Cholera[15]	Dukoral (WC-rBS)	2 y (min)	3 (2–5 y)	≥7 days (min)	≥7 days (min)	Every 6 mo	Minimum age
			2 (≥6 y)	<6 wk (max)	<6 wk (max)	Every 2 y	Minimum age
	Shanchol and mORCVAX	1 y (min)	2	14 days		After 2 y	Definition of high risk
Meningococcal[16]	MenA conjugate	9–18 mo (5 μg)	1				Definition of high risk; vaccine options; 2 doses if <9 mo with 8-wk interval
	MenC conjugate	2–11 mo	2	8 wk		After 1 y	Definition of high risk; vaccine options
		≥12 mo	1				
	Quadrivalent conjugate	9–23 mo	2	12 wk			Definition of high risk; vaccine options
		≥2 y	1				
Hepatitis A[17]		1 y	At least 1				Level of endemicity; vaccine options Definition of high-risk groups
Rabies[18]		As required	3	7 days	14–21 days	See WHO website footnote	Definition of high risk, booster
Recommendations for Children Receiving Vaccinations From Immunization Programs With Certain Characteristics							
Mumps[19]		12–18 mo with measles containing vaccine	2	1 mo (min) to school entry			Coverage criteria >80%; combination vaccine
Seasonal influenza (inactivated tri- and quadrivalent)[20]		6 mo (min)	2 (<9 y), 1 (≥9 y)	4 wk		Revaccinate annually: 1 dose only (See WHO website footnote)	Priority risk groups, especially pregnant women; lower dosage for children 6–35 mo
Varicella[21]		12–18 mo	1–2	4 wk to 3 mo per manufacturer recommendations			Achieve and sustain ≥80% coverage; pregnancy; coadminister with other live vaccines

Accompanying tables and footnotes to this table may be found at: http://www.who.int/immunization/policy/immunization_tables/en/

attending the campaign, irrespective of previous vaccination. This also means that only the aggregate number of doses given in supplementary immunization activities is recorded at the site of vaccination, and these doses are not counted in estimating routine immunization coverage.

Strategies and Practices to Strengthen Routine Immunization Systems and Improve Immunization Coverage. The term "routine immunization" is understood in two distinct ways that relate to the health system components required for delivering the services and to the specific strategies and activities to improve coverage with the scheduled vaccination doses, as described in Table 76.6. It is important to distinguish between these perspectives, as many routine immunization systems strengthening activities may not result in short-term or rapid improvements in vaccination coverage. Equally, many activities specifically designed to rapidly increase routine coverage may not result in stronger delivery systems but rather may use short-term solutions to overcome deficiencies in the delivery system.

Following the development of the GVAP, which provides a framework to guide immunization actions in the current decade (2011–20), a companion document was developed to provide more specific guidance on strategies and practices to achieve the immunization coverage goals in the GVAP. The Global Routine Immunization Strategies and Practices outlines four strategic directions to strengthen the delivery of scheduled immunization doses and improve coverage, namely:

- *Maximize Reach*: strategies and activities to ensure that vaccination services use all means at their disposal to reach beyond the currently reached populations and seek out and vaccinate those that remain unvaccinated. This includes new approaches to detect and identify those that remain unvaccinated, designing the services to reach them, building the capacity of vaccinators and peripheral managers, assuring the availability of vaccines and using all opportunities to vaccinate;
- *Manage the Program*: strategies and activities that support and maintain the managerial functions of the program, including the political commitment to the program, proper planning and budgeting processes, leadership and the competency of the program management team, and the process by countries to set national policies and guidance;
- *Mobilize People*: strategies and activities to engage with communities to create the demand for vaccination, mobilizing and communicating activities to promote vaccination, and dealing with vaccine hesitancy, false perceptions, and negative consequences of perceived AEFIs;
- *Monitor Progress*: strategies and activities to be able to direct and steer the program through monitoring program performance and disease occurrence and evaluating the program through surveys, assessments, and reviews at each of the various levels of the program from the national level to the service delivery point.

The Global Routine Immunization Strategies and Practices also identifies nine key investments that should be made to build and sustain the program. These investments are meant to highlight those key areas where the national governments of developing countries and their development partners should focus in the coming years. While several of these investments are for strengthening the health systems, others relate to investments in strategies to identify and specifically target populations who remain outside the reach of the health system. These investments should target the following areas:

- A capable and sufficiently resourced national program management team in each country;
- Tailored vaccination strategies to identify the undervaccinated and the unvaccinated and provide them with all needed vaccinations regularly;
- A comprehensive planning and monitoring process, from comprehensive multiyear plans and annual operational plans to the quarterly monitoring of implementation of these plans;
- Processes that ensure that sufficient funds reach the operational level of the program in a timely fashion;
- Enhance the performance of vaccinators and district managers by regularly and systematically strengthening their technical capacity, and improve their performance through supportive supervision;
- Modernization of vaccine management and supply chains to make sure that each vaccination session has sufficient amounts of the right and potent vaccines available;

TABLE 76.6 Distinguishing Features Between the Concepts of Strengthening Routine Immunization Services and Accelerating Routine Immunization Coverage

Securing the Foundation; Strengthen Routine Immunization Systems	Reaching Universal Immunization Coverage; Accelerate Routine Immunization Activities
"Routine immunization" refers to the part of the health **system** that allows vaccination to occur.	"Routine immunization" may also describe the process to regularly **deliver** vaccines according to the national vaccination schedule.
The term encompasses system components such as:	Routine vaccination coverage is the percentage of the target group that is provided with vaccination, and is a measure of the ability to reach the population.
• Program communication	Specific activities can be designed to boost routine immunization coverage rapidly, to reach stated coverage or disease control goals, but may frequently lack long-term sustainability.
• Vaccine supply and management with quality assurance	In addition to disease-specific activities and special projects such as the introduction of a new vaccine, a country's routine immunization program should implement tailored activities to increase routine immunization coverage where it is lagging. Within GRISP, "Reaching Universal Immunization Coverage" is reflected in strategies and activities such as:
• Service implementation and monitoring	• Detecting and reaching marginalized populations
It is the foundation on which the entire program is built and is a part of the overall health system of a country.	• Improving coverage equity, creating synergy with accelerated disease control activities
Many components of the immunization system are not unique to the immunization program but shared with all programs and components of the health system.	• Mobilizing and communicating for vaccination, and addressing vaccine hesitancy
Within GRISP, "Securing the Foundation" is reflected in the strategies and activities such as program leadership, human resource capacity building, vaccine availability and quality, political commitment, program planning and financing, policy guidance and monitoring and surveillance.	

GRISP, Global Routine Immunization Strategies and Practices.

- Good interactions and collaborations between communities and the immunization services;
- An information system that identifies and tracks the vaccination status of everyone targeted; and
- Sustainably expand the routine vaccination schedules to cover the entire life course.

Increasingly, the first investment in the national program leadership team to have competency and authority to direct the program is acknowledged as the one key factor that distinguishes good national vaccination programs from their poorly performing counterparts in other countries.

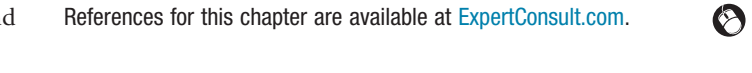
Dropouts and Missed Opportunities. In addition to the issues of accessibility (i.e., the location and timing of service delivery so that they are accessible and suitable for clients), the immunization program should also pay close attention to those clients who initially access services but then do not return for subsequent vaccinations. These clients are termed "dropouts" and are measured through the calculation of the difference between the doses administered at the two scheduled visits. In well-running programs, the dropout rate between the first dose and the third dose of DTP-containing vaccine (DTP3–DTP1 dropout rate) should be less than 10%. This measurement, together with other dropout rates such as the Measles-BCG dropout rate, gives a better insight into program performance than the coverage rate alone. A high dropout rate may point to utilization factors, such as the quality of the service, the affability and competence of the health staff, knowledge of the benefits of vaccinations, and the awareness among the clients or their guardians of the need for multiple vaccinations. While the DTP3–DTP1 dropout rate measures the utilization of health facility services more narrowly, the Measles-BCG dropout rate measures the dropout rate over a longer period.

To improve coverage it is equally important that missed opportunities to vaccinate are minimized. A missed opportunity is defined as "an occasion when a person eligible for immunization and with no valid contraindication visits a health service facility and does not receive all recommended vaccines." Two basic types of missed opportunities are defined:

- Giving overdue doses at vaccination visits scheduled for other vaccine doses. It has been estimated that the median DTP3 coverage could be improved by 8% globally (C. Sanderson, personal communication, 2015) and coverage of the first dose of measles could be improved by 7% if one or both vaccines were administered to children if they had not yet received these vaccines, but were age-eligible to receive them; and
- Giving overdue doses to eligible child or other persons when they visit a health facility for seeking care for conditions that do not contraindicate the provision of vaccination. The rigorous review of vaccination cards at every such opportunity, and the provision of any missed doses of vaccination, would boost coverage considerably. In addition, if infants accompanying adult patients seeking healthcare were considered for vaccination further gains could be made, and vice versa for tetanus toxoid coverage for adult women.

