outbreak region encompassed several countries (including Guinea, Liberia, and Sierra Leone) over a period of almost 2 years, resulting from rapid spread of the virus across borders and compounded by the difficulty of contact tracing and quarantine maintenance. As a result of international travel from the area of outbreak, Ebola virus–positive patients were identified for the first time in more distant countries, such as Nigeria, Mali, and the United States, and the total number of cases from the 2014 outbreak exceeds that of all previous outbreaks combined (Fig. 20.3).[52] Sequencing of clinical viral isolates from the outbreak revealed that the circulating variant, now named Makona, formed a separate clade from previously identified EBOV variants.[1]

Risk Groups

In several Central African outbreaks, ape carcasses testing positive for EBOV have been discovered in proximity to areas experiencing human EBOV infection.[53–55] Although no definitive chain of transmission has been established between infected apes and humans, it is thought that the reservoir of infection may reside in close proximity to great apes, and therefore bushmeat hunters and their family and village contacts represent a potentially high-risk population. The reservoir has been postulated to be the fruit bat,[56] creating risk groups among those close to their habitats, including miners who can be exposed to bat nests and tourists who explore caves. Any other causative factors that may play a role in initiating outbreaks remain unknown.

Local and international healthcare workers acting as first responders in outbreak settings represent a significant high-risk group for infection.[57,58] The identification of RESTV in pig farms in the Philippines in 2008 has suggested swine as another potential reservoir or intermediate host for Ebola virus, making pig farmers an additional potential risk group for the disease.[59] In addition to natural transmission, laboratory workers and handlers of NHPs are at increased risk for infection. Indeed, the very first cases of filovirus hemorrhagic fever were recognized in a primate facility in Marburg,

Germany, where the prototype filovirus, MARV, was identified. Finally, because the virus has been the object of development for bioterrorism and is classified as a Category A agent, there is concern about its potential use against military and civilian targets as a weapon of widespread human destruction.

Modes of Transmission and Reservoirs of Infection

During outbreaks, Ebola virus is transmitted by direct contact with the bodily fluids (blood, urine, saliva, feces, vomit, breast milk) or tissues of an infected subject, such as can occur during burial rites.[60] Ebola virus antigens and viral particles have been detected in the skin of infected individuals, with high antigen load around the sweat glands.[61] Previous filovirus outbreaks have suggested that virus may persist in immune privileged sites, such as the testes or the eye, even after peripheral viremia and clinical illness have normalized.[62,63] Observations after the 2014 outbreak showed that the semen of survivors can remain positive for virus for periods as long as 3 months or even longer, reemphasizing the risk of viral transmission through unprotected sexual contact.[64–66] Ebola virus has also been detected in the aqueous humor of the eyes of a survivor weeks after his remission, although no virus was detected in the conjunctivae or tears of the patient.[67] Although some evidence indicates that Ebola virus can also be transmitted via the aerosol route[68,69] and NHPs have been experimentally infected with Ebola virus via the aerosol route, the contribution of this mode of transmission in an outbreak setting is thought to be low.[8] Transmission from animals to humans is believed to occur via direct contact with infected animal blood or carcasses. Although the natural reservoir of infection is not known, the virus is presumed to be zoonotic because human index cases have been linked to direct contact with gorillas, chimpanzees, duikers,[55] swine,[59] or to unknown contacts within or around mineral mines[70] that harbor multiple bat species. Declines in great ape populations are reported to be coincident with EVD outbreaks in humans; however, NHPs are not thought to be the primary reservoir since the virus is highly pathogenic in these hosts, and long-term virus circulation in its reservoir presumes nonlethal infection. Epidemiological reporting from primary cases has led to speculation that bats may be the natural transmitting host for Ebola virus while other mammals may be amplifying hosts. Evaluation of field-caught bats revealed that partial viral sequences could be recovered from some animals, while others were seropositive against antigens from Ebola virus or the closely related MARV as measured by enzyme-linked immunosorbent assay (ELISA).[56,71] Even though Ebola virus has not yet been directly isolated from seropositive bats, rescue of replicating MARV from bats strengthens the hypothesis that they could also be a natural reservoir of Ebola virus.[72,73] Swine have also been proposed as another potential reservoir of Ebola, as some studies suggest that infection of pigs with either RESTV or EBOV is sublethal and generates high-titer virus in the lungs of infected animals.[74,75]

Significance as a Public Health Problem/Health Burden

For all *Ebolavirus* species from the first recognized outbreak in 1976 until 2013, the cumulative number of fatalities was approximately 1500 people. Most outbreaks were in isolated Central African locations and small in number, with sizes ranging from a handful of fatal cases to several hundred deaths in some of the larger outbreaks.[51,52] A similar pattern of outbreaks has been observed for the related filovirus MARV.[76] Despite the high mortality rate of EVD, the limited nature of these outbreaks meant that filoviruses were not a major focus of global public health initiatives. In March 2014, a new outbreak began in West Africa, a location atypical for *Ebolavirus* outbreaks, which continued unabated for nearly 2 years and grew to an unprecedented size and geographical coverage. In August 2014, the Ebola outbreak was designated an international public health emergency by the WHO[77]; however, as a result of challenges associated with population density, cultural beliefs, and contact tracing, the outbreak still continued through the following year. The West African outbreak changed public perception of the significance of ebolaviruses, as this outbreak alone had almost an order of magnitude more fatalities (11,315 people as of December 30, 2015) than the cumulative fatality total observed in all previous outbreaks combined.[14,52] The 2014 outbreak demonstrated that an outbreak of this size can have severe worldwide economic, social, medical, and public health consequences, affecting international travel and potentially limiting resources for treatment of other significant diseases such as malaria that have increased prevalence in the countries affected by ebolavirus epidemics. Although ebolaviruses are not the most significant pathogen in terms of absolute disease burden in Africa, the West African outbreak highlights the need for these viruses to remain a significant public health priority.

POSTEXPOSURE ANTIVIRAL TREATMENTS

Antisense and Small Interfering RNA Therapy

Experimental treatments including anticoagulant[78] and recombinant human protein C[79] therapy have shown limited protection against Ebola virus infection in NHPs. A viral RNA polymerase inhibitor, Favipiravir, efficient against influenza virus, also showed no benefit against infection in NHPs, but it was nonetheless given to human EVD patients under "compassionate use" in the latest outbreak.[80,81] Advanced antisense technology against EBOV VP35 and VP24 or MARV NP and VP24 administered within 1 hour of exposure showed partial protection against EBOV challenge and complete protection against MARV challenge in rhesus macaques, suggesting that complete protection against MARV does not imply a similar result for other filoviruses.[82] Similarly, repeated administration of small interfering RNA (siRNA) targeting VP24, VP35, and L protein was fully protective against EBOV challenge in NHPs when administered within 1 hour of infectious challenge.[83] More recently, EBOV-targeting siRNAs encapsulated in lipid nanoparticles protected 100% of NHPs against Ebola virus 3 days after viral exposure.[84] A Phase II clinical trial of this treatment began in Sierra Leone in early 2015, but was terminated because of a lack of therapeutic benefit. Although both antisense and siRNA treatment demonstrated significant protection in NHPs, naturally occurring mutations in the target sequence and a short window for treatment postinfection, possibly because of inhibition of RNAi by Ebola virus proteins,[36] may limit their use.

Passive Immunization

Enveloped viruses such as Ebola virus represent a potential target for passive immunization because high-titer Ig against the viral GP can be generated by either vaccination or natural infection of an appropriate host. However, the broad virus tropism for nearly all tissues, the large filamentous virion and the high quantity of surface GP trimers necessitates a high concentration of antibody for in vivo virus inactivation. The primary mode of virus entry is via macropinocytosis, with exposure of the GP receptor binding domain occurring only after the virus enters intracellular acidic compartments, thus

reducing accessibility of critical epitopes to passively transferred antibodies.

Early studies showed some success with passive immunotherapy in mouse[85,86] and guinea pig models[87,88] where the disease is less virulent, as compared to that seen in primate models; however, NHPs are the preferred animal model for studying EBOV because pathogenicity and immune responses in NHPs recapitulate human disease better than the responses seen in rodent models.[89] Infection of rodents occurs only after serial passage of human EBOV in the rodent host, and inherent differences between wild-type and adapted viruses and/or the animal model become evident when vaccine or treatment successes in rodents fail to translate into NHP protection.[42,88] One of the first successful passive transfer EBOV NHP studies involved administration of hyperimmune equine Ig to *Papio hamadryas* baboons prior to infectious challenge. Injection of the hyperimmune equine serum (1:8192) prevented viral replication in 100% of treated animals when injected 2 hours before challenge.[90] In contrast, 30 minutes after Ebola challenge, injection of a higher serum titer of 1:65,536 failed to protect all the animals. In another study, the administration of equine IgG to cynomolgus macaques just after EBOV infection only delayed fatal outcome by 1 to 2 days.[91]

Surprisingly a human survivor monoclonal antibody, KZ52, which showed potent in vitro neutralizing activity, was administered using a prechallenge schedule similar to that used for the equine serum but failed to protect macaques, suggesting that a polyclonal formulation may be required.[42,92] Therefore, mixtures of mouse-derived chimeric monoclonal antibodies (mAbs) given as cocktails of three antibodies were developed and showed protection from death when administered up to 5 days after EBOV challenge.[93–99] The FDA allowed the use of these mAb cocktails as an emergency treatment under a "compassionate use" clause, and clinical trials in Liberia and Sierra Leone will evaluate their efficacy as postexposure treatment. More recently, a simplified cocktail of two human mAbs—mAb100 and mAb114, both isolated from a survivor of the 1995 Kikwit EBOV outbreak—was tested in NHPs with the first administration given 1 day after infectious challenge. This mAb therapy prevented death in all animals and, unlike previous cocktails, protected against all clinical signs or symptoms of infection. mAb114 was further evaluated as monotherapy and showed complete protection from death in NHPs, with transient viremia but no clinical symptoms.[100] These more recent results indicate that mAb therapy can be optimized and suggest the potential for simplified and efficacious mAb-based therapeutics in humans.

Studies in pursuit of other possible immunotherapies in humans evaluated infusion of blood from convalescent patients into infected subjects. The treated patients survived EBOV infection, but administration of treatment was late in the course of infection so natural immune responses and/or clinical care could have played a role in recovery, and furthermore no control group was included in the study.[101] Currently, several Phase II/III trials are ongoing in West Africa to study the efficacy of convalescent plasma as a possible future treatment.[102]

ACTIVE IMMUNIZATION

Initial Approaches That Were Abandoned

Despite many years of experimental vaccine failures in NHPs, studies analyzing human samples showed that it is possible to develop adaptive immunity against Ebola virus, and suggested that an effective vaccine should induce cellular immune responses. However, because of the limited number and availability of human clinical samples over the course of historical Ebola outbreaks, the determination of a definitive correlate of survival was not possible. Therefore, studies of protective immunity against Ebola virus as well as vaccine efficacy have largely focused on animal models of infection. NHPs (rhesus or cynomolgus macaques) undergo a disease course that closely resembles clinical infection in humans, whereas guinea pigs and mice can be infected with an adapted virus, but undergo pathogenic changes that differ from those seen in human cases.[103,104] One of the earliest approaches for an Ebola virus vaccine tested the ability of a Vero cell-produced, formalin-inactivated virus to protect against infection in the guinea pig model.[105] Antigen-specific immune responses were not reported, and although protection was observed in the vaccine group, control animals receiving cell culture fluid lacking vaccine exhibited less than 30% mortality, suggesting that protection may have been nonspecific. Contradictory results regarding this vaccine have been observed in NHPs, with one study showing 50% protection and one study showing a failure to protect.[106,107] The lack of translation from the small animal model to primates was likely explained by either non-specificity of the guinea pig protection, greater sensitivity of the NHP model, or lack of relevant cellular immune responses necessary to clear virus-infected cells. In support of the latter interpretation, a recombinant GP protein subunit vaccine generated specific neutralizing antibody titers but yielded only partial protection in guinea pigs, likely because of the generally inefficient induction of cellular immunity by subunit protein vaccines.[108]

Early approaches to the development of an Ebola virus vaccine made use of a vaccine modality (virus inactivation) classically considered to elicit primarily humoral responses.[109] With the goal of establishing effective immune protection in primates, and ultimately in humans, the conflicting results of the early EBOV studies implied that a vaccine platform designed to elicit both humoral and cellular immunity might be more successful. The most common approach to elicit such a response is through the use of live attenuated vaccines, but the lethality of Ebola virus made this option untenable because of the potential risks associated with incomplete attenuation.

The limitations that impeded early Ebola virus vaccine development were finally overcome by the introduction of gene-based vaccination approaches that elicited both humoral and cellular immunity. The effectiveness of this approach was borne out with the first demonstration of immune protection against Ebola virus infection in the guinea pig infectious challenge model,[110] where immunization with plasmid DNA vectors encoding GP or NP conferred complete protection against lethal Ebola virus challenge, while uniform mortality was observed in unvaccinated controls. Analysis of vaccine-induced immune responses showed robust $CD8^+$ cytotoxic T lymphocyte (CTL) responses in both mice and guinea pigs to GP but not NP, and both antigens generated potent IgG titers that correlated with survival. Because passive transfer of hyperimmune sera from these animals did not protect naïve recipients, it is likely that IgG titers of sufficient quality or magnitude were not achieved or that protection required effector functions not present in serum. Indeed, subsequent studies in mice and guinea pigs illustrated that Ebola virus genes delivered by either plasmid DNA or viral replicons likely elicited protection through a cell-mediated mechanism since passive immunization with vaccine-induced immune serum did not prevent mortality.[111,112] Increased survival was observed with immunization regimens that produced both humoral and $CD8^+$ CTL responses,[112,113] and depletion of $CD4^+$ or $CD8^+$ T cells in immune animals eliminated protective immunity against Ebola virus challenge in mice.[114,115]

Description of Current Vaccines and History of Development

Vaccine efficacy trials cannot be ethically conducted in humans for lethal pathogens such as Ebola virus, so the FDA in 2002 instituted a new rule, 21 Code of Federal Regulations (CFR) Parts 314 and 601, that allows approval of biological products based on "evidence of effectiveness derived from appropriate studies in animals." In place of human field efficacy trials, marketing approval for a new product can be based upon efficacy demonstrated in an animal species that has been shown to predict relevant responses in humans.[116] Ebola virus infection of cynomolgus macaques represents a model that satisfies the requirements for vaccine licensure because the disease time course, pathophysiology and clinical symptoms closely mimic those observed in human EVD,[9] making this NHP infectious challenge model the most appropriate for advancing potential vaccine candidates into humans. The strategy for Ebola virus vaccine development has been to identify the most potent vaccines in rodents that showed promise for testing in primates. This goal proved elusive for several years because successful immunization in the rodent model was not recapitulated in primate models.[117] Although recombinant vaccinia viruses or Venezuelan equine encephalitis virus replicons encoding EBOV GP showed some protection in guinea pigs (rodents) against Ebola virus challenge, protection was not observed in NHPs.[118,119] Lack of protection in monkeys was not a result of a species defect in the ability of primates to mount an effective immune response because animals that survive infection develop immune memory that protects against a subsequent infectious challenge.[120,121] This suggested that protection of NHPs required the generation of broader and/or higher levels of immunity. To develop a more potent vaccine for primates, investigators augmented gene-based immunization that had been shown to protect rodents[110] by employing a heterologous prime-boost strategy in which immune responses primed by inoculation with plasmid DNA vectors expressing Ebola virus GP and NP were boosted by a subsequent injection of replication-defective recombinant adenovirus (rAd) vectors encoding the same gene products. rAd boosting of DNA-primed cynomolgus macaques generated Ebola virus-specific cellular and humoral immunity, and vaccinated animals were completely protected from challenge with a lethal dose of Ebola virus, providing evidence for the first time that vaccination could elicit protective immunity against EVD in primates.[122] Since that observation, Ebola virus immunization strategies have yielded increasingly promising approaches to prevention of infection in primates.[123] A single inoculation with rAd encoding GP and NP from Ebola virus elicited protective immunity against homologous challenge within 4 weeks of vaccination,[124] raising the possibility of accelerated immunization during outbreaks.[125] This single-shot approach has been extended to other vaccine platforms including replication-competent vesicular stomatitis virus (VSV) vectors,[126] and with a two-dose human parainfluenza virus vectored vaccine.[127] Generation of Ebola virus-like particles (VLPs) is based on the self-associating properties of some EBOV structural proteins.[30,128] 293T-cell–derived VLPs containing EBOV GP, NP, and VP40 administered intramuscularly with RIBI adjuvant three times at 42-day intervals protected NHPs against challenge with approximately 1000 PFU (plaque-forming units) of EBOV. The vaccinated animals had no detectable viremia following challenge, although minor hematologic and liver-enzyme effects, and increases in antibody titers and T-cell repertoires were observed postchallenge, indicating a failure to induce sterile immunity.[129]

Each of the protective vaccine platforms has potential advantages and limitations for their development as a human vaccine. VLPs require a more complicated (multishot) regimen, may face challenges for bulk production,[8] and are less flexible than gene-based strategies for rapid adaptation to target newly emerging variants or multiple *Ebolavirus* species. Viral-vectored vaccines may present challenges for safety or manufacturing if they are replication competent, and all viral vectors may exhibit reduced potency in the context of natural or vaccine-induced immunity against the vaccine vector.[130–132] This latter issue has been mitigated for rAd vectors through the development of nonhuman-derived rAds exhibiting low seroprevalence in humans.[133,134] These vectors have shown success for immunization against various diseases: chimpanzee (Ch) Ad3 for Ebola virus[135] and cancer,[136] ChAd63 in combination with modified vaccinia Ankara (MVA) for malaria,[137] and ChAd32 in combination with rAd6 for hepatitis C virus.[138] Although alternative rAd vectors are insensitive to preexisting immunity in humans[133,136,139] genetic differences between adenovirus vectors result in vector-specific T-cell immunity qualities that associate with inferior protection in NHPs. A single injection of rAd26, rAd35 or ChAd63 was inferior for protection against challenge in NHPs.[134,135,140] Prime/boost combinations with less potent rAd vectors protected animals from challenge for a short period postvaccination but long-term protection was still found to be compromised, likely because of suboptimal priming of antibody and T-cell immunity.[125,134,135]

Despite previous failures of Vero cell–produced, formalin- or γ radiation–inactivated Ebola virus to protect against challenge in the guinea pig and NHP models,[105,117,141] inactivated, whole Ebola virus was reassessed for its capacity to protect NHPs. A single intramuscular injection of hydrogen peroxide–inactivated, replication-defective (VP30-deleted) whole Ebola virus completely protected cynomolgus macaques against challenge 4 weeks after vaccination.[142] However the potential risk associated with manufacturer error during the inactivation process or recombination events with replication-defective virus in an environment with circulating wild-type virus decreases the safety of this approach as a vaccination strategy.

An alternative vaccine platform in development is based on human parainfluenza virus type 3 (HPIV3). A two-dose regimen of a combined intranasal and intratracheal inoculation of NHPs with HPIV3 encoding EBOV GP showed complete protection against EBOV challenge 39 days after the second immunization.[127] A newer study found that a single aerosol dose of HPIV3-EBOV-GP conferred complete protection against EBOV challenge 27 days postvaccination in NHPs, although low-level viremia was detected in some animals.[143] Because HPIV3 is a common infection, preexisting immunity in the human population could affect the platform's effectiveness in people, as was seen during early development of the rAd5 platform.[144–147]

Because an outbreak situation would demand fast-acting vaccines, following the strategy used to eradicate smallpox virus in 1988,[148] rapid protection such as that observed with VSV and rAd Ebola vaccines[123,124,126,135,149–151] would be needed for effective ring vaccination during an outbreak. Inducing long-term protection would also be crucial for assuring that the vaccinated individual, especially healthcare workers, would be protected during the entire outbreak period. Durable immunity was maintained with a ChAd3/MVA prime-boost combination in NHPs, where protection was still observed following infectious challenge approximately 1 year after vaccination.[135]

Translational development of experimental vaccines for human use through clinical trial testing began in 2003 with a Phase I trial of the first lead candidate, rAd5-GP demonstrating safety and immunogenicity.[124] This vaccine strategy was not pursued because of the high prevalence of preexisting immunity against Ad5 in humans, potentially impacting the

TABLE 20.1 Filovirus Vaccine Clinical Phase I Trial (2003 to 2014)

Study Start Date (Year)	Institution (Country)	Vaccine Platform	Constituents	Dose	No. of Subjects	Trial Number	Reference
2003	NIH (U.S.)	DNA	(EBOV + SUDV) ΔTM GP	2 mg or 4 mg or 8 mg	21	NCT00072605	152
2006	NIH (U.S.)	Ad5 vectors	(EBOV + SUDV) mutant GP	2×10^9 or 2×10^{10} PFU	36	NCT00374309	157

2014	NIH (U.S.)	ChAd3 vectors	(EBOV + SUDV) WT GP	2×10^{10} or 2×10^{11} PFU	20	NCT02231866	158

This table represents the different filovirus vaccine platforms evaluated in humans for their safety and immunogenicity.
Ad, Adenovirus; ChAd, Chimpanzee adenovirus; ΔTM, transmembrane deletion; EBOV, Ebola virus; GP, glycoprotein; MARV, Marburg virus; mg, milligrams; NIH, National Institutes of Health; PFU, plaque-forming unit; SUDV, Sudan virus; WT, wild-type.

immunogenicity of rAd5-based vaccines.[144–146] This trial was followed by a strategy of iterative and parallel candidate vaccine testing in NHPs and humans over the course of the next decade (Table 20.1).[116,123,140] The extensive database of safety and immunogenicity of these early clinical trials enabled accelerated review of the lead candidates, ChAd3-GP and VSV-GP during the 2014 outbreak. The vaccines were tested at international clinical trial sites, and the transition to Phase I and Phase II trials was streamlined by enhanced collaboration across research institutions, regulatory agencies, and manufacturing sponsors, and culminated in the first human efficacy trial based on ring vaccination using VSV-GP (Table 20.2).[152]

Constituents

Of five possible *Ebolavirus* species that might be targets for immunization, EBOV and SUDV have been targeted for inclusion in a candidate vaccine because of their high incidence and pathogenic potential relative to the other species: BDBV,[47] TAFV, and RESTV. RESTV has not yet been shown to cause disease in humans, and only one case of TAFV has ever been reported. BDBV is a relatively recently identified ebolavirus species with a cumulative case total of 185 people. However, cross-protection against BDBV following EBOV/SUDV-GP-encoding DNA/rAd5 vaccination has been demonstrated, possibly the result of sufficient genetic similarity between the BDBV and EBOV/SUDV GP genes, and thus demonstrating the potential of vaccine strategies that target EBOV and SUDV species to be sufficient for protection against BDBV.[153]

Tests of a prototype vaccine in cynomolgus macaques showed that addition of the GP gene from the SUDV Gulu variant to the existing Ebola virus GP vaccine did not reduce efficacy against subsequent challenge with Ebola virus. The efficacy of the vaccine was not altered if the antigens were expressed by multiple vectors or coincidentally in a single vector.[135,154] Furthermore, elimination of the NP gene from the vaccine did not diminish protection, thereby simplifying the vaccine for future development in human trials.[125] The transmembrane form of GP was necessary to assure complete protection against Ebola virus but introduction of a point mutation to decrease the cytopathic effect of GP overexpression did not alter the vaccine's protective potency.[125] The emergence of the BDBV species in 2007 highlights the need for vaccines to be cross-protective against existing and future ebolavirus species. Encouraging signs of such broad cross-protection were observed using a DNA/rAd5 vaccine regimen containing EBOV and SUDV GP that demonstrated potent induction of T-cell responses and uniform protection against BDBV challenge in a NHP model.[153] The West African Ebola variant (Makona) showed 97% identity to the Mayinga variant (DRC outbreak), suggesting that a vaccine protecting against the Ebola virus DRC variant will also protect against the Makona variant.[1] Variant cross-protection has been demonstrated in recent studies using the VSV vaccine platform, using an infectious Makona challenge in NHPs vaccinated with GP from a Kikwit variant.[155,156]

Manufacturers and Producers

Ebola vaccines are developed through close collaboration between government public health agencies and pharmaceutical companies. The ChAd3 vaccine is supported by the United States National Institute of Allergy and Infectious Diseases (NIAID) and GlaxoSmithKline. The Public Health Agency of Canada and NewLink Genetics in association with Merck Vaccines USA are developing the VSV vaccine. Janssen Pharmaceutical Companies of Johnson & Johnson and Crucell Holland Bavarian Nordic are codeveloping a vaccine comprised of the rAd26 vaccine and MVA-BN Filo in a prime-boost combination.

Dosage and Route

The majority of NHP studies deliver Ebola vaccines by the intramuscular route. In the original heterologous prime-boost vaccine in primates, DNA vectors were administered at a dose of 8 mg per inoculation using a needle-free injection system, and delivery of rAd vectors was performed using a conventional needle and syringe at a dose of 10^{12} particle units (PU). A subsequent pilot dose-ranging experiment in cynomolgus macaques demonstrated that the single-dose rAd Ebola virus vaccine still achieved 100% protective efficacy with a 100-fold dose reduction to 10^{10} PU.[125] A later study similarly found that a single dose of ChAd3 10^{10} PU was sufficient to uniformly protect NHPs against EBOV infection after high-dose challenge.[135] This dose is within a range that is well tolerated in humans for other rAd systems expressing a variety of recombinant genes. The safety of intramuscular delivery of a single injection of rAd5 encoding GP from EBOV and SUDV at either 2×10^9 or 2×10^{10} was demonstrated in a Phase I clinical trial.[157] Moreover, formulation of the rAd vectors at a unit dose up to 10^{11} PU permits scalable and affordable manufacture of pharmaceutical grade vaccine, and corresponds to the dose of ChAd3-GP vaccine used in Phase I and Phase II clinical trials.[158] When MVA vector was administered to extend the duration of protective immunity to 1 year after a ChAd3 prime, an MVA dose of 1×10^8 PFU was used in both the monkey infectious challenge studies and human clinical trials.[135,152]

DNA vectors are stable and easily manufactured at the doses needed for the induction of immune responses in

humans as shown by Phase I human studies that delivered the vaccine using a pressure injection device. A dose of 4 mg given three times at monthly intervals was shown to be safe and well tolerated.[159–161]

The VSV vaccine required 1 to 2 × 10^7 PFU of replicating vector for protection against challenge in NHPs,[162,163] and a similar dose was used during subsequent Phase I, Phase II, and Phase III clinical trials. In addition to the intramuscular injection route, some studies have evaluated the potency of Ad vectors delivered thought the respiratory tract or by sublingual administration but NHPs were only partially protected from an Ebola virus challenge by these alternative routes, thus favoring the use of intramuscular injection in vaccination.[164,165]

IMMUNOGENICITY OF VACCINES

Antibodies

To assess immunogenicity of Ebola virus vaccines, assays to evaluate humoral and cellular immune responses have been developed that allow bridging between animal efficacy studies and human clinical trials. Antigen-specific antibody responses are assessed using ELISAs to measure serum levels of IgG or IgM directed against Ebola virus GP. As measured by ELISA both the DNA and rAd components of the Ebola virus vaccine used alone or in prime-boost combination generated robust GP-specific Ig titers that correlated well with vaccine protective efficacy in the mouse, guinea pig and monkey models of infectious challenge.[110,122,124,125,140] In NHPs, antigen-specific IgG is detected by ELISA even when samples are diluted 1000-fold (10^3 titer) within 1 month after the last vaccination with three DNA inoculations, and the titers are boosted to 10^5 after subsequent inoculation with rAd. Accelerated immunization using a single rAd injection generates antibody titers that are generally observed to be somewhat lower than with the prime-boost regimen, in the range of 10^4, but peak titers are achieved earlier than with DNA immunization.[124] Three weeks after a single injection with ChAd3, IgG titers are on the order of 10^3 and increased after an MVA boost to peak at a titer of 10^5 4 weeks after the second injection.[135] Replicating VSV vectors generate antibody titers ranging from 10^2 to 10^4 2 to 3 weeks after a single immunization in NHPs.[149,163,166]

In a Phase I randomized human clinical trial, 20 of 20 vaccinees immunized with three doses of an Ebola virus DNA vaccine candidate generated positive antibody titers ranging from 1:30 to 1:4000 against at least one of the three vaccine-encoded antigens (Zaire NP, Zaire GP, and Sudan GP) as measured by ELISA irrespective of vaccine dose, which ranged from 2 to 8 mg of DNA.[160] A similar Phase I clinical trial testing a single 2×10^{10} VP dose of EBOV/SUDV-GP encoding rAd5 ($n = 23$) in humans detected antibodies, with titers peaking at 4 weeks postvaccination, against SUDV GP and EBOV GP in 100% and 55%, respectively, of vaccinated subjects.[157] More recently, a human study using a high dose of ChAd3 vector yielded titers on the order of 10^3 against Ebola virus GP, and showed cross-reactivity against SUDV GP and the Ebola virus Makona variant.[158] VSV vectors at a dose of 2×10^7 PFU also induce 10^3 titers against Ebola virus GP.[167] Except for the DNA vaccine human trial, which showed development of lower than expected antibody response 4 weeks after the last immunization ($\sim 10^2$ titer),[159,161] the range of antibody titers in the human trials was comparable to those observed in NHPs vaccinated with similar regimens, indicating that responses in the monkey model are predictive of human immune responses against ebolavirus antigens.

Cellular Responses

A role for cellular immunity in survival is supported by the observation of CTL activation approximately 10 days after onset of symptoms, in the recovery phase of infection.[41] Furthermore, early after symptom onset following SUDV infection, a greater number of activated $CD8^+$ T cells were detected in patients with a nonfatal outcome as compared to fatal cases, a result probably associated with increased clearance of infected cells.[43] More recently, the cellular responses in four EBOV-infected patients from the West African outbreak were analyzed and characterized.[168] While these patients were concurrently receiving several therapeutic treatments that could have affected progression of the natural immune response[168,169] and even though all four patients developed lymphopenia, activated B cells, $CD4^+$ and $CD8^+$ T cells were all observed from 10 days to as long as 2 months following onset of symptoms. $CD8^+$ T-cell responses were mostly specific for NP antigen, with more moderate responses against VP40 and very low-level responses against GP. Taken together, these data suggest that the immunosuppressive effects of EBOV previously reported, may be overcome in survivors.[170,171]

In an early study showing protection in macaques, proliferative $CD4^+$ T-cell responses were observed in DNA/Ad5 vaccinated NHPs.[122] In follow-up studies of a single-shot rAd vaccine, antigen-stimulated cytokine secretion was induced within 3 weeks of immunization in both $CD4^+$ and $CD8^+$ T lymphocytes.[124] Similar results were obtained in Phase I human trials testing Ebola virus GP vaccines delivered with rAd5 or DNA vectors; both $CD4^+$ and $CD8^+$ antigen-specific responses were detected in vaccinated study volunteers.[157,160] More recently, the quality of the $CD8^+$ T cells induced by Ad vectors was observed to correlate with survival in NHPs,[135,140] and this T-cell quality was also found to be conserved following vaccination in humans.[158,172,173]

Correlates and Mechanism of Protection

Vaccine development is facilitated by the identification of host immune responses that correlate with attenuated symptoms in exposed individuals. As a result of relatively small case numbers in historical Central African outbreaks and challenging conditions for clinical research, limited information was previously available concerning disease outcome and host responses in surviving cases. The much larger number of infected subjects in the latest West African outbreak is yielding new pathogenesis information and will hopefully provide novel observations regarding correlates of survival.[7,11,174–177] Data on individual immune responses are not yet available for the 2014 outbreak; however, it has been shown that serum from outbreak fatalities exhibited elevated proinflammatory cytokine levels, including interferon (IFN)-γ, interleukin (IL)-2, IL-10, tumor necrosis factor (TNF)-α, and IFN-α, as compared to levels in survivor or uninfected control sera, indicating that exaggerated and uncontrolled immune activation might be deleterious.[1,41,178–181] A study of convalescent patients showed a correlation between elevation in IgM or IgG levels and the disappearance of viral antigen,[63,182] suggesting that adaptive immune responses may have the potential to control viral loads during EVD. In studies of human cases from the 1996 Gabon outbreak, IgG against NP was detected in all survivors and against VP35 and VP40 in the majority of survivors after the onset of symptoms.[41,179] Interestingly, a study of the 2000 SUDV outbreak found that major histocompatibility complex class I genes (MHC-I) were a predictor of case outcome with a specific subclass of alleles of MHC-I, the human leukocyte antigen (HLA)-B locus, associated with higher virus load and fatal outcome.[183]

Although gene-based vaccines generate both humoral and cellular immunity, $CD8^+$ cellular immune responses appear to be crucial for protection against Ebola virus infection in experimental animal models. The potential importance of T lymphocytes was initially demonstrated by studies in rodent models using an adapted Ebola virus variant. Unfractionated T-lymphocyte transfer achieved protection from infection with an efficacy in recipient mice that was comparable to that in immunized donors.[112] In later studies, it was observed that knockout mice lacking specific T-cell effector functions were more susceptible to lethal infection than their wild-type counterparts,[114,184] and that adoptive transfer of Ebola virus antigen-specific CTL to naïve mice protected against subsequent infectious challenge.[112] In addition, early studies with DNA and rAd vaccines indicated a trend toward greater survival in animals exhibiting higher $CD8^+$ T-cell responses.[125] More recent studies employing immunodepletion techniques have identified $CD8^+$ T cells as the critical cellular component responsible for virus clearance in vaccinated NHPs and studies using passive transfer of antibodies failed to protect the animals from lethal challenge.[185] The depletion antibody used in this study (anti-CD8α) may have also depleted natural killer (NK) cells. Because NK cells are known to have an important role in innate immune responses and antibody-dependent cell-mediated cytotoxicity, the possibility of NK cell involvement in the mechanism of protection cannot be excluded. Furthermore, cross-protection against BDBV infection in NHPs vaccinated with an EBOV-specific DNA/rAd vaccine was achieved in the absence of BDBV-directed antibodies, reinforcing the requirement for T cells in vaccine-induced protection.[153]

However, the magnitude of T-cell responses is not the sole determinant of protective immunity because some vectors elicit robust antibody and T-cell responses but fail to afford uniform protection. In these cases, a specific quality of $CD8^+$ T cells capable of simultaneous secretion of IFN-γ and TNF-α upon antigen stimulation and performance of effector functions associates with protection.[186,187] Durable protective immunity requires this population in combination with a sufficient proportion of cells comprising a memory phenotype that secrete three cytokines simultaneously, IFN-γ, TNF-α, and IL-2.[140,188] This population of polyfunctional $CD8^+$ T cells has also been observed after ChAd3-GP injection in NHPs and in human vaccinees.[135,140,158,172,173] The role of cellular responses

in VSV EBOV vaccine protection is less clear. In some studies there appears to be a role for cellular immunity, as some animals survived in the absence of measureable antigen-specific IgG.[162] In contrast, animals depleted of $CD8^+$ T cells survived EBOV challenge; however, $CD8^+$ T-cell depletion was at the time of vaccination.[189] Because vaccination was several weeks before challenge, it is possible that antigen-specific cellular responses from residual nondepleted or rebounding T cells may have contributed to protection. This is supported by simian immunodeficiency virus (SIV) vaccine studies where rebound of $CD8^+$ T cells was observed within a week following infusion of anti-CD8 antibody.[190]

While $CD8^+$ cellular immunity is central to the mechanism of protection, rAd-based Ebola virus vaccines have demonstrated that GP-specific IgG ELISA titers provide a strong immune correlate of protection and provide a statistically significant marker of the overall protective immune response induced by vaccination. More specifically, studies in NHPs with rAd5-based vaccines demonstrated that an antibody titer of 1:3700 was predictive of 100% protection.[116] The strength of the ELISA correlate likely reflects the robust specificity and sensitivity of assays for IgG, and the cumulative nature of the antibody response. Concerning the VSV-based Ebola virus vaccines, it has been inferred that antibodies play a role in protection; however, depletion of circulating $CD20^+$ lymphocytes did not abrogate protection, and passive transfer which would show a definitive role of vaccine-induced antibodies, was not performed. Depletion of circulating $CD4^+$ lymphocytes did abrogate protection, but lack of protection cannot be definitively ascribed to deficits observed in the humoral immune response because $CD4^+$ T cells play an important role in both humoral and cellular immune responses.[189] A quantitative correlate of protection in terms of antibody titer has not been reported for the VSV-EBOV vaccine.

The current body of data suggests that Ebola vaccine antibody and T-cell responses are tightly linked, and the magnitude and quality of both the humoral and cellular immune responses determine protection against Ebola virus in the NHP model. The level of IgG response is an easy parameter to measure and to correlate with survival, but because T-cell quantity and quality affect survival, further evaluation of T-cell responses are also necessary.[135,140]

EFFICACY OF VACCINES

By the beginning of 2015, the number of infected people had been dramatically reduced giving hope for the end of the outbreak; but on the other hand, it has become more difficult to assess the efficacy of the different vaccines in the Phase I and Phase II clinical trials initiated during the outbreak.[48,158,159,161,167,172,191,192]

Although the window has closed for efficacy trials in the absence of high case numbers, clinical trials originally established to evaluate efficacy of ChAd3 and VSV Ebola vaccines in West Africa will continue as Phase II and survivor follow-up studies (see Table 20.2). Partnership for Research on Ebola Vaccines in Liberia (PREVAIL) was a Phase II/III, randomized controlled trial (RCT), with three arms: ChAd3, VSV, and a placebo conducted in a randomized and double-blind fashion.[193] The second trial, Sierra Leone Trial to Introduce a Vaccine against Ebola (STRIVE), was a Phase III study of the VSV vaccine. This clinical trial was a nonblinded, randomized trial that was changed from a stepped-wedge cluster trial (SWCT) into an RCT because of concerns that the original study design was complicated by regional variation in EVD incidence within the population, and therefore lacked the statistical power to determine true efficacy.[194] Finally, a Phase III ring vaccination trial conducted in Guinea for the VSV vaccine, "Ebola ça suffit" ("Ebola it's enough") used a study design that allowed all participants to receive the vaccine, by randomly assigning clusters to either immediate or delayed vaccination. An interim analysis reported that in clusters of contacts vaccinated immediately, there were no cases of EBOV with onset more than 10 days after entry into the study, whereas in the clusters vaccinated 21 days after randomization there were 16 cases, for an early point estimate of 100% efficacy.[195] The authors' reported a *P* value of .0036 for the estimated vaccine efficacy. However, this value did not fall below the predetermined threshold of success of .0027.[196,197] The absence of a placebo control group in this trial means that at least 190 clusters (95 clusters per arm) of approximately 50 subjects each would be required to evaluate true efficacy, numbers that will be difficult to attain with the decline of the West African outbreak.[195,198]

An initial efficacy signal is suggested by preliminary Phase III results but, in the absence of placebo-controlled studies, it is probable that vaccine efficacy determinations will have to continue in NHP models to support licensure using the Animal Rule or Accelerated Approval regulatory pathways.[116,199,200] In these pathways, immune responses will be bridged between NHP protection studies and the level of immune responses observed in human clinical trials.

Once a licensed vaccine becomes available, immunization of primary responder health professionals who are at risk of infection may permit further assessment of vaccine efficacy and evaluation of the durability of protection should another outbreak occur in the future.

DURATION OF IMMUNITY

The durability of Ebola virus vaccine-induced protective immune responses is best addressed in prospective long-term follow-up of immunized subjects, but requires empirical determination of an immune correlate in NHPs who are challenged following a long delay from the time of vaccination. In human volunteers immunized with DNA vectors only, both humoral and cellular Ebola virus GP-specific immune responses were detected through 52 weeks of follow-up, with antibody titers waning over time, with a half-life of approximately 6 months.[160] The duration of the antibody response may be enhanced by subsequent boosting of DNA vaccine recipients with rAd as has been shown in monkeys immunized with SIV antigens.[201] In these studies, antigen-specific antibody titers were maintained at constant levels for greater than 2 years following the rAd boost, and cellular responses, although decreasing somewhat relative to immediate postboost levels, were sustained at a magnitude greater than post-DNA prime responses. Similarly for the Ebola virus vaccine, rAd inoculation of DNA-primed cynomolgus macaques yielded antibody titers that were boosted by greater than 100-fold over those obtained with DNA or rAd alone.[122,125] Furthermore, DNA primed immunologic memory was durable for at least 1 year.[153] A single injection of ChAd3 provided 50% protection after 10 months in NHPs; a boost with MVA, 2 months after the ChAd3 injection increased the durability to 100% protection during 10 months, with a sustained high T-cell quality comprising both effector and memory T-cell responses.[135] In addition, ChAd3 vaccination of human subjects induces specific IgG responses up to 6 months after a single immunization or up to 5 months after a ChAd3/MVA prime boost combination.[172,191] The antibody kinetics will need to be followed yearly and the level of antibody responses will also need to be correlated with survival probability. Persistent immunity for the VSV-EBOV vaccine remains to be determined since data have not been reported regarding long-term

protection in NHPs or durability of antibody titers in human vaccinees.

SAFETY

In Phase I human trials, DNA and Ad5 vector Ebola virus vaccines proved safe and well-tolerated.[157,160] Minor injection site symptoms included pain or tenderness following injection using a needle-free injection system, and systemic symptoms reported by vaccinees were mild to moderate headache, myalgia, malaise, and fever; however, these symptoms were also reported by placebo controls. In a more recent clinical trial with study sites in the United States and Uganda, in which subjects received three doses of DNA vaccine, some participants reported mild to moderate pain at the injection site, headache, muscle ache, fatigue, or aching joints but these symptoms resolved rapidly.[159,161] In the ChAd3 trial, the majority of symptoms reported at all study sites (United States, Europe [United Kingdom and Switzerland], and Africa) were mild to moderate fever (resolved in 1 day), mild pain at the injection site, chills, headache, and fatigue, resolving within a day.[158,172,173,191]

In general, the EBOV VSV vaccine tested in the United States, Europe, and Africa showed mild to moderate injection site pain, fever, headache, myalgia, and fatigue.[167] However, at the Geneva, Switzerland study site, some subjects developed oligoarthritis, in association, in some cases, with vesicular dermatitis, skin vesicles containing VSV virus, and, in rare cases, some cutaneous vasculitis, all appearing during the first 2 weeks after vaccination[48,202]

PUBLIC HEALTH CONSIDERATIONS

An Ebola virus vaccine is indicated primarily for populations that can be identified as being at high risk for exposure to the virus, such as bushmeat hunters and others who are exposed to the natural virus reservoir in the forest, or international or local healthcare workers who are first responders during outbreaks. Although the mode of virus transmission to hospital personnel has not been definitively proven, exposure of healthcare professionals likely occurs through mucosal surfaces. Strict compliance with barrier and universal precaution practices can reduce exposure, but cases continue to occur because first responders are placed into direct contact with viremic patients under challenging conditions, often in temporary field hospitals and/or prior to diagnosis.[58] The discovery of Ebola virus in swine has raised considerable concerns since the proximity of humans and pigs in farms may favor adaptation to a more lethal form, and suggests that pig farmers may be potentially at risk. Laboratory workers who conduct research with infectious Ebola virus also constitute another risk group. Although research personnel perform experiments wearing protective suits under Biosafety Level 4 biocontainment, exposures have occurred in this population, usually involving accidental needle sticks. Finally, in the event of an Ebola virus-based bioweapon or bioterrorist attack, the ability to have immunized military personnel or first responders would be beneficial.

Until 2012, outbreaks of EVD have remained geographically localized and relatively contained, but since 2014, the high transmissibility and mortality of ebolaviruses, with their demonstrated ability to spread from human to human, has placed it among the most serious of emerging infectious diseases from the perspective of public health. In Africa, the endemic area of infection in the equatorial rain forest lies within reasonable proximity of two highly populated cities, Kinshasa and Brazzaville. Freetown and Conakry in Sierra Leone and Guinea respectively, all affected by the 2014 outbreak, are also important centers of West African economy and commerce. A formerly unrecognized public health concern has arisen with the discovery of virus remaining in "cured" subjects for weeks or months after resolution of EVD.[64,65,67,203] Therefore, close contacts of survivors may comprise a new risk group that should be considered in any vaccination strategy.[66,204]

The modern ease of international travel can facilitate spread of Ebola virus, as illustrated by imported cases on two occasions of MARV first from a Dutch traveler and later from an American traveler, both returning from Uganda. In the most recent outbreak, again a traveler was subsequently diagnosed as infected following his return to Texas from Liberia.[174,205,206] Exposure of infected individuals to a high-density population could result in a catastrophic outbreak. Fortunately, in the recent outbreak, new cases of EVD from imported patients in the United States were efficiently curtailed through rapid patient identification, isolation, and aggressive follow-up, rapidly limiting the potential for disease spread. More positively, the 2014 outbreak created a worldwide movement fostering international collaboration between laboratories and pharmaceutical companies, resulting in the rapid construction of research laboratories and hospitals and the development of coordinated treatment and vaccine strategies. Despite these advances, more effort is still needed to develop a healthcare emergency response system (PPE and treatment) within endemic areas, and to optimize protocols for rapid contact tracing and efficient mobilization of fully trained medical teams in the case of future outbreaks.

Finally, in addition to the public health concerns raised by ebolaviruses, previous reports of weaponization of the virus in the former Soviet Union raise concerns about the possibility of its use as a military threat or a bioterrorist agent.[207–210] In the case of either natural or deliberate introduction of these viruses into any population, it is important to recognize not only the potential loss of human life but also that fear and chaos caused by this highly aggressive, visible infection ultimately lead to economic disruption and a breakdown of social order if not swiftly and effectively countered.[211,212]

21 Enterovirus 71

Pele Choi-Sing Chong and Michel Klein

Enteroviruses (EVs), which have been classified into four species (A, B, C, and D), are positive-sense, single-stranded RNA viruses within the *Picornaviridae* family. They cause various clinical manifestations, including severe neurological diseases in young children.[1–4] More than 100 EV serotypes have been identified including polioviruses, coxsackieviruses A (CV-A), coxsackieviruses B (CV-B), echoviruses, and numerous EV serotypes. Since 1990, EV-A infections have become the primary cause of hand, foot, and mouth diseases (HFMDs). Since the almost complete eradication of poliovirus, EV-A71 has emerged as a major neurotropic virus responsible for severe neurological complications and has become a serious public health threat to infants and young children across the Asia-Pacific region.

HISTORY OF DISEASE

EV-A71 strain, BrCr,* was isolated in California in 1969 from the brain of a patient with encephalitis, although the emergence of the virus can be traced back to 1941.[5,6] Sporadic epidemics have since occurred worldwide, in particular, in Asia.[1–4,7–9] Major HFMD epidemics in Malaysia (1997), Taiwan (1998), Singapore (2008), and China (2008) were associated with severe neurological complications and fatal outcomes and prompted several countries to establish national surveillance programs for HFMD and/or EVs.[1–4] More than 10 million cases of HFMD with more than 3000 fatalities were reported in China between 2008 and 2012.[10,11] As a consequence of the considerable socioeconomic impact of EV-A71 infections on healthcare systems and the absence of an effective treatment, the urgent development and clinical evaluation of EV-A71 vaccines have been a national priority in some Asian countries such as China, Taiwan, Singapore and Malaysia.[4,12]

CLINICAL DESCRIPTION

EV-A71 preferentially infects infants and children younger than 5 years of age. However, approximately 70% of infections remain asymptomatic.[1–4] EV-A71 together with coxsackievirus 16 (CV-A16) is a major cause of herpangina and HFMD. HFMD is typically a self-limiting illness characterized by a papulovesicular or maculopapular rash, blisters of the hands, soles, and buttocks associated with painful ulcerative lesions of the mouth. It is highly contagious and efficiently propagated through household contacts by oropharyngeal secretions or fecal–oral transmission depending on the level of hygiene, water quality, and the extent of crowding.[13] EV-A71 infections may cause severe neurological disorders, including brainstem encephalitis, that can lead to fulminant neurogenic pulmonary edema associated with high mortality.[14] The average yearly fatality rate of patients with severe disease in Taiwan was reported to be 13%.[15] Children who recover from brainstem encephalitis are left with significant neurologic sequelae, including long-term impairment of neurological development and cognitive functions.[1–3,8,14–19] Symptomatic EV-A71 infections progress through four stages: HFMD/herpangina (Stage 1), central nervous system (CNS) involvement (Stage 2), cardiopulmonary failure (Stage 3), and convalescence (Stage 4).[20,21] EV-A71 elicits both humoral and cellular responses, but there is no correlation between neutralizing antibody levels and disease severity. This indicates that altered cellular responses, such as an imbalance in T-helper (Th)1/Th2 and Th17/regulatory T cell (Treg) ratios, play a significant role in disease outcome and are of potential prognostic value.[22–25] The presence of neutralizing antibodies did not reduce the incidence of infections caused by EV serotypes other than EV-A71.[26]

VIROLOGY

EV-A71 has been divided into three genetic lineages: A, B, and C; however, four new genotypes have been recently identified as D, E, F, and G.[4,12,27] After infection, viral RNA is translated into a polyprotein containing three regions: P1, P2, and P3 (Fig. 21.1). P1 encodes four viral structural proteins—VP4, VP2, VP3, and VP1—that are released by proteolytic cleavage (Fig. 21.1). The VP1, VP2, and VP3 proteins are exposed on the virion surface in its crystal structure[4,28] and are responsible for immune responses and host-receptor binding. VP1 contains the major neutralization epitopes and is used in viral identification and evolutionary analyses.

Pathogenesis as It Relates to Prevention

Sites of Infections

EV-A71 can infect a wide spectrum of cells. Virus tropism and pathogenicity depends on host-cell surface receptors and cellular *trans*-acting factors.[29–31] The identification of these receptors and the availability of transgenic mouse models have facilitated the understanding of EV-A71 pathogenesis.[32–37] Human skin and mucosal lesions likely result from direct infection of squamous cells. The tonsillar crypt epithelium supports viral replication and may be the source of replication at other sites, as well as of viremia, leading to neuroinvasion, possibly via a retrograde peripheral motor nerve route.[38–41] EV-A71 infection triggers apoptosis of brain-derived neural progenitor cells responsible for neurological sequelae.[42]

Host Receptor Factors

EV-A71 enters host cells via receptor-dependent mechanisms. Infected host cells produce both infectious and defective particles as shown in Fig. 21.1.[43–45] Cell-to-cell propagation contributes to pathogenesis. EV-A71 uses the ubiquitous human scavenger receptor class B, member 2 (hSCARB2) and the P-selectin glycoprotein ligand 1 (PSGL-1) to infect host cells. hSCARB2 is capable of viral binding, uncoating, and internalization, resulting in high EV-A71 infectivity. In contrast, the low infection efficiency of PSGL-1 expressing cells is a result of the inability of this receptor to induce viral uncoating.[35,37] Because of its ubiquity, hSCARB2 likely mediates systemic and neural cell infections. Indeed, hSCARB2 transgenic mice develop encephalitis after EV-A71 challenge.[36,37] PSGL-1, a sialomucin

*The nomenclature of EV-A71 strains is defined as patient's initials/year of isolation. For more information, see http://www.fda.gov/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/Guidances/default.htm.

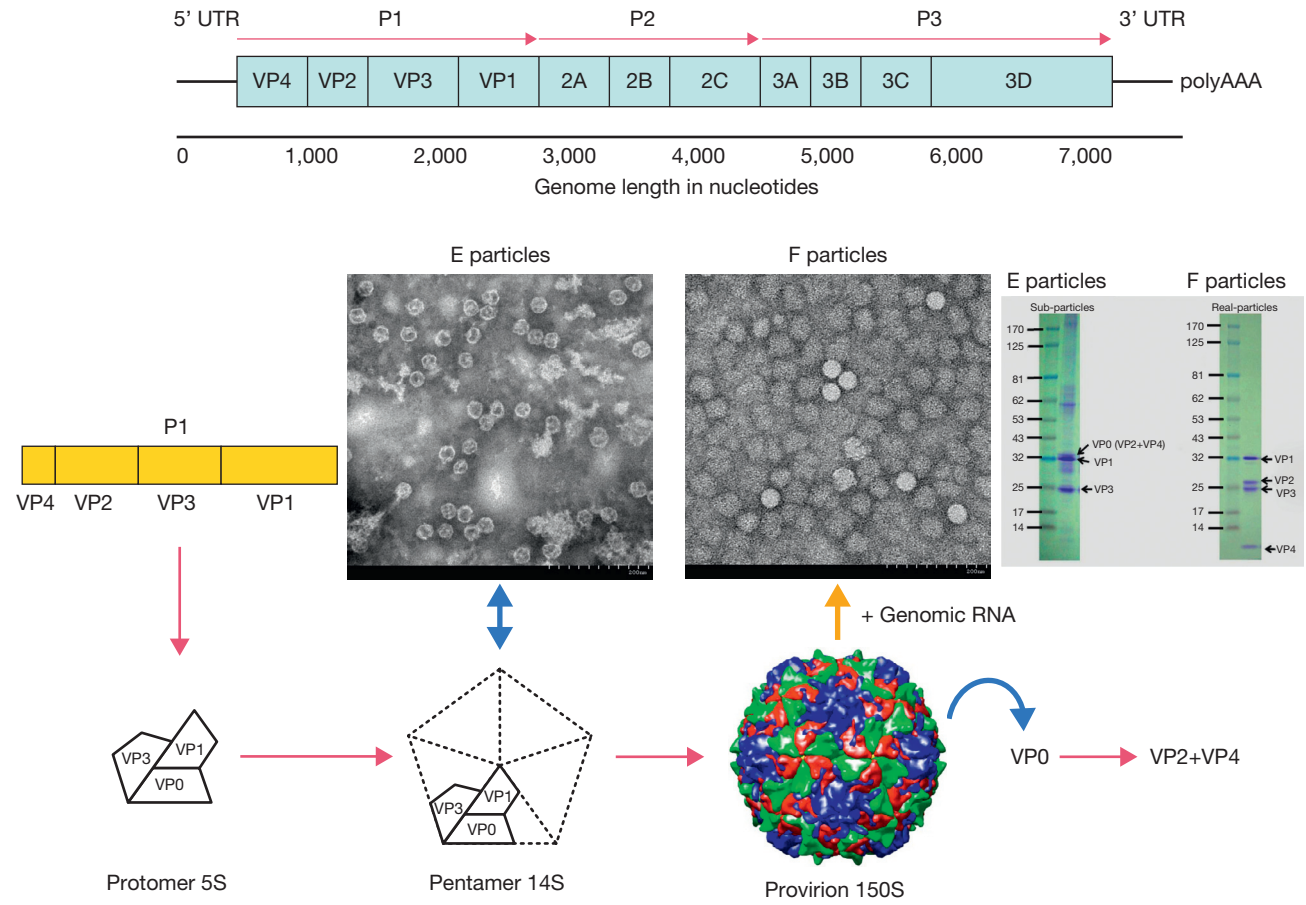

Figure 21.1. Schematic flowchart of EV-71 assembly. The single RNA transcript is translated into a polypeptide containing the P1, P2, and P3 domains. As shown in the figure, P1 is proteolyzed into the structural proteins VP0, VP1, and VP3. These proteins assemble into protomers (5S), five of which self-assemble to form a pentamer. Pentamers (14S) assemble into the provirion by procapsid self-assembly followed by progeny genome packaging. The final step of maturation involves the cleavage of VP0 to generate VP2 and VP4 and produce F-particles. A few purified E-particles (1/1000) contain viral RNA and VP0 (Liu CC et al., unpublished results). *(Modified from Cifuente JO, Lee H, Yoder JD, et al. Structures of the procapsid and mature virion of enterovirus 71 strain 1095.* J Virol. *87:7637–7645, 2013.)*

membrane-bound protein expressed on leukocytes, plays an important role in the early stage of inflammation. Replication of EV-A71 in endothelial cells, leukocytes, and dendritic cells result in the production of proinflammatory mediators. Extensive inflammatory responses with abnormal interleukin (IL)-6, IL-10, IL-13, and interferon (IFN)-γ cytokine levels as well as an increase in the levels of interferon-inducible protein 10 (IP-10), monocyte chemoattractant protein 1 (MCP-1), monokine induced by interferon-γ (MIG), and IL-8 chemokines in serum and cerebrospinal fluid (CSF) appear to be involved in the pathogenesis of EV-A71 brainstem encephalitis, autonomic nervous system (ANS) dysregulation, and pulmonary edema (PE).[46–49] Annexin-2, DC-SIGN, sialylated glycans, and heparin sulfate are other receptors that also play a role in EV-A71 pathogenesis.[50–52] The administration of intravenous immunoglobulins (IVIg) and milrinone has been shown to modulate inflammation and reduce ANS and PE.[46] The use of monoclonal antibodies against hSCARB2 and DC-SIGN, polycationic poly-D-lysine and/or an anti–heparin sulfate peptide could potentially inhibit viral entry and limit EV-A71 infection.[51]

EV-A71 Genotypes and Disease Severity

The relationship between EV-A71 genotypes and disease severity remains controversial. There is some evidence that specific mutations in the 5′ UTR (untranslated region), as well as in the VP1 and protease 2A coding regions,[53–57] are critical determinants of neurovirulence. Subgenotype C1 is rarely the cause of CNS complications,[58,59] whereas C2 was strongly linked to severe neurological disease.[3,59] Although subgenotype B4 was found to be less pathogenic than other subgenotypes in Malaysia,[60] other studies report that genotype B viruses are more likely responsible for neurological complications than genotype C viruses.[5] In Taiwan, EV-A71 genotypes B and C have been isolated from both mild and fatal HFMD cases.[61–63] Therefore, more careful and systematic analyses will be necessary to determine whether there is a correlation between EV-A71 genotypes and disease severity.

Prevention and Control Measures

Prevention and control measures of EV-A71 infections are primarily nonpharmaceutical, and meant to interrupt the chain of virus transmission using strict hygiene practices and avoiding contact between infectees and exposed individuals. Based on the World Health Organization (WHO) report, HFMD is a notified infectious disease in Japan (1993), Taiwan (1998), Malaysia (1998), Singapore (2000), and China (2009).[64] Early detection of outbreaks through physician-based sentinel clinics and automated alert and response systems to recognize the rare but severe forms of the disease are among the key

principles applied to minimize morbidity and mortality. WHO has proposed a risk-assessment framework[64] that defines criteria for appropriate interventions. However, an efficacious prophylactic vaccine is the best option to prevent EV-A71 infection and disease.

Diagnosis

Viral diagnosis is critical to confirm the EV-A71 nature of HFMD. Sample collection includes swabs from throat/nasopharynx, ulcers, and rectum, stools specimens, and samples from sterile sites such as vesicle fluid, CSF, serum, and urine. Virus isolation and identification are generally laborious and time-consuming to perform. Some clinical specimens require appropriate pretreatment before cell inoculation. Following virus isolation, the EV-A71 serotype can be identified by a conventional neutralization assay using "in house" reagents. However, reverse-transcription polymerase chain reaction (RT-PCR) amplification is the method of choice for the molecular identification of the virus.[43,65–67] It is a rapid, simple, and inexpensive method with 80% or greater sensitivity for blood specimens.[68,69] EV-A71–specifc primers should be adapted to the sequences of newly emerging EV-A71 genotypes and variants.[43,66] The indirect immunofluorescence assay (IFA) can also provide rapid identification,[70] but is relatively expensive.

An EV-A71 reference virus bank and reference reagents (broad neutralizing antibodies) are critical to the establishment of quality assurance system and test harmonization between laboratories to ensure the validity of serotyping and/or genotyping results in the future. The development of high-throughput multiplex polymerase chain reaction (PCR) assays for the simultaneous identification of multiple clinical EV isolates should greatly facilitate molecular epidemiology investigations in the future.[71,72]

Antiviral Drug Development

Currently, there is no approved antiviral drug against EV-A71. Pleconaril, a viral capsid inhibitor active against a number of EVs is inefficacious against EV-A71.[73]

EPIDEMIOLOGY

Incidence and Prevalence Data

Two patterns of epidemics have been reported since EV-A71 isolation in 1969: small-scale sporadic outbreaks with limited severe complications and large-scale epidemics with frequent CNS complications and deaths.[1,3,5,6,8,74–76] Fig. 21.2 summarizes the global incidence of large-scale epidemics with fatal outcomes observed in Europe, Malaysia, Taiwan, Singapore, Japan, Korea, China, and Vietnam. Japan was the first country in Asia to establish a comprehensive EV surveillance program with symptom-reporting and virus identification using molecular typing (http://idsc.nih.go.jp/iasr/index.html). Two

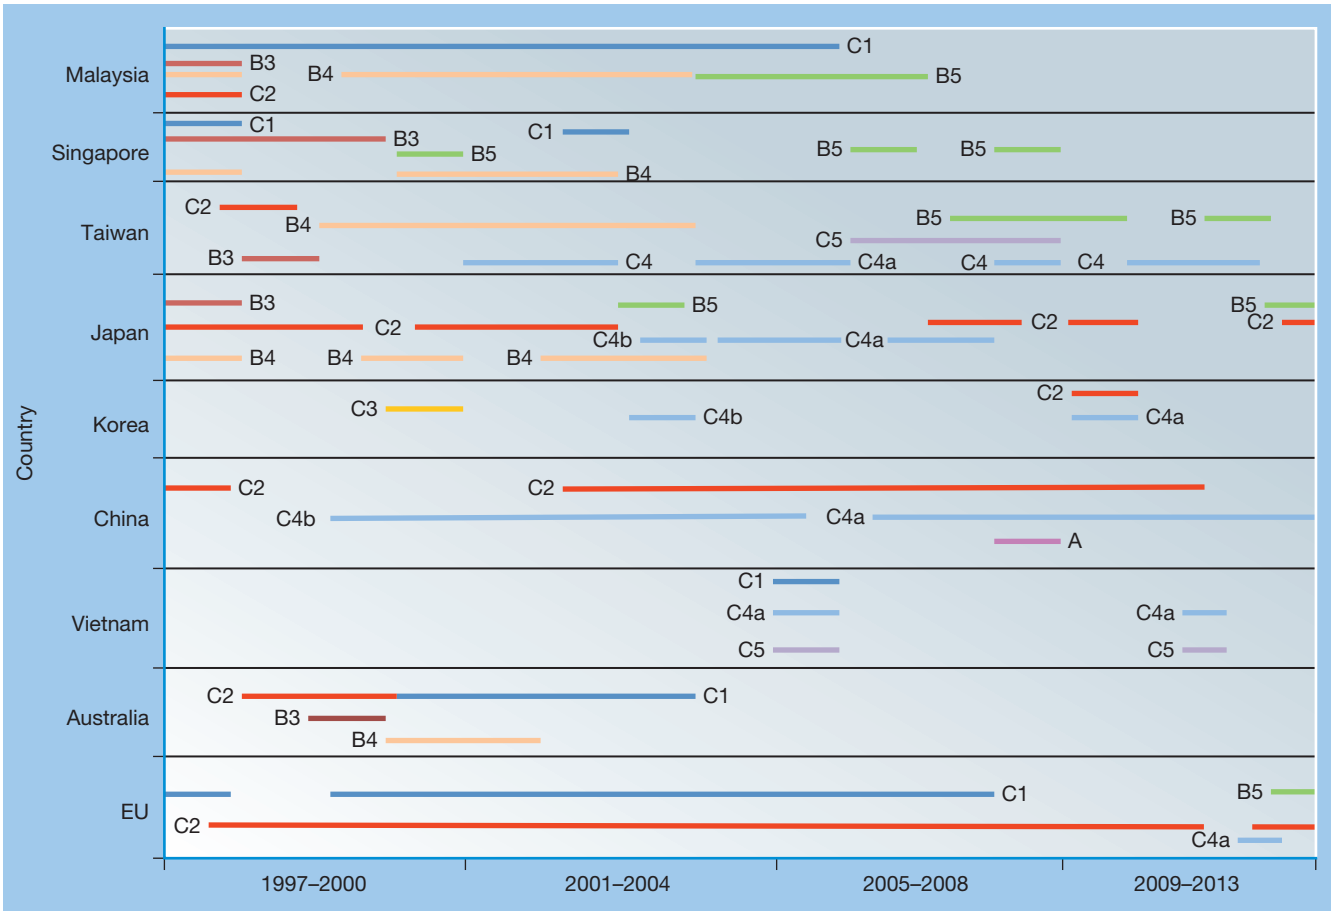

Figure 21.2. Geographic distribution of prevalent circulating EV-A71 genotypes and subgenotypes from 1997 to 2012. The annual distribution of EV-A71 genotypes and subgenotypes reported in this figure is a compilation of references 1, 3, 4, 12, and 126. EU includes the Netherlands, United Kingdom, Germany, France, Denmark, and Austria.

large-scale outbreaks occurred in 2000 and 2003.[75] While EV-A71 epidemics occur every 2 to 3 years, CV-A16 is more frequently the prevalent serotype.[77] Since 2000, Taiwan has a surveillance system for disease-reporting with systematic sampling of clinical specimens for virus isolation.[74,75] EV-A71 was among the top five EV serotypes isolated each year during the period 2000 to 2009 and was responsible for the most severe cases of HFMD. In Malaysia, EV-A71 epidemics occurred every 3 years while CV-A16 was detected during both epidemic and interepidemic periods.[75–78] In Singapore, large HFMD outbreaks were detected in 2002 and in 2005–2007, and nearly 30,000 cases were reported during the largest epidemic in 2008 with CV-A6 and EV-A71 being the predominant strains, followed by CV-A10.[79,80] In China, EV-A71 was the predominant serotype in the first HFMD epidemic in 2007 responsible for more than 80,000 cases, including 17 deaths (http://www.chinacdc.cn/). From 2009 to 2012, the surveillance registry recorded more than 10 million cases of HFMD of which more than 3000 were fatal.[9–12]

Clinical and Molecular Epidemiology

There is only one EV-A71 serotype, but EV-A71 has now been classified into seven genotypes: A to G.[4,27,81] Genotype A contains only the prototypic strain (BrCr). Genotypes B and C have six and five subgenotypes, B0 to B5 and C1 to C5, respectively. No association could be established between genotype and disease severity.[3] Since the 1990s, recurrent HFMD epidemics with neurological complications and fatalities have been reported in Europe and the United States.[1–6] The most severe EV-A71 epidemics spread through the Asia-Pacific region, including Australia, China, Hong Kong, Japan, Malaysia, Singapore, Taiwan, and Vietnam (see Fig. 21.2).[1–6] The first major EV-A71 outbreak occurred in 1997 in Malaysia where cocirculating neurovirulent B3, B4, C1, and C2 genotypes were responsible for 41 deaths among young children.[82] In Singapore, 30% of HFMD cases that affected thousands of children over a period of 7 years were caused by EV-A71, and subgenotypes B5 and C2 caused the largest epidemic in 2008.[80] Outbreaks of HFMD with severe neurological complications and herpangina that occurred in Japan between the late 1990s and 2013 were attributed to four cocirculating genotypes B4, B5, C2, and C4.[83] Between 2000 and 2011, Taiwan's CDC (Center for Disease Control) reported that between 93,000 and 140,000 cases of HFMD and herpangina occurred annually. EV-A71 was associated with 82% of severe cases. A major epidemic of EV-A71 subgenotypes C2 and B4 that caused 1.5 million infections and 78 deaths in 1998 was followed by smaller outbreaks of switching genotypes (Fig. 21.2).[84] More than 7 million HFMD cases caused by subgenotype C4 infections were reported in China between 2008 and 2012 of which more than 2450 were fatal.[10] Recently, subgenotype C5 was observed in severe pandemics associated with high mortality rates and spread through Vietnam in 2011 and Cambodia in 2012.[3,12]

Switching Genotypes and Genetic Recombination

EV-A71 epidemics occur cyclically every 2 to 4 years as a result of infections with single or multiple genotype(s)/subgenotype(s) and the unpredictable switching of genotypes/subgenotypes (see Fig. 21.2).[3,84,85] The cocirculation of several EV-A71 genotypes and CV-A16 during epidemics has been responsible for the intertypic and intratypic genetic recombinations responsible for the emergence of new variants.[3,83,85] Nearly all major HFMD outbreaks correlate with genetic variations caused by EV-A71 switches.[3,83–86] Thus a continuous monitoring of antigenic variation and genetic evolution is critical for epidemic control and vaccine design.

High-Risk Groups and Risk Factors

EV-A71 infections occur annually or semiannually depending on the country.[1–9] Their incidence is influenced by warmer temperatures and elevated humidity. The cyclic occurrence of epidemics in Malaysia coincides with new, naïve birth cohorts.[77–80,82] Human leukocyte antigen (HLA)-A33 and HLA-A2 have been linked to disease susceptibility and cardiopulmonary failure, respectively.[87] In general, children older than 2 years of age who are attending kindergarten or child-care centers, as well as coming from a family with more than 2 children and living in a rural area, were found to be risk factors for EV-A71 infections.[13,88,89] Only an early diagnosis can significantly reduce the risk of severe HFMD.[89–93]

SIGNIFICANCE AS A PUBLIC HEALTH BURDEN

Newer studies demonstrate that EV-A71 infection could cause long-term neurological sequelae.[90] In a prospective hospital-based case-finding study, 38 (21%) of 183 EV-A71 infections in children younger than 18 months of age developed neurological complications such as meningitis and encephalitis.[21] Based on national EV surveillance and two cross-section serological surveys, Lu and colleagues estimated that 130,617 Taiwanese children younger than 3 years of age were infected with EV-A71 in 1998 and that 273 (0.21%) developed neurological complications.[93] EV-A71 mortality rates heavily depend on healthcare accessibility and standards.

PASSIVE IMMUNIZATION

The indication for passive administration of IVIg is based on the assumption that immune sera have not only potential virus-neutralizing activity[64,68,69,94,95] but also nonspecific anti-inflammatory properties that could be beneficial in case of ANS dysregulation and PE associated with the production of proinflammatory cytokines (IL-6, IL-10, and IL-13), chemokines (IL-8, IP-10, MCP-1), and possibly MIG.[47–49,64,94–96] Their therapeutic effect may be IgG subclass, IgG concentration, and genotype dependent.[95] Although the early administration of IVIg had beneficial immunomodulatory effects in children with ANS dysregulation and brainstem encephalitis by reducing proinflammatory cytokine levels, and viremia,[13,90,94–97] its therapeutic activity remains controversial. The production of hyperimmune IVIg from Chinese donors with high titers of EV-A71 neutralizing antibodies could be a promising development; an early treatment with IVIg from selected donors in the mouse model showed a dose-dependent reduction in mortality.[94] However, the use of IVIg in significant infusion volume is not without risk and is very costly. Thus, IVIg efficacy needs to be unambiguously demonstrated before their use is recommended for passive immunization.

ACTIVE IMMUNIZATION

History of Vaccine Development

First EV-A71 Vaccine Candidate

During the epidemic in 1975 in Bulgaria, an inactivated EV-A71 whole-virus vaccine candidate was produced in Moscow. The vaccine was well tolerated and immunogenic in children 1 to 4 years of age,[98] but in the absence of subsequent outbreak, the vaccine was not evaluated for clinical efficacy.

Recent EV-A71 Vaccine Development

To avoid the risk of potential reversion to virulence of attenuated vaccines, chemically inactivated virion, synthetic peptides, recombinant subunits, virus-like particles, genetic and vector-based vaccines have been the preferred approaches to EV-A71 vaccine development.[4,9–12,75] In the absence of standardized antigens and immunological assays to assess the potency of vaccine candidates, it has been difficult to compare the efficacy of immune responses induced by prototypic EV-A71 vaccines. We used "in-house" standardized viral antigens and microneutralization assays to compare the immunogenicity of vaccine candidates produced by different platform technologies.[99] Vaccines were ranked in order of potency and efficacy: formalin-inactivated virion > recombinant virus-like particles > recombinant VP1 > synthetic neutralization epitope (VP1–43).

Synthetic Peptide-Based EV-A71 Vaccine

Synthetic peptides containing neutralization epitopes are safe. They also are well-defined and cost-effective immunogens that could be produced in developing countries. However, formulation in complete and incomplete Freund's adjuvants (CFA/IFA) that is not acceptable for human use is necessary to elicit only low neutralizing antibody titers, thus rendering peptide vaccines unattractive.[99]

Recombinant Subunit-Based EV-A71 Vaccines

It is well accepted that recombinant subunit vaccines are safe and cost-effective, but require strong adjuvants. Purified recombinant VP1 (rVP1) subunits produced in different expression systems could elicit good virus neutralizing antibody responses and protect newborn mice against lethal EV-A71 challenge.[1–4] rVP1, rVP2, and rVP3 elicited subunit-specific antibodies,[99] but only rVP1 formulated with CFA/IFA was capable of eliciting a 1/128 virus neutralization titer.

Virus-Like Particle–Based EV-A71 Vaccine Candidates

Recombinant virus-like particles (VLPs) produced from baculovirus or yeast expression systems mimic the conformation of authentic native viruses, but are safe because they are devoid of viral genome. VLPs elicit virus-neutralizing antibody responses in adult mice and protect newborn mice against lethal EV-A71 challenges by passive immunization. VLP-induced neutralizing responses are stronger than those elicited by synthetic peptides or rVP1.[99–101] Their safety, immunogenicity, and high-yield production make them ideal candidates for future combination vaccines.

Chemically Inactivated EV-A71 Virion Vaccines

Formalin-inactivated EV-A71 virions (FI-EV-A71) based on a B4 subgenotype formulated with alum elicited antibody responses that cross-neutralized different EV-A71 genotypes but failed to neutralize CV-A16.[99] Immunization with FI-EV-A71 C4 vaccines yielded similar results. Inactivated virions were shown to be significantly more immunogenic than the other EV-A71 vaccine prototypes, and to elicit potent cross-genotype neutralizing antibody responses in mice and non-primate models.[99,101–103] These results suggest that common neutralization epitopes (most likely conformational) are shared by different EV-A71 genotypes/subgenotypes, and that amino acid sequence substitutions between EV-A71 and CV-A16 can partially explain the failure of EV-A71 vaccines to cross-neutralize CV-A16. Reciprocally, inactivated CV-A16 virions could not elicit cross-neutralizing antibodies against a panel of EV-A71 genotypes.[67,104] Based on their promising protective ability and the success of inactivated polio vaccines (IPVs), inactivated EV-A71 virions were selected for the clinical development of stable and cost-effective HFMD vaccines.

Manufacturing Process of EV-A71 Inactivated Vaccines

The manufacturing process of EV-A71 vaccines includes several stages: selection and characterization of a genetically stable EV-A71 virus vaccine strain; qualification of cell substrates and virus seeds; evaluation and selection of serum-free culture medium for production; pilot scale upstream and downstream process development; optimization of chemical inactivation; and preclinical animal immunogenicity studies.

The EV-A71 E59 vaccine strain of the B4 subgenotype was isolated in 2000 and selected among more than 100 EV-A71 clinical isolates deposited at Taiwan's CDC as potential vaccine strains.[105] Full documentation and clear patient's medical history were provided as part of the regulatory requirements. As shown in Table 21.1, Sinovac Biotech Co Ltd, Vigoo Biologicals Co, and Chinese Academy of Medical Sciences (CAMS) in China developed the C4 H07, FY7VP5, and FY23 seed strains, respectively. Inviragen used a B2 subgenotype as vaccine strain.[4,12] Good manufacturing practices (GMP)-compliant Vero cell banks were readily available from American Type Culture Collection (ATCC), and used for EV-A71 production by National Health Research Institutes (Taiwan) (NHRI), Sinovac, Vigoo, and Inviragen, whereas CAMS used the KMB-17 cell-line. NHRI Vero-cell Master Cell Bank and Master Virus Seed of EV-A71 E59 strain were characterized according to U.S. Food and Drug Administration (FDA) guidelines,[2] tested by BioReliance (UK), and found to be free of retroviruses, bovine, and porcine viral contaminants and other adventitious agents.[105]

VP-SFM (GIBCO) serum-free medium was selected for the manufacturing process. Optimal virus yields were obtained at a 10^{-5} multiplicity of infection (MOI) at 37°C. Titers of infectious virus particles in production bulks were monitored using the $TCID_{50}$ (tissue culture infective dose) assay and measuring VP2 epitope content by quantitative enzyme-linked immunosorbent assay (Q-ELISA).[105–107] The overall recovery of virus purified by liquid chromatography after concentration ranged from 30% to 57%. Purified EV-A71 bulks prepared by NHRI and the Chinese manufacturers were inactivated with formalin (0.025%) whereas Inviragen used binary ethyleneimine.[108] The quality of inactivated EV-A71 virions was biochemically analyzed and used for immunogenicity studies. No contamination was observed in sterility tests at 18 months. The vaccine was stable after 18 months of storage at 4°C as confirmed by the absence of decline in virus neutralizing antibody titers over time in mouse immunogenicity studies. Microgram doses of vaccine formulated in alum elicited high neutralizing antibody responses against the E59 strain in mice, rats, rabbits, and macaques, as well as strong cross-neutralization titers against other EV-A71 B and C subgenotypes. These results provided the information required by regulatory authorities to move the vaccine to human Phase I clinical trials.

Chemically Inactivated EV-A71 Vaccines and Efficacy Trials

For regulatory, economic and market acceptability reasons, five chemically inactivated EV-A71 vaccines have been rapidly developed in the past few years.[4,12] The Vaccine R&D Center of the NHRI produced a B4-based FI-EV-A71 vaccine (EV-A71vac) and launched the first human Phase I clinical trial in adults in 2010. A single vaccine dose of 5 μg or 10 μg was safe and

TABLE 21.1 Summary of EV-A71 Candidate Vaccines[a] Tested in Human Clinical Trials

	Manufacturing Process		Clinical Trials				
Organization	Cell Lines and EV-A71 Vaccine Strain	Bioprocesses	Dosage (μg of Antigen)	Population Target	Sample Size	Status	References (ClinicalTrials.gov Identifiers)
NHRI (Taiwan)	Vero cell and EV-A71 B4 subgenotype (GMP certified)	Roller-bottle (SFM) Gel-filtration chromatography Formalin inactivation	5 and 10	Adults 20–43 yr	60	Phase I completed	109, 110 (NCT01268787)
Sinovac Biotech Co. Ltd. [a]The Chinese Academy of Medical Sciences (CAMS) and Sinovac Biotech vaccines have been approved by China Food and Drug Administration (CFDA).[127]
[b]The antigen dosage is calculated based on the report by Liang, et al.[122] that the specific activity of the EV-A71 antigen reference standard established in China is 421.1 U/μg.

highly immunogenic.[109] It elicited 100% seroconversion in naïve volunteers and strong virus neutralizing antibody (VNA) responses (geometric mean antibody titer [GMT] = 210) against the vaccine strain as well as against B1, B5, and C4a isolates in 85% of the vaccinees.[110] In contrast, neutralizing responses against C4b and CV-A16 were weak in 20% of the subjects and 90% of the vaccinees did not develop any VNA against an atypical C2 strain. Inviragen (Takeda Pharmaceuticals Co. Ltd) reported the results of a Phase I trial in adults with an inactivated EV-A71 B2 vaccine. All subjects who received 0.6 μg or 3 μg of vaccine at days 0 and 28 seroconverted and developed VNA GMTs of 323 and 452, respectively.[12]

Inactivated EV-A71 vaccines based on different C4 isolates were independently developed and evaluated by three different Chinese companies (see Table 21.1.)[4,12,111] The clinical efficacy of these vaccines formulated in alum was assessed in large Phase III trials involving more than 30,000 healthy infants and young children (6 to 35 months of age) who received two doses of vaccine 28 days apart or a placebo control. All three vaccines were found to be safe and well tolerated.[112–114] The most common side effects observed were induration, erythema, and pain at the injection site that resolved within 24 to 72 hours and a grade 3 fever. The rate of seldom-reported serious adverse events (SAEs) in vaccinees was not different from that observed in the control groups and were not causally related to vaccination. The Vigoo's vaccine[112] was greater than 90% efficacious against EV-A71–related HFMD and greater than 80% protective against EV-A71–associated serious diseases, including herpangina. In the Sinovac's trial, the incidence rate of EV-A71–associated disease was 0.3% versus 2.1% in the control group, corresponding to an 89.3% efficacy.[113] In the CAMS's study,[114] the seroconversion rate was 100% after two vaccinations, with a VNA GMT of 170.6. The vaccine was 97.4% efficacious against EV-A71–related diseases. All C4-based vaccines prevented herpangina and EV-A71–associated hospitalizations. Immune sera from subjects immunized with the Vigoo's and Sinovac's vaccines cross-neutralized the circulating EV-A71 genotypes and subgenotypes (B4, B5, C2, C5) associated with epidemics in recent years.[115] Furthermore, pre-existing antibodies due to stealth infections of young children did not interfere with vaccine efficacy against different EV-A71 genotypes.[115]

Immunological Correlates of Protection

Interestingly, the VNA titers decreased by half after 6 months but this waning did not affect vaccine efficacy.[111] Most importantly, Phase III results suggest that a VNA titer of 1/16 can serve as a correlate of protection against EV-A71–related HFMD.[12,111–114] A VNA titer of 14.7 U/mL was found to be

associated with a 50% protection against EV-A71 disease.[128] Despite differences in seed strains and manufacturing processes, C4-based vaccines have shown batch consistency and efficacy.[116]

Challenges for EV-A71 Vaccine Registration

Cross-Protective Ability Against Other EV-A

Both C4- and B4-based vaccines cross-neutralized the current circulating EV-A71 isolates,[110–115] but the B4 vaccine poorly neutralized an atypical C2 strain.[110] However, the degree of cross-protective ability of these vaccines against viruses from genotypes D, E, F, and G remains to be evaluated. In addition, they failed to protect against CV-A16 infections that are predominantly responsible for annual HFMD outbreaks.[110–115] It is likely that FI-EV-A71 vaccinations may not significantly reduce the number of clinical cases of HFMD during outbreaks. In this regard, bivalent FI-EV-A71/FI-CV-A16 vaccines that are being developed have elicited balanced protective responses against both viruses.[67,104] Furthermore, because of the possible emergence of new variants with increased virulence, only results from multinational efficacy trials will reveal if a monovalent vaccine can elicit broad protection against divergent epidemic viruses. To this end, a global surveillance network for EV outbreaks is urgently needed to monitor immune responses to EV-A71 vaccines in the future.

Duration of Immunity and Protection

A significant waning of antibody titer was noticed during the first 6 months after 2 vaccinations.[117] To ensure long-term antipoliovirus antibody persistence, the WHO recommended that a primary series of immunizations be followed by booster administrations.[118] Volunteers primed with one dose of EV-A71 vaccine at least in a Phase II clinical trial were enrolled to receive a booster dose.[116,117,119] A 10-fold increase at least in neutralizing antibody responses was induced by the booster injection, compared to placebo ($P < .0001$). The frequencies of adverse reactions were similar between vaccine and placebo groups. Therefore, a booster dose of EV-A71 vaccine 1 year after priming showed excellent immunogenicity and good safety profile. Although the Sinovac vaccine elicited robust protectino over a 2-year period,[127] only Phase IV studies will help define the optimal immunization schedule and determine whether a third immunization at 24 months is recommended for long-lasting protection. The development of mucosal vaccines that are attractive may not be necessary since parenteral immunization confers protection. Prospective studies should be conducted during EV-A71 and coxsackievirus epidemics to assess the role of cellular immunity in long-term cross-protection and viral pathogenesis. In addition, longitudinal studies are necessary to evaluate the efficacy of EV-A71 vaccines at controlling antigenic shift, virus fitness, and the emergence of new viruses.

Standardized Animal Models for Vaccine Potency Test

Macaques develop antibody responses to EV-A71 vaccines similar to those observed in human, but their use is limited by ethical and economic considerations.[37] Neonatal suckling mice and immunodeficient animals have widely been used in evaluating the protective efficacy of EV-A71 vaccine candidates, but they do not mimic human infection.[120] NHRI[36] and Fujii and colleagues[37] have successfully developed transgenic mice carrying the human receptor hSCARB2 that develop clinical symptoms similar to those observed in humans. The hSCARB2 transgenic mouse model once standardized will be useful to assess the cross-protective ability of vaccines against EVs in the future.

Vaccine Manufacturing Considerations

An ideal EV-A71 vaccine should be inexpensive, safe, compatible with large-scale production, easy to administer, and acceptable to parents. To this end, cooperation between research and development institutes and both Asian and global companies are urgently needed to improve and scale-up the current manufacturing processes for broad approval by regulatory authorities. As a result of intellectual property rights and proprietary technologies, information on the influence of culture medium and production systems on vaccine yields is lacking. However, both the roller-bottle and cell factory technologies used to produce current clinical lots are easy to operate, although labor intensive.

Clinical trials have revealed that administration of a 400-unit (1 μg) dose of EV-A71 vaccine twice achieved efficacy.[111–113] A 2012 publication[99] reports that a 40-L pilot-scale production batch could yield fifty thousand 1 μg doses of FI-EV-A71 at a cost of 0.4 U.S. dollar/dose. This translates into 200,000 doses of the lowest C4-vaccine protective dose (0.25 μg) as determined in a Phase III trial[114] at 0.1 U.S. dollar/dose. Although Chinese manufacturers could produce 40 million doses annually,[127] larger-scale production of EV-A71 vaccines will require an improvement of the current manufacturing processes. The use of bioreactors, microcarriers, and perfusion technology could increase cell growth and virus yield by one order of magnitude. To lower the production cost, a simple and efficient downstream chromatographic purification step could be optimized to copurify immunogenic defective and infectious virus particles.[107] Lee and colleagues[121] forecasted that routine immunization with a 70% efficacious EV-A71 vaccine sold at 25 U.S. dollars/dose would be of great economic value. With this profit margin and the new emerging vaccine markets in the Asia-Pacific region, the global vaccine companies should become interested in manufacturing EV-A71 and future multivalent HFMD vaccines.

Public Health Perspectives

Based on the current Phase III results, national EV-A71 immunization programs should be implemented in China to build strong herd immunity. A two-dose regimen vaccination should be administered to 6- to 7-month-old children and possibly a third dose at 18 to 24 months. Multinational efficacy trials will be critical to evaluate the degree of cross-immunity against circulating genotypes and subgenotypes. A global HFMD surveillance network is mandatory for continuous epidemiological monitoring and the detection of emerging EV-A71 variants. Harmonization and standardization of vaccine strains, quality control (QC) reagents and assays and animal models at the international level are urgently needed to evaluate the potency of vaccine candidates and determine which manufacturing process yields the most potent and most affordable products. In this regard, China has established national standards for vaccine evaluation.[122] Although the coadministration of FI-EV-A71 with Pediacel (Sanofi Pasteur) did not affect antibody responses against the individual components of the pediatric pentavalent vaccine, clinical trials should be conducted to determine whether EV-A71 vaccines could ultimately be combined with Expand Program of Immunization (EPI) vaccines which would greatly simplify immunization schedules.[123] EV-A71 vaccines also represent the first step toward the development of future multivalent HFMD vaccines.[124,125]

22 Epstein-Barr Virus Vaccines

Henry H. Balfour Jr

Epstein-Barr virus (EBV) is a ubiquitous human pathogen that infects at least 90% of the world's population.[1] EBV causes infectious mononucleosis, which can result in significant loss of time from school or work in developed countries.[2] EBV is responsible for a number of cancers including endemic Burkitt lymphoma,[3] nasopharyngeal carcinoma (NPC),[4] a subset of Hodgkin lymphomas,[5] lymphomas in HIV-infected individuals,[6] aggressive natural killer (NK) cell leukemia/lymphoma,[7] X-linked[8] and posttransplantation[9] lymphoproliferative disorders, and gastric carcinoma.[10] Finally, EBV infection, especially if it manifests as infectious mononucleosis, is considered to be a major risk factor for the development of multiple sclerosis.[11] Additional evidence for the EBV–multiple sclerosis connection is mentioned in the "Suggestions for Future Development of Epstein-Barr Virus Vaccines" section below.

Despite the enormous disease burden attributed to EBV, progress on EBV vaccines has been painfully slow partly because of the lack of a suitable animal model other than nonhuman primates, selection of the appropriate antigen and adjuvant, and debate over what such a vaccine could actually achieve.[12] An ideal prophylactic vaccine might be one that provides sterilizing immunity, meaning that after vaccination, the host can never be infected by the same pathogen. In reality, both live attenuated and subunit viral vaccines do not elicit sterilizing immunity. Rather, they reduce the severity of disease caused by subsequent natural infection. This is likely true for all vaccines, including EBV. There actually could be an advantage to this in that subclinical or mild "reinfection" would likely boost the host's vaccine-induced immunity and potentially extend its duration of protection.

CONSIDERATIONS FOR DEVELOPING PROPHYLACTIC EPSTEIN-BARR VIRUS VACCINES

A live prophylactic EBV vaccine would be unacceptable because EBV is oncogenic. Consideration must therefore focus on choosing a viral antigen or antigens most likely to prevent infection. A prototype candidate subunit prophylactic vaccine is gp350, the major envelope glycoprotein of EBV, first proposed by Epstein in 1976.[13] The reason is that EBV has exquisite specificity for human B cells via attachment of gp350 to CD21, also known as the CR2 receptor, the C3d receptor, or the EBV receptor.[14,15] Anti-gp350 antibody would be expected to block attachment of EBV to the B cell and hence prevent endocytosis of the virions into B cells where they can establish infection and latency. In support of this concept, gp350 antibody and EBV neutralizing antibody are closely associated.[16]

A number of studies in cottontop tamarins have confirmed that vaccine containing EBV gp350 can protect against a subsequent EBV challenge infection and associated malignancy.[17–19] However, the method of preparation of the vaccine appears to be crucial, because a major EBV membrane antigen (EBV-MA) vaccine purified by monoclonal antibody immunoaffinity chromatography rather than sucrose density gradient centrifugation elicited neutralizing antibodies in cottontop tamarins, but did not protect them from lymphoma after challenge with B95-8 strain EBV.[20] The most likely reason for this was that the monoclonal antibody was too specific and selected the wrong viral antigen.

Rhesus lymphocryptovirus (RLCV) infection resembles human EBV infection in that Rhesus macaques can be infected orally, shed RLCV from their throat, develop lymphocytosis and lymphadenopathy, and become latently infected.[21] A recent investigation by Sashihara and colleagues showed that RLCV gp350 vaccine protected against challenge infection and reduced viremia.[22] Three different vaccines were compared in this study: soluble RLCV, a virus-like replicon particle expressing RLCV gp350, and virus-like replicon particles expressing RLCV gp350, EBV nuclear antigen (EBNA)-3A and EBNA-3B. Animals given soluble gp350 had the highest gp350 antibody titers, the lowest rate of infection after challenge, and the lowest level of viral DNA in the blood 2 years after challenge. These results suggest that a prophylactic vaccine containing gp350 alone might be more effective than one targeting both gp350 and EBNA-3 proteins in reducing the incidence of infection and viral load in persons who are exposed to wild virus following vaccination.

PROPHYLACTIC EPSTEIN-BARR VIRUS VACCINES TESTED IN CLINICAL TRIALS

Two very different prophylactic vaccine constructs have been tested in humans: those designed to elicit gp350 antibodies and a vaccine to induce production of EBV-specific $CD8^+$ T-cells (Fig. 22.1).

Subunit gp350 Vaccines

Two subunit prophylactic gp350 EBV vaccines have been evaluated in human subjects. The first vaccine, developed by Gu and colleagues,[23] was created by transfecting human embryonic lung cells with a *Vaccinia* virus construct from the smallpox vaccine strain *Tien Tan*, which contained the major EBV-MA. The majority of this material, we now know, was gp350. Cells demonstrating cytopathic effect were harvested and the supernatant from these lysed cells was found to contain high titers of infectious recombinant virus.

After demonstrating that the candidate vaccine was immunogenic in rabbits, the investigators conducted a series of three clinical trials. The first study assessed safety by inoculating 11 healthy adults who had previously received the *Tien Tan* vaccine. Three vaccine recipients had febrile reactions and local vaccinia lesions with antibody responses to *Vaccinia*. The other eight subjects had mild inflammatory reactions at the scarification sites but no antibody responses to *Vaccinia*. None of the 11 volunteers had a rise in antibody titers to EBV. In the second trial, six school children ages 8 and 9 years who were latently infected with EBV and had previously received *Tien Tan* vaccine were administered the EBV vaccine. The vaccine was safe and 1 month after vaccination, eight of the nine developed antibodies to EBV-MA and to *Vaccinia* virus. None had a rise in antibodies against EBV viral capsid antigen (VCA), which meant that the response to EBV-MA was not a result of reinfection by EBV circulating in the community.

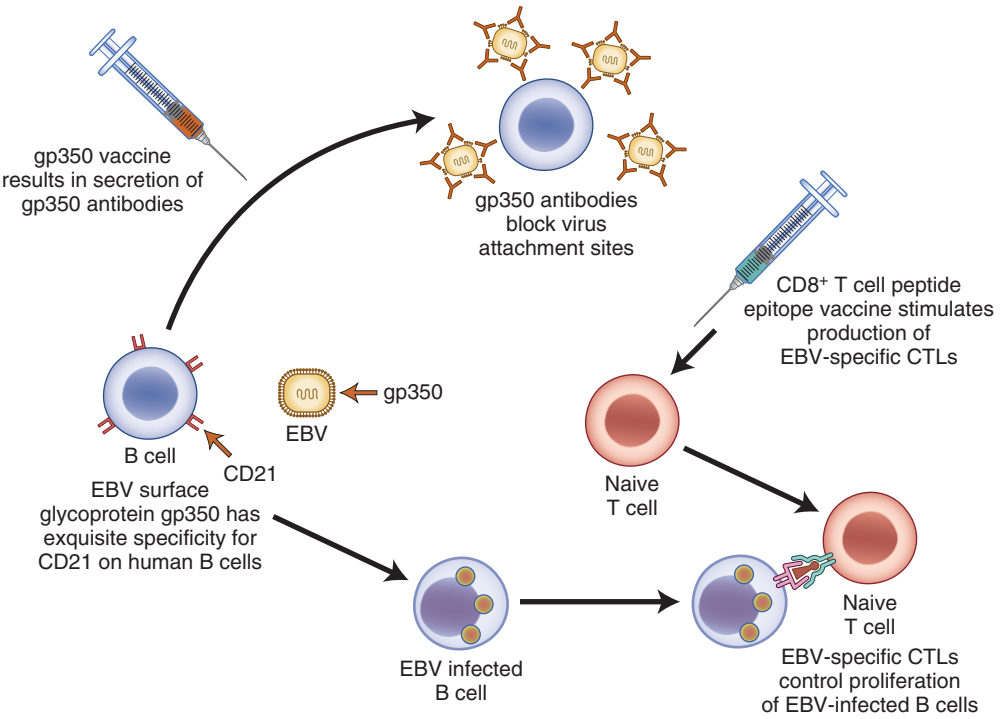

Figure 22.1. Prophylactic Epstein-Barr virus (EBV) vaccine strategies. gp350 and CD8+T cell peptide epitope vaccines. CTLs, cytotoxic lymphocytes.

The final trial enrolled 19 EBV-naïve children who were 1.7 to 2.8 years old and who had not received *Tien Tan* vaccine previously. Nine children were vaccinated while 10 served as unvaccinated controls. The vaccine was safe and all nine vaccinees developed antibodies to EBV-MA and *Vaccinia*. During 16 months of follow-up, three of nine vaccinees and 10 of 10 in the control group became infected with EBV as evidenced by development of antibodies against EBV VCA ($P = .003$, Fisher exact test, two-sided). This supports the authors' conclusion that "it has been shown for the first time that protection against and/or delay of EBV infection by the natural route is possible in humans." The authors state that "live *Vaccinia* vectors can be used and are efficacious." However, a live *Vaccinia* vector in a prophylactic vaccine is unlikely to be acceptable today given the severe adverse events associated with using smallpox vaccine to enhance bioterrorism preparedness.[24]

The second subunit prophylactic gp350 EBV vaccine that has been tested in human subjects was developed by Jackman and colleagues.[25] They reported the successful production of a recombinant gp350 in Chinese hamster ovary cells and showed by antibody and CD21 binding studies that it closely resembled native gp350. This construct administered with Freund adjuvant or alum elicited gp350 and neutralizing antibodies in rabbits. An EBV vaccine produced by this technology has been subsequently evaluated in four clinical trials.

Two sequential double-blind, randomized controlled trials were reported by Moutschen and colleagues.[26] The first was a Phase I study evaluating safety and immunogenicity of gp350 vaccine in 67 volunteers (mean age: 21.4 years; range: 18–25 years). The subjects were stratified by EBV antibody status and then randomized to receive 50 µg of gp350/0.5 mL adjuvanted with either 3-*O*-desacyl-4′-monophosphoryl lipid A and aluminum salt (AS04) or aluminum salt alone. Vaccine was administered intramuscularly according to a 0-, 1-, and 6-month schedule.

One severe adverse event was noted 10 days after receiving a second dose of gp350 adjuvanted with AS04. This previously EBV antibody-positive subject developed severe flu-like symptoms with headache and meningismus followed by arthritis of the knees, ankles, and lower back. The subject fully recovered within 2 months. The authors wrote that "a causal relationship with the vaccine could not be excluded."

Fifty-one of the subjects participating in the Phase I study were analyzed for immunogenicity. All 25 antibody-negative subjects had a gp350 antibody response when tested 1 month after the third dose of vaccine. The geometric mean titer (GMT) was significantly higher among the subjects given AS04-adjuvanted vaccine when compared with those who received alum as the adjuvant (727 vs 498). All 26 antibody-positive subjects experienced at least a fourfold rise in gp350 antibody titers, with the GMT slightly higher among those subjects given AS04-adjuvanted vaccine (1188 vs 1076). Neutralizing antibody responses were seen in 100% of antibody-negative subjects who received AS04-adjuvanted vaccine as compared with 44% among the antibody-negative subjects given gp350 with alum. Among the antibody-positive subjects, fourfold boosts in neutralizing antibody titers occurred in 71% of those given AS04-adjuvanted vaccine as compared with 56% given alum as the adjuvant. Thus, in the Phase I trial, gp350 adjuvanted with AS04 was consistently more immunogenic than gp350 adjuvanted with alum.

In the Phase I/II study, 81 EBV-naïve subjects (mean age: 21.8 years; range: 18–37 years) were randomized 1:1:1 to receive unadjuvanted vaccine, vaccine adjuvanted with AS04, or vaccine adjuvanted with alum. Like the Phase I study, vaccine was administered as a 50 µg of gp350/0.5 mL dose intramuscularly according to a 0-, 1-, and 6-month schedule.

The vaccine was considered to be safe, but one notable reaction was reported. A subject with a history of migraine experienced a severe headache associated with vomiting 27 days after receiving the second dose of vaccine. Because of the

vaccinee's past history of migraine, the relationship of migraine with the vaccination was classified as unlikely.

All 71 evaluable subjects had gp350 antibodies when tested 1 month after the third vaccination. The GMTs were as follows: unadjuvanted vaccine, 258; alum-adjuvanted, 1053; AS04 adjuvanted, 1251. The GMT of the group that received unadjuvanted vaccine was statistically significantly lower than the GMTs of the other two groups. A similar trend was noted for neutralizing antibodies assayed either by inhibition of EBV-infected B-cell proliferation[25] or by a competition immunoassay that measured the ability of vaccine-induced antibody to block binding of a murine anti-gp350 monoclonal antibody (72A1) to gp350.[27]

In summary, the Phase I/II trial of the gp350 vaccine confirmed the immunogenicity results of the Phase I study showing that AS04 was a better adjuvant than alum. The Phase I/II study also indicated that unadjuvanted gp350 was inferior to the adjuvanted preparations.

The third trial was a Phase II, placebo-controlled, double-blind study evaluating safety, immunogenicity, and efficacy of recombinant gp350 vaccine in EBV-naïve young adults ages 16 to 25 years.[28] The vaccine contained 50 μg of gp350 and 50 μg of AS04 in a 0.5 mL volume that was given intramuscularly according to a 0-, 1-, and 5-month schedule. The primary end point was the incidence of infectious mononucleosis disease in vaccine and placebo groups 18 months after administration of the second dose of clinical trial material as documented by clinical criteria along with EBV antibody responses to nonvaccine antigens. EBV infection was defined as development of EBV antibody responses to non-vaccine antigens in the absence of clinical infectious mononucleosis. The study enrolled 181 subjects (mean age: 20.6 years; 52% male; 97% white) who were assigned to vaccine or placebo in a 1 : 1 ratio. No serious adverse events were reported. Almost all (76/77; 98.7%) of the vaccine recipients who were not subsequently infected by wild-type EBV developed gp350 antibodies. The 72A1 competition immunoassay was employed to detect neutralizing antibody.[27] Neutralizing antibody levels peaked 1 month after the third dose "with 69.86% (95% confidence interval [CI], 58.00–80.06%) showing seroconversion at that point in time." Presumably, this pertained only to the vaccine recipients.

During the 19-month follow-up period, EBV vaccine did not prevent infection: 13 (14%) of 90 vaccine recipients became infected versus 18 (20%) of 91 placebo subjects. However, vaccine had a significant effect on the development of clinical disease. In the intent-to-treat population, infectious mononucleosis developed in only two (2%) of 90 vaccinees as compared with nine (10%) of 91 placebo recipients (P = .03; Fisher exact test; one-sided).

This study is noteworthy in that it was the first to demonstrate protection against clinical infectious mononucleosis by an EBV subunit vaccine.[29] However, it had limitations, including EBV viral loads were not measured, the neutralizing antibody results were difficult to interpret, and there was no assessment of cell-mediated immune responses.

The fourth study was a Phase I trial of recombinant gp350 vaccine with an aluminum hydroxide adjuvant in 16 pediatric renal transplantation candidates.[30] Subcutaneous dosing regimens of 12.5 μg or 25 μg of gp350 given three or four times (weekly for the first three doses with a fourth dose at weeks 30 to 32 if not yet transplanted) over a total of 32 weeks were well tolerated. Three subjects were excluded because they did not complete the two immunogenicity evaluations. All 13 evaluable subjects had an anti-gp350 antibody response but only four subjects made neutralizing antibody. Because there was no control group, vaccine efficacy could not be evaluated. This small Phase I trial showed that immunization of children awaiting transplantation for chronic renal disease is feasible, but the low amounts of adjuvanted gp350 given were probably insufficient to elicit an optimal immune response.

CD8$^+$ T-Cell Peptide Epitope Vaccine

A different vaccine approach is to control expansion of EBV-infected B cells by generating CD8$^+$ T-cell immunity to EBNAs. The potential role of these viral proteins in B-cell transformation precludes their use in whole-protein–based vaccines, and therefore a peptide vaccine was generated and tested in adult volunteers.[27] This trial used an EBNA-3A peptide epitope restricted by human leukocyte antigen (HLA)-B8 with tetanus toxoid formulated in a water-in-oil adjuvant as a source of T-cell help.[31] EBV-naïve adults between the ages of 18 and 50 years were given two vaccinations 2 months apart. Of the 14 enrolled subjects, eight individuals were immunized with a 5-μg dose of peptide with adjuvant, two were immunized with a 50-μg dose of peptide with adjuvant and, four received placebo. This strategy was effective at generating a peptide-specific CD8+ T-cell response in most individuals as measured by ex vivo peptide-specific interferon-γ production. During the 2- to 12-year follow-up, five of 10 vaccinees acquired wild-type EBV infection. One subject, most likely infected shortly after the first vaccination, developed infectious mononucleosis. Two of four placebo subjects were infected, one of whom developed infectious mononucleosis. Although all four subjects infected after two vaccinations were asymptomatic, suggesting that the vaccine may have prevented symptomatic EBV infection, the sample size was too small to definitively address this issue.

The practicality of epitope vaccines is limited by the fact that they only target specific HLA types and thus cannot be used in the general population. Nevertheless, epitope vaccines might be effective for prophylaxis for patients with posttransplant lymphoproliferative disorder (PTLD) whose HLA type is known. This trial was a proof of concept that an EBV vaccine that generated CD8+ T-cell immunity was safe and did not predispose subjects to disease after primary infection by wild-type EBV.

PROPHYLACTIC EPSTEIN-BARR VIRUS VACCINE CANDIDATES WITH IMMUNOGENICITY IN BALB/c MICE

Several novel EBV vaccines are promising in that they have demonstrable immunogenicity in mice. Ruiss and colleagues described the production of virus-like particles (VLPs) in which the EBV proteins EBNA-2, latent membrane protein 1 (LMP1), EBNA-3A, EBNA-3B, EBNA-3C, and BZLF1 were deleted or functionally inactivated.[32] Because the viral genome also lacked the terminal repeat signal sequences required for packaging viral DNA, the VLPs did not contain detectable EBV DNA. This vaccine was shown to have human B-cell tropism in vitro, and elicited EBV-specific neutralizing antibodies and cellular immune responses in BALB/c mice.

Cui and colleagues designed a tetramer containing the first 470 amino acids of gp350 and showed that this construct elicited approximately 19- to 20-fold higher gp350 antibody titers in vaccinated BALB/c mice as compared with its monomeric counterpart.[33] This concept could prove valuable if adjuvanted monomeric gp350 vaccines are ultimately shown to have unsatisfactory immunogenicity.

Ogembo and colleagues developed a subunit vaccine based on a novel Newcastle disease virus (NDV)-VLP platform consisting of EBVgp350/220 fused to NDV-fusion (F) protein.[34] The chimeric protein EBVgp350/220-F was incorporated into

the membrane of a VLP composed of the NDV matrix and nucleoprotein. The particles produced resembled native EBV in diameter and shape and were found to bind both CD21 and CD35. Vaccination of BALB/c mice with these EBVgp350/220-F VLPs elicited antibodies to gp350 that were predominantly of the immunoglobulin G_1 subclass, and neutralizing antibodies, which prevented infection of Raji cells by a recombinant EBV construct containing enhanced green fluorescent protein to enable quantitation.

TREATMENT OF EPSTEIN-BARR VIRUS–SPURRED DISEASES BY TRANSFERRING OR STIMULATING CELL-MEDIATED IMMUNITY

Therapeutic vaccines could be effective for a number of EBV-spurred diseases, especially NPC and EBV-positive lymphomas. The goal of therapeutic vaccines is to eliminate tumor cells by stimulating T-cell responses against the EBV antigens they express as listed in Table 22.1. Several reports suggest that providing EBV-specific cellular immunity can be beneficial at least in the short term.

In children at risk for PTLD after hematopoietic cell transplantation, intravenous infusions of EBV-specific T cells (mainly CD8+) from HLA-matched unrelated donors or mismatched family donors reduced EBV viremia and possibly caused regression of EBV disease in three of 10 patients.[35] Autologous cytotoxic T lymphocytes (CTLs) targeting LMP1 alone or LMP1 and LMP2 were given to 50 patients with histologically proven EBV lymphomas (Hodgkin lymphoma, 25; NK cell leukemia/lymphoma, 11; diffuse B-cell lymphoma, 7; miscellaneous diagnoses, 7). Twenty-nine high-risk or multiple-relapse patients treated in remission had a 2-year event-free survival rate of 82%, which the authors considered to be a therapeutic response.[36]

In another study, 10 patients with advanced, relapsed NPC were given infusions of autologous EBV-specific CTLs.[37] The CTL infusions were associated with reduced levels of EBV DNAemia and also appeared to have antitumor activity. Four of six patients with disease that was resistant to or had relapsed after intensive chemotherapy and radiation had complete or partial remissions. All four patients who were in remission at the time of CTL infusions remained disease free after 19 to 27 months.

Smith and colleagues treated NPC patients who had regional recurrent or metastatic disease with EBV-specific autologous T cells, which were generated by exposure to an adenoviral vector–based vaccine that encoded EBNA-1 fused to multiple CD8+ T-cell epitopes from LMP1 and LMP2.[38] EBV-specific autologous T cells were successfully expanded in 16 (73%) of 22 patients. The median overall survival of the 14 patients given CTLs was 523 days as compared with 220 days for six subjects who did not receive CTLs. The authors did not say whether or not this was statistically significant. They commented that "these preliminary observations will require confirmation in a formal Phase II randomized clinical trial."

Finally, in the realm of adoptive immunotherapy, 35 patients with metastatic and/or locally recurrent NPC were treated with chemotherapy followed by EBV-specific CTLs, which resulted in better response and survival rates than chemotherapy alone.[39] The authors concluded, "Our study achieved one of the best survival outcomes in patients with advanced NPC, setting the stage for a future randomized study of chemotherapy with and without EBV-CTL."

In the realm of therapeutic vaccines for NPC, Lin and colleagues used autologous dendritic cells incubated with LMP2 peptides to vaccinate patients with NPC.[40] After four injections into inguinal lymph nodes, $CD8^+$ T-cell responses to LMP2 were induced by the peptides in nine of 16 patients, two of whom also experienced tumor reduction.

Taylor and colleagues created a candidate poxvirus vector EBV vaccine expressing a fusion protein containing the carboxyl terminus of EBNA-1 (to stimulate $CD4^+$ T cells) fused to LMP2 (to stimulate EBV-specific $CD8^+$ T cells).[41] They showed that dendritic cells infected by this vaccine reactivated LMP2-specific $CD8^+$ T cells and EBNA-1–specific memory T cells in peripheral blood mononuclear cells from EBV antibody-positive donors.

A Phase I dose-escalation study using this same poxvirus vector EBV vaccine (called modified vaccinia virus Ankara with EBNA-1 and LMP2 [MVA-EL]) was conducted in 18 subjects with NPC.[42] Subjects received one of five doses ranging from 5×10^7 to 5×10^8 plaque-forming units (PFU) intradermally at 3-week intervals for a total of three inoculations. The vaccine was well tolerated with no evidence of dose-limiting toxicity. Overall, 15 of 18 patients developed T-cell responses to one or both vaccine antigens. There was a dose–response relationship with the highest dose producing the strongest response. A parallel dose-escalation study of EBV MVA-EL vaccine was performed on 16 subjects in the United Kingdom, with the recommendation being that the highest dose (5×10^8 PFU intradermally) be used for subsequent Phase I and Phase II trials because it produced the broadest and strongest immune response.[43]

TABLE 22.1 Expression of Latent Epstein-Barr Virus (EBV) Genes on EBV-Spurred Tumor Cells Are Targets for Therapeutic Vaccines or Adoptive Immunotherapy

Condition	Latent EBV Genes Expressed by Tumor Cells
Posttransplant lymphoproliferative disorder	EBNA-1, -2, -3A, -3B, -3C LMP1, LMP2
X-linked lymphoproliferative disease	EBNA-1, -2, -3A, -3B, -3C LMP1, LMP2
Hodgkin lymphoma	EBNA-1 LMP1, LMP 2
Nasopharyngeal carcinoma	EBNA-1 LMP 1, LMP 2
Burkitt lymphoma	EBNA-1

EBNA, Epstein-Barr virus nuclear antigen; LMP, latent membrane protein.

SUGGESTIONS FOR FUTURE DEVELOPMENT OF EPSTEIN-BARR VIRUS VACCINES

The global burden of EBV-associated diseases is enormous. EBV vaccines could potentially reduce this burden significantly. For prophylactic vaccines, ideal diseases for efficacy trials in order of probable success are infectious mononucleosis, PTLD, and endemic Burkitt lymphoma. A vaccine containing gp350 antigen is a logical first choice to test because gp350 vaccine has been shown to protect against infectious mononucleosis in a Phase II clinical trial.[28] Prevention or reduction in severity of infectious mononucleosis should be the end point of the next Phase II or Phase III efficacy trial because a susceptible population with a high incidence of this illness—college freshmen—is at hand. In prospective studies of EBV-naïve University of Minnesota undergraduates, the incidence of primary EBV infection among freshmen was 26%, and 75% of those infected had typical infectious mononucleosis.[44,45] Such a proposed efficacy trial of the vaccine would include

periodic viral load measurements on all subjects after vaccination, because there is a statistically significant correlation between the quantity of virus in the blood and disease severity.[44,46] If the vaccine is shown to reduce blood viral load among subjects who are infected with wild virus after vaccination, then its effectiveness in preventing malignancies appears promising. Increased blood viral loads have been associated with the development of PTLD,[47] and increased plasma EBV DNA correlates with a worse outcome in Hodgkin lymphoma.[48] To gain insight into the duration of protection, it would also be worthwhile to evaluate EBV gp350-specific memory T-cell responses in vaccinees and to determine whether T cells in vaccinated individuals undergo EBV-induced changes in interleukin-15 receptor expression.

PTLD would be the next logical disease to study because EBV-naïve hematopoietic stem cell or solid-organ transplantation candidates who are at the highest risk could be identified and vaccinated pretransplantation. This trial also could also assess the effect of vaccination on the quantity and duration of EBV DNAemia, which could be responsible for posttransplantation morbidity in the absence of full-blown PTLD. Endemic Burkitt lymphoma and NPC are serious malignancies and hence worthy targets for preventive trials. Burkitt lymphoma may be the better candidate for a field trial because its "incubation period" is shorter and there are known high-incidence geographic foci where investigations could be conducted.[49] EBV vaccine might also reduce the incidence of Hodgkin lymphoma. The gp350 vaccine has been shown to protect against infectious mononucleosis and a history of infectious mononucleosis increases the risk of EBV-positive Hodgkin lymphoma by more than threefold.[50]

An EBV vaccine could conceivably reduce the incidence and/or severity of multiple sclerosis (MS), which is a common neuroinflammatory disease with more than 2,000,000 cases worldwide. EBV is a prominent, if not the number one, environmental risk factor for MS. The evidence for this is that nearly 100% of MS patients have EBV antibody[51]; their antibody levels are markedly elevated especially against EBNA-1[52]; a history of infectious mononucleosis increases the risk of developing MS[53]; EBV-specific $CD8^+$ T-cell responses are elevated during active MS[54]; and therapies with monoclonal antibodies that deplete the B-cell reservoir of latent EBV[55] or infusions of autologous virus-specific T cells[56] have a beneficial effect in MS.

In terms of therapeutic vaccines, the MVA-EL vaccine that contains part of the carboxyl terminus of EBNA-1 to stimulate CD4+ T cells fused to LMP2 to stimulate EBV-specific CD8+ T cells is the leading candidate.[41–43] In addition to NPC, this vaccine could have activity against EBV-positive lymphomas because these tumor cells also express EBNA-1 and LMP2.

BARRIERS TO EPSTEIN-BARR VIRUS VACCINE DEVELOPMENT

The promising prospects for EBV vaccines cannot be fulfilled until some knowledge gaps and practical issues are overcome. A major problem in EBV vaccine development is to find an industry sponsor or a consortium of investors willing to support it. Sponsors, if found, face challenges in implementing successful field trials in humans. For example, the optimum vaccine formulation—including both the antigen construct and the adjuvant—needs to be determined. Would the best vaccine be adjuvanted gp350 alone or would gp350 combined with EBV gH, gL, and gB (to induce protection from infection of oral epithelial cells) be more effective?[57,58] Could adjuvants more potent than those used in the published trials be incorporated?

If the first Phase III trial is to prevent infectious mononucleosis, the major beneficiaries would be EBV antibody-negative individuals. Because EBV antibody prevalence is tightly related to age, and if the goal is to choose a vaccine cohort in which 50% of individuals are EBV-naïve, what age should be chosen? Two studies have found that the age-specific EBV antibody prevalence is different among whites and nonwhites.[59,60] Whites do not reach 50% antibody prevalence until their teenage years, whereas nonwhites reach it between the

TABLE 22.2 Status of Epstein-Barr Virus (EBV) Vaccines

Disease	Clinical Trials Reported	Comments
Infectious mononucleosis	Prophylactic vaccines: Adjuvanted gp350 vaccine 4 Phase I[23,26,30]; 1 Phase II[28] CD8+ T-cell epitope vaccine 1 Phase I[31]	The logical target for further development of a prophylactic vaccine
Nasopharyngeal carcinoma	Adoptive immunotherapy[37–39] Therapeutic vaccines: dendritic cells incubated with LMP2 peptides 1 Phase I[40] Modified vaccinia Ankara with EBNA-1 and LMP2 (MVA-EL) 2 Phase I[42,43]	Best data are for MVA-EL vaccine
Posttransplant lymphoproliferative disorder	Adoptive immunotherapy[35]	The second choice as target for further development of a prophylactic vaccine
EBV-positive lymphomas	Adoptive immunotherapy[36]	Clinical trial possible but would be lengthy and require a large number of subjects
Endemic Burkitt lymphoma		Clinical trial feasible in focal areas of East Africa where disease is endemic
Miscellaneous		
Chronic active EBV Gastric carcinoma X-linked lymphoproliferative syndrome Multiple sclerosis		Severity of these entities makes them worthy of prophylactic and/or therapeutic vaccine trials

ages of 4 and 6 years. This creates a dilemma for establishing a uniform vaccination policy.

A daunting challenge for therapeutic EBV vaccine trials is that subjects for these, most likely patients with NPC or lymphomas, have complex management strategies that can confound interpretation of the results. Nevertheless, based on some encouraging results discussed above, continuation of therapeutic vaccine trials is warranted.

CONCLUSIONS

EBV is a common worldwide human pathogen that causes acute and chronic infections, cancers, and autoimmune disease. Prophylactic and therapeutic vaccines could prevent or reduce the severity of some, if not all, of these conditions, but they are not yet available for general use (Table 22.2). Our charge is to find the resources from government, industry and/or philanthropy to conduct the studies necessary to make effective EBV vaccines available to all those who will benefit from them.

23 *Haemophilus influenzae* Type b Vaccines

Srinivas Acharya Nanduri, Andrea R. Sutherland, Lance K. Gordon, and Mathuram Santosham

Prior to use of vaccination, *Haemophilus influenzae* type b (Hib) was responsible for significant morbidity and mortality worldwide in children, especially in those younger than 2 years of age. In 2000 alone, an era when Hib vaccine was in routine use in nearly all high-income and most middle-income countries, and had virtually eliminated Hib pneumonia, meningitis, and other related illnesses, Hib was estimated to still cause 8.13 million cases and 371,000 deaths,[1] a burden of disease that ranked as a leading cause of death among children younger than 5 years of age globally. In addition to mortality, more than 30% of children who develop Hib meningitis suffer from neurologic sequelae.

In November 2006, the World Health Organization (WHO) universally recommended the implementation of Hib vaccination in all infant immunization programs worldwide, regardless of the availability of local or national surveillance data.[2] In 2008, the WHO estimated that more than 200,000 children died from Hib. While introduction of Hib conjugate vaccine was slower in developing countries than in industrialized countries, all countries except for China and Thailand have included Hib vaccine in the Universal Immunization Programs (UIPs), although China has achieved more than 50% uptake through the private market. India, which accounts for more than 20% of global child mortality, has introduced Hib into the UIP; however, the vaccine has been implemented in the UIP in only 16 of the 36 States and Union Territories as of August 2015. As of May 2015, a report from the International Vaccine Access Center (IVAC) at Johns Hopkins University noted that more than 35% of the world's children still do not have access to Hib vaccine because of lack of introduction or underimmunization.[3]

Routine use of Hib conjugate vaccines has resulted in a remarkable decline in Hib disease in developed and developing countries. Because most serious *H. influenzae* disease is caused by serotype b, efforts in vaccine development largely focused on Hib. Therefore, this chapter focuses primarily on the vaccines for Hib disease. However, other strains of *H. influenzae* are also important causes of illness, and more recent efforts in vaccine development for the other strains are also briefly reviewed.

HISTORY

H. influenzae was first identified as a pathogen in 1883 by Koch, who described small gram-negative rods in pus obtained from patients with conjunctivitis.[4] During the 1889 influenza pandemic, Pfeiffer isolated *H. influenzae* (which he called "Pfeiffer's bacillus") from postmortem cultures and described it as the causative organism of "influenza."[5] During the 1918 influenza pandemic, *H. influenzae* was recognized as a separate entity from the organism that causes influenza.[6]

In 1931, Pittman categorized *H. influenzae* into two major groupings: encapsulated and nonencapsulated.[7] Encapsulated strains produce a polysaccharide capsule, which is a major virulence factor. These capsules were further characterized into six antigenically distinct serotypes (a through f), which differ in chemical and antigenic composition.[7]

In 1933, Fothergill and Wright demonstrated that the great majority of Hib meningitis cases occurred in children younger than 5 years of age,[8] and that older children and adults had naturally acquired antibodies that were protective against serious Hib disease. In subsequent years, rabbit hyperimmune serum was used as an immunotherapy for Hib infections, and antibodies against the Hib polysaccharide capsule were demonstrated as the curative component.[9]

Despite the discovery of effective antimicrobial agents in the mid-1940s, Hib continued to cause significant morbidity and mortality. The case fatality ranged from 40% to 90%, and 30% to 40% of survivors had neurologic sequelae. Thus scientific advancements and recognized public health impact prompted efforts to develop effective Hib vaccines.

The first-generation Hib vaccine contained the pure polysaccharide of the Hib capsule. The polysaccharide vaccine was licensed for routine use in the United States in the early 1980s but was poorly immunogenic in children younger than age 18 months, and did not protect the age group with the highest Hib disease burden.[10] Several of the Hib conjugate vaccines that were evaluated in the mid 1980s were immunogenic in children younger than 2 years of age. Initially, the Hib conjugate vaccines were licensed for use in the United States in children between 12 and 18 months of age.[11] Subsequently, in 1990, two vaccines (PRP-OMP[polyribosylribitol phosphate–outer membrane protein] and PRP-CRM [polyribosylribitol phosphate–CRM_{197}]) were licensed for routine use among infants younger than 6 months age based on two efficacy trials.[12] The incidence of Hib disease dropped dramatically soon after introduction. Other developed countries adopted the vaccine soon after the United States with equally dramatic results. These vaccines have virtually eliminated Hib disease in areas in which they are routinely used.[13]

Uptake of the Hib vaccine was slow in low- and middle-income countries. In 2000, no Asian countries and only one country in the sub-Saharan African, South Africa, had adopted the Hib vaccine in the UIP. A few additional countries began to adopt Hib vaccines between 2000 and 2005, but uptake by low- and middle-income countries remained low. In 2005, the Hib Initiative which consisted of a consortium of four institutions (Johns Hopkins University, London School of Hygiene and Tropical Medicine, CDC [Centers for Disease Control and Prevention], and WHO) was established through funding by GAVI, the vaccine alliance.[14] The Hib Initiative helped stakeholders and Ministries of Health establish disease burden and strongly encouraged all GAVI-eligible countries to adopt Hib-containing vaccines. Currently, all the GAVI countries have introduced Hib-containing vaccines.

BACKGROUND (BOX 23.1)

Microbiology

H. influenzae is a non–spore-forming gram-negative coccobacillus. It requires two accessory (X and V) factors for growth in vitro, both naturally present in erythrocytes. The X factor is a porphyrin, such as hemin, and the V factor is nicotinamide adenine dinucleotide.[15] The requirement of both of these factors for multiplication differentiates *H. influenzae* from other *Haemophilus* species.

BOX 23.1 Key Points: Background

- Serotype b of *Haemophilus influenzae* (Hib) is the most important in human pathogenesis.
- Hib is a non–spore-forming, gram-negative coccobacillus.
- Hib was a leading cause of serious disease, particularly in childhood.
- Antibodies to the Hib polysaccharide capsule (polyribosylribitol phosphate [PRP]) provide protection against Hib disease.
- Compared with the pure polysaccharide vaccine, Hib conjugate vaccines are more immunogenic in younger children and induce immunologic memory.

A polysaccharide capsule is a major virulence factor for several bacteria, including *H. influenzae*. The capsule is thought to facilitate evasion of the mucosal immune response by resisting the bactericidal and opsonic activities of complement and protecting the bacterium from phagocytosis.[16,17] The greater pathogenic potential of type b encapsulated *H. influenzae* strains as compared with the other encapsulated *H. influenzae* serotypes has been the subject of intense investigation.[18–21] Hib possesses a capsule composed of polyribosylribitol phosphate (PRP), the structure of which was initially described in 1975.[22] The Hib polysaccharide capsule is thought to be effective for evading complement-mediated killing and to avoid splenic clearance.[16,23]

In addition to the chemical composition of PRP, certain aspects of the genetic basis of PRP capsule production could also explain the particular virulence of the type b capsule. All encapsulated strains have a *cap* locus that contains the genes necessary for capsule production. For type b strains, this region of genes is designated as *cap b*. Experiments have shown that the *cap b* region of particularly invasive type b strains contains a DNA duplication.[24–26] Several mechanisms have been proposed to explain how this *cap b* duplication/multiplication could result in increased virulence. First, strains with this duplication make more of the hydrophilic capsular polysaccharide, which may make them more resistant to dehydration during transmission or mucosal invasion.[18,27] Second, the presence of the *cap b* duplication has been shown to result in decreased susceptibility to complement-mediated lysis and opsonization.[28] Several isolates from the blood and cerebrospinal fluid (CSF) of invasive Hib disease cases have been shown to be heavily encapsulated strains with five or more copies of the *cap* locus.[24,25] (Importantly, some isolates of invasive strains of non–type b *H. influenzae* organisms have also shown amplification in their *cap* loci; the significance and prevalence of this mutation in non–type b strains is the subject of ongoing investigation.[29,30])

There are also noncapsular factors that contribute to the virulence of Hib and other *H. influenzae* strains. An important component of the *H. influenzae* cell envelope is the lipooligosaccharide (LOS), which contains endotoxin. It has been suggested that genes encoding LOS of type b strains result in the expression of certain surface-exposed epitopes that are toxic to the epithelial cells of the upper respiratory tract of animals.[31,32] The LOS of certain Hib strains may also aid in protecting the organism from host immune defenses by affecting the ability of the organism to survive and replicate in macrophages.[26,33] Another noncapsular virulence factor is the expression of pili. Several strains of *H. influenzae* are capable of expressing pili, which are considered to have a role in mediating adherence to host cells.[34] Piliated variants of Hib have shown increased binding to human oropharyngeal cells in vitro compared with nonpiliated organisms.[35] In addition, the ability to alternate between piliated and nonpiliated forms may also increase the virulence of the organism.[36] In a nasopharyngeal tissue culture model, Hib was shown to bind to the mucus above the epithelial surface, with piliated organisms having a growth advantage at this stage. At 12 hours into infection, Hib organisms were seen intracellularly, with nonpiliated bacteria having an advantage at this invasion stage.[37] This variable expression of pili enables the organism to adapt successfully at the different stages of colonization and infection, thus acting as an important virulence factor.[38]

Immunology

Anticapsular Antibodies and Titers

Pure polysaccharide antigens are recognized by B-cell receptors, but because they cannot be presented to T cells in conjunction with major histocompatibility complex class II molecules, they are T-cell independent.[20] With T-cell independent immune responses, the development of memory B cells does not occur, and immunologic memory is not induced. Thus, with the pure polysaccharide vaccines, there is no booster antibody response to revaccination.[39] In addition, polysaccharide antigens induce relatively low titers of serum antibodies in children younger than 2 years of age.[39] The reason for the poor antibody response in young children remains unclear, but on the basis of animal models has been attributed to immunologic immaturity, increased suppressor T-cell activity, immature antigen processing by macrophages, and absence of a late-appearing class of T-cell independent B cells that play a role in the production of antipolysaccharide antigen immunoglobulin (Ig) G antibody.[20,40]

Protein Conjugation

In the early 1930s, Avery and Goebel showed that the immunogenicity of small oligosaccharide or polysaccharide molecules could be increased by covalently bonding them to protein carriers.[36] Conjugating a protein carrier to Hib polysaccharide is an effective method for creating a vaccine capable of recruiting T cells into the immune response.[20] The resulting T-cell–dependent conjugate antigens differ from T-cell–independent polysaccharide antigens in two important ways. First, the protein-polysaccharide conjugate antigens are immunogenic in infants younger than 6 months of age. Second, protein-polysaccharide conjugate antigens are capable of eliciting a booster response.[20,41]

Pathogenesis

Hib is an obligate human pathogen that spreads from person to person via respiratory droplets and direct contact with respiratory secretions. It enters the body via the upper respiratory tract and colonizes the pharyngeal mucosa. Hib disease is caused by direct spread via the respiratory tract or by invasion of the pharyngeal mucosal surface and subsequent hematogenous spread. Disease episodes in which Hib is isolated from blood, CSF, or other normally sterile fluids such as pleural fluid are termed "invasive."

Individuals may remain colonized with Hib for up to 6 months without clinical symptoms or contracting disease.[42] In the prevaccine era, 3% to 5% of healthy preschool-age children in developed countries were asymptomatic Hib carriers.[43–45] Prevalence of pharyngeal carriage varies with age,[43,44,46] geographic location,[44,46] crowding,[43,44] and vaccine coverage[47,48] in the population. Before routine vaccine use in

the United States, carriage prevalence among white infants was low (0.7%) in the first 6 months of life and increased to approximately 2% in the 6- to 11-month age group.[44] The highest prevalence (up to 5%) was seen in the preschool-age group, and the prevalence gradually declined in adulthood.[43] However, among Navajo and Apache infants before the use of the Hib conjugate vaccines, the prevalence of carriage was 3% in children as young as 3 months of age,[46] which may have contributed to the high incidence rates of invasive Hib disease seen in young children in these populations.[49,50] Studies in India and Thailand from the prevaccine years showed Hib carriage prevalence of 6% to 8%.[51,52] Household crowding and attendance at a daycare center where there is an infected child are associated with an increased risk of carriage.[44,53,54] A study in Alaskan Native children showed that a ratio of more than two persons per room in a household was associated with increased Hib carriage risk (odds ratio [OR] 1.2; 95% confidence interval [CI], 1.1–1.5).[55] Only a small fraction of people colonized with Hib become ill. It has been hypothesized that disruption of the respiratory epithelium, such as with viral infection, cigarette smoke, or indoor air pollution, facilitates binding to and/or penetration of the upper respiratory tract by various bacteria.[56–58]

Recent viral infections are a risk factor for developing invasive Hib disease.[59] Viral infections could increase the risk for developing invasive Hib disease by facilitating attachment of Hib to the pharyngeal epithelium or invasion of Hib into the bloodstream.[60] One study showed that rats infected intranasally with influenza A virus had increased frequency and magnitude of bacteremia following subsequent inoculation with Hib.[61]

Once Hib enters the bloodstream, the organism causes disease at distant sites if not cleared by the host immune system. The occurrence of different disease syndromes is thought to depend, at least partially, on the density of organisms circulating in the host bloodstream.[62] For Hib meningitis, a density of 10^3 colony-forming units (CFU) per milliliter was needed in the bloodstream for at least 6 hours in infant primate models.[63] Studies in children with Hib meningitis demonstrate that the majority had more than 10^3 CFU/mL of Hib circulating in the blood at admission implying that serious consequences of infections with Hib such as meningitis are more likely to occur when there is a higher concentration of Hib in the blood.[64,65]

Laboratory Diagnosis

Hib is difficult to isolate in blood cultures. Culturing Hib from blood or other infected body fluids requires specific transport and growth conditions. Ideally, processing should occur within a few hours of specimen collection. Bacterial growth requires chocolate agar or another medium that contains the accessory factors hemin and nicotinamide adenine dinucleotide, a 3% to 5% carbon dioxide environment, and a constant temperature between 35°C and 37°C. Of note, antibiotic use before specimen collection reduces the sensitivity of culture significantly.[66]

Newer, immunologic, nonculture diagnostic methods are more sensitive and rapid, especially in settings where conditions for Hib isolation from traditional culture methods are not ideal because of the use of antibiotics prior to obtaining laboratory specimen or poor laboratory facilities for performing bacterial cultures. Studies demonstrate that analysis of CSF by polymerase chain reaction (PCR) has 100% sensitivity and 75% to 96% specificity compared with culture.[67,68] In addition, PCR is able to identify Hib in CSF even in the presence of prior antibiotic use.[68,69] Detection of the Hib polysaccharide antigen in the CSF is diagnostic of Hib meningitis. Available CSF antigen-detection methods include counterimmunoelectrophoresis (CIE), coagglutination, latex agglutination (LA), and latex particle agglutination (LPA). The CIE method uses an applied electrical field across a diffusion medium to evaluate the binding of an antibody to an antigen. Coagglutination involves mixing an agglutinin into a sample to observe the aggregation of the antigens. The LPA method involves mixing a sample with latex beads coated with an antibody to observe whether clumping occurs by an antigen binding with the antibodies. One study compared all three detection methods with CSF culture and found that LPA had a sensitivity of 78% and specificity of 100%; CIE, a sensitivity and specificity of 67%; and coagglutination, a sensitivity of 78% and specificity of 97%.[70] As with PCR, antigen detection can be more useful than culture in the diagnosis of Hib meningitis cases that have been pretreated with antibiotics.[71] These newer diagnostic techniques were essential to demonstrate the burden of disease, particularly in Asia where blood culture rates for Hib in CSF were low because of antibiotic use prior to diagnosis or poor/limited diagnostic capabilities.

The Hib polysaccharide antigen can also be detected in the urine. There has been interest in the use of urine antigen detection to aid in the diagnosis of Hib disease, particularly Hib pneumonia. In studies of patients with bacteremic pneumonia and meningitis, detection of antigenuria using LPA had a sensitivity of 90% to 100%.[72–74] In contrast, CIE had a very low sensitivity of 44%.[74] The specificity of the Hib antigenuria approach is limited by four factors: first, Hib carriage can cause Hib antigenuria even in the absence of clinical disease[75]; second, nonspecific agglutination can occur[76,77]; third, there is cross-reactivity with certain bacteria such as *Escherichia coli* K1 and K100 and *Streptococcus pneumoniae* type 6[74,76,78]; and fourth, vaccination with conjugate Hib vaccine has been shown to induce transient Hib antigenuria.[79] Studies in Navajo infants in the United States and in The Gambia have shown a prevalence of antigenuria in children of more than 80% in the first week following Hib conjugate vaccine, and antigen excretion persisted for several weeks after vaccination in some children.[80,81] In contrast, a study in Bangladesh showed transient antigenuria in only 8% of 90 vaccine recipients that lasted only 1 to 4 days after vaccination.[73] Urine antigen testing was explored as a field based/easier methodology; however, it was limited by poor specificity as it also was positive in carriage states. Given the widespread use of vaccine and decrease in disease burden, there is less interest now to explore such diagnostic methods.

Clinical Entities Caused by *Haemophilus influenzae* Type b

Hib can cause a variety of clinical syndromes such as meningitis, pneumonia, orbital cellulitis empyema, osteomyelitis, septic arthritis, cellulitis, bacteremia without focus, and infections of other organ systems. Other diseases that have been associated with Hib include epididymitis, endocarditis, peritonitis, and tracheitis. These diseases have virtually disappeared in areas that have adopted the conjugate vaccine. Nonetheless, it is important to educate healthcare providers in countries about the devastating consequences of Hib disease in countries where Hib vaccines are not used. Fig. 23.1 shows the distribution of bacterial culture–positive invasive Hib diseases seen globally in the prevaccine era. Unfortunately, even in developing countries that have adopted the vaccine, the poorest children who are at highest risk for disease and serious consequences of the disease may not have access to the vaccine. Hib can also cause diseases in the respiratory tract disease,

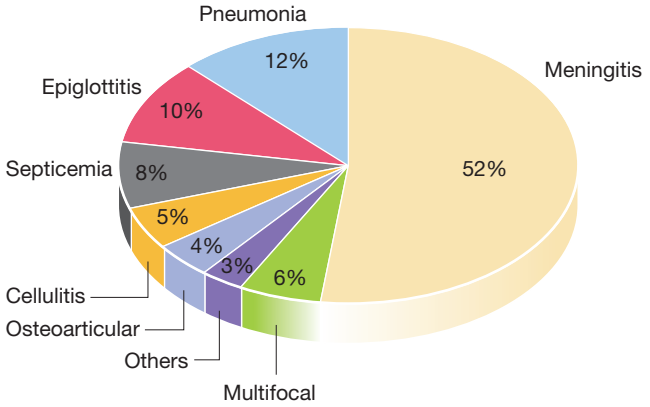

Figure 23.1. Distribution of clinical syndromes associated with invasive *Haemophilus influenzae* type b (Hib) disease worldwide. Worldwide spectrum of all classic (nonbacteremic pneumonia excluded) Hib diseases, taken from data for 3931 patients in 21 studies from various parts of the world. *(From Peltola H. Worldwide Haemophilus influenzae type b disease at the beginning of the 21st century: global analysis of the disease burden 25 years after the use of the polysaccharide vaccine and a decade after the advent of conjugates.* Clin Microbiol Rev. *2000;13:304.)*

including otitis media, sinusitis, and bronchitis. However, the majority of upper respiratory *H. influenzae* disease is caused by nonencapsulated organisms and not Hib.

Haemophilus influenzae Type b Clinical Features

Otitis Media/Sinusitis

Otitis media results when Hib reaches the middle ear by way of the eustachian tube from the site of colonization in the nasopharynx. Although nonencapsulated *H. influenzae* causes more than 90% of *H. influenzae* otitis media, one study from the preconjugate vaccine era showed that approximately 6% of *H. influenzae* otitis media confirmed by middle-ear fluid culture was caused by Hib.[82] In addition, Hib otitis media was often a precursor to more serious invasive disease. Otitis media caused by Hib is a risk factor and in some studies the primary focus of infection for invasive disease.[83,84] As with otitis media, nontypeable *H. influenzae* strains are the most common causes of acute and chronic sinusitis.[85,86] However, in the prevaccine era, Hib was also a documented cause of bacterial sinusitis.[87,88]

Pneumonia

Hib pneumonia cannot be clinically distinguished from pneumonia caused by many other bacteria or viruses. Furthermore, there are no laboratory methods that are noninvasive, sensitive, and specific for identifying Hib as the cause of pneumonia, as blood cultures are often negative.[89] Culturing of fluid collected transthoracically from peripheral consolidation or pleural effusion can identify the causative organism in some cases of pneumonia.[90] However, the procedure cannot be used to identify the etiology of nonconsolidative pneumonia without effusion, and transthoracic aspirates are too invasive for routine use. Blood cultures are highly specific for Hib pneumonia but have low sensitivity (10–20%).[91] Reliance on blood cultures alone can result in underestimations of the role of Hib in causing pneumonia. Bronchoscopy has sensitivity and specificity of more than 85% for the identification of the etiologic agent of pneumonia; however, the procedure is invasive and requires highly trained personnel with specialized equipment.[92] Sputum culture is of little value because young children usually cannot produce adequate sputum specimens, and there are high rates of false-positive results because many persons are asymptomatic carriers of Hib and it is difficult to differentiate carriage from infection. Also, oropharyngeal or nasopharyngeal carriage of Hib does not correlate with the occurrence of Hib pneumonia.

Because there is no sensitive, specific, noninvasive test to identify Hib pneumonia cases, the incidence of Hib pneumonia is difficult to estimate. An alternative approach to estimating the burden of pneumonia caused by Hib is the "vaccine probe" method.[93–95] A vaccine probe study is a randomized clinical trial of a vaccine of known efficacy. By measuring the difference in disease incidence between vaccinated and unvaccinated groups, a vaccine probe trial can estimate the vaccine-preventable disease burden. It should be noted that the burden of Hib disease estimated in this way is an underestimate of the true Hib disease burden because most vaccines are not 100% effective and most studies do not have 100% case ascertainment. In Indonesia and The Gambia, Hib vaccine was shown to prevent approximately 5% of cases of clinical pneumonia as defined by the presence of lower chest wall retractions.[93,95] In The Gambia and Chile, Hib vaccine prevented approximately 20% of pneumonia cases with alveolar consolidation.[94,95] In contrast, a significant reduction in radiologically confirmed pneumonia was not seen with Hib vaccine in Indonesia.[93] A case-control study in Bangladesh showed that three doses of Hib conjugate vaccine reduced radiologically confirmed pneumonia by 17% to 44%, with the measured effect varying depending on the radiologist and control group used.[96] Two case-control studies from South America also found that Hib conjugate vaccine prevented a substantial portion of radiologically confirmed pneumonia—31% in Brazil and 56% in Colombia.[97,98] These results from studies of Hib vaccine effectiveness against pneumonia vary owing to different methods and different case definitions, but they all show that Hib was an important cause of pneumonia in young children (Table 23.1). A review and metaanalysis of vaccine probe studies in children younger than age 5 years estimated that Hib is responsible for 5% (uncertainty range: 1–9%) of clinical pneumonia and 21% (uncertainty range: 3–36%) of pneumonia with radiographic consolidation worldwide in children younger than age 5 years.[1]

Meningitis

Infectious meningitis occurs when an organism invades the meninges, resulting in inflammation and edema. Several studies in animal models have shown that Hib enters the CSF via the choroid plexus, where inflamed capillaries allow the organism to enter the ventricular fluid.[99] The organism then multiplies and stimulates the release of cytokines and other inflammatory mediators. The classic symptoms of meningitis are fever, bulging fontanelle, stiff neck, and altered mental status; however, in young infants, these classic signs may not be present and meningitis may instead manifest as altered consciousness, poor feeding, hypothermia or hyperthermia, and/or irritability. Without treatment, case fatality ratios from Hib meningitis are as high as 90%. Even with appropriate treatment, case fatality ratios for Hib meningitis range from 3% to 5% to 60% depending on the type of healthcare available to the child and complications such as mental retardation, cerebral palsy, hearing loss, and seizure disorders are common.[100–102] Reported rates of neurologic sequelae following Hib meningitis in survivors range from 15% to 30% in

TABLE 23.1 Calculated Vaccine Efficacy for Pneumonia Using Different Case Definitions in Various Vaccine Probe Trials

Reference	Location	Case Definition	Vaccine Efficacy (95% Confidence Interval [CI])
CLINICAL TRIALS			
Gessner et al.[98]	Indonesia	Radiologically confirmed[a] Clinically defined[b]	–3.9% (not specified) 4.0% (0.7% to 7.1%)
Mulholland et al.[96]	The Gambia	Radiologically confirmed[a] Clinically defined[b]	21.1% (4.6% to 34.9%) 4.4% (–5.0% to 12.9%)
VACCINE EVALUATION

de la Hoz et al.[101]	Colombia	Radiologically confirmed[a]	47% (2% to 72%)
Baqui et al.[99]	Bangladesh	Radiologically confirmed[a]	34% (6% to 53%) in community control subjects; 44% (20% to 61%) in hospitalized control subjects

[a]Exact case definition varies, but this corresponds to consolidation or pleural effusion on chest radiograph as described by the World Health Organization (WHO).
[b]As defined by the WHO; includes tachypnea and retractions.
[c]Case definition included any of the following: alveolar consolidation, pleural effusion, erythrocyte sedimentation rate ≥40 mm/h, or bronchial breath sounds.

developed and developing countries.[103–105] A metaanalysis showed a median risk of 9.5% (95% CI, 7.1–15.3%) of at least one major sequela from Hib meningitis, with highest rates of long-term disabling sequelae occurring in low-income countries.[106] In developed countries, Hib meningitis had a case fatality ratio of at least 3%,[107] and case fatality ratios of 20% to 60% have been reported in developing countries, probably a result of poorer access to care and appropriate antibiotics.

Diagnosis of meningitis requires analysis of a CSF sample obtained by lumbar puncture. With appropriate transport and processing of specimens, analysis of CSF is a highly sensitive method for the diagnosis of Hib meningitis. However, in areas where appropriate laboratory support is not readily available, or antibiotics are given pre-CSF specimen collection, diagnosis of Hib meningitis can be difficult. A review and metaanalysis estimated a global Hib meningitis incidence rate of 31 per 100,000 (uncertainty range: 16–39 per 100,000) in children younger than age 5 years in 2000.[1] A study in Indonesia showed a vaccine-preventable, laboratory-confirmed Hib meningitis incidence rate of 16 (95% CI, 1.4–31) per 100,000 children younger than 2 years, but the rate of meningitis with CSF findings consistent with a bacterial cause (not necessarily culture-confirmed) prevented by Hib vaccine was 67 (95% CI, 22–112) per 100,000 children younger than 2 years of age.[93] The results of this study suggests that bacterial cultures identify less than 25% of probable meningitis cases in areas of the world where antibiotics are extensively used prior to obtaining CSF specimen.

Epiglottitis

Acute epiglottitis is the swelling and inflammation of the epiglottis and surrounding structures. Classic symptoms include sore throat, dysphagia, stridor, and high fever. If appropriate management, including airway establishment and antibiotic therapy, is not instituted, the disease can progress rapidly to airway obstruction and death. In the prevaccine era, Hib was responsible for 75% to 90% of epiglottitis cases in U.S. children.[108] Epiglottitis also was a common manifestation of Hib disease in other developed countries.[109,110] Rates in Scandinavia were extremely high; annual rates in Sweden ranged from 4.5 to 32 per 100,000, with the highest rates in children 3 to 4 years old.[109] However, epiglottitis was rare among indigenous populations in developed countries, including Australian Aboriginals and Alaskan/Canadian Inuit,[111,112] and in most developing countries.[113] The reason for this geographic difference is not clear but may relate to age at exposure. In populations with low epiglottitis incidence, the majority of serious Hib disease cases occurred in children younger than 1 year of age, suggesting that while early exposure to Hib led to other clinical presentations, later exposure predisposed to epiglottitis.

Septic Arthritis and Osteomyelitis

Septic arthritis is a result of an organism invading the synovial fluid and most commonly occurs in the lower extremities. Common clinical manifestations include joint pain, local swelling and erythema, limited range of motion, and fever. Sequelae are fairly common, including limitation of motion, limping gait, limb-length discrepancy, and abnormal bone growth.[114,115] In the prevaccine era, Hib was the most common cause of septic arthritis in children younger than age 2 years in the United States.[116] According to one study in Canada conducted before the availability of Hib vaccines, Hib was identified in 41% of cases of culture-positive septic arthritis.[117] Hib was a less-common cause of osteomyelitis in the prevaccine era. An estimated 5% of culture-positive osteomyelitis was caused by Hib.[117]

Facial and Orbital Cellulitis

Before conjugate vaccine introduction, Hib was a common cause of orbital, periorbital, and facial cellulitis.[118] Periorbital cellulitis caused by Hib was associated with bacteremia in up to 80% of cases, which was often associated with meningeal seeding and subsequent intracranial infection.[118–120] Hib was also a cause of facial cellulitis, including a syndrome of buccal cellulitis accompanied with bacteremia. In one series of facial cellulitis cases in the United States before the use of Hib vaccines, 82% were attributed to Hib.[121]

Non–Type b Encapsulated *Haemophilus influenzae* Disease

While non–type b encapsulated *H. influenzae* can cause meningitis and sepsis, the overall invasive disease burden resulting from non–type b encapsulated *H. influenzae* is low in relation to that caused by the type b strains. In the United States between 1998 and 2000, the rate of non–type b *H. influenzae* invasive disease was 0.8 cases per 100,000 children younger than 5 years of age.[122] In Canada, the incidence of non–type b disease was 0.11 per 100,000 per year in 2011.[123] During the years 1992 to 2006, surveillance data from 14 European and other countries identified a 3.5% (CI 2.1–5.2) annual increase in invasive non–type b *H. influenzae* disease.[124]

Nontypeable *Haemophilus influenzae* Disease

Nontypeable *H. influenzae* strains are ubiquitous colonizers of the respiratory tracts of children and adults.[125,126] Studies document pharyngeal carriage rates of approximately 50% in children younger than 2 years of age.[127] Nontypeable *H. influenzae* is a well-known cause of otitis media, sinusitis, and pneumonia.[128,129] Rarely, the organisms can cause invasive disease as well, particularly in children younger than 4 years of age and in people with underlying serious medical conditions, especially in those who are immunocompromised.[126,130,131]

Treatment and Antibiotic Resistance

Treatment of Hib disease requires early assessment and identification of the illness, administration of appropriate antibiotic therapy, and supportive management of sequelae. Therapy should be based on patterns of antibiotic resistance in the community. In the United States, the American Academy of Pediatrics (AAP) recommends that initial empiric therapy for suspected Hib meningitis should be cefotaxime or ceftriaxone. Meropenem or the combination of ampicillin and chloramphenicol are alternative regimens.[132] The WHO recommends initial therapy with chloramphenicol in combination with ampicillin or benzylpenicillin for suspected Hib meningitis.[133] If the cause is unknown, some experts recommend the addition of vancomycin to the empiric regimen owing to widespread resistant pneumococci.[132] Subsequent therapy should be guided by the antibiotic susceptibility profile of the organism and clinical/national guidelines.

Chemoprophylaxis of household contacts is recommended in certain cases because of the occurrence of secondary infections. In the prevaccine era, several documented cases of Hib occurred in close contacts of index cases, such as co-daycare attendees and household contacts.[54,134,135] Rates of secondary disease were documented to be approximately 0.6% in one study, with contacts younger than 2 years of age at highest risk.[136,137] One national study showed that for Hib meningitis in the 30 days following initial illness, the risk for household contacts was 585 times the risk in the age-adjusted general U.S. population.[138] Currently, chemoprophylaxis with rifampin is recommended for all household contacts of a case of Hib if the household has a child younger than 12 months of age who has not received the primary series, a child younger than age 4 years who is incompletely immunized, or an immunocompromised child. Daycare contacts should receive prophylaxis only if two or more cases of invasive Hib disease have occurred within 60 days.[132] Antibiotics that are usually used for the treatment of meningitis often do not eliminate Hib from the upper airway; therefore, the index case may require a different antibiotic to eliminate carriage.[139]

The relevance of the recommendation for rifampin prophylaxis should be reevaluated in countries where there is widespread use of Hib vaccines. If the index case has been in contact with unimmunized children, it is appropriate to consider rifampin prophylaxis. Between 1972 and 1974, the first antibiotic-resistant Hib isolates were reported in Europe and the United States. Since then, the proportion of resistant strains has increased across the world.[140] Studies show that 20% to 60% of isolates produce β-lactamase and are resistant to ampicillin.[141,142] Other antibiotics to which resistance has been shown include chloramphenicol, tetracycline, and trimethoprim-sulfamethoxazole (TMP-SMX). Emerging resistance to the cephalosporins has been shown; for example, in Mali, of 207 Hib isolates from blood, 0.5% were resistant to ceftriaxone.[143,144] A study in Korea carried out between 1992 and 1997 showed that of 55 Hib strains, 15% had only intermediate susceptibility to cefprozil and cefaclor.[143] Multidrug-resistant Hib has also been demonstrated. In Bangladesh in a study carried out from 1999 to 2003, 31% of Hib isolates were multidrug-resistant.[145] In Spain, 11% of isolates in one study from year 2000 were resistant to multiple antibiotics, with 3% of strains resistant to ampicillin, tetracycline, and chloramphenicol.[146] In a study from Kenya looking at Hib susceptibility to amoxicillin, chloramphenicol, and TMP-SMX, of a total of 236 blood or CSF isolates from children admitted with meningitis or sepsis, 40% were resistant to at least two antibiotics and 28% were resistant to all three antibiotics. In addition, resistance to these three antibiotics increased significantly during the 9 years of the study spanning from 1994 to 2002.[147] Surveillance studies in Latin America from before the year 2000 demonstrated that 21% of invasive *H. influenzae* (type b and non–type b) isolates were β-lactamase producers, 21% to 32% were ampicillin-resistant, and 26% to 49% were TMP-SMX–resistant.[148,149] Significant levels of resistance to ampicillin, chloramphenicol, and TMP-SMX in addition to an increasing trend of β-lactamase–producing strains have also been seen in other Asian and African countries.[145,150,151] The problem of antibiotic resistance is particularly challenging in the developing world because Hib is often resistant to the antibiotics commonly used for empiric therapy and antibiotics that remain effective against Hib are expensive or unavailable. Although judicious use of antibiotics and continued development of new antimicrobial drugs should remain priorities, vaccination remains the most powerful tool for reducing the burden of antibiotic-resistant disease.

EPIDEMIOLOGY IN THE PREVACCINE ERA (BOX 23.2)

Before the routine use of Hib conjugate vaccines, more than 95% of all invasive *H. influenzae* disease was caused by serotype b.[152] The annual incidence of invasive disease caused by Hib in the general U.S. population was estimated at 20 to 88 per 100,000 children younger than 5 years of age,[153–155] with approximately 20,000 recognized cases each year, more than 50% of which were cases of meningitis.[156] Reported rates of invasive disease in Europe varied. Studies in Spain and France showed invasive disease rates of 12 and 21 cases per 100,000, respectively.[157,158] Reported rates in Scandinavia were higher; the incidences reported from Finland and Sweden were 41 and 54 cases per 100,000 children younger than age 5 years, respectively.[158,159] It is not clear whether these differences in reported incidence rates reflect differences in surveillance methods or true differences in disease incidence.[1]

Certain U.S. populations were at higher risk of Hib disease. For example, the incidence of invasive Hib disease in Navajo and Apache children was found to be 152 and 250 per 100,000 children younger than 5 years of age, respectively.[49,160] Alaskan Eskimos were documented to have rates of invasive Hib disease of 491 per 100,000 children younger than 5 years of

BOX 23.2 Key Points: Epidemiology in the Prevaccine Era

- Before routine use of *Haemophilus influenzae* type b (Hib) conjugate vaccines, more than 95% of invasive *H. influenzae* disease was caused by serotype b.
- The annual incidence of Hib invasive disease in the general U.S. population was estimated at 20 to 88 cases per 100,000 children younger than age 5 years before Hib conjugate vaccine introduction.
- Young age (<2 years) is the predominant risk factor for invasive Hib disease.
- Other risk factors for invasive Hib disease include belonging to certain racial or ethnic groups, lower socioeconomic status, living in crowded conditions, and having concomitant serious medical conditions, particularly HIV infection.
- The WHO estimates that in 2000 (before widespread vaccine use), Hib was associated with more than 8 million serious illnesses and 371,000 deaths per year. The majority of these occurred in resource-limited settings where the Hib conjugate vaccines were not in routine use.

age.[161] Australia reported similar population differences in rates of Hib invasive disease. Nonindigenous children had an incidence rate for Hib invasive disease ranging from 33 to 60 cases per 100,000 children younger than 5 years of age, while indigenous children were found to have rates as high as 500 per 100,000 children younger than 5 years of age.[162]

Studies in Africa have consistently found high rates of Hib disease. For example, in Uganda and The Gambia, the incidence rates of Hib meningitis in children younger than 5 years of age were 88 and 60 per 100,000 before vaccine introduction, respectively.[162] Significant rates of Hib disease have also been documented in the Middle East and the Pacific island countries.[163–165]

In Asia, data on Hib disease burden have emerged more recently.[166–168] A review of studies from Asia published between 1998 and 2009 showed that Hib was identified in 60% of studies that reported the etiology of bacterial meningitis and that the incidence rate of Hib meningitis ranged from 0.98 to 28 per 100,000 children younger than 5 years of age.[168] A surveillance study of children younger than age 5 years in Sri Lanka showed Hib was responsible for 50% of the 108 meningitis cases in which an etiology was identified.[169] A prospective population-based surveillance study in India showed a Hib meningitis incidence of 7.1 per 100,000 (95% CI, 3.1–14.0) children younger than 5 years.[170] An expert panel that reviewed the literature on Hib disease in Asia concluded that many studies underestimated the true incidence of Hib because of antibiotic use before diagnostic testing, delayed contact with health providers, low rates of lumbar puncture, and inadequate specimen processing.[166] Another possible explanation for the low observed incidence of Hib meningitis in some countries is that widespread antibiotic use may actually change the epidemiology of Hib disease by altering transmission patterns or the progression of disease. In an effort to address these issues, vaccine probe studies were carried out in Indonesia and Bangladesh.[93,96] In Indonesia, Hib conjugate vaccine prevented 67 (95% CI, 22–112) cases of probable bacterial meningitis and 158 (95% CI, 42–273) cases of clinically diagnosed meningitis or seizures per 100,000 child years in children younger than 2 years of age.[93] Of note, the incidence of laboratory-confirmed Hib meningitis was only 16 per 100,000 child years in children younger than 2 years of age, suggesting that even under clinical trial conditions, laboratory confirmation of Hib meningitis is difficult. As noted, the burden of Hib pneumonia is difficult to measure, but several studies have shown that Hib conjugate vaccine prevents a significant proportion of clinical pneumonias and pneumonias with radiographic consolidation in children.[1,93,96]

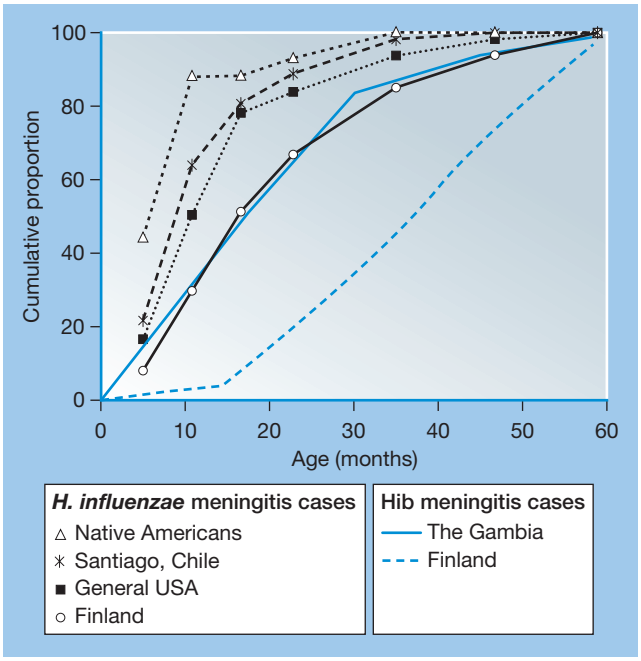

Figure 23.2. Cumulative proportion of *Haemophilus influenzae* type b (Hib) meningitis cases by age and geographic location. Figure shows cumulative proportion of cases of *H. influenzae* meningitis at successive ages <60 months for children in Santiago, Chile and cumulative distribution of Hib meningitis cases by age in The Gambia and Finland. *(Data from Ferreccio C, Ortiz E, Astroza L, et al. A population-based retrospective assessment of the disease burden resulting from invasive Haemophilus influenzae in infants and young children in Santiago, Chile.* Pediatr Infect Dis J. *1990;9: 491 and Watt JP, Levine OS, Santosham M. Global reduction of Hib disease: what are the next steps? Proceedings of the meeting Scottsdale, Arizona, September 22–25, 2002*. J Pediatr. *2003;143[6 Suppl]: S165.)*

Risk Factors

Age

Age is a major risk factor for invasive Hib disease, with children younger than 2 years of age at highest risk. Of note, the incidence of invasive Hib disease in children younger than 2 months of age is low, presumably owing to protection from transplacentally derived maternal antibodies. The age at which peak attack rates occur varies by geographic location. Fig. 23.2 shows the distribution of Hib meningitis cases by age in different geographic locations. Data from 1978 to 1998 from Western Europe showed that the majority of cases occurred in the second year of life, and fewer than 20% of cases had occurred by 6 months of age,[171] while in indigenous and developing country populations, the majority of cases occurred in the first year of life, with 30% to 50% of cases having occurred by 6 months of age.[49,112,151,172]

Race/Ethnicity

The risk of invasive Hib disease has been reported to be elevated in several ethnic groups. In the prevaccine era, African American children in the United States had rates of Hib meningitis that were up to fourfold higher than white children.[173–175]

As mentioned in "Epidemiology in the Prevaccine Era" above, Native American populations in Alaska and the continental United States had the highest incidence of invasive Hib disease in the world.[49,50,112,160] A similar higher incidence of invasive Hib disease was seen in Australian Aboriginal populations when compared with the non-Aboriginal population.[111] Whether differences in rates between various ethnic groups are a result of biological differences in the host or other factors, including genetic or environmental factors, remains unclear.[176] One study found that after controlling for various sociodemographic factors and for sickle cell disease, African Americans did not have a higher rate of Hib disease than other races.[176] Some studies have looked for genetic markers that may be associated with increased disease risk in certain communities.[177,178] Genes that increase *and* decrease susceptibility to Hib disease have been identified. For example, in Alaskan Eskimos, children with a γ-marker (GM) allotype were found to have increased susceptibility to invasive disease if associated with the human leukocyte antigen (HLA)-DR8 allele but a decreased susceptibility if associated with the HLA-DR5 allele.[179]

Sociodemographic Factors

Several factors that are often used as surrogate markers for low socioeconomic status have been associated with increased risk of Hib disease, including low household income, low parental education, and large household size.[173,180–182] The independent effect of each of these and other related risk factors has been difficult to isolate. In a multivariate analysis, Cochi and colleagues showed that household crowding was associated with a 2.7-times increased odds of Hib disease (95% CI, 1.3–5.6).[176] Other investigators also found that household crowding resulted in increased risk of Hib disease.[183–185] An increased number of siblings, particularly of preschool and elementary school age, and the presence of extended family groups were associated with an increased risk of Hib disease.[175,181,182,184] Daycare attendance also had a strong association with increased risk of invasive Hib disease, particularly in children younger than 2 years of age.[84,137,176,186] Hib can survive for up to 48 hours on toys that were placed in the mouths of children who were asymptomatic Hib carriers; therefore, communal toys may serve as fomites for the transmission of Hib.[187] Given that these sociodemographic factors would also impact vaccine access and coverage, their influence on disease still remains relevant and difficult to quantify.

Concomitant Medical Conditions

Serious medical conditions, particularly conditions resulting in immunosuppression, are also recognized risk factors for Hib disease. Hemoglobinopathies such as sickle cell disease, complement deficiency, antibody deficiency, and asplenia, are associated with increased risk of Hib disease.[188–191] The incidence and severity of Hib disease is also higher in adults and children with HIV infection.[192,193] Antecedent viral respiratory infections are associated with increased Hib carriage and increased susceptibility to Hib meningitis.[46,59] This could be from the enhanced transmission of virus through the increased production of respiratory secretions or damage to the respiratory epithelium by the virus, resulting in increased attachment or invasion by Hib into the bloodstream.[194]

Breastfeeding

Several studies show that in children younger than 6 months of age, breastfeeding is protective against invasive Hib disease.[84,176,181,186] Although the mechanism for protection is unknown, it is thought to be from immunologic or nutritional cofactors that are transmitted from the mother. Studies have shown that human milk contains secretory antibody to the Hib PRP capsule.[195]

PASSIVE IMMUNIZATION

Bacterial Polysaccharide Immunoglobulin

Passive immunization with bacterial polysaccharide immunoglobulin (BPIG) hyperimmunoglobulin was tested in high-risk children in the late 1980s. BPIG was prepared from the plasma of adult volunteers immunized with Hib polysaccharide vaccine, a four-valent meningococcal vaccine, and pneumococcal polysaccharide (14- or 23-valent) vaccines. Compared with conventional immunoglobulin, BPIG contained 10 to 60 times higher concentrations of antibody to Hib polysaccharide.[196] Infants were randomized to receive BPIG or saline placebo at 2, 6, and 10 months of age in a double-blind trial among White Mountain Apache infants in Arizona. The point estimate of efficacy for 4 months following BPIGG administration was 86% (95% CI, −11% to 100%).[197] However, because of the necessity of frequent large-volume injections, the relatively high cost and the subsequent availability of effective conjugate vaccines for this age group, BPIG was not licensed for use in the United States.

ACTIVE IMMUNIZATION (BOX 23.3)

The first definitive demonstration that invasive Hib infections were vaccine preventable was a Finnish trial during an epidemic of meningococcal disease during which a Group A meningococcal vaccine efficacy study was conducted with an investigational Hib capsular polysaccharide (PRP) vaccine as control.[198,199] Statistically significant efficacy of the Hib vaccine was demonstrated in children older than 24 months of age. There were too few children in the 18 to 24 months age group to evaluate efficacy, while children younger than 18 months were not protected.[200] The age-related differences in efficacy correlated well with age-related differences in antibody responses to vaccination. Analysis of infection rates in children who received the vaccine suggested that a level of 1.0 μg/mL of anti-PRP antibody, obtained 1 month after vaccination, was predictive of protection against infection for a period of at least 3 years—that is, the presence of an antibody level of at least 0.15 μg/mL. Analysis of infection rates in children who received the meningococcal vaccine showed that children having a naturally acquired level of 0.15 μg/mL of anti-PRP antibody were resistant to infection.[201] The antibody assay used for this study was a Farr-type radioimmunoassay for total antigen binding protein, which, while useful and well standardized, provided no information regarding the nature of the immune response. For the purposes of vaccine development, the Finnish study provided two useful benchmarks: (a) 1.0 μg/mL of anti-PRP antibody 1 month after vaccination was predictive of protection for longer than 3 years (i.e., presence of

BOX 23.3 Key Points: Active Immunization

- The pure polysaccharide (polyribosylribitol phosphate [PRP]) vaccine is effective in children older than 24 months of age but not in children younger than 18 months of age.
- The *Haemophilus influenzae* type b (Hib) conjugate vaccines are safe and effective in children as young as 6 weeks of age.
- Invasive disease rates have decreased dramatically with routine use of Hib conjugate vaccine in a variety of settings.

antibody levels of at least 0.15 μg/mL), and (b) naturally occurring antibody levels above 0.15 μg/mL were associated with short-term protection. Vaccine development was principally guided by the goals of achieving a 1.0 μg/mL or higher response to vaccination, considered predictive of protection, and an acceptable duration of immunity assessed in long-term follow-up studies as the maintenance of a minimum 0.15 μg/mL circulating antibody.

POLYSACCHARIDE VACCINE

Immunogenicity and Correlates of Protection

As mentioned above the first Hib vaccine to be field-tested was the pure capsular polysaccharide (PRP) vaccine. The level of antibody response to PRP vaccine is age-dependent. After one dose, 8% to 20% of children younger than 12 months of age had an antibody concentration of more than 0.15 μg/mL, and only 2% had a concentration of more than 1.0 μg/mL.[159,202] By contrast, up to 45% of children ages 12 to 17 months had an antibody concentration of more than 1.0 μg/mL, and 50% to 75% of children ages 18 to 23 months mounted such an antibody response.[39,159,201] More than 90% of 4- to 5-year-olds responded with a strong antibody response.[203] While a range of doses elicited a significant immune response in older children, no difference in response was seen in children younger than 12 months of age who were given doses ranging from 0.2 to 50 μg of PRP.[9,204]

The PRP capsular polysaccharide of Hib bacteria is characterized as a T-cell–independent immunogen. While inducing a strong immune response in adults,[205,206] it induces a more modest but still protective level of immunity in children older than 24 months of age.[198] However, the unconjugated PRP vaccine did not induce protective antibody levels in infants younger than 1 year of age.[201,207,208] Characteristic features of the T-cell–independent antibody response to polysaccharide immunogens include the absence of booster responses after administration of repeated doses of the vaccine and the absence of anamnestic responses on reexposure to the antigen.

Persistence of antibody response following immunization is also age-dependent. In children younger than 2 years of age, antibody concentrations rapidly declined to levels similar to unimmunized children in the first few months after vaccination.[39,209] In a follow-up study of children vaccinated with one dose of PRP at ages 18 to 35 months, children who were 1.5 years postvaccination had geometric mean antibody titers of more than 1.0 μg/mL, but children who were 3.5 years postvaccination had geometric mean titers of only around 0.5 μg/mL.[39]

Efficacy

As discussed previously, in a trial designed to evaluate the efficacy of a meningococcal vaccine during an epidemic, the Hib polysaccharide vaccine was used as the control. Finnish children ages 3 months to 5 years were randomized to receive meningococcal vaccine or the Hib polysaccharide vaccine. Children ages 18 to 71 months who received Hib polysaccharide vaccine had a statistically significant reduction in bacteremic Hib disease incidence, and vaccine efficacy was estimated to be 90% (95% CI, 55–98%). Of note, in children younger than 18 months of age, there was no statistically significant difference in rates of bacteremic Hib disease between the two groups.[159,200] Based on these results, the vaccine was licensed in the United States in 1985 for use in children older than 23 months of age and for children 18 to 23 months of age who are considered at high risk for invasive Hib disease.[210] Subsequent case-control studies in the United States demonstrated a range of efficacy of 55% to 92% in children 24 to 72 months old.[211,212]

In general, PRP vaccines were found to be extremely safe in field trials and postmarketing studies, with no association between PRP vaccine and serious reactions found in a 1-year postmarketing surveillance study.[213] There was some concern about an increased risk for Hib infection in the 1 week following vaccination with PRP.[214–217] This corresponded to the observation that the anti-PRP antibody concentrations fell in the first few days after vaccination.[218] Black and colleagues found a 6.4-fold increased risk in the week after vaccination (95% CI, 2.1–19.2) versus a 1.8-fold increase (95% CI, 0.3–10.2) shown by a CDC study conducted across the United States.[214,216] The affected children in both studies were thought to be high risk; they were African American, attended daycare, and had underlying medical conditions.[217] Owing to the subsequent availability of Hib conjugate vaccines, interest in further defining the safety and efficacy of PRP vaccines waned.

CONJUGATE VACCINES

History and Development

While the potential for prevention of Hib disease by vaccination was clear from the Finnish efficacy trial using the pure PRP vaccine, it wasn't until the 1980s that innovative vaccine development accelerated. In addition to the pure PRP polysaccharide vaccine, investigational approaches included partially purified capsular polysaccharide complexes with bacterial membrane fragments,[219] adjuvanting PRP by coformulation with whole-cell pertussis vaccine,[220–222] and PRP conjugated to either diphtheria toxoid, PRP-D,[223] CRM_{197} mutant diphtheria toxoid (HbOC),[224] group B meningococcal outer membrane protein (OMP)[225] or tetanus toxoid PRP-T.[226]

Vaccine development in the 1980s was also stimulated by The National Childhood Vaccine Injury Act of 1986, which included the creation of National Vaccine Program. Another major contributor to the very productive decade of Hib vaccine development was the creation, starting in 1980, of a program for the accelerated development of vaccines within the U.S. Department of Health and Human Services.[227] Through a consultative process managed by the National Academy of Sciences, priorities for the development of new vaccines addressing diseases of importance in the United States and globally were evaluated. Critically, a very high priority was established for the development of vaccines for the prevention of Hib. This allowed the National Institute of Allergy and Infectious Diseases (NIAID) to focus its resources on approaches to accelerating development of new vaccines. Core to this initiative was the NIAID's announcement that it would sponsor a Phase III pivotal efficacy study of a candidate vaccine. NIAID issued two requests for proposals, one to clinical investigators for the design and conduct of the Phase III study and a second parallel request for proposals to vaccine developers for the selection of the best available vaccine for accelerated development in the sponsored efficacy study. In addition to requesting written proposals, the NIAID formed an expert panel to advise on the selection of both the study design/site and of a vaccine to be evaluated in the NIAID study. Investigators were invited to periodic meetings of the expert panel to present and defend their proposals; however, it was a precondition of eligibility that, while confidential to the public, all presentations had to be made in the presence of all contenders. This process assured not only the benefits of the expertise of the independent panel members, but also the deep subject-matter expertise of the principal developers of each of the vaccines and study plans. The NIAID sponsored efficacy study[112,220] was only one of several ways in which the

NIAID program has assisted in the accelerated development of Hib and other vaccines.

Hib vaccines used in the United States include PRP 1985-1988, PRP-D 1987-2000, PRP-CRM_{197} 1990-1997. Hib vaccines currently distributed in the U.S. include PRP-OMP, first licensed in 1989, and PRP-T vaccines, first licensed in 1993. As with all vaccines there has been continued product development well past initial licensure. The first two vaccines to be licensed for immunization of infants below 6 months of age were the PRP-OMP and the HbOC. Both were licensed in 1990. The HbOC vaccine was licensed as a three-dose primary series with a booster dose at 15 months of age or as soon as possible thereafter, and the PRP-OMP was licensed as a two-dose primary series with a booster dose at 12 months of age.[12] While all the PRP conjugate vaccines produced good immune responses after the primary series, only the PRP-OMP vaccine induced a "protective" antibody response after a single dose at 2 months of age. In the efficacy trial conducted on the Navajo reservation, there were eight cases of Hib in the placebo group and zero cases in the vaccine group between the first and second doses ($P < .005$).[12,228] Subsequently an efficacy trial was conducted in The Gambia, which was the first trial to demonstrate efficacy in a developing country against meningitis and blood culture–positive pneumonia. In addition, in a post hoc analysis, The Gambia trial demonstrated a 21% reduction in X-ray–documented pneumonia.[95]

Molecular Basis for Conjugate Vaccines

The objective of developing PRP polysaccharide–protein conjugate vaccines was to convert PRP from a T-cell–independent immunogen to a T-cell–dependent immunogen. The underlying principal was originally described by Landsteiner[229] and first applied to bacterial polysaccharides by Avery and Gobel.[36] Essentially the approach is to combine the T-cell–independent PRP polysaccharide and a T-cell–dependent protein into a single molecule by covalent conjugation. The resulting hybrid molecule has the ability to stimulate a T-cell–dependent antibody response conferred by the carrier protein and the antigenic epitopes of both the carrier protein and the PRP capsular polysaccharide. The carrier protein stimulates activation and proliferation of antigen-reactive T cells, which influence how antigen-reactive B cells respond to the antigenic epitopes on the conjugate. In a T-cell–dependent response, antigen-reactive B cells can either proliferate resulting in an expanded population of antigen reactive B cells or may differentiate into antibody-secreting plasma cells. The proliferation of antigen-specific T and B cells, referred to as clonal expansion, is largely responsible for immunologic memory, the ability to mount an anamnestic or accelerated antibody response on subsequent exposure to the antigen. B-cell differentiation into antibody secreting plasma cells is, however, an end-stage process. The design of a conjugate vaccine consequently involves balancing the stimulation of high levels of circulating antibodies versus high levels of memory cells, enabling anamnestic response to infection. Although the balance will differ between vaccines, Hib conjugate vaccines stimulate both protective levels of circulating antibody and the ability to mount anamnestic responses on challenge.[230–232]

Formulations

Four conjugate Hib vaccines have been developed. Table 23.2 lists the manufacturers and formulations available for use in the United States. Table 23.3 is a similar list of WHO prequalified vaccines for purchase by United Nations agencies for global use. The protein carrier, PRP component size, and chemical linkages are different for all four conjugate vaccines, and there are some differences in the elicited immune response. The vaccines should all be stored between 2°C and 8°C.

PRP-D was produced by Connaught Laboratories. It contained medium-sized lengths of the polysaccharide linked to the diphtheria toxoid carrier. There were no added adjuvants. Thimerosal was added as a preservative. PRP-D was the first Hib conjugate vaccine to be licensed in the United States. It was licensed in the United States for children 15 to 59 months of age in 1987. This product is no longer available. Licensure was based on the demonstration of efficacy in a large-scale field trial conducted in Finnish infants.[233]

The HbOC vaccine contains oligosaccharides derived from purified PRP from the Hib Eagan strain. These are coupled by reductive amination to purified CRM_{197}, a nontoxic variant of diphtheria toxin isolated from *Corynebacterium diphtheriae* C7 (β197). The HbOC vaccine was licensed in the United States in October 1990 for immunization of infants younger than 6 months of age based on a trial conducted at Kaiser Permanante in Southern California by Black and colleagues.[234] This product is no longer available.

The PRP-OMP vaccine is based on a purified PRP from the Hib Ross strain. This is covalently bonded to an outer membrane protein complex of the B_{11} strain of *Neisseria meningitidis* type B. The mixture is formulated with aluminum hydroxyphosphate sulfate and 0.9% sodium chloride. The vaccine was licensed for use in all infants in the United States in December

TABLE 23.2 *Haemophilus Influenzae* Type b Conjugate Vaccines Available in the United States

Product	Trade Name (Manufacturer)	Hib Protein Carrier	Amount of *Haemophilus* b PRP Per Dose (μg)
PRP-OMP	PedvaxHIB (Merck & Co.)	Outer membrane protein complex of *Neisseria meningitidis* strain B_{11}	7.5
PRP-T	ActHIB (Sanofi Pasteur)	Tetanus toxoid	10
PRP-T	Hiberix (GlaxoSmithKline) (booster dose only)	Tetanus toxoid	10
PRP-T/MenCY	MenHibRix (GlaxoSmithKline)	Tetanus toxoid	2.5
PRP-OMP/hepatitis B	Comvax (Merck & Co.) (primary series and booster dose)	Outer membrane protein complex of *N. meningitidis* strain B_{11}	7.5

Product	Trade Name (Manufacturer)	Hib Protein Carrier	Amount of *Haemophilus* b PRP Per Dose (μg)
PRP-T/DTaP-HepB-IPV	Hexaxim (Sanofi Pasteur)	Outer membrane protein complex of *Neisseria meningitidis* strain B_{11}	12
HbOC/DTwP	QuattVaxem (Novartis)	Diphtheria toxin CRM_{197}	10
PRP-T/DTwP	TETRAct-HIB (Sanofi Pasteur)	Tetanus toxoid	10
PRP-T/DTwP	Diphtheria-Tetanus-Pertussis (whole cell)–*Haemophilus influenzae* type b (Serum Institute of India)	Tetanus toxoid	10
HbOC/DTaP-HepB	Quinvaxem (Berna Biotech Korea Corporation, a Crucell Company)	Diphtheria toxin CRM_{197}	10
PRP-T/DTwP	Pentabio (Biofarma, Indonesia)	Tetanus toxoid	10
PRP-T/DTwP	Diphtheria-Tetanus-Pertussis (whole cell)–Hepatitis B–*Haemophilus influenzae* type b (Biological E, India)	Tetanus toxoid	11
PRP-T/DTwP	Tritanrix-Hib (GlaxoSmithKline)	Tetanus toxoid	10
PRP-T/DTwP	Euforvac-Hib (LG Lifesciences, Republic of Korea)		
PRP-T/DTwP	Easyfive-TT (Panacea Biotech, India)	Tetanus toxoid	10
PRP-T/DTwP	Shan-5 (Shantha Biotechnics Private Ltd., India)	Tetanus toxoid	10
PRP-T	Quimi-Hib (Center for Genetic Engineering and Biotechnology, Cuba)	Tetanus toxoid	10
PRP-OMP	Pedvax (Merck & Co.)	Outer membrane protein complex of *N. meningitidis* strain B_{11}	7.5
HbOC	Vaxem Hib (Novartis Vaccines and Diagnostics s.r.l.)	Diphtheria toxin CRM_{197}	10
PRP-T	ActHIB (Sanofi Pasteur)	Tetanus toxoid	10
PRP-T	*Haemophilus influenzae* type b (Serum Institute of India)	Tetanus toxoid	10

DTaP, diphtheria, tetanus toxoids, and acellular pertussis: DTwP, diphtheria and tetanus toxoids combined with whole-cell pertussis; HbOC, Hib oligosaccharide conjugate; HepB, hepatitis B; Hib, *Haemophilus influenzae* type b; IPV, inactivated polio vaccine; PRP, polyribosylribitol phosphate; PRP-OMP, PRP–outer membrane protein; PRP-T, PRP conjugated to tetanus toxoid.

1990 based on an efficacy trial conducted on the Navajo Indian reservation.[228]

PRP-T is made by covalently binding PRP to tetanus toxoid derived in some instances from *Clostridium tetani* Harvard strain. The PRP-T currently available in the United States is produced as a lyophilized powder that is reconstituted at the time of use with 0.4% sodium chloride and contains no preservative. This vaccine was licensed in the United States in March 1993. The licensure of PRP-T was based on immunologic correlates of protection. None of the vaccine manufacturers report the presence of antibiotics in any of the monovalent or combination Hib vaccines.

Immunogenicity

PRP-D elicited a geometric mean antibody response of more than 1.0 μg/mL in a group of 141 children 15 months or older after just one dose.[235] In children 9 to 15 months of age, all subjects achieved antibody titers of more than 1.0 μg/mL after two doses; although titers waned in the following year, a booster dose induced a strong antibody response.[236] However, in children younger than 6 months, the immune response was limited.[221] In addition, the antibody response was suboptimal in some high-risk children, including children with cancer.[237]

The three other conjugate vaccines are highly immunogenic when given to children 18 to 24 months or older.[238,239] The response in younger infants varies among vaccines (Fig. 23.3). HbOC, while relatively poorly immunogenic after one or two doses at 2 and 4 months of age, elicits antibody titers greater than 1.0 μg/mL in the majority of recipients after the third dose at 6 months of age.[240,241] The antibody levels induced after the third dose at 6 months of age were slightly higher than with PRP-OMP and were similar to those from PRP-T.[242] The induced antibody is bactericidal and has a statistically significantly greater avidity than the antibody induced by PRP-OMP and PRP-T.[243] The clinical significance of this increased antibody avidity is unknown.

PRP-T has an immunogenicity pattern similar to that of HbOC.[240,242] Some studies have shown that this vaccine is the most immunogenic of the three available Hib conjugate vaccines after completion of a three-dose primary series[240,241]; whether that translates to improved efficacy is unclear. The elicited antibodies are bactericidal, with a similar isotype distribution as HbOC.[244]

Unlike the other Hib conjugate vaccines, PRP-OMP elicits antibody titers of more than 1.0 μg/mL in 70% to 80% of children after just one dose given at 2 months of age.[225,245–248] After the second dose at 4 months of age, some studies showed that more than 90% of children achieved antibody

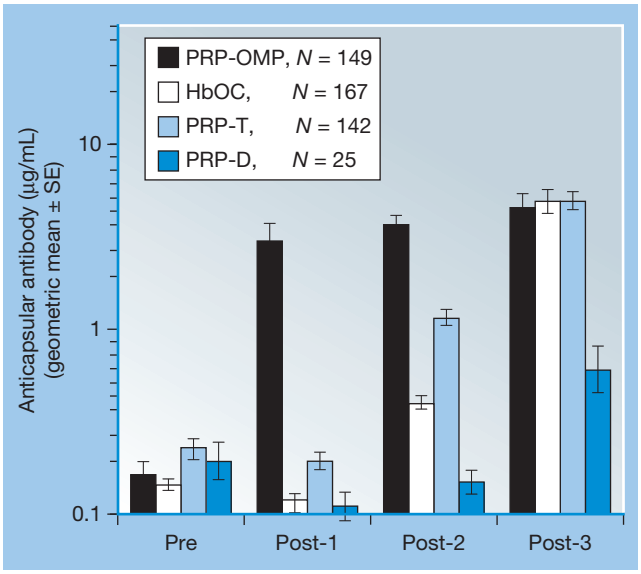

Figure 23.3. Immunogenicity of the *Haemophilus influenzae* type b conjugate vaccines in infants vaccinated at 2, 4, and 6 months of age. HbOC, *H. influenzae* type b oligosaccharide conjugate; PRP, polyribosylribitol phosphate; PRP-D, PRP-diphtheria; PRP-OMP, PRP–outer membrane protein; PRP-T, PRP conjugated to tetanus toxoid; SE, standard error. *(Modified from Granoff DM, Anderson EL, Osterholm MT, et al. Differences in immunogenicity of three Haemophilus influenzae type b conjugate vaccines in infants*. J Pediatr. *1992;121:87–194.)*

titers more than 1.0 µg/mL.[249,250] A study in high-risk Native American children showed that 1 month following the second dose at 4 months of age, 67% of Apaches and 75% of Navajos had antibody titers more than 1.0 µg/mL.[248] A third dose did not result in significantly increased antibody concentrations in most studies; therefore, the primary series for this vaccine consists of only two doses.[240,241,247] In children given a booster dose of PRP-OMP at 12 to 15 months of age, a clear booster response is seen.[251] However, the peak antibody titer achieved after the booster dose is lower than with the other two vaccines. It has been shown that as against Hib conjugated to CRM_{197} and tetanus toxoid, Hib conjugated to the outer membrane protein (OMP) of *N. meningitidis* engaged human Toll-like receptor 2 (TLR2) expressed in human embryonic kidney (HEK) cells. In mice where the TLR2 was knocked out, the antibody response to Hib-OMP was not as robust as in wild-type mice with the TLR2 intact.[252] This immune-stimulating capacity of the OMP has been attributed to the meningococcal PorB protein, which was shown elsewhere to activate B cells and other antigen-presenting cells through upregulation of CD86 with the involvement of TLR2.[253] This additional immune stimulating activity when compared to the other carrier proteins might be a reason for the relatively higher immunogenicity of the Hib-OMP vaccine after the first dose.

Because of the ability to induce antibody responses after the first dose in young infants, PRP-OMP was evaluated in newborns as a possible means of providing earlier protection against invasive Hib disease; unfortunately, antibody levels were substantially diminished in children through the first year of life, suggesting immune tolerance if the vaccine is administered soon after birth.[254] In contrast, a study in Finland found that children receiving PRP-T at 2 days of age had a geometric mean antibody concentration of 0.12 µg/mL at 4 months of age, which was significantly higher than in unimmunized children. Subsequently vaccinating the children again at 4 months of age elicited a strong antibody response, suggesting that children vaccinated as neonates are protected against invasive Hib disease.[255] The antibody induced by PRP-OMP has lower avidity and bactericidal activity compared with the antibody elicited by the other conjugate vaccines.[243] The differences in antibody titers and avidity induced after the primary series and booster doses of the different conjugate vaccines have not been shown to have any clinical significance. PRP-OMP may have a theoretical advantage in populations in which high rates of Hib disease are seen in children younger than 6 months of age or in which incomplete immunization is more likely. In populations such as the Navajo and Apache in the United States where high rates of Hib disease were observed in children younger than 6 months of age, routine use of PRP-OMP has virtually eliminated invasive Hib disease.[256]

Some studies showed differences in immunogenic response to the Hib polysaccharide vaccine in certain ethnic groups; for example, Siber and colleagues showed that Apache children had 10-fold lower geometric mean Hib antibody concentration after immunization than white children (0.34 vs 3.6 µg/mL; $P < .01$) at the age of 24 months, approximately 5 to 6 months after immunization. Similarly, PRP-D had very low immunogenicity in Alaskan Native infants compared with nonnative children.[257,258] However, ethnic differences in immune response have not been shown with the other Hib conjugate vaccines when tested in numerous developed and developing country settings.

Interchanging HbOC and PRP-OMP, as well as HbOC and PRP-T, for the primary series or the booster dose is equally or more immunogenic than using a single vaccine for the entire series.[259,260] Use of HbOC for the booster dose following a two-dose primary series with PRP-OMP has been shown to induce a higher antibody response compared with giving PRP-OMP as the booster dose (geometric mean antibody titer 7.46 vs 29.5 µg/mL; $P < .05$).[261] Use of a single vaccine has been highly effective in many different settings; whether certain combinations of vaccines in the Hib series can improve effectiveness has not been established.[244]

As previously discussed, serum anti Hib capsular polysaccharide antibody levels greater than 1 µg/mL are associated with long term protection and 0.15 µg/mL with short-term protection. An interesting finding with significance for decrease in carriage of Hib at the population level was that among vaccinated infants, the serum anti Hib capsular polysaccharide antibody level required for protection against carriage was greater than 5 µg/mL as measured a month after the third dose. The levels needed for protection against colonization are much higher than those needed to protect against invasive disease.

Combination Vaccines. Combination vaccines containing Hib conjugate vaccine have also been shown to be highly immunogenic in a variety of settings.[262–264] The initial combination vaccines contained the Hib conjugate vaccine in combination with diphtheria, tetanus, and pertussis (DTP) containing the whole-cell pertussis. In fact, this is the combination that is currently used in most developing countries. However, the hepatitis B surface antigen has also been added to the current Hib-containing combination vaccines that are used in developing countries. In the United States and other developing countries, DTP component of the Hib containing combination was replaced with diphtheria, tetanus, and acellular pertussis (DTaP) because of the reduced reactogenicity of the latter vaccine. Initial studies demonstrated reduced

immunogenicity in Hib containing combination vaccines that were combined with DTaP; however, this reduced immunogenicity has never been shown to be of clinical significance. Several other combination vaccines containing different antigens are now available in the market. All these new combination vaccines are safe and induce adequate Hib antibody levels. For example, the DTaP-HBV (hepatitis B virus)-IPV (inactivated polio vaccine)-PRP-T hexavalent vaccine when studied in Western Europe and the Philippines showed that 93% to 100% of children had an anti-PRP titer of 0.15 μg/mL 1 month after the primary vaccination series.[264]

Carrier Priming

Administration of a vaccine's carrier protein at a time before the administration of a conjugate vaccine that contains that same protein is termed *carrier priming*. Carrier priming may result in enhanced immune responses to Hib conjugate vaccine, but the immunologic consequences of carrier priming are unclear.[265–267] Because most children have early exposure to vaccines containing diphtheria and tetanus toxoids, it has been suggested that use of diphtheria or tetanus toxoid as the carrier for Hib conjugate vaccine may confer an immunologic advantage.[268] Animal studies have shown immunologic enhancement with carrier priming.[269,270] Several clinical trials have demonstrated an enhanced antibody response following PRP-T administration in children who had previously received DTaP vaccine and suggested that the effect may be at least partially from carrier priming.[271–273] In a clinical trial in Denmark, infants were given PRP-T at 5 to 6 months of age and randomized to receive tetanus toxoid as part of the diphtheria-tetanus–inactivated polio (DT/IPV) vaccine before, during, or after this dose. The primed group that received prior priming with DT/IPV had threefold higher antibody levels than the unprimed group. The group that received only concomitant priming had no difference in antibody levels compared with the unprimed group.[274] The clinical significance in terms of vaccine efficacy of carrier priming for the Hib conjugate vaccines remains unclear.

Efficacy

Clinical trials of the protective efficacy of PRP-D were conducted in Finland and Alaska. Between 1985 and 1987, an open-label non–placebo-controlled trial was conducted in Finland in which all children born on the odd days of the month received 25-μg doses of PRP-D at ages 3, 4, 6, and 14 to 18 months. The protective efficacy of PRP-D against invasive Hib disease after three doses was 90% (95% CI, 79–96%). Following the booster dose, the protective efficacy was 100%.[233] The Alaskan trial recruited Native Alaskan infants between 1984 and 1988. Infants were randomized to receive PRP-D or placebo at 2, 4, and 6 months of age. The protective efficacy after three doses was 35% (95% CI, −57% to 73%).[257] Because of the availability of other conjugate vaccines with superior immunogenicity and efficacy, particularly in young and high-risk children, PRP-D was not used in most countries and is no longer manufactured.

Two large prospective trials showed the clinical efficacy of HbOC. In the late 1980s, an unblinded, nonrandomized study was conducted in California, in which all children between 6 weeks and 6 months of age were given a three-dose series with HbOC vaccine; findings were compared with those for unvaccinated children between 7 and 18 months of age. Vaccine efficacy after two doses was 100% (95% CI, 47–100%) and after three doses was 100% (95% CI, 68–100%); however, efficacy after just the first dose was lower (26%; 95% CI, −166% to 80%), but the data are limited to the small number of cases occurring after a single dose.[234] A second trial in Finland compared the efficacy of HbOC with PRP-D when given at 4, 6, and 14 to 18 months of age. After two doses, the vaccine efficacy was 87% (95% CI, 69–96%) for PRP-D and 95% (95% CI, 76–99%) for HbOC. There were no episodes of invasive Hib disease following the booster dose in either group.[275]

PRP-OMP was evaluated in a randomized, double-blind, placebo-controlled trial on the Navajo Indian reservation, a population previously established to be at high risk for invasive Hib disease. Infants were randomized to receive the vaccine or placebo at 2 and 4 months of age. Overall efficacy was 95% (95% CI, 72–99%). Of note, protection began after the first dose. Between the first and second doses of vaccine or placebo, there were eight cases of Hib disease in the placebo group and none in the vaccine group (vaccine efficacy, 100%; 95% CI, 15–100%).[228] The PRP-OMP vaccine was subsequently found to be effective in postlicensure trials in several populations and countries, including Los Angeles County, California, Navajo and Apache Indians, Australia, and Israel.[276–279] Dramatic reductions in Hib disease incidence have been demonstrated in all populations in which the vaccine has been used.

Two large PRP-T trials were started in the United States but were discontinued in October 1990 when the recommendations for use of HbOC in infants were instituted. In the mid-1990s, a large vaccine trial was conducted in The Gambia, comparing PRP-T mixed with DTP with DTP alone. This trial showed a protective efficacy of 95% (95% CI, 67–100%) against all invasive Hib disease after three doses. Efficacy after a single dose for all invasive Hib disease was 44% (95% CI, −85% to 85%).[95] PRP-T reduced clinical pneumonia and radiologically confirmed pneumonia in several clinical trials. The efficacy for the prevention of clinical pneumonia as defined by the WHO was 4.4% (95% CI, −5% to 12.9%), and for radiologically defined pneumonia, efficacy was 21.1% (95% CI, 4.6–34.9%). The efficacy for the prevention of blood culture–positive pneumonia after three doses of vaccine was 100% (95% CI, 55–100%).[95] PRP-T was also highly efficacious against invasive Hib disease in trials in Britain, Chile, and Finland.[280–282] There have been no comparative efficacy trials of the three commonly used Hib conjugate vaccines. All three seem highly and equally efficacious.

In many of the developing countries, a large number of children do not receive all the recommended doses of multidose vaccines like Hib. A metaanalysis of eight prospective controlled trials of different conjugate Hib vaccines found that pooled vaccine efficacies against invasive disease after one, two, and three doses were 59%, 92%, and 93%, respectively.[283] This analysis did not address the long-term protection or the requirement for booster dose of conjugate vaccines as the trials followed up participants for 24 months only. This is discussed later in the chapter.

Effectiveness/Impact

Hib vaccine has been highly effective in developed and developing countries. In the United States, the introduction of the Hib conjugate vaccine resulted in a decrease in the incidence of Hib disease of more than 98%.[122,154] There were also substantial indirect effects ("herd immunity") induced by the vaccine.[278] Similar success has been documented in Canada and several countries in Western Europe.[284–289] Several developing countries have also noted dramatic declines in Hib disease with use of the Hib vaccines.[162,290] In Chile, a 90% decline in the rate of invasive Hib disease was demonstrated.[282] After Hib conjugate vaccine introduction, the annual incidence rates of Hib meningitis in The Gambia decreased from

more than 200 per 100,000 children younger than 1 year of age in the early 1990s to none per 100,000 in 2002 and from 60 to no cases per 100,000 in children younger than 5 years of age.[47] In Uganda, vaccine effectiveness, with two or more doses, was 99% (95% CI, 92–100%) against Hib meningitis using neighborhood control subjects and 96% (95% CI, 80–100%) using hospitalized control subjects.[291] In Senegal, the annual rate of Hib meningitis in children younger than 1 year of age went from 33 to 1.4 per 100,000; similar success was documented in Mali.[292,293] Some studies have shown decreases in rates of clinical pneumonia, as well as pneumonia with radiographic consolidation and clinical pneumonia, following Hib vaccine introduction.[97,98,294] Following routine introduction in Chile, Hib vaccine was shown to have 80% effectiveness ($P = .039$) against bacteremic pneumonia and empyema.[295] In the Nha Trang province of Vietnam, within 2 years of introduction of the Hib vaccine, the annual incidence of radiographically confirmed pneumonia decreased by 39% among children younger than 5 years of age.[294]

The importance of sustained vaccination against Hib was highlighted during a Hib vaccine shortage in the United States between November 2007 and March 2008 because of a vaccine recall that left only one manufacturer of Hib vaccine. Small outbreaks were reported in Minnesota and Pennsylvania during this time; the five cases reported to the Minnesota Department of Health in 2008 represented the highest number since 1992.[296] Even though the CDC had emphasized that all children should complete the primary immunization series during this period, vaccine coverage for the Hib primary series was 7.8% to 10.3% lower than that for DTaP and pneumococcal vaccine coverage at eight sentinel sites around the country.[297] This finding highlights the need for all children to complete the primary Hib immunization series and the need to ensure a consistent vaccine supply.

Substantial declines in levels of pharyngeal Hib carriage have been documented following Hib vaccination.[298] In Navajo and Apache children in the United States ages 3 months to 4 years, inadequate vaccination increased the odds of carriage by 2.66 (95% CI, 1.00–7.05).[46] Following routine immunization in this population, oropharyngeal carriage rates decreased to 0.3% (95% CI, 0–1.3%).[299] The carriage rates in The Gambia in unvaccinated children fell from 7.7% to 3.8% following routine vaccine introduction.[47,172]

There are conflicting data on differences in effectiveness among the available Hib conjugate vaccines. Delayed immunization and continued circulation of Hib may have caused an increase in Hib disease among Alaskan Native children following a shift from PRP-OMP to HbOC.[300] The data from Alaska suggest that under certain unusual epidemiologic circumstances, PRP-OMP may be more effective than HbOC. As a consequence, PRP-OMP is the primary vaccine used for certain Alaskan Native and Native American populations. In contrast, a review of surveillance data from 1993, when the Hib vaccine was introduced, to 2013, found that there was no increase in incidence of Hib disease in indigenous Australian children living in high incidence regions in the first 4 years following a change from the PRP-OMP vaccine to PRP-T vaccine.[301] However, all three available Hib conjugate vaccines have been successfully used to achieve very low levels of Hib disease. For example, PRP-T has been highly effective in The Gambia despite delayed immunization in many children, suggesting that indirect effects may contribute to protection of infants who have received only a single dose of PRP-T.[47] It is possible that in most situations, the differences in immunogenicity of the Hib conjugate vaccines may not translate into differences in effectiveness because of reduced circulation of Hib seen in most mature immunization programs.[302]

Haemophilus influenzae Type b Vaccine in Special Populations

Premature Infants

In the United States, the AAP recommends that premature infants be immunized according to their chronological age.[132] Data on the immunogenicity of Hib conjugate vaccines in premature infants are mixed. Two studies showed that following two doses of PRP-OMP at 2 and 4 months of age, just over 50% of premature infants achieved a PRP antibody titer of more than 1 μg/mL compared with more than 90% of term infants.[303,304] Similarly, one study showed that a significantly higher percentage of preterm infants had antibody titers less than 1.0 μg/mL compared with term infants (77% vs 57%) following three doses of PRP-T.[305] However, other studies comparing three doses of HbOC or PRP-T in preterm with term infants showed relatively little difference in the immune response.[306,307] In a study looking at persistence of the antibody response, Heath and colleagues[305] showed that 5 to 6 years following three doses of PRP-T, preterm infants had a significantly lower geometric mean antibody titer than did term infants ($P < .05$). The optimal dosing schedule for premature infants is unclear, and most experts continue to recommend that premature infants receive the Hib conjugate vaccine in accordance with their chronological age to provide protection against Hib disease in the first 2 years of life.[132]

Immunosuppressed Populations

HIV-Positive Persons. HIV-positive children and adults have been documented to have higher rates of invasive Hib disease with increased morbidity and mortality compared with HIV-negative persons.[308–310] A recent metaanalysis of three studies from South Africa estimated that HIV-infected children have a 7.4-fold increased risk of invasive Hib disease (uncertainty range: 2.9- to 22-fold).[1] Therefore, there has been great interest in the immunogenicity and efficacy of Hib conjugate vaccines in this population.

Madhi and colleagues studied 66 HIV-positive children who were not receiving antiretroviral therapy in South Africa.[311] The children were approximately half as likely (relative risk: 0.54; 95% CI, 0.43–0.69) to have antibody concentrations of 1.0 μg/mL or more following vaccination with PRP-T than were children without HIV infection. The estimated vaccine failure rate based on geometric mean antibody titers in HIV-positive children was 35.1-fold higher (95% CI, 14.6–84.6) than in their HIV-negative counterparts.[311] Similarly, poor antibody responses in HIV-positive persons have been documented in other studies, particularly in persons with high HIV viral loads.[312,313] Children with more severe or symptomatic HIV disease also demonstrate less antibody response.[314] In contrast, HIV-positive persons receiving antiretroviral treatment have an improved antibody response to the vaccines compared with before treatment.[315] Overall efficacy of Hib conjugate vaccine in untreated HIV-positive persons was shown to be 43.9% (95% CI, −76.1% to 82.1%); although this is lower than in HIV-negative persons, vaccination for Hib is still considered an important preventive measure for children infected with HIV.[316] There has been some suggestion that a booster dose might be warranted in HIV-positive children in countries where the routine immunization program uses only the primary series; however, because it is unclear whether antibody levels are an appropriate marker of protection in HIV-positive persons, this issue warrants further study.[314]

Other Immunosuppressive Conditions. Persons with deficient immune systems are at increased risk for invasive Hib

disease. Hib vaccines have been evaluated in persons with a number of immunodeficiency conditions, including organ transplantation and sickle cell disease. Hib vaccines are safe and effective in renal transplant recipients, although close monitoring must continue for invasive Hib disease because children undergoing dialysis and transplantation for chronic renal failure have occasionally been documented to experience Hib conjugate vaccine failures.[317,318] Studies suggest that immunizing a bone marrow transplant recipient before transplantation will result in improved antibody responses to Hib vaccines in the recipient compared with other techniques such as increasing the number of lymphocytes in the graft.[319] Some studies suggest that recipients immunized after transplantation may require an added booster dose at 24 months of age.[320] Persons with hemoglobinopathies may benefit from vaccination before splenectomy.[321] An open-label study in children younger than age 5 years with sickle cell disease demonstrated a geometric mean antibody titer of more than 3 μg/mL following one dose of PRP-OMP, and more than 18 μg/mL following a booster dose of PRP-OMP.[322]

Duration of Protection and a Booster Dose

Currently, most developed countries are using a two- or three-dose primary vaccination series with a booster dose in the second year of life, although the timing of the primary series is different in different countries. An immunogenicity study in Finland showed that the geometric mean antibody titer in children immunized with the primary series between 3 and 7 months of age fell to approximately 0.3 μg/mL at 18 months of age. Titers rose sharply following a booster dose and declined to approximately 5 μg/mL during the next 6 months. However, children between 2 and 8 years from their last vaccine dose did not exhibit significant further decline in antibody level; the mean antibody concentration for this group was 3.4 μg/mL. In addition, children 9 to 10 years of age who had received the primary series plus booster schedule in infancy had antibody titers 3.6-fold higher than children who had never received the vaccine.[323] A study in Sweden also showed long-term antibody persistence. Nine years after receiving three doses of PRP-T at 3, 5, and 12 months of age, the geometric mean antibody titer in the 56 study children was 4.16 μg/mL.[324] A follow-up study was conducted in Canada of children initially having been randomized to receive four doses of PRP-T (at 2, 4, 6, and 18 months of age) or PRP-D at 19 months of age.[325] At 4 to 5 years of age, the anti-PRP geometric mean antibody concentration in the PRP-T group was 2.2 μg/mL vs 0.7 μg/mL in the PRP-D group ($P < .001$). Four weeks following a booster dose of PRP-T, the geometric mean antibody titer rose to 98.4 μg/mL in the PRP-D group and 102 μg/mL in the PRP-T group (difference not significant). These results were consistent with persistent immunologic memory resulting in a booster immune response several years after immunologic priming.

In the United Kingdom, routine vaccination with the Hib conjugate vaccine was begun in 1992 with a three-dose primary series only at ages 2, 3, and 4 months without a booster dose.[110] A catch-up dose of Hib conjugate vaccine was given to older children. There was a rapid and dramatic decline in the incidence of Hib disease; however, starting in the late 1990s, a small increase in Hib cases in preschool-age children was noted (134 cases in 0- to 4-year-olds in 2002 vs 31 cases in 1996 in the same age group).[308,326] An anti-PRP antibody concentration study in 3- to 5-year-olds in the United Kingdom showed that antibody concentrations were higher in children who had been immunized in 1991 than children in the late 1990s ($P < .02$); this difference may have been a result of differing immunogenicities of vaccine formulations (including a change from whole-cell to acellular pertussis) or varying rates of Hib carriage in the community over time (see below).[327] A similar experience was noted in Ireland, with one to four cases seen from 1996 to 2003, compared with 10 cases in 2005.[328] As a result, in the United Kingdom in 2003, a second catch-up campaign was launched, offering all children ages 6 months to 4 years another dose of Hib vaccine.[329] Subsequently, the incidence of invasive Hib disease declined rapidly.[110]

The United Kingdom and Ireland now recommend a three-dose primary series at ages 2, 3, and 4 months and a booster dose at 12 months of age. In contrast, The Gambia uses a three-dose primary vaccination series without a booster, and Hib disease in preschool-age children has not been seen.[47] It has also been suggested that the experience in the United Kingdom may have been unique because of the vaccination catch-up campaign. High coverage achieved by the campaign may have reduced natural boosting opportunities due to reduced circulation of Hib.[330,331] A study in the United Kingdom comparing geometric mean antibody titers following an episode of invasive Hib disease between vaccinated and unvaccinated children found that children who had been vaccinated with the primary immunization series had higher geometric mean antibody titers than unvaccinated children ($P < .001$).[332] This study suggests that children who received the primary series responded to natural infection with a boosted antibody response, but that for some children, the primary series alone did not protect against invasive Hib disease.

Interestingly, the increase in rates of invasive Hib disease in the United Kingdom coincided with the distribution of Hib vaccine in combination with acellular pertussis vaccine as compared with whole-cell pertussis vaccine. Unlike combined vaccines with whole-cell pertussis, DTaP-Hib combinations have shown reduced immunogenicity to the Hib component (geometric mean antibody concentration, 0.38 μg/mL; 95% CI, 0.19–0.78) than with Hib administered separately (geometric mean antibody concentration, 3.10 μg/mL; 95% CI, 1.78–5.39), and, therefore, the concern was raised that acellular pertussis–containing Hib vaccines resulted in defective immunologic priming.[333] It has been suggested that the avidity of the anti-PRP antibody to Hib antigen may be a better measure of immunologic priming rather than antibody concentration.[334] One study showed a lower prebooster ($P = .0189$) and postbooster ($P < .001$) anti-PRP antibody avidity to Hib antigen in persons vaccinated with DTaP-Hib compared with persons vaccinated with DTaP and Hib separately.[335] In comparing geometric mean antibody titers after administration of DTaP-Hib, Goldblatt and colleagues showed an anti-PRP IgG geometric mean concentration of 1.23 μg/mL (95% CI, 0.98–1.58) just after initial vaccine administration, but then a titer of 0.25 μg/mL (95% CI, 0.21–0.30) before the booster dose, and a titer of 7.86 μg/mL (95% CI, 5.3–11.7) following the booster dose. This led them to suggest that despite the relatively lower immunogenicity of DTaP-Hib, adequate priming does occur following the primary series, but that the waning antibody concentration before the time of the booster dose may warrant the introduction of a booster.[336] A similar phenomenon with DTaP-HBV-IPV/Hib combination primary series yielding lower antibody levels than when Hib conjugate vaccines were administered separately is seen. However, it was also shown that the avidity and opsonic activity of the antibodies are the same. Maturation of antibody response as indicated by an increase in avidity over the postprimary to prebooster period was similar with separately injected Hib conjugate vaccine and the combination vaccine.[337] A later analysis of data from clinical trials concluded that there was no difference between the functional

activity of the DTaP-IPV-Hib combinations and DTwP-Hib combinations with the authors positing that the IPV component might have additional immunostimulating activity. Furthermore, all the different combination vaccines elicited the same opsonophagocytic and bactericidal activity as well as the same ability to protect in a passive infant rat protection assay as diphtheria and tetanus toxoids combined with whole-cell pertussis (DTwP) containing Hib vaccines after a booster dose.[338]

The importance of a booster dose and ongoing exposure to Hib for long-term protection remains controversial. Most developing countries that have introduced the Hib vaccine are using a three-dose primary schedule, mainly using combination vaccines with a whole-cell pertussis component, without a booster dose. A multicountry evaluation of Hib meningitis and nasopharyngeal carriage in four South American countries among children younger than 5 years of age suggested that high coverage of the vaccine was very important regardless of whether a booster dose was used.[339] In The Gambia, while in the Western region Hib disease has been under control for the 15 years since the vaccine was launched, in the Eastern region there has been a resurgence in Hib cases leading a few in the country to suggest the need for a booster dose.[340,341] Long-term surveillance for invasive Hib disease in developing country settings will be needed to determine whether a booster dose will be needed.