Use of Financial Incentives for Increasing Immunization Coverage. There is growing interest in the use of financial incentives to achieving higher immunization coverage and improved health outcomes.[103] Results-based financing is a broad term that includes a variety of incentive schemes to provide resources to individuals, households, healthcare providers, and district or local-level governments, whereby payment is conditional on the achievement of agreed-on and measurable outcomes. Although there is potential to improve coverage with such programs,[200] the overall quality of evidence is still relatively low.[201] Countries with weaker management and monitoring and evaluation systems in place can face challenges in implementing results-based financing mechanisms, and the impact of results-based financing in countries with weaker health systems is unclear. Other forms of incentive approaches to improving immunization coverage include national vaccine legislation that mandates immunization and often includes the provision of a budget line for vaccine procurement. Vaccine legislation is widely used in the Americas and is a prerequisite to gaining access to the PAHO Revolving Fund.

Fostering Integrated and Coordinated Approaches



Integration or better coordination in the delivery of immunization and other primary healthcare services provides opportunities to improve the coverage of both immunization as well as the other healthcare interventions by reducing missed opportunities for immunization and using immunization visits for counselling to improve care-seeking behaviors for other interventions; for example, care-seeking for diarrhea and pneumonia. As the health workers delivering the different services are often the same in many developing countries, coordination between the different programs in terms of health worker training, program planning, supervision, and monitoring can lead to efficiencies and improved coverage with all the relevant interventions.

The Global Action Plan for Pneumonia and Diarrhoea, developed jointly by the WHO and UNICEF[202] and the Comprehensive Cervical Cancer Control Guide to Essential Practice[203] are two examples of such coordinated and comprehensive approaches to controlling pneumonia, diarrhea, and cervical cancer.

CONCLUSION

Immunization is one of the most cost-effective health interventions. Through its use 2 to 3 million deaths are estimated to be averted each year. Developing countries that carry the disproportionate burden of disease stand to gain the most from immunization and since the establishment of the EPI more than 40 years ago have realized significant health gains by scaling-up the coverage with vaccination. With the expanding portfolio of vaccines, targeting diseases that are still important causes of death and disability in many developing countries, immunization has a large untapped potential for saving lives and improving the health of populations in developing countries. An estimated 25 to 26 million future deaths could be averted in low- and middle-income countries through the introduction and scale-up of currently available vaccines.[16] However, the addition of an increasing number of vaccines to the immunization programs of developing countries has exposed the fragility of their health systems. Fortunately, there are solutions to the problems that these countries face, which, if applied, can lead to improving the health of their populations.

77 Community Protection

Paul E.M. Fine, Kim Mulholland, J. Anthony Scott, and W. John Edmunds

Vaccines are given to people to protect them against disease. They are also given to reduce transmission of infection, thereby preventing disease even in nonvaccinated persons and protecting communities. The extension of perspective from individuals to their communities is the business of public health. The use of an increasing number of different vaccines, in all populations of the world, represents a major, evolving, and highly complicated intervention into human ecology.

For the past several decades, this subject has been discussed largely with reference to the concept of *herd immunity*, a term that refers to the prevalence or proportion of immune persons in a population, but that is often used with reference to indirect protection of nonimmune persons, attributable to the presence and proximity of immune persons (in effect by the vaccine-derived protection of those who would otherwise infect them).[1–3] Much of the discussion has concentrated on the issue of indirect protection of nonimmune persons and its implication of threshold levels of immunity, which, if achieved and maintained, should lead to the elimination of an infection from a population. Although this is clearly of theoretical interest and public health importance, the emphasis on such thresholds has turned attention away from other, more important, community implications of vaccination programs. In recognition of this, the editors of this volume suggested a broadening of the scope of this discussion, under the term *community protection*. The phrase is appropriate insofar as individuals can be protected by vaccines without being themselves immune, through reduced community transmission. In this context it is important to acknowledge, at the outset, that both individual and community protection may also be achieved from the direct and indirect effects of other interventions, including drugs, education, and environmental changes, which are beyond the scope of this chapter and book.

The shift in perspective from the individual to the community raises many programmatic issues about vaccination, including schedules, consent, contraindications, legal enforcement and exemptions, access, public versus private providers, fixed versus mobile services, routine versus targeted programs, campaigns, coverage, monitoring, and evaluation. Many of these issues are covered with respect to particular vaccines and programs elsewhere in this volume. Here we consider more general issues concerning the distribution and implications of vaccine-derived immunity in communities. In simplest terms, one might expect disease incidence to be reduced by a factor equal to the product of vaccine coverage and vaccine efficacy. But the real world is not that simple, and, to predict a program's impact, we must also consider other issues, such as (1) the distribution of vaccines and of disease risk in communities (neither of which is ever uniform or random); (2) the nature of the immunity induced by the vaccine (measured in terms of partial or complete protection against infection, or reinfection, or against disease, or even against transmission, as well as its natural boosting or waning over time); and (3) the indirect protection of nonimmune persons by the presence of immune persons (the traditional focus of herd immunity discussions).

The issue of indirect protection of nonimmune persons is central to discussions of community effects of vaccination. Such protection applies to important segments of society: to children too young to have been vaccinated, to immunocompromised or elderly persons who cannot make an adequate immune response, to persons with contraindications to vaccination, to persons in whom vaccine-induced immunity was incomplete or has waned, and to those who are unvaccinated, either by choice or because they do not have adequate access to vaccines. The social benefits of such indirect protection have important policy implications, including provision of a rationale for mandating immunization. It provides a justification for the vaccine injury compensation program in the United States: a child who is vaccinated is not only deriving direct protection but is also helping to protect the community; hence, society has some obligation for any injuries incurred by the vaccination. In addition, it is important in determining the full costs and benefits of immunization policies; as new vaccines have become increasingly costly, issues of indirect protection benefits become increasingly important in determining whether to introduce new vaccines and to whom they should be given. The community implications of indirect protection are indeed broad.

After a brief historical review, this chapter summarizes the theory and experience that have evolved to describe various aspects of community immunity, and then considers these principles with reference to major vaccines in use today.

HISTORICAL BACKGROUND

Although both Jenner[4] and Pasteur[5] recognized explicitly the potential of vaccines to control and even to eradicate specific infections from populations, neither is known to have considered the practical issues involved in the application of vaccines to populations. Smallpox vaccination was introduced widely in Europe and North America during the early 19th century, with increasing success over time. Its enforcement through legislation would have long-lasting effects on public acceptance of vaccines, including the appearance of the first antivaccination sentiment opposed to this intrusion by states into the bodies of their citizens. This remains a major issue today.[6] Close observers noted interesting implications of vaccination—for example, William Farr commented as early as 1840, "The smallpox would be disturbed, and sometimes arrested, by vaccination which protected a part of the population," probably the first recorded recognition of indirect protection by vaccines.[7]

The early years of the 20th century saw important advances in our understanding of the dynamics of infections in populations as a function of the balance of infectious, susceptible, and immune individuals. Several factors contributed to this—in particular, the increased understanding of disease patterns in communities, which arose from the introduction of morbidity (in addition to mortality) notification schemes, the growth of immunology as a discipline, and the development of a theoretical framework linking these data and disciplines together.

The first published use of the term *herd immunity* appears to have been in a paper published in 1923 by Topley and Wilson, entitled "The spread of bacterial infection: the problem of herd immunity."[8] The paper described one of a series of classical studies on epidemics of various infections in closely

monitored populations of laboratory mice, and introduced the term in this manner: "Consideration of the results obtained during the past five years … led us to believe that the question of immunity as an attribute of the herd should be studied as a separate problem, closely related but in many ways distinct from, the problem of the immunity of an individual host." They went on to pose an "obvious problem to be solved: Assuming a given total quantity of resistance against a specific bacterial parasite to be available among a considerable population, in what way should that resistance be distributed among the individuals at risk, so as best to ensure against the spread of the disease, of which the parasite is the causal agent"?

Wilson later recalled that the phrase "herd immunity" had first arisen in the course of a conversation with Major Greenwood (G.S. Wilson, personal communication, 1981), and Greenwood employed it in his 1935 textbook, *Epidemics and Crowd Diseases*.[9] Although these authors did not distinguish explicitly between direct and indirect protection stemming from vaccine-derived immunity, later authors picked up the phrase and applied it in particular to the indirect protection afforded to nonimmune persons by the presence and proximity of immune persons.

The population implications of immunization programs became a major issue during the last quarter of the 20th century, in association with the widespread introduction of vaccines in all populations of the world. Discussion was stimulated in particular by the success of the global smallpox eradication program, as well as by the creation in 1974 of the World Health Organization's (WHO's) Expanded Programme on Immunization, and the setting of targets to "eliminate" or to eradicate several infectious diseases through vaccines: global targets to eradicate polio and to eliminate neonatal tetanus, and national and regional goals to eliminate measles and rubella.[10] These massive efforts encouraged a body of theoretical literature exploring the population implications of immunization programs, including much discussion of the extent of indirect protection by vaccines, and of coverage criteria for eradication of infection. Although much of the initial theory assumed that immunity was a simple property, that individuals were either fully immune or fully susceptible, and that the protection was solid and permanent against both infection and disease, it became increasingly clear during the 1980s and 1990s that this was incorrect, and that different infections and vaccines could induce different degrees of protection against infection, against disease, and even against infectiousness, and that these different sorts of immunity could wane or be boosted over time. More recent research has attempted to measure these different forms of immunity and to incorporate these subtleties into evaluations of immunity at the community level.[11]

THEORETICAL ARGUMENTS

The focal point of much of the theoretical work on community immunity has been the recognition that, if an infection or vaccine induces some degree of immunity against infection, then some nonimmune people will be protected indirectly, by the presence and proximity of immune persons, and transmission should stop in a population prior to the infection of all susceptible individuals. This insight encourages the estimation of threshold numbers or proportions of immune persons necessary for this cessation to occur. An elegant body of theory has evolved around this issue, developed initially to describe the implications of introducing fully immune people into randomly mixing populations, but subsequently extending to more realistic scenarios.

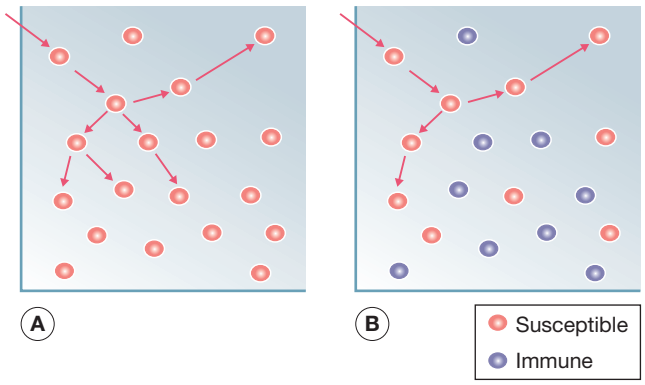

Figure 77.1. Simple diagram illustrating three generations of transmission after introduction of an infection into a fully susceptible population **(A)** and into a population containing immune persons **(B)**. Although it is clear from this diagram that some people may be shielded from infection in population **B**, similar shielding can also occur in **A**.

Fig. 77.1 illustrates (very simply) the principle of indirect protection by showing susceptible and immune individuals in a population, with arrows indicating the spread of an infection. Actual transmission patterns depend on the distribution of susceptible persons in space and time (social mixing patterns), and some susceptible persons may be shielded from infection by being surrounded by immune persons. However, representations such as Fig. 77.1 fail to show that, even if there were no immune individuals at the start of an outbreak, infections may *generate* immune persons who can in turn block transmission and lead to termination of an epidemic before all individuals become infected. We thus need to consider dynamics.

Mass Action Approach

The crucial argument was introduced in 1906, by William Hamer, in the context of a discussion of the dynamics of measles in London.[12] He argued that the number of new cases ($\mathbf{C}_{t+1}$) in a time period equal to the serial interval of the infection (thus one generation of cases, or approximately 2 weeks for measles) is a function of the product of the numbers of infectious cases and of susceptible persons in the previous time period (C_t and S_t, respectively; Fig. 77.2). In simple terms,

$$\mathbf{C}_{t+1} = \mathbf{C}_t \times \mathbf{S}_t \times r \qquad \text{[Eq. 1]}$$

where r is a transmission parameter, or contact rate—in effect, the proportion of all possible contacts between susceptible and infectious individuals that lead to new infections (so, $r \ll 1$). For example, if there are 10 cases and 90 susceptibles, there are 900 possible connections between cases and susceptible persons. The transmission parameter r is the proportion of those possible contacts resulting in transmission and new cases. To simulate successive changes over time, the number of susceptible persons is recalculated for each new time period as

$$\mathbf{S}_{t+1} = \mathbf{S}_t - \mathbf{C}_{t+1} + \mathbf{B}_t \qquad \text{[Eq. 2]}$$

where S_{t+1} is the number of susceptible persons in the next time period and B_t is the number of new susceptible persons added (e.g., born into) the population per unit time. (Note that **bold** symbols are used in this chapter to denote **numbers** of individuals, and nonbold symbols to denote proportions or other descriptive statistics [Table 77.1].) The relationship in Eq. 1, that future incidence is a function of the product of current prevalence and current numbers susceptible, is known

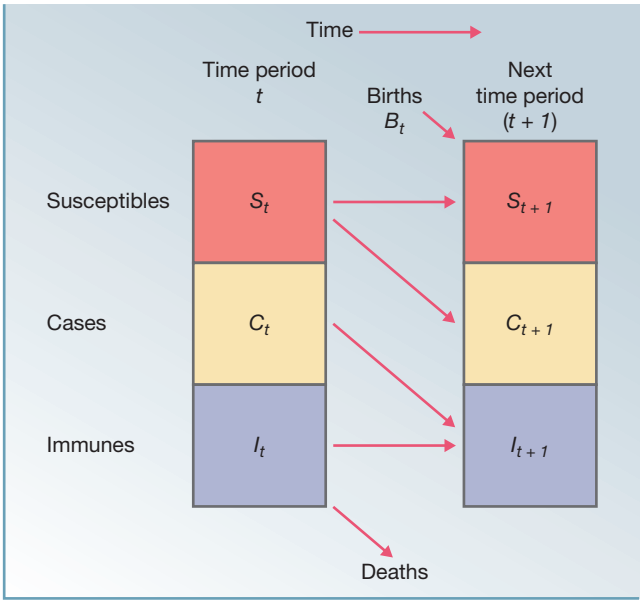

Figure 77.2. Relationship between susceptible persons *(S)*, infectious cases *(C)*, and immune persons *(I)* in successive time intervals (*t*, *t* + 1) in the simple discrete time mass action model. In each time period, some ($\mathbf{C}_{t+1}$) susceptible persons become cases, and the others remain susceptible. Each case is assumed to remain infectious for no more than a single time period (= serial interval). $\mathbf{B}_t$ individuals enter as susceptible births during each time period (e.g., Eq. 2 in the text).

TABLE 77.1 Variables in Theoretical Arguments Concerning Infection Dynamics and Herd Immunity Thresholds

Symbol[a]	Variable Definition
$\mathbf{C}_t$, $\mathbf{C}_{t+1}$	Numbers of cases in successive serial intervals
$\mathbf{S}_t$, $\mathbf{S}_{t+1}$	Numbers of susceptible individuals in successive serial intervals
$\mathbf{I}_t$, $\mathbf{I}_{t+1}$	Numbers of immune persons in successive serial intervals
$\mathbf{B}_t$	Number of new susceptible persons (i.e., births) per serial interval
r	Transmission parameter for the simple mass action model, interpretable as the proportion of all possible contacts between cases and susceptible persons that lead to new infections
$\mathbf{S}_E$	Epidemic threshold number of susceptible persons (if exceeded, incidence increases)
$\mathbf{T}$	Total population size
H	Herd immunity threshold (proportion of immune persons in a population required to prevent large outbreaks from occurring): $H = 1 - \mathbf{S}_E/\mathbf{T} = 1 - 1/\mathbf{R}_0$
$\mathbf{R}_0$	Basic reproduction number (average [expected] number of secondary cases attributable to a single case introduced into a totally susceptible population)
$\mathbf{R}_n$	Net reproduction number (actual number of transmissions per case)
S	Proportion of susceptible persons in a population
A	Average age at infection
L	Average life expectancy in years
C	Vaccine coverage
C_H	Vaccine coverage to achieve herd immunity threshold
P	Protective efficacy of vaccine (proportion protected among vaccinees)
P_i	Protective efficacy of vaccine in terms of susceptibility to infection (proportion of vaccinees who are rendered nonsusceptible to infection)
P_t	Protective efficacy of vaccine in terms of transmissibility (proportion of vaccinees who fail to shed organisms despite becoming infected)

[a]**Bold** symbols represent numbers of individuals; nonbold symbols represent proportions or other descriptive statistics.

as the epidemiologic law of mass action, by analogy with the physicochemical principle that the rate of a chemical reaction is a function of the product of the concentrations of the reactants. Often expressed as a differential (continuous time) rather than a difference (discrete time) equation, as here, this relationship underlies much theoretical work on the dynamics of infections in populations.[13] Note that Eqs. 1 and 2 include no explicit term for immune persons. By implication, deaths prior to infection are not considered in this simplest model (i.e., in each period, the same number of immune persons die as susceptible people are born into the population). The introduction of terms for immune persons; for individuals incubating the infection; for population growth and selective mortality of susceptible, infected, and immune persons; and for age is explored at length in the literature, but the terms do not change the basic message emphasized here.[13]

Fig. 77.3 shows what happens when Eqs. 1 and 2 are iterated, and it serves to illustrate several principles of the epidemiology of those acute immunizing infections, such as measles, mumps, rubella, chickenpox, poliomyelitis, and pertussis, that affect a high proportion of people in unvaccinated communities. First, the model predicts cycles of infection incidence, which are well recognized for many of the ubiquitous infections of childhood (Fig. 77.4). The incidence of infection rises above and dips below the birth rate, or the rate of influx of new susceptible persons. Second, the number of susceptible people also cycles, around a number that is sometimes described as the epidemic threshold (S_E). Rearrangement of Eq. 1 to $C_{t+1}/C_t = S_t \times r$ reveals that this threshold number of susceptible persons is numerically equivalent to the reciprocal of the transmission parameter r, as incidence increases (i.e., $C_{t+1} > C_t$) when, and only when, $S_t > 1/r$, and thus $S_E = 1/r$. In the example illustrated in Fig. 77.3, $r = 0.0001$ and S_E is thus 10,000. The correspondence between the case and susceptible lines in the figure illustrates this relationship: whenever case incidence exceeds the birth rate, the number of susceptible people falls (as it must), and vice versa. Also, whenever the number of susceptible people rises above the epidemic threshold, incidence rises, and vice versa.