Safety

The three conjugate Hib vaccines have been given to millions of children during the past 20 years with few reports of serious adverse events.[342] Rare reports of transverse myelitis, thrombocytopenia, anaphylaxis, and Guillain-Barré syndrome have been temporally associated with Hib vaccine administration.[343,344] A review by the Institute of Medicine of the polysaccharide and conjugate Hib vaccines did not find adequate evidence to establish or reject a causal relationship between the vaccines and these disease entities.[344] A review of adverse events reported to the Vaccine Adverse Event Reporting System (VAERS) for the years 1990 to 2013 did not identify any new or unexpected safety concerns for Hib vaccines.[345] HbOC is extremely safe.[346] PRP-OMP has a similar safety profile; local and febrile reactions were seen in early trials but decreased after the addition of the aluminum phosphate adjuvant that presumably slowed the release of the reactogenic components.[228,245] PRP-T is associated with higher rates of local reactions such as erythema or induration than the PRP vaccine; however, higher rates of systemic or severe adverse events were not seen in one comparison study.[324] The higher rate of local reactions is thought to be a consequence of preexisting high levels of tetanus immunity in older children.[281,324]

Immunization Schedules and Recommendations. The AAP, the American Academy of Family Physicians, and the Advisory Committee for Immunization Practices have issued indications and recommendations for Hib vaccine in the United States.[132,347] These groups have recommended that for the HbOC and PRP-T vaccines, children should receive three doses at 2-month intervals and a fourth dose at 12 to 15 months of age. For PRP-OMP, two doses 2 months apart comprise the primary series, with a booster at 12 to 15 months of age. Immunization can start as early as 6 weeks of age, but because of possible immune tolerance, Hib conjugate vaccine should not be given earlier. For all three vaccines, any conjugate vaccine may be interchanged for the primary series or the booster dose. For premature infants, immunization should be given at the infant's chronological age in accordance with the schedule for all infants. Children who have completed the series but who are undergoing a splenectomy should be revaccinated 7 to 10 days before the procedure. Although there is some evidence that immunosuppressed patients (as a result of HIV, immunodeficiency, or malignancy) may benefit from additional booster doses, there is no absolute recommendation at this time.

The WHO recommends that HbOC, PRP-T, or PRP-OMP be given as a complete primary series with the three doses given at the same time as the DTP vaccine doses. It is suggested that the first dose be given as early as 6 weeks of age and the second and third dose given at 4- to 8-week intervals. A typical schedule for the primary series is doses at 6, 10, and 14 weeks of age of the child.[348] Most of the developing countries that have introduced combination vaccines use the DTwP-containing combinations. There is no absolute recommendation for giving a booster dose, although some experts suggest that a booster dose may be needed if there is evidence of disease resurgence in the future.[302,348,349]

In the future, some developing countries are likely to switch to Hib-containing combination vaccines that contain DTaP. It is unclear if making such a shift would result in resurgence of disease. This issue needs to be carefully monitored in order to evaluate the long-term impact of such changes.

Contraindications

The only contraindication to the Hib conjugate vaccines is previous hypersensitivity to the vaccine components.

Maternal Immunization

Vaccination of women before or during pregnancy is a potential approach to preventing early neonatal disease. A study in Arizona compared Hib antibody levels in infants born to women who were randomized to receive HbOC, PRP-OMP, or the 23-valent pneumococcal vaccine (Pneumovax 23, Merck Research Laboratories) before pregnancy. At birth, infants born to women vaccinated with PRP-OMP or HbOC had a higher geometric mean anti-PRP titer than infants born to women vaccinated with Pneumovax ($P < .01$). Furthermore, significantly fewer infants born to women vaccinated with PRP-OMP or HbOC had antibody titers less than 0.15 μg/mL at birth and 2 months of age compared with infants born to pneumococcal-vaccinated women ($P < .01$).[350] Studies in Texas and The Gambia in which women were vaccinated during the third trimester of pregnancy also showed significantly higher levels of anti-PRP antibody in infants born to vaccinated women.[351,352] Maternal immunization has not been pursued as a strategy for prevention of Hib disease owing to the relatively low incidence of disease in newborns and the reduction in disease in incompletely vaccinated infants because of indirect protection associated with widespread Hib conjugate vaccine use.

Vaccine Failures

Although the Hib conjugate vaccines are highly efficacious, occasional cases of invasive Hib disease occur in fully immunized persons. Considerable research has been done to identify risk factors for vaccine failures. Early or accelerated dosing may be associated with vaccine failure.[331] Underlying serious medical illness and immunodeficiencies have also been implicated in vaccine failures. In a study in the United Kingdom and Ireland, Heath and colleagues found that of the children who were vaccinated before 12 months of age, 20% of vaccine failures had a clinical risk factor (defined as prematurity, malignancy, developmental delay/dysmorphism, Down

syndrome, or neutropenia).[353] Of children vaccinated after 12 months of age, 67% had a clinical risk factor, immunodeficiency, or both.[353] A long-term follow up of 175 vaccine failure cases showed that approximately 4 years after a breakthrough illness, 57% had anti-PRP antibody concentrations less than 1.0 μg/mL and 16% had concentrations less than 0.15 μg/mL, suggesting a possible need for additional vaccine doses.[354] Another study on the same cohort showed that these children with Hib vaccine failure were also more likely to have lower serotype specific pneumococcal antibody concentrations after administration of the pneumococcal conjugate vaccine as compared to age-matched controls. Younger vaccine failure cases were more likely to have nonprotective antibody levels against more pneumococcal serotypes than their age-matched controls, leading to the suggestion that children with Hib vaccine failure might be able to develop antibody concentrations against encapsulated organisms but only when they are older.[355] An underlying genetic susceptibility in the immune system has been suggested as another host factor that could be responsible for vaccine failures. In the above discussed cohort of vaccine failure cases in the United Kingdom and Ireland, two recessive single nucleotide polymorphisms (SNPs) in *TIRAP* and *IL10* genes showed evidence of association with specific clinical manifestations of invasive Hib disease.[356]

Characteristics of the Hib strain may also be associated with vaccine failure. Cerquetti and colleagues showed that strains from persons experiencing vaccine failure were more likely to have multiple copies of the *cap* locus (≥3) than strains causing invasive disease in unimmunized persons.[357] The actual role of the *cap* amplification to the virulence of the organism and any associated clinical significance warrants further study.

Alternative Formulations

Combination Vaccines. The need for combination vaccines to simplify and improve compliance with an increasingly complex childhood vaccination schedule is well recognized. Several DTP-Hib-hepatitis B combinations have been developed and are widely used.[349] Concurrent administration of Hib conjugate vaccine in the same syringe as DTaP vaccine has been extensively evaluated. In several studies, significantly lower titers of anti-PRP antibody have been demonstrated in children who receive the DTaP-Hib combination than in children who receive Hib conjugate vaccine in a separate syringe.[336,358,359] However, the clinical relevance of this decreased immune response is unclear. The majority of children still exhibited titers of more than 0.15 μg/mL.[359] This decreased response is not seen when the whole-cell DTP vaccine is combined with the Hib conjugate vaccine.[360] Infants who are given a DTaP-Hib primary series exhibit a strong booster response when given the Hib conjugate vaccine in the second year of life, showing the establishment of immunologic memory.[331,336,359] In addition, the DTaP-Hib combination vaccines have demonstrated clinical effectiveness.[333,361] A clinical vaccine effectiveness study against invasive Hib disease in Germany showed 97.5% effectiveness (95% CI, 96.3–98.4%) after receipt of at least one dose of DTaP-Hib or DTaP-IPV-Hib and an effectiveness of 98.8% (95% CI, 98.2–99.3%) after three doses of DTaP-Hib or DTaP-IPV-Hib vaccine.[362]

Numerous combinations have been evaluated, including DTaP-IPV-Hib,[362–364] Hib-Hep B,[365] DTaP-Hep B-Hib,[366,367] and DTaP-Hep B-IPV-Hib.[331,368,369] The combination vaccines containing Hib that are licensed and in common use in the United States and many developed countries are shown in Table 23.2 (see also Chapter 15).

POSTVACCINE ERA: PUBLIC HEALTH CONSIDERATIONS

Herd Protection

Immunization with the Hib conjugate vaccine prevents establishment of new pharyngeal carriage in immunized persons.[46] If the proportion of children who have been immunized in a population is sufficient, there is a reduction in transmission of Hib, and unimmunized persons are protected because they have reduced exposure to the organism; reduction of disease in an unimmunized segment of a population in which a large proportion has been immunized is commonly referred to as "indirect effect" or "herd protection." Several studies have shown evidence of herd immunity with the introduction of Hib vaccine.[45,370,371] On the Navajo Indian reservation, with coverage rates ranging from 20% to 60%, invasive disease incidence decreased by 56% to 73%.[278] A study looking at data from 1989 to 2007 from Ontario, Canada, showed that infant Hib vaccination, introduced in 1992, led to a decrease in disease caused by Hib in all age groups.[372] This has important implications, particularly in developing countries where lack of infrastructure may prevent complete vaccination of the population. For example, in The Gambia, Hib vaccine was introduced in the mid 1990s, but vaccine supply has been interrupted at times and coverage with three doses of vaccine has ranged from 62% to 75%.[47] Nevertheless, invasive Hib disease has virtually disappeared there.[47]

Serotype Shift

There has been investigation into whether widespread use of the Hib conjugate vaccine can result in a change in the serotypes of *H. influenzae* most likely to cause invasive disease. Theoretically, the decrease in Hib carriage rates could open up ecological niches in the human pharynx, resulting in increased rates of carriage and disease due to other *H. influenzae* serotypes. Whether there has been a change in the rates of disease caused by non–type b encapsulated or nontypeable *H. influenzae* since the introduction of the conjugate Hib vaccines remains unclear. In the United States, population-based surveillance by the CDC from 1998 to 2000 did not show an increase in rates of non–type b *H. influenzae* invasive disease, nor has a shift been seen in Europe.[122,373] A population-based study of Navajo and White Mountain Apache children younger than 5 years of age did not find evidence of an increase in non–type b invasive disease rates after introduction of the Hib conjugate vaccine.[299] However, some studies have shown increases in non–type b *H. influenzae* serotypes in the postvaccine era, particularly with serotype a. A study of Alaskan residents showed an increase from 0.5 per 100,000 persons to 1.1 per 100,000 persons per year in invasive infections with non–serotype b strains of *H. influenzae.*[371] Specifically, whereas there was no *H. influenzae* a disease identified prior to 2002, from 2002 to 2011, the incidence of *H. influenzae* a disease was 5.4 per 100,000 among children younger than 5 years of age. Almost all but two cases out of 29 occurred in Alaskan Native children.[374] Similarly small increases have been noted in Australian Aborigine children and in a surveillance study of five metropolitan regions in England.[375,376] In the Navajo and White Mountain Apache population, while no increase in non–type b disease was noted in the postvaccine era, the rate of *H. influenzae* type a disease continued to be significantly higher than the general U.S. population.[256] In Ontario, Canada, a nearly threefold increase in incidence rates of nontypeable and serotype f *H. influenzae* infections was noted.[372] Of note, all reported increases in invasive non–type b *H. influenzae* disease rates since the introduction of the Hib vaccine

have been very small compared with the decreases in Hib disease incidence. Following vaccine introduction, estimated annual incidences of invasive non–type b encapsulated and nontypeable *H. influenzae* disease have been approximately 30-fold lower than that of Hib disease in the prevaccine era in studies in the United States and the United Kingdom.[131,376–378] The phenomenon of serotype shift has been seen with *S. pneumoniae* since the introduction of the seven-valent pneumococcal conjugate vaccine. Increases in pharyngeal carriage, otitis media, and possibly invasive disease caused by nonvaccine serotypes have been documented.[379–381] The reasons why serotype shifts might be more likely to be associated with pneumococcal vaccination compared with Hib vaccination are unclear. One hypothesis is that pneumococcal carriage is more common and multiple colonizing events result in increased competition between strains; in contrast, encapsulated *H. influenzae* organisms have lower rates of carriage, fewer colonizing events, and, therefore, less competition.[382]

FUTURE VACCINES

As the pediatric immunization schedule becomes more and more complex, developing more combination vaccines is an area of active interest, as are vaccine candidates for nontypeable *H. influenzae* disease and *H. influenzae* type a. Several candidate vaccines have been shown to reduce carriage in the ear and nasal mucosa of animal models.[383–385] An oral vaccine against nontypeable *H. influenzae* has been shown to reduce the incidence and severity of exacerbations of chronic bronchitis in small clinical trials.[386] A lipopolysaccharide-based conjugate vaccine showed good safety and immunogenicity in a Phase I study in adults and may soon be evaluated in children.[387] Future emphasis will likely be on elucidating correlates of protection against nontypeable *H. influenzae* disease that will facilitate the development and testing of more vaccine candidates.[388]

BOX 23.4 Conclusions

- Hib is the most important cause of serious *Haemophilus influenzae* disease.
- Several safe and highly efficacious vaccines are available against Hib disease.
- The effective use of Hib conjugate vaccines has virtually eliminated disease in developed countries and in the developing countries where it has been introduced.
- Use of Hib conjugate vaccine has increased globally, but many children still do not have access to this effective vaccine.

CONCLUSION (BOX 23.4)

The evaluation and implementation of Hib vaccines around the world has been one of the major public health accomplishments in the past decade. GAVI estimates that by 2020, the routine use of Hib vaccines would have prevented more than 7 million deaths.

24 Hepatitis A Vaccines

Francisco M. Averhoff, Yury Khudyakov, and Noele P. Nelson

Contagious jaundice was recognized by the Greeks at the time of Hippocrates and by the ancient Chinese[1]; however, the earliest recorded outbreaks of jaundice that appear epidemiologically to have been hepatitis A occurred in Europe in the 17th and 18th centuries.[2] Early in the 20th century, Cockayne[3] concluded that sporadic and epidemic forms of jaundice were probably manifestations of the same disease, and McDonald[4] postulated that a virus might be involved. Epidemic hepatitis has been a military problem for centuries, and major outbreaks occurred among British, French, German, and Romanian troops in World War I and among French, American, Commonwealth, and Axis troops in World War II.

The first scientific evidence that hepatitis A was an enterically transmitted viral infection was obtained during World War II from studies among experimentally infected volunteers. In a classical series of experiments, Havens[5] and Neefe and colleagues[6] were able to show that volunteers in whom infectious hepatitis had developed were protected from subsequent challenge with the same virus and with infectious material obtained from a separate outbreak. Havens and colleagues [5,7] also demonstrated that intramuscular injection of pooled normal human immunoglobulin could prevent or attenuate the disease, and the practice was rapidly adopted. During an epidemic among American soldiers near the end of World War II in the Mediterranean theatre, more than 2700 American soldiers were administered immunoglobulin, which resulted in an 86% reduction in the incidence of disease among immunized troops.[8]

By the end of World War II, volunteer studies had clearly established that infectious hepatitis was enterically transmitted and was caused by a filterable agent—presumably a virus—that was relatively heat-stable but could be inactivated by chlorine.[6] The disease seemed to be caused by a single agent, seemed to be associated with lifelong immunity, and was preventable by administration of normal immunoglobulin. During the 1950s, it became apparent that infectious hepatitis was clearly distinct from serum hepatitis in mode of transmission and etiology. [9–11] MacCallum earlier had proposed that the epidemiologically distinct diseases be known as hepatitis A and B, replacing the terms infectious hepatitis (hepatitis A) and homologous serum hepatitis (hepatitis B).[12] This suggestion was adopted in 1952 by the World Health Organization's First Expert Committee on Viral Hepatitus.[1] Fecal samples collected from studies during the 1950s were critical in the subsequent identification of the etiologic agent of the disease by electron microscopy in 1973 (Fig. 24.1).[13]

WHY THE DISEASE IS IMPORTANT

Annually, an estimated 100 million-plus hepatitis A virus (HAV) infections result in significant morbidity and 15,000 to 30,000 deaths globally; most of this burden occurs in lower- and middle-income countries where 80% or more of the population can be infected by late adolescence in the poorest countries.[14–16] In high-income countries, with more advanced standards of hygiene and sanitation, the greatest risk of infection is low and when it occurs, it is often from travel to endemic countries and foodborne outbreaks.[17,18]

BACKGROUND

Clinical Description

Hepatitis A is an acute infection of the liver. The incubation period for hepatitis A ranges from 15 to 50 days after exposure with the mean incubation period being approximately 28 days.[6,19,20] The average incubation period has been reported to be shorter among patients who acquired HAV infection by parenteral transmission from contaminated blood products and among nonhuman primates infected parenterally compared with those infected orally, and the incubation period also depends on the infectious dose.[21–23]

Infection with HAV, as evidenced by the detection of HAV-specific immunoglobulin (Ig) M antibody in serum, may produce a wide spectrum of outcomes ranging from inapparent (asymptomatic, without elevation of serum aminotransferase levels), to subclinical (asymptomatic, with elevation of serum aminotransferase levels), to clinically evident (with symptoms). Clinical manifestations typical of acute hepatitis include jaundice and dark urine, but symptomatic hepatitis A without jaundice also occurs.

The clinical symptoms of acute hepatitis A in an individual patient are indistinguishable from those caused by other forms of viral hepatitis. The onset of the prodromal period, particularly in older children and adults, can be abrupt and is characterized by increasing fatigue, malaise, anorexia, fever, myalgias, dull abdominal pain, nausea, and vomiting. Pediatric patients may have diarrhea or, less commonly, upper respiratory symptoms including cough and coryza.[24,25] Typical signs and symptoms of hepatitis will appear several days to a week following the onset of the prodromal period and include darkening of the urine (bilirubinuria) which is followed by jaundice (yellow discoloration of the sclera, skin and mucus membranes) and pale-colored stools. Additional physical findings may include hepatomegaly and tenderness. Pruritus, caused by cholestasis, occurs in less than 50% of patients, but may be severe.

The frequency of symptoms with HAV infection is strongly influenced by age. Children are less likely to have symptomatic infection compared with adults; 50% to 90% of infections acquired before the age of 5 years are asymptomatic, whereas 70% to 95% of infected adults will have symptoms.[26–28] Jaundice is rare among young children, occurs more frequently among adolescents, and is experienced by the majority of adults with hepatitis A.[28,29]

The duration of illness varies, but most patients feel better within several weeks. In a large 1989 Shanghai outbreak, 90% of a subset of 8647 hospitalized patients observed carefully had recovered completely in 4 months, and all had recovered in 1 year.[19] In a study of 59 patients in the United States, about two-thirds recovered within 2 months, 85% within 3 months, and nearly all by 6 months.[30] Relapse, consisting of renewed symptoms, elevated liver function test results, and detection of virus in stools, has been found in up to 10% of cases, but recovery from relapse is universal.[30–32] Infection with HAV has not been found to cause chronic infection, and immunity after infection is thought to be lifelong.

TABLE 24.1 Atypical Clinical Manifestations and Complications of Hepatitis A Virus Infection

Relapsing hepatitis A
Fulminant hepatitis A
Extrahepatic manifestations
Transient rash or arthralgias
Papular acrodermatitis of childhood
Cutaneous vasculitis
Cryoglobulinemia
Guillain-Barré syndrome
Other neurologic syndromes (e.g., myeloradiculopathy, mononeuritis, vertigo, meningoencephalitis)
Renal syndromes (acute renal failure, nephrotic syndrome, acute glomerulonephritis)
Pancreatitis
Hematologic (including aplastic anemia and thrombocytopenia)
Cholestatic hepatitis A
Hepatitis A triggering autoimmune hepatitis[8]

Data from references 30 and 35–76.

Complications

A cholestatic form of hepatitis A has been reported in which patients experience persistent jaundice, usually accompanied by pruritus.[30,33,34] Other atypical clinical manifestations and complications, including immunologic, neurologic, hematologic, pancreatic, and renal extrahepatic manifestations, are rare (Table 24.1).[30,35–76] Complications, including premature rupture of membranes or placental separation, have been reported among pregnant women with acute hepatitis A.[77–81]

The overall case-fatality rate varies according to the population studied. Among hospitalized patients with hepatitis A in Australia, the mortality rate was estimated to be 0.14%.[82] In the large 1988 Shanghai epidemic that involved primarily adolescents and young adults, there were 47 deaths (0.015%) recorded among the 310,746 diagnosed cases.[83] Case-fatality rates during communitywide outbreaks in the United States have ranged from 0.1% to 0.7%.[84,85] The case-fatality rate in the United States ranges from near 0% in healthy children to less than 2% in older adults.[86–88] The most severe form of the disease, fulminant hepatitis A, is rare, but mortality is as high as 60%.[89,90] Host factors reported to be associated with an increased risk of fulminant hepatitis include older age[69,90–92] and underlying chronic liver disease,[92–101] although some reports have identified chronic hepatitis C as a risk factor for severe disease whereas others have not.[99–102]

Morbidity and mortality associated with hepatitis A in developing countries has been documented among children; however data are limited.[103,104]

Treatment

No specific therapy is available for hepatitis A, and management is supportive and in most patients, admission to the hospital is not necessary. Activity, including exercise, should not be restricted among healthy patients who can tolerate it, as there does not appear to be an adverse impact on the course of illness. Abstinence from alcohol is recommended, although there are few objective data that demonstrate a benefit. Medications, particularly those metabolized by the liver or that are potentially hepatotoxic, should be used with caution because their half-life may be prolonged and/or promote additional insult to the liver. Hospitalization may be necessary for patients who become dehydrated from vomiting and is necessary for those who develop fulminant hepatitis.

Hepatitis A is occasionally complicated by cholestasis which can result in pruritus (itching); approximately 7% of cases were affected in one series of 59 hospitalized patients.[30] A brief course of corticosteroids has been reported to shorten the course and reduce symptoms, primarily itching, but recovery is universal, even without treatment.[34] In the rare event of fulminant hepatitis with hepatic failure, hospitalization with intensive care is indicated and most patients survive.[105,106] Liver transplantation may be indicated in some cases of fulminant hepatitis, but because survival without transplantation is relatively high, up to 80%, and no single factor is predictive of poor outcome, it has been difficult to establish criteria for choosing transplantation candidates.[35,69,70,106,107] Persistent HAV infection has been demonstrated in some transplant recipients, but whether this affects survival is unknown.[71]

Virology

HAV is a member of the Picornaviridae family, which includes the enteroviruses and rhinoviruses of humans. While HAV resembles enteroviruses in most morphologic and physical aspects, owing to several unique features, HAV has been placed into its own genus, *Hepatavirus*.[108,109] The HAV genome is composed of single-stranded linear RNA molecule of 7478 nucleotides (strain HM175) (Fig. 24.2).[110] Like other picornaviruses, the genomic RNA has positive polarity, a relatively long 5′ untranslated region (UTR) of 735 nucleotides typical of picornaviruses, followed by a single, long open reading frame of approximately 6,681 nucleotides coding for a polyprotein of 2227 amino acids, in turn followed by a short 3′ UTR ending with a virus coded poly(A) tail. Sequence analysis of the HAV genome reveals its gene order is also characteristic of picornaviruses with the structural genes coded by the 5′ third of the open reading frame and the nonstructural proteins coded by the remainder. Although HAV is similar to the other picornaviruses in physical and molecular structure, it has little similarity to other picornaviruses at the nucleotide or amino acid sequence level.[110]

As with other picornaviruses, the 5′ end of the genome does not have a cap structure but instead has a small, covalently bound, virus-coded protein termed VPg (3B protein).[111] The 5′ UTR has a predicted secondary structure similar to other picornavirus UTRs and includes an internal ribosomal entry site for cap-independent translation.[112,113] Translation begins at one of two in frame AUG codons at nucleotide position 735 or 741.[114] Following a translation terminator sequence, the genome ends with a 3′ noncoding region of 63 nucleotides that is followed by a poly(A) tail of varying lengths typical of picornavirus genomes. The polyprotein of picornaviruses has been divided

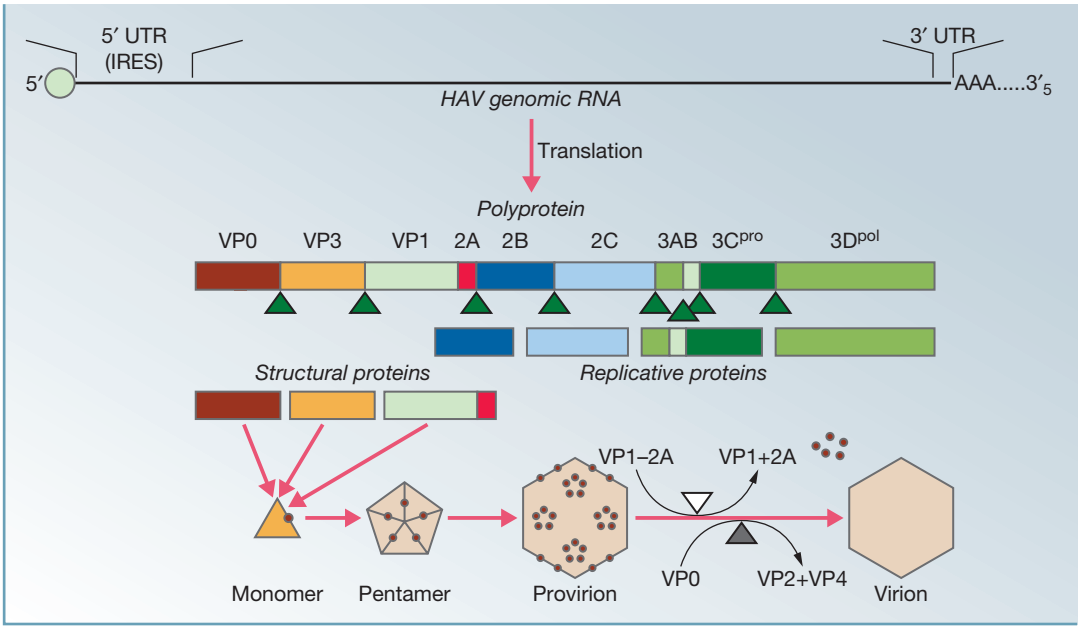

Figure 24.2. Organization of the RNA genome of hepatitis A virus (HAV), polyprotein cleavage, and viral assembly. The 7.5-kb positive-strand RNA is covalently attached to VPg (5′ end) and has a poly(A) tail. The 5′ untranslated region (UTR) of 734 nucleotides functions as an internal ribosome entry site (IRES) to initiate translation (*vertical arrow*) of the precursor polyprotein of 2227 amino acids. The single viral protease, $3C^{pro}$, cleaves itself from the polyprotein and subsequently cleaves elsewhere in the polyprotein to yield the structural protein precursors VP0, VP3, and VP1–2A (PX) and replicative proteins 2B, 2 C, 3A, 3B (VPg), and 3D (RNA-dependent RNA polymerase). VP0, VP3, and VP1–2A probably remain associated as a monomer and then form pentamers that are a stable precursor in capsid formation. Assembly of 12 pentamers together with RNA forms the provirion, after which 2A is susceptible to cleavage by host cell protease(s) *(open arrowhead)*. The final maturation cleavage of VP0 to VP2 and VP4 *(solid arrowhead)* is dependent on the encapsidated viral RNA. *(From Wasley A, Feinstone SM, Bell BP. Hepatitis A virus. In: Mandell GL, Bennett JE, Dolin R, eds.* Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases, *7th ed. Philadelphia: Elsevier; 2010:2367–2388.)*

into three parts, termed P1, P2, and P3. The four capsid proteins, VP1, VP2, VP3, and VP4, are coded by the first 2373 nucleotides (P1) and the nonstructural proteins by the remainder (P2 and P3). The gene order and protein function of HAV are similar to the other picornaviruses. However, there are differences in the details of the protein cleavages, the size of the capsid proteins, myristoylation at the N-terminus, and the inclusion of the small VP4 in the virion particle.[115–121]

The 2A protein of poliovirus has proteinase activity and makes the VP1/2A cleavage. However, the 2A of HAV has no known function and is not required for replication, but at least the N-terminus is needed for particle assembly.[122,123] The 2B and C proteins are believed to be involved in replication. Mutations leading to cell culture adaptation and attenuation in animals have been mapped to these regions.[124] Protein 3C is the virion protease that is responsible for all proteolytic cleavages of the HAV polyprotein except the VP0 cleavage.[115–117] Protein 3D is the viral polymerase responsible for the replication of the genomic RNA.

Because HAV can survive in the environment, can contaminate food and water, and can be concentrated by shellfish, methods to inactivate this virus have been studied. HAV is more resistant to heat than other picornaviruses.[125] While HAV may be incompletely inactivated (depending on the conditions) by exposure to 60°C for 10 to 12 hours, complete inactivation has been reported after heating to 70°C for 4 minutes, 5 seconds at 80°C, and virtually instantly at 85°C.[126] HAV may survive extended periods in shellfish, water, soil, and marine sediment.[127] Outbreaks of hepatitis A have been reported following ingestion of partially cooked shellfish, suggesting that the usual steaming conditions used to cook shellfish may be inadequate to destroy the virus. HAV can be reliably inactivated by autoclaving (121°C for 30 minutes).[128] The virus is resistant to most organic solvents and detergents and a pH as low as 3.[129,130] HAV can be inactivated by many common disinfecting chemicals, including hypochlorite (bleach), and quaternary ammonium formulations containing 23% HCl found in many toilet bowl cleaners.[130] Photoinactivation of HAV in solution by the addition of porphyrins has been demonstrated.[131] Currently, licensed vaccines are inactivated by 1:4000 formalin at room temperature for at least 15 days to exceed complete inactivation by at least threefold.

There seems to be only one HAV serotype throughout the world.[132–134] People who were infected by HAV in one part of the world are not susceptible to reinfection in another part of the world, and immunoglobulin prepared in a variety of developed countries or vaccines developed from single strains of HAV protect travelers throughout the world. One vaccine approved in the United States was developed from a genotype I virus originally isolated from an Australian patient (HM175); the other vaccine was derived from a genotype III virus originally isolated from a Costa Rican patient (PA21). Although the two vaccine strains differ by 16.8% in the nucleotide sequence of the structural protein coding region, no significant antigenic differences were observed in a cross-cross neutralization assay, and both viruses reacted nearly identically with a panel of 18 monoclonal antibodies.[133,135]

The antigenic composition of the HAV capsid has been extensively analyzed through binding studies of neutralizing monoclonal antibodies and neutralization escape mutants.[136] Neutralization epitopes of HAV are contained primarily within predicted loop regions on the structural proteins VP1 and VP3. However, neutralizing monoclonal antibodies

do not recognize either oligopeptides predicted to contain neutralization epitopes or denatured individual viral capsid proteins, and antibodies raised against these synthetic oligopeptides do not neutralize, suggesting that these neutralization epitopes are conformational and not linear. Binding competition assays of neutralizing monoclonal antibodies have indicated that the neutralization epitopes are contained within a closely related antigenic site.[136,137]

Details of HAV replication have been incompletely elucidated owing to its relatively inefficient growth in vitro. Like other picornaviruses, HAV is believed to bind to the cell through a specific cellular receptor inserted into the plasma membrane. An HAV cellular receptor molecule from monkey kidney cells termed havcr1 is a mucin-like glycoprotein stalk topped by an immunoglobulin-like structure. Binding of HAV to cells that express havcr1 is blocked by a specific monoclonal antibody to the receptor, and the complementary DNA (cDNA) coding for havcr1 can be transfected into nonpermissive cells, rendering these cells permissive for virus binding, entry, and translation. However, nonpermissive cells transfected with havcr1 cDNA do not generally support the replication of complete infectious virus.[138] The cys-rich immunoglobulin-like region of HAVCR1 is sufficient for binding of HAV. Soluble forms of HAVCR1 containing the cys-rich region plus the mucin-like region neutralize and uncoat HAV, whereas forms containing only the cys-rich region bind but do not uncoat HAV, suggesting that the mucin-like region provides the correct scaffolding for the correct presentation of the cys-rich region or interacts with the viral particle.[139] The HAV receptor havcr1 is identical to the T-cell immunoglobulin and mucin domain (TIM1). TIM1 is known to regulate T-cell activation and has been implicated in atopic disease.[140] Some studies have identified an inverse association between HAV infection and atopy in humans, and there has been the suggestion that this could be related to the effect of HAV infection on TIM1-induced T-cell differentiation.[140]

Unlike many viruses that activate the CD4+ CD25+ regulatory T-cells (Tregs), HAV temporary impairs Treg functions during acute infection.[141] Direct binding of HAV to HAVCR1 on Treg inhibits the cell functions.[142] The transitory block of Treg may lead to removal of pathogenic T cells, providing protection against development of autoimmune and allergic states.[143] Following receptor binding and entry, HAV follows the general replication strategy of other picornaviruses in uncoating, translation, RNA replication, and assembly. Like other picornaviruses, replication of HAV is intimately related to the cytoplasmic membranes, and proteins 2C and 2BC have been shown to interact with and induce rearrangement in these membranes.[144] HAV uses a unique "membrane hijacking" mechanism. At least a fraction of HAV circulating in blood of infected humans and chimpanzees is enveloped into the host cell membrane, which prevents recognition of the form of HAV by antibody in enzyme immunoassays. Enveloping of HAV with the host membrane may affect neutralization with antibody and potentially assists in spreading HAV infection in the liver.[145]

The features of HAV replication in cell culture also distinguish it from many other picornaviruses, and these characteristics are important for vaccine production; for example, HAV is cultured in human lung fibroblast cells, MRC-5, using medium-perfused bioreactors for production of inactivated hepatitis A vaccine VAQTA. The virus generally grows slowly and to low titers. Most HAV strains do not significantly interfere with host transcription or translation, and the virus does not cause a cytopathic effect or kill the cells in which it is growing. Instead the virus readily establishes persistently infected cells, and the virus remains largely cell-associated. A few cell culture–adapted viruses that grow rapidly exhibit a cytopathic effect and cause cell death through apoptosis.[146–148]

Many HAV strains have been isolated in cell culture directly from clinical material, although the procedure may take several weeks or even months of adaptation to in vitro growth.[148] A cell line derived from human hepatoma cells, Huh-7 cells, seems to have the capacity to grow field isolates of HAV.[149] In addition, cells of nonprimate animal origin have now been shown to support at least limited growth of HAV.[150–152]

Cell culture of HAV has been used to alter the phenotype of the virus primarily for growth characteristics and attenuation of virulence. Attenuated strains of HAV have been selected by multiple tissue culture passages, and cold adaptation has been achieved by passage at reduced temperature.[153–155] Some mutations responsible for these altered phenotypes have been determined by molecular cloning and sequencing of the mutant and comparing its sequence with the parental strain. Mutations within the 5′ UTR and mutations within the 2B and 2C coding regions of HAV RNA are associated with enhanced virus replication in vitro.[124,156]

HAV is known to infect humans, at least chimpanzees among the great apes, and some species of monkeys. The most extensively characterized models are the chimpanzee and two New World monkeys, tamarins and *Aotus* (owl) monkeys.[134,157,158] The presence of antibodies in some primate species at the time of capture might indicate that there is a reservoir of infection in nature or cross-reactive antibodies with monkey viruses. In some regions of Africa and Asia, where HAV is endemic, species of macaques and *Cercopithecus* monkeys are often infected with simian or possibly human strains of HAV. Transmission of HAV to primate handlers is well documented. However it has not been determined if these monkey isolates are true simian HAVs or human viruses that have infected monkey colonies where they have persisted and adapted.[159] Limited HAV replication has been demonstrated in guinea pigs.[160] Therefore, while HAV may be transferred to nonhuman primates and even lower-order animals, it is not clear if any of these species serve as a reservoir for HAV in the environment, which could then be a source of human infections.[160]

Pathogenesis as It Relates to Prevention

HAV is generally transmitted by the fecal–oral route, and this acid-resistant virus can survive passage through the stomach. It was found in tamarins and chimpanzees that approximately $10^{4.5}$ intravenous doses were required to infect the same species by the oral route.[23] The primary site of HAV replication is in the liver, although there are also experimental data in chimpanzees that HAV may replicate in the oropharynx.[161,162] The virus has been identified by immunofluorescence in the epithelial cells of the intestinal crypts of the jejunum and ileum of experimentally infected monkeys.[161,163] The period of viremia has been measured by a sensitive reverse transcriptase–polymerase chain reaction in 13 naturally acquired human cases and five experimentally infected chimpanzees. HAV RNA was detected an average of 17 days before the peak alanine aminotransferase (ALT) level and persisted an average of 79 days after the peak ALT. The average total duration of viremia was 95 days, but the range was between 36 and 391 days.[164] Although other organs might be seeded by the viremia, HAV, like many other picornaviruses, seems to be highly organ-specific, and the primary pathologic process in hepatitis A is restricted to the liver. Virus is shed from infected liver cells into the hepatic sinusoids and the bile canaliculi, passes into the intestine, and is excreted in the feces, where it may be found in high titers early in the infection.[165–167]

Because HAV is generally not cytopathic in cell culture, the pathologic findings in experimental animals and humans show little hepatocyte damage at the peak of viral replication. Immune mechanisms, in particular cell-mediated immune responses, have been postulated to explain the hepatic injury.[168,169] In contrast, circulating antibodies are probably more important in limiting spread of virus to uninfected liver cells, which, in combination with specific T cells, are responsible for termination of the infection.[169–171] As HAV has a positive strand RNA genome virus that goes through a double-stranded intermediary during its replication cycle, infection by HAV should be a strong inducer of type I interferons. HAV uses several molecular mechanisms to disrupt early innate immune responses controlling induction of interferon synthesis,[172,173] which results in a limited type I interferon response in the liver infected with HAV. Experimental animal models showed that HAV does not noticeably induce expression of interferon-stimulated genes (ISGs) despite the approximately 100-fold greater abundance of HAV RNA in the liver than during acute infections with other hepatitis viruses.[174, 175] The cellular helicases, RIGI and MDA5, and Toll-like receptor 3 (TLR3) are pattern recognition receptors that are activated by double-stranded RNA (dsRNA) and initiate the interferon signaling cascade.[176] Many viruses have evolved mechanisms to evade the interferon system. For example, the hepatitis C virus (HCV) protease cleaves RIGI, thus disrupting downstream signaling. It was recently shown that HAV has a mechanism that is similar to HCV. The 3ABC precursor of the HAV 3C protease is targeted by the transmembrane region of protein 3A to the mitochondrial membrane, where it then cleaves the mitochondrial antiviral signaling protein, MAVS. The cleavage of MAVS in turn disrupts the downstream interferon pathway and inhibits the production of interferons and interferon-induced antiviral proteins.[173]

In addition to the 3ABC intermediate, other products of incomplete processing of the HAV polyprotein play an important role in mitigating interferon response. For example, the 3CD intermediate disrupts TLR3 signaling and, consequently, interferon production.[172]

Although liver damage (as measured by ALT elevations) begins at about the same time that circulating antibodies become detectable, there are no data suggesting that the pathology is antibody-mediated, but is more likely from cytotoxic T lymphocytes. Although passive immunization with immunoglobulin can provide complete protection against infection, no data exist suggesting that already infected patients can be treated by infusion of antibodies.[177] The effectiveness of immunoglobulin also suggests that mucosal immunity is not required for prevention of HAV infections.[178,179]

Diagnosis

Hepatitis A is indistinguishable from other forms of acute viral hepatitis on clinical grounds, although the diagnosis may be suspected in a patient with typical symptoms during an outbreak. The diagnosis requires serologic detection of specific antibody responses to HAV and is confirmed by detection of HAV-specific IgM in a single acute-phase serum sample (Table 24.2).[180–182] The HAV-specific IgM antibody appears early in the illness, is usually present at the time the patient seeks medical attention, and declines to undetectable levels within 6 to 12 months in most cases. The presence of HAV-specific IgM in the serum is regarded as evidence of current or recent infection (Fig. 24.3).[183] Serologic assays can be initially negative in up to 10% of patients who are tested soon after onset of symptoms and testing should be repeated if hepatitis A is suspected clinically, particularly in the setting of an ongoing outbreak.[184,185] In addition, cases of positive test results for IgM

TABLE 24.2 Available Tests for Hepatitis A Virus and Antibody to Hepatitis A Virus

Tests	Uses and Comments
Anti–hepatitis A virus (HAV)/total antibody (radioimmunoassay [RIA]/enzyme-linked immunosorbent assay [ELISA])[a]	Determine immunity/susceptibility before vaccination epidemiologic studies
Anti-HAV/IgM-specific (RIA/ELISA)[a]	Primary test for diagnosis of current or recent infection
Anti-HAV/oral fluid (ELISA)	Research application in epidemiology
Neutralizing antibody (radioimmunofocus inhibition [RIFIT]; HAV antigen reduction assay [HAVARNA])	Research use, particularly for characterizing types of antibody induced by vaccination Very labor intensive; not widely available or well standardized
Viral culture (cell culture)	Research use only because virus grows slowly on initial isolation
HAV antigen (RIA/ELISA)	Research use for detecting virus in various specimens (i.e., cell culture)
HAV RNA (nucleic acid testing/polymerase chain reaction)	Research applications Epidemiologic studies and outbreak investigations Environmental studies
Liver biopsy (light or fluorescent microscopy)	Research with animal inoculations Rare diagnostic dilemma or unusual clinical manifestations Not indicated for most hepatitis A cases

[a]Only ELISAs are currently commercially available.

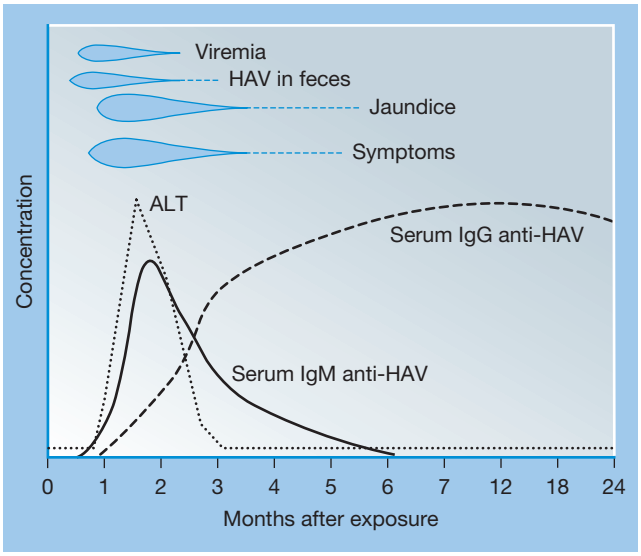

Figure 24.3. Clinical, virologic, and serologic events after hepatitis A virus (HAV) infection. ALT, alanine aminotransferase; Ig, immunoglobulin.

anti-HAV more than 1 year after infection have been reported. Furthermore, false-positive results among persons who have no other evidence of recent infection have been observed, reflecting a low positive predictive value of the test when used to test asymptomatic persons inappropriately.[186,187] Biochemical evidence of hepatitis consists of elevated levels of serum bilirubin and serum hepatic enzymes, including ALT, aspartate aminotransferase (AST), alkaline phosphatase, and γ-glutamyltranspeptidase. Elevations in AST and ALT levels occur most consistently and may precede the appearance of symptoms by a week or more (Fig. 24.3). Except for patients with relapsing or cholestatic hepatitis A, serum bilirubin and aminotransferase levels usually return to normal by 2 to 3 months after illness onset.[31]

A desire to monitor vaccine-induced protective immune responses prompted development of several in vitro assays for detection of HAV-neutralizing antibodies[188–190] and serologic assays that differentiate HAV immunity acquired after infection from immunity acquired after vaccination with inactivated hepatitis A vaccine.[191–193] None of these assays has found a broad application in the field or is commercially available. Several diagnostic assays for the detection of HAV antibody in oral fluid have been developed[194–197] to support population-based seroprevalence studies.[198–202] Although ease of oral fluid collection might simplify the logistics of anti-HAV testing, application of oral fluid tests to clinical management and practical epidemiology has been hampered by the lack of commercial assays.

Other tests are rarely used for the diagnosis of HAV infection (see Table 24.2). Viral detection assays generally have not been useful because wild-type HAV is extremely difficult to isolate in cell culture, usually requiring weeks or months. Because virus shedding peaks before the onset of clinical illness, antigen detection systems usually are insufficiently sensitive to detect HAV in stool samples. Polymerase chain reaction (PCR) techniques have been useful in certain clinical, epidemiologic, and environmental studies.[195–205] Although highly sensitive nucleic acid tests based on PCR could potentially be used in the diagnosis of acute HAV infections, no approved commercial assays are available. Commercially available serologic tests that measure total anti-HAV are used most often in epidemiologic investigations or in determining susceptibility to HAV infection as both natural infection and vaccine-acquired immunity will result in the presence of total anti-HAV (as IgG antibody).

Molecular Epidemiology

HAV is genetically heterogeneous.[135] Originally, HAV was classified into seven genotypes using a 168-nucleotide fragment of the HAV genome containing the VP1/P2A junction,[132] but it was recently reclassified into six genotypes, I to VI, based on sequences from the VP1 region.[206] Clear differences in clinical outcomes among the genotypes are not established. Despite multiple genotypes of HAV, there is one recognized serotype. Genotypes I, II, and III circulate among humans and genotypes IV, V, and VI infect simians.[132,207] Genotypes are divided into subtypes A and B. Geographic distribution of HAV genotypes and subtypes is not uniform. Genotype I has a worldwide distribution, with subtypes IA and IB frequently cocirculating. Subtype IA is prevalent in South and North America, Europe, Asia, and Africa, while subtype IB is predominant in the Middle East and South Africa. Recent evaluation, however, suggests that subtype IB is more abundant in South America than previously thought.[208] Genotype II seems to have a West African origin but it is not frequently detected.[209] Genotype III circulates globally; however, its prevalence varies among geographic regions.[207,208] Recently, an increase in subtype IIIA infections was reported in Korea, Russia, and Estonia.[210–212] Circulation of more than one subtype and genotype in certain geographic regions provides an opportunity for coinfection and recombination. Recombination between cocirculating HAV subtypes has been reported.[213–215]

HAV genetic heterogeneity is used for the identification of HAV strains and for outbreak investigations. The detection and sequencing of HAV RNA from water, food, and blood or saliva of infected individuals provide important information for tracing HAV strains and identifying the source of waterborne and foodborne hepatitis A outbreaks.[216,217] Molecular investigations are mainly conducted using short HAV genomic regions, usually VP1/P2A junction.[208] However, analysis of whole-genome sequences showed that the VP1/P2A sequences may be shared by different HAV strains and that more than one closely related HAV strain may be involved in a single foodborne outbreak.[218] Exposure to several HAV strains has been reported during outbreaks associated with person-to-person transmission in endemic regions.[219–221]

Genetic characterization of HAV strains collected during outbreak investigations has revealed important trends in HAV dissemination in different epidemiological settings. For example, identification of a few, large monophyletic clusters of the subtype IA HAV strains and sharing of these strains during outbreaks among men who have sex with men (MSM) from several countries in Europe indicates infrequent introductions of HAV strains into broad MSM networks capable of sustaining the introduced HAV variants for a prolonged period; the presence of many unique HAV variants and small monophyletic clusters of subtypes IB and IIIA among travelers returning from endemic countries emphasizes introduction of numerous HAV strains that do not spread broadly in Europe.[222,223] Detection of subtype IIIA among injection drug users was interpreted as a frequent introduction of HAV to these communities in developed countries through contaminated drugs originating in Central and South Asia where this subtype is prevalent.[222,224–227]

EPIDEMIOLOGY

Worldwide Disease Patterns

Hepatitis A occurs worldwide, but major geographic differences exist in endemicity and resulting epidemiologic features (Fig. 24.4).[16] The degree of endemicity is closely related to hygienic and sanitary conditions and other indicators of the level of development. Under conditions of overcrowding, especially when there is limited access to clean water and inadequate disposal of human feces (e.g., high endemicity; Fig. 24.5), HAV infects most people early in life, when infection is rarely clinically apparent. Where high standards of hygiene and sanitation exist, most children reach adult life without encountering the virus. Distinct patterns of HAV infection can be described, each with characteristic age-specific profiles of anti-HAV prevalence and hepatitis A incidence, attributable to prevailing environmental (hygienic and sanitary) and socioeconomic conditions (Fig. 24.5).[16,227] However, it is becoming increasingly challenging to generalize about endemicity in developing countries as prevalence patterns of HAV infection vary among regions within a country and among social strata; in addition, data are often missing or obsolete.[227]

In areas of high endemicity, represented by the least-developed countries (i.e., parts of Africa, Asia, and Central and South America), poor socioeconomic conditions allow HAV to spread readily (see Fig. 24.4).[16] The lifetime risk of infection exceeds 90%, in such countries and occurs primarily in early childhood[228] when asymptomatic infection predominates. Nearly the entire population is infected before reaching

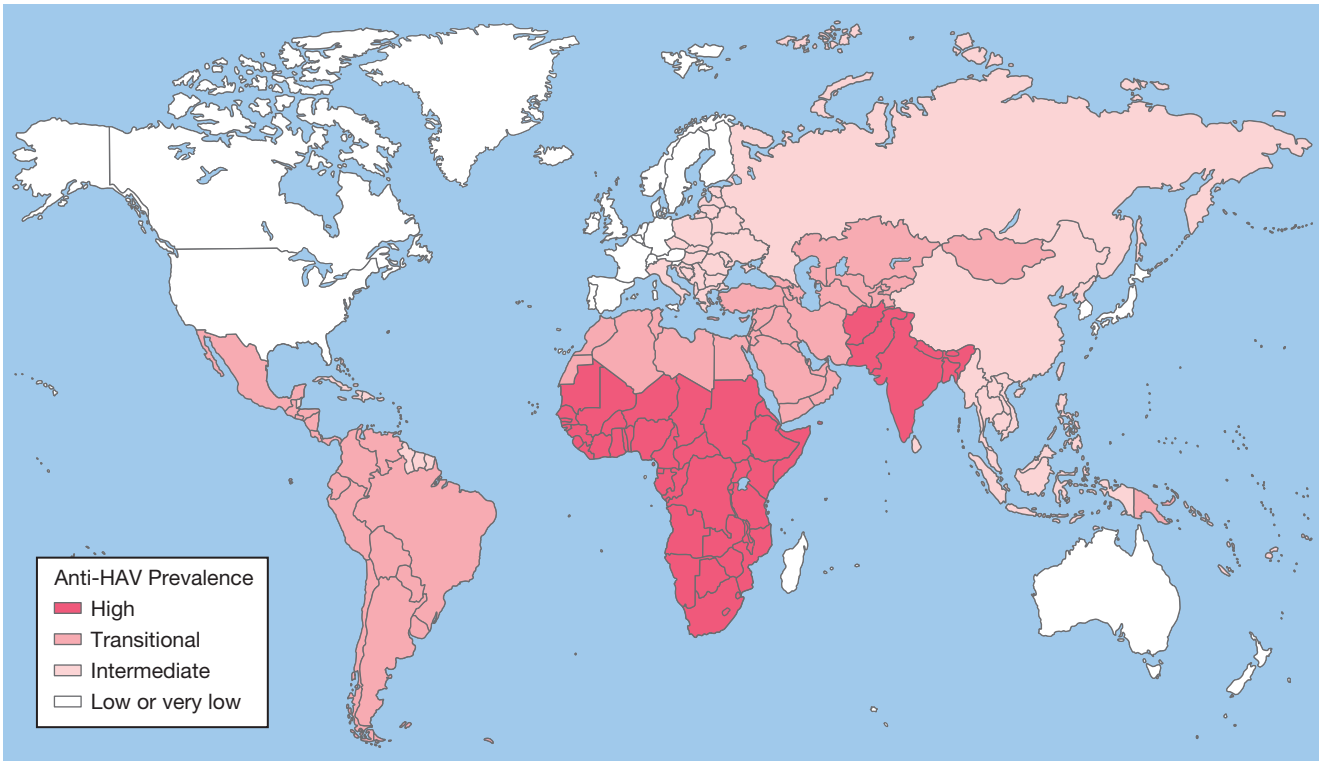

Figure 24.4. World map indicating patterns of endemicity of hepatitis A virus (HAV) infection (generalized from available data). Antibody to HAV prevalence patterns of high (red), intermediate (dark pink), low (light pink), and very low (white) endemicity are shown. *(From Jacobsen KH, Wiersma, ST. Hepatitis A virus seroprevalence by age and world region, 1990 and 2005.* Vaccine. *2010;28:6653–6657.)*

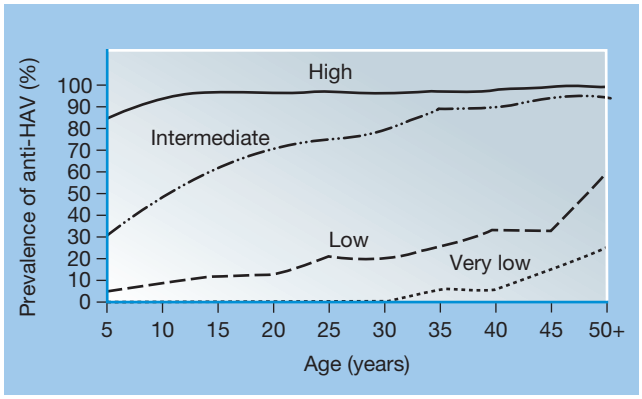

Figure 24.5. Patterns of hepatitis A virus (HAV) infection worldwide. Anti-HAV, antibody to HAV.

adolescence, as demonstrated by the age-specific prevalence of anti-HAV (see Fig. 24.5).[229–231] Susceptible adults in these areas are at high risk of infection and disease, but reported disease rates are generally low and outbreaks rarely reported, owing not only to the high prevalence of immunity in the population, but also to the lack of adequate surveillance. High endemicity patterns also may be seen in some ethnic or geographic groups within highly developed countries, such as the aboriginal children in northern Australia.[232] Travelers to high endemic areas from the developed world also are at high risk.[233]

In areas of moderate endemicity, HAV is not transmitted as readily because of better sanitary and living conditions, and the predominant age of infection is older than in areas of high endemicity (see Figs. 24.4 and 24.5).[16,234] Paradoxically, the overall incidence and average age of reported cases are often higher than in highly endemic areas because high levels of virus circulate in a population that includes many susceptible older children, adolescents, and young adults, who are likely to have symptoms with HAV infection.[235] Large common-source food- and water-associated outbreaks can occur because of the relatively high rate of virus transmission and large number of susceptible persons, especially in the higher socioeconomic level. An extreme example of an outbreak in intermediate endemicity populations occurred in Shanghai in 1988, with more than 300,000 cases associated with consumption of clams harvested from water contaminated with human sewage.[19] Nevertheless, person-to-person transmission in communitywide epidemics continues to account for much of the disease in these countries. Unimmunized travelers from the developed world to these areas also are at risk.[24,233]

In the United States, Canada, much of Western Europe, and other developed countries, the endemicity of HAV infection was described as low, but is now trending toward very low (see Figs. 24.4 and 24.5);[16] in low endemic countries relatively few children are infected. This level of endemicity is characterized by a low incidence of infection and disease, with disease often occurring in the context of communitywide outbreaks. In the United States, communitywide outbreaks have become increasingly rare and most recently transmission is characterized by common-source outbreaks, international travel, and contact with an infected person, a pattern of transmission more consistent with very low endemicity.[236] Low-endemicity countries experience a cyclic pattern of disease incidence with peaks every 5 to 10 years, as has been noted previously in the United States and in other developed countries with temperate climates. Population-based seroprevalence surveys show a gradual increase in the prevalence of anti-HAV with increasing age, primarily reflecting declining incidence, changing endemicity, and resultant lower childhood infection rates over time

(see Fig. 24.5).[237] In countries that have very low endemicity (e.g., Scandinavian countries, and now the United States and Canada), most cases occur in defined risk groups such as travelers returning from areas of high or intermediate endemicity and risk populations, such as users of injection drugs.[238] The changing epidemiology in the United States has also been influenced by universal vaccination recommendations for children.

Changes in the epidemiologic pattern of HAV have occurred in countries undergoing rapid development accompanied by improvement in sanitation standards and clean water supplies.[15] Shifts in age-specific prevalence patterns that reflect a transition from high to intermediate endemicity (see Fig. 24.5) show declines in childhood and adolescent HAV seroprevalence as the numbers of susceptible people at older ages at which there is greater associated morbidity and mortality, and greater risk for large communitywide outbreaks of hepatitis A, grow.[15,239–251] Considerable hepatitis A–related morbidity and associated costs occur with this shift in epidemiology, even in developing countries.[89,252] In the United States, as a result of significant decreases in incidence, owing in large part to universal childhood vaccination, there have been decreases in morbidity and mortality among children and adolescents, resulting in the average age of hepatitis A–related hospitalizations and deaths increasing.[253,254] Although overall hepatitis A morbidity and mortality have decreased dramatically in the United States, the proportion of persons hospitalized for hepatitis A in recent years are more likely to have liver diseases and other comorbid medical conditions.[254]

Epidemiology in the United States

Although large national outbreaks were recognized during the 1950s, data collection for hepatitis A in the United States started in 1966 (Fig. 24.6). The highest number of hepatitis A cases recorded in the United States was in 1971, approximately 60,000 cases (incidence: approximately 29 cases per 100,000 population). In 1995, when hepatitis A vaccine was licensed in the United States, more than 31,000 cases of hepatitis A had been reported (incidence: 12 cases per 100,000 persons) making hepatitis A one of the most frequently reported vaccine-preventable diseases (Fig. 24.6).[255] In the period 1996 to 1999, the Advisory Committee on Immunization Practices (ACIP) recommended targeted vaccination for children at 2 years of age in states with high hepatitis A rates.[256,257] Incidence rates declined sharply following implementation of these recommendations (Fig. 24.6).[236] In 2006, universal vaccination was recommended in all states for all U.S. children starting at 1 year of age.[86] The number of reported cases in the United States reached an all-time low in 2011 of 1398 cases, representing a 95.5% decline in reported cases since the first vaccine recommendation in 1996. The first increase in cases since 1995 occurred in 2012 (1562 total cases) and again in 2013 (1781 total cases); these increases have been coincident with a 2013 multistate outbreak of hepatitis A, and may be partly a result of increased reporting associated with heightened awareness around the outbreaks as there was substantial media reporting of the events.[17] In 2014, a total of 1,239 cases of hepatitis A were reported from 50 states to the CDC, a 30.4% decrease from 2013.[236] Most importantly, hepatitis A rates have declined since vaccine introduction—from 11.7 cases per 100,000 population in 1996 to between 0.4 and 0.6 cases per 100,000 population in 2011–14—a greater than 20-fold decline [236,258]

Young children typically have asymptomatic or unrecognized infections, and have historically, prior to vaccine introduction, played an important role in the epidemiology of hepatitis A in the United States, serving as a major reservoir for HAV transmission.[259] Prior to vaccine introduction in the United States, the highest hepatitis A rates were reported among children 5 to 14 years old, with approximately one-third of cases occurring among children younger than 15 years of age,[257] while the majority of infections were among asymptomatic children younger than 5 years of age.[260] Hepatitis A rates among children have declined more sharply than among adults since vaccine introduction and, since 2009 rates among both adults and children have been less than 1.0 case per 100,000 population despite small fluctuations in incidence (Fig. 24.7).[255,261] In 2014, persons aged 20 to 29 years had the highest rate (0.55 cases per 100,000 population) and persons aged 0 to 9 years had the lowest rate (0.10 cases per 100,000 population).

In the United States rates of hepatitis A among Hispanics have historically been higher than those of other racial/ethnic populations. Rates among Hispanics declined 94% from 1997 to 2007 (1.4 cases per 100,000 population); in 2009, the rate

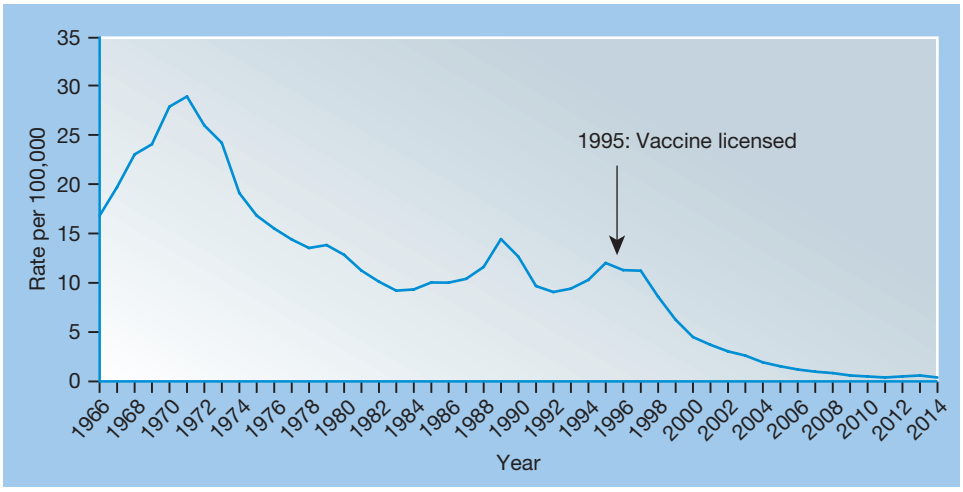

Figure 24.6. Hepatitis A incidence in the United States: 1966–2014. *(Data from the Centers for Disease Control and Prevention, National Notifiable Diseases Surveillance System, Atlanta, GA.)*

was the lowest ever recorded (0.8 per 100,000).[255,261] Rates among all racial and ethnic groups have declined dramatically and comparably in the United States, including Alaska Natives/Native Americans who have traditionally experienced among the highest rates (Fig. 24.8).[236] Mortality associated with hepatitis A in the United States is uncommon; of the 80 deaths reported in 2013 most were among older adults, and none were reported in 2014.[236]

In the United States, before hepatitis A vaccine was widely available, hepatitis A occurred in large nationwide epidemics approximately every decade.[262] The highest rates and the majority of cases occurred in the western and southwestern states.[86,257,263] With the advent of routine vaccination of children, large communitywide outbreaks and cyclic peaks have ceased. The geographic variations that characterized hepatitis A incidence in the past[263] have disappeared.

In the United States, prior to the introduction of vaccine when community outbreaks and outbreaks in childcare centers were common, studies of outbreaks where serologic testing of household contacts was performed found that 25% to 40% of contacts younger than 6 years of age had serologic evidence of acute HAV infection,[264,265] resulting in some immunity among children as they entered adolescence and adulthood.[28,266] A nationally representative serosurvey (for the years 2007–2010) focusing on ages 6 to 19 years in the United States, reported a 37.6% prevalence of immunity to hepatitis A measured by anti-HAV levels—a 13.1% increase compared to the prevaccine era (the years 1988–1994)—reflecting the increased immunity among children as a consequence of vaccination. However, results from National Health and Nutrition Examination surveys conducted for the periods 1988–1994, 1999–2002, and 2003–2006 indicate an overall decline in the age-adjusted seroprevalence of anti-HAV in the U.S. population from 32.5% in 1988–1994 to 26.7% in 2003–2006, presumably as herd immunity has prevented infection among adults.[267] Substantial declines in HAV infections among children have resulted in decreased age-specific seroprevalence rates among U.S. adults and therefore an increase in susceptibility to HAV among older adults.[267,268] The 2013 multistate outbreak of hepatitis A occurred largely in adults with few cases among vaccinated and unvaccinated children.[17] In summary, the epidemiology of hepatitis A in the United States is fundamentally changed as endemic transmission, outbreaks in childcare centers, and large community outbreaks have been virtually eliminated by the childhood vaccination program. We are likely to continue to see a greater proportion of cases among adults because of travel and outbreaks associated with imported food contaminated with HAV, although the overall risk of hepatitis A to the United States population is greatly diminished.

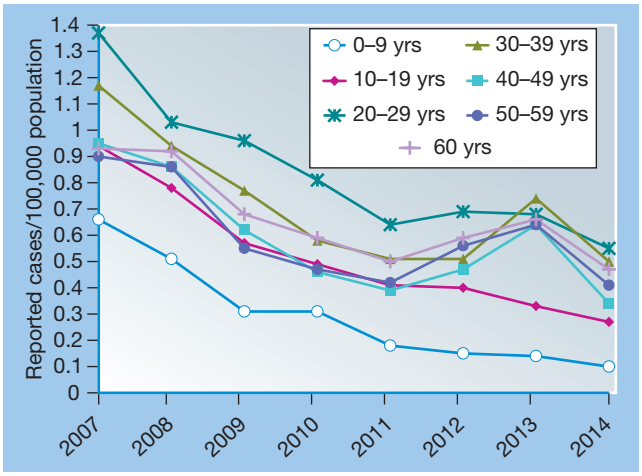

Figure 24.7. Incidence of acute hepatitis A by age group in the United States: 2007–2014. *(Data from the Centers for Disease Control and Prevention, National Notifiable Diseases Surveillance System, Atlanta, GA.)*

Potential Sources of Infection

In 2014, only 7% of hepatitis A cases reported in the United States had a risk factor identified; the other 93% either had no risk factor identified or data were missing.[236] Of the 7% with a risk factor identified, international travel was the most commonly identified risk.[236] Other potential sources of infection identified in the United States in 2014 include injection-drug use, MSM, association with daycare (child or employee), association with a recognized food/waterborne outbreak, and other contact with a hepatitis A patient. Common source food exposures are likely to continue to occur with sporadic

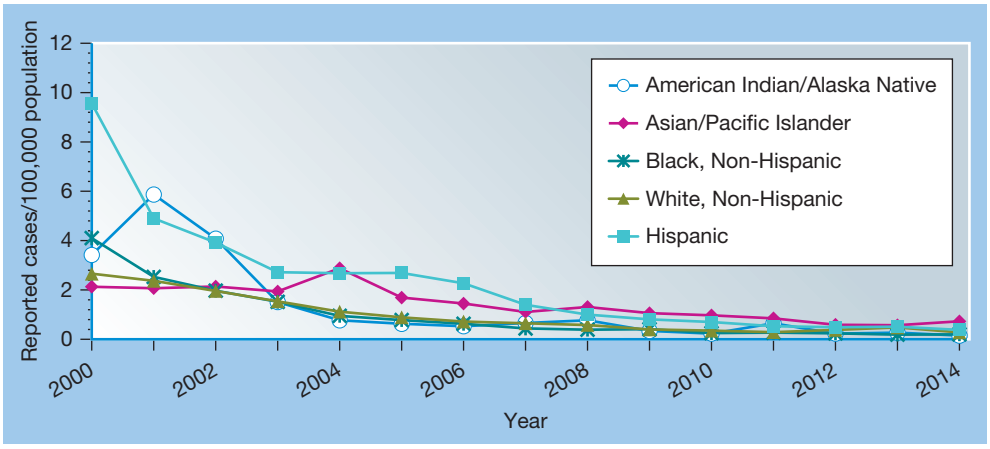

Figure 24.8. Incidence of acute hepatitis A by race/ethnicity in the United States: 2000–2014. *(Data from the Centers for Disease Control and Prevention, National Notifiable Diseases Surveillance System, Atlanta, GA.)*

outbreaks being reported in Europe and North America, as well as other countries with low levels of endemic transmission of hepatitis A.[17,269,270]

Specific Groups and Settings

International Travel. Hepatitis A is a risk for unvaccinated persons from developed countries who travel to regions with high, transitional, or intermediate endemicity (see Fig. 24.4).[271–273] A study published in 2006 of Swiss travelers estimated the risk to be 6 to 30 cases per 100,000 months of stay in developing countries among persons who did not receive immunoglobulin or vaccine before departure.[274] The risk may be higher among travelers staying in areas with poor hygienic conditions[275] and varies according to the region and the length of stay. Declines in the number of hepatitis A cases attributed to improved infrastructure in endemic countries are now reported for travelers from some European countries.[276,277] In the United States, international travel is a commonly reported risk factor.[236,278] In the United States and Europe, hepatitis A in travelers, especially children, traveling to endemic countries to visit relatives and friends accounts for an increasing proportion of reported cases. Compared with persons traveling for work or recreation, these persons generally have trips of longer duration and, by staying in family settings rather than in hotels, may have greater exposure to HAV circulating in the community. These persons also are less likely to seek or to adhere to pretravel advice.[279–286] Travelers who acquire hepatitis A infection during their trip may also transmit the virus to others on their return.[287] Vaccination of international travelers to endemic regions remains an important consideration for pretravel preparations.[288]

Contacts of International Adoptees. International adoptees with asymptomatic hepatitis A may transmit the virus to family members and close contacts. Most adoptee-associated cases of hepatitis A are among unvaccinated nontraveling contacts of the adoptee exposed during the first 60 days after arrival in the United States; secondary and tertiary transmission have been described.[289–292] One study of 270 adoptees who received serologic testing within 4 months of arrival in the United States found that 1% had evidence of acute hepatitis A, and rates varied by country of origin; furthermore, all acutely infected adoptees were asymptomatic.[292] A retrospective review from Minnesota from 2007 to 2009 identified 21 hepatitis A cases among international adoptees younger than 60 months of age.[293] Another study found the prevalence of acute HAV infection to be 4.6% among international adoptees based on screening of adoptees from 2006 to 2010; the study made note of the substantial interruption of care and social support associated with secondary caretaker infection.[294] Screening of international adoptees from endemic areas has been suggested as a preventive measure; however, there is a need for a better understanding of the impact and public health importance of international adoptees introducing hepatitis A into the community, including consideration of the effort and expense of screening as compared to the benefits.

Users of Illicit Drugs and Homeless Populations. In recent decades, outbreaks of hepatitis A have been reported among illicit drug users in North America, Australia, and Europe.[84,87,226,295–302] In the United States, these outbreaks involved users of injected and noninjected methamphetamine, who accounted for up to 30% of reported cases in communities during outbreaks in some settings.[90,298,303,304] Cross-sectional serologic surveys have demonstrated that injection drug users have a higher prevalence of anti-HAV than the general U.S. population.[305–310] A randomized intervention trial of 469 injection (70%) and noninjection (30%) drug users in methadone maintenance, found 56% were anti-HAV–positive.[311] Transmission among injection drug users probably occurs through percutaneous and fecal–oral routes.[298] Similarly, homeless populations in the United States and Europe may have increased seroprevalence of hepatitis A and are recognized in occasional outbreaks.[312] The risk of hepatitis A may be related to sexual and illicit drug use practices, years as a homeless person, and country of origin.[299,312–314]

Men Who Have Sex With Men. Hepatitis A outbreaks among MSM have been reported in urban areas in the United States, Canada, Europe, and Australia, and may occur in the context of an outbreak in the larger community.[302,303,315–320] Outbreaks among MSM have been reported in Europe during 2008–2009 in Ireland, Poland, and Italy[321–323]; however, seroprevalence surveys have not consistently demonstrated an elevated prevalence of anti-HAV among MSM compared with a general population of similar age.[305,324] Some studies conducted during outbreaks and seroprevalence surveys have identified specific sex practices associated with illness, whereas others have not demonstrated such associations.[306,315,318] A recent large cross-sectional prevalence study among MSM conducted from 1994 to 2000 in the United States found a similar prevalence of anti-HAV as in the general population of similar age.[325] The study also found that factors associated with HAV infection among MSM in nonoutbreak settings are likely similar to those among non-MSM, although the risk of HAV infection from community outbreaks among MSM exists and could be prevented with vaccination.

Transfusion and Healthcare-Related Transmission. Transfusion-related hepatitis A is rare (see "Bloodborne" below).[326] The risk of infection in patients with hemophilia is unknown, but results of one serologic survey of persons with hemophilia before the licensure of hepatitis A vaccine suggested they might have been at increased risk.[327] Outbreaks have been reported in Europe and the United States among patients who received factor VIII and factor IX concentrates.[328,329] However, no HAV infections attributed to blood products were identified in an analysis of serosurveillance data collected from 140 hemophilia treatment centers in the United States between 1998 and 2002, suggesting that improved viral inactivation procedures, donor screening, and increased hepatitis A vaccination coverage among clotting factor recipients has reduced the risk of HAV transmission.[330]

Outbreaks of hepatitis A have been reported in neonatal intensive care units following transmission to hospital staff from a neonate with asymptomatic HAV infection acquired from a blood transfusion.[331–334] One episode of transmission was reported in association with an experimental treatment with lymphocytes incubated in serum from a donor with HAV infection.[335]

Nosocomial transmission of hepatitis A from adult patients to healthcare workers also is rare because most patients with hepatitis A are hospitalized after the onset of jaundice, when infectivity is low, but it has been reported in association with fecal incontinence of patients.[336–338] Healthcare workers were not found to have an increased prevalence of anti-HAV compared with control populations in serologic surveys conducted in the United States from 1977 to 1982.[339]

Foodborne and Waterborne. Foodborne hepatitis A outbreaks are of increasing concern globally, particularly in Europe and the United States. Historically, in the United States they were most commonly associated with contamination of food during preparation by a food handler with HAV infection.[217,340–345] Food contaminated before retail distribution,

such as lettuce or fruits contaminated at the growing or processing stage, can be the source of hepatitis A outbreaks, some of which can be large or spread over a wide geographic area.[205,346–351] Since 2000, common source food exposures, such as the 2003 outbreak associated with contaminated green onions[350] and more recently contaminated berries imported from countries with endemic transmission of hepatitis A, have been increasingly recognized in hepatitis A low and very low endemic regions.[269,270,352–354] According to the Rapid Alert System for Food and Feed database in Europe, 35 notifications of HAV in food were reported between 1999 and 2013 in eight European Union countries from multiple food sources. In such outbreaks, trace back to the contaminated product and isolation of HAV has proven to be challenging.[270,352,353]

Mixed frozen berries were implicated in a hepatitis A genotype 1A outbreak in Italy in 2013.[270,352,355] An outbreak likely associated with berry mix buttermilk cake imported frozen from Germany[357] occurred in 2013–2014. Other recent outbreaks of HAV genotype IB illness associated with food from the Middle East were also reported. A Nordic outbreak (Denmark, Finland, Sweden, and Norway) occurred in 2012–2013 from contaminated strawberries, suspected to have originated from Egypt and Morocco.[358,359] Frozen pomegranate arils from Egypt were implicated in an outbreak in Canada in 2012, and imported pomegranate arils from Turkey were associated with a multistate outbreak in the United States in 2013.[17] Semidried tomatoes from Turkey were associated with cases in Europe and Australia in 2009–2011.[269,360,361]

In low and very low endemic countries, outbreaks related to contaminated shellfish have become less common but are still occasionally identified.[362–366] Waterborne hepatitis A outbreaks are rare and generally are related to sewage contamination or inadequate treatment of water.[367–369]

Although results of some serologic surveys conducted among sewage workers in Europe indicated a possible elevated risk of HAV infection, findings have not been consistent.[370–372] In published reports of three serologic surveys conducted among U.S. sewage workers and appropriate comparison populations, no substantial or consistent increase in prevalence of anti-HAV was found among sewage workers.[373–375] No work-related instances of HAV transmission have been reported among sewage workers in the United States.

Institutions for Persons With Developmental Disabilities

Historically, HAV infection was endemic in institutions for developmentally disabled people, but with smaller facilities, improved conditions, and vaccination, the incidence and prevalence of infection have decreased and outbreaks rarely are reported in the United States.[86,255,376] However, unvaccinated disabled adults cared for in group homes may be at risk from living in close quarters, and often being incontinent and nonverbal.[377] Unvaccinated staff working in group homes may also be at risk during such outbreaks. During April to July 2013, an outbreak in Michigan occurred in which eight unvaccinated residents of five group homes for adults with disabilities were diagnosed with hepatitis A, and one died.[377]

MODES OF TRANSMISSION

HAV is primarily transmitted by the fecal–oral route. The virus replicates in the liver, is excreted in bile, and is found in highest concentrations in stool.[378] Because of the high concentration of HAV in the stool of infected persons, fecal excretion of HAV is the primary source of virus. Virus can be demonstrated in stool for 14 to 21 days before to 8 days after the appearance of jaundice. The highest concentrations are during the 2-week period before jaundice develops or liver enzyme levels become elevated, followed by a rapid decline after the appearance of jaundice (see Fig. 24.3).[13,337,378] Epidemiologic studies demonstrated that peak infectivity and the greatest risk of transmission occur during the 2 weeks before onset of symptoms.[10] Shedding of HAV may continue for longer periods in infected infants and children than in adults. With the use of PCR techniques, HAV RNA has been detected in stools of infected newborns for up to 6 months after infection.[331] Excretion in older children and adults has been demonstrated 1 to 3 months or longer after clinical illness.[164,331,379–381] Although chronic shedding of HAV does not occur, the virus has been detected in stool during relapsing illness.[30,32,382]

The infectious dose of HAV in humans is not known. During the period of viremia, which begins during the prodrome and extends through the period of liver enzyme elevation (see Fig. 24.3), HAV concentrations in blood are several orders of magnitude lower than in stool.[162,164,383,384] However, in experiments conducted in nonhuman primates, HAV was several orders of magnitude more infectious when administered by the intravenous compared with the oral route, and animals were successfully infected with low concentrations of HAV administered by the intravenous route.[23] Although HAV occasionally may be detected in saliva in experimentally infected animals,[162] transmission by saliva has not been demonstrated.

Enzyme immunoassays and PCR may detect defective (noninfectious) and infectious viral particles. Thus, the detection of HAV antigen in the stool by enzyme immunoassays or HAV RNA in the serum or stool by PCR does not indicate whether the person is infectious. It is likely that the period of infectivity is shorter than the period during which HAV RNA is detectable in stool. For practical purposes, children and adults with hepatitis A can be assumed to be noninfectious 1 week after jaundice appears.

Person to Person

Person-to-person transmission by the fecal–oral route is the predominant means of HAV transmission globally.[303,385] Most transmission occurs among close contacts, particularly in households and extended family settings.[264,265,386] In areas of endemic transmission, young children have the highest rates of infection and are often the source of infection for others, primarily because infections in this age group are usually asymptomatic and standards of hygiene are generally lower among young children than among adults.[260,264,265,386]

Foodborne and Waterborne

HAV can remain infectious in the environment,[387] allowing for common-source outbreaks and sporadic cases to occur from exposure to fecally contaminated food or water. Many uncooked foods have been implicated as the source of outbreaks. Cooked foods also can transmit HAV if the cooking is inadequate to kill the virus or if the food is contaminated after cooking, as commonly occurs in outbreaks associated with infected food handlers.[217,340,341,344,388,389] Hepatitis A inactivation has been demonstrated when exposed to 90°C temperature for 180 seconds.[390] Contaminated [390] shellfish were responsible for a large outbreak in Shanghai in 1988.[19,391] Although outbreaks continue to be reported,[362–365] shellfish-associated HAV outbreaks in the United States and other developed countries are increasingly uncommon.[366,392] Several large outbreaks traced to produce contaminated before distribution have been reported in recent years from the United

States, Europe, and Australia.[17,205,269,346,350,351,361,393] Waterborne outbreaks of hepatitis A are uncommon in developed countries, but have been reported from countries with poor water sanitation and infrastructure.[394]

Bloodborne

Transfusion-related hepatitis A is rare because HAV does not result in chronic infection. In the developed world, blood donors are routinely screened for elevated aminotransferase levels, further decreasing the risk of transmission during the viremic prejaundice phase of infection. Transmission by transfusion of blood or blood derivatives collected from donors during the viremic phase of infection has been reported, including outbreaks in Europe, Korea, and the United States among patients who received factor VIII and factor IX concentrates prepared using solvent-detergent treatment to inactivate lipid-containing viruses.[326,328,329,384,395–398] HAV is resistant to solvent-detergent treatment, and contamination presumably occurred from plasma donors with hepatitis A who donated during the incubation period. Since 2002, nucleic acid amplification tests such as PCR have been applied to the screening of source plasma used for the manufacture of plasma-derived products in the United States. These assays have sufficient sensitivity to remove most units of blood or plasma that contain HAV.[326,330,399] In settings where such procedures are not followed, infection from HAV remains as a remote possibility.

Vertical

Rare published case reports describe intrauterine transmission of HAV during the first trimester, resulting in fetal meconium peritonitis.[400,401] After delivery, two infants were found to have a perforated ileum. The risk of transmission from pregnant women in whom hepatitis A develops in the third trimester of pregnancy to newborns seems to be low.[78,402] However, newborns who acquire infection in this manner are usually asymptomatic, and an outbreak among hospital staff related to exposure to an infected asymptomatic infant has been reported.[403]

SIGNIFICANCE AS A PUBLIC HEALTH PROBLEM

The World Health Organization (WHO) estimates that more than 100 million cases occur annually, resulting in an estimated 15,000 to 30,000 deaths per year.[14,16] The burden of disease is closely linked to the economic development of a country (see "Worldwide Disease Patterns," above, and Fig. 24.5). In the United States, Canada, Western Europe, and other developed countries, endemic transmission is low to very low with small numbers of cases being reported, and a substantial proportion associated with a common-source outbreak or international travel. A recent analysis of data from the United States revealed not only cases but also hospitalizations and death have decreased substantially.[254] There have been major declines in incidence since introduction of hepatitis A vaccine in the United States in the 1990s; less than 1500 cases were reported in 2014. However, 45% of acute hepatitis A cases with available data were hospitalized, and none died.[88,236,261] The decrease in disease, coupled with the successful vaccination program in the United States, has resulted in the prevalence of immunity acquired from infection reduced among young adults, leaving a substantial proportion of this population without natural or vaccine-induced immunity.[267]

PASSIVE IMMUNIZATION

Until the licensure of hepatitis A vaccines, immunoglobulin (previously known as γ-globulin or immune serum globulin) was the mainstay of prevention for HAV after exposure through administration of passive antibodies. This product has also proven useful for prevention of hepatitis A in travelers, Peace Corps volunteers, military personnel, and persons recently in close contact with a person with hepatitis A, as well as to control outbreaks in childcare centers.[404–406] In the United States, GamaSTAN (Grifols Therapeutics Inc., Research Triangle Park, NC) is currently the only available hepatitis A immunoglobulin (IgG anti-HAV) product.[407] Immunoglobulin is prepared by a serial cold ethanol precipitation from pools of plasma, collected from tens of thousands of donors. Donors are screened for hepatitis B virus (HBV), HIV, and HCV by serologic and other assays.[408,409] Since 1995, immunoglobulin prepared in the United States has been required to be negative for HCV RNA by PCR amplification or to be produced using a method that ensures additional virus inactivation.[409] The manufacturing process removes contaminate enveloped and nonenveloped viruses, including HIV, HBV, HCV, as well as low levels of Creutzfeldt-Jakob disease (CJD)/variant CJD (vCJD) agent infectivity.[407]

Since licensure of inactivated hepatitis A vaccines, vaccination is preferred for preexposure and postexposure prophylaxis, and the use of immunoglobulin for preexposure and postexposure prophylaxis is limited. Immunoglobulin is indicated in persons for whom the vaccine is contraindicated, and in certain situations for international travel and postexposure prophylaxis (see "Preexposure and Postexposure Prophylaxis" below) (Table 24.3).[410]

Seroprotective levels (see section on correlates of protection below) of anti-HAV (ie, 10–20 mIU/mL) appear rapidly after preexposure intramuscular injection of Ig.[177] Peak levels of immunoglobulin are reached in approximately 2 days after injection.[411] Immunoglobulin is 80% to 90% effective in preventing hepatitis A when administered before exposure or within 2 weeks after exposure.[177,412–415] Whether immunoglobulin completely prevents infection or leads to asymptomatic infection and the development of persistent anti-HAV (passive–active immunity) is related to the amount of time between exposure and immunoglobulin administration.[24,414,416] Immunoglobulin has not been successful in controlling communitywide hepatitis A outbreaks, owing in part to the transient nature of protection, coverage rates, perhaps the lack of herd immunity, and the frequency of unrecognized infection.[417]

Although the prevalence of antibody to HAV in the population has been declining, and in the United States there is no standard for anti-HAV levels in immunoglobulin preparations, no clinical or epidemiologic evidence of decreased protection from immunoglobulin has been observed.[86,418]

Serious adverse events from immunoglobulin are rare. Because anaphylaxis has been reported after repeated administration to persons with IgA deficiency, these persons should not receive immunoglobulin.[419] Immunoglobulin is also contraindicated for persons who have severe thrombocytopenia or any coagulation disorder.[419] Pregnancy and lactation are not contraindications to immunoglobulin administration.

Immunoglobulin should be administered intramuscularly only, preferably in the deltoid muscle of the upper arm or the anterolateral aspects of the upper thigh in children younger than age 24 months.[410]

Immunoglobulin can be administered at the same time as most inactivated vaccines. It does not interfere with the immune response to oral poliovirus vaccine or yellow fever vaccine; immunoglobulin, however, can interfere with the response to live attenuated virus vaccines (e.g., measles,

TABLE 24.3 Recommended Preexposure Prophylaxis for International Travel and Postexposure Immunoprophylaxis

Age/Health Status	Immunoglobulin (Ig) Dosage[a]	Hepatitis A Vaccine
PREEXPOSURE PROPHYLAXIS FOR INTERNATIONAL TRAVEL		
Infants <12 mo,[b] persons allergic to vaccine or who elect not to be vaccinated	*For length of stay:* <3 mo: Ig 0.02 mL/kg 3–5 mo: Ig 0.06 mL/kg >5 mo: Ig 0.06 mL/kg (repeat every 5 mo for extended travel)	None; vaccinate infants at age 12 mo
12 mo–40 y	None	One dose of hepatitis A vaccine as soon as possible before departure[c]
>40 y and persons with special conditions[d]	*For length of stay:* <3 mo: IgG 0.02 mL/kg 3–5 mo: Ig 0.06 mL/kg >5 mo: Ig 0.06 mL/kg (repeat every 5 months for extended stay)	Ig *and* one dose of hepatitis A vaccine as soon as possible before departure[c]
POSTEXPOSURE PROPHYLAXIS FOR PREVIOUSLY UNVACCINATED PERSONS[e]		
Infants <12 mo,[b] persons with special conditions[d]	Ig 0.02 mL/kg within ≤2 wk of exposure; efficacy of Ig administered >2 wk after exposure not established	None; vaccinate infants at age 12 mo
Healthy persons 12 mo–40 y	None	Hepatitis A vaccination as soon as possible
Persons >40 y	Ig 0.02 mL/kg within 2 wk of exposure preferred	Hepatitis A vaccine can be used if Ig is not available

[a]For preexposure prophylaxis, administer Ig ≤2 weeks before departure. Intramuscular preparations of Ig should never be given intravenously, and the intravenous preparations of Ig are not intended for hepatitis A prevention and are formulated at a lower globulin concentration. Hepatitis A vaccine should be administered as soon as possible before departure. Immunoglobulin and hepatitis A vaccine should be administered at separate sites if administered at the same visit. For postexposure prophylaxis, Ig should be administered as soon as possible within 2 weeks after exposure.

[b]Children younger than 1 year (for whom vaccine is not licensed) and persons with a contraindication to vaccination should receive Ig 0.06 mL/kg, repeated every 5 months during exposure.

[c]The hepatitis A vaccine series should be completed with a second dose 6 months after the first dose.

[d]Special conditions: immunocompromised persons, persons with diagnosed chronic liver disease, and persons for whom vaccine is contraindicated.

[e]Persons who previously received a dose of hepatitis A vaccine should complete the series. Persons who previously received a complete series of hepatitis A vaccine need no further treatment.

From Novack R, Williams I, Bell B. Update: prevention of hepatitis A after exposure to hepatitis A virus and in international travelers: updated recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Morb Mortal Wkly Rep. *2007;56:1080–1084.*

mumps, and rubella [MMR] vaccine and varicella virus vaccine) when administered either as individual or combination vaccines.[86,419,420]

ACTIVE IMMUNIZATION

History of Vaccine Development

Hepatitis A vaccine for active immunization was developed in a manner similar to that used for poliovirus vaccines. As for poliovirus vaccines, the initial breakthrough came with the in vitro cultivation of HAV in cell lines suitable for vaccine production.[153] HAV was successfully propagated in cell culture obtained from marmoset liver cells in 1979.[16] Since then, formalin-inactivated, cell culture–produced, whole-virus vaccines have been approved in much of the world.[421,422]

The cell culture–adapted HAV strains CR326F and HM175 were found to be highly attenuated in humans and have been tested as live attenuated vaccine candidates in primates and to a limited extent in humans.[423–426] For both strains, inoculums of greater than 10^6 tissue culture infective doses (TCIDs) were required to induce an antibody response in volunteers. That the vaccines infected volunteers was never proved because the only evidence was seroconversion, which could have been induced by the antigenic mass contained in the inoculums rather than new antigen produced by replication.

The entire nucleotide sequences of the wild-type and the vaccine variant of HM175 have been determined.[114,156] A full-length, infectious cDNA clone of the cell culture–adapted virus was made,[427,428] and the mutations responsible for cell culture adaptation and attenuation were determined by the molecular construction of chimeric viruses.[124,156,428] Substitutions and deletions in the 5′ noncoding region and substitutions in the 2B/2C coding regions were found to be important for cell culture adaptation and attenuation of virulence. However, mutations throughout the genome contributed to improved in vitro replication.[429]

Description of Current Vaccines and History of Development

Inactivated and live attenuated hepatitis A vaccines have been developed worldwide. The WHO recommends vaccination in countries with intermediate to low endemicity.[16]

In 1995, the first inactivated U.S. Food and Drug Administration (FDA)-approved HAV vaccine Havrix (GlaxoSmithKline Biologicals, Rixensart, Belgium) became available in the United States; a second inactivated HAV vaccine VAQTA (Merck & Co, Inc., West Point, PA) was introduced in the United States in1996.[86] In 2001, a combination hepatitis A and hepatitis B vaccine (Twinrix, GlaxoSmithKline, Research Triangle Park, NC) was approved in the United States for persons age 18 years or older. These vaccines have been approved for use throughout much of the world (Table 24.4).[421,422]

Similar inactivated vaccines have been licensed or registered in Europe, Canada, China, and other countries.[430–432] VAQTA is based on strain CR326F of HAV isolated in Costa Rica and was the first strain to be successfully cultivated in vitro.[153] CR326F initially was isolated in a fetal rhesus kidney

TABLE 24.4 Major Constituents and Recommended Schedules for Selected Inactivated Hepatitis A Vaccines[a]

Manufacturer	Trade Name	HAV Strain	Adjuvant	Dosage	Age	Volume (mL)	Schedule (mo)[b]
Merck & Co., Inc.	VAQTA	CR326F	Aluminum hydroxyphosphate sulfate	25 U 50 U	12 mo–18 y ≥19 y	0.5 1.0	0, 6–18 0, 6–18
GlaxoSmithKline Biologicals	Havrix	HM175	Aluminum hydroxide	720 EL.U. 1,440 EL.U.	12 mo–18 y ≥19 y	0.5 1.0	0, 6–12 0, 6–12
Sanofi Pasteur, Inc.[377]	Avaxim	GBM	Aluminum hydroxide	80 U 160 U	12 mo–15 y ≥16 y	0.5 0.5	0, 6–18 0, 6–18
Crucell Vaccines Inc.[385]	Epaxal	RG-SB	Virosomes composed of 10 μg purified influenza virus hemagglutinin and 100 μg of phospholipids (immunopotentiating reconstituted influenza virosome)	25 IU	≥12 mo	0.5	0, 6–12
Sinovac Biotech Ltd.	Healive	TZ84	Aluminum hydroxide	250 U 500 U	12 mo–15 y ≥16 y	0.5 1.0	0, 6 0, 6

EL.U., enzyme-linked immunosorbent assay units; HAV, hepatitis A virus; IU, international units; U, units of HAV antigen.
[a]Licensed ages, dosages, and schedules vary among countries. All vaccines are administered by the intramuscular route in a two-dose series. Some vaccines contain other constituents. Refer to the product insert for more information.
[b]Zero months represents the timing of the initial dose; subsequent numbers represent months after the initial dose.

cell line, FRhK6. After 15 passages, it was transferred to human embryonic lung diploid fibroblast (MRC-5) cells for an additional 28 passages.[422] Havrix is based on strain HM175 of HAV, isolated from stool of a patient in a family outbreak in Australia.[433] It was originally adapted to cell culture by a series of 30 passages in primary green monkey kidney cells followed by adaptation to MRC-5 cells.[421] Twinrix contains inactivated HAV and noninfectious recombinant hepatitis B surface antigen. The purified HBsAg is obtained by culturing genetically engineered *Saccharomyces cerevisiae* yeast cells. Each antigen is separately adsorbed onto aluminum salts and pooled during Twinrix formulation.[434]

Avaxim (Sanofi Pasteur, Lyon, France), based on the GBM strain of HAV, is licensed in Europe, Canada, and other areas.[435] This strain was isolated and propagated on primary human kidney cell culture for 10 passages, followed by adaptation to human diploid fibroblast cells during 20 passages.[436–438] Inoculation of chimpanzees showed that the strain had been attenuated by passage.[439] This vaccine also is produced in the MRC-5 human diploid fibroblast cell strain and is processed in a way similar to the U.S.-licensed vaccines.[430]

A vaccine developed at the Swiss Serum Institute, called Epaxal, is licensed by Crucell Vaccines Inc. (Leiden, The Netherlands) in most countries in Europe and Canada, in many countries in South America, and other parts of the world.[431,440–443] The RG-SB strain of HAV used in this vaccine is harvested from disrupted MRC-5 cells and inactivated by formalin. The liposome adjuvant, immunopotentiating reconstituted influenza virosomes (IRIV) is composed of phosphatidylcholine, phosphatidylethanolamine, and hemagglutinin from A/Singapore/6/86-like H1N1 strain of influenza virus. It is hypothesized that IRIVs may stimulate humoral and cellular immunity by binding to macrophages and other cells primed by influenza virus.[440]

More than one inactivated vaccine is available in China. Healive (Sinovac Biotech Ltd., Beijing) is based on formalin-inactivated HAV strain TZ84 cultivated in 2BS human fetal lung diploid fibroblast cells. Pediatric and adult formulations are available; 0.5 mL/250 U for persons ages 1 to 15 years; 1.0 mL/500 U for persons age 16 years or older.[432,444]

A freeze-dried, live attenuated HAV vaccine has also been used in China (Zhepu, Zhejiang Pukang Biotechology Co. Ltd., Hangzhou)[155,445–448] and is immunogenic in trials conducted in India.[449,450] The vaccine uses the H2 strain, a derivative of the cell culture–adapted, attenuated strain of HM175.[424,428,429] A randomized trial demonstrated detectable antibody for 8 years after the vaccine was administered either as a single subcutaneous dose or a single dose plus a booster dose at 12 months, suggesting that a booster dose is not needed in immunocompetent persons.[447] Because the virus is highly attenuated, large inoculums (≈10^7 $TCID_{50}$ [median TCID]) are needed to produce an immune response in humans.

Constituents

All available inactivated vaccines include HAV antigen, but the units by which the antigen content is expressed are different for each vaccine (see "Preparations" below). Owing to the different assays used and the lack of an accepted standard, it is not possible to compare the antigen content of the various vaccines (see Table 24.4). Havrix, VAQTA, Avaxim, and Healive contain aluminum hydroxide or aluminum hydroxyphosphate as an adjuvant. Epaxal uses liposomes as the adjuvant. Avaxim is formulated using 2-phenoxyethanol as a preservative; the other vaccines are formulated without preservatives. No hepatitis A vaccine contains antibiotics; however, residual antibiotic from the manufacturing process might be present in trace amounts in Havrix (neomycin), Avaxim (neomycin), and Epaxal (polymyxin B). Hepatitis A viral particles are concentrated and purified during the manufacture of all the vaccines. Differences in the content of nonvirion proteins exist between the vaccines, but these differences have not been found to be clinically relevant.

Manufacture

Inactivated hepatitis A vaccines are produced in similar ways. The vaccine virus is grown in cell culture, harvested by cell lysis, and inactivated with formalin. Differences relate to the viral purification processes.

Preparations

Both inactivated monovalent hepatitis A vaccines licensed in the United States are available in pediatric and adult formulations. All monovalent inactivated hepatitis A vaccines have

formulations available for persons at least 1 year old; all are available in two-dose schedules and are administered intramuscularly (see Table 24.4).[442,451,452]

Combination inactivated hepatitis A and recombinant hepatitis B vaccine (Twinrix; GlaxoSmithKline, Rixensart, Belgium) is available in the United States for persons age 18 years or older in a three-dose schedule (0, 1, 6 months), or in a four-dose "accelerated" schedule (days 0, 7, 21–30, and 12 months) for adults.[453–458] The vaccine's performance seems to be equivalent to that of each of the single-antigen vaccines administered separately.[459] Pediatric formulations of Twinrix are available in Europe, Canada, and other parts of the world.[453,454,460]

Ambirix (GlaxoSmithKline) is a combination hepatitis A and hepatitis B vaccine formulation containing the same components and content as the adult formulation of Twinrix (1.0 mL), 720 EL.U. (enzyme-linked immunosorbent assay units) of the hepatitis A component and 20 µg of the purified recombinant HBV surface antigen. Ambirix is licensed in Europe for children 2 to 15 years old in a two-dose series (0, 6–12 months) given intramuscularly.[454]

A combination inactivated hepatitis A and recombinant hepatitis B vaccine has been introduced in China for adults and children (Bilive, Sinovac Biotech Ltd.).

Combination vaccines for the prevention of hepatitis A and typhoid fever among adolescents and adults are available in some countries. ViATIM (also known as Vivaxim, Sanofi Pasteur) contains 160 antigen units of inactivated HAV (similar to Avaxim) and 25 µg of *Salmonella* Typhi Vi capsular polysaccharide antigen packaged in a dual-chamber bypass syringe. Mixing of the two antigens occurs at the time the syringe plunger is depressed to start the intramuscular injection. Also present in the final 1-mL dose are 2.5 mg of 2-phenoxyethanol as a preservative and 0.3 mg aluminum hydroxide as adjuvant. To produce long-term protection against hepatitis A, a dose of hepatitis A vaccine is recommended 6 to 12 months later; maintaining immunity to *Salmonella* Typhi requires a dose of a single-antigen typhoid fever vaccine 3 years after the dose of ViATIM (the booster schedule for the U.S.-licensed capsular polysaccharide typhoid vaccine [which does not include hepatitis A] is every 2 years).[461,462] Hepatyrix (GlaxoSmithKline) contains 25 µg of *Salmonella* Typhi Vi capsular polysaccharide antigen and 1440 EL.U. of hepatitis A antigen combined in 1 mL of saline and aluminum hydroxide as adjuvant. The second dose is given 6 to 12 months after the first. Hepatitis A–typhoid fever combination vaccine performance seems to be similar to that of the single-antigen vaccines administered separately.[458,463]

Dosage and Route

Dosages and schedules vary according to country, and country-specific recommendations should be sought for current licensure information and recommendations (Table 24.5). Only Havrix, VAQTA, and Twinrix are licensed in the United States (see Table 24.4). Only Havrix is a WHO prequalified vaccine.[464]

Vaccine Stability

The vaccines should be stored at 2°C to 8°C, and Havrix and VAQTA have been shown to retain potency when kept for at least 2 years under those conditions.[421,465,466] Freezing destroys the vaccine, causing aggregation of the adjuvant particles. Any vaccine that was frozen should be discarded. The reactogenicity and immunogenicity of Havrix after storage at 37°C for 1 week and the stability profile of VAQTA when stored at this temperature for more than 12 months did not differ from those of vaccines stored at the recommended temperature.[467,468]

TABLE 24.5 Countries With Hepatitis A Childhood Vaccination Policies Reported by Country to WHO/UNICEF, 2014

Country	Year of Introduction	Number of Doses	Age at Administration of First Dose (Months)	Schedule Interval Between Doses (Months)

Immunogenicity of Vaccine

Antibodies

Anti-HAV concentrations are measured in comparison with a WHO reference immunoglobulin reagent and are expressed in milli-international units per milliliter (mIU/mL). Clinical studies with Havrix have generally measured antibody using an enzyme immunoassay and, with VAQTA, a modified radioimmunoassay. In extensive clinical trials in children and adults, the inactivated hepatitis A vaccines available in the United States have been found to be highly immunogenic. Both vaccines begin to be effective approximately 2 weeks after a single intramuscular dose. Although the concentration of antibody after vaccination varies with the dose and schedule of the vaccine, after a single dose of vaccine, antibody concentrations are higher than those produced by doses of immunoglobulin known to be protective.

A second dose 6 to 18 months later results in a boosted antibody concentration, but the final concentration is generally lower than concentrations measured after natural infection (Fig. 24.9).[469–472] By 4 weeks after one dose of vaccine, 90% to 100% of children age 1 year or older and adults respond with concentrations of antibody considered protective. The boost in antibody concentration following the second dose is likely important for long-term protection.[430,466,473–479] HAV-specific IgM antibody occasionally can be detected by standard assays, primarily if measured soon (ie, up to 4 weeks) after vaccination.[430,469]

Results of a number of studies indicate that the response of adults administered hepatitis A vaccine according to a schedule that mixed the two currently U.S.-licensed single-antigen vaccines was equivalent to that of adults vaccinated according to the licensed schedules with the single vaccine.[480,481] Mixed schedules with Epaxal and Havrix, and Avaxim and Havrix or VAQTA, have also been shown to be equivalent to schedules that used a single vaccine brand.[482–486] Based on limited data, the response to a second dose delayed for 20 to 31 months (Havrix), 24 to 66 months (VAQTA), or 30 to 54 months (Epaxal) was similar to that of the licensed schedules.[487–489] Schedules with shorter intervals between doses have not been studied using the currently licensed single-antigen formulations. Healive and Havrix have been shown to be comparable in healthy Chinese children.[490]

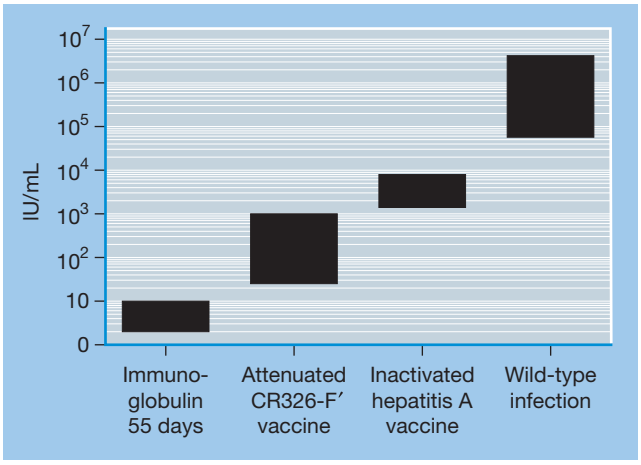

Figure 24.9. Comparative levels of antibody to hepatitis A virus (HAV) after administration of immunoglobulin, one dose of an attenuated hepatitis A vaccine, two doses of an inactivated hepatitis A vaccine, and natural infection. The detection limits of the hepatitis A virus antibody (HAVAB) assay are approximately 100 mIU/mL. *(From Lemon SM. Hepatitis A virus: current concepts of the molecular virology, immunology and approaches to vaccine development.* Rev Med Virol. *1992;2:73–87.)*

Hepatitis A vaccines are approved for children age 12 months or older (see Table 24.4). Studies in children as young as 2 to 6 months old suggest that the vaccine is safe for infants and that it is immunogenic for infants who do not have passively transferred antibody from previous maternal HAV infection.[474,491–497] Among infants who received hepatitis A vaccine according to a number of different schedules, infants with passively transferred maternal antibody at the time of vaccination responded, but final antibody concentrations were approximately one-third to one-tenth those of infants who did not have passively transferred antibody and were vaccinated according to the same schedule.[474,491–497] The clinical significance, if any, of these lower antibody concentrations is unknown. The majority of infants born to anti-HAV–positive mothers have lost detectable antibody by 12 to 15 months of age.[474,493,498–501] Most, but not all, infants vaccinated in the presence of passively transferred maternal antibody at ages 2, 4, and 6 months respond to a booster dose 6 to 12 months or later with an anamnestic response, suggesting that they had been primed by the primary series.[491,497,498,502] One long-term follow-up study found that seropositivity persists for at least 10 years in children vaccinated at younger than 2 years of age, regardless of presence of maternal anti-HAV.[503] Another study found anti-HAV persistence for at least 17 years in adults vaccinated as children.[504] A recent study evaluating cellular immunity in poor vaccine responders found that one dose of inactivated hepatitis A vaccine induced HAV-specific cellular responses; an increase in the frequencies of classical memory B cells, TCD8 cells, and central memory TCD4 and TCD8 cells, and an increase in cytokine production were observed. The HAV-specific T-cell immunity persisted independently of anti-HAV antibody levels.[505]

Correlates of Protection

The absolute lower limit of antibody needed to prevent HAV infection has not been determined. The concentrations of antibody achieved after passive transfer by immunoglobulin or active induction by vaccination are 10- to 100-fold lower than those produced in response to natural infection (see Fig. 24.9). The minimum level of neutralizing antibody to HAV necessary to prevent infection is not known, although it is likely quite low because immunoglobulin provides approximately 90% efficacy in preventing hepatitis A and very low levels of serum neutralizing antibody are detected in immunoglobulin recipients.[177,506] Anti-HAV concentrations of 10 to 20 mIU/mL 1 to 2 months after administration of immunoglobulin protect against hepatitis A.[177] Results of in vitro studies using cell culture–derived HAV indicate that even antibody concentrations less than 20 mIU/mL can be neutralizing.[507] Antibody levels ranging from 10 to 33 IU/mL using different assays have been proposed as the threshold for protection from HAV infection in humans.[508] Because no absolute protective level has been defined, the lower limit of detection of the particular assay being used has generally been considered the protective level; 10 mIU/mL has also been considered a protective level in some postvaccination studies,[509] although it has been proposed that any detectable concentration of IgG anti-HAV may even suggest protection.[178] Clinical studies of Havrix have used levels greater than 20 or 33 mIU/mL, as measured using enzyme immunoassays to define "protective levels"; studies of VAQTA have used levels greater than 10 mIU/mL as measured with a modified radioimmunoassay (hepatitis A virus antibody [HAVAB]).[474,491,510]

Some studies indicate that concentrations of antibody above the defined protective concentration can be measured as early as 2 weeks after one dose,[440,470,511] but distinct differences between the antibody induced by vaccine and the antibody detected in people who received immunoglobulin (which should be similar to antibody induced by infection) can be identified when results using different assays are compared (see Fig. 24.9).[512,513] In one study with similar radioimmunoassay (HAVAB) titers, adult immunoglobulin recipients had higher neutralization titers as measured by a radioimmunofocus inhibition test (RIFIT) and an HAV antigen reduction assay (HAVARNA), but negligible radioimmunoprecipitation titers compared with a group of vaccinated children when measured 4 weeks after receiving one dose of vaccine.[512] In another study using the RIFIT assay, the neutralizing geometric mean antibody titers of persons who received immunoglobulin with hepatitis A vaccine were five times higher compared with persons who received hepatitis A vaccine alone when measured 4 weeks after administration.[513] However, it has also been shown that immunoglobulin prepared from the serum of vaccinees could protect a chimpanzee from HAV infection when the titer of antibody achieved in the chimpanzee was similar to that found in humans receiving immunoglobulin prophylaxis.[514]

How soon neutralizing antibody appears after vaccination is not clear from published reports, owing to differences among assays, dosages of vaccine, and when antibody measurements were obtained. In one study, depending on the assay, 42% to 100% of children vaccinated with the currently licensed formulation had neutralizing antibody when measured 1 month after a single vaccine dose.[512] In another study, approximately two-thirds of adults vaccinated with a lower dosage than the currently licensed formulation were positive for neutralizing antibody 4 weeks after one dose, and virtually all were positive 2 weeks after a second dose, given 1 month after the first.[512] In a third study, 84% of adults vaccinated with one dose of the liposomal vaccine had neutralizing antibody 2 weeks later.[440]

Special Groups

Conditions that may result in reduced immunogenicity include HIV infection, chronic liver disease, and older age. Among adults with HIV infection, 50% to 95% had protective antibody concentrations after completing the vaccination series, and final antibody concentrations were considerably lower than those among HIV-negative persons.[515–521] Higher CD4+ T-lymphocyte count at baseline were associated with response to vaccination[516–519,522]; increases in CD4 cell count with highly active antiretroviral therapy and lower HIV plasma RNA levels improved vaccine response rates.[523,524] It is not clear if sex is associated with vaccine response; one study found that males had greater vaccine response than females (Armstrong)[519] and another study found that vaccine responders were more likely to be female (Weissman).[522] A retrospective observational study found that most HIV-infected adult initial responders to two doses of HAV vaccine, maintain seropositivity for 6 to 10 years.[525] From 84% to 100% of HIV-infected children with normal CD4+ cell levels may develop protective antibody concentrations after two or three doses of hepatitis A vaccine.[526–530] Higher counts or restoration of CD4+ T-lymphocyte counts and younger age at vaccination are associated with improved responses to vaccination.[529,531] The absence of detectable HIV RNA and higher CD4+ T-cell percentages at the time of vaccination are associated with higher anti-HAV responses.[530,532,533] The seroconversion rate to three and two doses of hepatitis A vaccine was similar in HIV-infected MSM, although lower than that in HIV-uninfected MSM who received two doses. Twinrix recipients might be more sensitive to HIV RNA level and higher CD4+ T-cell percentages and less likely to seroconvert than those administered Havrix. This is possibly a result of noncompletion of the vaccine series among Twinrix recipients.[532]

Among persons with chronic liver disease, seroprotection rates were similar to those observed among healthy adults, but the final antibody concentrations were substantially lower.[534–538] Seroprotection rates and seroprotective titers of anti-HAV IgG at 8 years after the last vaccine dose was comparable in children with chronic hepatitis C and controls.[539] Limited data from small immunogenicity studies among liver or kidney transplant recipients have yielded seroprotection rate estimates that vary from 0% to 97%,[540–542] and one study indicated that antibody levels declined more rapidly among successfully vaccinated transplant recipients compared with other patients.[543] The final antibody concentrations achieved among persons older than age 40 years may be somewhat lower than among younger persons, but response rates were similar.[477,509,543–545] Other factors, such as smoking and obesity, have not been evaluated for the currently licensed formulations.