This epidemic threshold implies a simple herd immunity criterion. If the *proportion* immune is so high that the *number* of susceptible people is below the epidemic threshold, then incidence will decrease. We can express this threshold algebraically as follows:

$$\mathrm{H} = 1 - \mathrm{S_E}/\mathrm{T} = 1 - 1/\mathrm{r}\,\mathrm{T} \qquad \text{[Eq. 3]}$$

where T is the total population size, S_E is the epidemic threshold number of susceptible people for the population, S_E/T is the proportion susceptible at the threshold, and H is the herd immunity threshold—that is, the proportion of immune persons that must be exceeded if incidence is to decrease. If the total population in the Fig. 77.3 example were 100,000, this would imply a herd immunity threshold (H) equal to $1 - 10{,}000/100{,}000 = 1 - 1/10$, or 90%.

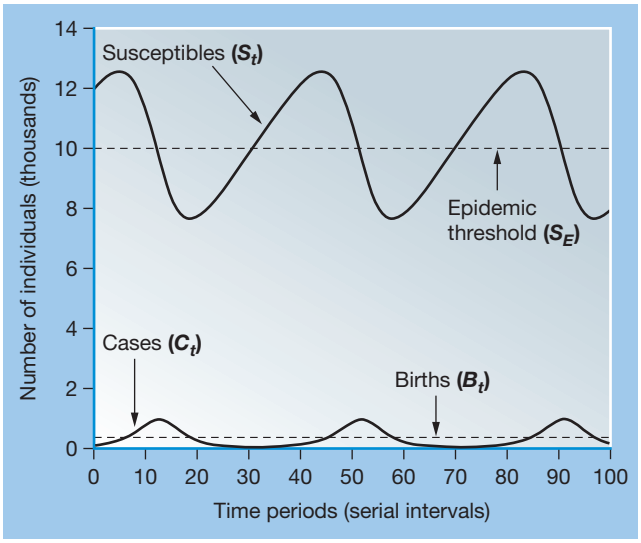

Figure 77.3. Results obtained on reiteration of Eqs. 1 and 2. The illustrated simulation was based on 12,000 susceptible persons and 100 patients at the start, $r = 0.0001$, and 300 births per time period. Note that the incidence of cases cycles around the birth rate, and that the number of susceptible persons cycles around the epidemic threshold: $\boldsymbol{S_E} = 1/r = 10{,}000$. If the total population were $\boldsymbol{T} = 100{,}000$, this implies a herd immunity threshold of 90%, and $\boldsymbol{R_0} = 10$.

Case Reproduction Numbers

We can approach this herd immunity concept from an alternative, and equally informative, perspective. If an infection is to persist, each infected individual must, on average, transmit the agent to at least one other individual. If not, incidence will decline and the infection will disappear progressively from the population. The number, or distribution, of actual onward transmissions per case thus describes the spread of an infection in a population, and it is a function of four things: (1) the duration of infectiousness; (2) the likelihood of transmission per "contact" between infectious and susceptible individuals; (3) the rate and pattern of contact between members of the host population; and (4) the proportion susceptible in the host population. Its value under any set of circumstances is known as the reproduction number of the infection, by analogy with standard demographic measures (the average number of progeny per individual per generation). This average number of actual transmissions should be at a maximum if all members of the host population are susceptible—in which circumstance it is known as a basic reproduction number $(\boldsymbol{R_0})$, defined formally as the average number of transmissions expected from a single primary case introduced into a totally susceptible population.[14,15] This definition *can* be translated directly into the mass action formulation (Eq. 1) by setting $C_t = 1$ and $S_t = T$, to represent the single case introduced into a fully susceptible population. The number of secondary cases, C_{t+1}, is then equivalent, by definition, to the basic reproduction number (R_0):

$$\mathbf{C_{t+1} = T \times r = R_0} \qquad \text{[Eq. 4]}$$

This basic reproduction number describes the maximal spreading potential of an infection in a population. Continuing with the example in Fig. 77.3, the introduction of a single primary case into the population of $T = 100{,}000$ susceptible persons should lead to 10 secondary cases (C_{t+1}=100,000 × 0.0001 = 10 = R_0). Table 77.2 shows examples of numerical values of this statistic that are applicable to different infections and derived by methods described later. Fig. 77.5A is an illustration of the concept.

TABLE 77.2 Approximate Basic Reproduction Numbers (in Developed Countries) and Implied Crude Herd Immunity Thresholds[a] for Common Vaccine-Preventable Diseases[b]

Infection	Basic Reproduction Number (R_0)	Crude Herd Immunity Threshold, H (%)
Diphtheria	6–7	83–85
Influenza[c]	1.4–4	30–75
Measles	12–18	92–94
Mumps	4–7	75–86
Pertussis[d]	5–17	80–94
Polio[e]	2–20	50–95
Rubella	6–7	83–85
Smallpox	5–7	80–85
Tetanus	Not applicable	Not applicable
Tuberculosis[f]	?	?
Varicella[g]	8–10?	?

[a]Herd immunity threshold (H), calculated as $1–1/R_0$.
[b]The values given in this table are approximate and crude; they do not properly reflect the tremendous range and diversity among populations, nor do they reflect the full immunologic complexity underlying the epidemiology and persistence of these infections. See text for further discussion.
[c]R_0 of influenza viruses probably varies greatly between subtypes.
[d]Note that immunity to *Bordetella pertussis* infection is not solid, and it wanes.
[e]Complicated by uncertainties over immunity to infection and variation related to hygiene standards.
[f]Protective immunity not defined.
[g]Immunity not sterile; herd immunity threshold not defined.
From Fine PEM. Herd immunity: history, theory, practice. Epidemiol Rev. *1993;15:265–302; and Anderson RM, May RM.* Infectious Diseases of Humans: Dynamics and Control. *Oxford, UK: Oxford University Press; 1991.*

If immune individuals are present in a population, then some of the contacts of infectious individuals will be with these immune persons, and hence will fail to lead to transmission. As a result, the average number of actual infection transmissions per case will be less than the basic case reproduction number, and this has been defined as the net, or actual, or effective, reproduction number (R_n).[13,14] The actual number of transmissions (R_n) should be equivalent to the basic case reproduction number (R_0) times the proportion susceptible in the population (S):

$$\mathbf{R_n = R_0 \times S} \qquad \text{[Eq. 5]}$$

By this expression, if the proportion susceptible (S) were equal to the reciprocal of the basic reproduction number of the infection $(1/R_0)$, the average number of transmissions per case (R_n) should be 1, and thus incidence should remain constant over time. Fig. 77.5B illustrates this, and it once again leads us directly to the herd immunity threshold (H). Because the proportion immune is just the complement of the proportion susceptible $(H = 1 - S)$, we have

$$\mathbf{H = 1 - 1/R_0 = (R_0 - 1)/R_0} \qquad \text{[Eq. 6]}$$

The same expression can also be derived just by combining Eqs. 3 and 4. As long as the proportion immune is maintained above this threshold, incidence should decrease, ultimately to the point of eradication of the infection from the population. Fig. 77.6 shows the relationship graphically, which shows the

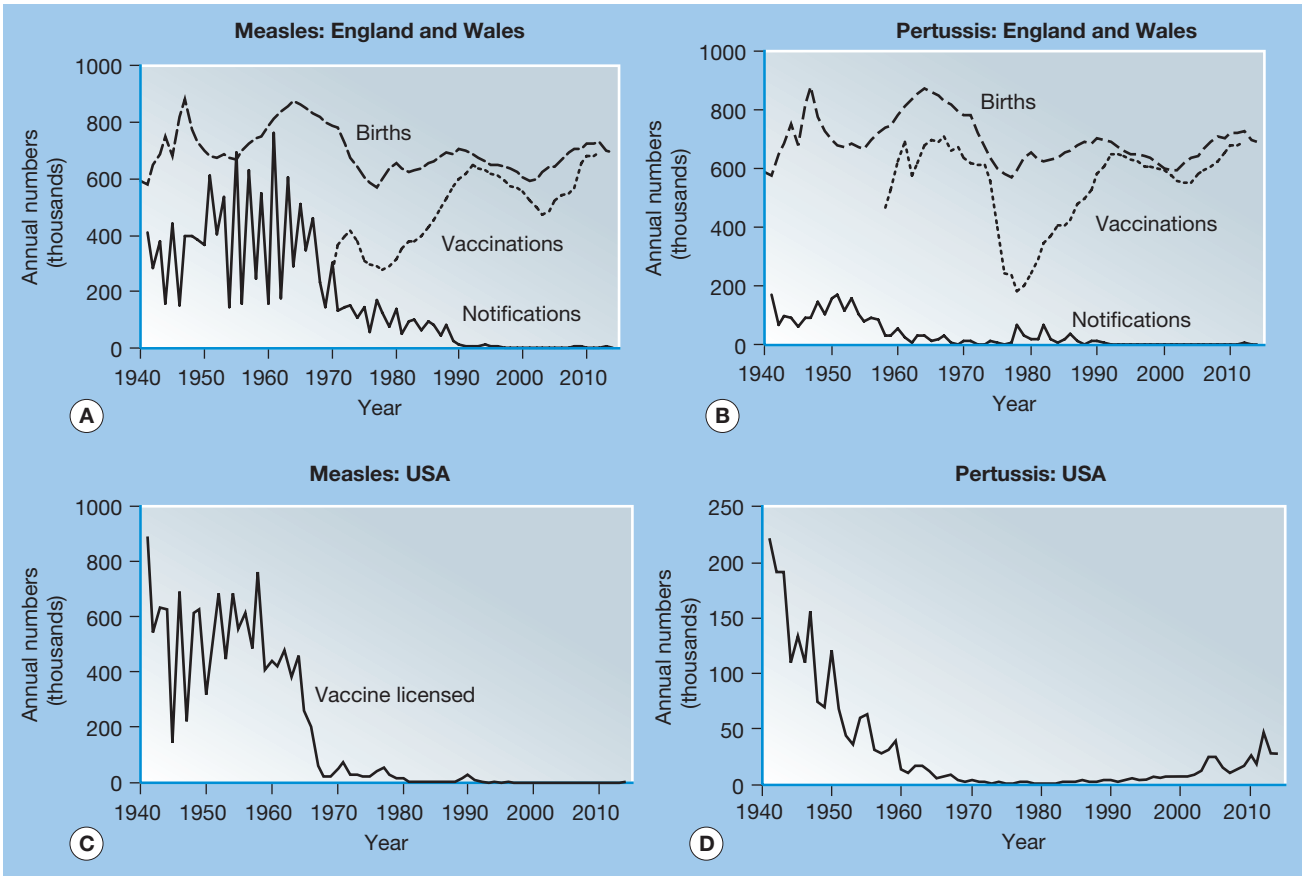

Figure 77.4. Reported incidence of common childhood vaccine-preventable diseases. Measles showed a tendency to biennial epidemics in England and Wales prior to vaccination **(A)**. This pattern was less dramatic in data for the entire United States **(C)**, because of the size and heterogeneity of the population (not all areas were in phase with one another). All areas showed a strong seasonal oscillation, in addition to the biennial cycle. Pertussis shows a 3- to 4-year cycle, with little obvious seasonality, in the United Kingdom **(B)**. This cycling is also seen in national data for the United States, in particular prior to 1970 **(D)**. Notification efficiency for measles was approximately 60% in England and Wales prior to vaccination, but it was considerably lower for pertussis, and for both diseases in the United States. Indigenous measles and pertussis persist in the United Kingdom (2503 and 1850 notified cases, respectively, in 2014); in the United States all measles cases since 2002 have been attributable to importation, and there were 28,660 pertussis notifications in 2014.

implications for persistence or decline of an infection depending on its basic reproduction number and the proportion of immune persons in the population.[1,13,16]

Estimation of R_0

Given this theoretical relationship between the basic reproduction number of an infection in a population and the herd immunity threshold, the estimation of R_0 becomes an important challenge. If the infection is so common that it affects virtually everyone in unvaccinated populations, as is the case with many of the acute immunizable diseases of childhood (e.g., measles, mumps, rubella, polio), one derivation of R_0 turns out to be relatively straightforward. According to the logic described earlier, R_0 is equivalent to the reciprocal of the average proportion susceptible in the population over an epidemic cycle (see Eq. 5 and Fig. 77.5B; note that the proportion susceptible cycles around $S_E/T = 1 - H$, as in Fig. 77.3 and Eq. 3). Dietz[16] pointed out that for immunizing infections the proportion susceptible is approximated by the average age at infection (A) divided by the average life expectancy in years (L), and thus $R_0 \approx L/A$. He went on to show that, for populations with exponential age structures (typically found in low-income countries), a better estimate of R_0 can be obtained with the following equation:

$$R_0 \cong 1 + L/A \qquad \text{[Eq. 7]}$$

Another method of estimating R_0, used in particular for influenza, is based on an analysis of the rate of increase in incidence in the early phase of an epidemic with a new virus subtype. In theory, incidence should increase by a factor equal to R_0 each generation, or serial interval (the time between successive cases in a chain of transmission, approximately 3 days for influenza). The effective reproduction number can also be estimated by this approach, if there is prior immunity in the population—and with knowledge of the fraction susceptible, it may then be possible to estimate R_0, although this latter step is typically more difficult.[17–19] Detailed discussion of the estimation of R_0 by these and other methods can be found in several references.[13,15,16] The herd immunity thresholds cited in Table 77.2 are based on these values, and provide crude estimates of the proportions of immune persons required, *in theory*, to eliminate these infections. As discussed below, and emphasized repeatedly in this chapter, these thresholds, even though widely cited, are based upon unrealistic assumptions (solid immunity, homogeneity, random

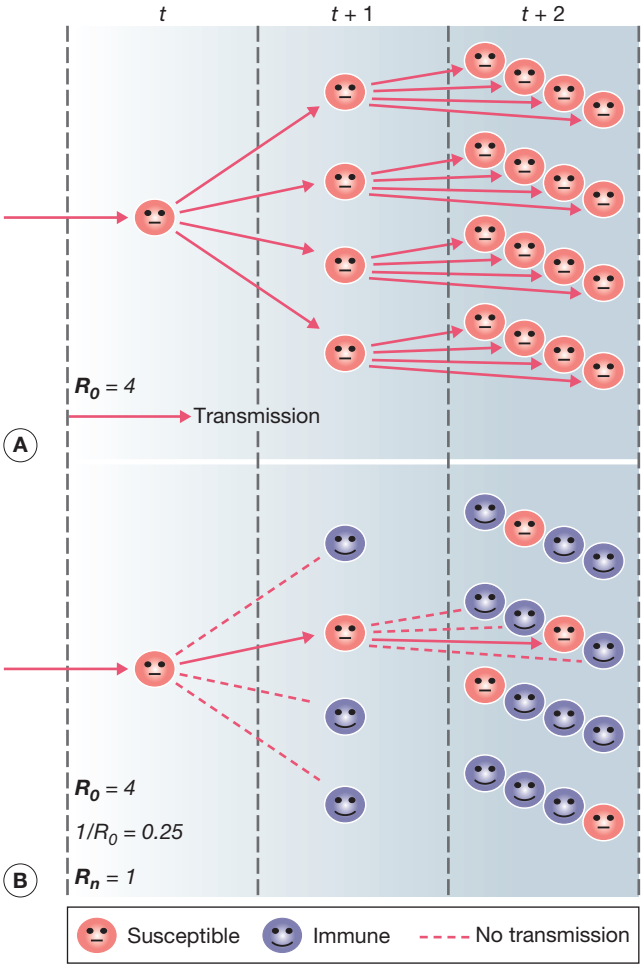

Figure 77.5. Implications of a basic reproduction number $R_0 = 4$. In each successive time (serial) interval, each individual has effective contact with four other individuals. If the population is initially entirely susceptible **(A)**, incidence increases exponentially, fourfold each generation (until the accumulation of immune persons slows the process). If 75% of the population is immune **(B)**, then on average only $S = 25\%$ of each set of four contacts lead to successful transmissions, and the net reproductive number $R_n = R_0 \times S = 1$.

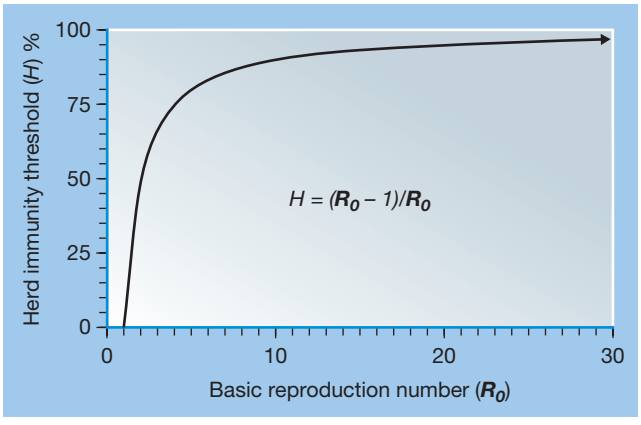

Figure 77.6. Relationship between herd immunity threshold *(H)* and basic reproduction number R_0, as in Eq. 6: $H = 1 - 1/R_0$.

mixing) and should not be thought to apply in real populations.