Up to 2% of "normal" adults may be low responders or nonresponders to primary and booster doses of inactivated hepatitis A vaccine. In one study, low response and nonresponse was associated with lack of a hepatitis A cellular receptor (havcr1) TIM1 on CD4+ T lymphocytes. No information was available to determine if these persons might also have a different susceptibility to HAV infection.[546]

Efficacy and Effectiveness of Vaccine

Hepatitis A vaccines are highly effective in preventing clinically apparent disease. In one study, 1037 healthy seronegative children 2 to 16 years old in a community with high hepatitis A rates and periodic outbreaks received a single dose of formalin-inactivated vaccine derived from strain CR326F (used to prepare VAQTA) or placebo. No cases of hepatitis A occurred in the vaccinated group beginning 17 days after vaccination. In the placebo group, 34 cases of hepatitis A were observed, yielding an estimated 100% vaccine efficacy, with a lower bound of the 95% confidence interval of 87%.[547] In a large field trial of approximately 40,000 Thai children 1 to 16 years old, the efficacy of inactivated vaccine (HM175 strain, used to prepare Havrix) was 94% (95% confidence interval, 79%–99%) after two doses (360 EL.U. per dose) administered 1 month apart.[380] The efficacy of the virosome-formulated hepatitis A vaccine derived from the RG-SB strain (used to prepare Epaxal) was assessed in a randomized, placebo-controlled, double-blind study among Nicaraguan children ages 1.5 to 6 years. Protective efficacy beginning 6 weeks after vaccination was 100% (95% confidence interval, 79.8%-100%).[548]

A number of studies and demonstration projects have evaluated the effectiveness of hepatitis A vaccines in controlling and preventing hepatitis A in communities. In areas with the highest hepatitis A rates, such as in Native American and Alaska Native communities,[549–551] vaccination of the majority of children, and in some cases adolescents and young adults, resulted in a rapid decline in disease incidence. With ongoing routine vaccination of children, these reductions in disease incidence have been sustained.[255,261,552–557] In larger, more heterogeneous communities with lower but consistently elevated hepatitis A rates, accumulating evidence from a number of countries indicates that sustained routine vaccination of children can reduce hepatitis A incidence markedly over time (see "Public Health Considerations" below).[18,217,218,223,255,261,263,489,490,558–560]

In 2012, the WHO Strategic Advisory Group of Experts (SAGE) on Immunization reviewed evidence of efficacy after

a single dose of inactivated hepatitis A vaccine in a randomized controlled trial in Nicaragua and from national use of a single-dose schedule of hepatitis A vaccine in Argentina.[561] The SAGE concluded that national programs may consider a single-dose schedule, although additional evidence of long-term immunogenicity are needed and for certain high-risk and immunocompromised individuals, a two-dose schedule is recommended.[16,562] Argentina includes a single-dose inactivated hepatitis A vaccine in their national immunization schedule at 12 months[561]; humoral immunity has been shown to persist for at least 5 years in Argentinean children.[563]

A 5-year follow up study in India showed that the single dose of live attenuated vaccine (Biovac-A) is well tolerated and provides long-term immunogenicity in healthy Indian children.[564] Another follow-up study demonstrated 10 year protection after administration of Biovac-A.[565]

Duration of Immunity

The duration of protection after vaccination is unknown; however, anti-HAV has been shown to persist in vaccine recipients for at least 17 years in adults administered inactivated vaccine as children with a three-dose schedule.[504,566–572] Vaccine recipients vaccinated as children with the previously recommended three-dose hepatitis A schedule were found to have similar protection for longer than 14 years after vaccination compared to those vaccinated with the two-dose schedule.[573] Another study demonstrates at least 20-year anti-HAV persistence among adults vaccinated with a two-dose schedule as adults. Detectable antibodies are estimated to persist for 40 years or longer based on mathematical modeling and anti-HAV kinetic studies.[574–576] Protection following natural infection is lifelong and may also be lifelong following vaccination.

Because the average incubation period for hepatitis A is 4 weeks and the anamnestic responses observed after the second vaccine dose are rapid and robust, it has been suggested that vaccine recipients who seroconverted will be protected even if their antibody levels have fallen below protective levels.[577] Cellular immunity might contribute to this protection. HAV-specific T cells are detectable after the primary vaccine series and undergo rapid expansion after a booster dose given 28 weeks after completion of a primary series.[546,578,579] A review of the single-dose use of inactivated hepatitis A vaccine found that protective anti-HAV antibody levels can persist for almost 11 years and increase or reappear after booster vaccination. These results suggest there is no indication for a booster dose of hepatitis A vaccine within 6 years after vaccination.[580] Another study evaluating single-dose vaccine suggested proliferation of classical memory B cells, although no substantial activation of HAV-specific memory B cells after the first dose.[505]

Safety (Adverse Events)

Common

Local injection site reactions (pain, tenderness, or erythema) that are mild and transient have been reported in as many as 21% of children and 56% of adults vaccinated. Systemic reactions, including fatigue, fever, diarrhea, and vomiting, occur in fewer than 5% of vaccinees. Headache has been associated with vaccination in up to 16% of adults and 2% to 9% of children.[380,430,435,440,443,457,581–584]

Rare

Between 1995 and 2005, more than 50 million doses of hepatitis A vaccine were sold in the United States, and more than 188 million doses were sold worldwide.[86] During that period, the Vaccine Adverse Events Reporting System (VAERS; maintained by the FDA and the Centers for Disease Control and Prevention [CDC]) received approximately 6000 reports of adverse events occurring after injection with hepatitis A vaccine. The most common events were minor and of brief duration, such as fever, injection-site reactions, rash, and headache. The 871 serious adverse events included Guillain-Barré syndrome, transaminitis, idiopathic thrombocytopenic purpura, and seizures among children.[86,583] Rare adverse events reported postmarketing include syncope, jaundice, erythema multiforme, anaphylaxis, brachial plexus neuropathy, transverse myelitis, encephalopathy, and others.[465,466] No serious adverse events among children or adults have been identified that could be definitively ascribed to hepatitis A vaccine.[582,583,585] For events for which incidence rates are available, such as Guillain-Barré syndrome, reported rates were not higher than reported background rates.[86]

In Immunosuppressed Persons

Most hepatitis A vaccines are inactivated and based on limited data, administration to immunosuppressed persons does not seem to be associated with a greater risk of adverse events compared with administration to persons with normal immune systems.[516,528,540,586] No data are available regarding the safety of live attenuated hepatitis A vaccines in immunosuppressed persons.

Spread to Contacts

The inactivated vaccines do not pose a risk of spread to contacts. They do not contain viable HAV. One study of a live attenuated vaccine did not find any seroconversion among unvaccinated classmates of vaccinated children.[587]

Prevaccination and Postvaccination Testing

Prevaccination serologic testing may be considered to reduce costs by not vaccinating persons with prior immunity, but it should take into account the cost of testing, vaccine cost, and the likelihood that the person will return for vaccination if susceptible.[588] Populations with a high prevalence of infection can include children, adolescents, and adults born in areas of high hepatitis A endemicity; older MSM[86,315]; and persons using illegal drugs.[305,308] Prevaccination serologic testing can be considered for older travelers and younger travelers who were born in a country that has high or intermediate hepatitis A endemicity. In the United States, national seroprevalence data show that among all age groups, seroprevalence of anti-HAV is less than 50%; consequently, prevaccination testing is not indicated. Vaccination of immune people is not harmful. Postvaccination testing is not indicated because of the high rate of vaccine response. Also, some commercially available testing methods cannot detect the low anti-HAV antibody concentrations generated by immunization.

Indications

Israel was the first nation-state to introduce universal childhood hepatitis A vaccination, followed by Bahrain in 2004, Argentina in 2005, and Panama and the United States in 2006 (see Table 24.5). By 2016, 17 countries have introduced universal childhood hepatitis A vaccination.[589] Recommendations for use of hepatitis A vaccine in the United States are discussed below (Table 24.6). The recommended immunization schedules can be found in Table 24.4. The U.S. recommendations were first issued by the ACIP of the U.S. Public Health Service,

TABLE 24.6 ACIP Recommendations for Routine Preexposure Use of Hepatitis A Vaccine

Group	Comments
All children at age 12–23 mo[a]	Integrate into routine childhood vaccination schedule; children not vaccinated by age 2 years can be vaccinated at subsequent visits
Children age 2–18 y	Maintain existing programs[b]; can be considered in areas without existing programs
International travelers	Except persons traveling to Canada, Western Europe, Japan, Australia, or New Zealand who are at no greater risk than in the United States (see Table 24.3)
Persons who anticipate close contact with an international adoptee	Includes unvaccinated household or regular babysitting contacts age ≥12 mo[a] of international adoptees from a country of high or intermediate hepatitis A endemicity during the first 60 days following arrival of the adoptee in the United States
Men who have sex with men	Includes adolescents
Illicit drug users	Includes adolescents
Persons with chronic liver disease	Increased risk of fulminant hepatitis A with HAV infection
Persons receiving clotting factor concentrates	
Persons who work with HAV in research settings	
Anyone who wants to obtain immunity	

ACIP, Advisory Committee on Immunization Practices; HAV, hepatitis A virus.
[a]Hepatitis A vaccine is not licensed for children younger than 12 months.
[b]States covered by 1999 ACIP recommendations (AL, AK, AZ, CA, CO, ID, MN, MO, NV, NM, OK, OR, SD, TX, UT, WA, WY, and selected areas in other states).[220]

the American Academy of Pediatrics, and other groups in 1996, and were updated in 1999, 2006, 2007, and 2009 (Table 24.6).[86,256,257,289,410,590] In addition, inactivated hepatitis A vaccine is indicated for any person who wants to obtain protection from hepatitis A.

Children

Vaccination should be completed according to licensed schedules and integrated into the routine vaccination schedule specific to each country (see http://www.who.int/immunization/policy/immunization_tables/en/ and http://www.cdc.gov/vaccines/schedules/). In the United States, it is recommended that all children receive hepatitis A vaccine at 1 year of age (i.e., 12–23 months of age) to avoid interference by passive maternal anti-HAV that may be present during the first year of life. In the United States, children who are not vaccinated by 2 years of age can be vaccinated at subsequent visits; vaccination can be considered for children 2 to 18 years old and for anyone who wants protection against hepatitis A infection.[86] Booster doses are not recommended at this time.[86]

Persons at Increased Risk of Hepatitis A or Severe Consequences as a Result of Infection

Susceptible persons who travel or work in countries with high or intermediate hepatitis A endemicity should be vaccinated or receive immunoglobulin before departure; vaccination is preferred (see Table 24.3; see "Preexposure Prophylaxis" below).[410] Persons who anticipate having close contact with an international adoptee from a country with high or intermediate hepatitis A endemicity,[289] persons working with HAV-infected nonhuman primates or with HAV in a research laboratory setting, persons using illicit injecting and noninjecting drugs, and adolescent and adult MSM should receive hepatitis A vaccination.[86]

The risk of hepatitis A from blood transfusion or from plasma derivatives is extremely low, but both have been reported.[326,328,329,384] Although manufacturers continue to develop methods to improve elimination of infectious HAV from their products, vaccination remains prudent. Persons with chronic liver disease are not at increased risk for hepatitis A; however, acute hepatitis A can have serious or fatal consequences.[94] All persons with such disease, regardless of the etiology of their liver disease, should be vaccinated against hepatitis A.

Outbreaks

There has been considerable interest in using hepatitis A vaccine to control ongoing communitywide epidemics. In areas that have implemented routine vaccination of children, outbreaks are rare. In general, vaccination efforts are better directed toward sustained routine vaccination of children to maintain high levels of immunity. Achieving high levels of coverage through mass vaccination sufficient to interrupt transmission and shorten the course of community outbreaks has not been demonstrated; however, susceptible persons in a community experiencing an outbreak can benefit from vaccination to prevent infection and disease.

Hepatitis A outbreaks in childcare centers are rare when routine vaccination programs of young children are implemented. When outbreaks are recognized, aggressive use of immunoglobulin is effective in limiting transmission,[28] and vaccination is effective in interrupting outbreaks.[591–594] Unvaccinated healthy persons 12 months to 40 years can be vaccinated for postexposure prophylaxis; immunoglobulin should be used for children younger than 12 months of age,

immunocompromised children, persons who have had chronic liver disease diagnosed, and those for whom vaccine is contraindicated. For persons older than age 40 years, immunoglobulin is preferred; vaccine can be used if immunoglobulin cannot be obtained.[410]

The frequency of outbreaks in hospitals, institutions, and schools is not high enough to warrant routine vaccination of persons in these settings, and there are limited data with respect to using vaccine to control outbreaks in these settings.[377] Although persons who work as food handlers are not at increased risk of hepatitis A because of their occupation, they may transmit HAV to others when they contract hepatitis A.[217,342] To reduce the frequency of evaluations of food handlers with hepatitis A and the need for postexposure prophylaxis of patrons, public health officials in some jurisdictions have instituted measures to promote hepatitis A vaccination of food handlers. However, because transmission from infected food handlers accounts for a very small proportion of cases nationwide, vaccination of food handlers is not likely to affect overall disease incidence and has not been found to be cost-effective.[594]

Contraindications and Precautions

The inactivated hepatitis A vaccines should not be used in persons with a history of a severe reaction to a prior dose of hepatitis A vaccine or allergy or hypersensitivity to the vaccine or any of its components. The safety of the inactivated hepatitis A vaccines in pregnancy has not been determined. Because the vaccine is produced from inactivated HAV, the theoretical risk to the fetus is low. A review published in 2014 of VAERS reports from January 1, 1996 to April 5, 2013 did not identify any concerning pattern of adverse events in pregnant women or their infants following maternal hepatitis A (Havrix, VAQTA) or hepatitis AB (Twinrix) immunizations during pregnancy.[595]

Preexposure and Postexposure Prophylaxis

After decades of effective use of immunoglobulin for postexposure prophylaxis, data now indicate the equivalency of hepatitis A vaccine in preventing symptomatic hepatitis A among healthy persons age 40 years or younger.[596–599] Hepatitis A vaccine is recommended in most circumstances for preexposure and postexposure prophylaxis because of the public health advantages of vaccination compared with immunoglobulin, which include induction of active immunity and longer protection, greater ease of administration, and greater acceptability and availability (see Table 24.3).[410]

Preexposure Prophylaxis

Hepatitis A vaccination is preferred to immunoglobulin for preexposure prophylaxis for persons who plan to travel or will live in countries that have high or intermediate hepatitis A endemicity. The first dose of hepatitis A vaccine should be administered as soon as travel is considered. For most healthy persons 1 to 40 years old, one dose of a single-antigen hepatitis A vaccine given any time before departure can provide adequate protection. Prevaccination serologic testing may be considered for persons who may have preexisting immunity, such as adults and older adolescent born in areas of high hepatitis A endemicity (see Fig. 24.5). Adults older than age 40 years, immunocompromised persons, and persons with chronic liver disease or other chronic medical conditions planning to depart to an endemic area in 2 weeks or less should receive the initial dose of the vaccine and simultaneously receive immunoglobulin (0.02 mL/kg) at a different anatomic injection site (see Table 24.3). Completion of the vaccine series according to the licensed schedule is needed for long-term protection. Immunoglobulin should be used for preexposure prophylaxis for infants younger than 1 year of age and for travelers who are allergic to vaccine or components.[289,410]

The use of hepatitis A vaccine with other vaccines that might be used for travelers has been studied among adults. There was no effect on the immunogenicity or reactogenicity of hepatitis A vaccine administered concurrently with diphtheria, polio (oral and inactivated), tetanus, hepatitis B, yellow fever, typhoid (oral and intramuscular), cholera, Japanese encephalitis, or rabies vaccines.[474,600–604] In studies among infants, simultaneous administration of hepatitis A vaccine did not affect the immunogenicity or reactogenicity of diphtheria-tetanus-acellular pertussis (DTaP); inactivated polio; MMR; hepatitis B; and *Haemophilus influenzae* type b vaccines.[474,605,606]

The usual dose of immunoglobulin for preexposure prophylaxis is a single intramuscular injection of 0.02 or 0.06 mL/kg (see Table 24.3). The lower dose is adequate to provide protection for up to 3 months, and the higher dose is effective for up to 5 months.[607] Even though readministration every 5 months is necessary for extended trips, hepatitis A vaccine, if not contraindicated, is preferred for such travelers. Intramuscular preparations of immunoglobulin should never be given intravenously, and the intravenous preparations of immunoglobulin are not intended for hepatitis A prevention and are formulated at a lower globulin concentration.

Several studies have evaluated administration of inactivated hepatitis A vaccine concomitantly with immunoglobulin to produce immediate and long-term immunity.[608–611] Although the proportion of persons who respond to vaccination was not reduced by coadministration of immunoglobulin, the antibody concentrations elicited were lower as compared to persons who received vaccine alone. For example, in one study, 1 month after completion of the vaccine series, the geometric mean antibody concentration among persons who received a dose of immunoglobulin (0.06 mL/kg) with the first dose of vaccine was 4872.3 mIU/mL (range: 3716.2–6388.2 mIU/mL) compared with 6497.8 mIU/mL (range: 5110.9–8 261.0 mIU/mL) among persons who received vaccine alone.[611] Because the concentrations induced by vaccination far exceed that needed for protection, these reductions are not considered clinically significant.

Immunoglobulin does not interfere with the immune responses to oral poliovirus or yellow fever vaccines or, in general, with inactivated vaccines. Immunoglobulin can interfere with the immune response to some live attenuated vaccines (e.g., MMR, varicella). Administration of MMR or varicella vaccine should be delayed for at least 3 months after receipt of immunoglobulin for hepatitis A prophylaxis. Immunoglobulin should not be given for at least 2 weeks after administration of MMR or at least 3 weeks after administration of varicella vaccine unless the benefits of the immunoglobulin are greater than the benefits of vaccination.[420]

Immunoglobulin should be used to protect children younger than 12 months of age and persons for whom the vaccine is contraindicated (see Table 24.3).[411] Hepatitis A vaccine is not licensed for children younger than 12 months of age; prevention of hepatitis A among infants will prevent the rare severe cases that occur and transmission to others after returning from abroad.[410]

Postexposure Prophylaxis

Unvaccinated persons who were recently exposed to HAV should receive postexposure prophylaxis as soon as possible. Such persons include close personal contacts of patients with

hepatitis A and other food handlers at establishments when a food handler is identified with hepatitis A.[217] Postexposure prophylaxis can be considered under certain conditions when outbreaks occur in childcare centers.[404,612] Hepatitis A vaccination is recommended for postexposure prophylaxis of healthy persons ages 12 months to 40 years and can be used for older persons if immunoglobulin is not available (see Table 24.3). When using hepatitis A vaccine for postexposure prophylaxis, single-antigen vaccine should be used; no data exist regarding the performance of a combination vaccine for prophylaxis after exposure to HAV. Immunoglobulin is recommended within 2 weeks of exposure for infants younger than 12 months, persons with immunocompromise or diagnosed chronic liver disease, and persons for whom vaccine is contraindicated, and is preferred for adults older than age 40 years. The efficacy of immunoglobulin administered 2 weeks or more after exposure has not been established. Once cases are identified that are associated with a food service establishment, it generally is too late to administer immunoglobulin, but patrons can be vaccinated. The usual dose of immunoglobulin for postexposure prophylaxis is a single intramuscular injection of 0.02 mL/kg (see Table 24.3).

The ACIP recommends hepatitis A vaccine for postexposure prophylaxis of healthy persons ages 12 months to 40 years based on the results of a study comparing the efficacy of hepatitis A vaccine and immunoglobulin in persons 2 to 40 years of age.[410,596] Hepatitis A can be more severe in older adults; vaccine has the advantage of providing long-term protection, but the vaccine response might be less robust in this population. A small number of studies report the immune responses to hepatitis A vaccine among adults older than age 40 years at 2 weeks after the first dose, suggesting that vaccination may be adequate as prophylaxis for older adults; the sample sizes, however, were small and/or the age distributions not discrete.[509,544,613] In one study the age-related seroconversion proportions 15 days after one 1440 EL.U Havrix dose were: 74% ($n = 125$) for ages 40 to 49 years; 54% ($n = 37$) for ages 50 to 59 years; 30% ($n = 10$) for ages 60 years and older.[613] Another study found 77% of adults ($n = 68$) ages 40 to 62 (mean: 48) years seroconverted.[544] A hepatitis A multistate outbreak response in 2013 highlighted the need for more evidence on vaccine for postexposure prophylaxis in older adults.[509,544,613–615]

VACCINE COVERAGE

Two-dose vaccine hepatitis A vaccine coverage is low in the United States compared to other recommended childhood vaccinations; in 2014, hepatitis A vaccine coverage for children 19 to 35 months of age was 85.1% and 57.5% for one or more and two or more doses, respectively.[616] In 2009, coverage for children ages 13 to 17 years was 42% and 29.5% for one- and two-dose coverage, respectively.[617] Among adults age 19 to 49 years, a group for which vaccine is only recommended for those at high-risk of HAV infection, in 2013 the total two-or-more-dose coverage was 12.3%, while coverage was 18.8% for travelers outside of the United States (to countries other than Europe, Japan, Australia, New Zealand, or Canada since 1995) and 14.5% for adults with chronic liver conditions.[618] When considering other adults for whom vaccination is indicated, a study evaluating adherence to vaccination guidelines reviewed the records of 705 patients with chronic liver disease found that hepatologists recommended vaccination for HAV in only 63% of eligible patients in an academic hospital-based hepatology clinic with variation among providers.[619] This study suggests the need for better education of providers and counseling of patients about the importance of vaccination. However, the benefit of hepatitis A vaccination targeting HCV-infected persons specifically has been questioned because of the low risk of mortality to HAV superinfection in low HAV incidence areas and the cost associated with vaccination.[620] A random sample of medical records of 1329 HIV-infected MSM in eight HIV clinics in six U.S. cities from 2004 to 2007 were reviewed—only 17% of HIV-infected MSM were vaccinated with hepatitis A vaccine and 47% screened.[621] This study also emphasized the importance of increasing screening and vaccination in this at-risk population.

Decreasing hepatitis A incidence in the United States results in reduced exposure to HAV in the population. National serologic data suggest an increasing proportion of susceptible adults in the United States.[17,618] This may place high-risk adult populations and older adults at greater risk for infection than in the past when most adult Americans reached adulthood with natural acquired immunity. The era of large community outbreaks in the United States appears to have passed, owing largely to universal childhood vaccination. However, there is a need to be vigilant to the impact of potentially greater susceptibility of older adults and persons at elevated risk for complications of HAV infection, although the overall public health impact is likely to be minor.[254,622]

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Effects of Vaccination

Effectiveness in Populations

Hepatitis A transmission patterns are influenced by many factors, including the age-specific prevalence of immunity, prevailing hygienic conditions, and the degree of pervasiveness of HAV in the environment. Many European countries without childhood vaccination programs have very low disease incidence. In the United States vaccination of successive cohorts of children has contributed to a sustained reduction in disease incidence nationwide. A number of studies and demonstration projects have evaluated the effectiveness of hepatitis A vaccine in controlling and preventing hepatitis A in populations with transitional and intermediate endemicity and high hepatitis A rates. Relatively small, homogeneous, usually rural communities include indigenous communities in North America and Australia and selected communities in Central and Eastern Europe and Israel.[257,552–557,623] In the absence of universal vaccination, hepatitis A epidemics typically occur every 5 to 10 years in these communities with transitional or intermediate endemicity.[555] Few cases occur among persons older than age 15 years; seroprevalence data indicate that 30% to 40% of children acquire infection by 5 years of age, and almost all persons have been infected by young adulthood.[549,550,624,625] Demonstration projects conducted soon after hepatitis A vaccines became available showed that routine vaccination of children living in these communities was feasible and that vaccination of the majority of children and, in some cases, adolescents and young adults, resulted in a rapid decline and sustained reduction in disease incidence.[556,557] For example, a 1992–1993 communitywide epidemic among Alaska Natives in one rural area was ended within 4 to 8 weeks of vaccinating approximately 80% of children and young adults.[556] A communitywide demonstration project in an endemic region of California vaccinated children aged 2 to 17 years of age during the period 1995 to 2000, resulting in major decreases in hepatitis A incidence among all age groups.[558] Universal vaccination of children can have the greatest impact on disease in countries and populations with intermediate or transitional hepatitis A endemicity. In the United States, the initial recommendations for vaccination were published in 1996 and called for routine

vaccination of children living in communities with the highest hepatitis A rates.[256] Following implementation of the recommendations, large decreases in incidence among these populations, including Native Americans and Alaska Natives, were observed.[554] The implementation of these recommendations, however, had little impact in the overall national incidence of disease. In 1999, the recommendations were expanded to include vaccination of children living in states, counties and communities with consistently elevated rates of hepatitis A.[257] In 2006, hepatitis A vaccine licensure was expanded to include vaccinating children beginning at age 12 months (previously vaccination could not begin earlier than age 2 years) thus facilitating program implementation by being more in line with the routine childhood vaccination schedule. Subsequently, universal vaccination of children was recommended in 2006, to include all children ages 12 to 23 months nationwide.[86] In the United States, this strategy has resulted in historic lows of reported hepatitis A incidence (see Fig. 24.6). Rates have declined most dramatically among children 2 to 18 years of age and are now similar across all regions of the country.[236] Mortality from hepatitis A has also fallen in parallel with declines in incidence.[254] Similar observations have been made in a growing number of countries and regions with diverse and heterogeneous epidemiology where the implementation of routine vaccination of children in one or more age cohorts in all or part of the country was followed by dramatic overall declines in hepatitis A incidence.[363,559,560,626–635] Review of coverage and surveillance data indicate that incidence declines have occurred with relatively modest levels of vaccination coverage achieved and incidence declines have been observed among unvaccinated age groups, suggesting a herd immunity effect.[263,559,636–638] One study that modeled the relationship between incidence and vaccination coverage in the United States estimated that herd immunity accounted for one-third of the cases prevented.[636]

Economic Considerations

Studies conducted in the early 2000s found that hepatitis A vaccination of young children or adolescents in high endemic areas of the United States could be cost saving from the societal perspective and have comparable effectiveness to other recommended vaccinations.[639,640] Another study estimated that cost-effectiveness of routine vaccination at age 1 year in the United States is greatly enhanced when the effect of herd immunity was included in the model, although the benefits declined over time.[268,641] An analysis from Argentina found favorable economics of routine hepatitis A vaccination of children in that country using a number of outcomes; this study assumed that the country was transitioning from high to intermediate endemicity, a situation where greater morbidity is expected.[642] However, results of economic analyses from China and Canada of routine vaccination of children were mixed.[643,644] The underlying assumptions, particularly baseline endemicity greatly influence estimates of cost-effectiveness.

Disease Control Strategies

The strategy of widespread routine vaccination of children at age 12 months, recommended by the ACIP in 2006,[86] has contributed toward a substantial reduction in the overall incidence of hepatitis A in the United States by preventing infection among children and younger persons that previously accounted for at least one-third of cases and served as a major source of infection for others. Sustaining routine vaccination of children will make elimination of indigenous HAV transmission in the United States an attainable goal. In the interim, a susceptible cohort of American adults remain.

As of 2014, 17 countries, including the United States, had recommendations for routine vaccination of children with hepatitis A vaccine (see Table 24.5).[589] Other developed countries with very low incidence, such as those in Western Europe, might potentially benefit from routine vaccination of children in addition to vaccination of persons in certain high-risk settings. Because most older children and adults remain susceptible to HAV in low-endemicity areas, there is a risk for disease outbreaks after introduction of the virus from an external source, such as contaminated food or returning international travelers as has been described in some Northern European countries.[286,645–647] Vaccination programs that focus on children in immigrant communities has been proposed and would likely reduce the risk to immigrant children and their contacts, although one analysis did not find such a strategy to be cost saving.[646] High rates of hepatitis A among indigenous children in north Queensland Australia led to a recommendation for routine vaccination of children in indigenous communities, with subsequent large decreases in incidence among indigenous and nonindigenous members of the community.[623] Similar decreases in hepatitis A have been documented throughout the world in countries implementing vaccination strategies that target select children.[363,629,632–635] Implementing and sustaining such vaccination programs is important to prevent the return of community outbreaks. The childhood vaccination program in the United States has contributed to the elimination of large communitywide outbreaks, although small outbreaks can occur among unvaccinated communities.

At present, routine hepatitis A vaccination is generally not indicated in developing countries, particularly those with highest endemicity where infection in early childhood is nearly universal and disease is believed to be uncommon (see Fig. 24.5). However, recent seroprevalence and morbidity data suggest that some countries or parts of countries are undergoing a transition to intermediate endemicity as economic development improves.[648] Surveillance data from India suggests an enormous burden of disease from hepatitis A, including numerous outbreaks annually[394]; most developing countries do not have surveillance and thus the impact of the disease remains unknown or unreported. Countries should be alert to the possibility that this fairly rapid transition to an epidemiologic pattern more typical of countries with moderate endemicity, with a substantial proportion of the population remaining susceptible into later childhood or adulthood, is likely to result in increases in hepatitis A–related morbidity and mortality. At that point, implementation of vaccination programs might become more feasible and cost-effective, particularly with a one-dose schedule.[16] Surveillance systems that can monitor trends in viral hepatitis, such as in India and Pakistan, are needed to inform vaccination policy.[394,649] In addition, analyses examining the relative cost-effectiveness of hepatitis A vaccination compared with other major public health priorities in developing countries are needed to support development of appropriate vaccination policy.[650–653] It is likely the global disease burden associated with hepatitis A will increase in the coming years because of continuing improvements in standards of living and sanitary and hygienic conditions.[16] Without use of hepatitis A vaccine, a larger proportion of the population will remain susceptible to HAV infection into adolescence and adulthood, and when infected have severe disease, contributing to an increase in the global burden; an estimated 15,000 to 30,000 persons die every year from hepatitis A.[14–16] If vaccine were available at a low cost and vaccination was shown to be cost-effective, some countries in which a considerable susceptible adolescent and adult population has developed might find it useful to include hepatitis A vaccination among their routine childhood immunizations.[654]

ERADICATION OR ELIMINATION

In the United States, vaccination of successive cohorts of children should eventually result in a sustained reduction in disease incidence nationwide, providing the opportunity to eliminate indigenous HAV transmission. Additional information on vaccine safety and duration of immunity will continue to be important. HAV has been considered as a target for eradication, but international bodies have not made this recommendation, primarily because of considerations of cost and feasibility.[655] At present, the disease can best be controlled by improving living conditions in the developing world and evidence based application of vaccination.

FUTURE VACCINES

Full-length infectious complementary RNA (cRNA) transcribed from the cDNA has been produced, which, on transfection into permissive cells, results in complete HAV replication.[427] Many of the mutations responsible for cell culture adaptation and attenuation in primates have been identified, although a virus with the ideal characteristics of in vitro growth combined with attenuation and immunogenicity in humans has not been produced.[124,156,428] There has always been an interest in the development of a live attenuated oral vaccine for hepatitis A analogous to the Sabin polio vaccine. Oral polio vaccine (OPV) was developed by the selection of strains of poliovirus that continued to replicate well in the gut but lost their ability to replicate in the central nervous system. Although gut replication of HAV seems to exist at a low level, it does not seem sufficient to induce a vigorous immune response. The selection of a virus that grows well enough in the target organ, the liver, to produce a good immune response but not clinical disease has been difficult to achieve.[423–425] In addition, the inactivated hepatitis A vaccines have been so effective that the need for a live vaccine is not a primary focus. In China, live attenuated hepatitis A vaccines have been licensed since 2008[16]; however, only inactivated hepatitis A vaccine formulations are currently WHO prequalified.[464] Development of recombinant hepatitis A vaccines has also been explored,[657] but it is not a straightforward problem. The important neutralizing epitopes of HAV seem to be conformational, and immunization with synthetic peptides or expressed single-capsid proteins has not induced an effective neutralizing antibody response.[658] Stapleton and colleagues[659] and others[660,661] took the approach of expressing the entire open reading frame of the HAV genome in recombinant vaccinia virus or baculovirus expression systems. Complete or partial capsid assembly seems to occur in cells infected with this recombinant vaccinia, and antibodies raised to these purified HAV synthetic capsids are neutralizing in vitro and protective in animals. Although the immunizing effect of such a vaccine might not be greater than that of inactivated vaccines, the potential reduced production costs could make it an attractive alternative.

At present, there is a licensed combination hepatitis A and hepatitis B vaccine. Additional hepatitis A combination vaccines in development include antigens for protection against Japanese encephalitis virus and hepatitis E, but to date none is currently available.[662,663] With the present recommendation for universal childhood immunization at 1 year of age in the United States, manufacturers may consider other potential combinations to fit in the childhood immunization schedule.

There is interest in a vaccine that would provide long-lasting immunity after a single dose, and a single-dose schedule is used in some countries, although the long-term efficacy is unknown but is under assessment.[16,561] Improved adjuvants or possibly larger doses of the antigen may result in long lasting protection with a single dose. Both U.S.-licensed vaccines use alum as the adjuvant. Killed HAV packaged in influenza virosomes is licensed in Europe.[441] Although this vaccine has not been proven superior to alum-adjuvanted vaccines, it seems to induce an adequate protective response. Other adjuvants might improve the responses to the point that a single dose would be sufficient for long-lasting protection. Such a vaccine should reduce the cost of immunization and solve delivery problems that may exist in some areas where hepatitis A vaccination would be desirable.

25 Hepatitis B Vaccines

Pierre Van Damme, John W. Ward, Daniel Shouval, and Alessandro Zanetti

Hepatitis has been recognized as a clinical entity since antiquity, but the diversity of viruses causing the infectious form of the disease has only recently been recognized. The first evidence that a form of hepatitis was transmitted by direct inoculation of blood or blood products was discovered when an outbreak of hepatitis occurred after a smallpox immunization campaign in Germany in 1883.[1] Jaundice developed in 15% of workers after they had been vaccinated with material prepared from human lymph; several hundred unvaccinated workers did not become ill. Further evidence of a parenterally transmitted form of hepatitis was documented early in the 20th century, when numerous outbreaks of jaundice were associated with reuse of syringes and needles without sterilization.[2–8] Blood products were confirmed as a source of hepatitis transmission through investigations of outbreaks of jaundice after yellow fever vaccination,[9,10] administration of measles and mumps convalescent plasma,[11–13] and transfusion of whole blood.[14]

The viral etiology of hepatitis was first established during the 1940s through experimental transmission to human volunteers.[15–20] The studies provided evidence of two distinct diseases: *infectious* hepatitis, transmitted by the fecal–oral route and primarily a disease of younger children, and *parenteral* or *serum* hepatitis, transmitted by percutaneous exposure to blood products and seen more often in adults. The respective terms *hepatitis A* and *hepatitis B*, first introduced in 1947,[21] were later universally adopted.[22] In the 1960s and 1970s a series of transmission and cross-challenge studies in humans confirmed the existence of these two distinct forms of hepatitis[23–25] and also that each virus generated homologous immunity after infection.

The largest outbreak of what is now recognized as hepatitis B was recorded in 1942, when 28,585 American soldiers inoculated with yellow fever vaccine developed jaundice and 62 died.[9] This outbreak was traced to a specific lot of vaccine that contained human serum; a follow-up study in the 1980s confirmed that hepatitis B virus was the cause.[26]

Of the five viruses known to cause hepatitis in humans, hepatitis B virus (HBV) is responsible for most of the global chronic hepatitis burden caused by viral hepatitis. Enormous progress has been made in understanding the etiology, natural history, epidemiology, and public health control of hepatitis B. The discovery of the etiologic agent of hepatitis B remains a remarkable scientific achievement. In 1965, Blumberg and colleagues described an isoprecipitin, which they termed *Australia antigen*, present in the serum of Australian aborigines.[27] Its distribution varied widely in healthy populations across the world, with a low prevalence (<1%) in North America and Europe, and a high prevalence (6% to 25%) in the tropics and Southeast Asia and in patients who had received multiple transfusions and blood products. The Australia antigen was shown by Prince to be related to HBV infection[28] and to be the surface protein of the virus.

HBV was visualized by electron microscopy as 42-nm viral particles that reacted with antisera to the hepatitis B surface antigen (HBsAg).[29] With the development of immunoassays for HBV antigens and antibodies,[27,29,30] the natural history of HBV infection was defined, and preventive strategies were designed, including the screening of blood for HBsAg to prevent transfusion-associated hepatitis B. In 1970, studies on the natural history of HBV infection revealed that boiling serum containing the virus destroyed its infectivity. The heat-inactivated material, however, retained its immunogenicity and partially protected subjects who were challenged with HBV.[31] The realization that HBsAg could serve as an immunogen to generate antibody to HBsAg (anti-HBs), and that this antibody protected against HBV infection, led to the development of prototype hepatitis B vaccines.[32,33] From the early 1980s, several plasma-derived hepatitis B vaccines were manufactured and licensed before recombinant DNA technology allowed the expression of large quantities of HBsAg in yeast and mammalian cells, enabling the production and licensing of recombinant hepatitis B vaccines.[34,35]

Epidemiologic studies in the 1970s and 1980s linked chronic HBV infection with chronic liver disease, including cirrhosis and hepatocellular carcinoma (HCC).[36,37] HBV-associated chronic liver disease was identified as a leading cause of death in adults worldwide, particularly in countries with a high prevalence of chronic HBV infection.[38–40] The recognition of hepatitis B as a serious global cause of morbidity and mortality led to major prevention and control efforts. Affordable vaccines are now available and effective prevention strategies are being deployed; 184 countries have introduced hepatitis B vaccine in their national infant immunization programs by the end of 2014, a major increase compared with 31 countries in 1992, the year that the World Health Assembly passed a resolution to recommend global vaccination against hepatitis B[41]; in addition, global initiatives exist to allow the world's poorest countries to obtain the vaccine. With continued expansion of routine newborn and infant hepatitis B vaccination, chronic HBV infection in children should be markedly reduced in the near future, resulting in declines in deaths from liver cancer and cirrhosis related to HBV.

BACKGROUND

Clinical Description

Infection with HBV causes a broad spectrum of liver disease, including subclinical infection, acute, clinically overt self-limited hepatitis, and fulminant hepatitis.[42,43] Persons infected with HBV can also develop persistent infection, which can lead to chronic liver disease and death from cirrhosis or HCC. The age of acquisition of HBV infection is the main determining factor in the clinical expression of acute disease and the development of chronic infection. Genetic characteristics of HBV might also contribute to outcome of infection.[44] Fewer than 10% of children younger than 5 years of age who become infected have initial clinical signs or symptoms of disease (i.e., acute hepatitis B), compared with 30% to 50% of older children and adults.[45] The risk for developing chronic HBV infection varies inversely with age: approximately 90% of infants infected during the first year of life develop chronic infection, compared with 30% of children infected between ages 1 and 4 years and less than 5% of persons infected as adults (Fig. 25.1).[46] Persons with chronic diseases such as renal failure, HIV infection, and diabetes are at increased risk for developing chronic HBV infection, presumably as a result of enhanced

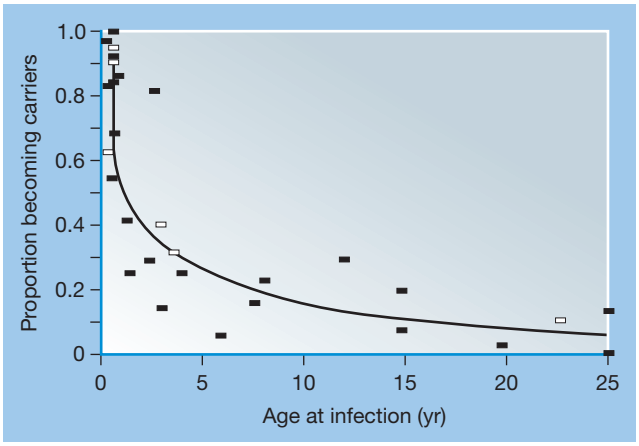

Figure 25.1. Studies evaluating the risk of chronic hepatitis B virus infection by age of infection. Filled squares represent data from developing countries; open squares represent data from developed countries. *(From Edmunds WJ, Medley GF, Nokes DJ, et al. The influence of age on the development of the hepatitis B carrier state.* Proc R Soc Lond B Biol Sci. *1993;253:197–201.)*

viral replication and ineffective immune clearance. It is estimated that 10% of the 40 million people infected with HIV worldwide are coinfected with HBV. Although HBV infection appears to have a minimal effect on the progression of HIV, the presence of HIV markedly increases the risk of developing HBV-associated liver cirrhosis and HCC.[47–50]

Acute Hepatitis B

The clinical manifestations of acute hepatitis B are indistinguishable from other causes of viral hepatitis; a definitive diagnosis requires serologic testing. The average incubation period is 90 days (range: 60 to 150 days) from exposure to onset of jaundice, and 60 days (range: 40 to 90 days) from exposure to onset of abnormal alanine aminotransferase (ALT) levels.[51,52] The prodromal phase of disease is variable and is characterized by insidious onset of constitutional symptoms that may include malaise, anorexia, nausea, occasional vomiting, low-grade fever, myalgias, and easy fatigability. In 5% to 10% of patients, a serum sickness–like syndrome develops during the prodromal phase that is characterized by arthralgias or arthritis, rash, and angioedema. Other extrahepatic manifestations that have in rare instances been reported in association with acute HBV infection include polyarteritis nodosa, membranous glomerulonephritis,[53] Gianotti-Crosti syndrome,[54,55] and aplastic anemia.[56] In patients with icteric hepatitis, jaundice usually develops within 1 to 2 weeks after onset of illness; dark urine and clay-colored stools might appear 1 to 5 days before onset of clinical jaundice. During the icteric phase, constitutional prodromal symptoms usually diminish, and right-upper-quadrant pain might develop as the liver becomes enlarged and tender. In 10% to 30% of patients with acute hepatitis B, myalgias and arthralgias have been described without jaundice or other clinical signs of hepatitis; in one-third of these patients, a maculopapular rash appears with joint symptoms.[57] Clinical signs and symptoms of acute hepatitis B usually resolve within 1 to 3 months.

Approximately 40% of persons in the United States with reported cases of acute hepatitis B are hospitalized.[58] Higher rates of hospitalization in other countries might be attributed to established patterns of medical care rather than disease severity. Fulminant liver failure occurs in approximately 0.5% to 1.0% of adults with reported acute hepatitis B cases, but rarely in infected infants and children.[59,60] Higher rates of fulminant hepatitis can occur in association with HBV–hepatitis delta virus coinfection.[61] Patients with fulminant hepatitis usually present with features of hepatic encephalopathy, including disturbances in sleep patterns, asterixis, mental confusion, disorientation, somnolence, and coma. The case-fatality rate among patients who develop fulminant hepatitis is approximately 20% to 33%, unless liver transplantation can be performed.[62,63] With liver transplantation, survival rates exceeding 80% have been achieved.[64]

The impact of treatment with the new antiviral agents on the case-fatality rate of severe or fulminant hepatitis B is unknown. Limited evidence suggests that antiviral agents such as lamivudine or other nucleoside or nucleotide analogs such as entecavir or tenofovir may alter the course and improve survival.[65–68]

Chronic Hepatitis B Virus Infection

Most of the disease burden associated with HBV infection occurs among persons with chronic infection.[69] Persons who have persistence of HBsAg in serum for at least 6 months are classified as having chronic infection. HBV replication persists throughout the course of chronic HBV infection, and the natural history of chronic HBV infection is determined by the interaction between virus replication and host immune response. Additional factors that can contribute to progression include gender, alcohol consumption, and coinfection with other hepatotropic viruses.

Chronic HBV infection is a dynamic process that may span several decades. It is characterized by up to four phases (Fig. 25.2),[70] including a period of active viral replication without active liver disease (immune tolerance phase),[71] a period of active viral replication and active liver disease (immune clearance phase), and a phase with low or absent viral replication and remission of active liver disease (inactive chronic HBV infection).[72] In addition, some patients with inactive chronic HBV infection experience reactivation of HBV replication. All four phases of chronic infection can occur in persons who acquire infection perinatally, whereas the latter three phases occur in persons who acquire infection as older children and adults.

The immune tolerance phase of perinatally acquired infections is characterized by high levels of virus replication, which correlates with hepatitis B e antigen (HBeAg) positivity and high levels of HBV DNA in serum.[73,74] However, these patients typically have no evidence of active liver disease, with normal ALT levels, no signs or symptoms of hepatitis, and minimal necroinflammatory activity on liver biopsy.[71,75] The absence of liver disease despite high levels of viral replication is believed to be attributable to immune tolerance. The initial phase of infection usually lasts 10 to 30 years. During this time, rates of spontaneous clearance of HBeAg from serum are less than 1% per year.[71,75,76] This low rate of HBeAg clearance accounts for the high prevalence of HBeAg among women of childbearing age in areas with high rates of perinatal HBV transmission.

The replicative phase in active liver disease is characterized by high levels of virus replication (see Fig. 25.2). These patients are usually HBeAg-positive, with high or fluctuating levels of HBV DNA in their serum. Evidence of active liver disease includes persistently or intermittently elevated ALT levels and necroinflammatory activity on liver biopsy. Development of fibrosis of the liver can lead to cirrhosis, which usually leads to an irreversible form of liver injury. Transition from this phase of chronic infection to the next phase occurs with reduction in viral load and sometimes clearance of HBV DNA with HBeAg seroconversion. The rate of spontaneous clearance of

HBeAg is approximately 10% to 20% per year, both in patients with perinatally acquired infections and in those who acquire infection at an older age.[76–79] Most patients are asymptomatic during this phase, but conversion to HBeAg negativity can be accompanied by symptomatic exacerbations, with increased ALT levels.[78–80] Hepatic decompensation might occur in approximately 2% of patients during these exacerbations, which can, in rare instances, lead to death from hepatic failure.[81] In some patients with suboptimal immune response and abortive immune clearance, repeated exacerbations can occur, with intermittent clearance of HBV DNA from serum and transient loss of HBeAg.[82,83] Repeated episodes of necroinflammation might increase the risk for developing severe chronic liver disease. Ultimately, the outcome of chronic infection depends primarily on the severity of liver disease at the time that HBeAg seroconversion occurs and HBV replication is diminished.

The phase of inactive chronic HBV infection is characterized by low or absent levels of virus replication and remission of active liver disease (see Fig. 25.2). Patients are typically HBeAg-negative, have antibody to HBeAg (anti-HBe), and have low or undetectable levels of HBV DNA in serum. Most patients who clear HBeAg have normal ALT levels and resolution of necroinflammation on liver biopsy, indicating resolution of active liver disease.[72,79,80,84,85] However, a small percentage of these patients continue to have moderate levels of HBV replication, elevated ALT levels, and chronic inflammation on liver biopsy despite HBeAg seroconversion.[84,86] These patients may also have residual liver disease and can be misdiagnosed as having chronic liver disease of unknown etiology if they are HBsAg-negative.[87,88] Patients who clear HBeAg typically remain HBsAg positive for long periods, even in the absence of detectable HBV DNA. The annual rate of HBsAg clearance among patients with chronic HBV infection is approximately 0.5% to 2%.[77,85,89,90] However, HBV DNA can be detected in up to 50% of these patients by polymerase chain reaction even after clearance of HBsAg.[91]

The phase of reactivation of HBV replication or HBeAg-negative chronic hepatitis B can occur in persons with inactive chronic HBV infection either spontaneously or as a result of immunosuppression (Fig. 25.3).[79,92,93] In addition, some patients progress directly from HBeAg-positive chronic hepatitis to HBeAg-negative chronic hepatitis.[94] In one study of Taiwanese patients followed for a median of 8.6 years after spontaneous HBeAg seroconversion, 67% had sustained remission, 4% had HBeAg reversion, and 24% had HBeAg-negative chronic hepatitis B.[94]

Chronic HBV infection is an important cause of morbidity and mortality worldwide.[95] For example, in cohort studies conducted in Taiwan, approximately 25% of persons who became chronically infected during childhood and 15% of those who became chronically infected at older ages died of HCC or cirrhosis.[36,96] In one population-based study, the incidence of decompensated cirrhosis among persons with chronic HBV infection was 0.5 per 1000 person-years.[85] In studies of persons with chronic infection referred to clinical centers, the incidence of cirrhosis is as high as 2% to 3% per year.[97,98] Risk factors for the development of cirrhosis in persons with chronic infection include older age, HBeAg positivity, heavy use of alcohol (>40 g/day), and increased ALT levels.[97–99]

Persons with chronic HBV infection are also at high risk for developing HCC.[38,40] The annual risk of HCC is estimated to be less than 1% for chronically infected persons without cirrhosis and 2% to 3% for persons with cirrhosis.[100] In a

Taiwanese study, rates of HCC were approximately 100 times higher among men who were HBsAg-positive (495 per 100,000 per year) than among those who were HBsAg-negative (5 per 100,000 per year).[37,101] Most HCC cases occur in men, with an average male-to-female ratio of cases of 3.7 : 1. Other risk factors for HCC in persons with chronic HBV infection include high levels of virus replication, older age, family history of HCC, presence of cirrhosis, HBV genotype (C > B) (see "Virology" below), coinfection with hepatitis C virus (HCV), and increased alcohol intake.[37,85,100,102–105] Although HCC is more common in persons with cirrhosis, approximately 30% to 50% of HBV-associated HCC cases occur in persons who do not have cirrhosis.[85] Clearance of HBsAg might decrease the risk for HCC[88]; however, HCC can occur in persons who develop chronic HBV infection and then clear HBsAg.[85,89,106]

Virology

Hepatitis B virus, previously called the Dane particle, is a 42-nm DNA virus that belongs to the Hepadnaviridae family comprising two genera: *Avihepadnavirus* infecting birds and *Orthohepadnavirus* infecting mammals. The avian member's include the duck HBV, heron HBV, Ross goose HBV, stork HBV, and parrot HBV. The detection of endogenous avian hepadnavirus DNA integrated into the genomes of zebra finches has revealed a deep evolutionary origin of hepadnaviruses that was not previously recognized, dating back over 40 million years.[107,108] *Orthohepadnavirus* has been identified in several mammals, including the woodchuck *(Marmota monax)*, the ground squirrel *(Spermophilus beecheyi)*, the pig *(Sus scrofa)*, and Old World primate genera including gorillas, chimpanzees, and gibbons. Orthohepadnaviruses, which show approximately 70% sequence homology to HBV, are not able to infect humans, but HBV is infectious for the great apes.

The outer lipoprotein envelope of HBV contains HBsAg, which is produced in excess amounts and also circulates in the blood as 22-nm spherical and tubular particles (Fig. 25.4). The inner nucleocapsid is a 28-nm icosahedral structure consisting of 180 copies of the HBV core protein, or hepatitis B core antigen (HBcAg), and it surrounds a single molecule of partially double-stranded DNA and a DNA-dependent DNA polymerase (Fig. 25.5).[109]

The HBV genome is a small, circular, partially double-stranded DNA molecule (complete minus strand and partial plus strand) that is approximately 3200 nucleotides in length (Fig. 25.6).[110] The virus efficiently uses its genetic information to encode four groups of proteins and their regulatory elements by shifting the reading frames over the same genetic material.[111] The pre-S/S gene has three separate open reading frames (ORFs) that encode three forms of HBsAg: the large (pre-S1), middle (pre-S2), and small (S) structural proteins of the virus envelope. The C gene has two ORFs (C and pre-C). The C ORF encodes the structural protein of the viral nucleocapsid (HBcAg), and the pre-C/C ORF encodes the nonstructural e protein, which is processed to produce soluble HBeAg. The X gene encodes the X protein (HBx), a small transcriptional transactivator that influences the transcription of HBV genes by regulating the activity of transcriptional promoters.[112] The P gene encodes a large polymerase protein that functions as both a reverse transcriptase for synthesis of the negative DNA strand from genomic RNA and an endogenous DNA polymerase for synthesis of the positive DNA strand using the negative strand as a template. Interestingly, P overlaps with all other coding regions, and mutations in the polymerase gene may also affect the overlapping S gene, with implications on viral infectivity, pathogenesis of liver disease, and resistance to treatments.

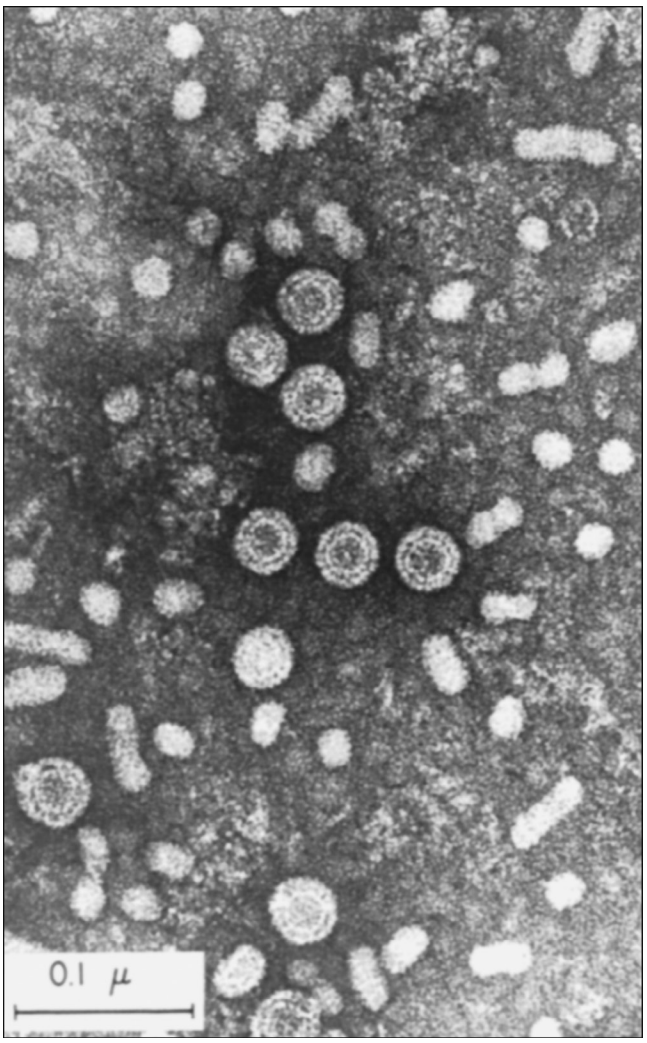

Figure 25.4. Electron micrograph of hepatitis B virus. Note Dane particles (43 nm) as well as spherical and tubular hepatitis B surface antigen particles (22 nm in diameter).

The HBV envelope contains a mixture of S, pre-S1, and pre-S2 HBsAg proteins in both glycosylated and nonglycosylated forms. These three proteins share the same carboxyterminus part but have different aminoterminal extensions. In particular, the S protein, which consists of 226 amino acids, is expressed in the largest quantities and is coded for by the S genomic region alone. The pre-S2, containing an extra N-terminal extension of 55 amino acids, is coded for by pre-S2 and S regions, and the pre-S1 protein, containing a further N-terminal of 108 or 119 amino acids—depending on the genotype—is coded for by the entire pre-S/S gene. Pre-S1 and pre-S2 proteins are also expressed individually in small quantities; these proteins contain a number of T- and B-cell epitopes and the pre-S1 protein appears to play an important role in the attachment of HBV to hepatocytes,[113–117] essentially through the sodium taurocholate cotransporting polypeptide (NTCP) receptor, recently identified as an entry receptor of HBV and HDV (hepatitis Delta virus).[118–120] Notably, the S protein contains the major site for binding of neutralizing antibody, designated the *a* determinant. Two other major determinants of the S protein also have been described; one has either *d* or *y* specificity, and the other has *w* or *r* specificity, determined by mutually exclusive amino acid substitutions in

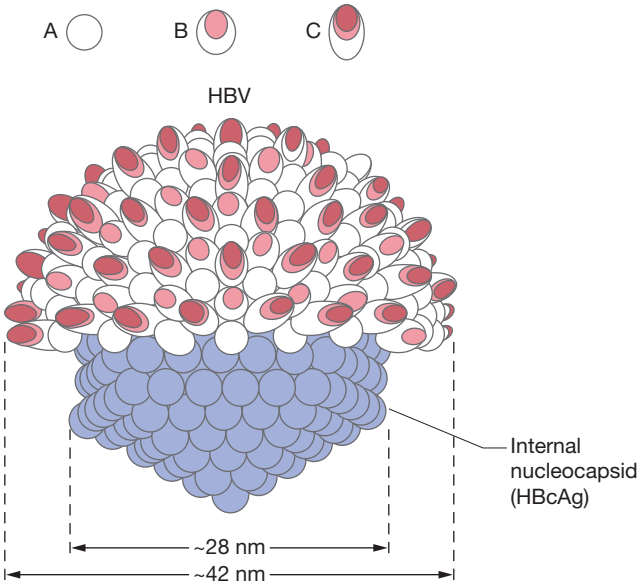

Figure 25.5. Schematic diagram of hepadnavirus particles. Individual subunits containing S protein only **(A),** S protein plus pre-S1 **(B),** and S protein plus pre-S1 and pre-S2 **(C)** are shown at the top of the figure. S proteins correspond to the white areas, pre-S2 to the light pink areas, and pre-S1 to the dark pink areas. The virus particles contain an internal nucleocapsid shown in the bottom split-open section. HBcAg, hepatitis B core antigen; HBV, hepatitis B virus. *(From Neurath AR, Thanavala Y. Hepadnaviruses. Boxes denote viral coding regions, with arrows indicating direction of translation. Outermost wavy lines depict the viral RNAs identified in infected cells, with arrows indicating direction of transcription. DR, direct repeat; ORF, open reading frame. *(From Ganem D. Hepadnaviridae and their replication. In: Fields BN, Knipe DM, Howley PM, et al, eds.* Fields Virology, vol. 2, *ed 3. Philadelphia: Lippincott-Raven; 1996:2706.)*

positions 122 and 160 of the S region of HBV DNA. All combinations of these determinants have been found, resulting in four major subtypes—*adw, adr, ayw,* and *ayr*—and nine minor subtypes. Antibodies to the *a* determinant confer protection to all these serotypes, whereas antibodies to the subtype determinants do not.[121] No apparent differences in infectivity or virulence of HBV have been attributed to HBsAg subtypes. However, these subtypes have a distinct geographic distribution worldwide and have been used in epidemiologic studies to identify patterns of virus transmission.[122] The most common subtype among persons with chronic HBV infection in the United States is *adw*.[123] Moreover, based on a minimal divergence of 8% of the complete genome sequences derived from several HBV worldwide isolates, at least 10 genotypes labeled alphabetically from A to J and a number of subgenotypes—with a minimal genetic distance of 4%—have currently been identified, showing different geographic and ethnic distributions.[124–128] For example, genotypes A and D are prevalent in Europe, the United States, and Africa, whereas genotypes B and C are prevalent in Asia. Genotype D predominates in the Mediterranean Basin and in the near Middle East up to India. Genotype E is by far the dominant genotype in West Africa, whereas genotypes F and H have mostly been isolated in Amerindian populations in different countries in the Americas. Finally, genotype G has no specific endemic areas in the world and is usually detected in coinfection with other HBV genotypes, mostly genotype A. More recently two additional genotypes, named I and J, were isolated in Laotian and Japanese patients,[129,130] respectively. Emerging evidence suggests that HBV genotypes and subgenotypes may play a role in determining the severity of the liver disease and treatment outcomes of HBV infection.[131–133]

Replication of the viral DNA genome occurs via reverse transcription mediated by the pregenomic RNA (pgRNA), for which polymerase plays a crucial role.

Both the nucleocapsid protein (HBcAg) and the e protein are translated from the C gene. HBcAg is essential for viral packaging and is an integral part of the nucleocapsid. It is not detectable in serum by conventional techniques, but it can be detected in liver tissue in patients with acute or chronic HBV infection. The e protein is processed by the endoplasmic reticulum, where it is cleaved and HBeAg is secreted. HBeAg is a soluble protein that is not part of the virus particle, but it can be detected in the serum of patients with acute hepatitis B and in persons with chronic HBV infection who have a high viral load. HBeAg is also expressed on the surface of hepatocytes[134] and might be an important target for the immune defense mechanisms that lead to the destruction of hepatocytes.[135]

HBV replication begins with attachment of the virus to the hepatocyte and penetration (Fig. 25.7).[117,120,136,137] After uncoating in the cytoplasm, the nucleocapsid is transported to the nucleus. However, it is unclear whether the nucleocapsid enters the nucleus or disassembles in the cytoplasm and delivers the viral DNA to the nucleus at the nuclear pore. Once in the nucleus, the single-stranded gap in the viral genome is repaired, and covalently closed circular DNA (cccDNA)—which is completely double stranded—is formed. Episomal HBV cccDNA persists in the hepatocyte as a stable mini chromosome organized by histone and nonhistone proteins. In

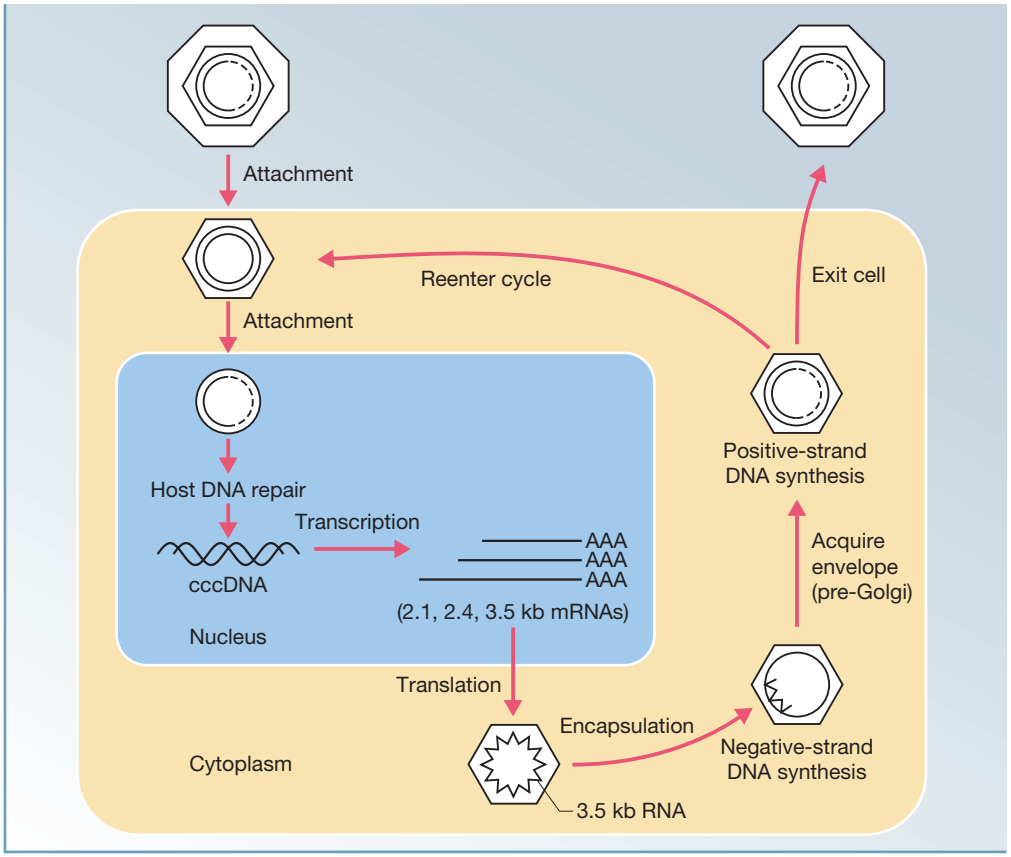

Figure 25.7. Hepatitis B virus replication cycle (see text for details). cccDNA, covalently closed circular DNA. *(From Butel JS, Lee TH, Slagle BL. Is the DNA repair system involved in hepatitis B virus-mediated hepatocellular carcinogenesis?* Trends Microbiol. *1996;4:119.)*

contrast to classic retroviruses such as HIV, integration of HBV DNA into the host genome is not necessary for viral messenger RNA (mRNA) synthesis or replication. However, integration of HBV DNA does occur during chronic infection, which might be an important factor for the development of HCC. The cccDNA acts as the template for production of four mRNAs, each of which is expressed from its own promoter.[136] A 0.7-kb mRNA transcript encodes for the X protein; a 2.1-kb mRNA transcript encodes for pre-S2 and S proteins; a 2.4-kb mRNA transcript encodes for pre-S1, pre-S2, and S proteins; and a 3.5-kb mRNA encodes for HBcAg, HBeAg, and polymerase. These mRNA transcripts are transported into the cytoplasm, where translation yields the viral envelope, core, precore, and X proteins and the viral DNA polymerase. The 3.5-kb mRNA is also a pgRNA that serves as a template for HBV DNA synthesis. Viral packaging occurs in the cytoplasm, where the pgRNA is encapsulated by newly synthesized HBcAg, and the polymerase synthesizes negative-strand DNA by reverse transcription. The pgRNA is then degraded by ribonuclease (RNase), an enzyme that resides on the polymerase.[138] After the negative strand is synthesized, the polymerase starts to synthesize the positive DNA strand.[139] However, the process is not completed, resulting in replicative intermediates consisting of full-length minus-strand DNA plus variable-length (20% to 80%) positive-strand DNA. Nucleocapsid particles containing these replicative intermediates bud from the pre-Golgi membranes, where they acquire HBsAg/pre-S protein–containing envelopes. Virus particles can then either exit the cell or be reimported into the nucleus and initiate another round of replication in the same cell.

Because of this strategy of replication, HBV shows a greater mutability (at least 100 times) than other DNA viruses. Mutations and variations that occur naturally or following antiviral therapy play important roles in viral infectivity, pathogenesis of liver disease, vaccine efficacy, and resistance to antiviral therapies.[140]

Hepatitis B Virus Mutants

HBV has a high frequency of mutations because the virus replicates via an RNA intermediate, using a reverse transcriptase (RT) that appears to lack a proofreading function leading to quasispecies. Mutations in the HBV genome can evolve from spontaneous errors of the viral polymerase, or as the consequence of pressure by the host immune system or by exogenous factors, including passive or active immunization as well as treatment with antiviral agents. As a result of overlapping ORF mutations within the HBV P can cause concomitant changes in the HBV surface gene (S) and vice versa. HBV quasispecies diversity is associated with response to antiviral therapy, disease severity, tumorigenesis, and long-term clinical outcomes. Mutations have been identified in all four HBV genes but have been most fully characterized in the pre-C/C gene, the polymerase gene, and the pre-S/S gene.[141–149]

Basal Core Promoter, Pre-C/C Gene Mutants

Two major groups of mutations that result in reduced or blocked HBeAg expression have been identified. The most common mutation in the ORF pre-C/C region is a guanine-to-adenine substitution at nucleotide (nt) position 1896 (G1896A) that results in a translational stop codon (from TGG to TAG) that abolishes the synthesis of HBeAg.[150,151] However, HBV DNA synthesis persists and may cause liver

damage with progression to cirrhosis and liver cancer. The G1896A mutation strongly depends on the viral genotype, being highly frequent among genotypes B to E and rare in A, F, and H strains; all G isolates harbor this mutation. Loss of HBeAg expression can also occur with mutations in the basal core promoter (BCP) region that regulates the expression of both HBeAg and core protein.[152] These mutations have been associated with fulminant hepatitis and severe chronic liver disease.[153,154] However, fulminant hepatitis can occur in the absence of such mutations.[155–157] Additional studies are needed to determine the pathogenesis and clinical sequelae arising from the selection of these mutants.

X Gene Mutations

Because the X ORF overlaps the BCP completely, promoter mutations can affect the amino acid sequence of the X protein. The most common BCP double mutations, occurring at nt 1762 (A1762T) and at nt 1764 (G1764A), can cause changes in the X protein that may affect its ability to transactivate the BCP. In addition, insertions or deletions in the BCP often shift the X gene frame, resulting in truncated forms of the X protein. These shortened X proteins lack the domain in the C terminus that is required for the transactivation activity of HBx antigen.[144,145,158]

Several mutations in the X gene are reported to be associated with progression of chronic hepatitis B and hepatocarcinogenesis.[159]

Polymerase Gene Mutants

Mutations of the polymerase gene have been associated with resistance to treatment with nucleoside or nucleotide analogs (NAs) and with viral persistence.[125,143–145,148,160–163] The most common of these mutations occur at codon 180 (the template binding site of the polymerase) and at codon 204 of the reverse transcriptase domain in the P gene.

Polymerase mutations have been demonstrated to emerge in up to 80% of patients after treatment with nucleoside or NAs. These mutations significantly decrease the efficacy of treatment.[165] The development of drug resistance due to mutations in the P gene is usually followed by a virological breakthrough (rise in HBV DNA levels of at least 1 log compared to nadir value), a biochemical breakthrough (ALT elevation), and worsening of liver disease.[166] Mutations of the Pol gene located within the catalytic domain of the RT region are particularly common after treatment with lamivudine (up to 80% after 48 months of treatment) but lower following treatment with other NAs.[167] To minimize the likelihood of resistance development and to increase the chance of achieving treatment goals, the currently available EASL (European Association for the Study of the Liver) guidelines recommend the choice of drugs with high potency and lowest rates of resistance as first-line treatment options.[168]

Because of the genome organization of HBV into overlapping reading frames, the emergence of polymerase mutants—favoring resistance—during long-term antiviral therapy can select viruses with crucial changes in the overlapping S gene, potentially able to alter the S protein immunoreactivity.[169–173] In this context, the widespread use of these drugs may cause the emergence of mutants potentially able to escape neutralization by vaccine-induced anti-HBs antibody and to infect successfully vaccinated people.[174,175]

Pre-S/S Gene Mutants

Isolates with pre-S deletions are often found. There is evidence that a set of mutations (deletion in the pre-S region as well as precore and BCP mutations) are significantly associated with progressive liver disease and HCC.[176,177]

Mutations in the S gene can lead to conformational changes in the common *a* determinant (shared by all HBV genotypes and serotypes), which spans amino acids 124 to 147 within the major hydrophilic region (MHR) of HBsAg and is in a form of two major loops and one minor loop with cysteine-disulphide bonds, protruding from the outer surface of the virus; the second hydrophilic loop (amino acids 139 to 147 or 149) is the major target for neutralizing anti-HBs induced by natural infection or vaccination (Fig. 25.8).[178] Neutralizing (protective) antibodies produced by vaccination are targeted largely toward the conformational epitope of the *a* determinant, providing broad protection against all HBV genotypes and subtypes. Thus, alteration of residues within this region of the viral surface antigen can determine conformational changes that can allow replication of HBV in vaccinated people.

The prototype of such mutants, the so-called G145R, which shows a point mutation from guanosine to adenosine at nt position 587, resulting in an amino acid substitution from glycine (G) to arginine (R) at position 145 in the *a* determinant of the surface antigen, was first observed in Italy some 25 years ago in infants born to HBsAg carrier mothers who developed breakthrough infections despite having received hepatitis B immunoglobulin (HBIG) and vaccine at birth.[179,180] Because the G145R substitution alters the projecting second loop of the *a* determinant, the neutralizing antibodies produced by vaccination are no longer able to recognize the mutated epitope. This mutant was infectious in experimentally infected chimpanzees.[181] Besides the G145R, other *S* gene mutations (alone or in combination) across the entire *a*-determinant region that are potentially able to evade neutralizing anti-HBs have been found worldwide.[142,182–184] Concerns have been expressed that these mutated viruses might allow replication of HBV in the presence of protective levels of anti-HBs (immunization escape mutants), negatively affecting the efficacy of vaccination.[183] In addition, these mutants might not be detected by some commercially available HBsAg assays based on antibodies to the wild-type virus, posing a potential threat to the safety of blood supply (diagnostic escape mutants).[185–188]

HBV infection with *S* gene mutant viruses has been reported to occur in anti-HBs antibody-positive infants born to HBV-infected mothers who received prophylaxis with HBIG plus hepatitis B vaccine,[179–181,189–193] in children who responded to vaccination,[194] and in liver transplant recipients who received for prophylaxis of relapse of HBV infection.[195–197] However, in population-based studies of infants born to HBsAg-positive mothers, *S* gene mutant viruses have not been found to be associated with a failure to prevent perinatal HBV transmission. In addition, preexposure vaccination of chimpanzees with currently licensed vaccines (not containing pre-S epitopes) conferred protection after intravenous challenge with the G145R HBV.[198] At present, no evidence exists that *S* gene mutants have spread in immunized populations or that these mutants pose a public health threat to hepatitis B immunization programs.[173–175,200] Further studies and enhanced surveillance to detect the emergence of these mutants, as well as those resulting from the onset of resistance to antiviral therapy, are a high priority in monitoring the effectiveness of current immunization strategies.

Pathogenesis

HBV is primarily hepatotropic. However, although HBsAg has been detected in organs other than the liver, there is little evidence to indicate primary replication in sites other than

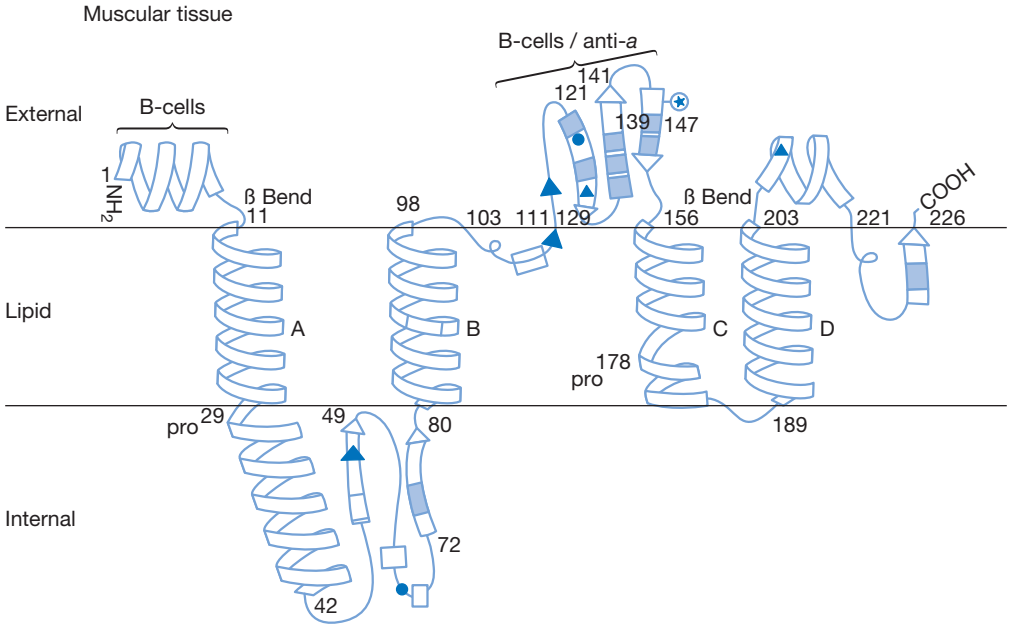

Figure 25.8. Secondary structure of hepatitis B virus surface (s) antigen in the lipid envelope as predicted by computer modeling. The shaded areas indicate the locations of sequence variations for w/r (s) and d/y (l) subtypes. *(From Howard C, Smith Stinh HJ, Brown SE, et al. Toward the development of a synthetic hepatitis B vaccine. In: Zuckerman AJ, ed.* Viral Hepatitis and Liver Disease: Proceedings of the International Symposium on Viral Hepatitis and Liver Disease, held at the Barbican Centre, London, May 26–28, 1987. *New York: Alan R. Liss; 1988.)*

hepatocytes. Most available experimental evidence suggests that HBV is not directly cytopathic, and that liver damage is produced by the cellular immune response to viral proteins in infected hepatocytes.[201] Extrahepatic manifestations that can appear during the prodromal phase of acute hepatitis B (e.g., arthritis, urticaria) and in patients with chronic infection (e.g., vasculitis, glomerulonephritis) appear to be mediated by immune complex formation.[57] Development of HCC in persons with chronic infection is apparently induced either directly by activating cellular oncogenes or inactivating tumor suppressor genes, or indirectly through chronic liver injury, inflammation, and the promotional effect of hepatocyte regeneration.[202]

Neonatal immune tolerance to viral antigens appears to play an important role in viral persistence in infants infected at birth, but the basis for poor T-cell response and the establishment of chronic infection in adults is not well understood.[73,74] Patients with acute hepatitis B whose infection has resolved have a vigorous T-cell response against multiple viral antigens, including the viral core, surface, and polymerase proteins. In contrast, persons who develop chronic infection have a weak or undetectable cellular immune response, suggesting that a less-efficient T-cell response might permit persistence of HBV.

Diagnosis

Antigens and antibodies associated with HBV infection include HBsAg, anti-HBs, total (i.e., immunoglobulin [Ig] G and IgM) antibody to HBcAg (anti-HBc), IgM anti-HBc, HBeAg, and anti-HBe. At least one serologic marker is present during the different phases of HBV infection (Table 25.1). Serologic assays are commercially available for all circulating markers except HBcAg, because no free HBcAg is secreted into the blood. However, HBcAg can be identified in liver tissue through immunohistologic assays.

The presence of a confirmed HBsAg result indicates current (or active) HBV infection. All HBsAg-positive persons should be considered infectious, yet infectivity is proportional to the magnitude of the viral load. In newly infected persons, HBsAg is the only serologic marker detected during the first 3 to 5 weeks after infection (Fig. 25.9). The average time from exposure to detection of HBsAg is 30 days (range: 6 to 60 days).[51,72] Highly sensitive single-sample nucleic acid tests can detect HBV DNA in the serum of an infected person 10 to 20 days before detection of HBsAg.[203] Transient HBsAg positivity has been reported for up to 18 days after vaccination with standard hepatitis B vaccine dosages,[204,205] and for up to 28 days after vaccination with the increased dosages used for hemodialysis patients.[206] This HBsAg positivity is clinically insignificant.

Anti-HBc appears at the onset of symptoms or liver test abnormalities in acute HBV infection and persists for life (see Fig. 25.9).[125] Acute or recently acquired infection can be distinguished by the presence of the IgM class of anti-HBc, which is detected at the onset of acute hepatitis B and persists for up to 6 months if the disease resolves. In patients who develop chronic hepatitis B, IgM anti-HBc can persist at low levels during viral replication, but they are usually not detectable by assays used in the United States. However, persons with exacerbations of chronic infection can test positive for IgM anti-HBc.[207] Because the positive predictive value of testing for IgM anti-HBc is low in asymptomatic persons, testing for diagnosis of acute hepatitis B should be limited to persons with clinical evidence of acute hepatitis or an epidemiologic link to a case.

In persons who recover from HBV infection, HBsAg is cleared from the blood, usually within 3 to 4 months, and anti-HBs develops during convalescence (see Fig. 25.9). The presence of anti-HBs typically indicates immunity from HBV infection. In addition, anti-HBs can be detected for several months after HBIG administration.[208] Persons who recover from natural infection are typically positive for both anti-HBs and anti-HBc, whereas persons who respond to hepatitis B vaccine develop only anti-HBs. In persons who become chronically infected, HBsAg and anti-HBc persist, typically for life (Fig. 25.10). HBsAg becomes undetectable in approximately

TABLE 25.1 Interpretation of Serologic Test Results for Hepatitis B Virus Infection

Serologic Marker				
HBsAg	**Total Anti-HBc**	**IgM anti-HBc**	**Anti-HBs**	**Interpretation**
–	–	–	–	Never infected
+[a]	–	–	–	Early acute infection; transient (up to 18 days) after vaccination
+	+	+	–	Acute infection
–	+	+	+ or –	Acute resolving infection
–	+	–	+	Recovered from past infection and immune
+	+	–	–	Chronic infection
–	+	–	–	False positive (i.e., susceptible); past infection; low-level chronic infection[b]; or passive transfer of anti-HBc to infant born to HBsAg-positive mother
–	–	–	+	Passive transfer after hepatitis B immunoglobulin administration or immune if concentration is ≥10 mIU/mL

Anti-HBc, antibody to hepatitis B core antigen; anti-HBs, antibody to hepatitis B surface antigen (HBsAg); IgM, immunoglobulin M; –, negative test result; +, positive test result.
[a]To ensure that an HBsAg-positive test result is not a false positive, samples with repeatedly reactive HBsAg results should be tested with a licensed (and, if appropriate, neutralizing confirmatory) test.
[b]Persons positive for only anti-HBc are unlikely to be infectious except under unusual circumstances in which they are the source for direct percutaneous exposure of susceptible recipients to large quantities of virus (e.g., blood transfusion or organ transplantation).

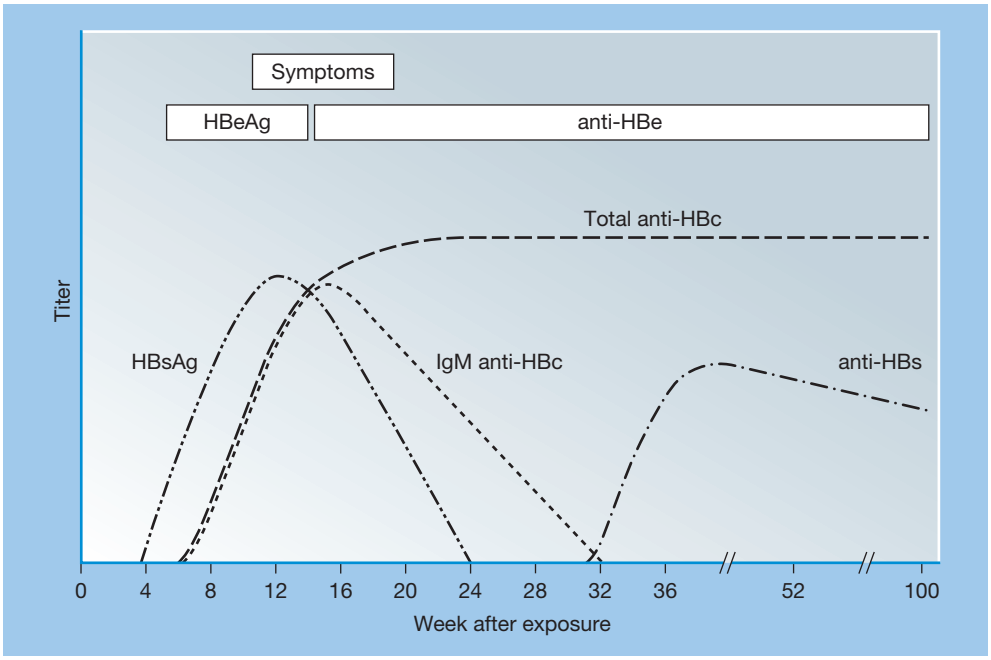

Figure 25.9. Concentrations of hepatitis B surface antigen (HBsAg), antibody to hepatitis B core antigen (anti-HBc), IgM anti-HBc, and antibody to HBsAg (anti-HBs) in patients with acute hepatitis B with recovery. Anti-HBe, antibody to HBeAg; HBeAg, hepatitis B e antigen; IgM, immunoglobulin M.

0.5% to 2% of chronically infected persons yearly, and anti-HBs develops in the majority of these persons.[77,89,90]

In certain persons, the only HBV serologic marker detected in serum is isolated anti-HBc. Isolated anti-HBc can occur after HBV infection in persons who have recovered but whose anti-HBs levels have waned, or in chronically infected persons in whom anti-HBs failed to occur and in whom circulating HBsAg is not detectable by commercial serology. HBV DNA has been detected in the blood of fewer than 5% of persons with isolated anti-HBc in the absence of detectable HBsAg.[209,210] In such patients, occult HBV infection is manifested by the presence of low levels of HBV DNA in serum and intranuclear HBV cccDNA in hepatocytes.[211,212] Such persons with occult HBV are unlikely to be infectious except when they are treated with immunosuppressive agents or are the source for direct percutaneous exposure of susceptible recipients to substantial quantities of virus (e.g., through blood transfusion or after liver transplantation).[93,213] Typically, the frequency of isolated anti-HBc relates directly to the prevalence of HBV infection in the population. In populations with a high prevalence of HBV infection, isolated anti-HBc most likely indicates previous infection, with loss of anti-HBs. In these individuals, hidden immunity to HBV may be unmasked through a single HBV vaccine dose that leads to an anamnestic anti-HBs response.

For persons in populations with a low prevalence of HBV infection, isolated anti-HBc is found in 10% to 20% of persons

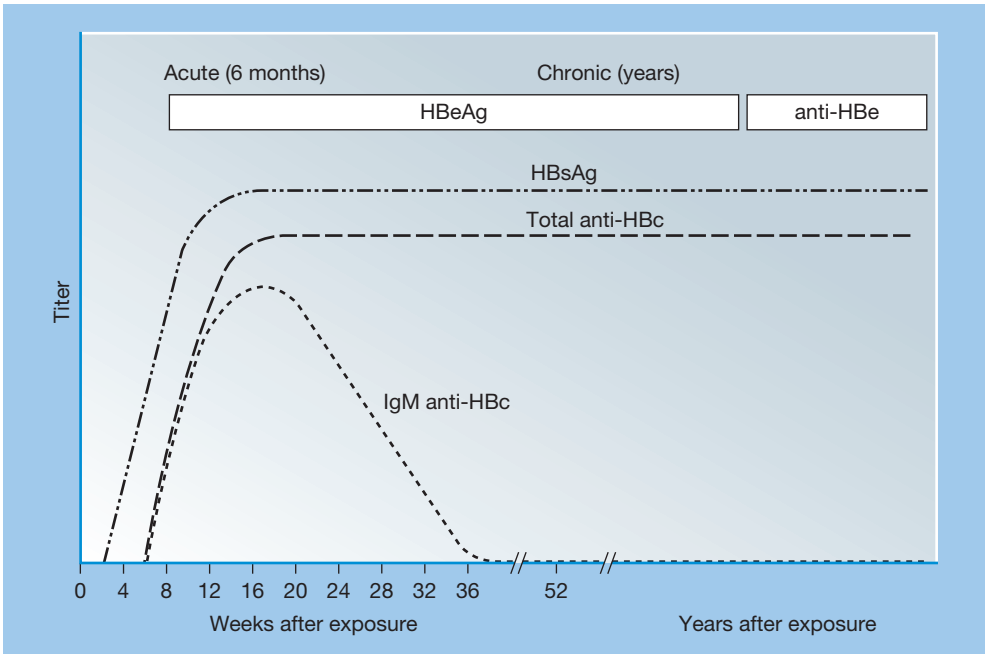

Figure 25.10. Concentrations of HBsAg, anti-HBc, and IgM anti-HBc during progression to chronic hepatitis B virus infection. Anti-HBc, antibody to hepatitis B core antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; IgM, immunoglobulin M.

with serologic markers of HBV infection,[210] and it often represents a false-positive reaction; the majority of these persons have a primary anti-HBs response after a three-dose series of hepatitis B vaccine.[214,215] Infants who are born to HBsAg-positive mothers and who do not become infected might have detectable anti-HBc for up to 24 months after birth from passively transferred maternal antibody.

HBeAg can be detected in the serum of persons with acute or chronic HBV infection. The presence of HBeAg correlates with high levels of viral replication (i.e., HBV DNA levels of 10^7 to 10^9 IU/mL, indicating high infectivity).[216,217] Loss of HBeAg correlates with low levels (i.e., HBV DNA levels of $<10^5$ IU/mL) of replicating virus, although some HBeAg-negative persons have HBV DNA levels up to 10^8 to 10^9 IU/mL.[100] A mutation in the precore region of the HBV genome has been found in HBeAg-negative persons with high HBV DNA levels.[150,218]

Treatment

No specific antiviral treatment is recommended for persons with acute hepatitis B, as approximately 95% of infected immunocompetent adults recover spontaneously with anti-HBs seroconversion.[219–221] Consequently, supportive care is the mainstay of therapy. Antiviral treatment may, however, be considered in patients with severe acute or fulminant hepatitis B.[219,222] In contrast, in patients with chronic hepatitis B (CHB), long-term antiviral treatment has been demonstrated to reduce the risk for disease progression and HCC by approximately 50%.[223] The U.S. Food and Drug Administration has approved six antiviral drugs for treatment of CHB: interferon-α (standard[224] and pegylated[225,226]) and five oral antiviral agents (lamivudine,[227] adefovir dipivoxil,[225,228] telbivudine,[229] entecavir,[230,231] and tenofovir).[232] To date, combination therapy has not been shown to be more effective than treatment with a single drug.[226,233] Guidelines for antiviral treatment in CHB were updated by the American Association for the Study of Liver Diseases (2009) and by the EASL (2012).[219,221]

Antiviral treatment is generally recommended for chronically infected patients on the basis of the presence of active disease (i.e., ALT levels more than twice the upper limit of normal), clinical or histologic evidence of progressive disease and fibrosis, or both.[234–236] The primary goal of treatment is to minimize progression of liver injury and fibrosis by suppressing viral replication.[224,237–239] The end points used to assess response include normalization of ALT levels (biochemical response); sustained clearance of markers of active HBV replication, including HBeAg seroconversion for HBeAg-positive patients and undetectable HBV DNA by polymerase chain reaction for HBeAg-negative patients (virologic response); histologic improvement on liver biopsy (histologic response); and sustained clearance of HBsAg (complete response).

Interferon-α and pegylated interferon-α are usually administered for 4 to 6 months, with durable virologic response rates of approximately 25% among patients with HBeAg-positive CHB, and 15% to 20% among patients with HBeAg-negative CHB.[226,233] For the five oral antiviral agents, virologic response rates as determined by undetectable HBV DNA in serum in controlled trials after 48 weeks of treatment were 76% with tenofovir, 67% with entecavir, 60% with telbivudine, 40% to 44% with lamivudine, and 21% with adefovir in patients with HBeAg-positive CHB. In patients with HBeAg-negative CHB, undetectable HBV DNA was reported in 93% of patients treated with tenofovir, 90% with entecavir, 88% with telbivudine, 60% to 73% with lamivudine, and 51% with adefovir.[225,226,228,230,231,233]

The optimal end point and duration of oral antiviral treatment for CHB has not been determined, and prolonged or even lifelong treatment must be considered in individual cases. In patients with HBeAg-positive CHB, durable virologic response rates of 16% to 24% have been achieved after 48 weeks of treatment with oral antiviral agents, even if treatment is stopped. However, in the majority of treated patients, particularly those with HBeAg-negative disease, HBV is suppressed but not eliminated, and relapse occurs when treatment is stopped.[240,241] Relapse can be associated with severe

exacerbation of disease, which might cause hepatic decompensation and death.[224] Thus, once started, treatment with oral antiviral agents is difficult to stop. Although these drugs have an excellent safety profile, the safety of long-term administration has not been demonstrated. The efficacy of long-term administration has also not been determined. A major issue related to long-term effectiveness is antiviral resistance. Resistance to lamivudine develops at a rate of 15% to 25% per year, reaching 70% to 80% after 4 years.[242] Resistance to adefovir is rare before completion of 2 years of therapy but reaches 15 to 20% by 4 years.[242] Although data are limited, the development of antiviral resistance with long-term use of entecavir has been described only in patients with preexisting lamivudine resistance[243] and so far has not been observed with tenofovir.[244]

BURDEN AND EPIDEMIOLOGY

Burden

HBV infection is a highly prevalent infection around the globe, the frequency and burden of which varies by region and subpopulation. Approximately 30% of the world's population (i.e., about 2 billion persons) have serologic evidence of HBV infection,[245] and of these, more than 240 million persons are living with chronic infection.[95,125,245,246] Based on a systematic literature review and an analysis of pooled data, an estimated 3.61% of the world's population or an estimated 248 million persons are HBsAg positive. By World Health Organization (WHO) region, the largest number of HBsAg-positive persons live in the Western Pacific and African regions (~95 million persons and 75 million persons, respectively), where most countries with high endemicity (≥8% prevalence) are located. However, countries of high endemicity can also be found in the Americas (e.g., Haiti) and European (e.g., Kyrgyzstan) regions. Countries with the highest population of HBsAg-positive persons include China (74 million), India (17 million), and Nigeria (15 million).[247]

HBV causes significant morbidity and mortality worldwide.[248–251] In 2013, approximately 686,000 HBV-infected persons died from causes related to acute infection (69,000 deaths), cirrhosis (317,000 deaths), and HBV-associated liver cancer (300,000 deaths), the sixth most common cancer globally and the second leading cause of cancer-related death worldwide. Of all cases of primary liver cancer, 70% to 90% are caused by HCC, for which HBV is a major cause.[252] The proportion of HCC attributed to HBV infection varies by the prevalence of HBV infection in the population. Accordingly, in Asia, HBV causes more than two-thirds of HCC in China, the Republic of Korea, and Vietnam, and 50% of the HCC in India, Thailand, and Malaysia. In countries of sub-Saharan Africa, 19% to 64% of HCC can be attributed to HBV infection. Data from the Global Burden of Disease Project in 2013 revealed that one-third of liver cancer–related deaths are among persons with HBV infection. Despite improvements in infant vaccination coverage, rates of HBV-related liver cancer remain high in some countries, reflecting HBV infection in persons acquiring the virus during childhood (before the implementation of routine hepatitis B vaccination) and the decades-long latency period before development of HCC.[253]

The lifetime risk for HCC in a chronically infected person is approximately 10% to 25%, which is 15 to 20 times greater than that for persons without HBV infection.[38,40] In a study conducted in Taiwan, rates of HCC among men who were HBsAg-positive were approximately 100 times higher than rates among those who were HBsAg-negative (495 vs 5 per 100,000 persons per year, respectively).[37,101]

Certain populations are disproportionately affected by HBV-related HCC. For example, whereas the incidence of HCC in women chronically infected with HBV ranges from 120 to 178 cases per 100,000 persons, among men, incidence ranges from 340 to 804.[248] The reasons for gender-related differences in HCC incidence remain unknown.

Other factors place certain persons with CHB at increased risk for developing HCC, including increasing age; HBeAg serostatus; increasing serum levels of HBV DNA and ALT; HBV genotype; concurrent infection with HCV, HBV genotype C infection, HDV, or HIV[97–99,253–257]; and cirrhosis, which is found in the majority of those who have HBV-related HCC (but not all patients with HCC will have had cirrhosis).[100,258–260] Behavioral factors that increase risk for HCC among persons infected with HBV include heavy alcohol consumption and aflatoxin ingestion.[261,262] Persons who achieve clearance of HBsAg (i.e., who have minimal or no viral replication) might be at decreased risk for HCC,[88] although HCC can occur in persons who clear the virus.[85,89,106,263,264]

Rates of new cases of HBV have declined substantially in the United States over the last several decades since implementation of routine hepatitis B immunization of infants recommended by the Centers for Disease Control and Prevention (CDC) in 1991.[265–267] In the two decades prior to publication of these guidelines, approximately 200,000 to 300,000 persons acquired HBV infection annually.[267,268] In contrast, only 19,000 new or acute hepatitis B cases were reported during 2012, reflecting an 86% decline in HBV incidence.[269,270] In 2013, the number of acute HBV infections increased 5%, reflecting cases associated with healthcare-related outbreaks and an increase in transmission of bloodborne infections among persons who inject drugs (PWID).[271–273]

In the United States, surveys suggest stable or decreasing rates of chronic HBV infection attributed to routine childhood vaccination. Data from the National Health and Nutrition Examination Survey (NHANES)[258] demonstrate that from 1988 through 2012, prevalence of past or current HBV infection decreased from 5.1% to 3.9%, representing approximately 10.8 million persons.[266] In 2011–2012, an estimated 0.3% of the U.S. population, or 847,000 persons were HBsAg-positive. HBsAg prevalence was lowest among persons 6 to 19 years of age (0.03%), a population with high rates of hepatitis B vaccination coverage, and highest among Asian-Americans (3.1%), 93% of whom were born in countries other than the United States. Actual rates of chronic infection among foreign-born persons are likely higher than those based on national surveys, as these persons are underrepresented in national surveys. Given that an estimated 54,000 persons migrate to the United States annually and considering country-specific HBsAg prevalence data, up to 2.2 million foreign-born persons could be living with HBV in the United States.

In 2010, a total of 1875 HBV-associated deaths (0.54 deaths per 100,000 population) were recorded in the United States.[274] Certain populations, such as Asians and Pacific Islanders, are at increased risk for HBV-related death. HCC incidence in the United States is highest among Asians and Pacific Islanders (7.8 per 100,000 persons),[275] and studies suggest that HBV infections account for approximately 80% of liver cancer–related deaths in the Asian community.[276] In 2013, 1873 HBV-related deaths were recorded in the United States.[270]

Substantial healthcare costs are associated with HBV infection, including those incurred from HBV antiviral therapy. From the late 1990s through the early 2000s, outpatient visits and hospitalizations for hepatitis B–related diagnoses increased more than fourfold in the United States, with a concomitant increase in healthcare costs, from $357 million in 1990 to $1.5 billion in 2003. Fortunately, this number has plateaued, dropping to $1.3 billion in subsequent years.[278]

Despite these figures, cost-to-benefit analysis shows that each $1 spent on primary prevention, including immunization, saves a net $1 in medical and work-loss costs.[279]

Routes of Transmission

Hepatitis B virus is transmitted by percutaneous (i.e., puncture through the skin) or mucosal (i.e., direct contact with mucous membranes) exposure to infectious blood or body fluids. All HBsAg-positive persons are potentially infectious, but those who are also HBeAg positive are *more* infectious because their blood contains high concentrations of HBV (typically 10^7 to 10^9 virions/mL). Although HBsAg has been detected in multiple body fluids, only serum, saliva, semen, and vaginal fluid have been demonstrated to be infectious.[280] HBV remains infectious for at least 7 days outside the body and can be found in very low concentrations on fomites, even in the absence of visible blood.[281–283] Primary sources of HBV infection are perinatal exposure from infected mothers, nonsexual person-to-person contact, sexual contact, and percutaneous exposure to blood or infectious body fluids. HBV is not transmitted by air, food, or water.

Perinatal Transmission

Infants born to mothers with chronic HBV infection can acquire perinatal HBV infection, which usually occurs at the time of birth; *in utero* transmission of HBV is relatively rare (accounting for <2% of infections transmitted from mother to infant),[284–287] and the virus is not transmitted through breastfeeding.[288] The likelihood of transmission is associated with time of maternal infection—pregnant women who acquire hepatitis B in the first and second trimester rarely transmit HBV to the fetus or neonate,[289,290] whereas approximately 60% of infants born to women infected during the third trimester become infected.[290] Risk for perinatal transmission is higher from mothers with a high viral load, which generally correlates with the presence of HBeAg in serum, whereas less than 10% of infants born to HBeAg-negative mothers develop chronic HBV infection.[291–294] Of infants born to HBeAg-positive mothers, 70% to 80% develop chronic HBV infection by age 6 months in the absence of postexposure immunoprophylaxis.

Perinatal transmission is a major source of HBV infection in many countries.[284–287,291,293–296] A mathematical model estimates that globally, an estimated 21% of future HBV-related deaths among persons who were not vaccinated at birth will be attributable to perinatal HBV infection.[95] In the United States, the race-adjusted prevalence of HBsAg among pregnant women is approximately 0.6%; the prevalence of HBeAg among HBsAg-positive pregnant women is approximately 35% among women of Asian descent and approximately 20% among other races.[297,298] When applied to 2003 U.S. natality data, race- and ethnicity-adjusted HBsAg prevalence estimates revealed that approximately 25,600 infants were born to HBV-infected pregnant women during 2008; without immunoprophylaxis, approximately 9600 of these infants would develop chronic HBV infection during their lifetime.[299]

Nonsexual, Person-to-Person Contact

HBV transmission can occur horizontally via nonsexual, person-to-person contact with HBsAg-positive persons. The risk of transmission increases with duration of exposure. Person-to-person transmission probably occurs from inadvertent percutaneous or mucosal contact with blood or infectious body fluids during certain activities, such as sharing toothbrushes or razors, contact with exudates from dermatologic lesions, contact with saliva through bites or other breaks in the skin, premastication of food, sharing of gum and other food items, and contact with HBsAg-contaminated surfaces.[280,300–305]

Households are typical settings for such transmission, particularly in highly endemic areas[306]; as a result, household contacts of HBsAg-positive persons are at high risk for HBV infection. Seroprevalence of HBV infection among household contacts of persons with chronic infection varies by study, ranging from 14% to 60%.[36,78,80,90,91,95,96,307–313] According to one study involving 302 hepatitis B–infected children referred for tertiary care in Ankara, Turkey, 38% of mothers, 23% of fathers, and 11% of other siblings were also HBsAg-positive. Other settings where person-to-person transmission typically occurs include childcare centers and schools.[314–320] Of all HBV-related deaths in the 2000 birth cohort worldwide, 48% will result from infection acquired in the early childhood period, according to the mathematical model of Goldstein and colleagues[95] (Table 25.2).

Routine hepatitis B immunization prevents person-to-person transmission; integrating hepatitis B vaccination into the routine infant immunization schedule beginning at birth would prevent or eliminate person-to-person transmission among young children. Although it is often recommended that household and other close contacts of persons positive for HBsAg receive hepatitis B vaccination, levels of hepatitis B vaccination coverage tend to be low among household contacts and other persons in risk populations.[321,322]

Sexual Transmission

HBV is efficiently transmitted during heterosexual and male-to-male sexual contact.[320,323–327]

Sexual transmission is a leading cause of HBV infection among adults in areas of low HBV prevalence, including the United States and Europe,[234,328] and it is a contributing cause of HBV transmission in moderately endemic (e.g., India, Bulgaria)[329,330] and highly endemic (e.g., China)[320,331] countries. The most common risk factors for sexual transmission include number of years of sexual activity, number of lifetime sexual partners, unprotected sex with an infected partner, unprotected sex with more than one partner, and history of another sexually transmitted infection. Among persons seeking

care for sexually transmitted infections, the prevalence of HBV infection is typically several times greater for men who have sex with men (MSM) than for heterosexual patients.[332–337] Unprotected anal sex increases HBV transmission risk for both MSM and heterosexual women.[338–340]

Percutaneous Exposure

In many developing countries, unsafe injections and other unsafe percutaneous or permucosal procedures conducted in medical and other care settings (i.e., acupuncture) contribute substantially to transmission of bloodborne pathogens (e.g., HBV, HCV, and HIV).[341–344] In the United States and Europe, HBV outbreaks continue to occur in dialysis centers, medical wards, surgery services, nursing homes, and residential care facilities.[269,345,346] The risk of infection after needlestick exposures to HBV is high—approximately 30% to 60% after inoculation with HBeAg-positive blood and 10% to 30% after percutaneous or permucosal exposure to HBeAg-negative blood.[347–349] By comparison, the risks of HCV and HIV transmission from percutaneous exposures are approximately 2% and 0.2%, respectively.[350,351]

As recently as 2000, unsafe injection practices have been estimated to cause up to 20 million HBV infections worldwide. However, exposures to unsafe injections decreased over the following decade, resulting in an estimated 91% reduction in injection-related HBV infection, or about 1.68 million new infections per year.[352]

Blood transfusions were once a frequent cause of HBV transmission. However, with (a) the advent of donor exclusion guidelines, (b) recommendations to invite voluntary, nonremunerated blood donors from low-risk populations, and (c) testing of donated blood for HBsAg, anti-HBc, and HBV DNA, transfusion-associated hepatitis B is now rare in the United States and many other industrialized countries.[353] Currently, the risk of receiving potentially HBV-infectious blood after donor screening and blood bank testing is approximately 1 in 500,000 per unit exposure.[354] This risk remains higher in countries where these measures have not been as successfully implemented. A 2000 study conducted in sub-Saharan Africa revealed that approximately 30% of blood donations were not screened for HBV.[355]

However, donor recruitment and screening of blood donations for bloodborne pathogens have improved in many sub-Saharan countries. From 2000–2004 to 2010–2011, the median annual number of units donated in each of 36 sub-Saharan countries evaluated increased, as did the number of countries screening at least 95% of blood donations for HBV; over this period, the median national prevalence of donation with markers of HBV infection decreased from 7% to 4%.[356]

Clotting factor concentrates from donors not tested for HBV, along with concentrates that were not mechanically processed to ensure viral inactivation, can transmit HBV and other bloodborne infections to patients with hemophilia and other clotting disorders.[357] Since 1987, clotting factor concentrates licensed in the United States and other industrialized countries have been manufactured by processes known to inactivate HBV.[358]

Injection of illicit drugs is a major nonmedical source of percutaneous exposures to HBV. Globally, injection-drug use is a common mode of HBV transmission; incidence rates of 10% to 31% per year have been reported among persons with illicit drugs (PWID).[359–363] Risk for HBV transmission increases with the number of years of drug use, with frequency of injection, and with sharing of drug-preparation equipment (e.g., cottons, cookers, and rinse water), independent of syringe sharing.[359,361,364] Sexual risk factors (such as selling sex for money or drugs) contribute to HBV transmission among drug users.[365]

In populations of PWID, global prevalence of HBV infection (anti-HBc positivity) ranges from 42% to 85%; prevalence of HBsAg also varies widely, at 2.8% in Brazil, 11.8% in the United States, and 21.3% in Estonia.[366] In 2010, an estimated 1.2 million (range: 0.3–2.7) PWID were HBsAg-positive worldwide, with an 8.4% prevalence of HBsAg among all among PWID.

Geographic Patterns of Transmission

The frequency and patterns of HBV transmission vary markedly in different parts of the world (Fig. 25.11). HBV prevalence is greatest in areas of moderate (≥2%) to high (≥8%) HBsAg endemicity, including most of Asia (except Japan and India), most of the Middle East, the Amazon basin, most Pacific Island groups, and Africa, particularly the western portion of the continent; however, certain populations in areas of low endemicity (e.g., Australian Aborigines, New Zealand Maoris, and Alaskan Native Americans) also have elevated prevalence of HBV infection. In the absence of vaccination, the lifetime risk for HBV infection is greater than 60% in areas of high endemicity; rates of chronic liver disease and liver cancer also are very high in these areas.[95]

In highly endemic countries, most infections are acquired during the perinatal period and early childhood, when the risk for developing chronic infection is greatest; acute hepatitis B is rarely detected because most infections in early childhood are asymptomatic. In recent years, many of these countries have successfully introduced hepatitis B vaccine into their routine childhood immunization schedule, resulting in lower HBV and HCC prevalences.[367–371]

For example, in 2002, China began routinely providing infants with a dose of vaccine at birth, followed by the complete hepatitis B vaccine series. As a result, from 1992 through 2006, HBsAg prevalence among children younger than 5 years of age declined from 9.7% to 1%[367]; however, despite these declines, prevalence remains high among older unvaccinated populations. In Alaska, after routine vaccination of infants and newborns in 1984, the incidence of HCC in children declined from three cases per 100,000 population (1984 to 1988) to zero cases, where it has remained stable since 1999.

In areas of intermediate endemicity, the lifetime risk for HBV infection is 20% to 60%, and infections occur in all age groups. Acute hepatitis B is common in these areas because many infections occur in adolescents and adults. However, high rates of chronic HBV infection are maintained primarily because of infections occurring in infants and children.

Most HBV infections in areas of low endemicity occur in adults in relatively well-defined risk groups,[95] but a high proportion of chronic infections might occur as a consequence of perinatal and early childhood exposures. In the United States, more than one-third of chronic HBV infections were acquired perinatally or in early childhood before implementation of perinatal hepatitis B prevention programs and routine infant hepatitis B vaccination.[265]

The contribution of perinatal HBV transmission to the overall hepatitis B disease burden varies substantially in different geographic regions. In eastern and southeastern Asian countries and the Pacific Islands, 35% to 50% of HBsAg-positive women are also HBeAg-positive.[300,372–375] In these countries, approximately 3% to 5% of all infants develop chronic HBV infection after HBV infection during birth, and as many as 30% to 50% of all chronic infections among children result from perinatal transmission. In areas of high endemicity where the prevalence of HBeAg among pregnant

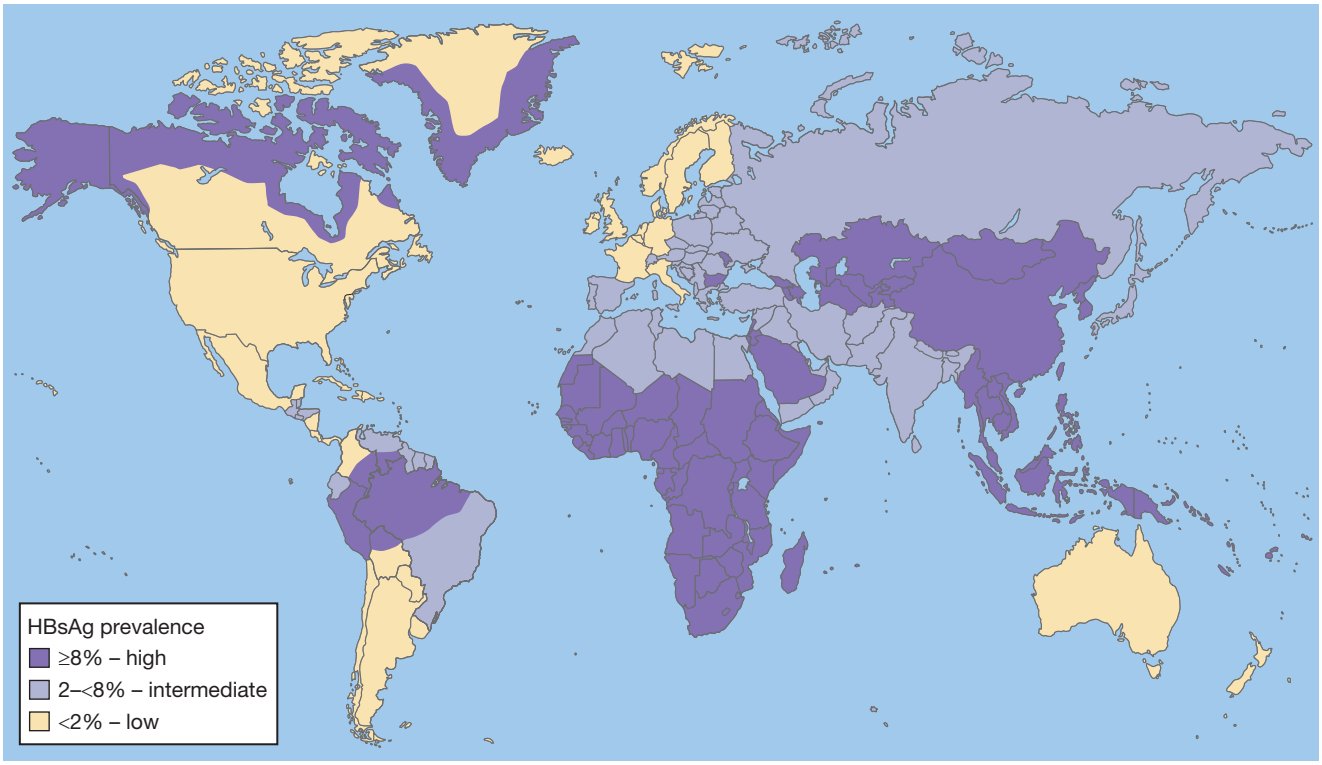

Figure 25.11. Geographic distribution of chronic hepatitis B virus infection. HBsAg, hepatitis B surface antigen.

women is low (i.e., Africa, South America, and the Middle East), perinatal HBV transmission contributes less to the pool of children with chronic infection than does postnatal early childhood transmission.[376–380] In general, fewer than 10% to 20% of all chronic infections among children in these areas result from perinatal exposures.

Risk Populations, Based on U.S. Data

In the United States the most common routes of HBV transmission are sexual contact and injection-drug use. From 2011 to 2013, injection-drug use surpassed sexual contact to become the most commonly reported exposure among cases of acute HBV infection reported to CDC accompanied by behavioral risk information. Of 606 such cases reported in 2013, a total of 55% were among persons reporting injection-drug use; 37% reported risks from heterosexual contact, and 7% were MSM. In some states, HBV transmission attributed to injection-drug use is reversing the decades-long trend of declining HBV incidence.[271]

Persons at Risk for HBV Infection Through Sexual Exposure

HBV is readily transmitted from an infected person to a susceptible partner during sexual contact. Serologic evidence of HBV infection (i.e., positive for anti-HBc) can range from 10% to 40% among adults seeking treatment in sexually transmitted disease clinics[325,337,381] and from 10% to 40% among MSM younger than age 30 years. Additional studies have identified HBV infection in 20% to 42% of susceptible heterosexual partners of persons with acute hepatitis B.[382–384] Among susceptible heterosexual spouses of persons with chronic HBV infection, the seroprevalence of HBV infection ranged from 25% to 59%.[307,308,385] Population-based serosurveys also have demonstrated an association between HBV infection and sexual health and behaviors. Whereas approximately 4.6% of the general population has serologic evidence of HBV infection,[386] NHANES data from 1999 to 2008 revealed a 9.1% and 15.5% prevalence of past or current HBV infection among persons who were positive for antibody to herpes simplex virus type 2 and among persons reporting having 50 or more sexual partners over their lifetime, respectively.[386]

Contacts of Persons With Chronic Hepatitis B Virus Infection

Studies demonstrate varying rates of HBV transmission, ranging from 15% to 60%, among susceptible household contacts of chronically infected persons[307–313]; 3% to 20% of these contacts are chronically infected.[387] Of household contacts, risk for infection is highest among sexual partners and children.[311–313] Before hepatitis B vaccine was integrated into the U.S. childhood immunization schedule, an estimated 16,000 children younger than 10 years of age were infected with HBV annually from nonsexual person-to-person contact occurring beyond the postnatal period[388]; at that time, an estimated 18% of persons with chronic HBV infection acquired their infections postnatally during early childhood.[279] Since the adoption of routine infant immunization in 1992, HBV transmission among children has declined dramatically.[389]

Hemodialysis Patients

Because hemodialysis presents frequent opportunities for blood exposures, hemodialysis patients are at increased risk for hepatitis B infection. However, in the 1970s, dialysis centers adopted infection-control procedures (i.e., routine HBV screening, hepatitis B vaccination of susceptible dialysis patients, and management of HBsAg-positive patients) that

dramatically reduced rates of transmission. In 2013, only one person with acute HBV infection reported hemodialysis as a risk.[390] According to recent surveys of U.S. dialysis centers, prevalence of HBV among dialysis patients ranges from 1.0% to 2.4%[391,392]; annual incidence of new HBV infections is low in these settings, at 0.12% (2002).[392] Despite this progress, hemodialysis patients remain at risk for infection, as evidenced by outbreaks of HBV infection among unvaccinated patients.[345,393]

Incarcerated Persons

The seroprevalence of HBV infection among incarcerated adults in the United States ranges from 14% to 47% for both prison and jail inmates; 1% to 11.4% of inmates have evidence of chronic infection,[394–399] and prevalence is highest among female prisoners.[400] The high prevalence of infection observed among incarcerated adults primarily reflects infections acquired before incarceration. However, HBV is known to be transmitted within correctional facilities; incidence of transmission in this setting has ranged from 0.82% to 3.8%.[401–403] Inmates can remain at risk for hepatitis B after release into the community. A study of recidivist women reported an HBV seroconversion rate of 12.2 per 100 person-years between incarcerations,[400–404] compared with an estimated incidence of 0.03 per 100 person-years for the general U.S. population.[400] Increased rates are likely attributed to a return to high-risk behaviors after incarceration.[405] In a nationally representative sample of adult men 15 to 44 years of age, those who were recently incarcerated were much more likely to report engaging in high-risk sexual behaviors.[406]

Injection-Drug Users

In 2013, injection-drug use accounted for more than half of new HBV infections in the United States.[269–271] In a seroprevalence study of HBV infection among injection-drug users (IDUs) admitted to drug treatment in six U.S. cities, 64% (range: 50% to 81%) were seropositive for anti-HBc, with seroprevalence increasing with age.[407] Other studies of IDU populations have revealed 20% to 70% of IDUs ever infected with HBV and a 3% to 6% prevalence of chronic infection.[405–416] IDUs are at increased risk for HDV infection, which can be associated with HIV among HBsAg-positive PWID. From 1999–2013, of 2175 HBsAg-positive U.S. military veterans who were tested for HDV, 73 (3.4%) tested positive; a history of injection-drug use was a major risk factor for HDV infection.[417] From 2005 through 2006, a total of 50% of HBV-infected IDUs in Baltimore had serologic evidence of exposures to HDV.[418] Of 115 HIV-infected persons enrolled in international clinical trials and who were also HBsAg-positive, anti-HDV was detected in 15 (13.3%) of the HIV/HBV coinfected study participants.[419]

The incidence of HBV infection among unvaccinated IDUs is high, ranging from 10 to 31 per 100 person-years.[361,363,420] Risk for HBV transmission increases with number of years of drug use, frequency of injection, and sharing of drug-preparation equipment (see Percutaneous Exposure).[359,361,363,420] The adoption of safe-infection strategies has led to decreased rates of HBV infection in this population, as have enhanced efforts to vaccinate IDUs against hepatitis B. Hepatitis B vaccination campaigns targeting IDUs through syringe exchange programs are cost saving[421]; however, rates of vaccination remain low in most cohorts of IDUs.[422–424] Recent increases in injection-drug use behaviors in the United States are contributing to increases in viral hepatitis incidence in some states.[272,425] For hepatitis B infection, most are among persons older than 30 years of age, an age group not reached by childhood and adolescent vaccination earlier in life.[271]

Persons at Risk for Occupational Exposure

In the United States, from 1998 to 2008 a total of 18 outbreaks were reported, resulting in 173 persons with incident HBV infection. Transmission was associated in most cases with unsafe injection practices occurring in inpatient, outpatient, and long-term care facilities, including nursing homes and assisted-living facilities.[426] During 2008–2014, another 23 outbreaks of HBV transmission were reported to CDC involving 175 cases; 17 of these outbreaks occurred in long-term care facilities.

Based on reported cases of hepatitis B in the United States, persons with diabetes mellitus have about a twofold greater risk of acute HBV infection.[427] Data for the period 1999–2010 from the NHANES, indicated a 60% higher seroprevalence of antibody to HBcAg (indicative of past or present HBV infection) overall among persons 18 years of age and older with diagnosed diabetes compared with those without diabetes. Lack of adherence to standard infection-control precautions and failure to implement longstanding recommendations against sharing fingerstick devices place diabetes patients at risk for acquiring infections from bloodborne pathogens such as HBV. Percutaneous exposures to HBV occur as a result of assisted monitoring of blood glucose and other procedures involving instruments or parenteral treatments shared between persons. Lapses in infection control during assisted blood glucose monitoring that have led to HBV transmission include multipatient use of fingerstick devices designed for single-patient use and inadequate disinfection and cleaning of blood glucose monitors between patients.

Studies conducted in the United States during the 1970s and 1980s demonstrated a 10% to 30% prevalence of HBV infection among healthcare workers.[428–433] At that time, infection was associated with frequency of blood contact, needlestick exposures, direct patient contact, and years of employment, and occurred mainly among certain occupational groups, including physicians, nurses, laboratory technicians, and emergency medical technicians. However, with the widespread vaccination of healthcare workers and implementation of standard precautions in healthcare settings, the incidence of new infections has declined substantially in the United States and is now less than that of the general population.[434] In many other countries, reaching a high HBV immunization coverage in healthcare workers remains a challenge.

Theoretically, public safety workers whose job duties present opportunities for exposures to blood are at increased risk for HBV infection.[435–437] However, although occupational exposures can occur, the prevalence of HBV infection in these workers (e.g., police officers, firefighters, and corrections officers) typically does not differ from that of the general population when adjusted for race and age.[422,435] Instead, infection among public safety workers is most often associated with nonoccupational risk factors.[435] No increased risk for HBV infection resulting from occupational exposures has been documented in persons infrequently exposed to blood or body fluids, such as ward clerks, dietary workers, maintenance workers, housekeeping personnel, lifeguards, teachers, and persons employed in child daycare settings.[432]

Developmentally Disabled Persons in Long-Term Care Facilities

High rates of HBV infection were documented among residents in institutions for developmentally disabled persons before hepatitis B vaccine was used in these facilities and integrated into the routine U.S. childhood immunization schedule.[438,439] In the United States, the risk for HBV infection in these institutions has declined substantially over the past three decades. However, because HBsAg-positive persons can

reside in these institutions, unvaccinated residents and workers remain at risk for HBV infection.

Travelers to Regions With Moderate or High Hepatitis B Virus Endemicity

Many travelers (24% to 49%) report activities or exposures that might place them at risk for hepatitis B transmission while visiting countries of moderate or high HBV endemicity, such as sexual contact with a new (local) partner, receipt of medical or dental care, and other direct exposures to blood.[440–442] At particular risk are persons traveling to endemic areas for the purpose of obtaining planned healthcare services (e.g., renal transplantation), which can expose these patients to HBV and lead to healthcare-associated HBV transmission to patients and their close contacts.[441,443] Although hepatitis B vaccination can greatly reduce risk for HBV infection among travelers, few (19% to 29%) travelers from low to more highly endemic areas for HBV recall having received hepatitis B vaccination before departing from their home countries.[440–442,444,445]

Studies of HBV incidence indicate that short-term travelers to areas where HBV infection is of intermediate or high endemicity are generally not at risk for HBV infection.[446–449] However, because length of time in an endemic country increases the likelihood of exposure to HBV, risk of HBV transmission is greatest for persons working or traveling in endemic countries over extended periods. One prospective study of 7887 travelers found that of two documented travel-associated HBV infections, both occurred among the 97 persons who worked abroad[448]; none of the 7317 persons traveling for vacation acquired HBV.[444,445] Another study of long-term missionaries in developing countries demonstrated that 5.5% became positive for anti-HBc, for an HBV incidence rate of 0.8 per 100 person-years.[450] In Amsterdam, a study of persons with acute hepatitis B reported over a 12-year period estimated an incidence rate of 4.5 per 100,000 travelers to HBV-endemic countries; 89% of cases were among long-term travelers or immigrants from highly endemic areas returning from visits with friends or relatives in their countries of origin.[447]

PREVENTION OF HEPATITIS B VIRUS

Passive Immunization

The discovery that passively acquired anti-HBs can provide protection against acute hepatitis B and chronic HBV infection when administered soon after exposure led to the development and therapeutic use of HBIG, a specific immunoglobulin containing high concentrations of anti-HBs. Currently, HBIG is recommended only for postexposure prophylaxis (often in combination with hepatitis B vaccine) in specific settings.[451]

HBIG is prepared by fractionation from serum containing high concentrations of anti-HBs and that has been screened for HBsAg and antibodies to HIV and HCV. The process inactivates the potential presence of HIV in the final product.[452,453] Since 1999, all HBIG products available in the United States and many other countries have been manufactured by methods that inactivate HCV and other viruses.

The efficacy of HBIG in preventing clinical hepatitis B or the development of chronic infection is approximately 75% in adults,[349,454,455] but the protection lasts only several months. HBIG is expensive and usually not affordable in the developing world.

A major use of HBIG is as an adjunct to hepatitis B vaccine in preventing perinatal HBV transmission. Untreated, 70% to 90% of infants born to HBeAg-positive mothers become infected at birth and develop chronic HBV infection.[296,456] Of these chronic infections, 75% can be prevented by treatment with HBIG started within 48 hours of birth and with subsequent doses at ages 3 and 6 months[295,457]; however, children living in a household with an infected mother often become infected after the first year of life.[300] Immunoprophylaxis with both HBIG and hepatitis B vaccine increases the efficacy of preventing perinatal HBV transmission from 85% to 95% and provides long-term protection.[296,297,458]

HBIG is also indicated for postexposure prophylaxis after needlestick or other percutaneous injuries, following the demonstration of the efficacy of HBIG alone in preventing acute clinical hepatitis B in needlestick recipients in two large multicenter trials.[348,349] With the availability of hepatitis B vaccine, postexposure prophylaxis protocols that take into account the vaccination and serologic status of the exposed person recommend administration of HBIG to unvaccinated persons and to vaccine nonresponders.

The efficacy of HBIG in preventing clinical hepatitis B or chronic HBV infection after sexual exposure to an acutely infected partner is also approximately 75% when administered within 7 days of exposure.[383] Current recommendations for postexposure prophylaxis after sexual exposure to an infected person include administration of HBIG and hepatitis B vaccine.

HBIG alone or in combination with an oral antiviral agent is also used for the prevention of HBV reinfection of liver grafts in patients undergoing liver transplantation because of fulminant or CHB.[459]

The standard dose of HBIG is 0.5 mL for postexposure prophylaxis of infants born to HBsAg-positive mothers and 0.06 mL/kg for all other indications. HBIG should be administered intramuscularly and may be administered simultaneously with hepatitis B vaccine but in a different injection site. For neonates (<1 month old) and infants (1 to 12 months old), HBIG should be administered intramuscularly in the anterolateral thigh using an appropriate needle length (usually ⅝ inch [or 1.5 cm] for neonates, and ⅞ to 1 inch [or 2.2 to 2.5 cm] for infants). For older children, adolescents, and adults, HBIG should be delivered in an appropriate muscle mass (e.g., deltoid or gluteal) using a needle length appropriate for the person's age and size.[460]

Various protocols exist that use high-dose HBIG intravenously or low-dose HBIG administered via the intramuscular or subcutaneous routes for HBV patients undergoing liver transplantation.[461,462]

In such patients who need long-term protection, HBIG was used previously as monotherapy, and it is used more recently in combination with oral nucleoside or NAs.[463]

Active Immunization

Development of Vaccines

Safe and effective hepatitis B vaccines have been commercially available since 1982. The American microbiologist Maurice Hilleman at Merck used three treatments (pepsin, urea, and formaldehyde) of blood serum together with rigorous filtration to yield a product that could be used as a safe vaccine. Hilleman hypothesized that he could make an HBV vaccine by injecting patients with hepatitis B surface protein. In theory, this would be very safe, as these excess surface proteins lacked infectious viral DNA. The first available vaccines were indeed produced by harvesting HBsAg (the 22-nm particle) from the plasma of persons with chronic HBV infection. Concerns about transmission of bloodborne pathogens, including HIV, from plasma-derived vaccines have proved to be unfounded.[464]

Subsequently, the development of recombinant DNA technology to express HBsAg in other organisms offered the potential to produce unlimited supplies of vaccine,[465–467] and recombinant DNA vaccines have replaced the plasma-derived vaccines (Table 25.3). Hepatitis B vaccines are formulated to

D, diphtheria; HepB: hepatitis B; Hib: *Haemophilus influenzae* type b; IM, intramuscular; P, pertussis (w, whole cell; a, acellular); SC, subcutaneous; T, tetanus.

Merck, Sharpe and Dohme (MSD) manufactures two hepatitis B–containing vaccines: Recombivax (Recombinant Hepatitis B), and Comvax (Hib Conjugate [meningococcal protein conjugate] and HepB [recombinant]). Recombivax has three presentations: pediatric single dose; adult single dose; and dialysis single dose. Comvax has one pediatric dose presentation. For both vaccines, administration is intramuscular and shelf life is 36 months at 2°–8°C. These vaccines are not prequalified by the WHO.

[a]For purchase by UNICEF and other United Nations Agencies.

[b]As of August 25, 2015. For updates, see www.who.int/immunization_standards/vaccine_quality/PQ_vaccine_list_en/en/.

[c]Shelf life is from the current licensing information for these vaccines.

contain 2.5 to 40 µg of HBsAg protein and an aluminum phosphate or aluminum hydroxide adjuvant[468]: 0.25 mg in pediatric-dosed vaccines, and 0.5 mg in adult-dosed vaccines. A new recombinant hepatitis B vaccine that is intended for adult patients with renal insufficiency uses alum and lipid A as adjuvants.[469] Since 1999, hepatitis B vaccines available in the United States for use in infants and children have not contained thimerosal as a preservative because of ill-founded concerns about possible neurodevelopmental effects of mercury.[470] However, there is no evidence of any harmful effects from the small amounts of thimerosal in hepatitis B vaccine.[471] Thimerosal continues to be used as a preservative in hepatitis B vaccines available in many countries and is particularly important in preventing bacterial contamination in multidose vials.

Recombinant DNA Vaccines

Most licensed recombinant DNA hepatitis B vaccines consist of a 226-amino-acid *S* gene product (HBsAg protein).[465] The yeast-produced vaccines, which are the most widely used, are manufactured by expression of HBsAg protein in genetically engineered yeast cells *(Saccharomyces cerevisiae)* that contain the *S* gene.[472] The expression plasmid generally contains only the 3′ portion of the *S* gene, and only the major HBsAg protein, without pre-S epitopes, is produced. As a result of biochemical and biophysical purification, there is no detectible yeast DNA and only trace amounts of yeast proteins (1–5%) in the final vaccine products.[473] Mammalian cell–derived vaccines (e.g., continuous mammalian cell line, like the mouse c127 clonal cell line) containing glycosylated pre-S1 and pre-S2 proteins, in addition to the major HBsAg protein, have also been produced in France, Germany, and Israel and are licensed in Israel, Hong Kong, India, the Philippines, and Vietnam.[35,474] Evidence exists that vaccines containing the pre-S1 and pre-S2 proteins induce a faster and higher anti-HBs response as compared to yeast derived S containing vaccines and might be effective in persons who have genetic nonresponse to the major HBsAg protein. However, the high cost of production for vaccines with pre-S1 and pre-S2 antigens limits their use and availability.[475–477]

In the production of recombinant DNA hepatitis B vaccines, working seeds are derived from a master seed of the transformed yeast. Whenever a lot of vaccine is needed, yeast from the working seed is used to start the fermentation in large vessels. The HBsAg is then purified to eliminate yeast components by various physical separation techniques, including chromatography and filtration. The expressed HBsAg polypeptide self-assembles into immunogenic spherical particles closely resembling the natural 22-nm particles found in the serum of persons with chronic HBV infection. The *a* determinant that is responsible for the most important immune response is exposed on the surface of the artificial HBsAg particle, as it is on the natural particle. The artificial particles differ from natural particles only in the glycosylation of HBsAg. In contrast to the production of yeast derived nonglycosylated small envelope antigen, mammalian cells transfected with the genes coding for two to three of the HBV envelope proteins secrete the glycosylated viral surface antigens particles into the growth medium from which they are purified by physical means.

Combination Vaccines

Several vaccine manufacturers have produced combination vaccines containing a hepatitis B vaccine component. These combination vaccines include diphtheria and tetanus toxoids and whole-cell pertussis (DTwP)–hepatitis B vaccine; DTwP-*Haemophilus influenzae* type b conjugate (Hib)–hepatitis B vaccine; diphtheria and tetanus toxoids and acellular pertussis (DTaP)–hepatitis B vaccine; DTaP–Hib–inactivated poliovirus vaccine (IPV)–hepatitis B vaccine; DTaP–IPV–hepatitis B vaccine; Hib–hepatitis B vaccine; and hepatitis A–hepatitis B vaccine. For each of these combination vaccines, the manufacturer has shown that the components remain sufficiently immunogenic to elicit protective levels of anti-HBs.[478–481]

However, a hexavalent (DTaP-IPV-Hib- hepatitis B) vaccine, licensed in Europe in 2000, was suspended from the market in 2005 because of concerns over its ability to provide long-term protection against hepatitis B. Until suspension, approximately 10 million doses were distributed worldwide, including almost 90% of the doses in Germany, Austria, and Italy. Studies

carried out 5 years after priming showed that most vaccinees that lost protective concentrations (≥10 mIU/mL) of anti-HBs had a strong anamnestic response when boosted with a single dose of monovalent hepatitis B vaccine.[482,483]

Follow-up studies carried out in teenagers primed as infants with such hexavalent vaccines are currently in progress to assess whether booster is needed to maintain long-term protection during adolescence and adulthood when risk of acquiring HBV does increase significantly.

Providers should not attempt to make extemporaneous mixtures of vaccines in the same syringe at the point of use because the results are unpredictable unless verified by the manufacturer and national disease-control authorities. Diphtheria-tetanus-pertussis (DTP)-containing hepatitis B combination vaccines from several manufacturers are increasingly used worldwide in universal immunization programs. When immunizing against HBV at birth, only monovalent hepatitis B vaccines should be used.

Stability of Vaccine

The recommended storage temperature for hepatitis B vaccine is between 2°C and 8°C. The vaccine is generally stable for 3 to 4 years from the date of manufacture if stored in this temperature range. However, the stability of hepatitis B vaccines from different manufacturers might vary considerably. Therefore, the package insert for each vaccine should be consulted for the manufacturer's recommended shelf life.

Most hepatitis B vaccines are relatively heat stable and have only a small loss of potency when stored at 20°C to 26°C for up to 1 year, at 37°C for 2 to 6 months, and at 45°C for 1 week.[484,485] No significant differences were found in seroconversion rates and levels of protective antibody between infants who received a first dose that had been stored in the cold chain and those who received a first dose stored for up to 1 month at tropical temperatures.[486] The excellent heat stability of hepatitis B vaccine allows the vaccine to be administered at birth to prevent perinatal HBV transmission during home deliveries where refrigeration is not available. In demonstration projects, use of hepatitis B vaccine in prefilled, single-use injection devices (e.g., Uniject) outside the cold chain has been reported to simplify logistics, minimize vaccine wastage, and facilitate the speed and efficiency of immunization at birth during home visits.[486,487] The outside-the-cold-chain use of hepatitis B vaccines could greatly enhance hepatitis B vaccine delivery in outreach services.[488–491]

Hepatitis B vaccine and combination vaccines that contain hepatitis B vaccine must not be frozen. The freezing of hepatitis B vaccine causes the HBsAg protein to dissociate from the alum adjuvant and thus to lose its immunogenicity/potency.[468,492,493] The freezing point of hepatitis B vaccine is approximately −0.5°C.[494]

Dosage and Route of Administration

The quantity of HBsAg protein per dose that induces a protective immune response in infants and children varies by manufacturer (range: 2.5 to 10 µg) and by composition of the envelope protein(s), and is partially related to the vaccine production processes. In general, the vaccine dosage for infants and adolescents is 50% lower than that required for adults. There is no international standard of vaccine potency expressed in micrograms of HBsAg protein, and the relative efficacy of different vaccines cannot be assessed only on the basis of differences in HBsAg content.[495]

Given the differences in the manufacturing processes, the quantity of HBsAg protein per dose that will induce a protective immune response differs among the various vaccine products depending on the recipient's age. Vaccines produced by each manufacturer have been evaluated in clinical trials to determine the age-specific dosage that achieves the maximal seroprotection rate. Persons who respond to hepatitis B vaccine (complete and correct schedule) with concentrations of anti-HBs of 10 mIU/mL or greater are protected against acute hepatitis B and chronic infection. The standard pediatric volume of administration is 0.5 mL. With lower volumes, a dose might be administered that is inadequate to produce the required immune response using standard hubbed syringes. Internationally marketed hepatitis B vaccines are considered immunologically comparable and can be used interchangeably.[496]

Hepatitis B vaccine should be administered by intramuscular injection in the anterolateral aspect of the thigh of infants and children younger than 24 months old, and in the deltoid muscle of older children, adolescents, and adults. Administration in the buttock is not recommended because of an association with decreased protective antibody levels in some studies, probably because of inadvertent subcutaneous injection or injection into deep fat tissue.[497] If hepatitis B vaccine is administered on the same day as another injectable vaccine, it is preferable to give the two vaccines in different limbs. If more than one injection must be administered in the same limb, the thigh is the preferred site of injection because of the greater muscle mass; the injection sites should be 1 to 2 inches (2.5 to 5.0 cm) apart so that any local reactions are unlikely to overlap.[460]

Although low dosages of hepatitis B vaccine administered intradermally have been shown to reduce costs of adult vaccination and to partially bypass low response,[498] this route of administration is technically difficult and currently not recommended because seroconversion rates among adults and children have been inconsistent.[499,500] This may change with the use of more standardized intradermal devices.[501–503] Data on the long-term protection afforded by the intradermal route are still limited.

No clinically significant increase in adverse reactions or interference in antibody responses has been observed when hepatitis B vaccine has been administered simultaneously with, but at a different site from, other childhood or adult vaccines.[460,478,479,504–511] Hepatitis B vaccine can be administered at the same time as other vaccines (e.g., DTP-containing, oral poliovirus [OPV], IPV, hepatitis A, Hib, measles, bacille Calmette-Guérin [BCG], and yellow fever vaccines). Hepatitis B vaccines do not interfere with the immune response to any other vaccine, and vice versa.[460] Thus, the birth dose of hepatitis B vaccine can be administered at the same time as the BCG vaccine, preferably within 24 hours of birth.[512]

Available immunogenicity data from "off-schedule" vaccination suggest that if the series is interrupted after the first dose, the second dose should be administered as soon as possible, and the second and third doses should be separated by an interval of at least 2 months; if only the third dose is delayed, it should be administered as soon as possible.[513–516] In any age group, interruption of the vaccination schedule does not require restarting the vaccine series.[517,518]

RESULTS OF VACCINATION

Vaccine Immunogenicity and Schedules

Historically, the standard three-dose hepatitis B vaccine series has consisted of two priming doses administered 1 month apart and a third dose administered 6 months after the first dose. Multiple schedules have been used successfully: at birth and at 1 and 6 months of age; at 2, 4, and 6 months of age; at 3, 5, and 11 months of age; at 8, 12, and 16 weeks and 12 or 15 months of age; and at 6, 10, and 14 weeks of age (in the WHO's Expanded Programme on Immunization [EPI]

TABLE 25.4 World Health Organization's Recommended Options for Adding Hepatitis B Vaccine to Childhood Immunization Schedules

BCG, bacille Calmette-Guérin; DPT, diphtheria-pertussis-tetanus; DTP, diphtheria-tetanus-pertussis; OPV, oral poliovirus.
[a]Option 1 is recommended in countries that are not yet targeting prevention of perinatal hepatitis B virus (HBV) transmission; options II and III are recommended in countries that are targeting prevention of perinatal HBV transmission.
[b]Only given in countries where polio is highly endemic.
[c]To prevent perinatal HBV transmission, the birth dose should be given as close as possible to the time of delivery, preferably within 12 hours.
[d]Monovalent vaccine.
[e]Monovalent or combination vaccine.

schedule) (Table 25.4).[519–525] Increasing the interval between the first and second dose of hepatitis B vaccine has little effect on immunogenicity or final antibody concentration.[517,526] Longer intervals between the last two doses result in higher final antibody concentrations but not seroconversion rates.[527] Postvaccination testing is recommended for certain persons whose subsequent clinical management depends on knowledge of their immune status, including some healthcare and public safety workers; chronic hemodialysis patients, HIV-infected persons, and other immunocompromised persons; and sex or needle-sharing partners of HBsAg-positive persons. An anti-HBs concentration of 10 mIU/mL or more measured 1 to 3 months after administration of the last dose of the primary vaccination series is considered a reliable marker of protection against infection.

Revaccination of Nonresponders

Of persons who did not respond to a primary three-dose vaccine series with anti-HBs concentrations of 10 mIU/mL or greater, 25% to 50% responded to an additional vaccine dose, and 44% to more than 70% reportedly responded to a three-dose revaccination series[528–534] or to a regimen with two vaccines (offered each in one deltoid region at the same visit) followed by the same regimen 2 months later. Better response to revaccination occurs in persons who have measurable but low (<10 mIU/mL) levels of antibody after the initial series.[528,529,532] One study identified no difference in response to revaccination in persons receiving double the standard vaccine dose.[530] Persons who do not have protective levels of anti-HBs 1 to 2 months after revaccination either are primary nonresponders or are infected with HBV. Many factors are related to HBV vaccination nonresponse, including age older than age 40 years, male gender, obesity, smoking, chronic kidney/liver diseases, HIV infection, genetic factors, impaired vaccine storage conditions, and administration of the vaccine in buttocks.[529,535–537] Recently several third-generation vaccines containing pre-S/S antigens were shown to induce an adequate anti-HBs response in the majority of primary nonresponders.[538]

Infants and Children

A variety of hepatitis B vaccine schedules have been shown to induce levels of seroprotection of greater than 95% in infants (see "Vaccine Immunogenicity and Schedules" earlier). Programmatically, there is an advantage to administering the three doses of hepatitis B vaccine at the same time as the three doses of other childhood vaccines (e.g., DTP, Hib, IPV), and these schedules will accommodate use of DTP-, IPV-, and Hib-containing combination vaccines. A hepatitis B vaccine schedule administered with DTP or Hib vaccine will prevent infections acquired during childhood as well as infections acquired later in life. However, these schedules will not prevent perinatal HBV infections because they do not include a birth dose. Therefore, concern has been expressed that increased use of combination vaccines might jeopardize perinatal hepatitis B prevention programs.[539] To prevent perinatal HBV transmission in settings where combination vaccines are used, a four-dose hepatitis B vaccination schedule is needed, with the first dose administered at birth. High titers of maternal antibodies do not interfere with neonatal immune response to vaccination.[540] Use of four-dose hepatitis B vaccine schedules, including schedules with a birth dose, has not increased vaccine reactogenicity.[542]

Certain premature infants whose birthweight was less than 2000 g might have decreased seroconversion rates after administration of hepatitis B vaccine at birth.[543] However, by age 1 month, all premature infants, regardless of initial birthweight or gestational age, have a response to vaccination that is comparable to that of full-term infants.[544–547]

WHO recommends multiple options for adding hepatitis B vaccine to existing infant immunization schedules without requiring additional visits for immunization (see Table 25.4).[468] Schedules should optimize the percentage of children completing the hepatitis B vaccine series, which can be achieved with earlier administration of vaccine.[525] The WHO-recommended minimal interval between doses one and two is 4 weeks, and the minimum interval between doses two and three is 4 weeks. Schedules with these minimal intervals (e.g., 6, 10, and 14 weeks) have seroconversion rates similar to schedules with longer intervals, albeit with lower final anti-HBs concentrations. The WHO minimal recommended intervals for infant hepatitis B vaccination are shorter than those recommended in the United States. Although data are limited regarding long-term protection for schedules with shorter intervals, alternative schedules are often not feasible. In addition, concerns about long-term protection are of less practical significance in countries of high endemicity where most HBV infections are acquired in childhood.

Adolescents

Hepatitis B vaccine schedules that have been demonstrated to induce seroprotection rates of greater than 95% in adolescents include doses administered at 0, 1, and 6 months; 0, 2, and

4 months; and 0, 12, and 24 months.[514,526,548–550] In addition, for adolescents 11 to 15 years of age, the adult dose of hepatitis B vaccine can be used for administration at 0 and at 4 to 6 months.[551,552] This two-dose schedule produces anti-HBs concentrations equivalent to those obtained with the pediatric dose administered on a three-dose schedule. After 10 years of follow-up in the Czech Republic, 85.9% of the adolescents (12 to 15 years old) vaccinated with the two-dose schedule had anti-HBs levels of 10 mIU/mL or higher, as did 85.1% of those who received three pediatric doses.[553] However, the adolescents who were vaccinated with the two-dose schedule had slightly lower geometric mean concentration 10 years after receiving the doses. In Belgium, a 5-year follow-up showed fewer adolescents (11 to 15 years old) had anti-HBs levels of 10 mIU/mL or higher if vaccinated via the two-dose schedule (79.5% vs 91.4%, vaccinated with three doses), but after a challenge dose, all subjects mounted a rapid anamnestic response, indicating immune memory.[554]

Adults

Hepatitis B vaccine induces a protective antibody response in approximately 30% to 55% of healthy adults younger than 40 years of age after the first dose, in 75% after the second dose, and in more than 90% after the third dose.[34,555] In adults older than 40 years of age, response rates decline with age, and by age 60 years, protective levels of antibody develop in only 75% of vaccinated persons.[488] Because an increased risk for HBV infection is an indication for hepatitis B vaccination and relatively high rates of seroprotection are achieved after each dose, vaccination should be initiated even if completion of the three-dose series cannot be ensured.

Host factors in addition to age that contribute to decreased vaccine response include smoking, obesity, HIV infection, genetic factors, and the presence of a chronic disease (e.g., diabetes, non-HBV chronic liver diseases, hemodialysis patients).[497,537,556–564]

Immunocompromised persons (e.g., HIV-infected persons, hematopoietic stem cell transplant recipients, and patients undergoing immunotherapy and or chemotherapy) have a suboptimal response to standard doses of hepatitis B vaccine.[557,565–568] Modified dosing regimens, including doubling of the standard antigen dose or administration of additional doses, might increase response rates. Immunization of bone marrow and stem cell donors against HBV induces anti-HBs seroconversion in recipients through adoptive transfer of immunity.[569] However, few data on the long-term protection with these alternative vaccination schedules and modified regimens are available.

Correlates of Protection

Anti-HBs is the only easily measurable correlate of vaccine-induced protection using serologic assays. An anti-HBs concentration of 10 mIU/mL or more measured 1 to 3 months after administration of the last dose of the primary vaccination series is considered a reliable marker of protection against infection: in vaccine efficacy studies, immunocompetent persons who developed anti-HBs concentrations of 10 mIU/mL or higher after vaccination had virtually complete protection against both acute disease and chronic infection for decades, even if subsequently, over time, anti-HBs concentrations declined to less than 10 mIU/mL. Indeed, the protective efficacy of hepatitis B vaccination is related to the induction of anti-HBs antibodies, but it also involves the induction of memory B and T cells.[570]

Therefore, vaccine-induced protection against HBV infection is defined as having an anti-HBs level of 10 mIU/mL or higher, measured 1 to 3 months after receipt of a complete and adequately administered vaccination course.[324,326,493,571–575] Yet, HBsAg vaccine-induced immunity protects against future infection but does not provide sterilizing immunity, as evidenced by HBcAg-specific and polymerase-specific CD8(+) T cells in vaccinated healthcare workers with occupational exposure to HBV.[576]

In immunocompromised patients who have ongoing exposure to HBV, annual anti-HBs testing is recommended, and booster doses are required to maintain anti-HBs concentrations of 10 mIU/mL or higher.[265]

Efficacy

Preexposure Vaccine Efficacy

Hepatitis B vaccine elicits development of antibody response to the *a* determinant, located in the surface antigen of HBV.[577] Anti-HBs is the serologic marker of vaccine-induced protection. The efficacy of preexposure hepatitis B vaccination has been demonstrated in randomized, double-blind, placebo-controlled clinical trials involving high-risk groups such as MSM, healthcare workers, hemodialysis staff members, and hemodialysis patients.[324,493,571,575,578–581] These studies demonstrated an overall efficacy of 80% to 100% (Table 25.5) and virtually complete protection against acute and CHB infection among persons who developed anti-HBs concentrations of 10 mIU/mL or greater, even if subsequently, over time, anti-HBs concentrations declined to less than 10 mIU/mL.

Postexposure Vaccine Efficacy

Among infants born to HBeAg-positive mothers, postexposure immunoprophylaxis with either plasma-derived or recombinant vaccine and HBIG is 85% to 95% effective in preventing chronic HBV infection (Table 25.6).[285–287,458,582–593]

In randomized, placebo-controlled clinical trials, administration of hepatitis B vaccine in a three- or four-dose schedule without HBIG, beginning less than 12 hours after birth, also prevents 70% to 95% of perinatal HBV infections among infants born to women who are positive for both HBsAg and HBeAg.[582,584,588,591,594] Population-based studies in areas with a high endemicity of HBV infection have demonstrated that active postexposure vaccination is highly effective in preventing infection when the first dose is administered soon after birth, the second at age 1 to 2 months, and the third at age 6 to 8 months (see Table 25.6).[595–597] These findings support the use of hepatitis B vaccine alone, particularly in countries where pregnant women are not screened for HBsAg and hepatitis B vaccine is routinely administered to all infants at birth.

Duration of Protection and Need for Booster Doses

After primary immunization with hepatitis B vaccine, anti-HBs concentrations decline rapidly within the first year and more slowly thereafter. Among children who respond to a primary three-dose vaccination series with anti-HBs concentrations of 10 mIU/mL or greater, 15% to 50% have low or undetectable concentrations of anti-HBs 5 to 15 years after vaccination.[598–605]

Among adult vaccinees, anti-HBs concentrations decline to less than 10 mIU/mL in 7% to 50% within 5 years after vaccination, and in 30% to 60% within 9 to 11 years after vaccination.[606–610]

The persistence of anti-HBs over time is correlated with the peak level of anti-HBs immediately achieved after primary immunization.[611] In other words, the higher the vaccine-induced concentration after the primary vaccination course, the longer the antibodies will persist. However, observational

studies have shown that a primary series of hepatitis B vaccine can prevent infection for more than 25 years, despite decrease or loss of vaccine-induced anti-HBs over time.[612–633]

A recent follow-up and response to a hepatitis B vaccine challenge study in Alaska confirms earlier observation of long-term protection, showing evidence of protection (anti-HBs >10 IU/L or response to challenge dose) in 94% of persons, and no chronic infections 30 years after vaccine administration.[633] This is similar to other long-term cohort studies in other parts of the world carried out through 20 to 25 years of follow up.[630,631] Indeed, in immunocompetent individuals, the specific immunity to HBsAg outlasts the presence of

vaccine-induced antibodies, conferring effective long-term protection against acute disease and development of HBsAg carriage, even in those showing waning or disappearance of anti-HBs.[634–638] Thus, a negative anti-HBs result does not necessarily indicate lack of immunity in vaccinated persons—it is immune memory that matters.[639] The mechanism for continued vaccine-induced protection is thought to be preservation of immune memory through selective expansion and differentiation of clones of antigen-specific B and T lymphocytes.[634,635]

To illustrate the prolonged duration of protection against hepatitis B, even after disappearance of antibodies, an anamnestic response was measured shortly after offering a challenge dose (the so-called boostability) in cohorts of vaccinees up to 30 years after primary vaccination (Table 25.7).[620,621,623,640–649]

Anamnestic responses have been demonstrated in 62% to more than 80% of subjects vaccinated 15 to 30 years earlier, which indicates that a high proportion of vaccine recipients retain immune memory and would develop an anti-HBs response on exposure to HBV.[633]

Recently, increasing evidence suggests that the immune memory may begin to wane after the second decade of vaccination, but this does not seem to imply increased susceptibility to clinically significant HBV disease, as no acute or chronic HBV cases were reported in any of the ongoing follow-up studies.[616,619,640,647,648] Thus absence of an anamnestic response after such booster vaccination may not necessarily mean that individuals are susceptible to HBV infection.[620,639] Further research is needed in this field.

Some long-term studies have documented breakthrough infections, illustrated by the seroconversion to anti-HBc, but virtually no clinically significant infections (acute diseases or carriage) were reported (Table 25.8).[607,622,623,642,644,648,650–654] From a public health point of view, prevention of carriage

remains of utmost importance: in a 20-year evaluation of the hepatitis B universal immunization program in The Gambia, Viviani and coworkers showed a vaccine efficacy of 67% against development of anti-HBc, and 97% against HBsAg carriage.[655] In a more recent evaluation of the infant vaccination program in The Gambia a 94% vaccine effectiveness was observed in fully vaccinated infants. Many of these fully vaccinated individuals had at some time been infected and experienced a nonsignificant breakthrough infection (anti-HBc positivity of 27%); chronic active hepatitis was not common and probably a consequence of perinatal infection from the mother. The study concluded full infant HBV vaccination does protect strongly against chronic HBV infection, but less strongly against ever having HBV infection.[656] Persons who have received only one or two doses of vaccine can also have detectable anti-HBs. However, long-term protection has been demonstrated only for immunocompetent persons who have completed a licensed vaccination series and have ever had an anti-HBs concentration of 10 mIU/mL or greater.[639]

On the basis of currently available scientific evidence, the WHO as well as advisory groups in the United States and Europe do not recommend routine booster doses of hepatitis B vaccine or periodic serologic testing to monitor anti-HBs concentrations for immunocompetent persons who have responded to vaccination or in universal immunization programs.[265,617,657]

For the next decade, additional data are needed regarding the potential need for boosters and the duration of protection against infection and disease after hepatitis B vaccination, including information on the potential role of natural subclinical boosting.

Vaccine-Associated Adverse Events

Adverse events after immunization against hepatitis B are infrequent and generally mild. Except for localized pain, placebo-controlled studies reveal that reported events (e.g., myalgia and transient fever) occur no more frequently among vaccinees than among persons receiving placebo (<10% among children, 30% among adults).[658] Data from numerous long-term studies fail to causally link serious adverse events to hepatitis B vaccination.[659] Reports of severe anaphylactic reactions are very rare, and data do not indicate a causal association between hepatitis B vaccine and Guillain-Barré

syndrome or demyelinating disorders, including multiple sclerosis. However, hepatitis B vaccine has been the subject of greatest concern regarding multiple sclerosis in France. In 1998, French media revealed possible occurrence of post–hepatitis B immunization multiple sclerosis. That same year the French health authorities abruptly ended routine school-based vaccination of adolescents, while adult vaccination began to be less widespread. Several epidemiological studies have been conducted to evaluate the association between hepatitis B vaccination and multiple sclerosis, and found no link. A recent nested case-control study using data from an U.S. Health Maintenance Organization (2008–2011) showed no longer-term association between hepatitis B vaccination and the risk of multiple sclerosis or other acquired central nervous system demyelinating syndromes, which argues against a causal association.[660] Furthermore, no epidemiologic data support a causal association between hepatitis B vaccination and chronic fatigue syndrome, arthritis, autoimmune disorders, asthma, sudden infant death syndrome, alopecia, or diabetes.[661–664] The WHO's Global Advisory Committee on Vaccine Safety as well as the recent report of the Institute of Medicine confirm the excellent safety profile of hepatitis B vaccine and continue to monitor the safety of this vaccine.[665]

Indications and Goals for Hepatitis B Vaccination

Global recommendations for HBV prevention and control are set by the WHO on behalf of its 194 member states and in consultation with the Strategic Advisory Group of Experts on Immunization. In 2009, the WHO issued a position paper updating its guidance for global hepatitis B prevention through immunization.[666] The following year, member states adopted Resolution WHA63.18,[667] which designated July 28 as World Hepatitis Day and called for comprehensive prevention and control of HBV infection and development of time-specific immunization goals. The WHO's strategy for hepatitis B immunization includes the following:

- Universal vaccination of infants within 24 hours of birth
- Full immunization of infants by routine immunization programs
- Catch-up vaccination of unimmunized cohorts
- Monitoring progress
- Assessing the impact of immunization.

RECOMMENDATIONS FOR HEPATITIS B VACCINATION

Vaccination of Infants at Birth

Because perinatal and early postnatal transmission are primary causes of chronic infections globally, the first dose of hepatitis B vaccine should be given as soon as possible (<24 hours) after birth, regardless of whether a country has low, intermediate, or high HBV endemicity.[666]

Ensuring that all infants receive a dose of hepatitis B vaccine within 24 hours of birth (i.e., a "birth dose" of vaccine) requires implementation of specific programmatic measures. Increasing the number of infants born in facilities or attended by trained health staff would improve birth-dose coverage. Coordination between immunization services and maternal and child health services is important for ensuring that vaccine is available at the place of delivery or immediately after birth. Expanding vaccine management systems and innovative outreach to provide vaccine for home births[490] will ensure that hepatitis B vaccine is available wherever births take place. Efforts to develop new heat-stable and freeze-stable hepatitis B vaccines will aid these attempts. In addition, health promotion efforts aimed at parents and training aimed at providers are needed to increase awareness about the importance of administering hepatitis B vaccine within 24 hours of birth.[489]

Some countries augment universal vaccination of newborns with maternal screening for HBsAg and the administration of HBIG and a dose of hepatitis B vaccine to infants born to HBsAg-positive mothers. For example, in the United States, timing of administering the birth dose of hepatitis B vaccine varies according to the HBsAg status of the mother (Box 25.1),

BOX 25.1 U.S. Hepatitis B Vaccination Recommendations for Infants, Children, and Adolescents: Summary

MATERNAL HEPATITIS B SURFACE ANTIGEN (HBsAg) TESTING

- All pregnant women should be tested routinely for HBsAg

VACCINATION OF INFANTS

At Birth

- Infants born to mothers who are HBsAg-positive should receive hepatitis B vaccine and 0.5 mL of hepatitis B immunoglobulin (HBIG) within 12 hours of birth, administered at different injection sites. The schedule should be completed as recommended for all infants (see "After the Birth Dose," below).
- Infants born to mothers whose HBsAg status is unknown should receive hepatitis B vaccine within 12 hours of birth. The mother should have blood drawn as soon as possible to determine her HBsAg status; if she is HBsAg-positive, the infant should receive 0.5 mL of HBIG as soon as possible but no later than age 7 days, and the vaccine series should be completed according to a schedule for infants born to HBsAg-positive mothers.
- Infants born to mothers who are HBsAg-negative should receive single-antigen hepatitis B vaccine before hospital discharge.

After the Birth Dose

- All infants should receive at least three doses of hepatitis B vaccine (either single-antigen vaccine or combination vaccine).
- For infants who weigh less than 2000 g at birth, the vaccination schedule varies with the HBsAg status of the mother. Those born to HBsAg-negative mothers should receive the first dose of vaccine 1 month after birth or at hospital discharge. For those born to HBsAg-positive mothers or to mothers with unknown status, the birth dose should not be counted as part of the vaccine series; three additional doses of vaccine (for a total of four doses) should be administered beginning at age 1 month.
- For all infants, the final dose in the vaccine series should not be administered before age 24 weeks (164 days). If the hepatitis B vaccine series is interrupted, the second and third doses should be separated by an interval of at least 8 weeks.
- Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg after completion of the hepatitis B vaccine series at age 9 to 18 months.

VACCINATION OF CHILDREN AND ADOLESCENTS

- All unvaccinated children and adolescents younger than 19 years old should receive the hepatitis B vaccine series.

and it is recommended that all pregnant women be tested routinely for HBsAg during a prenatal visit; testing should be repeated for pregnant women with ongoing risk behaviors and those with clinical signs of hepatitis.

The timely delivery of a birth dose of hepatitis B vaccine should be a performance measure for all immunization programs. To better monitor the delivery of this dose of hepatitis B vaccine and facilitate performance assessment, the birth dose should be differentiated from the two or three additional doses administered later in infancy. Full immunization performance will continue to be measured by coverage of three or four total doses.

Full Immunization of Infants by Routine Immunization Programs

To complete the primary hepatitis B vaccine series, the birth dose should be followed by two or three additional doses of vaccine administered at least 4 weeks apart. To help ensure completion of the vaccine series, doses should be given concurrently with DTP or other routine infant vaccinations.

When subsequent doses of hepatitis B vaccine are given in combination with other antigens (often referred to as Combo 1, Combo 2, and Combo 3 doses), the Combo 3 dose should contain the fourth dose of hepatitis B vaccine.

For infants who weigh less than 2000 g, the birth dose should be followed by three additional doses of vaccine administered according to the national vaccination schedule.

Administration of booster doses of hepatitis B vaccine is not warranted in routine immunization programs. Some infants born prematurely with low birthweight (<2000 g) may not respond well to vaccination at birth. However, by 1 month of chronological age, premature infants, regardless of their initial weight or gestational age at birth, are likely to respond adequately.[666,669]

For older children and adults, the primary series of three doses with appropriate intervals applies.

Catch-Up Vaccination of Unvaccinated Cohorts

Catch-up vaccination should be considered for cohorts of children with low rates of vaccination coverage. The need for catch-up vaccination in older age groups, including adolescents and adults, should be determined by the baseline epidemiology of HBV infection in the country. Vaccination efforts can be targeted toward age-specific cohorts and persons with particular risk factors for acquiring HBV infection.

In countries with intermediate or low endemicity, substantial disease burden may result from acute and chronic infection acquired by older children, adolescents, and adults born before implementation of universal vaccination recommendations. In these countries, implementation of routine infant immunization will produce broad population-based immunity to HBV infection over time, eventually preventing transmission among all age groups. However, catch-up strategies targeted at unvaccinated people in older age groups can hasten the development of population-based immunity and decrease the incidence of acute hepatitis B. Catch-up immunization typically involves age-specific cohorts (e.g., young adolescents) and populations at risk for HBV infection, such as health workers,[670] travelers to areas where HBV-infection is prevalent,[671] IDUs, MSM, and people with multiple sex partners.

Surveillance for and seroprevalence studies of HBV infection can help countries determine the populations at highest risk for acquiring infection, leading to more informed prevention efforts. In the United States, the Advisory Committee on Immunization Practices (ACIP) recommends immunization for persons at risk for HBV infection resulting from sexual, percutaneous, or mucosal exposures; travelers to areas with high or intermediate levels of endemic HBV infection; persons with certain medical conditions; and all persons seeking protection from HBV infection. In 2011, ACIP, after reviewing data regarding the risk of HBV transmission from contaminated glucose-monitoring devices and the role of immunization in infection control for this population, recommended hepatitis B vaccination for unvaccinated adults with diabetes (Box 25.2).[672]

Vaccination of Immunocompromised Persons

Immunosuppressive illnesses, including advanced HIV infection, chronic renal failure, chronic liver disease, and celiac disease, are associated with reduced immunogenicity after administration of hepatitis B vaccine. In people who are HIV-positive, several factors (e.g., viral load, $CD4^+$ cell count, sex, age, type and duration of highly active antiretroviral therapy [HAART], and the type of AIDS-defining illness) can affect immunologic response to hepatitis B vaccination. Early vaccination (before the $CD4^+$ count declines to <350 cells/μL) is recommended in HIV-infected patients to ensure adequate protection against hepatitis B infection. In one double-blind, randomized, controlled trial that compared the use of

BOX 25.2 Adults for Whom Hepatitis B Vaccination Is Recommended in the United States

PERSONS AT RISK FOR INFECTION BY SEXUAL EXPOSURE

- Sex partners of hepatitis B surface antigen (HBsAg)-positive persons.
- Sexually active persons who are not in a long-term, mutually monogamous relationship (e.g., persons with more than one sex partner during the previous 6 months).
- Persons seeking evaluation or treatment for a sexually transmitted disease.

PERSONS AT RISK FOR INFECTION BY PERCUTANEOUS OR MUCOSAL EXPOSURE TO BLOOD

- Current or recent injection-drug users.
- Household contacts of HBsAg-positive persons.
- Residents and staff of facilities for developmentally disabled persons.
- Healthcare and public safety workers with reasonably anticipated risk for exposure to blood or blood-contaminated body fluids.
- Persons with end-stage renal disease, including predialysis, hemodialysis, peritoneal dialysis, and home dialysis patients.

OTHERS

- International travelers to regions with high or intermediate levels (HBsAg prevalence of ≥2%) of endemic hepatitis B virus (HBV) infection.
- Persons with chronic liver disease.
- Persons with HIV infection.
- All other persons seeking protection from HBV infection.
- All unvaccinated persons with diabetes who are younger than 60 years of age, and those who are 60 years of age or older at the discretion of the clinician.*

*Recommended by the Advisory Committee on Immunization Practices (ACIP), October 2011.

a standard dose (20 μg) with a double dose (40 μg) of recombinant hepatitis B vaccine in 210 previously unvaccinated HIV-infected patients, a substantially higher seroconversion rate occurred with use of the double dose of vaccine, but only in the subgroup of patients with $CD4^+$ counts greater than 350 cells/μL.[673,674] Despite these data, vaccination should not be deferred for those with negative or indeterminate serologies while awaiting a rise in $CD4^+$ count to greater than 350 cells/μL.[674] Because some HIV-infected patients with $CD4^+$ counts less than 200 cells/μL *do* respond to vaccination, vaccination should be performed as previously recommended, with testing for anti-HBs done 1 to 2 months after completion of the series.

Patients experiencing chronic renal failure are at particular risk for infection with HBV. In some settings, these patients have been offered schedules containing more than three doses of vaccine, larger doses of vaccine, or both. Two metaanalyses have demonstrated that the three-dose schedule affords protection similar to that of more extensive schedules, although older age was associated with impaired immunologic response.[675] A recombinant hepatitis B vaccine prepared with a novel adjuvant system (aluminum phosphate and 3-*O*-desacyl-4′-monophosphoryl lipid A) is licensed in Europe and intended for patients older than 15 years of age with renal insufficiency. Applied in a four-dose schedule, the vaccine with the novel adjuvant is more reactogenic, but it elicits an earlier, higher, and longer-lasting antibody response than a corresponding series of four double doses of standard hepatitis B vaccine.[676,677]

TABLE 25.9 U.S. Guidelines for Postexposure Immunoprophylaxis of Unvaccinated Persons Who Are Exposed to Blood or Body Fluids That Contain Blood

Cause	Action
DISCRETE EXPOSURE TO AN HBSAG-POSITIVE SOURCE	
Percutaneous (e.g., bite or needlestick) or mucosal exposure to HBsAg-positive blood or body fluids that contain blood	Administer hepatitis B vaccine and HBIG[a]
Sexual or needle-sharing contact of an HBsAg-positive person	Administer hepatitis B vaccine and HBIG[a]
Victim of sexual assault/abuse by a perpetrator who is HBsAg-positive	Administer hepatitis B vaccine and HBIG[a]
DISCRETE EXPOSURE TO A SOURCE WITH UNKNOWN HBSAG STATUS	
Victim of sexual assault/abuse by a perpetrator with unknown HBsAg status	Administer hepatitis B vaccine[a]
Percutaneous (e.g., bite or needlestick) or mucosal exposure to blood or body fluids that contain blood from a source with unknown HBsAg status	Administer hepatitis B vaccine[a]

HBIG, hepatitis B immunoglobulin; HBsAg, hepatitis B surface antigen.
[a]Immunoprophylaxis should be administered as soon as possible, preferably within 24 hours. Studies are limited on the maximal interval after exposure during which postexposure prophylaxis is effective, but the interval is unlikely to exceed 7 days for percutaneous exposures and 14 days for sexual exposures. The hepatitis B vaccine series should be completed.

POSTEXPOSURE PROPHYLAXIS TO PREVENT HEPATITIS B VIRUS INFECTION

Timely administration of hepatitis B vaccination after sexual or percutaneous exposures to HBV can prevent HBV infection. Both passive–active postexposure prophylaxis (PEP) with HBIG and hepatitis B vaccine, and active PEP with hepatitis B vaccine alone have been demonstrated to be highly effective in preventing transmission after exposure to HBV.[678–681] The major determinant of the effectiveness of PEP is early administration of the initial dose of vaccine. The effectiveness of PEP diminishes as the interval between exposure and the initial dose lengthens.[51,682,683] Studies are limited on the maximal interval after exposure during which PEP is effective, but the interval should not exceed 7 days for needlestick[348,349,681] exposures and 14 days for sexual exposures. Recommendations for PEP vary by country; in the United States, ACIP recommends hepatitis B vaccine and HBIG for persons who are exposed to HBV through a discrete, identifiable exposure to blood or body fluids (Table 25.9).

PREVACCINATION AND POSTVACCINATION SEROLOGIC TESTING

Prevaccination Testing for Susceptibility

Globally, prevaccination serologic testing is not recommended as routine practice. However, where laboratory facilities are available and it is considered cost-effective, serologic screening may reduce the number of unnecessary vaccinations of people who are already immune to HBV infection. For example, in the United States, prevaccination testing may be cost-effective in adult populations with an HBV prevalence of greater than 20% (e.g., incarcerated persons).[684] In countries with low endemicity, prevaccination testing can be directed toward persons of all ages born in countries or regions with high or moderate endemicity and children with at least one parent from these areas; household, sex, and needle-sharing contacts of HBsAg-positive persons; MSM; and IDUs.[387,684]

Prevaccination testing also provides an opportunity to refer people with CHB for care and treatment. Because persons with chronic HBV infection serve as the reservoir for new HBV infections, identification of these persons through prevaccination and other testing approaches can complement vaccination strategies for elimination of HBV transmission, allowing primary prevention of ongoing HBV transmission. Regardless of the indication for serologic testing, people found to be infected with HBV should be referred for care and protected from stigmatization and discrimination.

If warranted, prevaccination testing can be done with a single test (anti-HBc) or with a panel of tests (e.g., anti-HBs and HBsAg). When a single test is used, anti-HBc is the test of choice because it identifies all persons with previous HBV infection, including persons with chronic HBV infection. If prevaccination testing for anti-HBs is used to identify immunity after prior HBV infection, HBsAg testing must also be performed to identify persons with chronic HBV infection. In most situations, the first vaccine dose should be administered immediately after collection of the blood sample for serologic testing, unless a provider is certain the patient will return for serologic test results and that vaccination can be initiated at that time if the patient is susceptible.

Postvaccination Testing for Serologic Response

Routine postvaccination testing for immunity also is not necessary, but it is recommended for high-risk persons whose subsequent clinical management depends on knowledge of

their immune status. Populations that should be considered for postvaccination testing include the following:

- Persons at risk for occupationally acquired infection* (i.e., healthcare workers and especially those involved in exposure prone procedures) as well as public safety workers).
- Infants born to HBsAg-positive mothers.
- Chronic hemodialysis patients, persons infected with HIV, and other immunocompromised persons.
- Sex partners or needle-sharing partners of persons who are HBsAg-positive.

When postvaccination testing is indicated, it should be performed 1 to 2 months after administration of the last dose of the vaccine series using a method that allows determination of a protective concentration of anti-HBs (≥10 mIU/mL). Persons found to have anti-HBs concentrations of less than 10 mIU/mL after the primary vaccine series are considered to be nonimmune and should be evaluated further to determine if they are nonresponders. Immunocompetent persons have long-term protection and do not need further periodic testing to assess anti-HBs levels. Immunosuppressed persons might need annual testing to assess anti-HBs concentrations. The European Consensus Group on Hepatitis B Immunity recommends annual testing for immunocompromised persons,[657] and in the United States, such testing is recommended for hemodialysis patients.[684]

REVACCINATION OF THOSE WHO DO NOT SEROCONVERT

Persons at increased risk of hepatitis B found to have anti-HBs concentrations of less than 10 mIU/mL after the primary vaccine series should be revaccinated. Administration of three doses on an appropriate schedule (Table 25.10), followed by anti-HBs testing 1 to 2 months after the third dose, is usually more practical than serologic testing after one or more doses of vaccine (see "Revaccination of Nonresponders" earlier in this chapter). In countries where a pre-S/S vaccine is licensed, immunization with one or two doses of such a vaccine could be considered. Persons who do not respond to revaccination should be tested for HBsAg. If the HBsAg test result is positive, the person should receive appropriate medical management, and any household, sex, or needle-sharing contacts should be identified and vaccinated. Persons who test negative for HBsAg should be considered susceptible to HBV infection and should be counseled about precautions to prevent HBV infection and the need to obtain HBIG PEP for any known or likely mucosal or parenteral exposure to HBsAg-positive blood.

Contraindications

Hepatitis B vaccine is contraindicated only for persons with a history of allergic reactions to yeast or any of the vaccine's components. Neither pregnancy nor lactation is a contraindication for use of this vaccine. Both premature infants and HIV-positive persons can receive this vaccine.

*In the United States, healthcare and public safety workers who have documentation of a complete vaccine series but who have never had postvaccination testing do not need serologic testing for anti-HBs unless they have a percutaneous or mucosal exposure to blood or body fluids.[685] If an exposure to an HBsAg-positive source or a source that is unknown or not available for testing occurs, the exposed person should be tested for anti-HBs and PEP should be administered if the serum anti-HBs concentration is less than 10 mIU/mL.

TABLE 25.10 Hepatitis B Vaccine: U.S. Schedules for Children, Adolescents, and Adults[a]

Age (yr)	Schedule
Children (1–10)	0, 1, and 6 mo[b] 0, 2, and 4 mo[b] 0, 1, 2, and 12 mo[b,c]
Adolescents (11–19)	0, 1, and 6 mo[b] 0, 1, and 4 mo[b] 0, 2, and 4 mo[b] 0, 12, and 24 mo[b] 0 and 4–6 mo[d,e] 0, 1, 2, and 12 mo[b,d]
Adults (≥ 20)	0, 1, and 6 mo[e,f] 0, 1, and 4 mo[e] 0, 2, and 4 mo[e] 0, 1, 2, and 12 mo[d,e]

[a]Children (not vaccinated during the first year of life), adolescents, and adults may be vaccinated according to any of the schedules indicated, except as noted. Selection of a schedule should consider the need to optimize compliance with vaccination.
[b]Pediatric/adolescent formulation.
[c]A four-dose schedule of Engerix-B is licensed for all age groups.
[d]A two-dose schedule of Recombivax-HB adult formulation (10 μg) is licensed for adolescents 11 to 15 years of age. When scheduled to receive the second dose, adolescents older than 15 years of age should be switched to a three-dose series, with doses 2 and 3 consisting of the pediatric formulation administered on an appropriate schedule.
[e]Adult formulation.
[f]Twinrix may be administered to persons 18 years of age and older at 0, 1, and 6 months.

Public Health Considerations and Impact of Worldwide Hepatitis B Vaccination Programs

Elimination of HBV transmission is now an achievable public health goal,[265,686–689] particularly in light of the proven effectiveness and safety of hepatitis B vaccine. Vaccination strategies for preventing HBV are effective, feasible, and well accepted; efforts are underway to ensure universal immunization of all infants as well as populations at highest risk for HBV infection and transmission. Challenges in achieving elimination include the setting of national goals for hepatitis B control; the provision of a birth dose of hepatitis B vaccine to all infants including those born outside of health facilities; the vaccination of all persons at high risk, including those in hard-to-reach and underserved populations; and building and sustaining support for existing hepatitis B immunization policies and programs.

Several epidemiologic and etiologic factors inherent to HBV necessitate the use of immunization strategies that differ from those used for other vaccine-preventable infections. For example, because infants infected with HBV at birth or early childhood are at greatest risk for developing chronic infection, vaccination of infants should optimally begin at birth, preferably within 24 hours.[527] Among infants born to HBsAg-positive mothers, a birth dose of hepatitis B vaccine reduces the risk for perinatal HBV transmission by 72% and by greater than 90% when combined with HBIG.[294,589,666]

Also unique to HBV are the additional populations at risk for infection, including healthcare workers, MSM, IDUs, persons who have multiple sex partners as well as immune suppressed patients with malignant and auto-immune diseases who are prone to HBV infection and reactivation unless protected against HBV prior to initiation of chemo or immunotherapy. Thus, hepatitis B immunization programs tailor efforts according to risk population, educating and reaching

these populations with targeted messages and ensuring that they and their susceptible contacts are vaccinated against HBV.

Hundreds of millions of persons of all ages have been vaccinated over several decades with hepatitis B vaccines, which have proved to be safe and highly effective. No serious adverse events are associated with hepatitis B immunizations,[666] and after completion of a routine three-dose schedule of hepatitis B vaccine, protection is achieved by greater than 95% of vaccine recipients.[666,684] In addition, studies have revealed levels of protection persisting for at least 23 to 30 years after vaccination.[612–633,639–655] Breakthrough infections are infrequent and rarely result in clinically apparent disease. Based on data from recent studies, a booster dose is neither warranted nor recommended for persons who have received routine infant immunization.[690,691]

Routine infant immunization has become a longstanding practice in more than 95% of countries, providing evidence for the effectiveness of hepatitis B immunization in significantly reducing or eliminating HBV transmission.[692] In general, studies conducted in high-HBV-endemicity areas have demonstrated declines in the prevalence of chronic HBV among children to less than 2% after routine infant immunization (Table 25.11).[693]

Countries that were early to adopt and implement universal hepatitis B immunization include Taiwan (1984), Bulgaria (1989), Malaysia (1990), The Gambia (1990), Italy, Spain, the United States (1991), and Israel (1992).[694–696]

Taiwan is perhaps the best example of an area with previously high endemicity showing a substantial decrease in the burden of hepatitis B and HBV-related diseases after the 1984 mass vaccination of newborns. The HBsAg prevalence in individuals younger than 20 years old decreased from 9.8% in 1984 to 1.3% in 1994, and to 0.6% in 2004 (Fig. 25.12).[693,697,698] The annual average incidence of HCC among children between 6 and 14 years of age decreased from 0.7 per 100,000 in 1981 through 1986, to 0.36 per 100,000 in 1990 through 1994.[699] In 2004, the HCC incidence for age groups of 6 to 9, 10 to 14, and 15 to 19 years decreased to 0.15, 0.19, and 0.16 per 100,000 person-years, respectively, clearly indicating the hepatitis B vaccine as the first vaccine against a major human cancer.[700]

HBsAg, hepatitis B surface antigen.
From Chen DS. Hepatitis B vaccination: the key towards elimination and eradication of hepatitis. Br J Hepatol. *2009;50:805–816.*

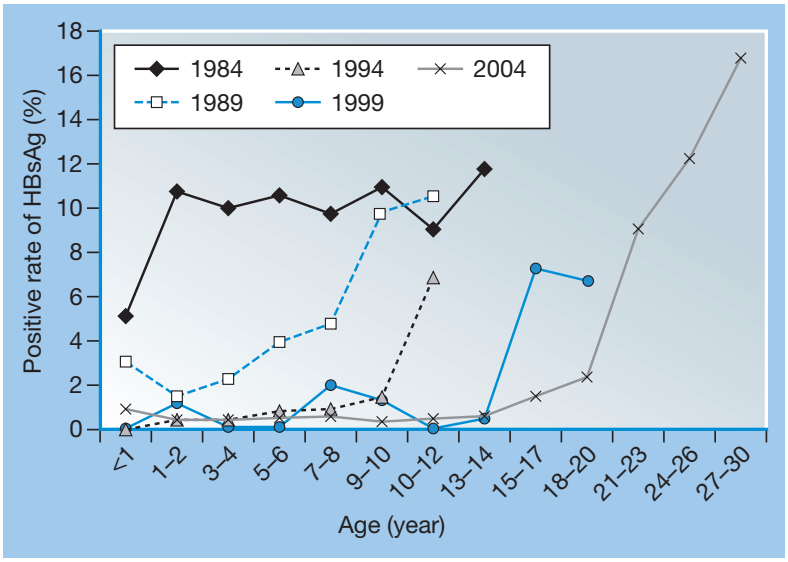

Figure 25.12. Prevalence of hepatitis B surface antigen (HBsAg) in healthy children in Taipei from 1984 to 2004. The mass hepatitis B vaccination started in July 1984. *(From Chen DS. Hepatitis B vaccination: the key toward elimination and eradication of hepatitis.* Br J Hepatol. *2009;50:805–816.)*

Likewise, in The Gambia, since the implementation of the universal infant immunization program in 1984, childhood HBsAg prevalence decreased from 10% to 0.5% in 2003.[522,603,656,701] In Malaysia, after vaccination, HBsAg seroprevalence in children from 7 to 12 years old decreased from 1.6% in 1997 to 0.3% in 2003.[702] Similar results have been achieved in other highly endemic countries, such as in South Africa (see Table 25.11).[703] Since the implementation of universal infant immunization in 1991, data from Hawaii showed a reduction of 97% in the prevalence of HBsAg. Moreover, in Hawaii, the incidence per 100,000 inhabitants of new cases of acute hepatitis B fell from 4.5 in 1990 to zero in 2004.[704] In Bristol Bay, Alaska, universal vaccination of children was introduced in 1981. Since then, a sharp decline in the incidence of acute hepatitis B (next to zero) was observed. Thanks to vaccination, generations of children and young adults are now free of chronic hepatitis infections. Moreover, a general trend toward decreasing incidence of HCC in individuals younger than 30 years of age has been observed.[705] A clear decline in HCC incidence was observed among children, from three cases per 100,000 population (1984 through 1988) to no cases since 1999.[368]

Surveillance data from Italy, where universal vaccination started in 1991 in infants as well as in adolescents, show a clear overall decline in incidence of acute hepatitis B, from 5 per 100,000 in 1990 to 0.9 per 100,000 in 2010. This decline was even more striking in individuals ages 15 and 24 years in whom the morbidity rate per 100,000 inhabitants fell from 17 in 1990 to less than 0.5 in 2010. Moreover, a generation of children and young adults (at present, 32 age cohorts in 2011) is emerging with virtually no markers of HBV infection.[640,706–710]

China, another highly endemic country, has made great strides in reducing HBV prevalence through vaccination. In 1992, national HBsAg prevalence was 9.8%, representing 120 million carriers of HBV and resulting in 300,000 deaths annually.[367] This dire situation prompted the Ministry of Health in China to recommend hepatitis B vaccination for infants. However, despite the 1992 Ministry of Health recommendations, high vaccine costs limited the uptake of recommendations nationally. In 2002, the government committed to covering hepatitis B vaccine–related costs and integrated hepatitis B vaccination into the routine infant immunization schedule, with a priority for administering a birth dose of hepatitis B vaccine to newborns within 24 hours of delivery.[711] According to a national survey, by 2006, HBsAg prevalence had declined to less than 1% among children 1 to 4 years of age.[367,712–714]

In studies conducted in Taiwan, rates of HCC among cohorts of children born after implementation of routine infant immunization in the mid-1980s declined by more than 50%.[699,715] Based on an evaluation of the hepatitis B vaccination program in China, during 1992 to 2009, hepatitis B vaccination prevented an estimated 24 million chronic HBV infections and 4.3 million future deaths from cirrhosis, HCC, and acute hepatitis.[712] In comparison, rates of HCC in older age groups and rates of other childhood cancers remained stable or increased during this period. These studies provide assurance that routine infant hepatitis B immunization is a well-conceived public health strategy that will benefit generations to come.[716]

The benefits of routine infant hepatitis B immunization have a ripple effect, extending far beyond protecting those who receive vaccine. Because infants and children tend to have high viral loads, they play a significant role in the transmission of HBV; vaccinating infants against HBV limits opportunities for horizontal transmission to susceptible household and community contacts. In addition, as cohorts of immunized children get older, vaccination programs that target newborns and infants have a substantial impact on prevalence rates in older populations. For example, in a study of university students in Taiwan, HBsAg prevalence dropped from 14.3% to 1.1% during 1995 to 2009 as a result of routine infant vaccination in that country.[717]

Hepatitis B vaccination is one of the most cost-effective public health interventions available, yielding a cost-per-life-saved of $4 to $36 in low-income countries.[718] Cost-to-benefit analysis has shown that perinatal hepatitis B prevention and routine infant hepatitis B immunization can save a net $1 in medical and work-loss costs for each $1 spent on immunization.[279] Other vaccine-based strategies, including universal adolescent vaccination and vaccination of at-risk adult populations, also have been found to be cost-effective or cost-saving.[421,719,720]

Despite the availability of hepatitis B vaccine since the early 1980s, barriers at that time impeded efforts to immunize infants and children against hepatitis B—for example, high vaccine costs, ill-founded concerns about using a plasma-derived vaccine during the first years of the AIDS epidemic, and the lack of global vaccine policies. By 1991, only 20 countries had implemented routine infant immunization against hepatitis B.[721]

Gaps in hepatitis B vaccine policy were first addressed in 1992, when the WHO called for all countries to incorporate hepatitis B vaccination into their national childhood immunization services,[721,722] stimulating broader adoption of hepatitis B immunization. By 1998, 90 countries were routinely administering hepatitis B vaccine to infants. However, by the end of 2000, only 32% of the global birth cohort had received three doses of hepatitis B vaccine, with a great majority of the unvaccinated infants living in developing countries.[723]

In the following decade, hepatitis B vaccination coverage grew rapidly (Fig. 25.13). By 2010, hepatitis B vaccination coverage among infants had reached an estimated 75% worldwide. This achievement was made possible through several developments, including removal of cost-related barriers. Throughout the 1990s, the cost of hepatitis B vaccine was $3 to $6 per dose; however, by 2010, the price had dropped to $0.185 to $0.40 per dose. Additionally, the GAVI Alliance (formerly the Global Alliance for Vaccines and Immunisation) was formed to provide targeted assistance for the countries with the lowest per capita gross national product. By 2004, 50% of the low-income countries receiving GAVI Alliance support had included hepatitis B vaccines in their routine immunization programs. China, India, and Indonesia, all of which received GAVI Alliance assistance, represented approximately one-third of the global birth cohort. In China, GAVI Alliance collaborations resulted in administration of a birth dose of hepatitis B vaccine, free of charge, to more than 25 million newborns living in the poorest and most remote provinces of western and central China; this initiative was expanded in 2002 to provide free hepatitis B vaccine to all newborns born in China. In India, a country with 1.5 million new HBV infections in the annual birth cohort, GAVI Alliance funds have improved vaccine infrastructure (e.g., increased availability of autodisposable syringes and vaccine) and supported hepatitis B vaccination in states with high-performing vaccination programs.[727] Similar collaborations have occurred worldwide. By the end of 2014, 184 countries had integrated hepatitis B vaccine into their national childhood immunization systems (Fig. 25.14). Global coverage with three doses of hepatitis B vaccines is estimated at 82% and is as high as 92% in the Western Pacific.[41]

The demonstrated progress made in global hepatitis B prevention, much of which is attributable to implementation of infant immunization programs, is commendable and can help

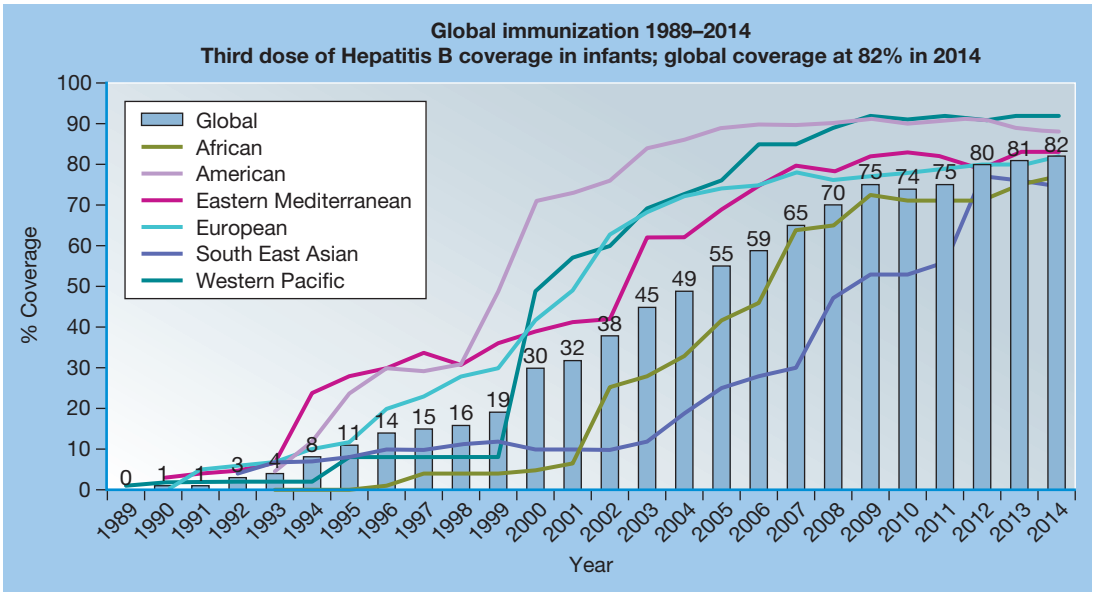

Figure 25.13. Evolution of the third-dose hepatitis B vaccine coverage in infant immunization programs, globally and by World Health Organization region (1989–2014). *(From World Health Organization. Immunization Coverage With 3rd Dose of HepB Vaccines in Infants, 2014. Available at http://gamapserver.who.int/mapLibrary/Files/Maps/global_hepb3_coverage.jpg. Data as of July 2015.)*

inform policy and programming for other vaccine-preventable infections. However, the goal of HBV elimination can be achieved only by overcoming known challenges to hepatitis B vaccination and building and sustaining support for hepatitis B vaccination, particularly in developing countries with limited health resources.

To reach full potential as a public health intervention, hepatitis B vaccination must be more readily available to protect vulnerable populations, beginning with a birth dose of hepatitis B vaccine. Data from a mathematical model demonstrate that 90% coverage with a birth dose could prevent 225,000 (16%) deaths from chronic liver disease over the life of the 2000 global birth cohort[95]; in 2006, only 27% of newborns received a birth dose of hepatitis B vaccine.[490] In 2009, the WHO recommended that a dose of hepatitis B vaccine be provided within 24 hours of birth for all infants globally to maximize the potential of routine infant vaccination in preventing HBV transmission.[666] This WHO guideline can be most readily implemented in settings where most deliveries occur in healthcare facilities, as hepatitis B vaccination coverage tends to be higher for infants born in birthing facilities than those born at home or other settings. For example, in China, an increase in facility births is credited with contributing to the large increase in birth-dose coverage of hepatitis B vaccine.[367,714] However, implementation of a birth dose of hepatitis B vaccine can be a challenge for industrialized countries. In the United States during 2009, national coverage with the first dose of hepatitis B within 3 days of birth was 61%, with coverage in states ranging from 23% to 81%.[729]

In light of these data, efforts should be undertaken to encourage facility-based births. Ideally, health workers responsible for delivery would be trained to administer hepatitis B vaccination immediately after birth in collaboration with obstetric staff (e.g., obstetricians, midwives, birth attendants) and immunization service providers; furthermore, coordination between immunization and maternal child health programs should be strengthened. Potential strategies for improving provision of a birth dose of hepatitis B vaccine have been identified and include training for obstetrical staff, removing or reducing costs of in-facility births for expectant mothers, implementing the hepatitis B birth dose as a national practice standard, using standing orders for administration of hepatitis B vaccination as part of routine medical care, and ensuring record keeping to enable program evaluation.[367,730]

Regardless of the success of these efforts, not all women will deliver in a health facility; strategies are needed to ensure that hepatitis B vaccine is administered as soon as possible after birth to infants delivered at home. However, achievement of this objective is complicated by the narrow window of time associated with effective hepatitis B vaccination. To be effective, hepatitis B vaccine should be given as early as possible after birth, preferably within 24 hours, which may not be feasible in all settings. As revealed by a review of Indonesia's immunization program and confirmed by studies in Vietnam and China, strategies to achieve high vaccination coverage rates among infants born at home are complicated by insufficient vaccine policy, training for birth attendants, notification systems for pending deliveries, and community support and confidence in the safety of hepatitis B vaccine.[731–733]

The need for a ready supply of appropriately transported and stored hepatitis B vaccine is also problematic.[731] Although manufacturers recommend hepatitis B vaccine distribution and storage at 2°C to 8°C, studies have shown the WHO prequalified hepatitis B vaccines to be heat stable. These data support the feasibility of vaccinating neonates delivered at home in remote areas or at health posts lacking refrigeration, as long as vaccine is accompanied by vial monitors to measure cumulative heat exposures.[488]

To remove these barriers, hepatitis B vaccination should be integrated into maternal-infant prevention services. Several global health initiatives are in place to facilitate adoption of hepatitis B vaccination at birth as a recommended preventive service for maternal and child health programs, including the United Nations Millennium Goals to reduce the mortality rate of children younger than 5 years of age and maternal mortality, between 1990 and 2015.[723,737,738]

Large increases in hepatitis B vaccine coverage and the long interval of time required to achieve vaccine-related reductions in HBV-related morbidity and mortality can undermine support for hepatitis vaccination in the face of competing priorities; to ensure sustained support, the success associated with existing policies and programs must be measured and communicated. Efforts to document achievement in hepatitis B vaccination are already underway globally, as illustrated by the WHO's recommendation that all WHO regions and associated countries develop control goals appropriate to their epidemiologic situations.[666] To address this recommendation, countries are encouraged to use HBsAg as a measure of the impact of immunization. Data can be collected using serologic surveys of HBsAg; data from these surveys, along with active disease surveillance and mortality data, can serve as main outcome measures.

Several successes in hepatitis B vaccination have been documented as a result of this recommendation. In September 2005, the WHO Western Pacific Region, which had a population of 1.8 billion in 2007, became the first WHO region to adopt a regional goal of hepatitis B control to be met by 2012. The hepatitis B control goal for this region was to reduce the prevalence of chronic HBV infection to less than 2% in children at least 5 years old by 2012, with an ultimate goal of an HBsAg seroprevalence of less than 1% in children 5 years old and younger.[739] The Western Pacific Region has made tremendous progress toward hepatitis B control through newborn and childhood hepatitis B vaccination. Among the 37 countries in the region, 27 (comprising 87% of the region's population) are estimated to have reached the 2012 goal for children at least 5 years of age.[740]

In the WHO European Region as of 2012, 47 of the 53 European countries (89%) had implemented a universal hepatitis B vaccination program. The most recent countries to follow the recommendation were Ireland (in 2008) and the Netherlands (in 2011). Still, six countries (Denmark, Finland, Iceland, Norway, Sweden, and the UK) adopt risk-group-targeted vaccination only, instead of adding a universal vaccination program. However, changing demography, increasing immigration, and the current vaccine costs make the cost-to-benefit ratios in these remaining low endemicity countries strongly in favor of universal HBV vaccination.[741–744]

On September 17, 2014 the Regional Committee for Europe approved a resolution EUR/RC64/R5 to adopt the "European Vaccine Action Plan 2015–2020" which defines a regional vision and goals for immunization and control of vaccine preventable diseases and outlines priority actions to achieve them. One of the major European Vaccine Action Plan (EVAP) goals is to strengthen hepatitis B control through immunization. The EVAP 2015–2020 states: "The Regional Office commits itself to prepare a program and action plan for the control of hepatitis B infection and identify targets for 2020." The overriding vision of hepatitis B control in the Region is that the children in all countries in the region would be free of CHB infection, defined as an HBsAg prevalence of 0.5% or lower in children 5 to 10 years of age by 2020.[745]

Linking hepatitis B vaccination with other global health initiatives also can help sustain existing hepatitis B vaccination programs. For example, because hepatitis B vaccination prevents liver cancer and cirrhosis, immunization efforts can be

linked to activities to reduce chronic, noncommunicable diseases; the United Nations (UN) General Assembly recognizes noncommunicable disease as an emerging global epidemic that is impeding achievement of UN Millennium Development Goals.[746] In a report to the UN secretary-general, delivery of hepatitis B immunization was considered a "best buy" intervention because it is inexpensive, highly cost-effective, and culturally acceptable. Because HBV coinfection is a health issue for persons living with HIV, active chronic HBV infection is now considered to be a condition for modifying antiretroviral therapy. This will necessitate increased screening for HBV in the population of HIV-infected persons. To intensify the global response to HIV/AIDS, the UN General Assembly adopted a resolution to reduce the high rates of HIV and hepatitis B coinfection by rapidly expanding access to appropriate vaccination for hepatitis B, and to diagnostics and treatment of HIV and hepatitis coinfections.[747]

Integrating hepatitis B vaccination with screening, care, and treatment can promote a synergistic approach to hepatitis B prevention. Therapies for HBV infection, which are most effective when taken early in the course of infection, have greatly improved over the past decade, underscoring the importance of linking infected persons to care and treatment. Through screening, public health programs have an opportunity to ensure that infected persons and their susceptible contacts receive needed care, such as counseling, medical evaluation, and treatment. Likewise, providers of hepatitis B care and treatment can refer susceptible close contacts of HBsAg-positive patients for hepatitis B vaccination, and therapies can improve the effectiveness of vaccination programs. Studies reveal that providing antiviral therapy to HBsAg-positive mothers with high HBV viral loads during the third trimester of pregnancy can lower the rate of perinatal infection among exposed newborns receiving hepatitis vaccine and HBIG.[748–752]

The importance of this type of synergy is reflected in recent viral hepatitis prevention policies; for example, in 2011, the U.S. government released an action plan to promote a coordinated approach to viral hepatitis care and treatment, which can be tailored to meet the needs of other countries seeking to improve hepatitis B prevention.

In May 2014, the World Health Assembly approved a resolution to improve the prevention, diagnosis, and treatment of viral hepatitis. The importance of implementing appropriate measures to protect groups such as people who inject drugs from infection and to improve the access to screening, diagnosis, and treatment.[753] The Global Health Sector Strategy on HIV/AIDS, 2011–2015, endorsed by the World Health Assembly in 2011 (resolution WHA64.14) has ended, and several member states have requested the WHO secretariat to start a process to develop a post-2015 strategy. In a technical briefing at the World Health Assembly in May 2015, member state commitments to finish to emerging hepatitis epidemic were heard. The department of HIV and Global Hepatitis Programme at the WHO is developing three global health sector strategies to cover HIV/AIDS, viral hepatitis, and sexually transmitted infections. The strategies will cover 2016 to 2021 and were finalized at the 69th World Health Assembly in 2016. At this World Health Assembly the first "Global Health Sector Strategy on Viral Hepatitis, 2016-2021" was adopted. This strategy highlights the critical role of universal health coverage, and the targets of the strategy are aligned with those of the sustainable development goals. The strategy has a vision of eliminating viral hepatitis as a public health problem; this is now encapsulated in the global targets of reducing new viral hepatitis infections by 90% and reducing deaths due to hepatitis by 65% by 2030.[754]

In 1993 and 1999, expert committees considering targets for disease control concluded that the elimination of HBV transmission is a feasible public health goal.[686,688] Infant immunization programs successfully implemented by almost all countries provide the framework for such elimination. Universal infant vaccination beginning at birth on a global scale, along with targeted efforts to vaccinate all children and adults at risk for HBV infection, can reduce the risk for HBV infection to zero. However, elimination of HBV transmission will require high vaccine coverage in multiple generations. Expanded access to diagnostic testing and HBV care and treatment provide additional opportunities to prevent both HBV transmission and related disease. Commitment of public health resources to eliminate HBV transmission will require recognition of the large global burden of disease, demonstration of the benefits of vaccination, and patience to realize the goals of vaccine-associated disease reduction.

FUTURE VACCINES

Existing hepatitis B vaccines are highly effective, and there is no evidence that new vaccines will be needed to eliminate HBV transmission in immunocompetent populations with recommended immunization strategies. Potential uses for new hepatitis B vaccines include enhancing seroprotection in nonresponders to existing vaccines (using pre-S1 and/or pre-S2, or adding new vaccine adjuvants instead of aluminum hydroxide),[477,755–760] decreasing the number of doses required for seroprotection, and providing protection against HBV infection with S mutant viruses.[474,759,761,762] The addition of CPG 7909 to hepatitis B vaccine is promising as the immunostimulatory activity of this adjuvant can help in achieving long-term protection in hepatitis B vaccine hyporesponsive populations like HIV seropositives, hemodialysis patients, oncologic patients, the obese, and the elderly.[759,761,762a,762b] Such experimental vaccines, currently under examination for licensure in the United States, are effective in patients with renal failure and on hemodialysis, in nonresponders to conventional yeast-derived vaccines, and in immunocompetent healthy individuals receiving only two vaccine doses instead of three.[474,477,759,761,762] A two-dose schedule (4 weeks apart) was shown to trigger higher seroprotective rates compared to a classical three-dose schedule (0, 4, and 24 weeks) with a conventional hepatitis B vaccine.[762c,762d] As it has been hypothesized that a lack in vaccine efficacy might be explained by a mismatch between vaccine genotype and endemic HBV genotype (*adw* vs *ayw*), if proven, the use of a modified HBV vaccine in specific regions could be considered.[763,764]

Yet, to date, CHB is still an incurable disease and despite the tremendous progress made in developing nucleoside/nucleotide analogs that efficiently suppress HBV replication, these agents do not eliminate the covalently closed circular HBV-DNA residing in the nuclei of infected hepatocytes. Consequently, development of therapeutic immunization for persons with chronic HBV infection and restoring the defective immune tolerance to HBV remains an important goal.[765,766]

Vaccines generating strong T-cell immunity with purified or recombinant vaccine antigens, and intradermal, oral, and nasal hepatitis B vaccines, which might be easier to administer and less expensive than injections, are also under investigation.[503,660,767–770]

26 Hepatitis C Vaccines

Sergio Abrignani, Petra Neddermann, Michael Houghton, and Raffaele De Francesco

Hepatitis C virus (HCV) is a leading cause of chronic liver disease worldwide. According to the World Health Organization,[1] 130 to 150 million people are chronically infected with HCV worldwide—approximately 3% of the world's population—and approximately 500,000 people die each year from HCV-related liver diseases. Importantly, 3 to 4 million more individuals are newly infected with HCV each year. A significant number of those newly infected will develop progressive liver disease, ultimately leading to liver cirrhosis and liver cancer. These scary numbers highlight the pressing need to develop vaccination strategies aimed at preventing and possibly eradicating HCV infection.

Although a prophylactic vaccine preventing HCV infection is not yet available, great progress has been made with respect to the development of increasingly more effective therapeutic regimens. Until recently, therapy for chronic HCV infection consisted of a combination of pegylated interferon-α (PegIFNα) and ribavirin. This approach, however, eradicates the virus in less than half of treated patients and is plagued with serious side effects. In recent years, the treatment paradigm for chronic HCV infection has undergone a revolution. New treatment regimens employing all-oral combinations of direct-acting antiviral agents (DAAs) lead to cure rates of greater than 90%, even in patients who failed prior interferon-based therapy.[2] The list of currently available DAAs include sofosbuvir, a pangenotypic nucleotide analog inhibitor of the RNA-dependent RNA polymerase; dasabuvir, a nonnucleoside polymerase inhibitor active against genotype 1; simeprevir, paritaprevir, and grazoprevir; NS3/4A protease inhibitors indicated for genotypes 1 and 4; and NS5A inhibitors ombitasvir, elbasvir (genotypes 1 and 4), ledipasvir (genotypes 1, 4, 5, and 6), daclatasvir, and velpatasvir (all genotypes). These drugs are used in different combination regimens, with or without ribavirin, depending on the viral genotype, liver disease staging, previous treatment history, and presence of comorbidities.[3,4] Furthermore, new drugs and treatment combinations are being developed with the objective of achieving a broader spectrum of action and possibly requiring a shorter duration of therapy.

The possibility of achieving a virological cure for chronic HCV infection is quite a remarkable feat; in fact, virus eradication is not possible in any other chronic viral infection. Thus, with the development of very effective antiviral drugs that are active on all HCV genotypes, global eradication of HCV by means of pharmacological treatment has become a theoretical possibility. In reality, however, three major challenges remain. First, in the absence of effective screening programs, HCV infection is underdiagnosed. Second, the high cost of these new therapies and the large number of HCV-infected individuals means that the healthcare systems, even in high-income countries, cannot afford to treat all patients. This limitation is even more pronounced in low- and mid-income countries. Third, reinfection remains possible even after successful curative therapy. For these reasons, an efficient HCV vaccine would still represent the most cost-effective and realistic means to significantly reduce the worldwide mortality and morbidity associated with HCV infection.

The scientific and clinical challenges that must be addressed and overcome in developing an efficacious HCV vaccine are substantial but may not be insurmountable. Among the difficulties that have hampered the development of a vaccine against HCV are its extreme genetic variability, the lack of small animal models for testing vaccines, and the fact that a cell culture system supporting the production of infectious HCV and allowing studies on virus neutralization in vitro became available only recently. Despite these issues, much progress has been made toward the identification of promising prophylactic vaccine candidates, and some of these candidate vaccines have started to be assessed in early clinical trials.