R_0, Rapidity of Spread, and Herd Immunity Thresholds

R_0 is a standard measure of the transmissibility of an infection, and hence of the potential rapidity of its spread in a population, per generation, or serial interval, of the infection. This can have very different real time implications, depending on whether the serial interval is relatively short (e.g., approximately 3 days for influenza) or relatively long (e.g., approximately 15 days for a measles-like infection).[17] Although the R_0 of influenza is appreciably smaller than that for measles (i.e., about 2 vs about 14) (see Table 77.2), influenza can go through 10 generations within a 30-day month whereas measles can go through only two generations, implying $2^{10} = 1024$ new cases of influenza at the end of the month compared with only $14^2 = 196$ for measles, if the populations were 100% susceptible at the start of each outbreak. (These are just illustrative numbers; of course, the increase in the number of immune persons would slow down the spread.) Despite this more rapid spread of influenza in a virgin population, consideration of the R_0 values shows that influenza should be more easily brought under control than measles: the herd immunity thresholds being H = 50% for influenza versus H = 93% for measles infection, assuming an R_0 for influenza of 2 and for measles of 14. This distinction has received much attention in recent discussions of the feasibility of controlling pandemic influenza.[18,20]

Implications of Population Heterogeneity

The elegant theory just summarized is built on extreme assumptions: that all individuals mix at random, that individuals are either fully susceptible or fully immune, and that the population is uniform (i.e., that all individuals behave the same way and all infected individuals are equally infectious). These assumptions are unlikely to hold for any infection in any human population. In recent years, there has been an effort to adapt the theory to more realistic assumptions, including heterogeneity of mixing patterns and of susceptibility and infectiousness.

The first attempt to consider the implications of population heterogeneity for herd immunity appeared in a 1971 paper by Fox and colleagues, entitled "Herd immunity: basic concept and relevance to public health immunization practices."[2] This paper, for many years the most frequently cited article on herd immunity, took a very different approach from that reviewed above and was based on simulation rather than on analytic argument. The authors set up a population of 1000 people, divided into family, school, and social groupings, and assigned different—but realistic—contact rates within and between these groups. Importantly, they did not consider age, nor did they consider an influx of susceptible persons into the population (the B_t term in Eq. 2). Their approach was thus applicable only to closed populations, and they were unable to address the larger issues of infections in dynamic populations.[1] Although the approach precluded estimation of a herd immunity threshold, it provided a first glimpse of the epidemiologic complexity inherent in heterogeneous populations, and it led the authors to be skeptical of simplistic notions of herd immunity.

Subsequent workers have used a variety of computer simulation and analytic approaches to explore more realistic assumptions than those underlying the simple mass action theory. In particular, there has been exploration of the important implications of age, recognizing the need to vaccinate as early in life as possible after maternal immunity has waned

and before exposure to wild-type infections.[12,20–22] These studies have allowed exploration of the effects of various vaccination strategies on the age distribution of infection—in particular, how low or moderate levels of vaccine coverage among infants or young children will change the dynamic equilibrium, slowing down transmission, and thereby leading to an increase in the average age at infection among those who fail to be immunized by the vaccine. These effects are particularly important for infections whose seriousness increases with age, such as rubella and, to a lesser extent, mumps, chickenpox, or polio.[1,12,23,24] For any vaccination program that targets one age group (often young children) but may impact others (e.g., the elderly) the pattern of contact between groups will be critical. To help predict these effects, a number of studies of contact patterns have been performed, the largest and most influential to date being the POLYMOD study, which documented contact patterns across eight European countries.[25] This study found remarkable consistency across Europe in the patterns of age-dependent mixing, with contacts being typically assortative (like with like), particularly in children and young adults.

There are many other forms of heterogeneity in human populations—in particular, geographic and social groupings—all of which have subtleties and are likely to confound one another, because different social groups tend to have different age and spatial patterns. Social groups may be separate or may overlap (e.g., neighborhood and occupational or school groupings) in different ways in different societies, and they may be associated with environments or behaviors that either encourage or discourage the transmission of infection. Consideration of such heterogeneities in simulation models has demonstrated that it is generally more efficient to target high-risk versus low-risk groups with vaccines, in the sense that the number of cases of disease prevented is greater per single vaccination in a high-risk than in a low-risk population.[26,27] However, a real vaccination program might be unwise to emphasize such a strategy, because of issues of social equity, and also because evidence shows that, in the absence of eradication, susceptible people continue to accumulate in the less-served areas and population mobility continues to seed virus into such populations.[28–30] Table 77.3 summarizes the implications of these several heterogeneities for the simple herd immunity threshold values as shown in Table 77.2.

On a more practical level, the nonuniformity of populations is used commonly either to target vaccines at high-risk groups or to facilitate widespread vaccine coverage. Thus the selective use of varicella vaccine in nurses or family members reduces the likelihood of varicella transmission to immunosuppressed patients. The targeting of hepatitis B vaccine in prisons provides protection to a population at high risk through intravenous drug use. Several European countries now recommend bacille Calmette-Guérin (BCG) vaccine only to high-risk communities. And school-based programs have been widely used in many countries to access large numbers of children.

Heterogeneity in Immune Status

Thus far, our discussion has implicitly assumed that immunity is one face of a simple binary property—that individuals either are susceptible or they are immune and protected from both infection and disease. For most infections, the real world is not like this at all. We know that immune responses are highly complex, involving humoral and cellular pathways, as well as a variety of cell types and chemical mediators, and that these vary among infections, among individuals, and over time. The epidemiologic implications of this heterogeneity are important.

The conventional epidemiologic measure of immunity induced by vaccination is known as *vaccine efficacy*, defined as the percent reduction in incidence of disease among vaccinated persons as compared with nonvaccinated, equally exposed controls. It is now recognized that this basic measure of vaccine-derived immunity is itself ambiguous, insofar as 80% efficacy could mean either that 80% of vaccinees are totally protected, by some all-or-none mechanism of protection, or that the vaccine-derived immunity is only "partial," such that the level of susceptibility in all vaccinated individuals has been reduced by 80%.[31] This distinction has profound implications both for measurement of vaccine effects (e.g., whether it is more appropriate to use risks or person-time rates in calculations) and for our understanding of immunity (e.g., whether certain immune responses are fully protective or only partially so, perhaps more effective against low-dose than against high-dose challenge, or more protective against closely related compared with more distantly related antigenic types of the pathogen). The combined epidemiologic and immunologic implications of the distinction between all-or-none and partial protection are not yet well understood.

It is known that immunity can wane with time, and thus boosters are recommended for many vaccines. The rate at which this waning occurs differs between infections and

TABLE 77.3 Implications of Various Assumptions for Theoretical Estimates of the Herd Immunity Threshold

Variable and Assumption	Implications for Herd Immunity Threshold *(H)*	References
Maternal immunity	If vaccines are not effective until maternal immunity wanes, crude *H* estimates are too low. This can be corrected by considering that a child is not born until maternal immunity disappears.	13
Variation in age at vaccination	Herd immunity effect is greatest (*H* threshold lowest) when vaccination occurs at the earliest possible age. Delayed vaccination implies that threshold coverage level will be higher than simple estimates.	13, 51
Age differences in contact rates or infection risk	Implications vary with relationship between age and contact rate. Falling contact rates with age implies that true *H* may be lower than simple global estimate.	21, 22
Seasonal changes in contact rates	Seasonality may imply lower herd immunity threshold if seasonal change is marked, and fadeout can occur during low transmission period.	21, 250
Geographic heterogeneity	In theory, geographic differences in contact rates may permit elimination with lower overall vaccine coverage than that implied by *H* based on total population, by targeting high-risk groups.	30
Social structure (nonrandom mixing)	Social structure can have complicated implications because it implies group differences in vaccination uptake and infection risk. Existence of vaccine-neglecting high-contact groups means true *H* will be higher than simple estimates. This effect can be very large.	2 (and others)

vaccines, being relatively slow for measles, for example, and higher for pertussis. The term *boosting* is interesting in this context, as there is increasing recognition that immunity to several infections (e.g., varicella, pertussis) is enhanced through repeated natural exposure throughout life.[32] In the absence of natural boosting reexposures, the risk of reinfection or reactivation disease may increase with time, many years after the first encounter.

Beyond these quantitative differences in immunity, there are also important qualitative differences, dependent on whether, and to what level, any protection acts against infection, against reinfection, against severe or mild disease, or against infectiousness (transmissibility). For some infections (e.g., measles), vaccine-induced immunity may protect similarly against infection and against disease, whereas for others (e.g., polio, pertussis, diphtheria, rotavirus), the vaccine-induced protection appears stronger against disease. It also may reduce shedding of the agent by infected persons (e.g., polio, pertussis). We understand the biologic mechanisms for some of these differences—for example, live oral poliovirus vaccines induce local enteric immunity and hence are more effective against poliovirus infection than are killed, parenterally administered poliovirus vaccines. It is in theory possible to measure these different forms of protection epidemiologically, by collecting data on both infection and disease status of people, and by estimating vaccine efficacy conditional on the vaccination status of both the source and the recipient of potential transmission. Such data are sometimes available,[33] in particular in the context of household secondary attack rate studies, but their rarity means that most of our epidemiologic measures of immunity overlook these distinctions. This oversight does not mean that the distinctions are unimportant.

Implications of Heterogeneity in Immune Status for Vaccine Effects

Vaccines reduce disease by direct protection of vaccinees and by indirect protection of nonimmune persons. Indirect protection depends on a reduction in infection transmission, and hence on protection (immunity) against infection, not just against disease. If a vaccine were to protect only against disease, and not at all against infection, then it would have no influence on infection transmission in the community and there would be no indirect protection (vaccination of one person would have no influence on any others in the community). It would be possible to reduce disease with such a vaccine but not to eradicate the infection. This is an extreme scenario (although it has been discussed in the context of tetanus, diphtheria, pertussis, and inactivated poliovirus vaccines), but we can explore more plausible circumstances.

We first assume that vaccine-induced immunity is a simple all-or-none affair, such that a proportion (P) of vaccinees are fully protected against an infectious agent. If vaccine coverage is C, then a proportion $P \times C$ of the total population will be rendered fully immune. Under these circumstances, from Eq. 6, the coverage required to reach the herd immunity threshold (C_H), and thereby bring about a sustained reduction in incidence, will be as follows:

$$C_H = (R_0 - 1)/(R_0 \times P) \qquad \text{[Eq. 8]}$$

If, in contrast, a vaccine can protect to some degree against infection (a proportion P_i of vaccinees are rendered no longer susceptible to infection) and can also reduce transmissibility, that is, infectiousness (a proportion P_t among those vaccinated persons who do become infected do not shed, or shed fewer, organisms and hence cannot transmit infection), then, as shown by Longini and colleagues,[33] the coverage required to reach the herd immunity threshold (i.e., to reduce incidence) should be as follows:

$$C_H = (R_0 - 1)/(R_0[P_i + P_t - P_i \times P_t]) \qquad \text{[Eq. 9]}$$

This expression is a way of illustrating the importance of vaccine-mediated reductions in infectiousness, as well as in reducing susceptibility to infection. If protection induced by the vaccine against infection (P_i) and transmissibility (P_t) are both 100%, this equation reduces to Eq. 6, and the critical herd immunity coverage threshold is just $(R_0 - 1)/(R_0)$. However, if, for example, the vaccine induced only 60% protection against infection, and 40% protection against transmissibility among those who were infected, the critical coverage threshold to reduce infection incidence should be $(R_0 - 1)/(R_0 \times [0.6 + 0.4 - 0.24]) = (R_0 - 1)/(R_0 \times [0.76])$, thus about 4/3 times, or 33% higher, than the simple $(R_0 - 1)/(R_0)$ estimate. One should not expect precision in such estimates, but this result makes intuitive sense. The overall effect of a vaccine in reducing *disease* incidence in a community will combine these two mechanisms: protection against infection transmission, and direct protection of vaccinees against disease. These properties are important for understanding the effects of several vaccines in common use (e.g., polio, pertussis, diphtheria) and are likely to be even more important for several vaccines currently under development (e.g., malaria, hookworm, HIV).

THE REAL WORLD

We turn now to compare the observed impact of community vaccination programs with what was and is predicted by theory, and to highlight a variety of particular issues raised by individual vaccine-preventable diseases. Readers are referred elsewhere in this text for further details on the infections and vaccines used here as examples.

Smallpox

The initial WHO encouragement toward global eradication of smallpox came in a resolution passed by the 12th World Health Assembly in 1959, which stated that "eradication of smallpox from an endemic area can be accomplished by successfully vaccinating or revaccinating 80 percent of the population within a period of four to five years, as has been demonstrated in several countries."[34] The wording is of interest because of its explicit stipulation of a herd immunity threshold, and also because of its implication that waning vaccine-derived immunity might pose an obstacle to achieving the threshold (thus the call for revaccination).

The disappearance of smallpox from many populations, despite the continued presence of large numbers of unvaccinated susceptible persons, was evident from the historical record (as was noted by Farr more than 150 years ago).[7] This is consistent with relatively low estimates of basic reproduction numbers and hence relatively low herd immunity thresholds for the interruption of smallpox transmission (see Table 77.2).[35] The 1959 WHO recommendation implied an R_0 of 5. Although this is consistent with more recent estimates,[36] the 80% target was based originally on experience alone, having been made before the development of the theory described earlier. The validation of such estimates, however derived, remains difficult. The actual value must have varied among populations and been higher in crowded urban than in rural settings. Beyond that, the severity of smallpox, in particular of variola major, was such that outbreaks typically encouraged active intervention (different forms of quarantine, contact tracing, and ring vaccination), so it is not always clear to what extent the course of any particular epidemic was determined

by the general levels of immunity or by targeted emergency measures.

Arita and colleagues assembled data on crude population densities and smallpox vaccination coverage in African and Asian countries during the late 1960s and early 1970s.[37] Despite problems of nonuniform distributions of populations and of vaccinations, let alone the vagaries of the vaccination statistics themselves, these data indicate that smallpox disappeared early from countries in which the crude density of susceptible persons (unvaccinated individuals) fell below 10 persons/km^2 (corresponding to 80% immunity in populations with crude population density less than 50 persons/km^2). The infection persisted in more densely populated regions, however, especially in Nigeria (54 persons/km^2), Pakistan (83 persons/km^2), India (175 persons/km^2), and Bangladesh (502 persons/km^2). Whether continued reliance on routine populationwide vaccination programs might ultimately have been sufficient to eliminate smallpox from the more densely populated nations of Africa and Asia is now a moot point. If the threshold of 10 susceptible persons per square kilometer is a guide, then 98% vaccination coverage would have been necessary for Bangladesh—and such coverages were impracticable. However, it was recognized by 1970 that variola virus could be eliminated from populations more efficiently by a policy of active case detection, contact tracing, and the breaking of individual chains of transmission by quarantine and ring vaccination, than by relying on overall coverage from routine or mass vaccination programs.[38] In effect, the focus of prevention activity shifted from the population back to the individual, and the heterogeneity of the population was itself exploited to achieve eradication of the disease. The success of this policy is now a matter of record.[35]

Among the major lessons from the smallpox program was the inadequacy of relying on reported vaccine uptake statistics and herd immunity predictions in planning and managing an eradication program. Many experiences illustrated that reported data could be extremely unreliable, and high coverage statistics often obscured the fact that important segments of a population were inadequately vaccinated and could serve to maintain and transport the infection for long periods and distances.[35,38]

The disappearance of smallpox from many populations before the intensive campaigns of the final eradication program is consistent with the idea that indirect protection of unvaccinated susceptible persons contributed importantly to the overall decline of this disease. Beyond that, the persistence of the disease in densely populated third-world countries, despite apparent vaccination coverages far in excess of the WHO's recommended 80% herd immunity threshold, reflects the importance of population heterogeneities in vaccine coverage and in transmission risk. The smallpox experience thus demonstrates both the validity and the limitations of herd immunity in practice. It should also be appreciated that several features of the natural history of smallpox favored the shift in strategy toward targeted vaccination—in particular, the high case-to-infection ratio and characteristic pathology (which facilitated detection of cases), the long incubation period (7 to 19 days), and the relatively low transmissibility (which coincided with clinical lesions and hence facilitated control by identification of contacts and ring vaccination). Without these features, much greater emphasis would have had to be placed on raising the communitywide prevalence of immunity to achieve eradication of this disease.