VIROLOGY

HCV was identified in 1989 as the major cause of transfusion and community-acquired non-A non-B hepatitis.[5,6] It is an enveloped, single-stranded RNA virus classified as a member of the *Hepacivirus* genus within the Flaviviridae family.[7] The 9.6-kb positive-sense RNA genome contains a single open reading frame encoding a polyprotein of approximately 3000 amino acids, flanked by highly structured 5′ and 3′ untranslated regions (UTRs), required for RNA replication and translation.[8]

Viral RNA released into the cytoplasm of the host cell is translated via an internal ribosome entry site (IRES) located in the 5′ UTR,[9] giving rise to an approximately 3000-amino-acid-long polypeptide that is cleaved into 10 different products (core, E1, E2, p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B) (Fig. 26.1).[10]

HCV RNA replication takes place in the cytoplasm, in association with a virus-induced intracellular membrane structure termed "membranous web,"[11] and is directed by the error-prone RNA-dependent RNA polymerase encoded by the viral NS5B gene. This is a low-fidelity polymerase that introduces frequent mutations into the viral genome, generating quasispecies.[12] The extreme genetic variability of HCV, dwarfing that of HIV, provides a selective advantage for the evasion from immune control and is believed to contribute to the remarkable persistence of HCV in infected individuals.[13] Thus, the 5′ and 3′ UTRs, as well as the *core* gene are highly conserved, whereas the remaining viral genes and the corresponding proteins exhibit various but substantial levels of heterogeneity.[14] The site of greatest variability is within the N-terminal region of E2 envelope glycoprotein (hypervariable region 1 [HVR1]). This region is the major target of virus-neutralizing antibodies.[15–20] Recent structural insights into the aminoterminal domain of E1 and the core domain of E2 have revealed unexpected folds not present in glycoproteins from related viruses.[21] In vitro–produced HCV particles have been only recently visualized by electron microscopy.[22] Based on available data, HCV appears to be the most structurally irregular member of the *Flaviviridae* family: particles are spherical, with spike-like projections, and heterogeneous in size ranging from 40 to 100 nm in diameter. By analogy to related viruses, HCV virions are thought to consist of an icosahedral lattice of E1/E2 heterodimers bound to a cell-derived lipid bilayer membrane surrounding a nucleocapsid built from multiple copies of the core protein, which, in turn, package the genomic RNA. HCV is invariably found in association with low-density and very-low-density lipoproteins (LDL and VLDL), resulting in

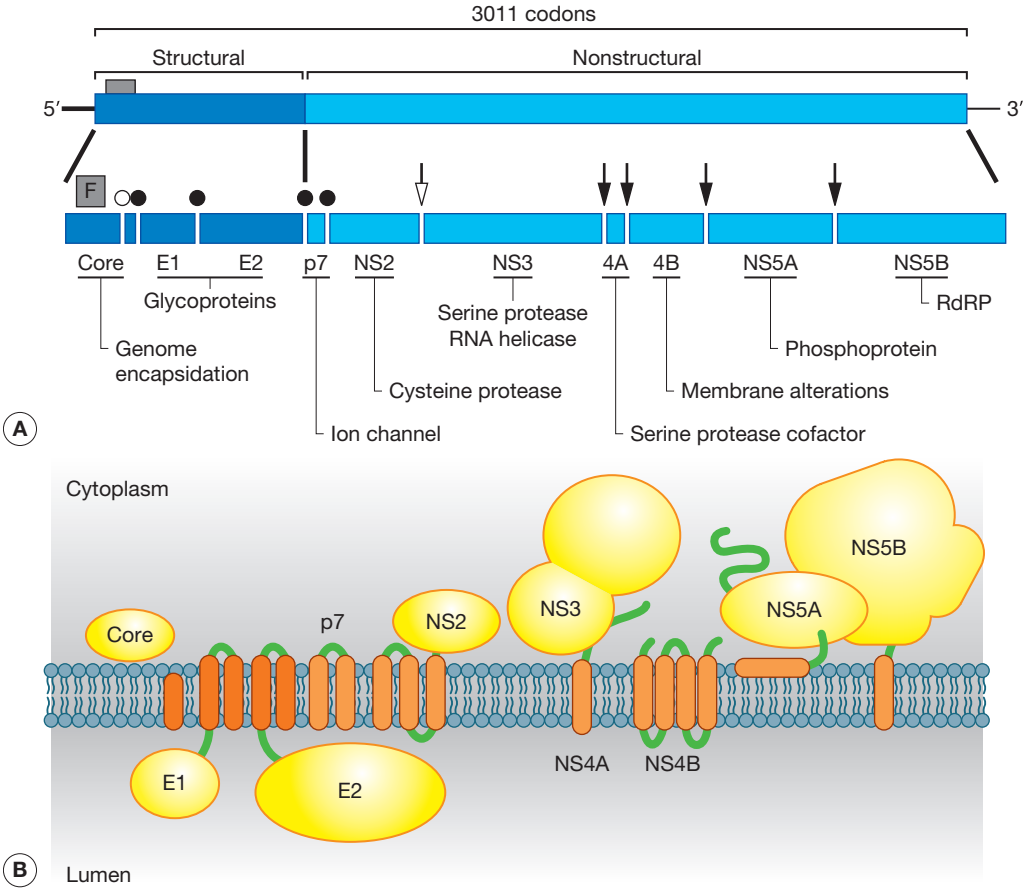

Figure 26.1. Hepatitis C virus (HCV) genes and gene products. A, The structure of the viral genome, including the long open reading frame encoding structural and nonstructural genes 5′ and 3′ untranslated regions (UTRs). The polyprotein processing scheme is shown. The C-terminal third of the polyprotein, core to p7, is processed by host cell signal peptidase, giving rise to the structural proteins, namely the N-glycosylated envelope virion glycoproteins, E1 and E2, and the core (C) protein, and to the nonstructural protein p7, an ion channel of the viroporin family. *Closed circles* refer to signal peptidase cleavage sites. The C protein is further cleaved by host signal peptide peptidase to yield the smaller species that appears to be the form found within virions circulating in the bloodstream. The *open circle* refers to the signal peptide peptidase cleavage site. A variable frameshift during translation of the C region results in the synthesis of the F protein (also called ARFP or core + 11).[193,194] This is a protein of unknown function and significance, but antibodies to these proteins circulate in patients chronically infected with HCV.[195] The remainder of the polyprotein is cleaved by two viral enzymes. The cysteine protease residing in nonstructural protein 2 (NS2) cleaves between NS2 and NS3 *(open arrow)*. The NS3 serine protease is activated by interaction with NS4A and catalyzes processing at all other sites within the NS region *(solid arrow)*. **B,** The topology of HCV proteins with respect to the cellular membrane is indicated. *(From Lindenbach BD, Rice CM. Unraveling hepatitis C virus replication from genome to function.* Nature. *2005;436:933–938.)*

the so-called lipo-viro-particles.[23] Infection of the hepatocyte by HCV depends on a complex set of receptors (CD81, scavenger receptor class B type I, claudin-1, and occludin), as well as several auxiliary molecules, facilitating adsorption of the virus to the cell (e.g., glycosaminoglycans, LDL receptor) or virus entry (e.g., epidermal growth factor receptor, Niemann–Pick C1-like cholesterol absorption receptor).[24] Of these, only the tetraspanin cellular protein CD81 and scavenger-receptor B1 (SR-B1) are believed to bind directly to the HCV envelope glycoprotein E2.[25,26]

For many years, it was impossible to propagate HCV in cell culture. Subgenomic HCV replicons were originally established for genotype 1b.[27] More recently, the panel of available replicons has expanded to include isolates from genotypes 1a, 2a, 3a, 4a, 5a, and 6a.[28–30] Because of a lack of structural proteins, however, subgenomic replicons could not be used to study immune responses against the virus. A fully permissive cell culture system supporting the production of infectious HCV only became possible with the identification of a genotype 2a isolate cloned from the serum of a Japanese patient with fulminant hepatitis, which was termed JFH1.[31] This breakthrough has allowed the generation of infectious hybrid viruses in vitro, in which the envelope glycoprotein genes of the 2a strain were replaced with equivalent genes from other HCV genotypes.[32] These key developments have opened up the field to investigations into HCV replication, virion structure, and virus-specific immune responses, as well as being valuable in the development of vaccines and new antivirals.

In addition to the above culture systems, a convenient and safe experimental model used to study HCV entry is based on the HCV pseudotype particles (HCVpp). HCVpp are obtained by exploiting a retrovirus in which HCV E1 and E2 substitute for the endogenous retroviral envelope proteins.[33–35] Because the HCVpp system can express a range of HCV glycoproteins originating from different isolates and genotypes, it represents an excellent platform for the establishment of a virus-neutralizing antibody assay.[36]

HCV can only infect humans and chimpanzees. Historically, attempts to develop small animal models of infection were based on the transplantation of human liver cells into

immunodeficient mice.[37] Whereas these have represented useful small animal models to study antiviral agents, they are unsuitable to study the immune response because of the lack of B-cell–mediated and T-cell–mediated immunity. Only very recently was a humanized mouse with a human immune system and liver tissue developed.[38] This was obtained by expressing in Balb/C Rag2(−/−) γC-null mice a fusion protein of the K506 binding protein and caspase 8 under control of a hepatocyte-specific promoter that induces liver cell death. Transplantation of human $CD34^+$ human hematopoietic stem cells and hepatocyte progenitors into the transgenic mice led to efficient engraftment of human leukocytes and hepatocytes. These animals, termed AFC8-hu HSC/Hep, supported HCV infection in the liver and generated a human immune T-cell response against HCV, and also developed hepatitis and fibrosis. An alternative method to overcome species barriers to HCV infection builds on the observation that CD81 and occludin comprise the minimal set of human factors required to render mouse cells permissive to HCV entry. Thus, transgenic mice were constructed that stably expressed human CD81 and occludin (Rosa26-Fluc mice[39]). These animals support HCV entry, but innate and adaptive immune responses restrict HCV infection in vivo.[39,40] Blunting innate antiviral immunity in these genetically humanized mice infected with HCV, however, resulted in measurable viremia over several weeks.[40] Alternatively, transgenic expression of human CD81 and occludin in an ICR (imprinting control region) mouse background yielded transgenic ICR mice that can support persistent HCV infection, with complete replication cycle and hepatopathological manifestations, without the need for targeting the disruption of interferon-stimulated genes.[41] Future work will assess the usefulness of these models in vaccine research.

HEPATITIS C VIRUS INFECTION

The major site of HCV replication is the hepatocyte. HCV has also been reported to infect other cell types, most notably B cells and dendritic cells,[42–46] but also cells in the intestine[47] and in the central nervous system.[48] However, the issue of extrahepatic HCV infection remains controversial.[49]

Historically, transmission seemed to occur primarily via direct parenteral exposure to contaminated blood. The frequent transmission of HCV that occurred in transfusion recipients before the discovery of the virus has now disappeared with the advent of serologic tests based on the detection of antibodies to viral proteins and on the direct detection of HCV RNA. As of today, intravenous drug use, unprotected sex with multiple partners, and viral exposure during invasive medical procedures (e.g., surgery, dialysis, and dental treatment) are factors associated with the highest degree of risk for HCV infection. After infection, HCV RNA appears in the plasma within a few days and usually shows a peak within the first few months. The inflammatory processes leading to initial liver injury, as assessed by serum elevation of the liver specific alanine aminotransferase (ALT) enzyme, generally occur within 1 to 3 months. The absence of correlation between HCV RNA levels and liver damage[50] suggests that HCV does not exert a direct cytopathic effect on the infected cells. At present, liver damage is postulated to be primarily caused by the infiltration of inflammatory cells, which cause extended inflammation that in turn causes hepatocyte damage and death. Although the mechanisms involved in initiating and maintaining an inflammatory response in the HCV-infected liver are not completely understood, the currently accepted model implicates the $CD8^+$ cytotoxic T-lymphocyte (CTL) T-cell response in mediating most if not all the liver damage that is associated with chronic viral hepatitis.[51] According to this model, hepatocyte injury is initiated by the cytolytic activity of HCV-specific CTLs and CTL-produced cytokines, such as IFN-γ, and IFN-γ–inducible chemokines (e.g., CXCL9 and CXCL10), recruit into the liver parenchyma large numbers of antigen-nonspecific inflammatory cells that have the potential to amplify the liver damage. Notably, work in animal models of viral hepatitis shows that platelets play a key role in T-lymphocyte–induced liver damage by facilitating the intrahepatic accumulation of CTLs.[51–53]

If infection is not resolved within the first 6 to 12 months, patients generally remain infected for life. Chronically infected patients have viral loads that typically range from 10^5 to 10^7 genomes per milliliter of serum. The virions have a rapid turnover, with a half-life of about 3 hours and up to 10^{12} viral particles per day are produced in an infected person.[54]

Natural History of Hepatitis C Virus Infection

Acute HCV infection is usually subclinical, as the symptoms are typically mild or absent. Between 15% and 50% of acute hepatitis C infections resolve spontaneously, whereas chronic infection develops in 50% to 85% of infected persons. During chronic inflammation of the liver, regeneration of tissue occurs up to a certain point, after which hepatocytes are replaced with fibrotic tissue that can subvert liver structure and function.[55] This condition can lead to cirrhosis and can, in some cases, progress to liver failure or hepatocellular carcinoma. In up to 20% of patients with chronic HCV infection, progressive liver damage develops, leading to end-stage disease, usually during a period of 10 to 30 years.[56] Owing to direct and indirect effects of HCV on lipid and glucose metabolism, respectively, chronic HCV infection is also often associated with liver steatosis and insulin resistance, which have the potential to synergize with the inflammatory liver disease.[57,58] The spectrum of severity of HCV-associated liver disease and its rate of progression show a high degree of variability between persons and are influenced by several cofactors, including age at infection, gender, host genetic variability, viral genotype, exposure to alcohol and other toxins, immune status, coinfections, and the presence of metabolic syndrome.[59] Chronic HCV infection has also been associated with extrahepatic diseases[60] such as mixed cryoglobulinemia, membranoproliferative glomerulonephritis, non-Hodgkin B-cell lymphoma, lichen planus, and porphyria cutanea tarda.

In recent years, it has become clear that an infected person's ability to clear HCV spontaneously, or following IFN-based treatment, is genetically determined. In fact, high rates of spontaneous clearance of acute HCV infection and high-sustained virological response rates following treatment with Peg-IFNα/ribavirin are associated with specific polymorphisms of the *IL28B* gene.[61] While the IL28B genotype does not have a significant value in predicting a patient response to the new IFN-free, all-oral DAA regimens, the presence of such a genetic determinant of spontaneous viral clearance is bound to have a significant impact on the host's ability to mount a protective immune response following vaccination and, therefore, may have to be considered in the design of clinical trials aimed at assessing the effectiveness of vaccines for HCV.

EPIDEMIOLOGY

A recent metaanalysis aimed at estimating the burden represented by HCV epidemics suggested that, globally, the estimated prevalence of people with anti-HCV antibodies increased from 2.3% to 2.8% between 1990 and 2005 (from >122 million to >185 million people).[62] Central and East Asia and North Africa/Middle East are estimated to have the highest prevalence (>3.5%); South and Southeast Asia, sub-Saharan Africa, Andean, Central, and Southern Latin America,

Caribbean, Oceania, Australasia, and Central, Eastern, and Western Europe have moderate prevalence (1.5% to 3.5%); whereas Asia Pacific, tropical Latin America, and North America have low prevalence (<1.5%). At the level of individual countries, Egypt is thought to have the highest prevalence of chronic HCV in the world, estimated at approximately 15% to 20%. What led to an HCV epidemic of this proportions in Egypt is the extensive use of parenteral antischistosomal therapy in a mass treatment setting, a practice discontinued only in the 1980s.[63]

Seven different major HCV genotypes and many subtypes have been distinguished phylogenetically, with 30% to 50% sequence variation among viral genotypes and 15% to 30% among different subtypes.[64,65] Globally, genotype 1 is the most common (46%), followed by genotype 3 (22%), genotype 2 (13%), genotype 4 (13%), genotype 6 (2%), and genotype 5 (1%).[66] Definitive data regarding the prevalence of genotype 7 are still lacking. Genotype 1b is the most common subtype, accounting for 22% of all infections. Significant regional and countrywide variations in genotype distribution exist. Infections in Europe, North America, and Latin America are predominantly genotype 1. North Africa and the Middle East have large genotype 4 populations, primarily as a consequence of the extraordinarily high prevalence of this genotype in Egypt. Excluding Egypt, genotype 1 becomes predominant also in this region. Asia is primarily affected by genotype 3, followed by genotype 1, with the former being very common in India, Nepal, and Pakistan. Finally, genotype 1 predominates in Australia, followed by genotype 3.[66]

Transmission of HCV seems to occur via direct parenteral exposure to contaminated blood. The frequent transmission of HCV that occurred in transfusion recipients before the discovery of the virus has disappeared with the advent of serologic tests based on the detection of HCV-specific antibodies or the direct detection of HCV RNA. At present, a history of intravenous drug use represents the major risk factor for newly acquired hepatitis C infection.[67] Other possible sources of parenteral exposure to HCV are surgical and dental procedures and folk practices such as piercing and tattoos.[68] Although the risk of sexual transmission is low, sexual partners of infected persons still account for a certain percentage of HCV infections.[69] Vertical transmission also occurs particularly in mothers with high viral load or who are coinfected with HIV.[70–72] Coinfection with HIV and HCV is common in intravenous drug users (IVDUs) of illicit drugs, and importantly the immunosuppression associated with HIV infection results in higher HCV titers and more rapid progression to cirrhosis and end-stage liver disease.[73]

IMMUNE RESPONSE TO HEPATITIS C VIRUS

HCV has adapted to escape host immune control, in most cases progressing into a persistent infection. Moreover, unlike for many other viruses, resolution of acute HCV infection does not necessarily result in sterilizing immunity upon reexposure to the virus. Nonetheless, approximately 20% of the acute HCV infections are spontaneously cleared, indicating the existence of effective adaptive immune responses. A detailed understanding of the immune mechanisms that contribute to rapid control of an acute HCV infection, after 25 years of studies in humans and chimpanzees, however, is still lacking. Moreover, there is still considerable uncertainty about the relative contribution of humoral versus cellular immune response to the resolution of infection.

Several studies show that recovery from acute HCV infection is associated with the induction of a multispecific T-helper cell type 1 (Th1)-type $CD4^+$ T-helper and $CD8^+$ CTL T-cell responses to the virus.[74] This is evidenced, for example, by the associations of class I human leukocyte antigens[75–77] and class II antigens[78] with spontaneous virus clearance, the temporal association of resolution of infection with HCV-specific IFN-γ–secreting T cells,[79] and the generation of polyfunctional, durable $CD4^+$ and $CD8^+$ T-cell subsets directed against multiple HCV antigens in spontaneous resolution.[80,81] Additionally, T-cell depletion experiments with chimpanzees confirmed the essential role of both the $CD4^+$ T-helper and the $CD8^+$ CTL T-cell responses in controlling HCV infection.[82,83]

Whereas the importance of cellular immunity in controlling HCV infection is well established, the role of the humoral immunity in recovery from infection is less clear. However, an increasing number of studies suggest that B cells and neutralizing antibodies (nAbs) could also play an active role in the spontaneous resolution of HCV infection. Antibodies produced during acute HCV infection target epitopes within both structural and nonstructural viral proteins. However, all known nAbs target epitopes within the HCV envelope glycoproteins E1 and E2, or the E1/E2 heterodimer. Most characterized nAbs are directed against regions of E2 that interact with the viral entry factors CD81 and scavenger-receptor B1 (SR-BI) (Fig. 26.2).[84]

Longitudinal analysis of HCV infection cohorts revealed a clear association between eradication of acute viremia and the presence of antibodies able to block entry of HCV pseudoparticles into cultured hepatocytes.[85,86] Additional recent evidence suggests that early induction of cross-reactive nAbs during acute infection strongly correlates with spontaneous clearance of HCV.[87–90] nAbs also play an important role in persons who have previously cleared their primary infection but become infected on reexposure to the virus.[91] In this study, nAbs were detected during the acute infection phase in 60% of reinfected participants who went on to clear the reinfection, but were not detected in two patients who progressed to chronic infection. Overall, these studies suggest that the development of a nAb response during the early phase of infection could be critically implicated in viral clearance. Even during chronic infection, nAbs may mediate some control of HCV as hypogammaglobulinemic persons experience a more severe and rapidly progressing liver disease.[92,93] Consistent with this view, passive transfer of nAbs also has been shown to protect humans and animal models against viral challenge. Passive immunization using human immunoglobulin preparations also has shown efficacy in preventing HCV transmission following blood transfusion,[94] sexual activity,[69] and liver transplantation.[95] Recently, a human monoclonal antibody targeting E2 was shown to prevent HCV infection in the chimpanzee model.[96] Antibodies targeting the HCV envelope glycoproteins also have been shown to protect against heterologous virus challenge in human liver-chimeric mouse model.[97,98]

Now that HCV can be propagated in cell culture, assays for viral nAbs are available. In fact, the availability of cell culture viruses with envelope proteins of the HCV genotypes 1 to 7 (JFH1 intergenotypic recombinants) permitted cross-neutralization studies in vitro.[32] Using these intergenotypic recombinant viruses, sera obtained following infection with HCV genotypes 1a and 4a cross-neutralized genotype 1a, 4a, 5a, and 6a viruses, but not genotype 2a and 3a viruses,[99] suggesting a clustering of genotypes that could be important for future development of passive and active HCV immunoprophylaxis strategies. In the chimpanzee model, infusion of anti–genotype 1a HCV immunoglobulins with high-titer in vitro cross-neutralizing HCV antibodies prevented the infection by genotype 1a or 6a HCV, but failed to protect the animals against genotype 4a or 5a,[100] indicating that more work is needed in this area of research.

HCV has evolved several mechanisms to persist in the human host and to evade the adaptive and innate immune

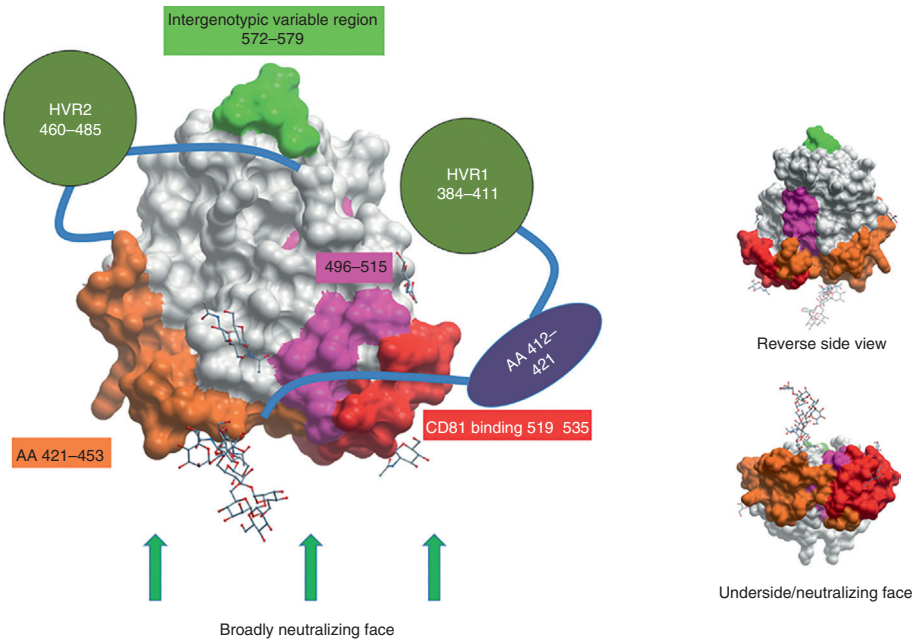

Figure 26.2. Representation of hepatitis C virus (HCV) E2 glycoprotein structure. E2 is a globular protein with three regions of hypervariability—HVR1, HVR2, and intergenotypic variable region—shown in *green*. Domains whose structures are currently unknown are depicted as shapes apart from the structure. HVR1 is predicted to mask a hydrophobic region that is sensitive to neutralizing antibodies (nAbs). E2's broadly neutralizing face is shown, where many broadly nAbs bind, comprises CD81-binding loop (in *red*), residues 421–453 (in *orange*), residues 502–520 (in *pink*), and residues 412–421 (in *purple*). The possible positions of some glycans are shown as sticks and balls. *(From Cashman SB, Marsden BD, and Dustin LB. The Humoral immune response to HCV: understanding is key to vaccine development.* Front Immunol. *2014;5:550.)*

responses. At the level of innate immune response, the virus has evolved the ability to disrupt the cellular signaling pathways leading to IFN synthesis and to block antiviral activity of IFNγ-sensitive genes.[101,102] Moreover, the binding of E2 to CD81 directly inhibits natural killer (NK) cell activity,[103,104] providing the virus with a mechanism aimed at limiting the antiviral activity of NK cells early in the infectious process.

HCV has also developed several ways to elude the adaptive immune response. First, the virus exists as a population of viral quasi-species that is sufficiently immunologically distinct to enable the emergence of variants that elude host humoral and cellular immune responses.[105] Thus, HCV produces with high-frequency escape mutants to both CTLs[106] and to nAbs directed to the envelope glycoproteins.[15,16,18,107,108] HCV has also evolved a number of indirect mechanisms to evade antibody responses. These include the association of HCV with lipoproteins,[23,109–111] possibly leading to the interference of antibody binding. The viral envelope is also heavily glycosylated and the presence of these modifications protects the virus against the development and binding of nAbs (see Fig. 26.2).[112–114] Another possible mechanism of escape from the immune response may be related to the finding that HCV infects cells not only by the direct uptake of cell-free virus following virus engagement with specific cell receptors, but also through direct cell-to-cell transmission.[115] Unfortunately, this last mode of transmission is shielded from the action of nAbs.[116] Finally, the activity of effector T cells specific for the virus can be impaired as a consequence of persistent HCV infection.[117,118] In this respect, it is worth noting that immunization of mice with adenoviral vectors expressing HCV core or F protein leads to T cells with reduced production of effector molecules such as granzyme B and IFN-γ.[119] These results reveal a potential new strategy of immune modulation by HCV-derived F and core proteins, and may have important implications in vaccine design.

Despite the strategies HCV puts in place to blunt the host immune response, when the host has the ability to elicit early and broad Th1-type $CD4^+$ and $CD8^+$ T-cell responses to the virus[79,82,83,120–127] and also has an NK receptor repertoire that facilitates innate immune clearance of virus,[128] then eradication of virus can occur (Fig. 26.3).

In conclusion, infected humans and chimpanzees who mount early, multispecific $CD4^+$ and $CD8^+$ T-cell responses to HCV proteins can eradicate the virus. In addition, many experimental studies have provided evidence that broadly neutralizing antibodies to HCV can offer some protection against heterologous viral infection in vivo.

PROTECTIVE IMMUNITY AGAINST HEPATITIS C VIRUS

Studies in the chimpanzee challenge model and of multiply exposed humans have demonstrated that there is significant natural immunity against HCV. In one chimpanzee study,[20] an animal was infected by intrahepatic administration of an infectious RNA derived from HCV strain HCV-1 (1a subtype). Following resolution of the acute infection, the animal was shown to be resistant to an intravenous rechallenge with a homologous virus. No viremia could be detected following rechallenge, indicating that sterilizing immunity was generated during the first infection. Importantly, a subsequent challenge with heterologous 1a or 1b strains induced only a low, transient viremia before disappearance of the virus from plasma and the liver.[20] Similar results were obtained in separate chimpanzee studies in which animals were challenged and then rechallenged with different infectious viral inocula.[129,130] Opposite results have been obtained in another chimpanzee study,[131] in which protection against chronic HCV infection was observed only after rechallenge with homologous, but not heterologous, genotypes. Moreover it has been

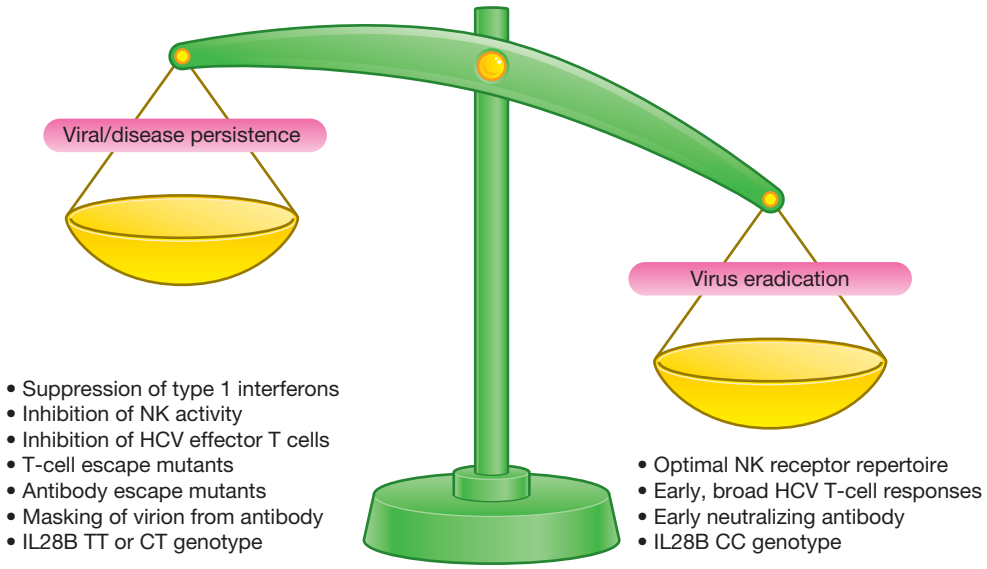

Figure 26.3. Current view about immunological correlates of protection against hepatitis C virus (HCV) infection and chronic hepatitis. NK, natural killer.

more recently reported that previously infected chimpanzees are not consistently protected against reinfection or persistent infection after reexposure to the identical hepatitis C virus strain.[132]

In humans, evidence of cross-protective immunity has been reported in a prospective study of IVDUs from the United States. Strikingly, the incidence of persistent viremia in IVDUs who had recovered from a previous infection was 12-fold lower than that in IVDUs who had not experienced a previous infection, as shown using multivariate analyses.[133] As seen also in the chimpanzee, peak viral loads were substantially higher (by almost 2 logs) in the first-time infections as compared with reinfections. In addition, HIV coinfection produced persistent HCV infection in all cases, indicating the importance of an intact immune response in recovery.[133] Interestingly, it was recently reported that the reduced risk of HCV persistence in IVDUs previously recovered from HCV infection correlated with T-cell responses, and prolonged antigenic stimulation seems to be required to maintain humoral responses.[134]

Collectively, these chimpanzee and human data provide evidence for the existence of immunity to HCV and, importantly, suggest the existence of cross-protective immunity within and between commonly occurring HCV genotypes. It is important to note, however, that not all reinfections in IVDUs are resolved without progression to chronicity,[133] indicating that natural immunity to HCV is incomplete and not as effective as that found following infection with hepatitis A and B viruses. It should also be mentioned that earlier studies in the chimpanzee model have concluded a lack of protective immunity to HCV.[135] This apparent contradiction may be a result of the earlier studies measuring immunity in terms of sterilizing immunity, rather than as the ability to prevent the development of chronic infection.

In summary, the current consensus is that the development of an early, broad, and multispecific T-cell response during acute viral infection is associated with spontaneous clearance of infection. Similarly, protection from reinfection correlates with the breadth and magnitude of a multifunctional $CD8^+$ T-cell response and also with the quality, functional potency, and cytotoxic potential of HCV-specific $CD8^+$ T cells responding against diverse HCV epitopes. It is also increasingly clear that the presence of nAbs against the virus envelope glycoproteins can be protective and is often associated with the rapid clearance of viremia. Therefore, it would be desirable for an optimal vaccine to induce a strong and broadly cross-reactive cellular immune response as well as cross-neutralizing antibodies.

STRATEGIES FOR A HEPATITIS C VIRUS VACCINE

Historically, the strategies for the development of HCV vaccines have included approaches aimed at (1) preventing initial infection (i.e., providing sterilizing immunity), (2) preventing the development of chronic viral persistence that occurs in the majority of natural infections, or (3) clearing the virus in persons who already have an established chronic HCV infection (i.e., therapeutic vaccines).[136] In consideration of the huge genetic variability of HCV, achieving broad, sterilizing immunity by vaccination could prove practically impossible. However, because the clinically relevant disease is chronic and not acute hepatitis, an HCV vaccine that would not elicit sterilizing immunity but rather prevented persistence of the virus, allowing a self-limited acute infection, would be entirely acceptable. Accordingly, the goal for the prophylactic HCV vaccines being currently developed is not prevention of infection but prevention of viral persistence.[137] Conversely, therapeutic vaccine approaches are not currently being pursued in light of the success of the new antiviral agents in providing a definitive virological cure.

To date, a number of HCV vaccine approaches, including subunit vaccines and genetic vaccines (i.e., plasmid DNA and viral vector vaccines), have been tested clinically (Table 26.1) or in the chimpanzee model. These approaches are briefly reviewed below.

Vaccines Based on Adjuvanted Recombinant Hepatitis C Virus Proteins

Historically, the first prophylactic vaccine candidate tested for HCV consisted of a C-terminally truncated recombinant E1 protein formulated with aluminium hydroxide (alum) adjuvant (T2S-918/InniVac-C[138]). This vaccine was shown to elicit anti–E1 antibodies in healthy volunteers.[138] Development of

TABLE 26.1 Summary of Outcome of Chimpanzee Vaccination/Challenge Studies Performed With Adjuvanted Recombinant gpE1/gpE2 Formulations[a]

Viral Challenge	Group	Total	Acute Infection	Chronic Infection (%)	*P* Value[b]
Homologous	Adjuvanted gpE1/gpE2	12[c]	7[c]	2 (17)	.03
HCV-1 challenges	Unimmunized control animals	10	10	7 (70)	
Heterologous	Adjuvanted gpE1/gpE2	19	19	3 (16)	.02
HCV-H77 challenges	Unimmunized control animals	14	14	8 (57)	
Total	Adjuvanted gpE1/gpE2 Unimmunized control animals	31 24	26 24	5 (16) 15 (63)	≤.001

gp, glycoprotein; HCV, hepatitis C virus.

[a]These studies were performed during the course of many years. Typically, animals were immunized with 30–80 μg gpE1/gpE2 in various oil/water adjuvants (MF59 ± MTP [muramyl tripeptide] or MF75 ± MTP or MF59 ± CpG [cytosine phosphate guanine]) at months 0, 1, and 6 approximately, followed by intravenous challenge 2–4 weeks later with 10–100 chimpanzee infectious doses of HCV-1 or HCV-H77. Both strains belong to the 1a subtype that predominates in North America. Circulating levels of viremia were measured using reverse transcription–polymerase chain reaction assays for HCV genomic RNA for at least 1 year postchallenge. Qualitative transcription-mediated amplification (TMA) assays were also performed in some animals.

[b]*P* values (Fisher exact test) refer to chronic carrier rates between control animals and vaccinees.

[c]In five vaccinees challenged with homologous HCV-1 virus, no viremia could be detected at any time postchallenge in plasma peripheral blood mononuclear cells (PBMNCs) or liver biopsy samples; thus, they were considered to have been sterilized.

From Houghton M. Prospects for prophylactic and therapeutic vaccines against the hepatitis C viruses. Immunol Rev. *2011;239:99–108.*

this vaccine candidate, however, was stopped as no effects on viremia or progression to fibrosis in individuals with chronic HCV infection were observed.[139]

In a study with a different vaccine candidate,[140] a chimpanzee was immunized with insect cell–derived recombinant E1 and E2 derived from HCV strain N2 and a peptide spanning the E2 HVR1 region from HCV strain 6. The two envelope proteins, which lacked the C-terminal transmembrane anchors, were expressed and purified separately. The HVR1 peptide was conjugated to keyhole limpet hemocyanin and immunizations were performed with Freund adjuvant. The conclusion, derived from a series of immunizations and challenges in the same animal with HCV strain 6, was that sterilization against infection was dependent on high anti-HVR1 antibody titers rather than total anti-E2 or anti-E1 titers.[140,141] The outcome of challenging with other viral strains was not reported, however.

In a more recent study,[142] the immunogenicity of E1 and E2 as separate proteins was assessed in chimpanzees using recombinant E1 and an HVR1-deleted form of E2 produced in human Vero cells (HCV 1b BE11 strain). After vaccination with either protein adjuvanted with alum, immunization of chimpanzees with either E1 or E2 alone induced antigen-specific T-helper cytokines of similar magnitude. Unexpectedly, the capacity to neutralize HCVpp in vitro was observed only with serum from animals vaccinated with E1. Furthermore, only E1-vaccinated animals exposed to a different HCV-1b inoculum (strain J4) were protected from viral persistence.

The E1/E2 heterodimer is generally considered to be a more native reflection of the HCV virion than either ectodomain alone.[143] Consequently, full-length E1/E2 heterodimers have long been considered and evaluated as candidate HCV vaccine antigens. A vaccine consisting of the recombinant E1/E2 heterodimer derived from mammalian cells has been tested extensively for efficacy in chimpanzees (Table 26.2).[144–148] Combined with oil/water-based adjuvants, this vaccine elicited antienvelope antibodies as well as T-helper cell responses to E1 and E2 in this animal model. When the vaccinated animals were challenged experimentally with homologous viral inocula, the highest responding animals (in terms of anti–E1/E2 antibody titers) were completely protected against infection. Using sensitive reverse transcription–polymerase chain reaction assays, no viremia was detected in serum or liver samples at any time after challenge in these "sterilized" animals. This apparent sterilizing immunity correlated directly with anti-E2 antibody titers that prevent the binding of E2 or the virus itself to CD81.[149] Furthermore, although lower-responding animals became infected, the majority underwent an abortive acute infection that did not result in the persistently infected carrier state.[144,147] Overall, these data showed that the progression rate to chronic infection was significantly lower in vaccinees than in unimmunized control animals.[145] These pioneering studies provided the first data supporting the feasibility of a vaccine against HCV because they indicated the capability of recombinant envelope glycoprotein immunization to either elicit sterilizing immunity or to prevent the progression to chronic infection following an acute, transient infection after viral challenge.

This work was subsequently extended to address the key question of vaccine protection against challenge with a different viral strain of the same genotype. (The vaccine strain, HCV-1, and the challenge strain, HCV-H, are both members of the 1a genotype that predominates in the United States). Although none of these animals were sterilized against this heterologous viral challenge, the majority failed to develop into persistent carriers of the virus, unlike the situation with control unvaccinated animals and for human infections (see Table 26.1).[145] Protection against viral challenge correlated with the vaccine-induced anti–E1/E2 responses. Importantly, antisera from several of the immunized chimpanzees were shown to exhibit in vitro cross-neutralizing activity.[150] Based on the encouraging preclinical data, a clinical development program was started aimed at assessing tolerability and immunogenicity of the E1/E2 complex purified from Chinese hamster ovary cell lines and formulated with the oil/water M59 adjuvant.[151,152]

Strong T-helper cell responses were elicited in the human volunteers along with substantial anti–E1/E2 antibody titers that were similar to those elicited in vaccinated and protected chimpanzees. Additional analyses showed that most vaccinees developed antibodies that could neutralize the infectivity of HCVpp bearing envelope glycoproteins derived from the homologous 1a strain, HCV-1.[151] Moreover, it was recently shown that antisera from selected vaccinated individuals—although with varying efficacy—were capable of neutralizing

TABLE 26.2 Clinical-Stage Prophylactic and Therapeutic Vaccine Candidates

Vaccine	Efficacy	Stage
PROPHYLACTIC VACCINE CANDIDATES		
Chiron/Novartis: Recombinant E1/E2 in oil/water adjuvants[144,151,152]	Protects chimpanzees against chronic infection[144]	Phase I[151,152]
Okairos/GlaxoSmithKline: Ad6/electroporated DNA prime/boost[186] Chd3NSmut/MVA-NSmut (chimpanzee adenovirus/MVA prime/boost)[188]	Protected chimpanzee from acute or chronic infection following heterologous viral challenge[186] Broad $CD4^+$ and $CD8^+$ T-cell response[188,190]	Phase II[178]
IMMUNOTHERAPEUTIC VACCINE CANDIDATES		
Innogenetics (T2S-918/InnoVac-C): Alum-adjuvanted E1 glycoprotein[138]	Boosts humoral and cellular immune responses to E1 in healthy volunteers[138] and in chronic hepatitis C patients[139]	Phase II[139] Program stopped as no effects on viremia or fibrosis progression
Intercell AG (IC41): HCV peptide cocktail with polyarginine[165,166]	Designed to boost $CD4^+$ and $CD8^+$ responses to conserved T cell epitopes using novel adjuvant	Phase II in combination with Peg-IFNα[167,169]
Globe Immune (GI-5005): Heat-killed yeast expressing core-NS3 fusion protein[171]	Primes specific $CD4^+$ and $CD8^+$ T cells in mice.[172] Moderate antiviral activity in chronic hepatitis C patients[173]	Phase II in combination with Peg-IFNα[196,197]
Tripep (ChronVac-C): DNA-based vaccination with NS3/4A-expressing plasmid)[175]	Elicits $CD8^+$ T cells that clear liver cells expressing HCV proteins in transgenic mouse model. Small viral load reduction in chronic hepatitis patients[175]	Phase Ib[175]
CIGB-230: Mixture of plasmid expressing HCV structural antigens with a recombinant HCV core protein[176]	Possible amelioration of fibrosis in chronic hepatitis patients, despite no effect on viremia	Phase Ib[177]
Transgene (TG4040): Modified Vaccinia Ankara virus expressing NS proteins (NS3-NS5B)[198]	$CD4^+$ and $CD8^+$ response in chimpanzee; viral load reduction of up to 1.5 $\log_{10}$ in chronic hepatitis C patients[181]	Phase II in combination with Peg-IFNα[182]

HCV, hepatitis C virus; Peg-IFNα, pegylated interferon-α.

chimeric cell culture-derived viruses (HCVcc) expressing the structural proteins of strains representing all seven major HCV genotypes.[153] No further progress in clinical development has been reported for this vaccine candidate.

Expression of a core-E1-E2 gene cassette in insect cells has been reported to result in the generation of 40- to 60-nm viral-like particles (VLPs) resembling the putative HCV virions.[154] After partial purification, insect-cell produced VLPs appeared to be immunogenic in mice[155] and baboons.[156] In addition, these VLPs were shown to induce specific $CD4^+$ and $CD8^+$ cell responses in chimpanzees.[157] Upon HCV challenge with a homologous HCV strain, all four animals became infected but after 10 weeks three of them cleared the virus and one continued to have intermittent viremia with low HCV RNA levels. While an increase in the magnitude of peripheral and intrahepatic T cell and proliferative response against HCV structural proteins was observed, no HCV-specific antibody response was detected. The outcome of challenges with other viral strains, or results of clinical trial using this approach have not been reported. In addition, developmental issues exist for E1/E2 vaccine. Indeed the heterodimer has to be purified as intracellular material from endoplasmic reticulum of mammalian cells, making it difficult to scale up its production.

Recombinant core protein has also been investigated as a potential component of an HCV vaccine based on the following rationale. First, broad HCV-specific $CD4^+$ and $CD8^+$ T-cell responses, including those to the core protein, are associated with recovery from HCV infection.[79,121,125–127] Second, the core protein is the most conserved HCV polypeptide and contains $CD4^+$ and $CD8^+$ epitopes that are highly conserved among the different HCV genotypes, which should therefore facilitate the generation of cross-protective immunity.[158,159] Third, recombinant core protein has been shown to self-assemble into particles[160] with concomitant high immunogenicity in animal models. Through administration of a recombinant *Escherichia coli*-produced HCV core protein formulated as "immunostimulatory complex" (ISCOM) it has been possible to prime strong $CD8^+$ CTL activity (and $CD4^+$ activity) in rhesus macaques.[161] (ISCOMs are particulate antigen delivery systems composed of antigen, cholesterol, phospholipid and saponin, while ISCOMATRIX is a particulate adjuvant comprising cholesterol, phospholipid and saponin but without antigen. The combination of an antigen with ISCOMATRIX is called an ISCOMATRIX vaccine.[162]) Based on the encouraging preclinical data, a Phase I study was performed[163] aimed at the evaluation of the immunogenicity of the HCV core/ISCOMATRIX vaccine in healthy people. Antibody responses were detected in all but one of the participants receiving the vaccine. However, $CD8^+$ T-cell responses were only detected in two of the eight participants receiving the highest dose.[163] The results of this study suggest that the development of a protein-based HCV vaccine capable of priming cross-reactive HCV-specific $CD8^+$ T-cell responses in humans will require further investigation.

Numerous $CD4^+$ and $CD8^+$ epitopes that are conserved among the different HCV genotypes reside within structural and nonstructural proteins.[158,159,164] The inclusion of a multiplicity of these epitopes could facilitate the vaccine-mediated generation of broadly cross-reactive cellular immune responses to the virus, which could then result in the elicitation of cross-protective immunity against different HCV genotypes. One such approach involves the assembly of "HCV polytope vaccines" consisting of a consecutive sequence of these conserved HCV T-cell epitopes[154,155] in the form of a recombinant

polypeptide or DNA vaccine. Focusing the immune response on a collection of highly conserved epitopes that can be presented by diverse human major histocompatibility complex (MHC) class I and class II antigens may optimize the generation of strong, cross-protective immunity and possibly avoid the "dilution" of the immune response to variable, more mutable HCV epitopes. In line with this notion, IC41, a peptide vaccine candidate,[165,166] contains five peptides encoding four HCV specific human leukocyte antigen (HLA)-A2 restricted CTL epitopes and three highly promiscuous CD4+ T-cell epitopes (from the core, NS3 and NS4 proteins) adjuvanted with poly-L-arginine to augment Th1/Tc1 (IFN-γ) responses. The sequences contained within these epitopes are highly conserved in the most prevalent HCV genotypes. The inclusion of poly-L-arginine was shown to be important for the production of functional IFN-γ–secreting T cells in a healthy volunteer Phase I trial.[165] Discouragingly, in the setting of chronic infection this vaccine caused only a moderate drop in viremia that did not correlate with the size of the T-cell response[167,168] and did not prevent virological relapses when used as late add-on to standard Peg-IFNα/ribavirin therapy.[169]

Following a different approach, Houghton and colleagues[145] vaccinated naïve chimpanzees with a yeast-derived fusion polyprotein comprising NS3, NS4, NS5, and core proteins. Following purification and formulation with the ISCOMATRIX adjuvant, a group of five chimpanzees were vaccinated at months 0, 1, and 2 before experimental challenge intravenously with the heterologous 1a strain, HCV-H77, at month 3. Vaccination resulted in the appearance of vigorous HCV multispecific CD4+ and CD8+ T-cell responses in the liver prior to experimental challenge and infection. Following challenge, both acute viremia and hepatitis were significantly ameliorated in comparison with control animals that were similarly challenged. Surprisingly, however, none of the five vaccinees went on to eradicate viremia up to 18 months post-challenge. This result contrasts starkly not only with data obtained with the recombinant E1/E2 heterodimer vaccines, but also with many other vaccine candidates tested in the chimpanzee model in which some vaccinees were always observed to eradicate acute viremia following viral challenge. Although it is difficult to make firm conclusions from a vaccine study involving just five animals, it remains a formal, disturbing possibility that this vaccine may actually have increased the rate of chronicity rather than decreasing it.[145]

The use of whole heat-killed recombinant *Saccharomyces cerevisiae* yeast that has been genetically modified to express targeted molecular immunogens (tarmogens) has also been assessed, but only in a therapeutic setting. Tarmogens are sensed by dendritic cells and stimulate both innate and specific cellular immune responses.[170] This technology has been used for the design of an HCV vaccine candidate (GI-5005) that encodes a core-NS3 fusion.[171] GI-5005 demonstrated robust immunogenicity in preclinical in vitro and in vivo models.[172] Disappointingly, in patients with chronic hepatitis C, GI-5005 monotherapy displayed only a marginal antiviral efficacy[171,173] and was not tested preclinically or clinically in a prophylactic setting.

Vaccines Based on Hepatitis C Virus Complementary DNA

Intramuscular or intradermal injection of recombinant DNA plasmids has been shown to result in effective protein expression in vivo and in the induction of an immune response in small animal models. This initial success, however, has not yet been translated into humans as the efficiency of DNA uptake and gene expression appear to sharply decrease with the size of the immunized organism.

In the chimpanzee model, only one small DNA vaccine study has been reported to date.[174] To optimize the immunogenicity, the recombinant construct was designed by fusing the ectodomain of E2 (aa 384–715) to the C-terminal, transmembrane region of CD4, to favor sequestration of the encoded E2 glycoprotein to the outer cell surface. DNA was administered using a bioinjector into the quadriceps at weeks 0, 9, and 23, followed by experimental challenge with homologous monoclonal virus 3 weeks later. Importantly, both vaccinees resolved their acute infections quickly, whereas the control, unvaccinated animal became chronically infected following viral challenge. Although humoral and cellular immune responses to the vaccine were observed in only one animal out of two, both vaccinated animals displayed lower viral titers following challenge and developed hepatitis earlier than control animals consequent to primed immunity.[174]

As of this writing, two DNA vaccine candidates have entered human experimentation, both limited to a therapeutic rather than a prophylactic setting. The first candidate, ChronVac-C, is based on a codon optimized HCV nonstructural NS3/4A DNA-gene expressed under the control of the cytomegalovirus immediate early promoter. The vaccine has entered a Phase I/IIa clinical trial in HCV genotype 1–infected patients to assess safety, immunogenicity, and therapeutic potential.[175] Following dosing of the vaccine by intramuscular electroporation, two patients had moderate viral load reductions and development of HCV-specific T-cell responses that coincided with the time of the viral load reductions.[175] However, there are no published data on the effectiveness of ChronVac-C as prophylactic vaccine.

A different group vaccinated chronically HCV infected patients in a Phase I study with a therapeutic vaccine containing a combination of a DNA plasmid expressing HCV structural antigens and recombinant HCV core protein[176] (CIGB-230). The patients, all nonresponders to previous antiviral treatment, received six doses of vaccine by intramuscular injection at 4-week intervals. nAbs directed against heterologous viral pseudoparticles and HCV core-specific T cell responses developed in the majority of patients. Despite persistent viremia, an improvement in liver histologic findings, with a reduction in fibrosis, was reported for nearly half of the vaccinated patients,[177] making the observed result difficult to interpret.

Hepatitis C Virus Vaccines Delivered by Viral Vectors

The use of a defective or attenuated viral vector to deliver vaccines can offer improved immunogenicity as a result of a wide tropism of the vector, including that of antigen-presenting cells, as well as being able to stimulate innate immune responses that, in turn, stimulate adaptive immune responses to the encoded vaccine antigens. Furthermore, the use of a vector that is already used as a vaccine itself offers a potential advantage with respect to safety, manufacturing, and distribution issues. Finally, many vectors allow the insertion of large inserts or multiple genes or both, thus facilitating the induction of a broad, cross-protective immune response, particularly useful against heterogeneous agents such as HCV.

Modified vaccinia Ankara (MVA) is an attractive vaccine vector because of an excellent safety record and pronounced immunogenicity. In particular, MVA is particularly effective as a boosting vector, broadening and increasing the magnitude of preexisting T-cell responses.[178] A DNA prime/MVA boost approach was reported by Rollier et al.[179] Briefly, they vaccinated chimpanzees with DNA plasmids encoding HCV core-E1-E2 and NS3 and subsequently boosted with recombinant MVA encoding core-E1-E2 and NS3 genes. This DNA

primed-MVA boosted immunization induced strong Th1- and Th2-cytokine responses together with strong HCV specific CD8+ T-cell response as well as high HCV-specific antibody titers. A subsequent challenge with a heterologous virus demonstrated that the DNA primed-MVA boosted immunization was associated with control of HCV viral levels in the acute stage. However, despite control of HCV in plasma and liver in the acute period, three of four vaccinated animals developed persistent infection.

TG4040 is a recombinant polyantigenic T-cell vaccine based on MVA that has advanced in clinical trials as a therapeutic vaccine. TG4040 encodes the HCV NS3, NS4, and NS5B proteins. It was originally tested in HLA31 class I transgenic mice and shown to produce strong long-lasting cross-reactive HCV-specific $CD8^+$ and $CD4^+$ T cells.[180] These responses could be readily boosted by an additional dose of vaccine given after 6 months, indicating that the vaccination protocol was able to induce effective memory T-cell responses. The safety and biological activity of TG4040 as a candidate therapeutic vaccine has been evaluated as monotherapy in a Phase I study in 15 treatment-naïve HCV patients.[181] Of 15 patients, six received three weekly injections of vaccine and the remaining patients received a fourth injection at 6 months. Vaccine-induced HCV-specific cellular immune responses were observed in five of the 15 patients. A significant decrease in circulating levels of HCV RNA was observed in eight patients. The greatest viral load reductions were observed in patients who had achieved the strongest vaccine-specific T-cell responses. TG4040 was investigated as candidate therapeutic vaccine in further clinical studies in combination with Peg-IFNα and ribavirin. TG4040 in combination with Peg-IFNα/ribavirin was relatively well tolerated, but no significant advantages where observed versus the standard of care (i.e., Peg-IFNα/ribavirin alone) in terms of number of patients who achieved a sustained virological response.[182]

Another group has used a replicating *Vaccinia* virus expressing HCV structural and nonstructural genes to immunize four naïve chimpanzees. Following experimental challenge with homologous virus, all four vaccinees resolved their acute infections without progressing to the carrier state, whereas two control animals developed chronic infection after the same challenge,[183] providing further support for the ability of prophylactic vaccination to prevent the development of the chronic, carrier state.

Adenoviral (Ad) vectors expressing HCV proteins have also been considered as prophylactic or therapeutic (or both) T-cell vaccine candidates. Ad vectors are particularly attractive for this approach because of their superior potency at T-cell priming in primates and humans.[184] The main potential drawback of Ad vectors is preexisting immunity to the vector, which can lead to its clearance before a response is elicited to the inserted immunogen. However, this issue can be overcome in part by use of low-prevalence serotypes or by using chimpanzee adenovirus as the gene vehicle.[185]

Proof-of-concept chimpanzee studies were performed in which naïve animals were first immunized twice with a replication-defective Ad6 vector encoding for the whole HCV NS region (NS3 to NS5B of genotype 1b, BK strain).[186] Subsequently, boosting of immune responses was achieved by repeated electroporation of a naked DNA vaccine harboring the same HCV sequence. This regimen elicited HCV-specific and multispecific $CD4^+$ and $CD8^+$ T cells in four of the five vaccinees. Following a delayed experimental challenge with a heterologous 1a strain, these four animals showed a clear amelioration of acute viremia and hepatitis followed by eradication of viremia. In contrast, the weak responder to the vaccine exhibited viremia and hepatitis similar to that shown in control, unvaccinated animals and this vaccinee became a chronic carrier of the virus, as in the case of four of the five control, unvaccinated animals challenged with the same 1a viral strain (Fig. 26.4).

Based on these initial encouraging data, human Ad6 and chimpanzee adenovirus 3 expressing the HCV BK NS3- NS5B gene cassette with loss-of-function mutations in the HCV polymerase gene[187] (Ad6-NSmut- and ChAd3-NSmut, respectively) were tested in a Phase I clinical trial in healthy volunteers.[188] Ten patients receiving the highest dose of Ad showed robust, multispecific and cross-reactive T-cell responses. However, boosting with heterologous Ad was not as effective as observed in preclinical species, presumably because of the high level of cross-reactive antibody against the Ads in humans.[188,189] A prime-boost regimen based on ChAd3NSmut boosted with a MVA carrying the same HCV sequence (MVA-NSmut) was assessed in a Phase I clinical trial in healthy volunteers.[190] The results of this trial showed that HCV-specific T cells induced by ChAd3 are optimally boosted with MVA, and generate very high levels of both CD8+ and CD4+ HCV-specific T cells targeting multiple HCV antigens. Sustained memory and effector T-cell populations were generated, and T-cell memory evolved over time with improvement of proliferation and polyfunctional properties after the heterologous MVA boost. This ChAd/MVA vaccine regime has progressed to a Phase II clinical trial enrolling an HCV-naïve IVDU populations at high risk for infection (ClinicalTrial.gov Identifier: NCT01436357). This study, sponsored by the National Institute of Allergy and Infectious Diseases (NIAID), is set up to assess whether this regimen can enhance the rate of spontaneous resolution of acute HCV infection.

FUTURE DIRECTIONS

Several years ago, prospects for effective vaccination against HCV were considered remote because of the high propensity of this virus to promote chronic persistent infections, evidence that convalescent humans and chimpanzees could be readily reinfected following reexposure, and the considerable genetic heterogeneity of this virus. Today, we can be more optimistic for several reasons. First, we now know that the spontaneous eradication of virus occurs in a significant fraction of acute infections and is associated with specific immune responses to the virus. Recapitulation of such immune responses by appropriate vaccination, therefore, becomes a realistic option. Second, clear evidence for some natural immunity has emerged in humans and chimpanzees. These studies have shown that convalescent humans and chimpanzees are protected from chronic infection against reexposure to virus in the majority of cases, even against divergent viral strains.

So far, the most promising approaches to HCV vaccination include the use of recombinant envelope proteins to elicit nAbs and $CD4^+$ T cells[144–148] and defective or attenuated viral vectors to enhance priming of humoral and cellular ($CD4^+$ and $CD8^+$) immune responses to multiple HCV nonstructural gene products expressed by the vector.[186,188,190] Ideally, any future HCV vaccine should elicit broad humoral (anti–E1/E2) and cellular immune responses. Several prophylactic or therapeutic vaccine candidates have reached human clinical trials (see Table 26.2) and more approaches are in preclinical development, including for example a heterologous prime-boost immunization with Ad vectors expressing E1-E2 glycoprotein followed by recombinant E1/E1 heterodimer.[191] With the availability of a system to propagate HCV in vitro, the possibility of using an inactivated HCV vaccine has also started to be explored.[192] In the future, it will be important to better determine correlates of protection, duration of memory of vaccine-induced protection, and the ability to cross-protect against diverse genotypes and to identify optimal vaccine formulations.

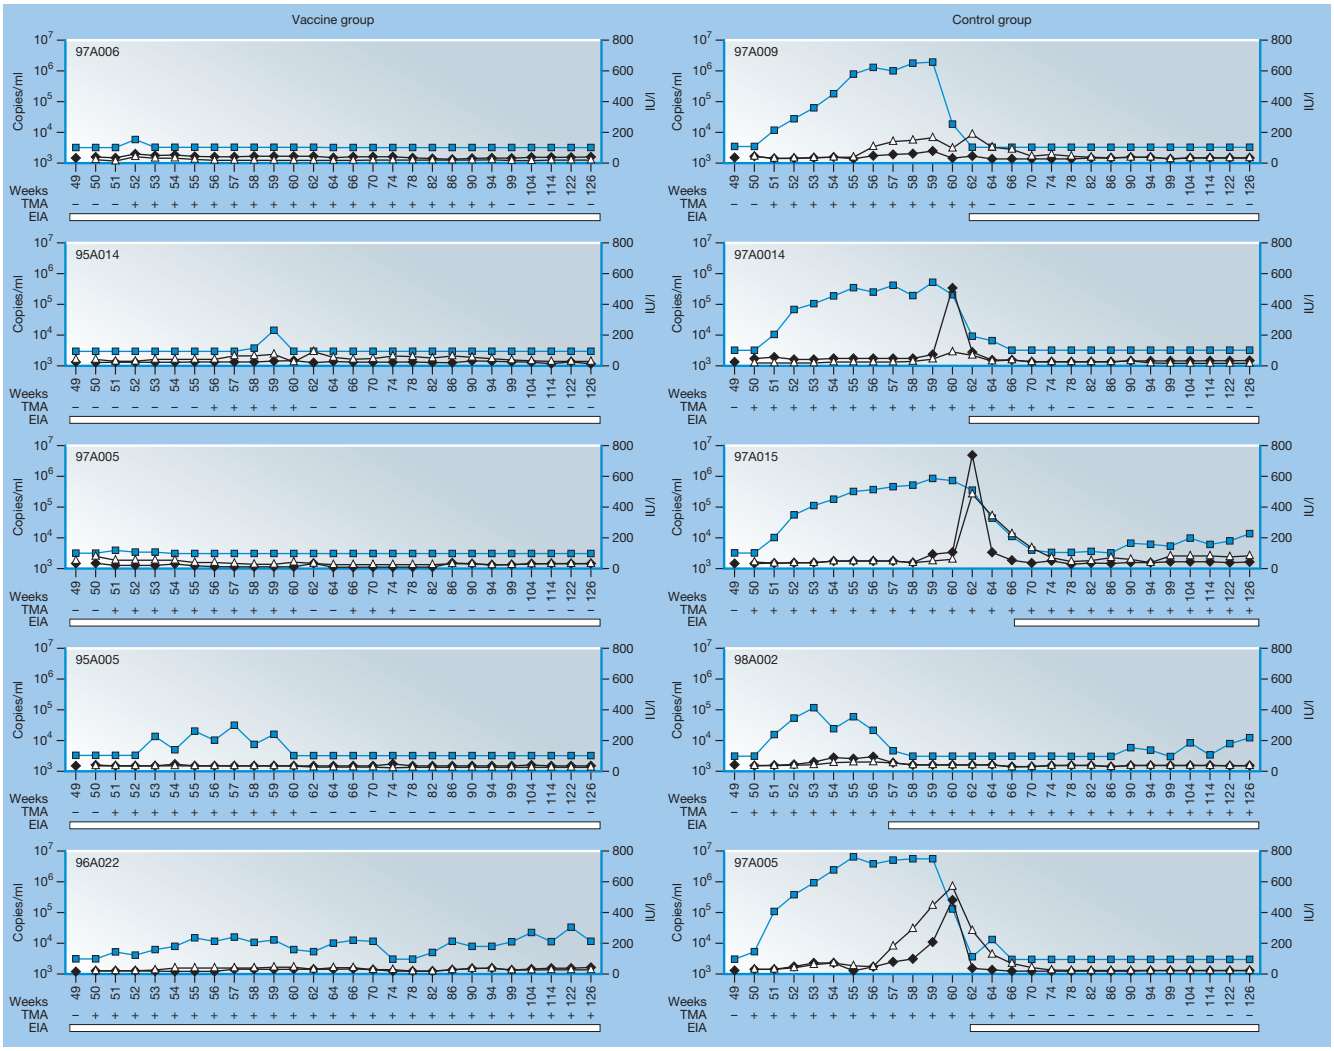

Figure 26.4. Kinetics of hepatitis C virus (HCV) RNA, alanine aminotransferase (ALT), γ-glutamyl transpeptidase (GGT), and HCV-specific antibody response in vaccinated and control chimpanzees. The course of acute HCV infection (18-month follow-up) is shown for vaccinated *(left panels)* and control *(right panels)* chimpanzees. *Blue squares* represent the kinetics of HCV RNA measured in plasma samples using a branched DNA assay, and *black diamonds* and *white triangles* represent kinetics of ALT and GGT liver enzymes, respectively. Data points at T = 49 weeks represent the average ALT and GGT values calculated from 10 time points before challenge. Results of the qualitative HCV RNA assay (TMA [transcription-mediated amplification]; detection limit: 50 copies/mL) are reported as + or – at the bottom of each graph. Anti-HCV seroconversion is indicated by a white bar across the bottom of each graph. *(From Folgori A, Capone S, Ruggeri L, et al. A T-cell HCV vaccine eliciting effective immunity against heterologous virus challenge in chimpanzees.* Nat Med. *2006;12:190–197.)*

Some issues surrounding clinical and preclinical development of a prophylactic HCV vaccine, however, remain to be resolved. A serious challenge to the development of a prophylactic HCV vaccine is represented by the fact that it is no longer possible to use the chimpanzee model in HCV research in Europe and in the United States. Thus, more research is needed to improve and validate small animal models of HCV infection that could be used to assess the efficacy of vaccines and to define the immune correlates of protection preclinically. Moreover, because of the relatively low incidence of new infections in the developed world, it is challenging to identify the appropriate at-risk population to enroll in an efficacy trial for a preventive HCV vaccine. Posttransfusion infection risk has been eliminated by donor screening, and other high-risk groups suitable for efficacy testing can have inherent difficulties such as lack of compliance (IVDUs), low incidence of infection (healthcare workers), lack of supporting infrastructure (in many developing countries where incidence of infection is high), or ethical issues (in prisoner populations where prevalence and incidence of infection are both high). Despite these difficulties, the first double-blinded, randomized, placebo-controlled trial of a prophylactic HCV vaccine in IVDUs is underway as of this writing in Baltimore.[178] Successful completion of this trial will determine whether a T-cell response primed with nonstructural HCV proteins is sufficient to reduce rates of chronic disease following acute infection. Moreover, it will also provide important support that vaccine efficacy trials of this kind are feasible. Taken together, the prospect of an HCV vaccine appears today as a realistic objective for the near future. Considering that chronic infection with HCV is one of the most common causes of primary liver cancer, this would mean that an important cause of global morbidity and mortality would be controlled and—possibly—eradicated.

27 Hepatitis E Vaccines

Harry R. Dalton, Jacques Izopet, and Ningshao Xia

Hepatitis E was not recognized as a distinct disease until 1980, when waterborne epidemics of hepatitis in India, previously thought to have been caused by hepatitis A virus (HAV), were shown to have occurred in persons who were already immune to HAV.[1,2] Three years later, the etiologic agent (tentatively designated as "epidemic non-A non-B hepatitis," or "enterically transmitted non-A non-B hepatitis") was transmitted to a volunteer and to cynomolgus monkeys.[3] The viral genome was cloned and sequenced in 1990,[4] and the virus was renamed hepatitis E virus (HEV) with four genotypes (genotypes 1 to 4, HEV1 to HEV4). In retrospect, it is probable that most waterborne clinical hepatitis occurring in developing countries in the first half of the 20th century or earlier was hepatitis E and not hepatitis A.[5]

For many years, hepatitis E was thought to be largely restricted to endemic developing countries, and only of clinical relevance in developed countries in returning travelers. Over the last few years this notion was shown to be mistaken, as hepatitis E is endemic in many developed countries. In such settings, it is largely a porcine zoonosis caused by HEV genotypes 3 and 4 (HEV3 and HEV4), and human infection is surprisingly common.[6]

CLINICAL DESCRIPTION

Acute Hepatitis E

In developing countries hepatitis E is caused by HEV1 and HEV2, and mainly affects young adults. Infections are sporadic, with occasional large outbreaks involving hundreds or thousands of cases. The incubation period is approximately 40 days, and infections may range from inapparent to fulminant hepatitis, with an overall reported mortality of approximately 1%. Clinical signs and symptoms may include malaise, anorexia, abdominal pain and tenderness, nausea, vomiting, fever, and jaundice. Biochemical evidence of hepatitis includes elevated serum levels of liver enzymes and bilirubinemia; these generally return to normal within 6 weeks of onset.[7] The clinical features of hepatitis E in developed countries are similar to those seen in endemic developing nations, and are indistinguishable from those observed in any form of acute viral hepatitis. However, there are some important differences (Table 27.1), the most notable of which is that acute hepatitis E in developed countries is commonly asymptomatic and clinical illness is mostly observed in middle aged and elderly males.[6–10]

Chronic Hepatitis E

Chronic infection with HEV occurs in the immunosuppressed, including transplant recipients, patients with hematological malignancy, and individuals with HIV.[11–14] To date, chronic infection has only been documented with HEV3. The best characterized population is transplant recipients in developed countries, where up to 60% of such patients develop chronic infection after exposure to HEV. Chronically infected patients usually have no symptoms, are not icteric, and have modestly elevated serum alanine aminotransferase (ALT) (100–200 IU/L). Untreated, rapidly progressive chronic liver disease ensues, with 10% becoming cirrhotic within 2 years.[13]

Hepatic Complications

In developing countries, the mortality of acute hepatitis E is approximately 1%. This is largely from acute hepatic failure in pregnant women with associated fetal loss.[7] Acute liver failure is commonly seen in patients with underlying chronic liver disease, with an associated mortality of up to 70%.[15] In developed countries, the mortality rate ranges from 3% to 10%. Most deaths occur from acute liver failure in older males with underlying chronic liver disease. These data are an overestimate of the population based mortality, as asymptomatic cases (>90% of cases) were mostly not included in these hospital-based case series. Of transplant patients with untreated chronic infection, 10% are cirrhotic within 2 years. In such patients chronic liver failure requiring (re)transplantation commonly develops, and a number of such cases have died.[7]

Extrahepatic Complications

A number of extrahepatic manifestations have been described in association with hepatitis E, including acute pancreatitis,[16] thrombocytopenia,[8] cryoglobulinemia,[17] autoimmune thyroiditis,[18] acute myocarditis,[8] and a range of neurologic injuries.[19] Such complications have been described in both acute and chronic infections and in developing and developed countries. Neurologic complications are the most commonly described, with 8% of patients presenting with a neurological illness in one case series.[8]

The most commonly described neurologic syndromes are Guillain-Barré syndrome (GBS), neuralgic amyotrophy (NA), and meningoencephalitis. Recent studies from Europe of cohorts of GBS and NA patients showed that 5% and 10%, respectively, had evidence of acute hepatitis E (HEV3) at the start of their neurological illness.[20,21] In such patients the hepatitis was mild or asymptomatic and the neurologic symptoms and signs dominated the clinical picture. The mechanisms of neurologic injury are unknown. In some cases HEV RNA has been recovered from the cerebrospinal fluid. In one patient, HEV quasispecies compartmentalization was documented, with differences in HEV RNA found in the virus isolated from the blood and HEV isolated from the cerebrospinal fluid.[22] This suggests that, at least in some cases, HEV may be directly neurotropic.

VIROLOGY AND PATHOGENESIS

HEV is a spherical nonenveloped virus that is 27 to 34 nm in diameter. The virus circulating in the blood during acute or chronic infection is associated with lipids and is distinct from the nonenveloped virions shed in feces.[23,24] The HEV genome is a positive-stranded RNA of approximately 7.2 kb. The genome consists of a short 5′ noncoding region that is capped with 7-methylguanosine, three open reading frames (ORFs), and a short 3′ noncoding region that is terminated by a stretch of adenosines.

TABLE 27.1 Comparison of Hepatitis E Virus Genotypes 1 and 2 With Genotypes 3 and 4

	HEV 1 and 2	HEV 3 and 4
Geographical distribution	Asia (HEV1) Africa (HEV1 and HEV2) Mexico (HEV2)	Worldwide, including developed countries (HEV3) Japan, China, Europe (HEV4)
Source of infection	Obligate human pathogen	Zoonotic Blood supply
Route of infection	Oral-fecal via infected water	Oral via consumption of infected pork Parenteral, iatrogenic (blood supply)
Risk of infection from blood supply	Low	High
Outbreaks	Yes	No
Intrafamilial spread	No	No
Clinical attack rate	1:2	<1:10
Demographics	Mainly affects young adults	Mainly affects older men (median age, 63 years; M:F = 3:1)
Chronic infection	No	Yes, in the immunocompromised Rapidly progressive liver disease if untreated: 10% are cirrhotic within 2 years Viral clearance is usually achieved with a 3-mo course of ribavirin monotherapy
Can second HEV infections occur?	Yes; not well documented	Yes Not well documented for HEV3 Well documented in HEV4; more likely in women who have a milder hepatitis than that seen in primary infections
Clinical course	Self-limiting hepatitis in most	Self-limiting hepatitis in most
Pregnancy	Mortality rate of 25%	Increased mortality rate not seen
Underlying chronic liver disease	Increased mortality rate	Increased mortality rate
Neurological sequelae	Yes; poorly documented	Yes

HEV, hepatitis E virus.

ORF1

ORF1 encodes a nonstructural protein of approximately 1700 amino acids containing several functional domains.[25] These include a methyltransferase/guanyltransferase responsible for capping the viral genome, a papain-like cysteine protease, a macrodomain, a helicase exhibiting RNA 5′ triphosphatase (NTPase), RNA unwinding activity, and an RNA-dependent RNA polymerase. A variable region containing a proline-rich hinge, called the polyproline region (PPR), is located between the protease and the macrodomain. The PPR is an intrinsically disordered region where segments of human gene have been identified in vitro and in vivo.[26–30] This region could be involved in virus adaptation to the host.[31,32] A greater heterogeneity of PPR quasispecies at the acute phase of HEV infection was found in immunocompromised patients who develop chronic infection than in individuals with resolving infection.[26]

ORF2

ORF2 encodes the viral antigen corresponding to the capsid protein of 660 amino acids which form the capsid through dimerization.[33] Each monomer contains a shell domain (S), a middle domain (M), and a protruding domain (P).[33–35] During assembly, capsid monomers self-assemble into dimers and subsequently in decamers that encapsidate the viral RNA. The virion-sized capsid is a T=3 icosahedral capsid while the recombinant HEV capsid protein can self-assemble into a T=1 virus-like particle (VLP) that retains the antigenicity of the native HEV virion.[36] Immunological and structural studies of the capsid protein have contributed to the hepatitis E vaccine development.[37,38] A high heterogeneity of HEV quasispecies in the region encoding the M and P capsid domains was associated with evolution of chronic HEV infection in immunocompromised patients.[39]

ORF3

ORF3 encodes a small protein of 133 or 114 amino acids that is involved in the release of virus from cells. The ORF3 protein interacts with the capsid protein in a manner dependent upon phosphorylation of ORF3 at Ser80.[40] The ORF3 protein also contains a PSAP motif that specifies interactions with TSG 101, a host ESCRT-I protein involved in the budding of many enveloped viruses.[41,42]

Taxonomy

HEV belongs to the *Hepeviridae* family (International Committee on Taxonomy of Viruses). The classification is still evolving because of the continuing increase in the number of novel strains of the virus in various animal species and the availability of full-length genome sequences. There are several genotypes found in mammals, birds, and fish. A classification that divides the *Hepeviridae* family into two genera, *Orthohepevirus* and *Piscihepevirus*, was recently proposed.[43] Within the *Orthohepevirus* genus, four species have been designated that infect mammalian species (*Orthohepevirus A*, *Orthohepevirus C*, and *Orthohepevirus D*) and avian species (*Orthohepevirus B*). The *Orthohepevirus A* species contains HEV strains that are able to infect humans and are divided into four major genotypes (HEV1 to HEV4). HEV1 and HEV2 have been recovered only from humans whereas HEV3 and HEV4 have been recovered principally from humans and swine.[44] Other genotypes, including strains from rabbits,[45,46] wild boars,[47,48] and camels,[49]

also belong to *Orthohepevirus A* species. All genotypes of HEV infecting humans belong to the same serotype. The *Orthohepevirus B* (infecting chicken), *Orthohepevirus C* (infecting rat and ferret), and *Orthohepevirus D* (infecting bat) species and the *Piscihepevirus* (infecting trout) genera contain strains that apparently do not infect humans.[50]

DIAGNOSIS

Hepatitis E is diagnosed by detecting viral RNA (reverse transcription–polymerase chain reaction [RT-PCR]) in the serum or feces or both during the incubation period or early acute phase of disease or, more commonly, by demonstrating anti-HEV antibodies of the immunoglobulin (Ig) M class or a rising titer of anti-HEV antibodies of the IgG class in the serum during the late acute phase or convalescent phase of the illness.[51] Commercial enzyme-linked immunosorbent assays for detecting such antibodies have been developed. They vary considerably in sensitivity and specificity,[52] and are not licensed in the United States.

TREATMENT

Acute hepatitis E is usually a self-limiting illness and requires no treatment. Patients with acute hepatitis E and underlying chronic liver disease have a poor prognosis,[53,54] and a small number of such patients have been treated successfully with ribavirin.[55] Patients with chronic infection (defined as persisting viremia >3 months) should be treated. In transplantation recipients, the first step is to reduce the level of immunosuppression, if possible. This achieves viral clearance in approximately 30% of transplantation recipients. If this is not possible or unsuccessful, then a 3-month course of ribavirin monotherapy should be given. This achieves a sustained viral response in approximately 85% of cases. The duration of therapy should be longer if HEV RNA is detected in the stool at the end of 3 months of treatment.[56]

EPIDEMIOLOGY

Incidence, Prevalence, and Modes of Transmission

In developing countries, HEV1 and HEV2 are transmitted via contaminated water as a consequence of inadequate sanitation. In addition to sporadic cases occurring throughout the year, many small and occasional large-scale outbreaks also occur.[57] Outbreaks are frequent in Asia and Africa and result in high morbidity and mortality particularly when occurring in refugee camps. Every year an estimated 20 million HEV infections occur globally, resulting in more than 3 million clinical cases and 70,000 deaths.[58] Pregnant women are particularly vulnerable with the case-fatality rate reaching 30% in the third trimester of pregnancy.[59] HEV can be transmitted to the fetus resulting in an estimated 3000 stillbirths per year.[58] Anti-HEV seroprevalence can reach 80% and increases dramatically between the ages of 15 and 30 years except in Egypt where children less than 10 years of age have high levels of previous exposure to HEV.[60] The incidence of infection varies between and within countries and over time.[60,61]

In developed countries, although some sporadic cases of hepatitis E are caused by HEV1 and HEV2 in persons returning from Asia and Africa, most of the cases are caused by HEV3 (worldwide) or HEV4 (mainly in Asia) that are transmitted locally from an animal reservoir. In France, since the optimization of diagnostic tests and adaption of testing algorithms in 2012, 99% of HEV infections reported by the National Reference Center are autochthonous. An important route of infection is by consumption of uncooked or poorly cooked pork meat or game meat (wild boar, deer, rabbit).[7] It has been demonstrated that cooking temperatures of 71°C for 20 minutes are required to fully inactivate the virus.[62] Several studies from the United Kingdom and France demonstrated HEV contamination in food containing raw pork liver with frequencies ranging from 3% to greater than 30%, depending on the categories of products.[63–67] Direct contact with HEV-infected animals is another possible route of transmission of HEV. Prevalence of anti-HEV antibodies is higher in veterinarians, swine handlers and forestry workers, than in other population categories in different countries.[68–70] The waterborne route of infection may also be important for HEV3 and HEV4. HEV3 has been detected in untreated waste water, swine manure, swine slurry storage facilities, and river water.[60] HEV3 also has been detected in shellfish, and an outbreak on a cruise ship was caused by the consumption of mussels.[71] Finally, transfusion-transmitted HEV infection has been documented in Japan, the United Kingdom, and France.[72–80] Plasma, including amotosalen-treated plasma, platelets, and red blood cells can transmit HEV, but no transmission by plasma-derived products has yet been documented.

Anti-HEV seroprevalence in industrialized countries ranges from 10% to more than 50% using the same assay. In European blood donor populations, seroprevalence is 12% in England,[81] 27% in the Netherlands,[82] 29% in Germany,[83] and 52% in southwestern France.[66] Variations of seroprevalence are seen in differing geographic locations in the same country for unknown reasons. A common characteristic is an increasing seroprevalence with age indicating cumulative exposure to the virus during life.[66] The seroprevalence of HEV in the general population was 23% in China during the period 2005 to 2006,[84] and in another study from China, seroprevalence was 38% in the general population and 48% in swine farmers.[85] The seroprevalence was 6% in the United States during period 2009 to 2010.[86,87] However, because of the relatively low sensitivity of serological assays used, the true HEV seroprevalence in these countries is probably underestimated. The annual incidence of HEV infection in developed countries is 0.2% in the United Kingdom,[81] 0.7% in the United States,[88] 2% to 3% in southern France,[89,90] and 4.3% in China.[91] The frequency of HEV infections in minipools of plasma (24 to 96 samples) from blood donations is 1 in 1430 in China,[92] 1 in 2200 in France,[93] 1 in 2700 in the Netherlands,[82] 1 in 1240 to 1 in 6925 in Germany,[94–96] and 1 in 2848 to 1 in 14,520 in the United Kingdom (Tables 27.2 and 27.3).[77,97,98] Based on these data, each year there are more than 100,000 infections in France and in the United Kingdom, and more than 2 million infections in the United States.

Risk Groups

In developing countries, the group at general risk of infection is young adults. Those at increased risk of adverse outcome are pregnant females and individuals with underlying chronic liver disease. In industrialized countries, the groups at general risk are middle-aged and elderly males and recipients of blood products. Those especially at risk include the immunosuppressed and patients with chronic liver disease.

Significance as a Public Health Problem

The global burden of disease associated with HEV is unknown. An estimate from 2005 suggested there were 20 million infections during that year (see "Incidence, Prevalence, and Modes of Transmission" above[58]). However, this estimate did not include the impact of HEV in industrialized countries nor the

HEV, hepatitis E virus; IgG, immunoglobulin G.
"Highly endemic" has been arbitrarily defined as an incidence of HEV viremia in blood donors >1:2500 and/or seroprevalence of >20%. Seroprevalence studies have been restricted to those employing the highly sensitive and partially validated Wantai anti-HEV IgG assay, as other assays have shown to have very poor sensitivity. HEV RNA was genotype 3 in all cases, except where stated.
[a]Deconstructed solvent-detergent–treated minipools.
[b]Of those with HEV viremia, 57% were genotype 1 and 43% were genotype 4.

[c]Only 3237 donors tested.

emerging clinical phenotype of HEV-associated disease (e.g., neurological complications) and is likely to be an underestimate. The prevalence of chronic infection in European transplant centers is 1% to 2%.[7]

PASSIVE IMMUNIZATION

While low preexisting anti-HEV antibodies (<7 WHO-units/mL) seemed not to protect HEV reinfection in immunocompromised organ recipients,[89] individuals with naturally acquired anti-HEV antibodies are protected from hepatitis E reinfection and severe hepatitis E in endemic areas.[99–101] Repeated challenges, passive immunoprophylaxis and antibody neutralization studies in monkeys have shown that antibodies to HEV can protect against HEV infection and hepatitis.[102–105] However, immunoglobulin prepared in endemic countries failed to protect, probably because of the relatively low titers of anti-HEV.[106] Whether an immunoglobulin preparation with high titer of anti-HEV could be protective remains to be studied.

ACTIVE IMMUNIZATION

Active immunization is usually achieved by prophylactic vaccination, but the choice of antigen is crucial in terms of vaccine efficacy. For example, HEV proteins encoded by ORF1 are enzymes and other cell-modulation effectors involved in HEV life cycle. Thus, the antibody against an ORF1 protein would not recognize HEV during viral infection and might only protect through cellular immune mechanisms.[107,108] Antibody to the ORF3 protein is nonneutralizing in cell models and immunization of nonhuman primates with recombinant ORF3 provides only partial protection.[109,110] In contrast, the capsid protein encoded by ORF2 appears to be the ideal candidate for a hepatitis E vaccine. Antibodies to plasmid open reading frame 2 (pORF2) cross react with all four serotypes.[111]

Antibodies to the capsid protein neutralize HEV in vitro and in vivo and protect nonhuman primates against hepatitis E and HEV infection.[110,112,113]

When the existing hepatitis E vaccines were developed there was no robust cell culture for HEV available. Although HEV cell culture system has recently been established to produce some specific strains of HEV isolated from chronic hepatitis E patients,[114–116] the virus yield is still limited for the development of attenuated or inactive vaccine. For this reason a variety of systems were applied to generate recombinant proteins as potential immunogens. Functional domains for neutralization site formation and particle assembly were studied in *Escherichia coli* or in insect cells from baculovirus vectors. Several elements for VLP assembly in insects and key regions for particle reassembly in vitro derived from *E. coli* expression system were identified by truncation mutational analysis.[117]

Native HEV virions arrange in a T=3 icosahedral lattice of pORF2 and pack HEV RNA genomes through the positive-charged capsid N-terminal. The structures of various truncates were well characterized in near-atomic resolution by X-ray crystallography and cryoelectron microscopy,[33–35,37,38,103,118] and the B-cell and T-cell epitopes were characterized by immune assay, structural biology, and virology. The crystal structures of the truncated pORF2 of aa 112–608 forming T=1 VLPs showed that the HEV capsid contains three major domains: specifically, the S domain, P1 domain, and P2 domain (also designated as E2s domain).[35,37] The outermost E2s domain seems to be the core antigenic region of pORF2 harboring most of the key neutralization sites, some of which are essential for virus–host interactions and are responsible for the induction of neutralizing antibodies.[33,37,103] Another truncated version that contains aa 14–608 form T=3 virion-sized VLPs, which assemble with the binding of RNA.[36]

Two VLP-based vaccines against HEV have been developed and entered clinical trials, both containing P2 domains (E2s domains).[119,120] A baculovirus-expressed vaccine candidate of 56 kDa (aa 112–607) was evaluated by GlaxoSmithKline (Rixensart, Belgium).[119,121–123] The other vaccine is a further truncated version of pORF2 aa 368–607, designated as HEV 239, with the trade name Hecolin (Xiamen Innovax Biotech, Xiamen, China), which was expressed in an *E. coli* system and can self-assemble into VLPs in vitro, with a diameter of 20 to 30 nm.[120,124,125] HEV 239 vaccine, with a robust manufacturing process, considerable production capacity, and well-defined quality control,[126] has been available in China since 2012. These two vaccines were subjected to clinical trials. In addition, another vaccine candidate with VLPs spanning aa 452–617 of genotype 4 HEV expressed in *E. coli* was combined with a commercial inactivated hepatitis A vaccine.[127] The individual components of the combined vaccine were immunogenic, and HEV components appear to protect nonhuman primates from hepatitis E.[128]

Several other approaches to vaccine development have been pursued. These include a DNA vaccine, chimeric virus particles, fusion proteins, an oral vaccine, and an adeno-associated virus (AAV) delivery vaccine. None of these approaches have been used in humans.[129–139]

PRECLINICAL TRIALS: SAFETY, IMMUNOGENICITY, AND EFFICACY

Different approaches to develop a recombinant vaccine using bacterial, animal, insect, and plant cells have been applied.[140] Two genotype 1–derived recombinant antigens, rHEV (recombinant hepatitis E vaccine) (baculovirus-expressed 56-kDa antigen; GlaxoSmithKline),[122] and HEV 239 (Xiamen Innovax),[124,125,141] demonstrated safety, immunogenicity, and efficacy in monkey models before being assessed in clinical trials.

Two formulations (1 μg or 10 μg antigens adsorbed to alum adjuvant at a volume of 0.5 mL) and two vaccination schedules (one dose or two doses administered 4 weeks apart) of the rHEV (GlaxoSmithKline) vaccine were tested in rhesus monkeys.[119] One month following the last dosing, the monkeys were challenged intravenously with 10,000 50% monkey infectious doses (ID_{50}) of HEV genotype 1, 2, or 3. Both the two-dose and single-dose regimens protected monkeys from hepatitis E, with an efficacy of 100% (95% confidence interval [CI], 65–100) and 78% (95% CI, 29–94), respectively. The vaccine similarly protected against challenge with homologous HEV genotype 1 and heterologous genotypes 2 and 3. Another study showed that the efficacy of protection against hepatitis E remained for at least 12 months after the second vaccine dose.[142]

The *E. coli*–expressed HEV 239 vaccine (Xiamen Innovax) was assessed similarly.[120] Two doses of 5 μg, 10 μg, or 20 μg HEV 239 adsorbed in alum adjuvant were administered 4 weeks apart and induced comparable antibody responses that peaked at week 7. The monkeys were then challenged with 10^4 or 10^7 genome equivalents of HEV genotype 1 or 4. All the formulations of HEV 239 vaccine completely protected the monkeys from symptomatic or asymptomatic HEV infection by the lower viral dose. When challenged with 10^7 genome equivalents of virus, the HEV 239 vaccinated monkeys were completely protected from acute hepatitis E while partially (75%, 95% CI 46.2–90.9) protected from HEV infection. The protective efficacy against homologous HEV (genotype 1) or heterologous HEV (genotype 4) infection was similar.

CLINICAL TRIALS: SAFETY, IMMUNOGENICITY, AND EFFICACY

Both the rHEV and HEV 239 vaccines have undergone clinical evaluation and HEV 239 was licensed and then launched in China in 2012.[143]

In an open Phase I study of the rHEV vaccine, 88 seronegative healthy American volunteers ages 18 to 50 years were enrolled and assigned to four groups to receive 1 μg, 5 μg, 20 μg, or 40 μg doses of vaccine at 0, 1, and 6 months after enrollment.[144] The vaccine was well-tolerated. The vaccine elicited detectable anti-HEV titers in at least 88% of those in the 5 μg, 20 μg, and 40 μg groups. The 1-μg formulation appeared to be less immunogenic (66% seroconversion).

Based on these encouraging data, a double-blind, placebo-controlled Phase II clinical trial of rHEV vaccine was conducted in Nepal, where homologous genotype 1 HEV is highly endemic.[122] In this trial, 2000 participants with low to negative anti-HEV titers, 99.6% of whom were men, with a mean age of 25.2 ± 6.25 years (range: 18 to 62) randomly received 20 μg rHEV or placebo at 0, 1, and 6 months and were followed up for a median of 804 days. Most of the reported adverse reactions were mild and occurred with similar frequency in the two groups. No serious adverse events were related to vaccination. Three vaccine doses elicited complete seroconversion among the participants but antibodies in approximately half of them dropped to undetectable levels 2 years later. One month after the last dose, 66 hepatitis E cases developed in the placebo group while three cases developed in the vaccine group, for a vaccine efficacy of 95.5% (95% CI, 85.6–98.6). In those who received at least one injection, the vaccine efficacy was 88.5% (95% CI, 77.1–94.2). During the period from 2 weeks after the second dose until the third dose, one case of hepatitis E developed in the vaccine group, and seven developed in the placebo group, suggesting that protection might be achieved with two doses of the vaccine, although the

difference was not statistically significant. The rHEV vaccine appeared to be as safe and efficacious; however, its further development was stopped by GlaxoSmithKline for commercial reasons.

The HEV 239 vaccine has been assessed through Phase I, Phase II, and Phase III clinical trials in China.[124,125,141,145] In the trials, the vaccine formulations contained 10 μg, 20 μg, 30 μg, or 40 μg of recombinant particulate HEV 239 antigens, which were adsorbed to 0.8 mg of aluminum hydroxide, suspended in 0.5 mL of buffered saline and given by intramuscular injection. The data from these clinical trials suggest that the HEV 239 vaccine is well tolerated and no serious adverse events (SAEs) associated with the vaccine were reported. In the Phase I trial, 44 healthy seronegative adults received two doses of 20 μg HEV 239 vaccine at months 0 and 1. The vaccine was well tolerated and serum biochemistry values showed no abnormal changes from the baseline values by day 60.[146] The Phase III clinical trial involved 112,604 participants who were 1 : 1 randomly assigned to the vaccine or the control groups. Local adverse events occurred more frequently in the HEV 239 group than in the control group. Local adverse events of grade 3 or higher, solicited systemic adverse events; unsolicited adverse events occurred at similar rates between the study groups.[125] Adverse events were mainly pain and swelling with itching at the injection site. Adverse events of grade 3 or more were reported very rarely. During the Phase III trial and the extended 4.5-year follow-up period, a comparable number of participants in both the vaccine and placebo groups experienced SAEs.[141] None of the SAEs were believed to be related to vaccination. Thirty-seven pregnant women in the HEV 239 vaccine group and 31 pregnant women in the control group were inadvertently vaccinated in the Phase III vaccine study.[147] The vaccine was well tolerated in the pregnant women with only one woman reporting grade 1 inoculation site pain. The weights, body lengths, and gestational ages of the newborns were comparable in both groups. The safety of HEV 239 was also evaluated in hepatitis B surface antigen (HBsAg)-positive persons, and the resulting data are reassuring.[148]

HEV 239 vaccine induces a robust and persistent immune response. Dose escalation and dose scheduling observations in the Phase II trial showed that 100% of the seronegative participants produced anti-HEV at month 7 after they received three doses of 10, 20, 30, or 40 μg HEV 239 vaccine.[124] Geometric mean concentrations (GMC) of anti-HEV IgG post vaccination were statistically similar between the three high dosage groups, while slightly higher than the 10 μg group; 3 doses were more potent than 2 doses. In the Phase III clinical trial, 11,165 participants were included in an immunogenicity subset; 5567 received three doses of 30 μg HEV 239 vaccine. Of the baseline seronegative participants, 99.9% seroconverted at 1 month after the last dose, and 87% remained seropositive at month 55. Geometric mean concentration (GMC) of anti-HEV IgG dropped from a peak of 14.96 WHO-units/mL (World Health Organization [WHO], WHO-units/mL, calibrated against WHO reference standard, National Institute for Biological Standards and Control, NIBSC catalog no. 95/584) at month 7, which is 25 times higher than that induced by natural HEV infection (0.6 WHO-units/mL), to 1.47 WHO-units/mL at month 19, and then slowly decreased to 0.27 WHO-units/mL by month 55.[125,141] For participants with preexisting antibodies, the antibody response was robust even after receiving only one shot.[141] The retrospective analysis of data in participants with or without HBsAg demonstrated similar immunogenicity.[148]

The HEV 239 vaccine is highly efficacious against symptomatic or overall HEV infection. In the Phase III clinical trial, 112,604 participants were randomly assigned to receive three doses of 30 μg HEV 239 vaccine or the hepatitis B vaccine (controls) at months 0, 1, and 6.[125] Symptomatic hepatitis E cases were active surveyed through 205 local sentinels, including community clinics, private clinics, and central hospitals. During the first follow-up year after the last dose, in the participants who received all three doses of the HEV 239 vaccine or the control vaccine in the requested time frames (per-protocol cohort), no HEV 239 vaccine recipients contracted hepatitis E. In contrast, 15 hepatitis E cases developed in the control group, indicating a vaccine efficacy against hepatitis E of 100% (95% CI, 72–100). For those who received at least one dose (modified intention-to-treat cohort), the efficacy was 96% (95% CI, 66–99) during months 0 to 18.[125] After receiving 2 doses and before the third dose (months 2–6), all five hepatitis E cases occurred in the control group and the efficacy was 100% (95% CI, 9–100).

In an extended efficacy study,[141] all the participants were blindly followed up for another 3 years. The long-term efficacy of HEV 239 for up to 4.5 years was 93% (95% CI, 79–98) in the per-protocol cohort (months 7–54) and 87% (95% CI, 71–94) in the modified intention-to-treat cohort (months 0–54). Of the 29 identified hepatitis E cases whose viral isolates were sequenced, 26 were infected with HEV genotype 4 (three in the vaccine group and 23 in the control group), and three were infected with HEV genotype 1 (one in the vaccine group and two in the control group).

HEV 239 vaccine appears efficacious against symptomatic and asymptomatic HEV infection. In the Phase III trial, the observed efficacy against HEV infection (indicated by anti-HEV IgG level increasing for four times or more in paired serum samples collected at 1-year intervals) in participants who had received at least one dose of vaccine was 77% (95% CI, 65–85) during the observation period up to month 31. It was estimated that a marginal antibody level (0.077 to 0.25 WHO-units/mL) may prevent infection in 74% of persons exposed to HEV.[99] Data from the Phase II clinical trial show that two doses of 20 μg HEV 239 administered at months 0 and 6 or months 0 and 1 can effectively protect from asymptomatic HEV infection with an efficacy of 85% (95% CI, 10–99) or 86% (95% CI, 13–99), respectively for at least 6 months.[124]

PROSPECTS FOR THE FUTURE

The most pressing issue for the immediate future is to make the vaccine available where it is most needed, in particular for use in large outbreaks in developing countries. For example, in the years 2012 to 2013 there was an epidemic of hepatitis E in South Sudan, with 5000 cases and more than 100 deaths, 50% in pregnant women.[149] At the time, as is currently the case, HEV 239 vaccine was only licensed for use in China. Had it been available for use, it may have prevented many cases and much morbidity and mortality. It seems likely that HEV 239 will be effective in this kind of emergency setting,[150] as its efficacy after two doses 1 month apart is 100%. The issue of vaccine availability in countries in need is complex. There are a number of issues that have impeded the use of HEV 239 in countries other than China, including lack of vaccine prequalification, insufficient data on the safety in pregnant women, and efficacy against genotype 1. These issues need urgent resolution.

In both developing and developed countries, hepatitis E has an adverse prognosis in patients with preexisting chronic liver disease. It would seem appropriate to consider vaccinating such individuals for HEV, alongside the existing recommendation that they should be vaccinated against HAV and hepatitis B virus. However, before this can be implemented, more data are required on the safety and effectiveness of HEV

239 in patients with chronic liver disease. Existing data show that it is safe and effective in carriers of HBsAg, but how many of the individuals in this study were cirrhotic is unknown.[148]

Finally, a safe and effective vaccine could potentially be used in the immunosuppressed, particularly transplant recipients, to prevent chronic infection. However, the safety and immunogenicity of the vaccine in this group of patients remain to be established.

28 Herpes Simplex Virus Vaccines

Lawrence R. Stanberry

"O'er ladies' lips, who straight on kisses dream, Which oft the angry Mab with blisters plagues…."

William Shakespeare, *Romeo and Juliet*, Act 1, Scene 4, p. 4

More than 2500 years ago Hippocrates used the Greek term herpes, meaning "to creep," to describe spreading skin lesions.[1] Since then mucocutaneous herpes simplex virus (HSV) infections have been viewed largely as nuisance diseases as most are self-limiting. This rather uninformed view fails to consider that HSV infections can be life threatening in the newborn, the severely malnourished, and the immunocompromised host; leave survivors severely neurologically impaired; result in blindness; trigger bouts of erythema multiforme; and that genital herpes increases threefold the risk of HIV acquisition.[2]

BACKGROUND

Clinical Description

The clinical illness caused by HSV is determined by the portal of entry, the immune status of the host, and whether the infection is primary or recurrent.

Genital herpes classically presents with vesiculoulcerative skin lesions which appear on mucosal and keratinized epithelium, as well as around the anal opening, buttocks, and/or thighs. Mild infections instead lack classical findings and may not be recognized as genital herpes,[3] but may have nonpathognomonic findings, including tingling, burning, itching, erythematous patches, and small skin fissures. Greater than 80% of primary genital HSV infections are asymptomatic or unrecognized,[4] and asymptomatic recurrent infections or asymptomatic viral shedding is also more common than clinically recognized recurrences and occur both in those with a history of symptomatic infections and those lacking such history.[5] While HSV-1 and HSV-2 can cause clinically indistinguishable primary infections they differ in their ability to cause recurrent infections with HSV-1 causing significantly fewer episodes of recurrent genital infection than HSV-2,[6] while the converse is true for oral–labial HSV infections.

Common oral–facial infections are generally caused by HSV-1.[7] Herpes gingivostomatitis is characterized by oral pain, fever (40°C–40.6°C), and vesiculoulcerative lesions throughout the mouth and pharynx. Herpes pharyngitis is less severe than gingivostomatitis with lesions generally limited to the tonsils and pharynx.[8] Herpes labialis is the most common recurrent oral–facial HSV infection and often is heralded by prodromal symptoms, including tingling, itching, burning, or pain, before the development of the herpetic lesions, which typically develop on the vermilion border of the lip, although lesions sometimes occur on the nose, chin, cheek, or oral mucosa.[9]

HSV can also cause other skin infections including herpes gladiatorum or scrum pox, herpes whitlow, and potentially life-threatening HSV infections among individuals with skin disorders.[10,11]

HSV infection of the eye may be primary or recurrent and is usually unilateral and may involve the conjunctiva, cornea, or retina.[12] Conjunctivitis is the most common ocular HSV infection. The distinguishing feature of corneal infection is dendritic or geographic ulcers.

Beyond the newborn period HSV encephalitis is almost always caused by HSV-1 and typically involves the frontal and/or temporal cortex. HSV is the most common cause of recurrent aseptic (Mollaret) meningitis and aseptic meningitis is seen in up to 15% of cases of primary genital herpes.[13,14]

Perinatal HSV infections are life threatening and most commonly result from mother-to-infant transmission.[15] The clinical manifestations are variable but broadly fall into one of three patterns of disease: (a) disease localized to the skin, eyes, or mouth (SEM); (b) encephalitis; or (c) disseminated infection.

HSV infections in the immunocompromised host, particularly those with compromised cellular immunity such as seen with AIDS, may be severe and life threatening.[16,17]

Complications

There are myriad complications associated with HSV infection. Acute genital herpes infection may be associated with urological and neurological complications, and recurrent genital herpes can cause intermittent and persistent neurological signs and symptoms, significant psychological morbidity,[18] and significantly increases the risk of HIV acquisition and transmission.[2] Cutaneous infections can result in erythema multiforme. Ocular HSV infections can result in blindness. Patients surviving HSV encephalitis may have severe neurological sequelae including blindness, deafness, cerebral palsy, and profound mental retardation. Death can result from infections in patients who are immunocompromised, those with immature immune systems, and those with skin disorders. There is also growing evidence that HSV neuronal infection may play a role in the pathogenesis of Alzheimer disease.[19]

Virology and Viral Antigens

HSV contains a double-stranded DNA genome of approximately 152 kilobases that encodes at least 84 proteins. The viral genome resides within an icosadeltahedral capsid which is surrounded by an outer envelope composed of a lipid bilayer containing at least 12 viral glycoproteins (Fig. 28.1). The envelope glycoproteins are the major targets for humoral immunity; glycoprotein B (gB), glycoprotein C (gC), glycoprotein D (gD), or glycoprotein H (gH)/glycoprotein L (gL) antibodies inhibit the absorption or neutralize HSV in vitro and antibodies to gB or gD inhibit neuron-to-keratinocyte spread in a cell culture system.[20] CD4 and CD8 cellular responses can be induced by a wide array of HSV proteins including glycoproteins (gB, gC, gD, gE, and gH), structural capsid and tegument proteins (gene products of UL 7, UL21, UL25, UL26, UL29,UL47, UL48, UL49, and the proteins VP5, VP11/12, VP13/14, VP16, VP22, and ICP8), and nonstructural proteins (ICP0, ICP4, and ICP27 and the gene product of UL50).[20] HSV-1 and HSV-2 have a similar genetic composition, genome organization, and extensive DNA and protein homology. One notable difference exists between the HSV-1 and HSV-2 glycoprotein G genes. This difference forms the basis for the current type-specific serological tests that are used to discriminate

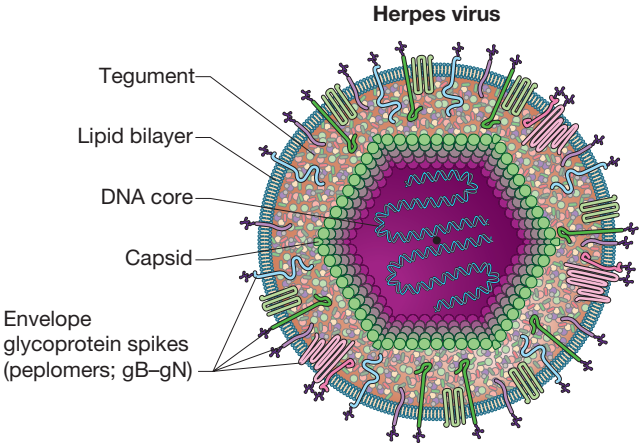

Figure 28.1. Herpes simplex virus structure.

accurately whether an individual is infected with HSV-1, HSV-2, or both.[21]

Pathogenesis as It Relates to Prevention

The pathogenesis of mucocutaneous HSV infections involves replication of virus at the portal of entry and uptake and spread via nerve fibers to regional sensory ganglia where further viral replication occurs and where latent infection is established.[22] Animal studies indicate that challenge with low doses of virus is sufficient to cause infection but that higher doses are required to cause clinically apparent illness.[23] During the initial infection innate and adaptive humoral and cellular immune responses limit viral replication and allow for control of the acute disease. Despite these responses the latent virus can periodically reactivate in sensory ganglia to produce progeny virus which is transported to the periphery where further replication occurs. This peripheral replication can result in symptomatic recurrent infection or asymptomatic shedding. It is important to note that hematogenous spread does not play an important role in the pathogenesis of infection except in the host with an immature or compromised immune system.[16] In considering the development of vaccines to control HSV infections an understanding of the pathogenesis provides three insights. First, the lack of hematogenous viral dissemination in healthy individuals means that an HSV vaccine cannot target prevention of viral spread in the bloodstream, a step that has proved key for other pathogens. Consequently, HSV vaccines may need to engender responses that protect at the portal of entry, that is, the genital or oral mucosa, or possibly sensory nerve endings and/or sensory ganglia. Second, higher doses of virus are required to cause disease than are needed to cause subclinical infection, which suggests that if a vaccine cannot prevent infection, it might be able to shift symptomatic disease to subclinical infection. Third, the ability of the virus to reactivate and cause recurrent infections despite the host having produced a variety of virus-specific adaptive responses suggests that it will be necessary for an effective vaccine to produce protective responses superior to what develops as a consequence of infection.

Diagnosis

HSV infections should be suspected based upon the history of exposure and clinical findings, particularly vesicular lesions; however, the clinical diagnosis of genital herpes is remarkably unreliable.[24] Suspicion of an HSV infection requires laboratory confirmation. Virus culture is the gold standard for mucocutaneous HSV infections. Virus typing should be done in conjunction with culture for suspected genital herpes as virus type is important in predicting the frequency of subsequent recurrent infections. Although not as sensitive as culture, direct detection of HSV antigens in clinical specimens can be done rapidly and has very good specificity.[25] The use of a polymerase chain reaction (PCR)-based assay for detection of HSV DNA is highly sensitive and specific, and even though of somewhat limited availability, it is emerging in routine clinical use and is the test of choice in examining cerebrospinal fluid in cases of suspected HSV encephalitis or meningitis.[26]

Serological tests can be used to support the clinical diagnosis of HSV infection in patients who present too late in the course of an acute illness for viral culture or viral antigen or DNA assays to be accurate. Immunoglobulin (Ig) M assays are unreliable and their interpretation made difficult by the fact that recurrent infections can trigger an anamnestic IgM response that can be misinterpreted as indicating an acute primary infection. To be helpful IgG tests should be type specific[21] and their results interpreted in the context of the disease manifestations and clinical history.

Treatment and Prevention With Antivirals

All symptomatic primary HSV infections probably warrant treatment. Acyclovir, valacyclovir, and famciclovir are the principal drugs used in the management of HSV infections. Early initiation of therapy results in maximum therapeutic benefit, but does not prevent the establishment of the latent infection. Likewise, treatment of recurrent infections does not eradicate the latent virus infection. Less commonly used drugs include foscarnet, cidofovir, trifluorothymidine, brivudin, and idoxuridine.

A landmark study determined that the chronic use of valacyclovir by patients with HSV-2 genital herpes could reduce the risk of transmission of infection to a susceptible heterosexual partner by 48%.[27]

EPIDEMIOLOGY

Seroprevalence

HSV-1 infection is generally spread through contact with contaminated oral secretions. HSV-1 seroprevalence rises rapidly in the first decade of life with 50% of European and 70% of American 10-year-old children being seropositive.[28] By the sixth and seventh decades 70% to 80% of adult Americans and Europeans are HSV-1 seropositive. Even though data on HSV-1 seroprevalence in the developing world are limited, studies suggest greater than 90% of adults in Africa and Asia are HSV-1 seropositive.[29] In contrast to HSV-1, HSV-2 seroprevalence is essentially zero in the first decade of life, rising sharply with the onset of sexual activity during adolescence, thus reflecting the primary mode of transmission. HSV-2 seroprevalence rates tend to increase steadily throughout the third and fourth decades of life among Europeans and Americans, reaching a peak of approximately 20% in Europe and 30% in the United States among generally low-risk populations, but with peak rates of approximately 45% and 60% for high-risk populations in Europe and the United States, respectively.[28] In general, Central and South America has HSV-2 seroprevalence rates similar to the United States and Europe, whereas parts of Africa generally have much higher rates and Asia tends to be lower; in any geographic area, however, there are great variations in HSV-2 seroprevalence rates among different populations.[29] Two American longitudinal studies provide some estimate of the rate of HSV-2 acquisition. In a vaccine trial involving high-risk volunteers followed prospectively, gender

was shown to influence acquisition of HSV-2 infection with a rate of 3.8 cases per 100 person-years of follow-up for men compared to 5.8 for women.[30] In this study, preexisting immunity to HSV-1 did not influence the rate of acquisition of HSV-2 infection but did increase the proportion of infections that were asymptomatic. A study of adolescent girls found an acquisition rate of 4.4 cases per 100 person-years of sexual activity for HSV-2 infection and reported that preexisting HSV-1 immunity affords girls protection against both HSV-2 infection and disease.[31] The impact of preexisting HSV-1 immunity on HSV-2 acquisition is controversial but needs to be considered in designing vaccine trials aimed at preventing HSV-2 infection or disease.

Incidence data are limited and underrepresent the magnitude of HSV infections as most HSV infections are asymptomatic.[32] Clinical studies of patients presenting with HSV disease indicate that most oral and nongenital skin infections, as well as central nervous system infections, outside the neonatal period are caused by HSV-1.[32]

ACTIVE IMMUNIZATION

History of Vaccine Development

The history of HSV vaccine development dates from the 1930s.[33] The initial work focused on therapeutic vaccines intended for the control of recurrent mucocutaneous HSV infections. Clinical assessment of prophylactic vaccines did not begin until the late 1940s.[34] Two major problems hampered early research: the lack of defined vaccine products and fatally flawed design of clinical trials. Early vaccines were crude preparations, exemplified by the 1938 vaccine developed by Frank which consisted of a formalin-treated HSV-2–infected brain emulsion prepared from rabbits dying of encephalitis.[35] These products were evaluated in open trials involving patients with oral, ocular, or genital HSV infections and using subjective patient assessment of improvement. The importance of randomized, blinded, placebo-controlled clinical trials was not appreciated until the landmark study of Kern and Schiff in 1964, which demonstrated comparable self-reported improvement in the frequency of recurrences for both vaccine and placebo recipients.[36] In the 1940s and 1950s, vaccines were made from virus grown in embryonated eggs and inactivated by physical means. By the 1960s vaccines were prepared by chemical or physical inactivation of virus grown in cell cultures. Between 1946 and 1982 more than two dozen clinical trials of experimental vaccines were reported but no vaccine was convincingly proven to be effective.[37]

The modern era of HSV vaccine development begun in the 1980s and 1990s has been largely unsuccessful (summarized in Table 28.1). Two studies, however, conducted in the 1990s were successful in establishing the feasibility of developing therapeutic and prophylactic HSV vaccines.

Therapeutic Genital Herpes Vaccine

Using a recombinant HSV-2 glycoprotein D (gD2) vaccine, Stanberry and colleagues developed the first experimental evidence supporting the concept of therapeutic immunization to control recurrent genital herpes.[45,46] Straus and colleagues[47] subsequently conducted a double-blind, placebo-controlled clinical trial investigating the effect of the vaccine on the frequency of symptomatic outbreaks in patients with genital herpes. Ninety-eight patients with documented genital herpes who reported four to 14 recurrences per year were randomized to receive deltoid injections of either 100 μg gD2 in alum or alum alone (placebo) at 0 and 2 months. Clinically recognizable recurrences were documented for 1 year. The vaccinees experienced fewer monthly recurrences than placebo recipients (mean: 0.42 ± 0.05 vs 0.55 ± 0.05), had significantly fewer virologically confirmed monthly recurrences (mean: 0.18 ± 0.03 vs 0.28 ± 0.03), and had a significantly lower median number of recurrences for the study year (4 [range: 0–17] vs 6 [range: 0–15]). The overall effect appeared greater during the first 4 months of the trial. By the nature of the study all participants were HSV-2 seropositive but the gD2 vaccine boosted neutralizing HSV-2 antibodies fourfold and gD2-specific titers sevenfold over baseline levels. Even though the overall effect was transient and modest, the results did establish the feasibility of treating an established HSV infection with a therapeutic

TABLE 28.1 Herpes Simplex Virus Vaccines Not Proven Effective in Clinical Trials

Vaccine	Developer or Manufacturer	Application	Comment	Reference
Cell-culture derived inactivated HSV-1	Skinner	Prophylaxis genital herpes	Clinical trials used historic controls, efficacy not established	37,38
Cell-culture derived inactivated HSV-1	Skinner	Therapeutic genital herpes	No clinical benefit in controlled trials	39

HSV, herpes simplex virus.

vaccine. A follow-up Chiron study using recombinant HSV-2 gB and gD combined with MF59, a squalene oil-in-water emulsion adjuvant, failed to demonstrate a therapeutic benefit in patients with recurrent genital herpes.[44] It is possible that the failure was the result of use of lower amounts of the HSV glycoproteins in the second trial (10 μg each of gB2 and gD2) compared to the first trial (100 μg gD2); however, it has also been postulated that the failure of the second vaccine might have been caused by the selection of the MF59 adjuvant, which principally augments antibody responses.[48] Important questions remain unanswered including these: What were the key immunological mediators of the effect (e.g., cellular versus antibody responses)? What was the critical site of the effect (e.g., genital skin or latently infected sensory ganglia)? Could therapeutic vaccines impact asymptomatic shedding and transmission as well as symptomatic recurrences? Animal studies indicate that induction or enhancement of HSV-specific cellular immune responses are required for a therapeutic effect and that therapeutic vaccines can reduce clinically recognizable recurrences as well as viral shedding.[49,50]

Prophylactic Genital Herpes Vaccines

In the 1980s, Chiron developed and tested a prophylactic HSV-2 vaccine consisting of truncated HSV-2 glycoproteins gD2 and gB2 with the adjuvant MF59. The vaccine was shown to be highly immunogenic but was ineffective in two randomized, double-blind, placebo-controlled studies.[30] The first study (Partners Trial) enrolled 531 HSV-2 seronegative sexual partners of HSV-2–infected persons, while the second study (STI Clinic Trial) enrolled 1862 high-risk individuals from sexually transmitted infection (STI) clinics. The trials were placebo controlled, with a 0-, 1-, and 6-month immunization schedule and an 18-month study duration. The primary outcome measure was acquisition of HSV-2 infection as assessed by seroconversion to HSV-2 antigens not present in the vaccine. The data from the two studies were combined for the analysis and while the overall efficacy of the vaccine was only 9% during the entirety of the studies, in the first 5 months the rate of HSV-2 acquisition was 50% lower among vaccine recipients compared to placebo recipients. A post hoc analysis of the data suggested there might be a difference in efficacy by gender with an efficacy rate of 26% in women compared with 4% in men. It may be worth noting that there appeared to be a trend toward protection in the Partners Trial in the vaccinated women compared to the placebo recipients (4.0 vs 8.8 cases per 100 person-years, respectively); however, the same trend was not observed in women enrolled from STI clinics (5.5 cases per 100 person-years for vaccine recipients vs 5.4 cases per 100 person-years for placebo recipients) (Table 28.2). The reasons why the adjuvanted subunit vaccine failed despite inducing high titers of HSV-2–specific antibody are unclear and, likewise, the explanation for transient protection in women is uncertain. The apparent trend toward protection in vaccinated women in the Partners Trial but not the STI Clinic Trial suggests that these two populations of women may respond to vaccines differently and that women in HSV-2 discordant relationships, who are repetitively exposed to subinfectious doses of virus, may be immunologically primed and hence respond more favorably to immunization.

In parallel with the Chiron HSV vaccine program, GlaxoSmithKline Biologicals was developing a subunit vaccine containing a CHO cell derived truncated gD2 antigen (20 μg) combined with alum (500 μg) and the potent adjuvant 3-de-0-acylated monophosphoryl lipid A (MPL) (50 μg). In a Phase I evaluation, the vaccine was shown to be well tolerated and capable of inducing humoral and cellular immune responses superior to gD2 and alum alone.[51] In the 1990s, the vaccine was evaluated in two multinational, double-blind, randomized, placebo-controlled consort studies.[52] The first study (007 Trial) enrolled 847 HSV-1– and HSV-2–seronegative partners (268 women) of HSV-2–infected individuals; the second study (017 Trial) enrolled 1867 HSV-2–seronegative partners (710 women) of HSV-2–infected individuals. The vaccine or control (alum-MPL in first study and alum in the second study) was administered intramuscularly at 0, 1, and 6 months. The study duration was 19 months. The primary outcome measure was protection against HSV-2 disease; in the first study the primary outcome was assessed in all participants (men and women) whereas in the second study the primary outcome was assessed in women only, with assessment in men being a secondary outcome measure. In the first study the HSV-2–infected partners were required to abstain from using suppressive antiherpes therapy, but were allowed to do so in the second study.

Overall, in both studies, the protection against HSV-2 disease offered by the vaccine and alum control were similar: the efficacy of the vaccine in the first study (007 Trial) was 38% in HSV-1– and HSV-2–seronegative men and women, whereas in the second study (017 Trial) it was 42% in HSV-2–seronegative women participants (see Table 28.2). In both studies there was a nonsignificant trend toward protection of HSV-seronegative women against HSV-2 infection (vaccine efficacy of 46% in the first study and 39% in the second study; $P = .08$ in each study). However, the gD2-alum-MPL vaccine afforded significant protection (vaccine efficacy of 73%–74%) against genital HSV-2 disease in women who had no preexisting antibody to either HSV-1 or HSV-2. There was no evidence that the vaccine was protective in women who were initially HSV-1–seropositive or in men. In the Phase III trials the vaccine was safe, generally well tolerated, and induced gD-specific neutralizing antibodies and a T-helper–1 (Th1) cell-mediated immune profile. Because neither study met its predetermined primary outcome (i.e., for the 007 study, prevention of genital herpes disease in HSV-2–seronegative men and women; for the 017 study, prevention of genital herpes disease in HSV-2–seronegative women), a third study (the HERPEVAC Trial for Women) was planned and undertaken.

During the course of the HERPEVAC study the results of a previously initiated multinational safety and immunogenicity trial became available. The study, involving 7460 volunteers (4968 in the vaccine group and 2492 in the placebo group), found the vaccine to be generally safe but did find significantly more local reactions, especially soreness, compared to placebo.[53] The reactions tended to be mild to moderate in severity, lasting less than 3 days, although severe local reactions were noted in 7.0% of participants receiving vaccine doses and in 1.2% of participants receiving placebo doses. The rate of local reactions did not increase with subsequent vaccine administrations or in subjects with preexisting HSV immunity. Interestingly, women receiving either the vaccine or placebo reported significantly more local and systemic adverse reactions than did men. With regards to immunogenicity, the vaccine induced higher titers of HSV gD-specific antibody than occurs following HSV infection.

The third Phase III trial (the HERPEVAC study) was cosponsored by GlaxoSmithKline and the National Institutes of Health and differed from the previous two Phase III trials in that the participants were young, HSV–seronegative women who were more representative of the general population as compared to participants in the previous trials who were at risk of genital HSV-2 infection because they were in a relationship with a sexual partner who had a history of recurrent genital herpes.[54] The randomized, double-blinded trial was conducted in 8323 women ages 18 to 30 years. The primary end point was reduction in genital disease caused by either

TABLE 28.2 Attack Rates and Vaccine Efficacy in Four HSV Vaccine Trials

	Chiron[a] gB/gD-MF59 Vaccine				GlaxoSmithKline[b] gD-AS04 Vaccine

Data from Corey L, Langenberg AG, Ashley R, et al. Recombinant glycoprotein vaccine for the prevention of genital HSV-2 infection: two randomized controlled trials. JAMA. *1999;282:331–340; and Stanberry LR, Spruance SL, Cunningham AL, et al. Glycoprotein-D-adjuvant vaccine to prevent genital herpes.* N Engl J Med. *2002;347:1652–1661.*

type 1 or type 2 HSV, but the vaccine did not meet this end point. Overall, vaccine efficacy was 20% confidence interval (CI) (–29, 50) against genital herpes disease; however, type-specific efficacy was found against HSV-1 but not HSV-2. After three doses of vaccine, the vaccine efficacy against culture-positive genital HSV-1 disease was 82% CI (35, 95). Vaccine efficacy against HSV-1 infection (with or without disease) was 35% CI (13, 52), but efficacy against HSV-2 infection was not observed (–8% CI [–59, 26]).

A substudy examined whether immunized women who became infected had comparable patterns of asymptomatic viral shedding to those observed in unimmunized HSV-infected women or whether they shed less virus,[54] as was shown in experimental animal studies.[55] The issue of asymptomatic shedding has important public health implications.[56] The substudy enrolled 43 participants (30 HSV vaccine recipients and 13 control subjects) who acquired HSV-2 infection during the trial. The women collected anogenital swabs on 60 consecutive days for quantitation of HSV-2 genome beginning 3 to 6 months after disease onset (24 women: 15 in the HSV vaccine group and nine in the control group) or seroconversion (19 women: 15 in the HSV vaccine group and four in the control group). Although the rate of viral shedding was higher among the HSV vaccine recipients compared with controls, 29% versus 17%, respectively (relative risk [RR] = 1.55, 95% CI [1.28, 1.86]), the mean quantity of HSV DNA on days with shedding did not differ between the two groups.

The lack of vaccine efficacy against HSV-2 in the HERPEVAC trial is puzzling in view of the previous two gD2 vaccine studies in discordant couples that found efficacy against HSV-2. The distinguishing feature of discordant couples is that they are a highly select group in which one uninfected partner is potentially repeatedly exposed to HSV by an infected partner. Attack rates of HSV-2 genital disease in the prior GlaxoSmithKline gD2 vaccine studies in discordant couples were high in the uninfected women (13.9% for 19 months or 8.4% per year) and were reduced significantly by vaccine (VE = 73% and 74% in the two trials; $P < .05$ in each case). For

the 007 and 017 trials, the primary end point was the occurrence of genital HSV disease in all subjects in Study 007 and in HSV-2–seronegative female subjects in Study 017. Vaccine efficacy was defined as the percentage reduction in the frequency of the end point among recipients of vaccine compared with the frequency among recipients of control injections; it was calculated as 1 − (attack rate among recipients of vaccine ÷ attack rate among recipients of control injections), with two-tailed 95% CIs, according to the Cochran-Mantel-Haenszel method.[52] Likewise, the Chiron gB2/gD2 vaccine appeared to have some effect in vaccinated women in the discordant couples (Partners) trial, but not in women who were recruited from STI clinics.[30] Potential reasons why the gD2 vaccine might protect women who were in a long-term relationship with an HSV-2–infected male partner (mean duration of relationship was 23 months) but not women in other high-risk relationships might include (a) an undefined immunologic priming event from chronic sexual exposure to HSV-2 antigens from the infected partner[57] that could be boosted by the subunit vaccine; (b) selection bias for a population of relatively HSV-2–resistant women who developed enhanced resistance from the gD2 vaccine; or (c) women in a long-term relationship have less frequent,[58] and perhaps less intense or less traumatic, exposure to HSV-2 because of the long-term nature of the relationship.

Vaccine efficacy against genital HSV-1 infections was demonstrated in the HERPEVAC trial but not in the original two GlaxoSmithKline discordant couple studies as too few cases of HSV-1 genital disease occurred in the original studies. As the HERPEVAC study recruited women from the general population it was anticipated that approximately 30% of the incident cases of symptomatic genital herpes would be caused by HSV-1. The gD2 antigen is derived from HSV-2 but shares significant homology with HSV-1 gD, which may explain the protection against HSV-1. The finding that the gD2 vaccine protected women recruited from the general population against HSV-1 genital infection but not HSV-2 genital infection might indicate some important difference in the immunobiology of the two viruses, and type-specific immune responses to vaccine antigen may reveal differences in antibody activity versus HSV-1 or HSV-2 or whether HSV-1 is more easily neutralized by vaccine-induced antibodies. It is also possible that the vaccine efficacy is influenced by the mode of virus transmission. It is generally believed that most cases of genital HSV-1 infection result from oral–genital sex rather than penile–vaginal sex.[59] Perhaps oral–genital sex results in exposure to lower concentrations of virus; possibly microabrasions associated with penile–vaginal sex facilitates transmission; or perhaps the cervical epithelium reached during penile–vaginal sex is more susceptible to HSV than the cells of the vaginal introitus, the cells most generally exposed during oral–genital sex. At this time, we can only speculate on the biological basis for the efficacy against HSV-1 genital infection but not against HSV-2 genital infection.

In comparing the results of the Chiron and GlaxoSmithKline vaccine programs, it may be worth noting that a major difference in the two vaccines was the adjuvant. The Chiron vaccine contained MF59 whereas the GlaxoSmithKline vaccine contained alum and MPL. The partial effectiveness of this glycoprotein vaccine compared to the failure of the Chiron glycoprotein vaccine suggests that adjuvant may be critical in facilitating the induction of important protective immune responses. More research is needed to understand the adjuvant effects as well as the unexpected gender-specific protection seen with the gD2-alum-MPL vaccine. Another important unanswered question is whether a vaccine that can protect against genital herpes can afford protection against nongenital HSV diseases.[60]

Correlates of Protection

The critical immune responses required of an effective prophylactic or therapeutic HSV vaccine are unknown although it is widely held that they are likely to be different for the two types of products.[61,62] Because HSV has evolved several strategies to evade the immune system[61] and because HSV infection in one anatomic site provides, at best, limited protection against HSV infection at a second site,[63] an evaluation of host responses to infection may not be a useful strategy for identifying protective immune responses. Animal studies suggest that neutralizing antibody is essential for prophylactic vaccination and a recent animal study demonstrated the importance of mucosal T cells in protecting against experimental genital herpes,[64] while the results of clinical trials suggest that robust T-cell responses will be necessary for effective prophylaxis and induction of effective immune responses will likely require some balance between innate and adaptive responses.[62,65] It is likely that the correlates of protection for prophylactic HSV vaccines will be both neutralizing antibody and T-cell responses greater than those seen in infected individuals. At this point it is unclear whether $CD4^+$ or $CD8^+$ T cells will be more important in affording protection against infection. Regarding therapeutic vaccines, it is clear that antibody is not a correlate of protection, and most evidence currently suggests that HSV-specific $CD8^+$ T-cell responses will be the key to protection. Recent studies on HSV CD8 T cells in animal ganglia suggest that latent infection may lead to CD8 T-cell exhaustion and hence compromise the ability of therapeutic vaccines to engender robust CD8 T-cell augmentation.[66]

Public Health Considerations

HSV infections are a global public health problem both as a consequence of HSV-induced disease and indirectly by enhancing the acquisition and transmission of HIV.[28,29] The United States is experiencing an ongoing epidemic of genital HSV infections.[4] The potential impact of the partially effective GlaxoSmithKline prophylactic vaccine will be limited by its gender-specificity and its lack of efficacy in HSV-1–seropositive women, a particular problem for the developing world where most individuals acquire nongenital HSV-1 infections in early life. Nevertheless, mathematical modeling of universal immunization of young women in the United States suggests that a partially effective vaccine could have a significant impact on the ongoing genital herpes epidemic.[67]

FUTURE VACCINES

Currently there are several companies with vaccines in early clinical development; all these candidates are intended for use as therapeutic vaccines.

The HerpV plus QS21vaccine being developed by Agenus, Inc., consists of a recombinant human heat shock protein (HSP)-70 complexed with 32 HSV-2 peptides and a proprietary QS21 adjuvant system (ClinicalTrials.gov Identifier: NCT01687595). Their Phase II results indicated the vaccine was well tolerated, more than half of the vaccine recipients developed a robust anti-HSV cytotoxic T-cell immune response, and in those patients there was a statistically significant 75% reduction in viral shedding ($P < .001$; CI: 46.2–88.6%).[68,69]

The GEN-003 plus Matrix-M-2 product being developed by Genocea Biosciences is a subunit vaccine containing HSV-2 ICP4 and gD proteins plus a proprietary saponin-based adjuvant system. In a Phase I/II clinical trial (ClinicalTrials.gov Identifier: NCT01667341) the vaccine was reported to be well tolerated and immunogenic, boosting antibody and T-cell responses for at least 12 months. At 6 months, the

group receiving a 30-μg dose of the vaccine showed a 65% reduction in the rate of recurrences and a 40% decrease in viral shedding. At 12 months the mean viral shedding rate had reverted to baseline levels.[70] A dose-ranging Phase II clinical trial has been initiated (ClinicalTrials.gov Identifier: NCT02114060).

VCL-HB01 and VLC-HM01 with Vaxfectin, developed by Vical, are plasmid DNA vaccines encoding one or two HSV-2 proteins in a proprietary cationic lipid-based adjuvant formulation. Results of a Phase I/II clinical trial showed that neither the monovalent nor the bivalent vaccine met the primary end point of viral shedding rate reduction from baseline. However, the bivalent vaccine achieved statistically significant reduction in a prospectively defined secondary end point of genital lesion rate at 3 months versus baseline (−49%; $P = .031$) with persistent of the effect at the 9-month time point (−57%; $P = .009$). The company announced that it plans to advance the bivalent vaccine to a Phase II trial in 2016.[70a]

Coridon/Admedus Vaccines, an Australian company, has in development an HSV-2 polynucleotide (DNA) vaccine.[71] The vaccine was reported to be safe and to engender a T-cell response in a Phase I study[72]; a Phase II trial reportedly began in April 2015.[73]

Sanofi Pasteur is developing HSV-529 vaccine, a replication-defective HSV-2 mutant deleted of two essential genes U_L5 and U_L29 and grown on a complementing cell line.[74] The vaccine is being tested in an ongoing National Institutes of Health–sponsored Phase I safety/immunogenicity study in healthy volunteers with or without HSV infection; the estimated completion date is October 2016 (ClinicalTrials.gov Identifier: NCT01915212). There are plans to combine the replication defective mutant with a glucopyranosyl lipid adjuvant from Immune Design with a goal of developing an effective therapeutic vaccine. A single deletion, replication defective vaccine was shown to safe and immunogenic but ineffective as a therapeutic vaccine in the 1990s.[75] No replication defective HSV vaccine candidate has been investigated in clinical trials for use as a prophylactic vaccine.

Ongoing research continues to explore interesting new vaccine strategies. Examples of recent preclinical studies include a DNA prime-formalin-inactivated-HSV-2 boost vaccine strategy,[65] a HSV-2 glycoprotein E deletion mutant being evaluated as a replication-competent, attenuated live virus vaccine candidate,[76] a two-step "prime-and-pull" strategy that uses conventional parenteral vaccination (prime), followed by vaginal chemokine application to "pull" activated T cells to the genital track, new genetically engineered virus constructs including a nonreplicating dominant-negative HSV-2 recombinant viral vaccine,[77] ICP0 deleted HSV-1 and HSV-2 mutants,[79,80] and a vaccine containing four HSV proteins designed to stimulate both humoral and T-cell specific HSV immune responses.[81]

29 Human Immunodeficiency Virus Vaccines

Marc P. Girard and Wayne C. Koff

Although the disease was most likely present in Africa for many decades earlier, it only was in the summer of 1981 that AIDS was first recognized in the human population as an outbreak of *Pneumocystis carinii* pneumonia among homosexual men in the United States.[1,2] There is evidence that AIDS initially spread from Central Africa to Haiti and then to the United States, then globally.[3,4] The disease is caused by the HIV, a lentivirus that is transmitted through sexual intercourse and through injection of infected blood or blood-derived products, and from mother-to-child.[5] It is characterized by the progressive depletion of $CD4^+$ helper T cells, which are the preferred target of the virus, and by a chronic activation of the immune system. This results in an immunodeficiency syndrome that paves the way to opportunistic infections, including pulmonary tuberculosis (a frequent complication), *P. carinii (Pneumocystis jiroveci)* pneumonia, *Mycobacterium avium-intracellulare* infections, toxoplasmosis, candidiasis, cryptosporidiosis, and a variety of viral infections (cytomegalovirus, hepatitis C, herpes simplex) as well as cancers, such as Kaposi sarcoma and non-Hodgkin B-cell lymphomas. Since 1981, an estimated 70 million people have been infected with HIV, and approximately 36 million people have died.[6] AIDS is notably the number one killer of young women of reproductive age in sub-Saharan Africa.

Several modalities can reduce HIV-1 infection rates in persons at risk of exposure, including screening of blood donors, awareness and counseling campaigns, monogamy and the use of condoms, expanded treatment of sexually transmitted infections, and male circumcision.[7–10] The use of a tenofovir vaginal gel, before and after sexual intercourse, has also been found to lower HIV-1 incidence rates among sexually active South African women after 2.5 years of use by 39%. Efficacy actually reached 54% among "high adherer" women who used the microbicide as instructed.[11–13] Preexposure prophylaxis (PrEP) using oral antiretrovirals such as Truvada pills (a combination of tenofovir and emtricitabine) demonstrated substantial efficacy in reducing the risk of acquiring HIV in high-risk individuals, including men who have sex with men (MSM).[14] Immediate postexposure antiretroviral therapy (ART) is another way to prevent transmission.[15,16] Antiviral treatment of HIV-infected adults was associated with a 92% reduction in HIV transmission to their uninfected partner.[17]

Transmission of HIV-1 from mother to child can also be successfully prevented by treating the infected mother with antiretroviral drugs.[18–21] Although full implementation of these preventive measures have the potential to drastically reduce the spread of the epidemic, as was observed in a few field settings such as Uganda,[22] in practice there are many obstacles, including scale-up difficulties, costs of the drugs and healthcare, and profound resistance to behavioral change. The best chance to curb the HIV epidemic, therefore, lies in the development of an effective vaccine. This remains the greatest unmet need and a public health priority as the epidemic continues.[23]

The development of an effective HIV vaccine is indeed hampered by the very properties of the virus (Table 29.1). The antiviral immune mechanisms that are induced in response to HIV infection, whether initial innate immune responses or later cell-mediated or specific antibody responses, fail to clear the virus. One reason is that HIV integrates as a provirus into the chromosomes of long-lived reservoir memory T cells where it can persist in a latent state.[24–26] The virus seeks refuge in follicular helper $CD4^+$ T-cells (T_{FH}) within the B-cell follicles, where it remains in a latent form[27–29]; the same phenomenon is observed with the simian immunodeficiency virus (SIV) in macaques.[28,30] The earlier the initiation of antiviral therapy, especially in children, the smaller is the size of the viral reservoir.[31–33] Reversing HIV-1 latency in HIV-infected persons has become, at this time, a major research objective, but it still remains an unmet goal.[34–36]

Another reason it has been so difficult to develop an effective HIV vaccine is the fast rate of replication of the virus, which, coupled with a high rate of mutation and recombination, rapidly leads to the emergence of quasispecies of viral clones that are able to thrive as escape mutants and evade both the cell-mediated and the humoral immune responses of the host.[37–41] At the same time, HIV-1 infection is accompanied by a downregulation of the major histocompatibility complex (MHC) class I antigen presentation at the surface of the infected cell, allowing for escape from antiviral cytotoxic T-lymphocyte (CTL) responses.[42,43] It has also been suggested that overwhelming virus replication at the time of primary HIV infection, together with chronic immune activation, lead to exhaustion of virus-specific CTLs and gradual impairment of cellular immunity, progressively leading to AIDS.[44–46]

How to elicit protective immune responses with a vaccine under such conditions remains a daunting challenge. Since 1987, more than 150 candidate HIV-1 vaccines or analogous vaccines against SIV have been developed and shown to elicit varying degrees of protective responses in nonhuman primate (NHP) models.[47–49] Many have also advanced to human clinical trials.[50–53] However, with the sole exception of the RV-144 Phase III trial, which evaluated a recombinant Canarypox (ALVAC) vector prime and recombinant HIV-1 envelope gp120 subunit protein plus alum boost and provided a modest 31% protection against HIV infection,[54,55] none of the vaccine candidates tested so far has shown efficacy in preventing HIV-1 infection or in controlling virus replication and delaying progression of disease in humans.

VIROLOGY

There are two well-defined etiological agents of AIDS, **HIV-1**[56–58] and **HIV-2**,[59] and both cause disease, but HIV-2 appears to be less aggressive and has a more restricted geographic spread. HIV-1 can further be subdivided into pandemic group M *(Major)* and less prevalent groups O *(Outlier)*,[60] N *(non-M, non-O)*[61] and P.[62] Only 15 cases of HIV-N infections and two cases of HIV-P infections have been reported to date, whereas HIV-O has been identified in approximately 1% of HIV infections in Cameroon, and in a few cases in Western countries.[63,64] HIV-1 group M can further be subdivided into subtypes or clades (see "Virus Variability" below).

HIV belongs to the genus lentivirus in the family *Retroviridae.* Lentiviruses are enveloped RNA viruses that typically produce slow, progressive infections after long periods of latency and persist in the host despite the host's active immune response. Their replication depends on the presence of an

active reverse transcriptase (RT), which transforms the RNA genome into a proviral DNA copy that integrates into the host cell chromosomes. Other lentiviruses are the simian, the feline, and the bovine immunodeficiency viruses; the Visna virus of sheep; the caprine arthritis-encephalitis virus; and the equine infectious anemia virus.

The genome of HIV is a single-stranded positive-sense RNA molecule, 9.5 kb in length, which encodes the typical retrovirus structural proteins Gag, further cleaved into $p18_{gag}$ (Matrix), $p24_{gag}$ (Capsid), and $p7_{gag}$ and $p9_{gag}$ (Nucleocapsid) proteins; Pol, itself cleaved into $p12_{pol}$ (Protease), $p68_{pol}$ (RT), and $p31_{pol}$ (Integrase); and Env, a 160-kDa glycoprotein eventually cleaved into a $gp120_{env}$ external subunit and a $gp41_{env}$ transmembrane subunit that together form trimeric spikes on the surface of the virion. In addition, the genome encodes a variety of nonstructural proteins, such as the regulatory proteins Tat and Rev and the accessory proteins Nef, Vif, Vpr, and Vpu (Fig. 29.1). Viral replication is initiated by the action of RT, which makes a proviral DNA copy of the RNA genome.

TABLE 29.1 Obstacles to the Development of HIV Vaccines

Absence of spontaneous recovery from natural infection

Transmission of the disease by mucosal routes
Transmission of the virus by infected cells
Integration of the viral genome into host cell chromosomes
Persistence of the virus in a latent state in resting memory T cells
Rapid emergence of viral escape mutants in the host
Downregulation of major histocompatibility complex class I antigen presentation
Masking of the broad neutralization epitopes on virion spikes
Lack of an ideal HIV-1 animal model, requiring long and expensive human clinical trials

The provirus migrates into the host cell nucleus where it integrates into host cell genes at the periphery of the nucleus, in close correspondence with the nuclear pore[65] and in contact with various nucleoporins. The integrated provirus is then eventually transcribed into a set of messenger RNAs (mRNAs) with various splicing patterns that encode the various viral proteins, or into full-length progeny viral RNA that is transported to the cytoplasm where it will be encapsidated into progeny virions.

Virions emerge from the infected cell by budding as immature, noninfectious virus particles in which the Gag polyprotein is still intact and arranged in a radial fashion.[66] Gag is eventually cleaved by the viral protease, resulting in a dramatic morphological rearrangement that leads to the formation of mature virus core and acquisition of infectivity. Assembly and egress of new virus particles most often occur at sites of transient contact between an infected cell and a naïve target cell, resulting in the formation of "virological synapses" in which the membranes of the two cells form protrusions that come together like interlocking fingers.[67–70] Virological synapses allow the virus to directly spread to the uninfected target cell and shield progeny virions from neutralizing antibodies.[71] However, many synapses appear to be porous and antibodies can enter.[72]

The HIV virion consists of an internal cone-shaped capsid built from 1200 molecules of capsid protein ($p24_{gag}$) and surrounded by the viral lipid envelope, wrapped on a scaffold of matrix protein ($p17_{gag}$), and spiked with some 15 trimers of the highly glycosylated protein gp160 (gp120 + gp41) (Fig. 29.2).[73–75] There is evidence that the envelope of the virus also contains numerous molecules of type II human leukocyte antigen (HLA)-DR and β_2-microglobulin borrowed from the host cell in which the virus last replicated, together with cell membrane proteins, including CD43, CD44, CD55, CD59,

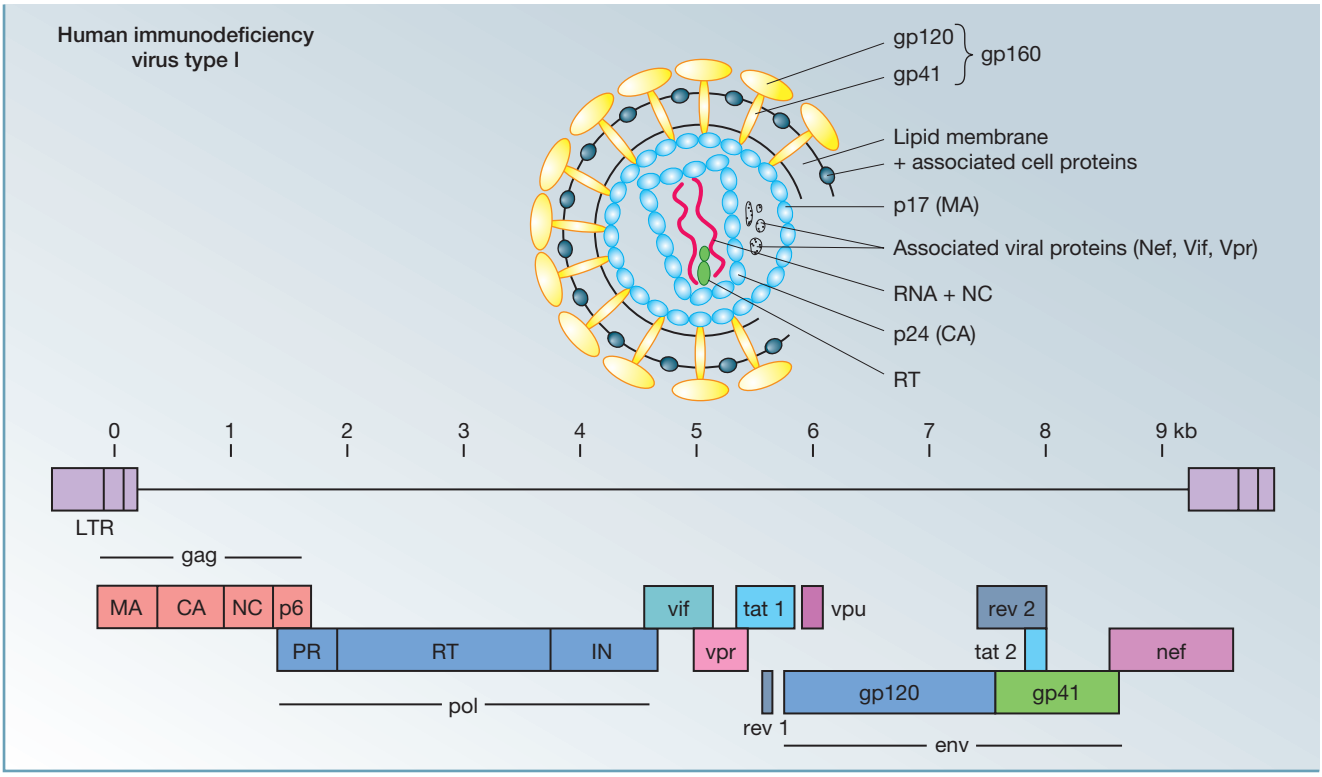

Figure 29.1. HIV-1 genomic organization and structure of the virion. CA, capsid; IN: integrase; MA, matrix; NC, nucleocapsid; PR, protease; RT, reverse transcriptase.

CD63, or CD71; leukocyte function–associated antigen (LFA)-1; and intercellular adhesion molecule (ICAM)-1.[76] This explains why the virus can be neutralized by antibodies to HLA-DR, LFA-1, β_2-microglobulin, or ICAM-1.[77]

The virus capsid contains two copies of the RNA genome associated with the nucleocapsid protein ($p7_{gag}$), together with the transfer RNA molecules that serve as primers for their reverse transcription. The capsid also contains internal viral proteins p1, p2, and p6, copies of viral proteins Vpr, Nef, and Vif, which play a role in the early events of HIV replication, and a few host proteins such as cyclophilin A, Tsg101, calmodulin, actin, cofifin, ezrin, and moesin.[78] Cyclophilin A binds tripartite motif (TRIM)-5α, an important mediator of innate antiretroviral immunity which is the basis for the resistance of Old World monkeys to HIV-1 infection and an important factor in the susceptibility of macaque monkeys to SIV infection.[79–83]

The ***env* gene** codes for the HIV-1 envelope gp160 glycoprotein that forms the trimeric spikes at the surface of the virion. gp160 folding, cleavage in the Golgi into noncovalently associated subunits gp120 (the external chain) and gp41 (the transmembrane chain), trimerization, glycosylation, and transport to the cell surface have been studied in detail.[83–85] Target cell tropism and attachment of the virus are determined by the gp120 moiety, which binds sequentially to the CD4 receptor then to the CCR5 or CXCR-4 coreceptors, whereas gp41 anchors the viral envelope spikes in the viral envelope and maintains their trimeric organization.[86] There is evidence that the $\alpha_4\beta_7$ integrin, the gut mucosal homing receptor, which is in a complex with CD4 in metabolically active $CD4^+$ T-cells, also serves as coreceptor.[87,88] The specific affinity of gp120 for $\alpha_4\beta_7$ provides a mechanism for HIV-1 to target activated T-cells in the gut-associated lymphoid tissue (GALT).[89] The membrane-proximal external region (MPER) of gp41 contains the receptor-binding site to the mucosal HIV-1–receptor galactosyl ceramide, as well as a calcium-binding site, and is one of the principal sites for binding of broadly neutralizing antibodies (bNAbs) (see below).[90,91] gp120 is heavily glycosylated at 25 to 35 glycosylation sites[92] with a mixture of high-mannose and complex sialic acid-containing carbohydrates,[73] that provides a 50 kDa "glycan shield" to neutralization epitopes.[93]

The ***gag* gene** is transcribed into either a *gag* or a *gag-pol* mRNA, whose translation yields $Pr55_{gag}$ and $p160_{gag\text{-}pol}$, respectively. $Pr55_{gag}$ is eventually cleaved to generate the $p17_{gag}$ matrix protein, the $p24_{gag}$ capsid protein, and the $p7_{gag}$ nucleocapsid protein. The $p7_{gag}$ nucleocapsid protein, which remains in tight association with the RNA genome, contains two zinc finger motifs that bind a zinc ion in a tetrahedral conformation necessary for packaging of viral RNA and infectivity.[94,95]

The ***pol* gene** encodes key viral enzymes, RT, which is associated with an RNase H activity, integrase, which allows the integration of the provirus DNA into the host T-cell genome, and the aspartyl proteinase, a homodimer of two subunits, which each contributes the amino acid triplet DTG to form the active site of the enzyme. The viral protease is required for virus maturation.

The ***tat* gene** encodes a *trans*-activating protein that prevents premature termination of provirus transcription through binding to a 59 residue stem-loop at the 5′ end of the nascent viral mRNA molecules called the *Tat-responsive element*, increasing production of viral mRNA several hundred-fold. The process involves the Tat-cdk9/cyclin T1 phosphorylation of RNA polymerase II.[96] Tat also plays a role in AIDS pathogenesis: free Tat molecules are released by HIV-1–infected cells[97,98] and activate, at a distance, uninfected $CD4^+$ T-cells through interaction with cell membrane lipid rafts and internalization followed by transport to the cell nucleus.[99] Anti-Tat antibodies are associated with long-term nonprogression.[98]

The ***rev* gene** encodes a protein that binds to a specific sequence element, the Rev-responsive element, which is present on the unspliced or single-spliced viral mRNAs that encode Gag, Pol, and Env. This allows their transportation from the nucleus to the cytoplasm and permits the expression of structural proteins Gag, Pol, and Env. Rev thus controls the switch from an early phase of the virus replication cycle, when only regulatory proteins Tat and Rev and accessory proteins Nef, Vif, Vpu, and Vpx are synthesized from multispliced mRNAs, to a late phase, when structural proteins are made and virions assembled.[100]

The ***nef* gene** encodes a major virulence factor, the myristoylated Nef protein, which contributes to the maintenance of high viral loads and promotes activation of resting T cells by selectively binding the p21-associated kinase 2.[101–104] Extracellular Nef also contributes to the depletion of $CD4^+$ T cells by interacting with the CXCR-4 receptor and inducing Fas ligand–mediated apoptosis of uninfected bystander $CD4^+$ T cells.[105,106] Intracellular Nef downmodulates cell-surface expression of both CD4 and class I MHC (HLA) antigens, thus providing infected cells with a mechanism for evading the host cellular immune response.[42,43,107,108] Transgenic mice that express the SIV *nef* gene in their $CD4^+$ T cells develop an AIDS-like disease with $CD4^+$ T-cell depletion, activation, and apoptosis.[109,110] As a corollary, SIV with a deletion in the *nef* gene (SIV Δnef) is attenuated and can serve as a live attenuated virus vaccine in macaque monkeys.[111–115] The Nef protein also increases viral infectivity by inhibiting the incorporation into progeny virions of two host-cell antiviral proteins, SERINC3 and SERINC5.[116,117]

The precise role and importance of the accessory proteins Vif, Vpr, and Vpu are still not completely deciphered (Table 29.2). Vpr binds cyclophilin A and induces cell-cycle arrest in G_2 and apoptosis[118,119]; it also enhances HIV replication in macrophages and nondividing cells by allowing entry of the

TABLE 29.2 Role of HIV-1 Accessory Proteins

Gene	Principal Role
Nef	Activation of resting CD4⁺ T cells Downmodulation of human leukocyte antigen Apoptosis of bystander CD4⁺ T cells
Vif	Inactivation of APOBEC3G
Vpr	Arrest of cell cycle in G_2
Vpu	Blockage of tetherin
Vpx	Blockage of TRIM5α and SAMHD1

SAMHD1, sterile alpha motif and histidine-aspartate–domain-containing protein 1; TRIM, tripartite motif.

viral preintegration complex into the nucleus of the cell.[119] Vpu forms ion channels in the cell membrane, which promotes the release of progeny virions from infected cells. It also antagonizes the action of tetherin (CD317/BST2), which opposes the release of fully formed virions at the surface of infected cells,[120,121] a role played by Nef in NHP lentiviruses,[122,123] as well as in HIV-1 group O virus strains.[124,125] Vpu also binds CD4 molecules and targets them to the proteasome, leading to their degradation. HIV-2 and SIV lack a *vpu* gene but carry another accessory gene, *vpx*, which appears to be a duplication of *vpr*[126–128] and counteracts the restriction factor SAMHD1 (sterile alpha motif and histidine-aspartate–domain-containing protein 1).[129]

Vif prevents HIV inactivation by APOBEC3G (A3G), which can edit the HIV-1 early reverse transcripts through cytidine deamination, leading to degradation of the provirus DNA.[130–132] Vif connects A3G to a polyubiquitination complex that leads to its proteasomal degradation.[133–135] A3G expression is one of the key determinants of innate immunity that counter HIV infection in humans and SIV infection in macaques.[136–143] The Vif protein also associates with cytoskeleton intermediate filaments and helps transport incoming virus to the cell nucleus.

VIRUS–CELL INTERACTIONS

Entry of HIV-1 into cells is a multistep process in which the Env glycoprotein interacts with attachment factors and engages the CD4 receptor then the CCR5 or CXCR-4 coreceptor. Thus, virus entry can be efficiently prevented by targeting the CD4 binding site on gp120 using either a composite molecule such as the eCD4-Ig[144] or a broadly neutralizing monoclonal antibody such as VRC01 or 3BNC117.[145] Adhesion of the virions to target cells results from nonspecific interactions between gp120 and charged groups at the surface of the cell, such as heparin sulfate proteoglycans. Major HIV attachment factors are syndecans[146] such as DC-SIGN, a mannose-binding lectin at the surface of dendritic cells (DCs) and macrophages.[147] Immature DCs capture the virus by their surface DC-SIGN, internalize it by endocytosis into multivesicular endosomal bodies, and transmit it to T cells by exocytosis into the extracellular medium in association with vesicular exosomes. Transmission from DCs to T cells thus does not require a second round of infection and provides HIV an avenue for escaping immune responses.[148]

HIV-1, HIV-2, and SIV use as their main receptor, the CD4 (OK-T4) molecule, which is present on the surface of T-helper lymphocytes (CD4⁺ T cells), monocyte-macrophages, lymph node follicular DCs, Langerhans cells in the skin, and microglia in the central nervous system.[149,150] The virus can also infect CD4⁻ cells such as glial cells, natural killer (NK) cells, brain endothelial cells, gut epithelial cells, and probably epithelial cells in the genital tract by using the glycolipid galactosyl ceramide as a receptor.[151]

The CD4-binding domain of the gp120 molecule is a complex conformational motif comprising a recessed pocket flanked by variable regions with considerable glycosylation.[152,153] Monomeric gp120 seems to be a highly flexible molecule in which neither the receptor (CD4)-binding nor the coreceptor (CCR5 or CXCR-4)-binding sites are properly formed.[154–156] Binding of gp120 to CD4 triggers conformational changes in the molecule, including the displacement of the V1V2 hypervariable loops, which results in the exposure of the coreceptor binding site (Fig. 29.3). The choice of the CCR5 or CXCR-4 coreceptor is largely dependent on the amino acid sequence of the V3 loop, which thus determines which type of cells the virus can infect.[157–159]

Binding of gp120 to the coreceptor in turn triggers conformational changes in the gp41 ectodomain, resulting in exposure of the highly hydrophobic, glycine-rich, N-terminal fusion peptide, which needs to be inserted into the target cell membrane to initiate virus–cell fusion (see Fig. 29.3).[160–162] The rod-like trimeric structure of gp41 comprises three parallel N-terminal α-helices ("heptad repeats") assembled as a coil in the center with three antiparallel C-terminal α-helices packed on the outside.[163–165] Binding of gp120 to the cell surface triggers a first change of conformation of gp41 which adopts an extended conformation referred to as the "prehairpin intermediate."[166,167] This allows the gp41 N-terminal fusion peptide to be projected into the target cell membrane. Refolding of the gp41 heptad repeats in to a hairpin conformation reconstitutes the six-helix bundle and places the fusion peptide and the transmembrane segment of gp41 at the same end of the molecule, bringing the viral and cell membranes together and initiating fusion. This process is very reminiscent of the virus–cell fusion mechanism mediated by the influenza virus HA molecule.[168,169] It has been suggested that several HIV-1 envelope trimers must cooperate and assemble into an aster to create a fusion pore needed for virus core entry.[165] The postfusion form of gp41 probably presents distinct antigenic motifs to the immune system.[170]

Most HIV-1 isolates obtained at the time of primary infection and during the asymptomatic period of the disease use the CCR5 coreceptor and for that reason are called **R5.** R5 HIV-1 strains are macrophage-tropic **(M-tropic)**, replicate in peripheral blood mononuclear cells (PBMCs) and in effector memory CD4⁺ CCR5⁺ T cells, but do not form syncytia in culture nor infect transformed CD4⁺ T-cell lines.[171] Emerging late in infection in association with progression to AIDS are T-lymphotropic **(T-tropic)** isolates, called **R5-X4,** which primarily use the CXCR-4 coreceptor, can replicate in immortalized T-cell lines, and can form syncytia in CD4⁺ T-cell cultures.[172] A subset of T-tropic HIV-1 strains has been adapted to grow in CD4⁺ T-cell lines and has become T-cell line-adapted **(TCLA),** losing their ability to grow in PBMCs and to use the CCR5 coreceptor. They are for that reason, called **X4.** Unlike HIV-1, both M-tropic and T-tropic SIV isolates use CCR-5 but not CXCR-4.[173]

A remarkable resistance to HIV-1 infection was observed in individuals with a 32-bp deletion in both alleles of the CCR5 gene, which encodes the CCR5 coreceptor.[174–179] The deletion is thought to have occurred approximately 4000 years ago in Northern Europe, where its frequency today can reach up to 10% to 15% in some populations, whereas it is totally unknown in the African and Asian populations.[180,181] The frequency of the Δ32 homozygosity, which is 1% to 3% in the general white population, reaches up to 25% in uninfected hemophiliacs.[182] A few individuals who are

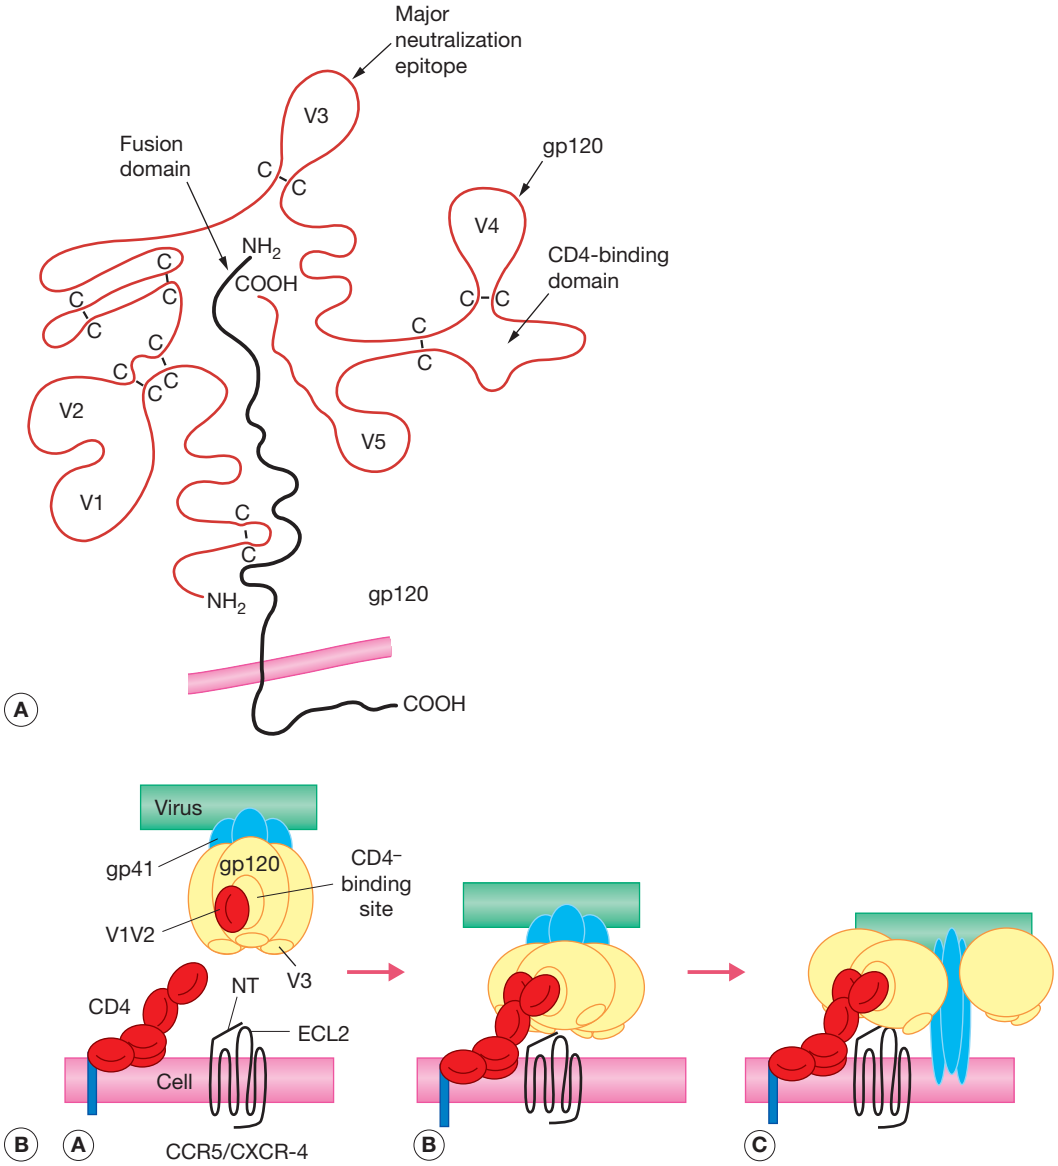

Figure 29.3. A–B, Interaction of the Env spike with target cell receptor and coreceptor.

homozygous for the Δ32 mutation have nevertheless been found to be infected with HIV-1, suggesting they probably were infected with an X4 virus strain.[183] Other genetic polymorphisms in the chemokine receptors that can affect host resistance or susceptibility to HIV-1 infection have also been identified.[184,185]

Penetration of HIV-1 through the mucosal barrier of the genital or the intestinal mucosa can involve uptake of the virus by intraepithelial Langerhans cells or DCs, as is observed in pluristratified squamous epithelia such as those of the vagina and exocervix, the anus, the oral cavity, and the esophagus. It can also happen by translocation of the virus across simple columnar epithelia such as those of the endocervix, rectum, and intestinal tract by the mechanism of transcytosis.[186]

CLINICAL DISEASE

AIDS can be viewed as a "tale of two infections"—(a) an acute infection in which the virus massively depletes mucosal lamina propria and intraepithelial $CD4^+$ T cells in the genital and GALTs, and (b) a chronic infection in which the wounded immune system progressively dies.[187,188] The major site of HIV replication is the GALT and mesenteric lymph nodes,[189] because these tissues are rich in highly activated $\alpha_4\beta_7^+$ $CCR5^+$ $CD4^+$ memory T cells that are the primary target of the virus.[171,190] Average content of HIV-1 proviral DNA per million $CD4^+$ T cells is on average five times higher in the gut than in the peripheral blood.[191] Both viral RNA and proviral DNA remain concentrated in the gut of patients receiving ART even though their viral loads have become undetectable.[192]

HIV-1 replication first occurs in a small number of resting $CD4^+$ T cells in the genital mucosa in the case of sexual transmission.[193] In 80% of sexual transmission cases, a single (founder) R5 virus clone establishes productive clinical infection, even though multiple sequence variants may be transmitted.[194–198] Within 1 day after atraumatic SIV vaginal exposure, plasmacytoid DCs line the endocervical submucosa and express numerous inflammatory markers, including

chemokines that attract $CD4^+$ $CCR\text{-}5^+$ T cells within the endocervix, thus initiating an inflammatory cascade leading to an influx of potential target T cells. At the same time the founder virus undergoes rapid mutations, eventually yielding a swarm of related molecular clones that form a "quasispecies"[199] and allow for optimal selection of variants which readily escape the host immune response.[37,39–41] Ultradeep sequencing has revealed that during the first weeks of infection, the virus explores an extraordinary array of potential escape routes in the process of evading the earliest $CD8^+$ T-cell responses, with dramatic shifts in the frequencies of epitope variants, probably because of a complex interplay between viral fitness and immune escape.[41,200] In contrast to heterosexual transmission, injection drug use seems to be associated with the transmission of multiple founder viruses.[201]

The initial viral eclipse phase lasts for only a few days and is followed by an explosive viral expansion that leads to unabated viral replication in activated $CD4^+$ T cells especially in the GALT,[89] constituting the primary, acute phase of infection. The patient experiences an acute febrile phase with disseminated lymphadenopathy, rash, and arthralgia, reminiscent of an episode of infectious mononucleosis. A transient decrease in total lymphocyte count and an inversion of the CD4-to-CD8 ratio are observed. This is accompanied by Gag p24 antigenemia and high plasma viral loads.

HIV-1 infection rapidly leads to the onset of a generalized chronic immune activation with increased T-cell turnover, increased polyclonal B-cell activation, increased frequencies of T cells with an activated phenotype ($CD38^+$, $HLA\text{-}DR^+$), and increased production of proinflammatory cytokines and chemokines.[26] Chronic immune activation is thought to result from increased permeability of the intestinal epithelium to bacterial products such as lipopolysaccharides,[202–204] the concentration of which in the blood correlates positively with viral load and negatively with $CD4^+$ T-cell count in both HIV-1– and HIV-2–infected humans.[205] Similar correlations are observed in SIV infection in macaque monkeys, but not in SIV-infected sooty mangabeys, which do not develop AIDS. The influx of microbial products and the increased amount of inflammatory cytokines in the blood of infected individuals induce the upregulation of PD-1 (programmed death-1) on lymphocytes and monocytes that results in interleukin (IL)-10 production and impairment of T-cell responses.[206–209] It also results in apoptosis of noninfected bystander $CD4^+$ T cells, which are readily found in HIV-1–infected humans or SIV-infected macaques[210–212] and show strongly upregulated expression of the PD-1 marker.[213] PD-1 expression was found to correlate with HIV viral load and inversely correlate with T-cell counts.[214] The degree of systemic immune activation is today considered a better predictor of disease progression than plasma viral loads.

Studies of pathogenic and nonpathogenic lentiviral infections in NHPs suggest a major role for T-helper (Th)17 cells in controlling the infection, as Th17 cells secrete IL-17, a cytokine that helps maintain the integrity of the mucosal barrier.[215–218] Early destruction of Th17 cells is explained by the fact that they express the CCR5 coreceptor and thus can serve as preferential targets for virus replication.[219,220] Pathogenic SIV infection in macaques, as well as HIV-1 infection in humans, is associated with loss of Th17 cells and an increase in the frequency of $CD4^+$ $CD25^+$ $Foxp3^+$ regulatory T cells (**Tregs**).[221–225] Foxp3+ Treg cells secrete transforming growth factor-β and IL-10, and dampen the CTL response to HIV infection.

The primary, acute phase of infection ends when the cellular immune system responds. A long asymptomatic period of clinical latency follows, corresponding to the chronic phase of infection (Fig. 29.4). During that phase a slow-but-steady

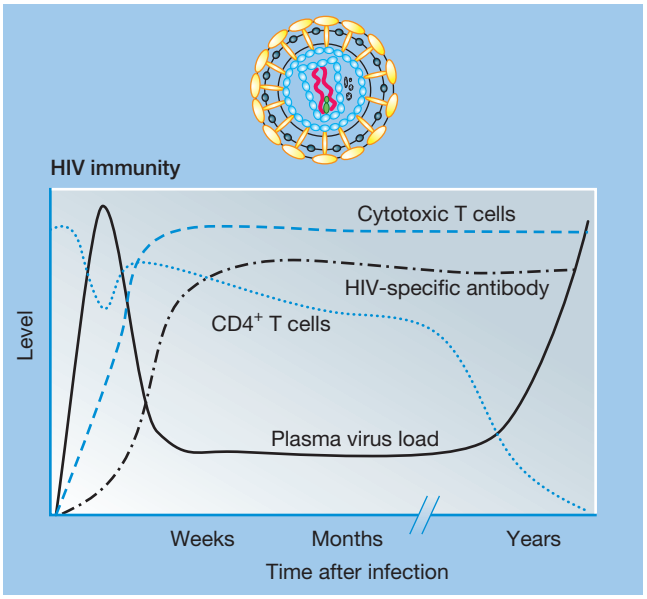

Figure 29.4. Diagrammatic representation of the evolution of virological and immunological markers during the course of a typical HIV-1 infection.

decline in $CD4^+$ T cells number is observed. A humoral immune response occurs and the patient becomes seropositive, except in very rare cases of rapid progression to AIDS[226]; the patient is less infectious than during the primary phase of the disease because viral replication continues at a more restrained pace. The major site of virus replication again is the GALT, essentially the colon and rectum.[227] The plasma viral load, which peaked during the acute phase of infection at values of 10^6 to greater than 10^7 viral RNA copies per milliliter, declines and remains at a relatively stable plateau (the **set-point**) during chronic infection. The set-point differs from patient to patient and serves as an indicator of disease progression. It remains high in **fast progressors,** who rapidly progress to AIDS, whereas it falls to relatively low values in **long-term nonprogressors,** who contain viremia spontaneously and progress to disease slowly. Thus, patients with more than 10^5 HIV RNA copies per milliliter of plasma at set-point are 10-fold more likely to progress to AIDS during the following 5 years than those with less than 10^5 copies/mL. In a few seropositive persons, called **elite controllers** or **elite suppressors,** viral loads spontaneously fall below the limit of detection by standard clinical assays (<50–75 viral RNA copies/mL).[228,229] However, even in these patients, virus replication continues at a low pace, as judged from the observation that the *rt* and *env* genes of the resident HIV-1 strain undergo sequence changes over time.[230,231]

HIV-1 rapidly evades neutralizing antibody responses during the course of infection in an individual.[38,93] The virus also readily escapes specific CTL responses.[232–239] Of note is the fact that some viral escape mutations in response to immune pressure come at a fitness cost to the virus,[240] which eventually reverts to wild-type sequences after transmission to a new host.[241–243] Selective pressures within microenvironments of different anatomic compartments result in the emergence in various tissues of distinct, independently evolving replication-competent quasispecies.[244]

The asymptomatic phase of the infection can last from a few months to more than 25 years, after which symptoms occur, following onset of opportunistic infections. At times, HIV infection can also manifest itself as a purely cachectic

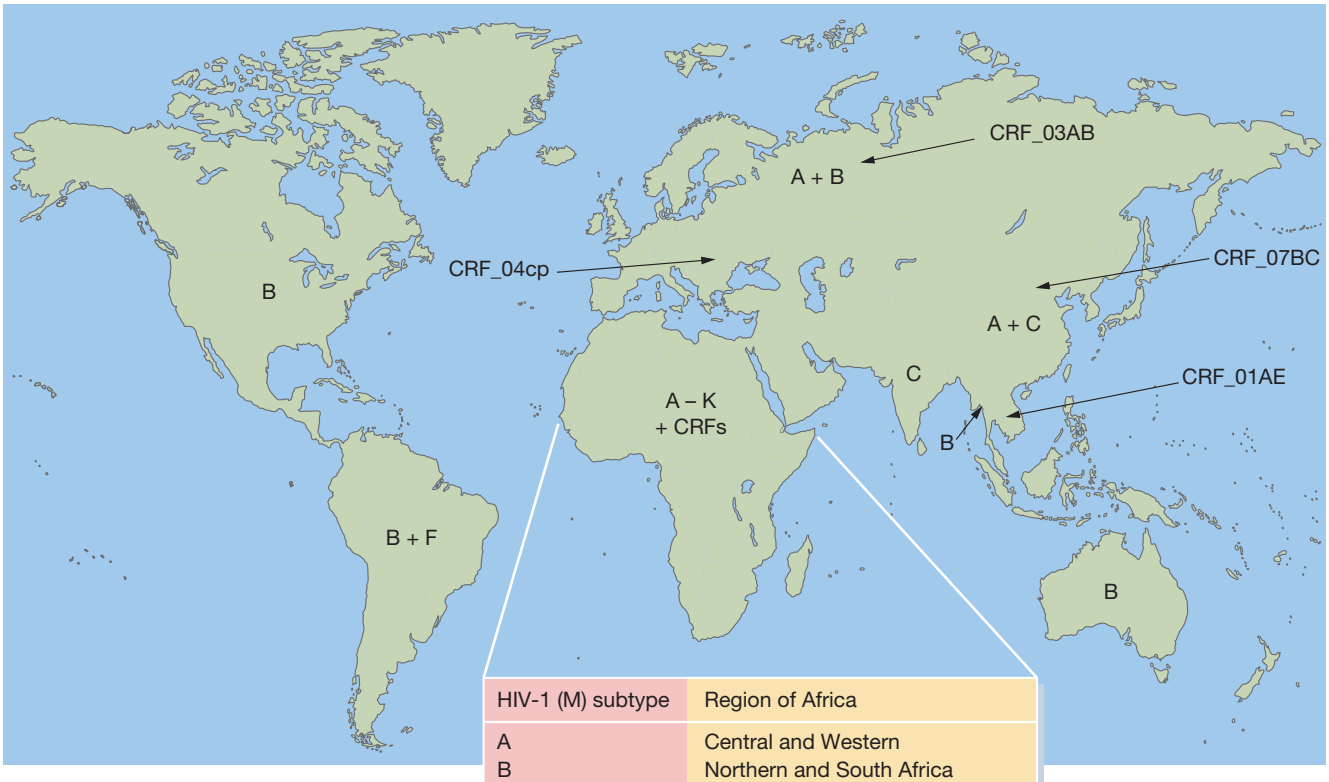
disease, to which the name *slim disease* has been given in Africa. It can also cause a neurological syndrome such as acute encephalitis or progressive dementia (the "AIDS dementia complex"). The symptomatic phase of the disease is accompanied by a return of *gag* p24 antigenemia, an accelerated decrease in the number of $CD4^+$ T cells, and a greatly increased virus load. The number of peripheral T cells producing HIV-1 can reach 1 in 10, with production of up to 10^{10} virions per day.[245–248]

Direct killing of $CD4^+$ T cells by HIV-1 cannot however explain the full spectrum of AIDS pathogenesis. Chimpanzee-adapted strains of HIV-1 are cytopathic for chimpanzee $CD4^+$ T cells, grow in chimpanzee macrophages-monocytes, and replicate efficiently in chimpanzees, but usually do not cause AIDS in the animal.[249,250] Similarly, SIVmac infection in African NHP such as mandrills or sooty mangabey monkeys remains chronic and almost never progresses to AIDS.[251–255] Natural NHP hosts that are infected by SIVs in the wild, show no evidence for destruction of their $CD4^+$ T cells, although they maintain high plasma viral loads[256–258] and do not exhibit superior cellular immune control of viremia.[259] SIV-infected sooty mangabeys do lose $CD4^+$ T cells but develop double-negative ($CD3^+$, $CD4^-$, $CD8^-$) T cells that are able to maintain efficient immune responses and prevent the appearance of AIDS.[260]

Interestingly, these SIV-infected African monkeys show no evidence for persisting chronic immune activation[261] and no evidence for apoptotic $CD4^+$ T lymphocytes, in contrast to HIV-1–infected humans or SIVmac-infected macaques.[218] These observations strengthen the likely role of chronic immune activation being caused by microbial translocation in the eventual collapse of the T-cell compartment in the course of infection.[202,262–264] Hyperactivation overwhelms the immune system and gradually causes a collapse of immune-protective mechanisms, leading to AIDS. This is observed even in "elite controllers," who show abnormal T-cell activation levels leading to progressive $CD4^+$ T-cell loss in the absence of detectable viremia.[265] In addition, other mechanisms have been suggested to account for the depletion of $CD4^+$ T cells, such as cytolytic attack by HIV-1–specific CTLs of bystander $CD4^+$ T cells that have bound virus-shed circulating gp120 molecules; apoptosis of bystander $CD4^+$ T cells mediated by circulating Tat or Nef proteins, molecular mimicry between the ectodomain of gp41 and IL-2, leading to the induction of anti–IL-2 antibodies that could block the interaction of the cytokine with its receptor[266]; and apoptosis of bystander T cells triggered by incomplete reverse transcripts during abortive HIV infection.[267,268] Abortive HIV replication leads to $CD4^+$ T-cell death by pyroptosis and drives the $CD4^+$ T-cell depletion in HIV-infected persons.[268] The death of uninfected bystander $CD4^+$ T cells has also been linked to the expression of the ligand to the NK cell receptor NKp44, which makes $CD4^+$ T cells sensitive to NK lysis.[269,270] The mechanism involves a gp41 motif located between residues 618 and 623, the 3S motif, which is able to elicit the expression of the cellular ligand of NKp44 (NKp44L) through binding to the receptor of the C1q complement factor gC1qR. Indeed, anti-3S antibodies inhibit NKp44L expression on $CD4^+$ T cells and elicit protection against NK-cell–mediated $CD4^+$ T-cell loss in NHP models.[271,272]

AIDS patients are anergic to recall antigens, as seen by lack of delayed-type hypersensitivity (skin test) in vivo and by lack of T-helper cell proliferation in vitro. The unresponsiveness to recall antigens has been interpreted as the consequence of HIV infection of follicular DCs, which severely impairs the ability of these cells to present antigens in vitro and which triggers the secretion of IL-10.[273,274] Anergy was indeed found to correlate with destruction of the lymph node follicles.[275,276] Patients with AIDS also show increased levels of tumor necrosis factor (TNF)-α, IL-1, IL-2, and IL-6, interferon (IFN)-α and IFN-β, β_2-microglobulin, and neopterin, an interleukin produced by macrophages in response to TNF-α.[277]

Not all exposures to HIV, however, lead to infection and not all HIV infections lead to AIDS. Only one-third of infants born to infected untreated mothers acquire infection, heterosexual transmission occurs approximately between 1 out of 100 and 1 out of 1000 exposures,[278–281] hemophiliacs exposed to infected blood products do not consistently get infected,[282] and some commercial sex workers and seronegative partners in serodiscordant couples appear to remain uninfected despite repeated extensive exposure to HIV-1.[283,284] These **highly exposed persistently seronegative (HEPS)** persons, also simply called **exposed uninfected (EU)** persons, have been the object of numerous studies to try to decipher possible correlates of protection that could be used for the development of protective HIV vaccines (see below).



VIRUS VARIABILITY

HIV-1 exhibits a remarkable degree of genetic variability in the host that results from the error-prone nature of RT (approximately 3×10^{-5} mistakes per replication cycle), together with high rates of virus production (up to 10^{10} particles per day per infected person during the acute early phase of infection) and high frequency of recombination (seven to 30 crossover's per genome, per round).[245,285] In general, genetic diversity among virus clones within an individual is approximately 2% to 3%.

HIV-1 strains in group M are found worldwide and show major diversity. They have been divided into 10 **subtypes**, or **clades**, designated by letters A to K,[285,286] which are approximately equidistantly related and exhibit 25% to 35% amino acid sequence difference in their Env protein. HIV-1 subtype B predominates in industrialized countries, as well as in Latin America and the Caribbean, but causes less than 12% of all global infections.[287,288] HIV-1 subtype C, in contrast, accounts for nearly half (48%) of all global infections and predominates in Southern Africa, Eastern Africa, and India. Subtypes A and D are more common in Central Africa, with subtype A appearing to have followed heroin trading routes into Eastern Europe.[289] East African HIV-1 infections are predominantly caused by subtype C and to a lesser extent by subtypes A and D.

In addition, numerous HIV-1 interclade recombinant viral strains have been detected, an indication that superinfection by a second HIV-1 strain is not uncommon.[290–295] Recombinant virus strains which contain genetic material from more than one subtype and which are circulating widely in the population have been designated **circulating recombinant forms (CRFs)**.[285,296] The greatest diversity of HIV-1 subtypes and recombinants is found in Central Africa where all clades and many CRFs are present (Fig. 29.5). In West Africa, all clades are also detected with the dominant variants being CRF02_AG and subtype G. All major subtypes and many CRFs and unique recombinant forms are similarly found in Western and Central Europe. CRF03_AB is prevalent in Russia and Central Asia, whereas in East Asia, the epidemic is dominated by CRF07_BC, CRF08_BC, and CRF01_AE, and in South-East Asia by CRF01_AE-often wrongly called *subtype E*.[287]

The biological significance of such a high degree of variability remains unknown. There are no clear genotype–serotype relationships between subtype or CRF sequences and neutralizing antibody patterns. Presumably, a recombinant virus strain that becomes predominant in an individual has some type of selective advantage over the parental strains, either because of enhanced fitness or immune evasion. When

Figure 29.5. Geographic distribution of major HIV-1 M group subtypes.

such a recombinant emerges as the predominant strain in an epidemic in a population, this also must be the result of significant selective advantages. The fear that an HIV strain would readily escape from too narrow an immune response induced by a vaccine is in favor of the development of vaccines that target multiple HIV antigens and if possible multiple viral subtypes, so as to provide as broad as possible a protection. This has also led to the development of fully synthetic genes derived from theoretically defined **consensus** or ancestral HIV envelope sequences,[297–299] which were found to be superior to many wild-type immunogens for inducing cross-subtype T-cell and B-cell immune responses.[300,301] Similarly, **mosaic antigens** have been developed with sequences derived from in silico algorithms that closely match the sequences of natural HIV-1 strains worldwide and maximize the overlap between them.[302–305]

There is convincing evidence that HIV originated in NHPs.[306,307] Several independent crossing of the species barrier from chimpanzees living in Western Central Africa led to HIV-1 groups M, N, and O in humans, whereas multiple independent transmissions of SIV from West African sooty mangabeys led to HIV-2.[4,308–311] Thus, HIV-1 groups M, N, and O are phylogenetically close to SIVcpz, a commensal virus in chimpanzees *Pan troglodytes*, whereas HIV-2 is closely related to SIVsmm, a commensal virus in sooty mangabey monkeys *(Cercocebus atys)*; the SIV, which causes AIDS in Asian rhesus macaques *(Macaca mulatta)*, is similarly closely related to SIVsmm from sooty mangabeys. Recently identified HIV-1 group P is related to SIVgor, a commensal virus in gorillas.[62,312]

All these viruses belong in the same group of lentiviruses that infect a wide range of NHP species in Africa,[313–315] where multiple cross-species transmissions in the wild have been documented.[316–318] Molecular clock estimates indicate that HIV-1 group M probably established itself in the human population at the beginning of the 20th century (1884–1924),[319] group O in the 1920s (1890–1940),[320] and group N in the 1960s (1948–1977).[4] In fact, SIVs have been present in African primates for more than 30,000 years, suggesting that humans most probably had many chances of sporadic encounter with these viruses for millennia.[321] Humans are still naturally exposed today to infection by diverse SIVs, as illustrated by the high frequency and diversity of lentiviruses that can be encountered in primate bush meat in Southeastern Cameroon.[322,323]

EPIDEMIOLOGY AND DISEASE BURDEN

HIV transmission occurs essentially through homosexual or heterosexual intercourse, through injection of blood or blood-derived products, and from mother-to-child transmission during pregnancy, at delivery, or through breastfeeding.[5] Recently infected subjects are potentially more infectious than infected individuals in the chronic phase of the disease: it has

been suggested that up to 50% of new HIV-1 infections are acquired from newly infected individuals.[279,324–326] The importance of the acute infection period for subsequent transmission events is related to both the level of plasma viral load during the early phase of disease and to virus-specific properties.[278] Thus, virions isolated from SIV-infected macaques at the time of primary infection are more infectious than those from the chronic phase of infection,[327] possibly because a greater number of defective virus particles are circulating during the chronic than during the acute stage of disease[198] and/or because lack of protective antibodies at primary infection stage substantially increases virus infectivity.[328] The difference in sexual behaviors makes MSM add to their risk of infection because receptive anal intercourse has a relative risk of 1.43%, which is approximately 10 times higher than that of receptive vaginal intercourse.[329]

Since 1981, more than 36 million people have died of AIDS. HIV-1 is the fourth largest infectious killer in the world with an annual toll of approximately 1.2 million deaths,[330,330a] the great majority of which occurs in sub-Saharan Africa. As of 2014, UNAIDS estimated that 36.9 million people were living with HIV-1 infection worldwide, including 2.5 million children younger than 15 years of age. Of these 36.9 million people, 25.8 million lived in sub-Saharan Africa and approximately 5 million in Asia. Approximately 2 million people become infected each year, 95% of whom live in developing countries.[330,330a] The number of new infections is equally distributed among men and women, but infection rates in young African women are close to three times higher than those among young men, reflecting the degree to which gender inequities are driving the epidemic. This is also true in Asia, as young girls are frequently steered toward sex work by their families.

The HIV-1 epidemic has expanded at an alarming rate in the 1990s in sub-Saharan Africa, which hosts 80% of females living with HIV in the world. Highest infection rates are found among commercial sex workers, truck drivers, and seasonal migrant workers. Countless cases of mother-to-child transmission have been documented. In some African countries, overall prevalence in the adult population can be greater than 10%, with figures reaching up to 28% in some areas. Most severely hit are South Africa, with more than 5.5 million infected people, Botswana, Mozambique, Zimbabwe, Tanzania, and Ethiopia. In addition, sub-Saharan Africa faces numerous wars and civil conflicts, producing large numbers of refugees who are at heightened risk of contracting HIV. Through increased awareness campaigns, education and wider access to ART, many African countries are now seeing their incidence rates stabilize or even decrease. The incidence rate in African children has also started to decline, a result of the systematic use of antiviral therapy in pregnant women, as exemplified by programs implemented in South Africa, Swaziland, Botswana, and Namibia.

The estimated number of people living today with HIV-1 in Asia and the Pacific region is 5 million, but the accuracy of the figure is questionable, in view of the fast pace at which the epidemic has been expanding. Increasing sex trade, use of illicit drugs, and rates of sexually transmitted infections contributed to an increased vulnerability in the region. Improper blood donation practices in China and unsafe injection practices in healthcare settings in India and surrounding countries have resulted in hundreds of thousands of infections. Substantial transmission also occurs in MSM, with prevalence rates of 14% to 20% reported in male homosexual communities in India, Cambodia, and Thailand. Gender inequities play a major role in the epidemic. The female commercial sex industry facilitates transmission in Thailand, Cambodia, India, Nepal, China, Vietnam, and several other countries.

The estimated number of adults and children living with HIV-1 in Latin America and the Caribbean at the end of 2014 was 1.7 million. While in some countries HIV infections remained concentrated mainly in MSM and people who inject drugs, others were experiencing increasing rates of heterosexual transmission.

Since the mid-1990s, the Eastern European countries continue to experience a sharp increase in the number of new HIV-1 infections, most of which occur among people who inject drugs, commercial sex workers, and MSM. The number of HIV-infected persons in the region nearly tripled between 2000 and 2009, rising from 500,000 to 1.4 million, of which an estimated 940,000 were living in the Russian Federation and 440,000 in Ukraine.[331]

An estimated 2.3 million people are living with HIV-1 in industrialized countries (1.5 million in North America alone). In France, The Netherlands, and Spain, from one-third to three-fourths of new HIV-1 infections are concentrated among migrants. For the general population, highly active antiretroviral treatment (HAART) has considerably reduced disease progression to AIDS and transformed HIV infection from a deadly disease to a somewhat manageable chronic disease. However, success in treatment and care is not being matched by progress in prevention and new evidence of rising HIV-1 infection rates is emerging, particularly in marginalized communities. For example, in 2010, 1 in 16 black men in Washington, D.C. were HIV-infected, as were 1 in 10 MSM and 1 in 8 were people who inject drugs in New York City.[332] In several U.S. urban areas, the prevalence among MSM was as high as 30%. It is estimated that half a million Americans became infected with HIV in the 2000–2010 decade, including more than 55,000 in 2009 alone.[333] Washington, DC has been beset by an HIV-1 epidemic that rivals some in developing countries,[334] with rates in particular subsets of the heterosexual population as high as 5.2% (6.3% in women vs 3.9% in men).[335,336] HIV-1 infection rates among young people in Western nations are three times higher than in the early 2000s. HIV thus remains a major health threat in these countries.

IMMUNE CORRELATES OF PROTECTION

The immune correlates of protection against HIV infection in humans are still unknown,[337,338] mostly because of the lack of natural protective immunity against HIV. Most available data have been drawn from the study of chronically infected individuals, which does not imply that they would be associated with protection from infection if elicited by a vaccine.[339] Other data arose from the study of vaccine protection of macaques against experimental SIV infection. Possible immune correlates of protection can be of four types: neutralizing antibodies, cellular immune responses, nonneutralizing antibodies, and innate immune responses.

Neutralizing Antibodies

Neutralizing antibody responses to HIV-1 are unusually late, arising several weeks after infection.[340,341] In addition, most antibodies elicited during the course of HIV infection are nonneutralizing or neutralize only a narrow range of circulating viral strains,[93] and many target the highly variable loops in gp120 that act as antigenic decoys, such as the V1 loop,[342] the V2 loop,[343] or the V3 loop.[344–348] Broad neutralization epitopes actually exist on both gp120 and gp41,[348] and at the junction of gp120 and gp41, but they remain poorly accessible to the immune system because of conformation-dependent exposure on the molecule, hindrance by the "glycan shield," and masking by the hypervariable loops in gp120.[349] Although a subset of individuals infected with HIV-1 develop bNAbs a few

years after infection, only a small percentage of those subjects develop Abs that are both potent and broad.[350]

HIV-1 Env: The Target for Broadly Neutralizing Antibodies

HIV-1 has developed several strategies that together enable evasion of neutralization. First, there are relatively few native spikes of HIV-1 Env on the virion, whose surface is primarily composed of denatured spikes and host cell antigens, providing additional decoys for immune responses.[73,74] Second, variable regions of gp120 are highly immunogenic and provide additional decoys focusing immune responses away from conserved epitopes.[344,345,347,351,352] Third, conserved regions of HIV *env* are poorly immunogenic because of masking by a glycan shield over gp120,[93,353] and for other reasons, including steric hindrance,[156,354] and in some cases transient appearance.[170] Gp120 is heavily glycosylated at 25 to 35 glycosylation sites, and antigenically the majority of the glycans are similar to host cell carbohydrates. Last, it has been suggested that some epitopes have homologies with host cell proteins, and immune responses to these epitopes may be polyreactive and thus immunogenicity compromised by tolerance mechanisms.[355,356]

Until recently, the field was focused on four broadly neutralizing monoclonal antibodies identified several years ago. The first HIV-1 broadly neutralizing monoclonal antibody identified was b12, which binds to gp120 at the CD4 binding site.[357–360] The structure of b12 in complex with gp120 demonstrated that b12 binds to a conformationally invariant surface that overlaps a distinct subsurface of the CD4 binding site.[361] Two broadly neutralizing monoclonal antibodies, 2F5 and 4E10, have also been identified that target the MPER of gp41.[362–366] 2F5 binds the ELDKWA sequence in the heptad repeat 2 region of gp41, and 4E10 to the NWFDIT sequence at the point where gp41 inserts into the lipid bilayer.[367,368] These antibodies also attach to the viral membrane via their hydrophobic CDR H3 loops, which is a prerequisite for their neutralizing activity.[369,370] Furthermore, 2G12, a broadly neutralizing monoclonal antibody, targets the high-mannose cluster on the glycan shield of HIV-1,[371–373] and has a unique V(H) domain-exchange structure, with a multivalent binding surface that includes two primary glycan binding sites.[374]

Since 2009, application of novel technologies in recombinant human monoclonal antibody isolation have led to the identification of a large number of new, broader, and more potent HIV-1 specific neutralizing monoclonal antibodies than previously described. These new tools have revolutionized the HIV-1 vaccine field by providing new targets on HIV-1 Env which may now be exploited for vaccine design. The first of these advances came with the identification of PG9 and PG16, broad and potent neutralizing monoclonal antibodies targeting an epitope preferentially expressed on trimeric HIV-Env protein which spans conserved regions of variable loops of gp120.[375] These antibodies were identified by using a high-throughput neutralization screen of antibody, containing supernatants from approximately 30,000 memory B-cells from an HIV-1–infected donor.

Shortly following the identification of PG9 and PG16, antigenically resurfaced glycoproteins, that is, molecularly engineered glycoproteins designed to focus the immune response, were used as probes to identify sera from donors with neutralizing antibodies to the CD4-binding site. Harnessing immunoglobulin genes from B-cells from such donors led to the identification of VRC01 and related monoclonal antibodies which were also very broad and potent[376] and targeted the CD4-binding site. In addition, another monoclonal antibody termed HJ16 was identified that targets a novel epitope proximal to the CD4-binding site and is comparable in breadth to b12.[377]

Finally, a limited number of antibody specificities were found to mediate broad and potent serum neutralization from elite neutralizers, individuals identified by the breadth and potency of their serum for neutralizing standard panels of HIV-1 isolates.[378] Using this information, several additional broad and potent monoclonal antibodies have been identified from other elite neutralizers, with studies currently underway to identify their binding sites on HIV-1.[379] Shown in Fig. 29.6 are a structural model of the HIV-1 Env trimer and binding sites for these monoclonal antibodies, which now represent the principal targets for vaccine design.

These sites include the CD4-binding site on gp120 (the **VRC01** family), the glycan shield and the V1V2 region of gp120 (the **PG9** and **PG16** families), the V3 region of gp120 and the glycans centered on N332 (the **PGT121** family), the base of the spike including elements from both gp120 and

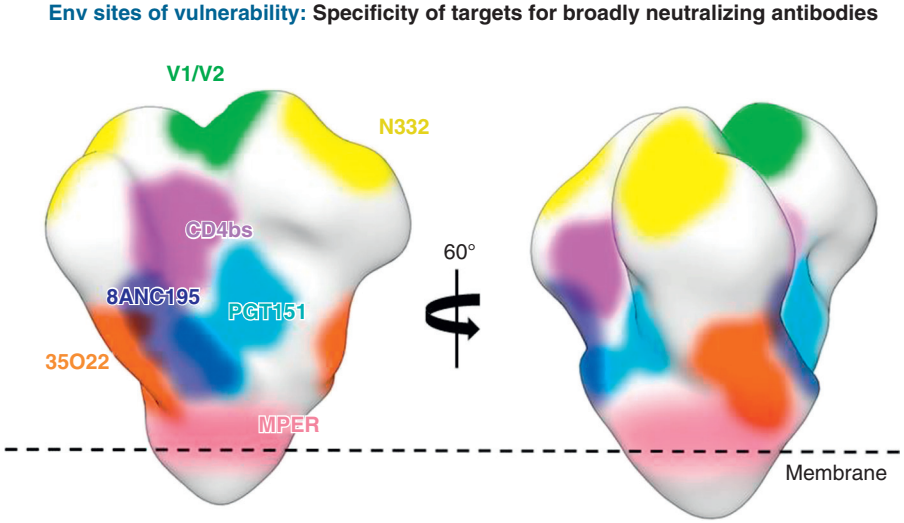

Figure 29.6. Env sites of vulnerability: specificity of targets for broadly neutralizing antibodies. *(From Ward AB, Wilson IA. Insights into the trimeric HIV-1 envelope glycoprotein structure.* Trends Biochem Sci. *2015;40[2]:101–107.)*

gp41 (the **35O22** bNAb), and the MPER of gp41 (the **2F5, 4E10, and 10E8** family).[380] Still another type of bNAb, **PGDM 1400**, was recently isolated from the plasma of a chronically infected donor using the HIV-Env trimer BG505 SOSIP-664 as an affinity reagent.[381] PGDM 1400 is exceptionally broad and potent, with a cross-clade coverage of 83% and a median IC50 of 0.003 μg/mL; it targets a three-dimensional epitope at the apex of trimeric gp120.

Recently, antibodies to a modified 3S gp41 motif with a W614A mutation were found to be able to neutralize a broad array of cross clade HIV-1 strains,[382] implying that the 3S region in gp41 could both be used as a bNAb epitope and elicit protection against $CD4^+$ T-cell depletion.[270,271]

Additionally, there has been a dramatic expansion in the number, breadth, and potency of bNAbs identified against HIV, as biomolecular tools such as single cell B-cell cloning and next generation sequencing become more refined. The site on the HIV-1 gp120 glycoprotein that binds the CD4 receptor is recognized by several bNAbs, many of which neutralize more than 90% of HIV-1 strains. The repertoire for effective recognition of this CD4 supersite comprises antibodies with paratopes arrayed about two optimal geometric orientations, one achieved by CDR H3 ontogenies and the other achieved by VH-gene-restricted ontogenies.[383] A new, broad, and potent neutralizing antibody, which targets the gp41 MPER 10E8,[384] is relatively unique as it does not bind phospholipids, is not autoreactive, and binds the cell-surface envelope. The structure of 10E8 in complex with the complete MPER has revealed a site of vulnerability comprising a narrow stretch of highly conserved gp41-hydrophobic residues and a critical arginine or lysine just before the transmembrane region. These findings have reinvigorated vaccine design efforts targeting the highly conserved MPER region of HIV-Env.

bNAbs targeting the trimer apex of HIV envelope are also a favored candidate for vaccine design because of their great neutralization breadth and potency, as characterized by a subset of the PGT series of antibodies.[385–387] However, methods of isolating bNAbs against this site have been limited by the quaternary nature of the epitope region.

The N-332 site, characterized by antibodies binding to the high-mannose patch, is also another major target for vaccine design[378] and from delineation of antibody recognition in polyclonal sera from patterns of HIV-1 isolate neutralization.[388] Antibody recognition of the N332 region is complex due in part to variability in neighboring loops and glycans critical to the epitopes. Recently, two classes of bNAbs within a single lineage directed to the high-mannose patch of HIV envelope were identified.[389,390] One branch, characterized by bNAb PGT128, has a six-amino-acid insertion in CDRH2 that is crucial for broad neutralization. Antibodies in this branch favor a glycan site at N332 on gp120, whereas, a second branch characterized by bNAb PGT130 lack the insertion and appear to favor the N-334 glycan site. PGT 128 complexed with a fully glycosylated gp120 outer domain at 3.25 angstroms revealed that the antibody penetrates the glycan shield and recognizes two conserved glycans as well as a short β-strand segment of the gp120 V3 loop, accounting for its high binding affinity and broad specificity.[391] Interestingly, in screening plasma of R5 SHIV infected macaques, one monkey was identified with bNAbs and mutagenesis studies mapped the epitope to the N-332 glycan site.[392,393]

Most recently, three groups have identified trimer-specific antibodies that represent novel sites of vulnerability and offer potential to serve as reagents for purification of HIV-Env trimers.[394–396] Monoclonal antibody PGT151 recognizes a glycan-dependent epitope on the prefusion conformation of gp41 and distinguishes cleaved from uncleaved Env trimers.[395] Monoclonal antibody 35022 also binds to a conserved epitope that stretched across gp120 and gp41,[394] and a monoclonal antibody termed 8ANC195 binds to a site that includes portions of gp41 and N-linked glycans adjacent to the CD4-binding site on gp120.[396]

The identification of these new broad and very potent neutralizing monoclonal antibodies has led to further characterization of the antibodies and the observation that most have high levels of somatic mutations and long heavy-chain complementarity determining region 3 (HCDR3), suggestive of extensive affinity maturation.[397–401] For example, the mean number of mutations in an immune response to influenza is approximately 5%, whereas variable heavy-chain mutations for PG9/PG16 and VRC01 range from 11.9% to 31.2%, respectively.[52] The HCDR3 lengths for the broadly neutralizing monoclonal antibodies range from 14 to 30 amino acids, and it has been suggested that B cells' long HCDR3s may be eliminated at the naïve B-cell stage, a hypothesis proposed to account for the difficulties in eliciting such antibody responses.[402,403]

Indeed, bNAbs usually appear on average after 2.0 to 2.5 years of infection, probably because of a need for antibody affinity maturation[404,405] and in persons with higher viral plasma load, suggesting a need for chronic antigen exposure.[406–410] They can nevertheless also be found in infected infants.[411] The development of bNAbs also seems to be driven by immune escape and superinfection mechanisms.[412–414] Up to 50% of subjects ultimately develop neutralizing antibodies with a degree of breadth, but only approximately 1% of the donors, designated as **elite neutralizers**, show unusually potent neutralizing serum activity against a majority of clades.[350]

Experiments in the macaque model have shown that SIV or simian-human immunodeficiency virus (SHIV) infections can be prevented by bNAbs, whether administered by passive immunization, or through vector delivery using an adeno-associated virus (AAV) vector able to continuously express in vivo immunoadhesins derived from bNAbs.[415] Similar protection results by bNAbs expressed from an AAV vector against HIV infection were obtained in a humanized mouse model.[416,417] Similarly, neonatal macaques could be protected from oral SHIV challenge by passive immunization with bNAbs b12, 2G12, and 2F5.[418,419] The therapeutic efficacy of bNAbs was also demonstrated in SHIV-infected adult macaques.[420,421] bNAbs are therefore not associated with control of viremia in the host,[407,422–424] but they can be protective against live virus challenge. Fc-γ-receptor (FcγR)-mediated effector function contributes substantially to the capacity of bNAbs to block virus entry, suppress viremia and confer therapeutic activity.[425]

The major challenge for HIV vaccine development at this time is to translate these findings into the design of immunogens capable of eliciting bNAbs, which could be used as a vaccine (see below)[354,401,426–432]

Cell-Mediated Immunity

Multiple studies have shown that $CD8^+$ T-cell responses control SIV or SHIV replication and the level of the set-point viral load in infected rhesus macaques. The best evidence came from the demonstration that experimental depletion of $CD8^+$ T cells resulted in a rapid and dramatic increase in viremia and accelerated the lethal outcome of the disease in the animals.[433–435] Accidental reemergence of virus and progression to AIDS in long-term protected, DNA-MVA (modified vaccinia virus Ankara) vaccinated macaques was observed at 4 years after challenge with $SHIV_{89.6P}$, coincident with a loss of T-cell function together with appearance of escape mutations in CD8 epitopes.[436] Transient depletion of $CD8^+$ T cells

in rhesus macaques that controlled the replication of SIVmac for 1 to 5 years resulted in 100-fold to 10,000-fold increases in viremia; control was reestablished when the $CD8^+$ T cells returned, at which time some subsets of subdominant $CD8^+$ T cells expanded more than 2500-fold above predepression level.[437] Infection of female macaques with nonpathogenic $SHIV_{89.6}$ used as an attenuated, live vaccine generated protection against uncontrolled SIV replication following vaginal challenge,[438] but depletion of $CD8^+$ T cells at the time of the challenge again completely abrogated protection, demonstrating that it was the $CD8^+$ T cells in the genital tract that controlled viral replication and delayed progression to AIDS.[439]

Efficient control of SIV infection after repeated low-dose rectal challenge with SIVmac239 was also observed in approximately 50% of rhesus macaques vaccinated with a replicating cytomegalovirus (CMV) vector expressing Gag, Rev, Tat, Nef, and Env that efficiently induced effector memory $CD4^+$ and $CD8^+$ tissue-resident T cells. Protection was observed whether the animals had been challenged by the intravenous, intravaginal, or intrarectal route. Complete elimination of the challenge virus after 1-year follow-up was documented in 13 out of 24 monkeys, none of which showed evidence for neutralizing antibodies, but all of which developed $CD4^+$ and $CD8^+$ T cells in lymph nodes and mucosal tissues.[436,440,441] The persistence of the vaccine vector seems to be the key to the long-term maintenance of virus-specific effector memory T cells (T_{EM}) able to eliminate all infected cells. However, the difference between the 50% of vaccinated monkeys controlling SIV and the 50% of monkeys not capable of controlling SIV infection remains unexplained.

Efforts at elucidating the potentially protective immune response of individuals who remain resistant to HIV-1 infection,[442,443] have also helped shed light on the role of cell-mediated immunity in protection.[444] **Elite controllers** or **elite suppressors** appear to completely control viral replication for up to 30 years, maintain viral loads below the level of detection by standard assays, and most often do not show signs of disease progression.[445] Elite suppressors rarely develop bNAbs,[409,446,447] but they all show potent cellular immune responses.[448] Upon stimulation, their HIV-specific $CD4^+$ T cells proliferate and secrete multiple cytokines, including IL-2, whereas cells from chronic progressors do not proliferate and secrete only IFN-γ. The presence of strong virus-specific $CD4^+$ T-cell responses also distinguishes nonpathogenic HIV-2 infections from HIV-1 infections.[449,450]

Even more strikingly than $CD4^+$ T cells, HIV-specific $CD8^+$ T cells appear to play a key role in the control of viral replication in elite suppressors. This is demonstrated in part by the overrepresentation of certain HLA alleles such as HLA-B*57 and HLA-B*27 in elite suppressor cohorts,[451–453] and that macaque monkeys with the MHC class I Mamu-B*08 allele achieve the elite suppressor status. The central role of HLA class I in controlling HIV-1 infection,[454–456] was highlighted by the International HIV Controllers Study, which followed a large cohort of HIV patients and showed that HLA types B*57:01, B*27:05, and B*14 were protective, whereas types B*35 and C*07 were associated with progression to AIDS.[457] Allele combinations like HLA-B*57:01-Cw0602, HLA-B*27:05-Cw0102, or HLA-B*38:01-Cw1203 have the strongest impact on nonprogression.[458]

While HIV-specific $CD8^+$ T cells from patients with progressive disease typically secrete only IFN-γ, those from elite suppressors are multifunctional, secrete multiple cytokines,[459–461] express CCL3 (macrophage inflammatory protein [MIP]-1α) and/or CD107a, undergo degranulation,[462] and proliferate in response to stimulation.[463,464] They are also much more efficient at granzyme B delivery and killing of infected $CD4^+$ T cells.[465,466] Moreover, they express perforin immediately upon antigen-specific stimulation, without the need for prior proliferation or the addition of exogenous cytokines.[467] HIV Gag-specific T-cell responses, especially those directed at conserved regions in $p24_{gag}$[430] and $p7_{gag}$, have been found to dominate in rectal mucosa of HIV controllers, in magnitude as well as breadth,[468] and often are more abundant in gastrointestinal mucosa than in blood.[469] Long-term nonprogressors have more polyfunctional responses, higher-magnitude and broader $p24_{gag}$-specific proliferation, and higher levels of IL-2 and TNF-α production than do progressors.[470]

HIV-specific helper T cells and $CD8^+$ CTL responses to multiple HIV epitopes have also been demonstrated in EU persons.[471,472] Some of the Nairobi EU sex workers seroconverted after they took a break from sex work, which was associated with a loss of HIV-specific CD8 responses, and suggested a waning of HIV-specific immunity following reduced antigenic exposure,[473] thus the need for a continuous antigenic stimulation to maintain the effectiveness of the CD8 T-cell response.

The conclusion that T cells, especially $CD8^+$ T cells, can limit virus replication and control viral set-point viremia also stems from vaccine experiments in the macaque/SIV model. Indian rhesus macaques vaccinated intracolorectally with a peptide prime/MVA boost adjuvanted with Toll-like receptor (TLR) agonists and IL-15 controlled virus replication after high-dose intrarectal SIV challenge. In addition to a strong stimulation of A3G (see below), protection correlated with antigen-specific polyfunctional $CD8^+$ T cells.[142] Correlation was observed only above a threshold of approximately 2% $CD8^+$ T cells, below which no effect of $CD8^+$ T cells on viral load was observed.

A vaccine that would generate effector memory T cells at mucosal target sites and high avidity, polyfunctional CTLs able to inhibit viral replication through granzyme B–mediated killing of infected target T cells would likely elicit efficient long-term control of HIV infection.[474–482]

Nonneutralizing Antibodies

Nonneutralizing antibodies that bind to HIV antigens on the surface of HIV-infected cells by their Fab fragments can recruit by their Fc fragment innate immune cells that possess an FcγR, including antigen-presenting cells, NK cells, or monocyte/macrophages. Such FcγR-mediated recruitment of innate immune cells can lead to either killing of the infected cell, referred to as **antibody-dependent cellular cytotoxicity (ADCC)**, or to inhibition of viral replication, referred to as **antibody-dependent cell-mediated virus inhibition (ADCVI)**.[483,484]

Studies in animal models have shown that protection of newborn monkeys against oral SIV infection by passive immunization with a nonneutralizing anti-SIV serum correlated with ADCVI activity in the serum.[485] Immunization with a replicating recombinant adenovirus followed by boosting with an Env subunit vaccine partially protected rhesus macaques against mucosal challenge with SIV or pathogenic SHIV that result from ADCC and ADCVI responses in the absence of a neutralizing antibody response.[486–489] Although unable to afford protection against productive clinical infection, nonneutralizing antibodies that bind HIV-Env are able to limit the number of transmitted/founder viruses involved in transmission.[490] In addition, there is evidence that reduced viral loads at both the acute and chronic stages of infection significantly correlate with both ADCC and ADCVI.[491–493] Both ADCC and ADCVI activities are, in turn, directly correlated with antibody affinity, suggesting the importance of antibody maturation for functionality. Thus, Fc-dependent effector

functions of antibodies elicited by vaccination may be a major factor in effective protection against infection. It was shown that immunization of mice with HIV-Env alone elicited an Env-specific antibody response with reduced Fc effector functions, whereas immunization with virus-like particles (VLPs) containing Gag-Pol and Env led to a balanced Env-specific humoral immune response with a pronounced inflammatory Fc glycan profile.[494]

Most anti-gp41 antibodies are of the nonneutralizing type and are directed either at the immunodominant C-C loop in gp41 (cluster I) or at epitopes located in the MPER segment (cluster II). Cluster II antibodies mediate ADCC and other Fc-mediated antiviral activities.[495–497] A recent study in which gp41-specific antibodies were cloned from the memory B-cell compartment of HIV-1–infected individuals showed that clones targeting cluster II epitopes accounted for 49% of all anti-gp41 reactive B cells.[498] The gp120-depleted gp41 stumps observed on the surface of HIV virions are probably in the triggered, six-helix bundle form and may be the chief source of this type of antibody response.[499,500]

Anti–HIV-1 bNAbs may also be mediators of ADCC, as suggested for antibody b12 whose infusion in the native form protected eight of nine monkeys against high-dose vaginal SHIV challenge, whereas the same dose of a mutated version of b12 with no capacity to bind to FcγRs protected only four of nine macaques.[501,502] Another bNAb, 2G12, seems to afford better protection in vivo than would be expected from its neutralization potency in vitro.[373,503] Modification of Fc fragment glycosylation of 2G12 was capable of improving antiviral activity by enhancing ADCC and ADCVI, as shown by comparing various glycoforms produced in wild-type and glycoengineered plants.[504] Similarly, the in vitro neutralization potency of antibodies 2F5 and 4E10 was substantially increased when the cell line used for assessment of HIV-1 neutralization was engineered to express FcγRI,[497,505] or to a lesser extent, FcγRIIb.[506] 2F5 at a few mg/mL concentrations elicited ADCC against both X4- and R5-HIV–infected monocytes or monocytic cell lines.[507] Usually, enhancing the Fc receptor function of bNAbs much improves their protective efficacy against SHIV mucosal challenge.[425,508]

In humans, the appearance of ADCVI in acutely infected subjects occurs as early as the CTL response; that is, much earlier than the neutralizing antibody response.[340,483] Elite controllers exhibit more potent ADCC activity than viremic individuals, whereas neutralizing antibody activity tended to paradoxically be higher in viremic subjects.[509] HIV-1 Env-specific ADCC was detected in a number of early studies,[496,510] as well as in human clinical trials, where its presence correlated with protection against infection.[511,512] ADCC was also detected in breast milk.[513,514] Polyfunctionality of the Fc receptor depends on immunoglobulin (Ig) G subclass selection. Thus, in the moderately successful RV-144 clinical trial (see below), nonneutralizing antibodies with high Fc-mediated effector functions were elicited through the selective induction of short-lived IgG3; whereas in the unsuccessful VAX003 trial, the gp120 vaccine elicited IgG_4 responses with monofunctional Fc functions.[515]

Another important function of some nonneutralizing antibodies, especially IgAs, appears to be the inhibition of virus transcytosis. Mucosal transcytosis-blocking IgAs have been detected in the cervicovaginal secretions of HEPS women in discordant couples[516] and in sex worker cohorts.[517,518]

HEPS persons, also known as EU persons,[519,520] show no HIV-1–specific plasma IgG,[521–523] but exhibit HIV-1–specific mucosal IgGs and IgAs,[521,524–527] with IgAs targeting gp41, especially the Gal/Cer binding site in the MPER of gp41.[528,529] A mucosal gp41-specific Fab IgA library was constructed and cervical B cells from these women were used to generate libraries of gp41 MPER-specific monoclonal IgAs that were able to inhibit HIV-1 transcytosis across an epithelial cell membrane in vitro.[530] gp41 MPER-derived immunogens were able to elicit transcytosis-inhibiting, nonneutralizing IgAs and to provide mucosal immunity in NHP models.[531,532] IgAs with HIV-1–neutralizing activity could also be recovered from plasma and saliva from HEPS persons.[533,534] Mucosally administered dimeric IgAs were shown to elicit efficient protection against mucosal SHIV challenge in macaque monkeys.[535,536]

Innate Immunity

Viral infections usually result in strong activation of the innate immune system that precedes the development of adaptive immune responses.[537,538] Lentiviral infections are no exception. Innate immunity responses are among key determinants of the outcome of HIV-1 infection.[136,139,140,539]

SIV infection of African green monkeys or sooty mangabeys was found to induce a strong but rapidly controlled innate response.[540,541] The activation of innate immune cells, essentially plasmacytoid DCs, proceeds through recognition of HIV-1 or SIV by Toll-like receptors (TLRs), especially TLR7 and TLR8,[542,543] and leads to the production of antiviral cytokines[538,544] such as TRIM22 and type I IFN.[545–548] In turn, IFN-α upregulates intrinsic host restriction factors, such as tripartite motif (TRIM) proteins, including TRIM5α,[549] and human APOBEC3G (hA3G), which can edit the HIV-1 early reverse transcripts through cytidine deamination, leading to degradation of the provirus DNA.[130,132]

A striking inverse correlation was found between A3G mRNA levels and HIV viral loads, and a positive correlation between A3G mRNA levels and CD4 cell counts in HIV-1–infected subjects.[550,551] Mucosal immunization of macaques against SIV led to persistent expression of A3G,[137] and elevated A3G was demonstrated to mediate resistance of monocyte-derived DCs to HIV-1 infection.[138,552] The use of TLR agonists and IL-15 as vaccine adjuvants in macaques had a remarkable effect on protection against mucosal SIV challenge: the adjuvants alone without vaccine antigen elicited enhanced A3G mRNA expression in DCs, monocytes/macrophages, and $CD4^+$ T cells, resulting in significant decreases in the set-point plasma and colon tissue viral loads following rectal SIV challenge.[142]

Another member of the APOBEC3 family that might be involved in innate immunity against HIV-1 is APOBEC3B, as judged by the fact that a naturally occurring deletion in the APOBEC3B gene was significantly associated with increased susceptibility to HIV-1 infection, progression to AIDS and viral set-point.[553]

Acute HIV-1 infection also results in the activation and expansion of $CD3^-$ NK T cells,[554,555] which, in combination with appropriate HLA class I ligands, are associated with better control of HIV-1 replication and slower disease progression.[556–559] NK cells make up half of the IFN-γ–producing cells in HIV-1 peptide-stimulated PBMCs from HIV-infected persons.[560] NK activity is increased in "long-term nonprogressors"[561,562] and in EU subjects.[562,563] The expression of certain alleles of killer immunoglobulin receptors (KIRs) on NK cells, such as KIR3DS1 or 3DL1, in combination with HLA-Bw4801, was associated with the slowest rate of progression to AIDS in large cohort studies.[557]

NK cell activity was found to be enhanced in EU subjects in the absence of target stimulation, providing these persons with an improved immune response to resist HIV infection.[559] NK activity is also increased in acute SIV infection of African NHP, but not in rhesus macaques, which develop full-blown disease.[564] The variety of NK cells and NK cell receptors makes their study complex but the discovery of innate memory in

NK cells may offer interesting perspectives for vaccine development.[55,565] Cytokines such as IL-21 or IL-15 may help induce or improve NK cell responses.[566]

Several other factors of innate immunity also play a role in the control of lentivirus infection, such as p21, an inhibitor of cyclin-dependent kinase present in $CD4^+$ T cells[567,568]; T-bet, a master transcription factor that promotes the expression of IFN-γ, granzyme B, and perforin by $CD8^+$ T cells[569]; IL-27[570]; and TRIM5α, which controls macaque susceptibility to SIVsmE660[81,83] and was found to be associated with protection from HIV-1 infection in some sex worker cohorts.[571] The p21 inhibitor appears to reduce the susceptibility of activated $CD4^+$ T cells and human macrophages to HIV-1 replication through inhibition of transcription of the proviral DNA. It also can block reverse transcription. The expression of both p21 and T-bet is upregulated in $CD4^+$ T cells from elite controllers and experimentally knocking out p21 substantially increases cell susceptibility to HIV-1.[572] Another antiviral innate immunity factor is TRIM21, which neutralizes virus–antibody complexes inside the cell by binding to antibodies that remain attached to virus particles and targeting the virus–antibody complex to the proteasome, thus mediating the intracellular disabling of the virus.[573]

It is now evident that innate immune mechanisms contribute to control of HIV, but it is not clear if and how the response could be harnessed through vaccination.[140,442,574] Ongoing systems biological approaches to SIV immunization studies in macaques are focused on identifying innate signatures that may predict adaptive immune responses, and thus might facilitate efforts to modulate innate immunity to more effectively enhance adaptive immunity.

CANDIDATE HIV VACCINES: PRECLINICAL DEVELOPMENT

The development of an HIV vaccine is a formidable challenge. An effective HIV vaccine should be able to induce durable immunity and prevent the acquisition of infection and/or reduce virus replication in infected persons so as to slow down disease evolution and reduce viral transmission.[574–578] The first Phase I trial of an HIV vaccine was conducted in the United States in 1987 using a gp160 subunit vaccine. Since then, more than 170 vaccines have been tested in more than 250 Phase I/II clinical trials, involving more than 27,000 healthy human volunteers.[50,51,579] HIV-1 vaccines that were developed and tested in humans were first based on induction of neutralizing antibodies, then on induction of cellular immune responses.[54,580–584] Studies show that robust mucosal immunity, high-avidity polyfunctional T cells, and bNAbs are potentially important factors in protective immunity against HIV-1,[585,586] but the studies also highlight the need to design vaccines that can induce more potent immune responses than those that are elicited by natural infection, as the latter provide very poor protective immunity.[49,52,587] As classical vaccine strategies based on attenuated live virus or whole inactivated virus show severe limitations because of safety considerations and HIV variability, most efforts to develop HIV vaccines have focused on newer vaccine approaches. This section discusses vaccine development efforts in animal models; human vaccine trials are reviewed in a later section.

Most of the efforts to develop and evaluate HIV vaccines are borne by public sector research agencies (e.g., the National Institutes of Health [NIH], the Centers for Disease Control and Prevention [CDC], and the Walter Reed Army Institute of Research [WRAIR] in the United States; the Agence Nationale de Recherches sur le SIDA et les Hépatites Virales (ANRS) in France; the Karolinska Institute in Sweden); international development agencies (e.g., United States Agency for International Development [USAID]; United Kingdom Department for International Development [UK-DFID], and the European Union agencies and development donors); and nongovernmental organizations (NGOs) (e.g., International AIDS Vaccine Initiative [IAVI], New York, NY; Bill and Melinda Gates Foundation [BMGF], Seattle, Washington); together with initiatives in the World Health Organization (WHO) and UNAIDS. The HIV Vaccine Trials Network (HVTN) established by the National Institute of Allergy and Infectious Diseases (NIAID) in 2000, with 25 clinical sites on four continents, represents a major resource for clinical HIV vaccine research. Complementary clinical trials partnerships have been developed by the U.S. Military HIV Research Program in Africa and Thailand, and by IAVI in Africa and India. The European Union has created the European and Developing Countries Clinical Trials Partnership (EDCTP) with the aim of helping developing countries build their capacity for testing the efficacy of new drugs, microbicides, and vaccines. Major efforts have also been made by the vaccine industry in developing and testing candidate HIV vaccines, including Phase IIb/III clinical trials.

In 2003, recognizing the enormity of the scientific challenge, leading investigators and major funding organizations formed the Global HIV Vaccine Enterprise, an alliance of independent organizations committed to working together to accelerate the development of an HIV vaccine.[588] A strategic scientific plan was drafted in 2005 and updated in 2010.[589] The plan aims at accelerating clinical trials of promising vaccine candidates, bridging the gaps between basic and clinical research, facilitating exchange of reagents and data, enhancing global collaborations, and fostering the development of young scientists and clinicians in the field of HIV vaccine research.

Animal Models

HIV-1 can be transmitted to chimpanzees[590,591] and pig-tail macaques *(Macaca nemestrina)*, but neither of these models can reproduce the pathology of human AIDS. HIV-1 also can replicate in immunodeficient transgenic mice engrafted with human fetal lymphoid tissues ("SCID-hu" mice) or with adult human peripheral blood leukocytes ("hu-PBL-SCID" mice)[592] or in humanized immunodeficient mice transplanted with human cord blood hematopoietic stem cells.[593–595] More recently, humanized mice have been used to study efficacy of vector-delivered bNAbs in prevention of HIV infection.[596,597]

The SIVmac is easily transmitted to and readily causes AIDS in rhesus macaques, especially in those from India.[598,599] Indeed, infection of macaque monkeys with SIVmac recapitulates the pathogenic effects of HIV-1 in humans and provides the most reliable animal model for testing antiviral therapies and candidate vaccines against HIV-1 available today.[600–603] As with HIV-1, the first cellular targets for SIV are the $CD4^+$ $CCR-5^+$ memory T cells in the lymphoid tissue of the genital tract and in the GALT, which has unique anatomical and functional features that makes it a major reservoir for virus sequestration, persistence, and ongoing replication.[227] The percentage of $CD4^+$ T cells in the lamina propria of the gut of SIV-infected macaques dramatically decreased from 67% in uninfected animals to 6% at 21 days postinfection.[189,604–609] Mucosal transmission of HIV can also be modeled in the SIV-rhesus macaque system, including cell-associated virus transmission.[610–612]

Plasma viral loads at the peak of primary SIV infection and at the set-point during chronic SIV infection in macaques parallel those observed in HIV-1–infected humans.[611] Some animals maintain high viral loads and quickly progress to AIDS, as human **fast progressors,** while others contain viremia spontaneously and progress to disease slowly, as HIV-1–infected human **long-term nonprogressors,** or those who

maintain barely detectable viral loads without treatment, such as human **controllers.**[613] Several monkey MHC class I haplotypes, such as Mamu-A*01, Mamu-B*08, and Mamu-B*17, have been identified which correlate with elite control of viral loads and relative resistance of the animals to progression to SIV-induced AIDS,[614,615] as has been observed in humans with haplotypes HLA-B*27, HLA-B*57, or HLA B*58, in HIV controllers and elite controllers.[452,616–622]

There is only, however, a limited number of SIV isolates that can be used to test protection across genetically diverse virus strains, a major obstacle for any field test of an HIV vaccine. Also, because of a complete difference between the SIV and HIV-1 Env antigenicity, the SIV/macaque model does not allow evaluation of the role of HIV-specific neutralizing antibodies in vaccine-induced protection.[623] To alleviate this difficulty, replication-competent chimeric SIV/HIV viruses called **SHIVs** were engineered that combine the *env-tat* and *rev* genes from HIV-1 with the *gag-pol-vif* and *nef* genes from SIVmac and replicate to high titers in cynomolgus and rhesus monkeys.[624,625] Serial passages of these hybrid viruses in monkeys can lead to the emergence of stable pathogenic SHIV strains able to induce $CD4^+$ T-cell depletion and AIDS in the animals, such as $SHIV_{89.6P}$, an X4 virus,[626,627] or $SHIV_{SF162P3}$, an R5 virus.[628] The relative transmissibility of an R5 clade C SHIV ($SHIV\text{-}1157_{ipd3N4}$) via different mucosal routes was found to parallel the relative risk of sexual transmission in humans, rectal challenge requiring the least virus, followed by vaginal and then oral routes,[629] as observed in humans.[630–633]

As a result, the SHIV/macaque model is widely used for preclinical testing of candidate HIV vaccines. Paradoxically, however, highly virulent X4 SHIVs, such as $SHIV_{89.6P}$, are relatively easy to control by vaccination, casting doubts on their validity as a model for HIV vaccine efficacy, especially when the end point is control of infection.[226,602,623,634]

Monkey models suffer from the fact that a very high dose of virus is typically used to challenge the animals in vaccine protection efficacy experiments so as to achieve 100% take of the virus in the placebo group after a single exposure. These doses are higher than the amount of virus in natural exposures in humans.[635,636] The difficulty was eliminated by using repeated low-dose mucosal challenges, after it was shown that low-dose SIV challenges (10–50 $TCID_{50}$ [median tissue culture infective dose]) resulted in the same viral and immunological kinetics of infection as a high-dose challenge.[637] More recently, protection in macaques with analogous candidates to an HIV vaccine evaluated in clinical trials was shown to be dependent on the dose of SIV at challenge exposure.[638]

One variable in the HIV vaccine field related to the use of SIV and SHIV models that would benefit from standardization is the definition of "protection" in the context of vaccine and challenge studies. Although it is clear that complete prevention of infection is synonymous with protection, it is less clear when the measurement of protective efficacy is suppression of viral load, or reduction in per-exposure acquisition risk following repetitive viral challenges.[639] Another limitation of monkey models stems from the usually low number of animals that can be used in vaccine experiments, whose results therefore often lack sufficient statistical significance.

Live Attenuated Vaccines

The observation that *nef*-deleted mutants of SIV were attenuated and could serve as a live vaccine to elicit protection against challenge with pathogenic SIV in rhesus macaques served as a model for live attenuated HIV vaccines.[111,113,640] The result was confirmed by using as a vaccine a molecular clone of SIVmac that had been attenuated by a 12-base pair deletion in the *nef* gene, C8, which provided complete protection against infection with a full-length, pathogenic molecular clone, J5.[112] Deletion of *nef*, alone or in combination with deletions in *vpr* and in the long terminal repeat region,[641] showed no drastic effect on virus growth in cell culture.

SIVΔ*nef* was actually found to establish a lifelong, persistent low-grade infection that protects monkeys against disease following challenge with pathogenic virus but generally does not protect them from infection. The actual correlates of protection remain incompletely deciphered,[115] but evidence is in favor of the induction of a long-lasting CTL response.[642–644] It was recently demonstrated that the degree of SIVΔnef-mediated protection against intravenous wild-type SIVmac239 challenge strongly correlates with the magnitude and function of SIV-specific, effector-differentiated T cells in the lymph node but not with the responses of such T cells in the blood or with other cellular, humoral and innate immune parameters.[477] However, other potential correlates of protection have been suggested, including local antibody production and concentration in the path of virus entry, and immune complex–inhibitory Fc receptor interactions that reduce target cell availability.[645,646]

Similarly, nonpathogenic $SHIV_{89.6}$ established persistent infection in monkeys that, following mucosal challenge with SIV, provided protection against uncontrolled virus replication, but not against infection. A clear role for $CD8^+$ T cells in protection was documented.[439,647] Macaques previously exposed to low doses of HIV-2 also demonstrated a virus-specific cellular immune response and were protected against uncontrolled virus replication when challenged intrarectally with SIV.[648]

SIVΔ*nef* is not totally attenuated and may still cause AIDS when administered orally to infant monkeys.[649] It also could revert to full-size *nef* virulence in some animals.[650] Additional deletions or mutations could further attenuate its virulence but at the expense of protective efficacy. Efforts to make the virus safer included the construction of replication-competent SIVΔ*nef* viruses that expressed the human IFN-γ gene[651] or the herpes simplex thymidine kinase gene.[652]

Yet, the prospect of using a live attenuated HIV vaccine in humans has enormous safety concerns owing to the high mutation rate of the virus, and thus the approach was not tested in humans. A few individuals infected with HIV-1 for long periods of time without any sign of AIDS were found to be infected with *nef*-deleted viruses[653,654] but these persons eventually experienced late decline in their CD4 T-cell counts[655,656] and slowly developed AIDS.[657] As a result, there is no development of live attenuated HIV vaccines as an ongoing strategy for the prevention of HIV-1 infection.

Whole Inactivated Vaccines and Virus-Like Particles

The best way to inactivate HIV or SIV without destroying the antigenicity of the viral envelope glycoproteins was mild oxidation with aldithriol-2 to remove the essential Zn^{2+} ions from the Gag and Int proteins,[94] alkylation with *N*-ethyleneimine,[658] or through UV inactivation of the viral RNA with the help of psoralen.[659] The immunogenicity of the resulting preparations was modest, perhaps as a result of the low number of glycoprotein spikes per virion.[75] Immunization with an inactivated SIV vaccine did not protect monkeys against SIV infection, but the animals showed decreased levels of viremia after challenge.[660]

When coexpressed in insect cell cultures using a baculovirus vector or in mammalian cell cultures using a poxvirus vector, the HIV or SIV Gag and Env proteins spontaneously assembled to form VLPs that were made of only the viral core and envelope proteins.[661,662] SIV VLPs were tested as a vaccine

in NHPs by a variety of routes,[663] but their immunogenicity was found to be modest. No bNAb was elicited by HIV-1 VLPs in mice or guinea pigs, even when the sequence of gp41 or that of the gp41 MPER was included in the construction.[664]

The success of the human papillomavirus (HPV) and hepatitis B vaccines, both of which are VLPs, has led many investigators focused on eliciting bNAbs to evaluate different VLP platforms. Strategies aimed at dampening nonneutralizing epitopes, or using prime-boost approaches with viral vector–VLP combinations, are currently being evaluated.[665,666]

Hybrid VLPs were also engineered by fusing the MPER from gp41 to the N-terminus of the hepatitis B surface antigen,[667] or to bovine papillomavirus (BPV)-L1 capsid protein, which spontaneously forms VLPs.[668] Peptides with the sequence of the gp120 V3 loop or of a known CTL epitope, P18, were also fused to BPV-L1 VLPs.[669] None of the resulting chimeric VLPs were found to elicit more than low titers of HIV-specific antibodies and none could elicit HIV-1–neutralizing antibodies.

Subunit Vaccines

Env Subunit Vaccines

Subunit protein vaccines were initially developed based on monomeric HIV-1 gp120 or gp140 (gp160 deleted of the transmembrane and intracytoplasmic domains of gp41) that were presented either in their soluble form or as related synthetic peptides (V3 loop), using alum as an adjuvant. These vaccines were found to induce neutralizing antibodies that targeted the V3 loop in gp120 and protected chimpanzees against challenge with a homologous or near-homologous HIV-1 X4 strain, but not against challenge with a distant virus strain nor with a primary R5 HIV-1 isolate.[670–675] Passive immunization with a monoclonal antibody targeting the V3 loop was also shown to protect chimpanzees against homologous X4 virus challenge.[676] Similarly, in the SHIV/macaque model, vaccines based on gp120 were able to provide protection against homologous X4 SHIV challenge,[677] but not against challenge with a heterologous SHIV with a different envelope specificity.[678] In contrast, immunization of macaques with R5 SIVmac gp120 formulated with a variety of adjuvants, liposomes, or immunostimulating complexes[679] was unsuccessful at providing protection against SIV challenge.[680]

Recombinant soluble HIV-1 envelope proteins have been the target of intensive investigation, as one of the major obstacles in HIV vaccine development remains the inability of current immunogens to elicit bNAbs. Numerous approaches have been explored[681,682] including:

- Trimeric gp140 molecules (gp120 + the ectodomain of gp41) stabilized by the addition of heterologous trimerization domains at the C-terminus of the gp41 sequence[683,684] and similar trimers with a deletion of the hypervariable V2 loop, so as to better expose the neutralization epitopes that overlap the CD4-binding site.[343,685,686] Systemic immunization or a combination of systemic and mucosal immunization with the **ΔV2 gp140** subunit vaccine emulsified with water-in-oil adjuvant MF59 protected female rhesus macaques against intravaginal challenge with a homologous SHIV.[687]
- Trimeric gp140 molecules internally stabilized by a disulfide bond between gp120 and gp41 (**"SOS" proteins**). Their immunogenicity was tested using priming with a DNA plasmid encoding the SOS protein and repeated boosting with the purified SOS trimers. This regimen resulted in high titers of neutralizing antibodies against virus strains of the same clade but only low levels of cross-clade neutralizing antibodies.[688,689] More recently, using a bioinformatics approach to identify HIV isolates sensitive to bNAbs, a most-recent-common-ancestor (MRCA) sequence for the HIV-Env was determined, and the Env from clade A viral isolate BG505 was found to have the highest degree of homology to the MRCA.[690] Using the sequence of BG505 as a template, a cleaved HIV-Env SOSIP trimer was stabilized and analyzed by X-ray crystallography and cryoelectron microscopy, and found to be antigenically near native.[691–693] HIV-1 neutralizing antibodies induced by this native-like trimer gave higher titers of autologous neutralizing antibody than the monomeric gp120, but failed to elicit bNAbs.[694]
- Oligomeric gp140 molecules covalently coupled to synthetic mimics of the CD4 receptor, or "single-chain gp120 derivatives" covalently linked to the first two domains of the human or simian CD4 molecule, so as to induce in the Env molecule the same conformational changes that take place at the time of virus entry and to expose potential neutralization epitopes that overlap the coreceptor-binding site.[695,696] The **single-chain** antigen was indeed found to elicit in macaques neutralizing antibodies to CD4-induced epitopes,[25,697] which were able to accelerate control of viremia upon challenge with $SHIV_{162P3}$.[698] Efforts to elucidate the correlates of protection suggest that antibody-dependent cellular cytotoxicity with limited antigen-specific T-cell activation played an important role.[699]
- A cocktail of Env immunogens derived from globally prevalent HIV strains, or more simply from representatives of each of the different clades[700–702] in the hope that **multivalent Env** vaccines will broaden the spectrum of neutralizing antibodies.[703,704]
- Fully synthetic genes derived from theoretically defined **consensus** or **ancestral** HIV envelope sequences[297–299] that were found to be superior to many wild-type immunogens for inducing cross-subtype T-cell and B-cell immune responses and antibodies that neutralized a spectrum of HIV-Env pseudoviruses.[300] The M-group "CON-S" and a clade B-based "CON-B" Env protein[705,706] each elicited antibodies with good titers and breadth of responses against tier-1/HIV-1 viruses, but not against isolates that are more difficult to neutralize.[301]
- **Mosaic antigens** with sequence derived from in silico algorithms to closely match the sequences of natural HIV-1 strains worldwide and maximize overlap between them.[302,303] An HIV-1 mosaic M trimer was recently generated, but also failed to elicit bNAbs.[707]

Despite these many efforts and of unabated attempts at designing mimics of the viral envelope spike or specifically tailored Env preparations,[349] the quest for immunogens able to efficiently elicit high-titer bNAb has remained unsuccessful so far,[86,354,428,430,431,708] and continued efforts to find an optimal immunogen design and delivery are ongoing (see below). The formulation of gp120 or gp140 under the form of immunostimulating complexes with saponin derivative Quil A, or in combination with water-in-oil emulsions containing QS21 or muramyl dipeptide derivatives, or with specific adjuvant formulations such as MF59, resulted in the induction of high gp120-binding antibody titers with neutralizing activity against closely matched X4 virus strains, but not against primary HIV-1 isolates.[709–713]

Induction of 2F5- or 4E10-like fusion-blocking antibodies by immunization with recombinant oligomeric gp41 molecules or formulations of the gp41 MPER has similarly been mostly a failure. Displays of constrained 2F5 epitope in the context of various protein scaffolds induced high antibody titers against the primary amino acid sequence of the epitope, but failed to elicit neutralizing antibodies against HIV-1

isolates,[664,713,714] confirming the need to adequately mimic the native conformation of the epitope,[715,716] as well as the likely importance of the lipid membrane and hydrophobic context for the binding of 2F5 and 4E10 antibodies to their respective epitopes.[717–719] The challenges of eliciting bNAbs against HIV are further detailed below.

Tat Vaccines

Subunit vaccines based on the accessory protein Tat have also been developed in the hope that immune responses directed at antigens such as Tat that are expressed very early in the virus replication cycle might lead to containment, if not abortion of infection.[720,721] Eight genetic variants of Tat have been identified as of this writing.[722] Both anti-Tat antibody and Tat-specific CTLs correlate with reduced viremia and slow progression to AIDS.[723,724] Conflicting results have been reported following immunization of rhesus macaques with Tat protein, formalin-inactivated Tat ("Tat toxoid"), or Tat peptides. These vaccines elicited little or no protection against challenge with SIVmac239, $SHIV_{33}$, or $SHIV_{89.6P}$.[725–728] In contrast, immunization of cynomolgus macaques with Tat protein or DNA encoding Tat elicited control of infection following challenge with $SHIV_{89.6P}$.[729–732] A Tat-Nef fusion protein that was combined with a gp120 subunit vaccine in AS02 adjuvant was found to prevent the development of disease in rhesus macaques for at least 2.5 years following challenge with $SHIV_{89.6P}$, especially when presented as a DNA vaccine formulation.[733,734] HIV Tat vaccines might thus show better efficacy when combined with other HIV antigens.[735–739]

Nucleic Acid Vaccines

In view of the lack of success of vaccines to elicit bNAbs for prevention of HIV-1 infection,[424] early HIV vaccine development focused on vaccines that would induce T-cell responses, especially a $CD8^+$ CTL response aimed at controlling HIV infection. Vaccines that stimulate the T-cell arm of the immune response are not expected to protect against infection, but rather to protect against appearance of disease by reducing viral load, slowing down $CD4^+$ T-cell decline and preventing, or at least retarding, the occurrence of symptoms.[740] Naked DNA vaccines and live vectored recombinant vaccines have been developed based on this strategy.[50–52,741] Reduction of viral loads in HIV-infected individuals should also result in lower probability of virus transmission to seronegative partners.

DNA vaccines (also referred to as genetic vaccines) are bacterial plasmids that carry the gene(s) encoding one or several desired antigens, and which, once injected into the muscle or the dermis of an animal, express the desired antigen(s) in situ, leading to induction of an antigen-specific cellular immune response.[742–745] However, the immune potency of DNA vaccines in humans and NHPs has generally been mediocre, inducing weak helper T-cell responses and little, if any, antibody and $CD8^+$ T-cell responses.[746,747] Improved immunogenicity was obtained through the use of synthetic genes with optimized codons,[748] the insertion of engineered B7 costimulatory molecules, the coexpression of cytokines such as IL-12, IL-15, or granulocyte-macrophage colony-stimulating factor (GM-CSF) to serve as vaccine adjuvants, and the simple repetition of vaccine injections three successive times,[749–753] which resulted in greatly enhanced expansion of polyfunctional memory $CD8^+$ T cells. A DNA vaccine expressing mosaic sequences of potential T-cell epitopes from HIV-1 M group Env was also found to induce $CD8^+$ T-cell responses with significantly greater breadth than similar vaccines with natural sequences.[304,305,480] DNA vaccines also have been employed to elicit broad cell-mediated immune responses to conserved antigens.[754]

Among strategies for further improvement of DNA vaccine potency[755] are novel means of vaccine delivery, such as needleless injections (the Biovector device),[756,757] formulation of the DNA onto microparticles, as was done using cationic microparticles,[758] or on gold beads administered by gene gun,[759,760] delivery of the DNA transcutaneously with the Nanopatch microprojection device,[761–763] or the use of electroporation and an electroporation device.[764–768] Combined effects of IL-12 and electroporation greatly enhanced the potency of DNA vaccination in macaques.[765] Optimized plasmid DNAs encoding the majority of SIV proteins and delivered to macaques by electroporation, elicited strong cellular and humoral responses against the vaccine Gag, Pol, Env, Nef, and Tat antigens, and decreased viremia in both the acute and chronic phases of infection following challenge with SIVmac.[769] Similar protection results were observed against a SHIV clade C challenge using DNA plasmids expressing SIV Gag and Pol and HIV-1 clade C Env that were delivered by electroporation.[770] Moreover, enhanced immunogenicity of HIV-1 DNA was obtained by delivery of the DNA via electroporation through both intramuscular and intradermal routes.[771]

A topical plasmid DNA vaccine formulated in a nanoparticle with polyethylenimine-mannose and glucose, DermaVir, was developed to deliver DNA-encoded antigens to Langerhans cells.[772,773] DermaVir formulated with HIV-1 Gag plasmid in the presence of a IL-15–encoding plasmid significantly enhanced Gag-specific central memory T cells, as measured by IFN-γ ELISPOT(enzyme-linked immunospot).[774]

DNA vaccines have also been coadministered with protein, a strategy that yielded enhanced humoral immune responses in mice and macaques.[775] Still, the best immunogenicity results with DNA vaccines have been obtained using a prime-boost strategy, that is, delivering the DNA vaccine as a prime, later to be followed by a live recombinant vaccine booster immunization.[776] Thus, immunization of macaques with a DNA-Env vaccine followed by a polyvalent Env formulation was able to elicit a more diverse antibody response, with higher antibody avidity and improved cross-clade neutralizing activity, albeit only against relatively easy to neutralize isolates of HIV-1, together with cross-subtype T-cell responses.

With the limited success of DNA vaccines in humans, greater attention is now focused on the potential of mRNA-based vaccines.[777,778] These vaccines provide the flexibility of DNA vaccines, but with the potential for enhanced immunogenicity and safety. One of the keys to realizing the potential of mRNA based vaccines is the efficient delivery of the mRNA to the cell's cytoplasm to enable expression of the encoded antigenic protein. Self-adjuvanted mRNA has advanced to clinical trials for cancer immunotherapy. It is well tolerated and immunogenic,[777] and is the first HIV-based mRNA vaccine candidate expressing a native-like trimer of HIV-Env. Self-adjuvanted mRNA will likely enter clinical trials in 2016–2017 by IAVI and CureVac Inc. Self-assembled nanomicelles based on polyethyleneimine-stearic acid copolymer delivered HIV-1 gag encoding mRNA to Balb/c mice and induced antigen-specific humoral and cellular immune responses.[778]

mRNA-based vaccines can be further enhanced by engineering as self-amplifying RNA vaccines.[779–784] Potent immune responses in rhesus macaques were induced by nonviral delivery of self-amplifying RNA vaccines expressing HIV-1 envelope with a cationic nanoemulsion.[779] Moreover, preclinical proof of concept with this approach has also been achieved for influenza, respiratory syncytial virus, rabies, Ebola, CMV, and malaria.[782]

Live Recombinant (Vectored) Vaccines

Live recombinant vaccines are made of a live viral or bacterial vector that is engineered to express a variety of exogenous antigens in the cytoplasm of targeted T cells, in this case HIV-1 genes. The antigens are eventually broken down in the proteasome of the transduced cell and presented as externalized peptides in the context of MHC class I molecules, thus priming for a $CD8^+$ T-cell response. Alternatively, antigen-presenting cells can phagocytose transduced cells that become apoptotic and present antigenic peptides to CTLs through cross-presentation. If the vaccine contains too few antigens, virus escape mutants with mutations in T-cell epitopes can readily emerge.[614] Vaccine impact on control of viral loads has been the best with vaccines that express multiple HIV-1 proteins including Env.[784,785]

Numerous vectors have been engineered into live recombinant vaccines (Table 29.3).[786–789] Most of these vectors had previously been made replication-defective by deletion of essential genes, such as the E1A gene in adenoviruses, or a series of genes in the New York vaccinia virus strain (NYVAC). Other vectors are spontaneously unable to replicate in primates, such as Canarypox (ALVAC), Fowlpox, or the attenuated vaccinia virus strain MVA. Replication defectiveness allows for greater safety, but may result in decreased immunogenicity of the candidate vaccine, necessitating a considerable increase in the dose of vaccine (number of particles of recombinant).

One of the major challenges for live recombinant vaccine immunogenicity is the subsequent immune response to the vector, which dampens the take of the vaccine and subsequent expression of the vectored antigens: this applies both to the difficulty with using the same vectored vaccine for repeated immunizations and to the situation of pre-existing immune responses to the vector in the general population. This is especially true for adenovirus serotype 5 (Ad5), against which the human population shows a high prevalence of neutralizing antibodies.

TABLE 29.3 Vectors Used for the Engineering of Live Recombinant Vectored HIV or Simian Immunodeficiency Virus Vaccines

Bacillus Calmette Guérin (BCG; NIH, Japan)[1007–1009]
Salmonella (IAVI, University of Maryland)[1010,1011]
Other bacterial vectors: *Lactobacillus, Streptococcus, Listeria*[1012]
Poxvirus vectors (MVA, NYVAC, Fowlpox, and Canarypox [ALVAC] viruses)[1013]
Human ΔE1A replication-defective adenoviruses Ad5, Ad11, Ad24, Ad26, and Ad35[1014–1016]
Replication-competent human Ad5 *hr* mutants[486]
Nonreplicating chimpanzee adenoviruses AdC68, AdC6, and AdC7[1017–1019]
Picornavirus vectors (Poliovirus, Rhinovirus)[805,1020]
Venezuelan equine encephalitis virus (VEEV; Alphavax)[799]
Adeno-associated virus (AAV; IAVI/Targeted Genetics)[1021]
Sendai virus (SeV; NIH, Japan)[824,1022]
Vesicular stomatitis virus (VSV; Yale University/Wyeth; IAVI)[804,1023,1024]
Newcastle disease virus (NDV; Mount Sinai, New York, and Kyoto University, Japan)[1025]
Measles virus (MV; Pasteur Institute/GlaxoSmithKline)[1026,1027]
Rhesus cytomegalovirus (RhCMV; Oregon Health and Science University)[436,440,441,803]
Live attenuated rubella vector (FDA)[1028]

FDA, U.S. Food and Drug Administration; IAVI, International AIDS Vaccine Initiative; MVA, modified vaccinia virus Ankara; NIH, National Institutes of Health; NYVAC, New York vaccinia virus strain.

Live recombinant vaccines mostly elicit T-cell responses, especially $CD8^+$ T-cell responses, but different vaccine vectors delivering the same antigen can elicit $CD8^+$ T cells with different fine specificities.[790] It was recently observed that multiple innate immune pathways may contribute to the immunogenicity of the Ad5-vectored vaccines.[791] MVA recombinants were found to induce in NHPs potent CTL responses able to partially control virus loads after challenge with pathogenic SHIV or SIV.[792–794] A NYVAC vector that expressed the *gag, env,* and *pol* genes of SIV provided protection against challenge with SIVmac by the rectal route but not by the intravenous route.[795] An Ad5 vector expressing SIV-Gag was similarly found to attenuate infection and mitigate disease progression following challenge with a pathogenic SHIV,[796] but the same or similar constructs provided a lower and only transient level of protection against SIV infection.[434,797,798] More recently, two novel NYVAC-based HIV vaccine candidates expressing HIV 1 clade C soluble trimeric gp140 and gag as VLPs were developed and are being tested in preclinical studies.[666]

Replication-defective alphavirus "replicons" are attractive vectors because they undergo enormous amplification in the host. Also, they have the potential to target DCs, resulting in efficacious antigen presentation. The most developed replicon system is that of the Venezuelan equine encephalitis virus (VEEV),[799,800] which was shown to elicit potent protective immune responses in macaques.[801] In addition, the Venezuelan equine encephalitis replicon particles have the capacity to act as strong adjuvants to other vaccines, including the induction of mucosal immune responses.[802]

A replication-competent vector that has recently shown great promise is rhesus CMV (RhCMV), which elicited immune responses capable of immediate viral control upon challenge with SIVmac, in 13 of 24 vaccinated monkeys.[436,440] In fact, 12 macaques maintained undetectable plasma viral loads for a year with occasional transient blips of detectable virus. This was characterized by predominantly undetectable cell-associated viral load in blood and lymph node mononuclear cells; no depletion of effector-site $CD4^+$ memory T cells; no induction or boosting of SIV Env-specific antibodies; and induction and then loss of T-cell responses to an SIV protein (Vif) not included in the RhCMV vectors. Protection correlated with the magnitude of the peak SIV-specific $CD8^+$ T-cell responses in the vaccine phase, and occurred without anamnestic T-cell responses. Moreover, SIV protein-expressing RhCMV vectors elicit SIV-specific $CD8^+$ T cells that recognize unusual, diverse, and highly promiscuous epitopes, including dominant responses to epitopes restricted by class II MHC molecules.[803] Remarkably, protected rhesus monkeys lost signs of SIV infection, showing a consistent lack of measurable plasma- or tissue-associated virus using ultrasensitive assays. Extensive ultrasensitive quantitative polymerase chain reaction (PCR) and quantitative PCR with reverse transcription analyses of tissues from RhCMV/SIV vector-protected monkeys necropsied 69 to 172 weeks after challenge did not detect SIV RNA or DNA sequences above background levels. Moreover, replication-competent SIV was not detected in these monkeys by extensive coculture analysis of tissues or by adoptive transfer of 60 million hematolymphoid cells to naïve rhesus macaques, compared with SIV-infected elite controllers whose cells infected naïve macaques following adoptive transfer.[441] Recently, replication-competent vesicular stomatitis virus (VSV) expressing functional Env[804] protected against heterologous SHIV challenge in rhesus macaques (C.L. Parks, personal communication, 2015).

Live recombinant vaccines can also be used to elicit neutralizing antibodies, as was done for the HIV-1 2F5 epitope. A combinatorial library of human rhinoviruses displaying the 2F5 epitope (ELDKWA) was constructed and screened with the

2F5 monoclonal antibody. The best 2F5-binding chimeras were shown to elicit antibodies capable of neutralizing HIV-1 pseudoviruses of diverse subtypes and coreceptor usage, albeit, as with other neutralizing-antibody approaches, only neutralization-sensitive isolates.[805] Molecular characterization of the chimeras will hopefully clarify how to improve the presentation of the 2F5 epitope in future vaccine designs.[806] More recently, with new information on the HIV trimer, vectors are being designed to display conformationally intact functional HIV-1 envelope trimers.[804]

PRIME-BOOST IMMUNIZATION REGIMENS

DNA Prime-Live Recombinant Vaccine Boost

Multiple comparative studies in NHPs have demonstrated that the immunogenicity of live vectored vaccines was significantly improved when administered as a boost after initial priming with a DNA vaccine.[434,807–810] As an example, DNA-Ad5 prime-boost improved by sevenfold the magnitude of HIV-1 Env-specific T-cell responses as compared to Ad5 recombinant vaccine alone, resulting in induction of multifunctional CD127+ central and effector memory T cells, and increased by 100-fold the Env-binding antibody response.[811] Such a synergy between the DNA and the live recombinant vaccines was observed in NHPs whether the live vaccine used for boosting was MVA,[812,813] NYVAC,[814] VSV,[815] or Ad5.[816] Priming with DNA followed by a recombinant viral vector boost, was shown to be an effective approach for inducing immune T-cell responses and eliciting control of viral loads in SHIV or SIV challenge studies in macaques.[434,435,815,817–820]

A study of T-cell correlates of vaccine efficacy at controlling viral replication after low-dose heterologous mucosal challenge with SIVsmE660 was carried out in macaques immunized with a DNA-Ad5 prime-boost regimen that expressed SIVmac Gag, Tat, Pol, Rev, Vif, Vpr, and Vpx.[821] The vaccinated animals showed a 1.9 log reduction in peak viral loads, a 2.6 log reduction in set-point viral loads, and intact $CD4^+$ T-cell counts 1 year after challenge,[819] which correlated with the breadth of the T-cell responses directed against Gag and Vif as measured by IFN-γ ELISPOT assays. Surprisingly, the ability of prechallenge peripheral blood-derived $CD8^+$ T cells to suppress viral replication in vitro did not predict the control of viral loads in vivo, perhaps reflecting the fact that the assay was not run with T cells present in mucosa-associated lymphoid tissues where viral replication is concentrated.

Prime-boost immunization of rhesus macaques using a DNA expressing the SIV *gag*, *pol*, *vif*, and *vpx* genes for priming followed by boosting with a live Sendai virus (SeV) expressing SIV *gag*, resulted in long-term control of virus replication and preservation of central memory $CD4^+$ T cells after SIVmac challenge.[822–824] In contrast, DNA vaccine priming did not seem to improve the protective efficacy of a live chimeric Ad5 hexon hypervariable region 48 (Ad5HVR48) vector expressing SIV Gag, Pol, Nef, and Env against SIV challenge in rhesus monkeys.[825] Topical priming immunization with Gag-DNA and Env-DNA plasmids using DermaVir followed by boosting with gp140 resulted in control of viral load set-point in four of five macaques upon challenge with pathogenic R5 $SHIV_{162P3}$.[826]

Several DNA-MVA prime-boost studies have also been done in NHPs.[404,827–830] The DNA-MVA vaccine regimen was found to result in efficient control of viral loads and to significantly slow down $CD4^+$ T-cell depletion in monkeys challenged with pathogenic $SHIV_{89.6P}$.[807] The association of a single intradermal or intramuscular inoculation of GM-CSF DNA with the DNA prime enhanced the avidity maturation of non-neutralizing anti-Env IgG in the plasma and the presence of long-lasting antiviral IgA in rectal secretions of rhesus monkeys, but had no effect on the elicited T-cell responses. Upon rectal challenge with $SHIV_{89.6P}$, the animals with the highest avidity anti-Env antibodies and an enhanced IgA response had up to a 1000-fold reduction in peak viremia, demonstrating the importance of avidity for nonneutralizing antibody-mediated control of viral infection.[831,832] Similar observations were made with DNA-MVA prime-boost vaccination against clade B (strain ADA) or clade C (strain IN98012) HIV-1, followed by challenge with R5 $SHIV_{SF162P3}$, which showed inverse correlation between the avidity of the anti-Env antibodies and peak postchallenge viremia.[833] DNA-MVA prime-boost immunization was shown to induce in rhesus macaques high-frequency virus-specific $CD4^+$ $CD28^+$ central memory T-cell responses with a polyfunctional repertoire[834] that were associated with a survival advantage following challenge with SIVmac251.[835] More recently, CD40L-adjuvanted DNA/MVA SIV vaccine was found to enhance protection against neutralization-resistant mucosal SIV infection.[836] Alphaviral replicon DNA expressing HIV antigens has also been shown to be an effective prime for MVA or with a protein subunit boost.[837] A broadened immune $CD8^+$ T-cell response was obtained by using mosaic HIV vaccines in a DNA prime-vaccinia virus boost regimen, resulting in responses to more CTL epitopes of each viral protein and to more variant sequences of each epitope than did consensus immunogens.[305]

Prime-Boost Using Two Different Live Recombinant Vaccines

Another type of prime-boost vaccine regimen was developed using two different live recombinant vectors expressing the same antigen, such as an Ad5 vector followed by a poxvirus vector[838]; or two successive adenovirus vectors, such as Ad11 followed by Ad35,[839] or Ad26 followed by Ad5[435,840] or by Ad35; or two successive poxvirus vectors. Responses of rhesus monkeys to an Ad5-poxvirus (MVA or ALVAC) prime-boost regimen were significantly greater than those elicited by homologous regimens with the individual vectors. Similar findings were obtained with a bacille Calmette-Guérin (BCG) prime-recombinant adenovirus boost.[840]

Ad26 prime/Ad5 boost elicited cellular immune responses with augmented magnitude, breadth, and polyfunctionality as compared to the homologous Ad5-only regimen. After viral challenge, the Ad26/Ad5 vaccinated animals showed a 1.4 log reduction of peak and a 2.4 log reduction of set-point viral loads, as well as reduced AIDS-related mortality, as compared to control animals.[435] In another experiment, Ad26 and MVA vectors expressing the SIV Gag, Pol, and Env antigens were compared in a series of parallel prime-boost vaccination regimens in rhesus macaques. The Ad26/MVA and MVA/Ad26 regimens were more potent inducers of Gag-specific and Env-specific binding antibody responses and Gag-, Pol-, and Env-specific $CD8^+$ and $CD4^+$ T-cell responses than DNA/MVA or MVA/MVA. They also induced the best control of infection after repeated intrarectal challenge with SIVmac.[841]

Adenovirus/poxvirus and adenovirus/adenovirus vector-based vaccines, expressing HIV-1 mosaic Env, Gag, and Pol, afforded a significant reduction in the per-exposure acquisition risk following repetitive, intrarectal $SHIV_{SF162P3}$ challenges. Protection against acquisition of infection correlated with vaccine-elicited binding, neutralizing, and functional nonneutralizing antibodies.[639]

Live Vectored Vaccine Prime-Protein Boost

Quite a different prime-boost regimen strategy was developed using a combination of a live vectored vaccine as a prime

followed by a protein subunit vaccine as a boost, in the hope to stimulate both the humoral and the cellular arms of the immune system. For instance, rhesus monkeys were immunized with an ALVAC-SIV prime followed by SIV gp120 boosts. Of the 12 animals challenged rectally with repeated low doses of SIVmac, three were completely protected, two of which showed good ADCVI responses.[842,843] The same type of prime-boost was used in the RV-144 trial in humans, using an ALVAC-HIV prime and an HIV-1 gp120 boost (see "Human Efficacy Trials of HIV-1 Vaccines" below).

Priming systemic immune responses with intramuscular immunization with ALVAC-SIV vaccines, followed by intravaginal HPV pseudovirions (HPV-PsV-SIV/gp120) boosting, expanded and/or recruited T cells in the female genital tract. High-avidity antibody responses to the envelope gp120 V1/V2 region correlated with delayed SIVmac251 acquisition, whereas virus levels in mucosal tissues were inversely correlated with anti-ENV $CD4^+$ T-cell responses. In addition, $CD8^+$ T-cell depletion in animals with controlled viremia caused an increase in tissue virus load in some animals, suggesting a role for $CD8^+$ T cells in virus control.[844]

A nonneutralizing antibody response was induced in rectal secretions by a replicating Ad5hr-SHIV prime/gp120 protein boost that provided partial control of virus replication after SHIV challenge in macaque monkeys.[486,487] Improved control of infection against intrarectal SIVmac challenge was similarly provided to macaques by immunization with replication-competent Ad5hr recombinants expressing SIV Env and SIV Gag followed by boosting with SIV gp120[845]; in both experiments, ADCC and transcytosis-blocking antibody activities were found to correlate with reduction in chronic viral load after challenge, suggesting that nonneutralizing mucosal antibodies helped control cell-to-cell viral spread during the course of infection.[491,492]

More recently, NYVAC was found to be a more effective vector than ALVAC in stimulating HIV-specific cellular and humoral immune responses in rhesus macaques in prime-boost studies in combination with gp120 clade C protein, and is now advancing to human trials.[846] Heterologous prime-boost regimens with a recombinant chimpanzee adenoviral vector and adjuvanted F4 protein elicited polyfunctional HIV-1–specific T-cell responses in macaques, suggesting that regimens combining adjuvanted protein and low-seroprevalent chimpanzee adenoviral vectors represent an attractive vaccination strategy for clinical evaluation.[847]

Finally, rhesus monkeys primed with Ad26 vectors expressing SIVsmE543 Env, Gag, and Pol and boosted with AS01B-adjuvanted SIVmac32H Env gp140 demonstrated complete protection in 50% of vaccinated animals against a series of repeated, heterologous, intrarectal SIVmac251 challenges that infected all controls. Protective efficacy correlated with the functionality of Env-specific antibody responses. Comparable protection was also observed with a similar Ad/Env vaccine against repeated, heterologous, intrarectal $SHIV_{SF162P3}$ challenges[848]; these strategies are now advancing toward clinical trials.

DNA Vaccine Prime-Protein Boost

Still another type of prime-boost immunization regimen has been studied, combining DNA vaccine for priming with an *env* protein subunit vaccine for boosting, and provided successful protection from SHIV challenge in macaques.[849,850] Using a mixture of *env* DNA plasmids for priming and a mixture of rgp120 proteins from different HIV-1 clades for boosting[851] neutralizing antibodies were generated against primary HIV-1 isolates belonging to different virus subtypes. Immunization of rhesus macaques using this type of prime-boost regimen and enhancing the immunogenicity of the rgp120 boosts by the addition of a QS21 adjuvant protected four of six monkeys against rectal challenge with an R5 SHIV.[852]

More recently, studies have been undertaken using a DNA+vector prime, plus an HIV-Env protein boost. Studies with DNA+recombinant NYVAC prime, followed by an HIV-Env protein boost comparing transmitted-founder B clade Env (B.1059), a global group M consensus Env (Con-S), and a global trivalent mosaic Env protein in rhesus macaques, found that in silico–designed global HIV-1 immunogens were capable of not only eliciting T-cell responses, but also of eliciting potent anti-Env antibody responses.[853] In addition, DNA and virus particle vaccination protects against acquisition and confers control of viremia upon heterologous SIV challenge.[854] Lastly, an enhanced synthetic multiclade DNA prime using a single HIV-Env consensus sequence or multiple constructs expressing HIV subtype-specific Env consensus sequences induced improved cross-clade reactive functional antibodies when combined with an adjuvanted protein boost in NHPs.[855]

Synthetic Peptide Vaccines

Initial attempts to use synthetic peptide immunogens focused on the V3 loop of gp120, including presentation as a multiple antigenic peptide system.[856] Multiepitopic combinations of peptides, fusion proteins, and long lipopeptides are at an early stage of clinical development, either alone[857,858] or in prime-boost combinations with live vector-based recombinant vaccines.[859,860] Peptide mimetics of the gp41 prehairpin fusion intermediate were able to elicit neutralizing antibodies against HIV-1 isolates.[861] HIV-1 lipopeptides with the sequence of Gag, Pol or Nef CTL epitopes have the capacity to elicit a $CD8^+$ T-cell response[862] and are being developed and tested as therapeutic vaccines.[863–865]

Synthetic long peptide (SLP) booster immunization in rhesus macaques primed with replication competent NYVAC-C induced a balanced CD4/CD8 T-cell and antibody response against the conserved regions of HIV-1.[866] Moreover, the humoral responses induced by a fusion gene expressing conserved regions of the HIV genome (HIVconsv) administered to macaques were assessed using six different vaccine modalities: plasmid DNA, human Ad5, Chimpanzee adenovirus serotype 63, MVA, Semliki Forest virus replicons, and adjuvanted overlapping SLPs. It was observed that only the SLP formulation induced antibodies recognizing linear HIVconsv epitopes.[867]

Mucosal Immunity

The genitourinary, rectal, or oral mucosa is the site of entry of HIV-1 in sexually acquired infections. Although oral transmission of HIV-1 is far less common than vaginal and rectal transmissions, infections through the oral route do occur through oral sex as well as vertically, from mother to child. Therefore, there is great interest and demand for vaccines that target mucosal sites of infection and would prevent virus entry and/or the establishment and dissemination of infection.[868–870] Oral vaccination usually gives an immune response in the gastrointestinal tract and in breast milk, while nasal immunization can promote strong IgA responses in both the female genital tract and rectum.[587,870–872] Thus, intravaginal inoculation of mice with an MVA recombinant expressing HIV-1 *env* was not immunogenic, whereas intranasally it induced a significant immune response in the genital mucosa, especially when combined with cholera toxin as an adjuvant.[873] A vaccination regimen including oral–intranasal–intratracheal priming with an adenovirus-SIV recombinant followed by boosting with gp120 in monophosphoryl lipid A emulsion

elicited rectal anti-gp120 IgA and IgG responses that were protective against rectal SIV challenge,[874] and oral immunization alone or oral and nasal immunizations with the same prime-boost regimen was significantly associated with protective mucosal immune responses.[875] Nonneutralizing mucosal antibody activities may thus be important contributors of immune protection.

A gp41-based vaccine candidate was manufactured by inserting trimeric rgp41 and a gp41 MPER peptide into virosomes (liposomes spiked with influenza virus hemagglutinin and neuraminidase [NA] glycoproteins). The vaccine was administered to female rhesus macaques by the intramuscular route followed by the intranasal route, which resulted in induction of transcytosis-blocking IgAs and ADCC-associated IgGs in cervicovaginal secretions, but no systemic neutralizing antibodies. The presence of transcytosis-blocking IgAs, moreover, correlated with full protection of the vaccinated females against repeated intravaginal challenge with R5 $SHIV_{SF162P}$ and partial cross-clade protection against vaginal challenge with a clade C SHIV. Altogether, the vaccine candidate prevented SHIV acquisition and/or sustained infection in 8 of 11 vaccinated animals,[531] with ongoing studies aimed at reproducing the protection observed by this vaccine regimen. These findings underscore the conclusion that protection may occur at mucosal sites in the absence of neutralization in serum as detected by conventional methods.[876]

Mucosal priming followed by systemic boosting with a fusion protein consisting of the cholera toxin B subunit and a gp41 MPER peptide similarly elicited mucosal anti-MPER IgA and IgG antibodies with significant transcytosis-blocking properties.[877] The induction of humoral immunity at mucosal sites could significantly benefit from specific mucosal adjuvants such as Eurocine L3.[878]

Mucosal adjuvants have also been used to enhance mucosal immune responses to HIV immunogens. α-Galactosylceramide (α-GalCer), a synthetic glycolipid agonist of NK T cells, was shown to enhance immunogenicity of vaccine antigens delivered using viral vectors by mucosal routes in murine and NHP models. Significant improvement in adaptive immune responses in systemic and mucosal tissues was demonstrated by including α-GalCer adjuvant for intranasal immunization of mice with VSV vector-expressing HIV Env and Gag antigens. Activation of NK T cells in systemic and mucosal tissues along with significant increases in adaptive immune responses were observed in rhesus macaques immunized by intranasal and sublingual routes with protein or adenovirus vectored antigens when combined with α-GalCer adjuvant.[879]

CHALLENGE OF ELICITING BROADLY NEUTRALIZING ANTIBODIES AGAINST HIV-1

The unprecedented variability of HIV-1 suggests that induction of bNAbs, for example, antibodies that target conserved regions on HIV-1 Env, will be an important component of a successful HIV-1 vaccine. However, immunization of humans with HIV-1 Env, either as subunit proteins or in vector-subunit prime-boost regimens, have failed to induce bNAbs. A major obstacle in the development of a safe and globally effective HIV-1 vaccine is the challenge of eliciting broad, potent, and durable neutralizing antibodies capable of preventing infection by diverse isolates of HIV-1 circulating worldwide.

Strategies to Elicit Broadly Neutralizing Antibodies Against HIV-1

Longitudinal studies of HIV-infected subjects have begun to reveal important insights in the evolution of bNAbs that is informing vaccine design.[880] CH103 neutralized 55% of HIV-1 isolates, with virus and antibody gene sequencing revealing both virus evolution and antibody maturation, as evolution of neutralization breadth was preceded by extensive viral diversification.[399] The evolution of a bNAb targeting the V1V2 apex revealed rapid development following initial selection of B cells with a long HCDR3 region and limited subsequent somatic hypermutation.[414] Lastly, in a recent lineage analysis, two B-cell lineages cooperated to induce the development of bNAbs.[881]

Several vaccine strategies (for reviews see ref. 681) have been used in attempts to elicit bNAbs against HIV-1, and to date, all have failed. There currently is not a single candidate vaccine that has successfully elicited bNAbs in clinical trials. These strategies can be divided into the following categories: trimer mimic, epitope mimic, consensus antigens and cocktails, and antiidiotypes.

Trimer Mimic

This approach aims to mimic the native trimer on the surface of the HIV-1 virion. Trimeric gp140 molecules (gp120 + the ectodomain of gp41) stabilized by the addition of heterologous trimerization motifs at the C terminus of the gp41 sequence,[683,684] and similar trimers with a deletion of the hypervariable V2 loop have been designed with the aim of better exposing the neutralization epitopes that overlap the CD4-binding site.[343,685,686] Similarly, trimeric gp140 molecules internally stabilized by a disulfide bond between gp120 and gp41 (SOS proteins) have been designed and screened preclinically.[688,689] Immunogenicity studies with these trimer mimics and other related trimer mimics have generally showed modest improvements in immunogenicity when compared with monomeric gp120.[694]

With the recent identification of broader and more potent neutralizing monoclonal antibodies, high throughput screens have been developed aimed at identifying HIV-1 Env proteins that preferentially bind these antibodies and using these proteins as the basis for the next generation of trimer mimic designs. The immunogenicity of HIV-1 envelope glycoprotein oligomers has been reviewed.[882]

Insights into the trimeric HIV-1 envelope glycoprotein structure by cryoelectron microscopy and X-ray crystallography, offer potential for iterative improvements in trimer design.[692,693,883] The recent structure of the BG505 trimer captured in a mature closed state by antibodies PGT122 and 35O22 revealed the prefusion conformation of gp41, and further defined parameters of immune evasion and immune recognition.[380] To systematically explore how immunization might be tailored to produce bNAbs, human Ig knock-in mice were generated with mice expressing the predicted germline or mature heavy chains of a potent bNAb to the CD4 binding site on HIV-1 Env.[884] To date, however, native-like HIV-Env trimers failed to activate B cells expressing such germline antibodies. Most recently, well-ordered trimers were generated by negative selection and display native-like properties.[885]

Mixtures of trimers, administered as cocktails or sequentially, are also being assessed to determine if increased breadth of neutralization can be obtained. A quadrivalent cocktail of clade C trimers elicited a greater magnitude of neutralizing antibodies against a panel of tier 1A and 1B viruses than any single clade C trimer alone, demonstrating that the mixture had an advantage over all individual components of the cocktail.[886]

Epitope Mimic

This approach takes a reverse vaccine engineering strategy, by focusing on the binding sites of bNAbs and attempting to

mimic such binding sites. Structural biology studies have now identified the binding sites for 2F5, 4E10, 2G12, and VRC01, with the 2F5 and 4E10 epitopes being linear, the 2G12 epitope focused on a distinct pattern of high-mannose carbohydrates, and the VRC01 epitope being discontinuous at the CD4 binding site, along with structures of trimer-specific antibodies described above.[883,887,888] Coupling linear epitopes to carriers, expressing such epitopes in nucleic acid or viral vectors, or placing these epitopes in carrier scaffolds are among the approaches being tested to elicit neutralizing antibodies to these epitopes.[354] One interesting approach that has generated modest improvements in neutralization breadth is the use of nonglycosylated outer-domain-derived HIV-1 gp120 immunogen.[889] The first epitope mimic now in early development for clinical trials is the engineered outer domain multimerized on nanoparticles.[890] This computational biological approach to structure-assisted vaccine design is similar to the successful proof of principle for epitope based design of a vaccine candidate against respiratory syncytial virus.[891] Most recently, the engineered outer-domain immunogen-induced antibodies with characteristics of VRC01-class bNAbs, including a short CDRL3 (light-chain complementarity-determining region) in knock-in mice.[892]

Synthetic peptide approaches are also in development as experimental HIV vaccines.[893] Synthetic, homogeneously glycosylated peptides that mimic hypervariable loops V1V2 and bind avidly bNAbs PG9 and CH01 have been designed, and V1V2 glycopeptide dimers bearing Man5GlcNAc2 glycan units bind with apparent nanomolar affinities to unmutated common ancestor B-cell receptors on naïve B cells, suggesting that these glycopeptide constructs may be attractive immunogens for targeting subdominant HIV-1 envelope V1V2-neutralizing antibody-producing B cells.[894] Computational designs of high-affinity epitope scaffolds by backbone grafting of a linear epitopes is also a strategy being employed to elicit bNAbs to MPER epitopes.[895] In addition, peptide mimetics of the gp41 prehairpin fusion intermediate provides for a starting point for immunogens to elicit bNAbs against the gp41 prehairpin intermediate.[861]

Consensus Antigens and Cocktails

In silico analysis of sequences from globally diverse isolates of HIV-1 has led to the development of consensus antigens for use in attempting to elicit bNAbs.[300] In addition, cocktails of HIV-1 Env, either as protein subunits, DNA prime + protein boost, or incorporation into viral vectors (e.g., DNA prime + Ad5 boost), have also been attempted[700–704] without much success. Algorithms to identify amino acid sequence motifs required for recognition by HIV-1 neutralizing monoclonal antibodies[896–898] may help in the design of improved consensus antigens.

Antiidiotypes

Fab fragments from CD4-binding site-directed human IgGs from HIV-1–infected long-term nonprogressors were used as immunogens in mice for hybridoma generation. Two hybridomas, P1 and P2, were shown to recognize the idiotype of the bNAb b12, and when used as immunogens in rabbits elicited strong anti-gp120 responses, with modest HIV-1–specific neutralizing antibody activity in the first preclinical proof-of-concept study of the antiidiotype approach.[899]

Summary and Future Directions

Induction of bNAbs against HIV-1 remains the greatest challenge in HIV-1 vaccine development. Recent identification of new targets on the HIV-1 virion for broadly neutralizing monoclonal antibodies has revitalized the field and offered several promising avenues for vaccine design. However, several key questions still remain including: Why does it take 2 to 3 years in HIV-infected subjects to elicit bNAbs? Why does this occur in only a subset of HIV subjects?[405] To address these questions, acute infection cohorts have been established and scientific consortia set up to probe the evolution of bNAbs.[880] Not much is known as to why HIV isolates fall into categories of neutralization-sensitive versus neutralization-resistant isolates at the molecular level. Understanding how HIV-Env differs from these sensitive and resistant isolates may help with vaccine design to elicit bNAbs. Interestingly, envelope glycans of HIV virions are almost entirely oligomannose antigens, in contrast to recombinantly generated gp120.[900] There is now a greater recognition of the role of glycans as key components of epitopes at supersites of bNAb recognition, including the V1V2 apex and N-332 sites, respectively.[901] Lastly, as more antigens emerge capable of binding the bNAbs, formulation of such antigens with novel carriers and adjuvants may potentiate the induction of bNAb responses.

PASSIVE IMMUNOPROPHYLAXIS AND IMMUNOTHERAPY

Although passive administration of monoclonal antibodies is effective in a variety of disease settings, there are no monoclonal antibody products that are licensed for use for immunoprophylaxis or immunotherapy for prevention or treatment of HIV infection.[902] While practical considerations may preclude the use of monoclonal antibody preparations as a prophylactic passive immunization strategy for prevention of HIV-1 infection in large populations of the developing world, it is possible to consider passive immunoprophylaxis in the context of prevention of mother-to-child transmission of HIV-1,[903] or potentially in a postexposure immunotherapy setting. However, it should be noted that efforts are ongoing to significantly improve half-life of antibodies, and thus future engineered antibodies may be utilized as for PrEP.[904] The recent advances described above, and the development of more broad and potent neutralizing monoclonal antibodies against HIV-1, has reinvigorated studies on passive immunoprophylaxis and immunotherapy.

Preexposure Immunoprophylaxis

One of the considerations for the use of bNAbs in a passive immunoprophylaxis setting is to provide proof-of-concept in humans that such antibodies can mediate protection against HIV-1. Such studies might also provide an indication of the levels of antibody required for protection, which would be helpful for HIV-1 vaccine development. However, the strategy would be more feasible for broader applications if the potency and longevity of the antibodies could be optimized. A variety of molecular engineering strategies have been developed that can increase the potency and half-life of antibodies in circulation.

Potency of ADCC can be enhanced through the FcRγIII receptor.[905,906] Half-life of antibodies can be significantly enhanced through modification of the neonatal Fc receptor.[907] Enhanced neonatal Fc receptor function improved protection against primate SHIV infection with bNAbs directed against the CD4 binding site of HIV-Env.[508] In addition, it was demonstrated that neutralizing 2F5 IgG at the portal of infection protected against vaginal SHIV challenge, whereas 2F5 Fab was not protective.[908] Moreover, modification of the glycoforms of monoclonal antibodies can be exploited to provide maximum efficiency for a given disease indication.[909]

More recently, passive transfer of modest titers of potent and broadly neutralizing anti-HIV monoclonal antibodies were shown to block infection in macaques, whereas no protection was observed following passive transfer of polyclonal highly functional low-dose neutralizing antibodies.[910,911] Somewhat surprisingly, the protective efficacy of bNAbs directed to the HIV-Env–versus–SHIV challenge was greater than antibodies directed against the CD4 receptor, despite comparable or greater neutralization potency in vitro by the anti-CD4 antibody.[912] Lastly, combinations of bNAbs provided improved neutralization profiles in vitro compared with individual bNAbs, suggesting that combinations of bNAbs should be considered for clinical use.[913] Future studies should also assess the protective efficacy of bNAbs against cell-associated mucosal transmission.[914]

Vector-Mediated Gene Delivery

As a result of the practical limitations for product development and large-scale application of passive immunoprophylaxis against HIV-1, other strategies are being explored, including the long-term expression of antibody by gene transfer, that is, vector-mediated gene delivery. Recombinant adeno-associated virus (rAAV) vectors have been shown to successfully deliver HIV-1 bNAb IgG1b12 to mouse muscle, with significant levels of HIV-1 neutralizing activity maintained in the sera of mice for more than 6 months after a single intramuscular administration of the rAAV vector.[915] These studies led to the recently successful demonstration of long-lived neutralizing activity and protection against SIV in monkeys.[415] To fully exploit this technology, iterative clinical trials aimed at optimizing the rAAV subtype and selection of genetic inserts will likely be required. At the time of this writing, a prototype rAAV-1 expressing the bNAb PG9 is currently being assessed in clinical trials for levels of expression and duration of PG9 neutralizing antibody (P.R. Johnson, personal communication, 2016).

AAV8-based vectors are also being evaluated as delivery vehicles for bNAbs and will soon be entering clinical trials.[417] An AAV8 vector encoding a simianized form of the CD4bs bNAb, VRC07 expressed antibody in macaques for 16 weeks at levels up to 66 μg/mL, although immune suppression with cyclosporine was needed to sustain expression. Gene-delivered simian VRC07 protected against SHIV infection in monkeys 5.5 weeks after treatment.[916] Successful implementation of AAV-mediated prophylaxis of HIV infection will require improvements in manufacturing processes for AAV, optimization of vector and insert for expression and durability, and demonstration in efficacy trials of prevention of HIV infection. Most recently, an engineered antibody like molecule eCD4-Ig, a fusion of CD4-Ig with a small CCR5-mimetic sulfopeptide, bound avidly and cooperatively to the HIV-1 envelope glycoprotein (Env) and was more potent at preventing infection than the best bNAbs. Moreover, rhesus macaques inoculated with an AAV vector stably expressed 17 to 77 μg/mL of fully functional rhesus eCD4-Ig for more than 40 weeks and these macaques were protected from several infectious challenges with SHIV-AD8.[144] Thus, in addition to delivering bNAbs, AAV may be considered as a delivery vehicle for viral inhibitory molecules, and therefore may be a platform for prevention of other viral infections beyond HIV.[917]

Lentiviral vectors for engineering of human hematopoietic stem cells are also being evaluated as a strategy for eliciting bNAbs. By transducing human cord blood CD34+ cells with lentiviral vectors encoding a monoclonal anti-HIV antibody, b12 (IgG_1), human B cells were programmed to produce in vitro up to 1.5 μg/mL of this bNAb.[918] Similarly, inhibition of in vivo HIV-1 infection of humanized nonobese diabetic (NOD)/severe combined immunodeficiency (SCID)/γ(c) (null) mice was observed by gene therapy of human hematopoietic stem cells with a lentiviral vector encoding the broadly neutralizing monoclonal antibody 2G12.[919] More recently, mutated self-cleaving 2A peptides were designed as a molecular rheostat to direct simultaneous formation of membrane and secreted anti-HIV immunoglobulins in lentiviral transgenesis studies.[920]

Postexposure Immunoprophylaxis and Immunotherapy

Passively transferred neutralizing antibodies can block lentivirus infection, but their role in postexposure prophylaxis is poorly understood. Immune escape from a single antibody would be expected, thus cocktails of monoclonal antibodies or polyclonal sera might be more beneficial. In this context, it was shown that postinfection passive immunotherapy with polyclonal immunoglobulin with high neutralizing titers against SIVsmE660 significantly controlled SIV infection in rhesus monkeys and accelerated de novo production of neutralizing antibodies.[921]

Preadministration of high-affinity humanized anti–HIV-1 monoclonal antibody KD-247 by passive transfer provides sterile protection of monkeys from heterologous SHIV infection, and postinfection passive transfer of KD-247 protected against SHIV-induced $CD4^+$ T-cell loss in macaque lymphoid tissue.[922]

There have been very few postinfection trials of HIV-1 bNAbs in HIV-infected subjects. Mixtures of 2G12, 2F5, and 4E10 were evaluated in six acutely and eight chronically infected subjects undergoing interruption of ART. Only 25% of the chronically infected individuals showed evidence of a delay in viral rebound, and only 2G12 appeared to be important for the in vivo effect.[923] Administration of the neutralizing monoclonal antibodies also led to an immediate, high activation of the complement system, even in the absence of viremia in the 14 participating HIV-1–infected individuals.[924]

More recently, however, owing to the greater potency and breadth of newly identified monoclonal antibodies, there has been a resurgence of interest in the potential of these bNAbs to provide therapeutic benefit and potentially be components of functional cure strategies. Administration of a cocktail of HIV-1–specific bNAbs, as well as the single glycan-dependent monoclonal antibody PGT121, resulted in a rapid and precipitous decline of plasma viremia to undetectable levels in rhesus monkeys chronically infected with the pathogenic $SHIV_{SF162P3}$.[421] Similarly, two new antibodies, directed to the CD4-binding site and the V3 region (3BNC117 and 10–1074, respectively), were assessed for their ability to block infection and suppress viremia in macaques infected with the R5 tropic SHIV-AD8, and were found when administered together to rapidly suppress plasma viremia for 3 to 5 weeks in some long-term chronically SHIV-infected animals with low $CD4^+$ T-cell levels.[420] These studies led to a first-in-man dose escalation Phase I clinical trial of 3BNC117, in uninfected and HIV-1–infected individuals, and showed that 3BNC117 infusion was well tolerated, and demonstrated favorable pharmacokinetics. A single 30 mg/kg infusion of 3BNC117 reduced the viral load in HIV-1–infected individuals by 0.8 to 2.5 log10 and viremia remained significantly reduced for 28 days.[145]

CLINICAL TRIALS OF HIV VACCINES

Since 1987, when the first preventive HIV-1 vaccine candidate entered clinical trials, several vaccine candidates have been evaluated in safety and immunogenicity trials, and four vaccine candidates have completed efficacy trials. Table 29.4

TABLE 29.4 Summary of Candidate HIV-1 Vaccines Evaluated in Recent Clinical Trials

Vaccine	Immunogenicity[a]	Comment
SUBUNIT PROTEINS, PEPTIDES, AND ADJUVANTS		
gp120: Alum, MF-59; QS21 MPL, MDP, MTP-PE, Liposome/lipid A, AS02a	gp120: ELISA; ADCC; CD4-binding Abs: neutralizing Abs against TCLA isolates; CD4 lymphoproliferation	Phase III efficacy trials of gp120 in alum showed no efficacy[581,582]
F4/AS01 (gag-pol-nef fusion protein)	Polyfunctional CD4 responses[971]	
Lipopeptides	$CD4^+$ and $CD8^+$ cellular immune responses[973]	
Trimeric gp140		
DNA PLASMIDS		
Naked DNA	Cellular immune responses (CD4>CD8), after multiple immunizations[1029]	As standalone candidates, naked DNA vaccines have generally been less immunogenic in humans, compared to preclinical small animal or NHP studies
Adjuvanted DNA: CRL005, IL-15, IL-12	No significant enhancement with adjuvants/ cytokines detected[820]	
Delivered by electroporation	Electroporation enhances immunogenicity[1030]	
Consensus/mosaic DNA		
VIRAL VECTORS		
Adenovirus types 5, 35, 26, 5/48 chimera, ChimpAd63 consensus, Ad mosaic	Adenovirus type 5 elicited cellular immune responses (CD8>CD4), with responses suppressed with antivector immunity[583]	Phase IIb trials: STEP trial in the Americas and Phambili trial in the Republic of South Africa (Ad5–HIV-1 trivalent vaccine)[584,932] showed no efficacy
Pox viruses: *Vaccinia*; MVA, MVA consensus/ mosaic; NYVAC; Fowlpox; Canarypox	Pox vectors: CD4 cellular immune responses >CD8 cellular immune responses	
Venezuelan equine encephalitis (VEE)	First generation VEE, AAV candidates weakly immunogenic	
AAV		
REPLICATING VECTORS		
Tiantan *Vaccinia*	Multiple replicating viral vectors have been demonstrated to be safe and immunogenic, with evidence of efficacy in NHP. First in-class clinical trials underway	
Measles (Schwarz)		
Vesicular stomatitis virus		
Sendai		
Adenovirus types 4 and 26		
PRIME-BOOST REGIMENS		
Vector prime + subunit boost • Canarypox + gp120 • Ad35 prime + gag–pol–nef fusion protein in AS01B	Canarypox (gag, env, prot) + go120 elicit binding Ab, ADCC, neutralizing Ab against tier 1 isolates, and CD4 lymphoproliferative responses	Phase III efficacy trial: RV-144 trial in Thailand (ALVAC-HIV vCP1521+AIDSVAX gp120 B/E)[54] 31% efficacy of Canarypox + gp120 against HIV-1 acquisition
DNA prime + vector boost • DNA + Ad5 • DNA + Ad35 • DNA + MVA • DNA + NYVAC • DNA prime + Ad35 + MVA • DNA prime + ChimpAd63 + MVA	DNA + Ad5 induce both $CD4^+$ and $CD8^+$ multifunctional T cells[1031]	Phase IIb efficacy trial HVTN 505 in men and male-to-female transgender persons who have sex with men (VRC-HIVDNA016–00-VP; VRC-HIVADV014–00-VP) showed no efficacy[945]
DNA prime + subunit protein boost • DNA + gp120	DNA + gp120 elicit polyfunctional T-cell responses and neutralizing antibodies against Tier 1 isolates[969]	
DNA prime + replicating vector • DNA + Tiantan vaccinia • DNA + VSV		
Vector prime + vector boost • Ad26 prime + Ad35 boost • Ad35 prime + Ad5 boost • Ad35 prime + MVA boost • MVA + Fowlpox • ChimpAd63 prime + MVA	DNA+NYVAC or MVA induce multifunctional $CD4^+ > CD8^+$ T cells[958,1032]	
Replicating vector prime + vector boost • Sendai + Ad35		

AAV, adeno-associated virus; Ab, antibody; Ad, adenovirus; ADCC, antibody-dependent cellular toxicity; ELISA, enzyme-linked immunosorbent assay; HIV, human immunodeficiency virus; IL, interleukin; MVA, modified vaccinia Ankara; NHP, nonhuman primate; NYVAC, New York vaccinia virus strain; TCLA, T-cell line-adapted; VEE, Venezuelan equine encephalitis.

[a]See HIV vaccine clinical trials database, www.iavi.org.

summarizes the vaccine concepts that have been tested in clinical trials and the references for further information on these concepts. This section summarizes advances made in the past few years and lessons learned from clinical trials of HIV-1 vaccines (for additional review, see reference 925), from the database maintained by the IAVI (www.iavi.org).

Human Efficacy Trials of HIV-1 Vaccines

gp120

The first HIV-1 vaccine concept to complete Phase III efficacy trials was the recombinant gp120 vaccine developed by VaxGen. Two gp120 proteins based on subtype B (MN, GNE8, termed AIDSVAX B/B) in alum were used for the first trial that enrolled 5403 volunteers who were at high risk for sexually transmitted HIV-1. The volunteers were randomized to receive either vaccine or placebo. The vaccine was shown to be safe in Phase I and Phase II trials, elicited neutralizing antibodies against T-cell laboratory-adapted neutralization-sensitive viruses, and protected chimpanzees from infection in preclinical studies. Participants from the United States, Canada, and the Netherlands received seven injections at 0, 1, 6, 12, 18, 24, and 30 months of study duration, and were seen for a final visit at 36 months. The AIDSVAX B/B vaccine appeared to be safe, but was not effective in preventing infection or altering the course of infection.[580,581,926,927] Further analysis of the magnitude and breadth of neutralizing antibody responses was conducted, and showed that most vaccines mounted potent neutralizing antibody responses against laboratory-adapted HIV-1 isolates such as HIV-1 MN, but very weak responses against circulating primary isolates of HIV-1.[928]

A related HIV-1 vaccine efficacy trial of two gp120 proteins based on subtypes B and CRF01A_E (AIDSVAX B/E) was the first to be conducted in a developing country (Thailand) and paved the way for the RV-144 trial (see below). The trial enrolled 2545 injection drug users, and the results concurred with the other trial—that is, the vaccine was safe but had no effect on prevention of HIV-1.[929] Taken together, the failure of the two AIDSVAX vaccines to prevent HIV infection or suppress virus load in vaccinated subjects who subsequently became HIV-1 infected served to accelerate clinical efforts to assess vaccine candidates that elicited cell-mediated immunity, and to spur basic research and preclinical efforts to design vaccines to elicit bNAbs (described above).

Adenovirus-5

The first HIV-1 vaccine concept aimed at eliciting cellular immune responses against HIV-1 that advanced to efficacy trials was the replication-defective Ad5-Gag-Pol-Nef vaccine developed by Merck. The rationale for the advancement of this vaccine concept to efficacy trials was based on data from Phase I trials and from NHP protection studies using the SHIV model. In Phase I trials, the Ad5-Gag-Pol-Nef vaccine was well tolerated and elicited cell-mediated immune responses based on ELISPOT assays in the majority of immunized subjects, although responses were diminished in subjects with high levels of preexisting immunity to Ad5.[930] In monkeys, analogous vaccines controlled SHIV infection but had limited effect against pathogenic SIV challenge (see above).[931]

A double-blind Phase IIb test-of-concept efficacy trial in 3000 subjects (the STEP Trial) was conducted to assess the efficacy of the Ad5-Gag-Pol-Nef vaccine. Subjects were randomized into either placebo or vaccine arms and received three immunizations of MRKAd5 HIV-1 Gag-Pol-Nef vaccine at 0, 1, and 6 months. The study was stopped early because it unexpectedly met prespecified futility boundaries at the first interim analysis, which suggested that continuation of the clinical trial was unlikely to demonstrate the benefit of the vaccine. The vaccine elicited cell-mediated immune responses in approximately 75% of a random sample of subjects, but did not prevent infection or reduce viral load. In an exploratory analyses of all study volunteers, irrespective of baseline Ad5 antibody titer, the hazard ratio (HR) of HIV-1 infection between vaccine and placebo recipients was higher in Ad5 seropositive men (HR 2.3 [95% confidence interval (CI) 1.2–4.3]) and uncircumcised men (HR 3.8 [95% CI 1.5–9.3]), but was not increased in Ad5 seronegative (HR 1.0 [95% CI 0.5–1.9]) or circumcised (HR 1.0 [95% CI 0.6–1.7]) men.[584]

A second Phase IIb trial of the same vaccine was conducted in South Africa (Phambili Trial). While the STEP Trial enrolled men and women in the Americas, Caribbean, and Australia, the Phambili Trial enrolled men and women in South Africa, where the modes of sexual transmission and HIV-1 risk, subtypes of HIV-1, and background Ad5 seroprevalence differed. Vaccinations were stopped after the first interim efficacy analysis of the STEP study crossed predetermined nonefficacy boundaries.[932] At time of stopping, the Phambili Trial also showed no efficacy for prevention or control of HIV-1 infection. Post hoc analyses of men enrolled in the STEP study showed a larger number of HIV infections in the subgroup of vaccinated men who were Ad5-seropositive and uncircumcised compared with a comparable placebo group. Unblinded, long-term follow-up of subjects from the Phambili study showed that 63 vaccine recipients (16%) had HIV-1 infections compared with 37 placebo recipients (9%), and that risk of HIV-1 infection did not differ according to the number of vaccinations received, sex, circumcision status, or Ad5 serostatus.[933]

Further analysis was undertaken on samples from the STEP Trial, in an effort to understand why the vaccine had no efficacy, and also to attempt to determine mechanisms for the observed enhanced number of infections in subgroups of vaccinees compared with placebo. Using ELISPOT and intracellular cytokine assays, high response rates (90% in male vaccinees) were observed, along with the finding that 66% of responding T cells expressed two or more antiviral cytokines, and responses persisted for more than a year.[583] Thus, although these assays were useful in screening immunogenicity, they were not predictive of efficacy. Recent sequence analyses indicated that the vaccine exerted immune pressure, that is, that sequences from infected vaccinees differed from those in placebos at specific sites, reflective of escape from vaccine-induced cellular immune responses.[934] However, vaccinees who responded positively in ELISPOT assays only recognized a median of one to two epitopes compared with more than 10 epitopes recognized in situations where virus control is observed in monkeys.[819] Thus, the lack of efficacy of the vaccine may have been from insufficient potency and/or breadth of epitope recognition. The mechanisms underlying increased HIV-1 acquisition in Ad5-seropositive uncircumcised subjects remain unclear.[935,936]

Canarypox Prime + gp120 Boost (RV-144)

Preclinical studies have shown that priming with one vaccine candidate, and boosting with another candidate, often yields greater levels of cellular and humoral immune responses than repeated immunization with a single vaccine (see above and Table 29.4). One of the first prime-boost concepts to be evaluated was the use of a Canarypox vector prime + Env protein boost, which advanced to efficacy trials in the RV-144 trial conducted in Thailand. Phase I trial data of this concept demonstrated that the vaccines were well tolerated, and stimulated T-cell–proliferative responses, binding antibodies, and ADCC,

as well as low levels of neutralizing antibodies primarily toward tissue culture laboratory-adapted isolates of HIV-1.

In a community-based randomized, multicenter, double-blind, placebo-controlled efficacy trial, the concept was assessed using two priming injections of recombinant Canarypox vector vaccine (ALVAC-HIV [vCP1521]) expressing subtype B gag/pro and subtype E env, developed by Sanofi Pasteur, at 0 and 1 month, plus two booster injections of ALVAC-HIV [vCP1521] and recombinant gp120 subunit vaccine (AIDSVAX B/E) developed by VaxGen at 3 and 6 months. A total of 16,402 healthy men and women in the Rayong and ChonBuri provinces of Thailand participated in the trial. In the modified intent-to-treat analysis, the vaccine efficacy in preventing HIV-1 infection was 31.2% (95% confidence interval [CI] 1.1 to 52.1, $P = .04$). In contrast, vaccination had no effect on the degree of viremia or the $CD4^+$ T-cell count in subjects in whom HIV-1 infection was subsequently diagnosed[54]; this was the first time a candidate HIV-1 vaccine had demonstrated efficacy in prevention of HIV-1 infection, and thus had a significant impact on the future directions for the field.

Since the demonstration of modest efficacy in the RV-144 trial, there has been extensive ongoing work in the search for an immune correlate of protection, but a correlate has yet to be confirmed.[55,937] Preliminary analysis of subjects from the trial indicated that nearly all subjects elicited binding antibodies to subtype B and E gp120s, and that these antibodies waned significantly after 6 months. ADCC responses were also prevalent in greater than 90% of subjects early postimmunization, and also waned over 6 months. In addition, in post hoc analysis at 6-month intervals, vaccine efficacy reached 60% through 12 months after initial immunization and then rapidly waned, and participants classified as high risk based on self-administered questionnaires had limited efficacy compared with those classified as low risk.[938] Most recently, a statistical evaluation of the RV-144 trial concluded that there was moderate evidence of low-level positive vaccine efficacy but still a greater than 22% chance existed to show no efficacy.[939]

For RV-144, analysis of immune correlates of risk showed that antibodies directed against the V1V2 region of gp120, in particular the IgG_1 and IgG_3 subclass mediating ADCC, seemed to play a role in protection, along with an inverse correlation with plasma Env specific IgA antibodies.[940,941] In addition, studies revealed that the ALVAC-HIV/AIDSVAX vaccine induced V2-specific antibodies that cross-react with multiple HIV-1 subgroups and recognize both conformational and linear epitopes.[942] More recently, using a computational framework for unbiased combinatorial polyfunctionality analysis of antigen-specific T-cell subsets (COMPASS), $CD4^+$ antigen-specific helper T cells were also identified as a potential correlate of protection in the RV-144 trial.[943] While a V1/V2-targeted comparison of the genomes of HIV-1 breakthrough viruses identified two V2 amino acid sites that differed between the vaccine and placebo groups, extension of the V1/V2 analysis to the entire HIV-1 genome identified additional signature sites that were not preferentially restricted to the vaccine immunogens. These data suggested that few of the genetic differences in breakthrough viruses were strongly linked to the RV-144 vaccine-induced immune pressure.[944]

Neutralizing antibodies elicited in this trial were less potent than in earlier clinical trials of the gp120 vaccine alone that failed to show efficacy. Cellular immune responses were weak and irregular, consistent with those observed in Phase I trials of this prime-boost vaccine combination. Plans are being implemented for additional preclinical and clinical studies aimed at focusing in on potential correlates of protection, as well as preliminary planning for a next series of efficacy trials to include licensure trials in Thailand of the same or closely related regimen, and for related trials in South Africa using poxvirus prime and subunit boost candidates developed against the prevalent clade C subtype circulating in southern Africa.

DNA Prime + Ad5 Recombinant Boost

Building on the prime-boost theme, a Phase IIb test-of-concept efficacy trial was conducted to assess the ability of the DNA prime + Ad5 boost vaccine approach to provide control of HIV-1 infection, for example, by decreasing the viral load end point, in subjects where HIV-1 infection is subsequently diagnosed postimmunization. The DNA vaccine included HIV-1 genes *gag-pol-nef* from subtype B, and the *env* gene from subtypes A, B, and C. The Ad5 booster has a similar set of genes as the DNA, with the exclusion of the *nef* gene.

The Phase IIb clinical trial (HVTN 505) enrolled 2504 men or transgender women who have sex with men to receive the vaccine (1253 participants) or placebo (1251 participants). The six-plasmid DNA vaccine was administered at 0, 4, and 8 weeks; the Ad5 vector boost was administered on week 24. The DNA/rAd5 vaccine regimen did not reduce either the rate of HIV-1 acquisition or the viral load set-point in the population studied. The primary analysis showed that week 28+ infection was diagnosed in 27 participants in the vaccine group and in 21 participants in the placebo group (vaccine efficacy: −25.0%; 95% CI, −121.2 to 29.3; $P = .44$), with mean viral load set-points of 4.46 and 4.47 HIV-1 RNA log 10 copies/mL, respectively. Analysis of all infections during the study period (41 in the vaccine group and 31 in the placebo group) also showed lack of vaccine efficacy ($P = .28$).[945]

Since the iPrEx (Iniciativa Profilaxis Pre-Exposición) study reported that PrEP with daily tenofovir disoproxil fumarate/emtricitabine reduced HIV infections by 44% among MSM and subsequent trials corroborated efficacy among heterosexual men and women, HVTN 505 was the first HIV vaccine efficacy trial where PrEP was offered. Most subjects (91%) believed taking PrEP would not change their willingness to stay in the vaccine trial. As new prevention technologies emerge, HIV vaccine efficacy trials will need to take into account their potential impact on HIV incidence in powering sample size and in development of primary end points.[946,947]

Future Phase I/II Safety and Immunogenicity Trials of HIV-1 Vaccines

The next two concepts likely to advance to efficacy trials will be heterologous prime-boost trials with adenovectors plus HIV-Env boost and DNA prime/poxvirus prime + HIV-Env boost.

Heterologous Adenovectors

Preexisting immunity to Ad5 diminishes immune responses to vaccines which use Ad5 as a vector. Alternate adenovirus serotypes as vaccine vectors may overcome this problem, particularly in the developing world where seroprevalence of Ad5 antibodies exceeds 80%. Preclinical studies show that combinations of two adenovirus vectors results in greater protection against a SIV challenge of rhesus monkeys than administration of individual vectors.[304] Moreover, heterologous vector combinations of Ad26 + MVA or Ad26 + protein also provided better protection.[639,848] In small, exploratory Phase I trials of Ad5 and Ad6 in a prime-boost regimen, it was concluded that combining two adenovirus vectors may be a useful vaccine strategy for circumventing isolated immunity to a single adenovirus serotype.[948]

The leading heterologous prime-boost program assessing adenovector as the prime is being conducted by a consortium of partners led by Johnson & Johnson, including Harvard-Beth Israel Deaconess Medical Center, NIAID HIV Vaccines Trials Network, Ragon Institute, and the IAVI, and focuses on the assessment of combinations of Ad26, MVA, and a trimeric gp140 subunit boost. Ad26 expressing HIV-Env was found to be safe and immunogenic, induced antigen-specific humoral and cellular immune responses, and was not accompanied by a detectable increase in mucosal inflammation.[949–951] Preclinical studies with Ad26 expressing mosaic HIV-1 antigens expanded the breadth and depth of cellular immune responses in rhesus monkeys.[952] Currently, the Johnson & Johnson consortium is assessing combinations of Ad26 and MVA expressing mosaic internal antigens and Env of HIV, and gp140 subunit boosts in Phase I clinical trials to determine the best regimen to consider advancing to efficacy trials (H. Schuitemaker, personal communication, 2015).

Ad35, chAd63 (chimp adenovirus 63), and chimeric Ad5/48 have also been assessed as vectors for HIV vaccines, and Phase I trials have been initiated with mucosally delivered Ad4 and replication-competent Ad26. Ad35 as an HIV vector was found to be safe and immunogenic alone and when combined with a subunit boost.[953,954] Interestingly, coadministration of Ad35 + subunit boost provided robust immunogenicity, and may be a novel strategy for simplifying immunization regimens. Ad63 provided significant priming for an MVA boost of a T-cell–based immunogen (HIVconsv) from functionally conserved regions of the HIV proteome.[955] The chimeric Ad5/48 expressing HIV-Env (Ad5HVR48.ENVA.01) was safe and immunogenic, with vector-elicited neutralizing antibody responses greater for Ad48 than Ad5, confirming that Ad-specific neutralizing antibodies in humans are primarily, but not exclusively, directed against the hexon hypervariable regions.[956]

DNA Prime + Poxvector Boost

Several groups are pursuing the development of prime boost approaches using DNA prime + poxvector boosts. GeoVax is advancing a DNA + MVA candidate, which is currently in Phase II trials. In Phase I trials, the vaccine was found to be well tolerated, with 77% and 42% of subjects eliciting $CD4^+$ and $CD8^+$ responses, respectively. In contrast, response rates for humoral immunity were more robust after three immunizations with MVA when compared with the prime-boost regimen.[957,958]

Sandstrom and colleagues[959] evaluated the safety and immunogenicity of another DNA + MVA candidate. Volunteers were immunized with DNA plasmids expressing gp160 of HIV-1 subtypes A, B, and C; Rev B; p17/p24 Gag A and B, and RTmut B by use of a needle-free injection system. The vaccine was administered with or without recombinant GM-CSF, and boosted with a heterologous MVA expressing Env, Gag, and Pol of CRF01A_E. The vaccine was well tolerated, and 92% of vaccinees elicited HIV-specific IFN-γ responses and 55% $CD8^+$ and 100% $CD4^+$ T-cell responses. The MVA vaccine was also tested independently of DNA priming. MVA or placebos were administered intramuscularly or intradermally at months 0, 1, and 3 to 48 healthy volunteers who were at low risk for HIV-1 infection. Cell-mediated immune responses were moderate in magnitude (median IFN-γ ELISPOT of 78 SFC/10^6 PBMC), but high in response rate (70% ^{51}Cr-release–positive; 90% ELISPOT positive; 100% intracellular staining–positive). Binding antibodies against gp120 and p24 were detectable in all vaccination groups, with ADCC detectable at the highest dose (40% positive).[960] The impact of preexisting immunity to vaccinia virus on the induction of HIV-specific responses after immunization of healthy volunteers with a HIV-1 DNA prime-MVA boost vaccine was also evaluated: preexisting immunity did not reduce the proportion of individuals who responded to HIV-1 antigens in the vaccine, but did lower the magnitude of responses.[961] More recently, broad and potent cellular and humoral immune responses were induced following a second immunization of MVA expressing HIV antigens in subjects previously immunized with DNA + MVA.[962] Lastly, a DNA + MVA multigenic combination based on an HIV Indian clade C was similarly found to be safe and immunogenic.[963,964]

A DNA + NYVAC prime-boost regimen was also found to be well tolerated and immunogenic. Intramuscular DNA priming at weeks 0 and 4 followed by NYVAC boosting at weeks 20 and 24 elicited ELISPOT responses, primarily to Env, in 90% of volunteers.[965] The DNA + NYVAC regimen also induced $CD4^+$ and $CD8^+$ HIV-specific immune responses in intestinal mucosa[966]; 83% of NYVAC-specific CD4 T cells expressed $\alpha_4\beta_7$ integrins and the HIV coreceptor CCR-5. These results suggested that the experimental DNA-C/NYVAC-C HIV vaccine regimen induced the homing of HIV-specific CD4 and CD8 T cells in the gut. It was also noted that the order of prime-boosting with NYVAC was important, with Ad5 prime + NYVAC providing greater immune responses than NYVAC prime + Ad5 boost.[967]

A DNA + replication-competent Tiantan *Vaccinia* virus vector expressing Env, Gag, Pol, and Nef is also under study in China, with Phase I trials completed. The Tiantan *Vaccinia* virus was based on the virus used in the smallpox eradication campaigns in China and further attenuated as an HIV-vaccine vector. The vaccines were well tolerated and elicited cellular immune responses.[968] Three immunizations of DNA followed by a boost with Tiantan *Pox* elicited high-levels of cellular immune responses based on intracellular cytokine staining to Env, Gag, and Pol (10/11 subjects) with lower levels (4/11 subjects) to Nef.

DNA + Protein

Priming with DNA followed by boosting with subunit protein is also being considered as a vaccine strategy for HIV-1 vaccines.[810] In Phase I trials, a regimen composed of a DNA prime formulation expressing five-valent Env and monovalent Gag, followed by a five-valent env protein boost elicited polyfunctional T-cell responses, as well as neutralizing antibody responses to primarily neutralization sensitive HIV-1 isolates.[969] However, adverse reactions were observed with this combination of DNA + protein in QS21 adjuvant, including delayed-type hypersensitivity reactions at prior DNA inoculation sites in 43% of subjects, and two cases of systemic vasculitis temporally related to inoculation with the protein + QS21 boost.[970]

Subunit Protein

As noted above, since the failure of the gp120 efficacy trial, preclinical efforts have focused on the development of subunit proteins capable of eliciting bNAbs; but as of this writing, no candidates have advanced to clinical trials. In addition, in the aftermath of RV-144, additional HIV-Env subunit proteins are being developed for combination prime-boost studies with poxvirus primes. At the time of this writing, the first of these HIV-Env–based subunit vaccines, based on HIV-1 subtype C had just entered Phase I trials in South Africa.

Subunit proteins in novel adjuvants are also being advanced, with the aim of eliciting cellular immune responses. A fusion protein (F4) containing four HIV-1 clade B antigens (Gag p24, Pol RT, Nef, and Gag p17) adjuvanted with AS01, a liposome-based vaccine adjuvant containing

3-*O*-desacyl-4′-monophosphoryl lipid A and the saponin QS-21 developed by GlaxoSmithKline has been assessed in Phase I trials. Two doses of the recombinant F4 protein (10, 30, or 90 μg/dose), adjuvanted with AS01 or reconstituted with water for injection, were administered 1 month apart to 180 healthy volunteers. The candidate was well tolerated and induced polyfunctional $CD4^+$ T-cell responses with the highest responder rates seen in the 10 μg F4/AS01 group (100% to three HIV-1 antigens and 80% to all four HIV-1 antigens). Vaccine-induced $CD4^+$ T-cell responses were broadly cross-reactive to all four antigens derived from HIV-1 clades A and C.[971] This candidate has been evaluated in coadministration with prime-boost trials with Ad35.[954]

Lastly, infant HIV type 1 gp120 vaccination (given between 0 and 20 weeks of age) was shown to be safe and to elicit robust and durable anti-V1V2 IgG responses and only rare envelope-specific IgA responses.[972]

Lipopeptides

The French National Agency for Research on AIDS and Viral Hepatitis's HIV-LIPO-5 vaccine includes five HIV-1 peptides, containing multiple CD8 and CD4 T-cell epitopes, coupled to a palmitoyl tail. In Phase I/II clinical trials, the lipopeptides were well tolerated, and stimulated $CD4^+$ and $CD8^+$ cellular immune responses in approximately 60% of subjects.[973] More recently, studies with these lipopeptides, in prime-boost regimens with ALVAC Canarypox vectors were halted because of myelitis potentially related to the lipopeptide vaccines. Only 42% of enrolled subjects received all four immunizations. No appreciable cell-mediated immune responses were detected in this study.[974]

Nucleic Acid and Viral Vectors

Electroporation of DNA, in combination with plasmid IL-12, was found to enhance immunogenicity, with nearly 90% of subjects developing cellular immune responses after three immunizations.[975] Most recently, additional replication competent vector based HIV vaccines have entered clinical trials, including adenoviruses (types 4 and 26), measles, Sendai, and VSV (see Table 29.4), with additional vectors based on CMV likely to enter clinical testing soon.

Summary of the Clinical Pipeline for HIV-1 Vaccines

Following the demonstration of modest efficacy in the RV-144 trial of ALVAC + gp120, efficacy trials of related and improved regimens are likely to begin in 2016 or 2017. In addition, heterologous adenovirus vectors expressing mosaic antigens, and DNA prime + poxvector boost approaches will also likely enter efficacy trials in the coming years. We also anticipate seeing additional replication competent vectors entering into Phase I trials, and hopefully the first HIV-Env subunit proteins to elicit bNAbs.

THERAPEUTIC VACCINES AND FUNCTIONAL CURE

Because HIV-1 infection progresses slowly and cellular immune responses have been temporally associated with initial control of acute infection, there has been significant interest in the development of therapeutic HIV-1 vaccines. However, studies with the first generation of such candidates—including protein subunits, inactivated virus, and other strategies—have shown short-term safety but poor or limited immunogenicity in HIV-infected individuals, and no conclusive clinical benefit.[976,977] More recently, strategies have focused on improving immunogenicity and evaluating the potential of these candidates in the context of antiviral therapy, or in situations of analytic treatment interruptions. Moreover, recent advances in understanding how anti-HIV immune responses are elicited and regulated prompted a surge of interest in harnessing these responses to reduce the HIV "residual disease" that is present in ART-treated HIV-infected individuals, through the use of cell-mediated immune-based vaccines and/or bNAbs.[978] The following section briefly summarizes the approaches for therapeutic intervention with HIV-1 vaccines.

Inactivated Virus

A therapeutic vaccine applied to the tonsils in SIV-infected rhesus monkeys was shown to maintain low viral loads after cessation of ART. Animals received 40 weeks of ART initiated 9 weeks after rectal SIVmac239 infection. During ART, animals were vaccinated (or not) with AT-2 inactivated SIVmac239 using CpG-C ISS-ODN (C274) or polyICLC as adjuvants. The lower viral loads observed in the vaccinated animals provide support for the potential benefit of mucosally delivered vaccines in therapeutic immunization strategies for control of HIV-1 infection.[979] A therapeutic vaccine, combining ALVAC and Remune, an inactivated HIV vaccine without gp120, or ALVAC alone followed by treatment interruption at 24 weeks were monitored to week 48 median time to a viral load of more than 50copies/mL were longer in each of the vaccinated groups compared to placebo, but the subsequent viral load setpoint was not different between the groups.[980]

Subunit Proteins and Peptides

A subunit HIV-1 gp160 vaccine was assessed in Phase I therapeutic immunization protocols, and repeated administration of doses at 0, 1, 2, 3, 4, 6, 9, and 12 months was shown to increase $CD4^+$ central memory cells.[980]

The native HIV-1 Tat protein was chosen as a therapeutic HIV-1 vaccine candidate, with the hypothesis that Tat-specific immune responses might provide control of infection. The vaccine was well tolerated and elicited anti-*tat* antibodies as well as T-helper responses.[981,982] Thirty HIV-positive volunteers receiving a stable regimen of ART with CD4 counts higher than 400 were recruited for the safety evaluation of LFn-p24C, a detoxified anthrax-derived polypeptide fused to the subtype C HIV *gag* protein p24. The vaccine was well tolerated and HIV-specific responses were associated with increases in CD4 counts following immunizations.[983]

Preliminary studies with an adjuvanted protein therapeutic HIV-1 vaccine showed a clinically acceptable reactogenicity and safety profile, and induced polyfunctional HIV-1–specific $CD4^+$ T-cell responses in ART-experienced and ART-naïve subjects.[984]

Another candidate vaccine, Vacc-4x, is being developed by Bionor Immuno AS as a therapeutic vaccine. The vaccine is comprised of four synthetic peptides sequences within the highly conserved HIV core protein p24, which are thought to induce T-cell epitopes. Vacc-4x was assessed in 51 patients infected with HIV-1 and found to be safe and immunogenic, inducing cell-mediated immune responses. This candidate is now undergoing additional, Phase IIa trials to assess the effect of the therapeutic vaccination on viral load compared with placebo.[984,985] More recently, a Phase II randomized double blind placebo controlled trial with this therapeutic vaccine showed that it was safe and immunogenic, and elicited a threefold reduction of viral load.[986]

Another peptide-based therapeutic HIV vaccine was evaluated in Phase I clinical trials (Opal-HIV-gag). The vaccine was administered intravenously after ex vivo incubation with autologous white blood cells. The study was terminated after a serious, potentially life-threatening event of hypotension and the product will not be further developed.[987]

Lipopeptides were also used as a therapeutic vaccine to study immunological responses and assess treatment interruption in HIV-1–infected patients. In a prospective open pilot study, 24 HIV-1–infected HAART-treated patients with undetectable plasma viral loads and CD4 T-cell counts above 350/mm were immunized at weeks 0, 3, and 6 with a candidate vaccine consisting of six HIV lipopeptides. New specific CD8 responses to HIV-1 epitopes were detected after immunization in 13 (57%) of 23 patients. At week 24, subjects were taken off HAART and monitored until 96 weeks. By 96 weeks, 8 of 24 patients had still not resumed HAART having maintained low viral loads, suggesting that a future randomized study with control arm would be warranted.[865]

Pulsed Dendritic Cells

The ANRS HIV-lipopeptide vaccine was also used to pulse monocyte-derived DCs. The vaccine was composed of five lipopeptides from Gag, Nef, and Pol. Monocytes were enriched from HIV-1–infected HAART-treated patients and were cultured for 3 days with GM-CSF and IFN-α. Once pulsed with the lipopeptides, and reinjected into their host, the cells were capable of eliciting HIV-1 antigen-specific responses. The safety and immunogenicity of this DC vaccine was evaluated in a Phase I/II clinical trial in chronically HIV-1–infected patients on HAART. The vaccine was found to elicit polyfunctional HIV-specific T-cell immunity associated with a decrease in viral load.[988]

Therapeutic immunization with HIV-1 peptide-loaded DCs was well tolerated in Phase I trials of HIV-1–infected subjects. Eighteen seropositive subjects on ART underwent leukophoresis to obtain PBMCs for DC generation. The DCs were pulsed with Gag, Env, and Pol peptides and influenza A matrix peptide, and administered either intravenously or subcutaneously at the dose of 3 or 10 million cells. Immunization significantly increased frequency of HIV-1 peptide-specific IFN-γ–positive cells.[989]

Targeting Canarypox-HIV vaccines to DCs elicited anti–HIV-1 immune responses in vitro, and this approach was advanced to Phase I/II trials to evaluate whether adding DCs to Canarypox-HIV vaccine improved virologic control during analytic treatment interruption. The vaccine was well tolerated, but did not lower viral load set-point during treatment interruption compared with the Canarypox vaccine alone, suggesting that additional methods to enhance the immunogenicity of DC-pulsed vaccines will need to be developed.[990]

The hypothesis that therapeutic vaccination against HIV-1 can increase the frequency and suppressive function of Treg cells, thereby masking enhancement of HIV-1–specific $CD8^+$ T-cell response, was assessed by immunization with autologous DCs loaded with HIV-1 Gag peptides. Immunization with a DC-based vaccine against HIV-1 caused a modest increase in Treg cell frequency and a significant increase in HIV-1-specific, Treg suppressive function. The Treg suppressive effect masked an increase in the vaccine-induced anti–HIV-1–specific polyfunctional responses.[991]