By an unfortunate irony, questions of community immunity to smallpox remain topical, decades after its eradication. Routine smallpox vaccination was discontinued everywhere by 1980, and more than 80% of the world's population is probably now susceptible to the infection (although vaccinia-induced protection wanes with time, and boosters were recommended every 5 years, there is evidence that 90% of individuals vaccinated 25 to 75 years ago still retain some humoral or cellular immune responsiveness[39,40]). Although smallpox (variola) virus was supposed to have been preserved in only two high-security laboratories (in Atlanta, Georgia, and in Novosibirsk, Russia), the fate of virus produced in biological warfare laboratories (especially in Russia) is uncertain, and it is now possible to recreate the virus de novo.[41,42] Given the low level of immunity in contemporary populations, the release or escape of such virus could lead to rapid and widespread dispersal, with devastating consequences. Concern over such an event has led to much discussion, to the enactment of mock outbreaks to test control approaches, to the decision on the part of several governments to replenish national supplies of smallpox vaccine, and to contingency plans for emergency vaccine deployment.[43–45] These discussions raise many important issues concerning community protection, such as whether healthcare workers or workers in other essential services should be vaccinated routinely or voluntarily; to what extent the vaccine can be diluted without seriously compromising its efficacy; and the extent to which resources should be deployed in any emergency for mass vaccination as opposed to targeted case finding, contact tracing, and ring vaccination.[46–49]

Measles

No disease has been studied more intensely with reference to community immunity than has measles.[1,2,12,13,21,50–55] There are two reasons for this. One is that measles has long been a favorite subject for theoretical modeling, because of its frequency, its easy recognition in epidemic form, its predictable behavior, and the high quality of available data. The second is that there has been serious discussion ever since 1967 of the possibility of eliminating measles both nationally and internationally.[56–62] Many of these discussions have touched on estimates and interpretations of herd immunity thresholds.

Published estimates of herd immunity thresholds required to eradicate measles have ranged from 55% to 96%, depending on the modeling approach and the assumptions employed (e.g., whether age or seasonality of transmission was included; the 55% estimate was published before development of the theory described previously).[56] The logic and the flaws underlying various estimates have been discussed elsewhere.[1,13,21,63] Measles is among the most highly transmissible of all directly transmitted infections (see Table 77.2), and thus its crude herd immunity threshold is likely to be very high, at least in urban populations—on the order of 95%. Given that the efficacy of measles vaccine even under good conditions is approximately 95%, that vaccination coverage can never be 100%, and that poor coverage tends to cluster in particular communities, this means that a single-dose measles vaccination policy is unlikely to be sufficient to eliminate measles from any large population. Recognition of this fact has led to recommendations for two-dose measles vaccination policies in many countries, with the first dose administered at approximately 1 year of age (after maternal immunity has declined), and the second usually at school age, in an effort to immunize those children who escaped vaccination as infants or in whom the initial vaccination failed to induce protective immunity (primary vaccine failures).[64] In addition, many countries in recent years have employed campaigns to deliver measles vaccines to all children up to the age of 5 years, or 12 to 15 years, in an effort to protect those who had escaped natural infection or successful vaccination.[65] These efforts have been pursued longest in Latin America, and more recently in Africa, where catch-up (initial mass campaign up to age 15 years), keep-up (enhanced

routine vaccination at 12 to 15 months), and follow-up (repeated campaigns among those younger than age 5 years) vaccination policies have succeeded in reducing measles incidence to very low levels.[66]

The reduction or absence of endemic measles in highly vaccinated communities allows the gradual accumulation of susceptible individuals (those who escaped vaccination or in whom the vaccine failed). This may lead to delayed epidemics after several years of little or no measles, known as "post–honeymoon-period epidemics," which typically involve older age groups than were traditionally involved in measles. Dramatic examples of such delayed epidemics have been observed in several countries, including the United States in 1990 (see Fig. 77.4 C) and Brazil in 1997.[67] Routine serologic surveillance in the United Kingdom revealed a gradual accumulation of susceptible persons in the early 1990s, and led to the prediction of such a delayed epidemic. A nationwide campaign was implemented in 1994 to vaccinate all children 5 to 16 years of age to remove this threat.[68] Continued measles virus circulation in several European countries reflects low vaccination coverage in particular populations and associated accumulation of susceptible persons.

Among the remarkable observations about measles is that immunity induced by natural infection appears to remain strong for life: thus, Panum observed that individuals exposed to measles in 1781 in the Faroe Islands were still immune when the virus was next introduced, 65 years later, in 1846.[69] However, the immune response to measles vaccine is weaker than that to natural infection, and antibody levels decline among vaccinated people no longer exposed to frequent boosting reexposure.[70] Among the implications of this change is a decline in average levels of maternal antibody in infants, which means that infants born to mothers who never experienced wild measles infection become susceptible to infection—and can be vaccinated successfully—at an earlier age than was the case in the past.[71,72]

The American Region of the WHO set a target of regional measles elimination in 1994 and succeeded in arresting continued transmission in November 2002, since which time all measles has been attributable to importations (given that measles virus has now circulated for more than a year in Brazil, the Americas are now again considered endemic for measles). This has confirmed the theoretical feasibility of measles eradication through a combination of high routine two-dose coverage supplemented in some countries by campaigns, along with intensified surveillance and aggressive outbreak response. All WHO regions, have now set measles elimination targets, and there is discussion of setting a global measles eradication target.[62] This raises a variety of population immunity problems, including measures to combat increasing antivaccine sentiment (a particular issue in Europe),[73] and policies relating to vaccination in a posteradication era. Some of the arguments relating to smallpox will be raised again, with the complications that measles is far more transmissible than smallpox and that it would spread more rapidly in a population without very high levels of immunity.

Rubella

Although the basic transmission dynamics of rubella are similar to those of measles, it raises very different questions relating to community immunity. Public health concern with rubella is concentrated on congenital rubella syndrome (CRS) and thus on infections occurring in women in their reproductive years.[24] Control can in theory be brought about either by reducing the proportion of women who are susceptible or by reducing their risk of infection. Vaccination of adolescent girls, as practiced in the United Kingdom between 1971 and 1988, emphasized the reduction of susceptible women by ensuring that a maximum percentage of women and girls would acquire either natural or vaccine-derived immunity prior to their reproductive years. In contrast, vaccination of boys and girls in their second year of life, as practiced in the United States since 1969, in the United Kingdom since 1988, and in many other countries, also leads to reduction of circulating rubella virus and hence to the reduction of risk of infection for any remaining susceptible persons in the population. In theory, the latter policy carries a risk if coverage is not high, because low vaccination coverage of young children of both sexes can reduce the transmission of rubella virus to such a degree that the proportion of reproductive-age women still susceptible to the virus, and the numbers of consequent cases of CRS, actually increase. Indeed, even if coverage is high, but no catch-up campaign is performed, the cohorts of children who would ordinarily have been infected during childhood may pass into young adulthood before being infected.

Several investigations have concluded that, for the incidence of CRS to decrease in the long term, the minimal vaccination coverage that must be achieved and maintained in young children of both sexes is in the region of 50% to 80%.[24,50,74,75] The higher the initial intensity of transmission in the population, the higher is the threshold of vaccination coverage required among young children to avoid increasing the incidence of CRS. Given that vaccination uptake rates in the early 1970s in the United States and the United Kingdom were on the order of 90% and 50%, respectively, each nation's strategy was probably appropriate under the circumstances of the time. In contrast, it appears that the situation in Greece was unfortunate, and that low levels of childhood vaccination during the 1980s may have actually increased the incidence of congenital rubella.[76] Because of the possibility that low childhood vaccination coverage could result in an increase in CRS, several countries have implemented supplementary programs to reduce adult susceptibility (e.g., postpartum vaccination of identified susceptible women, and routine testing of women at the time of marriage) at the same time that they began childhood rubella vaccination programs. Clearly, there needs to be caution about the use of combined measles-rubella vaccines in countries that are unable to achieve high and sustained coverage, and it needs to be recognized that immunity levels may be affected by selective use of rubella vaccines in the private sector in some populations.

Demographic factors can also influence rubella and CRS epidemiology. Small island states pose a particular problem. If the population is of insufficient size to maintain endemic circulation of rubella virus, susceptible persons may accumulate in older age groups between periodic introductions, leading to high rates of CRS, when rubella virus is introduced.[77] A different demographic effect may be underway in China, where the one-child policy is likely to have reduced rubella spread, leading to an increase in the average age at infection and increased CRS risk.[78] Rubella vaccination has now been introduced in China.[79]

Rubella is less transmissible than measles, and thus a lower prevalence of immunity should be required for its elimination (see Table 77.2). Indeed, rubella may disappear as a consequence of measles elimination activities in those countries that use combined measles-rubella vaccines, with little additional effort. Thus a target was set in 2003 to eliminate rubella virus transmission in the Americas by 2010, as a concomitant of their measles elimination initiative, and this appears to have been achieved in February 2009.[80] Rubella elimination has been discussed in other global regions, in particular in Europe, but rubella-containing vaccines are still not widely used in Africa or Asia. There will be much discussion and concern over rubella immunity levels in years to come in

association with debates over global measles eradication and whether to include rubella in any such initiative, and the related issue of maintaining high immunity levels in populations from which it has been eliminated.

Mumps

Mumps is similar to measles (both are paramyxoviruses maintained by respiratory spread), but it is less transmissible in household settings and appears to have a lower crude R_0 and hence a lower crude herd immunity threshold, than either measles or rubella (see Table 77.2). On the other hand, there is evidence that vaccine-induced immunity to mumps may decline more rapidly than immunity to measles or rubella (see Chapter 39), which must be considered when inferring actual levels of immunity in populations. The disease resembles rubella in being more important in adults (in men because of orchitis) than in children, and hence there is the theoretical potential for low vaccine coverage to increase morbidity on a population scale by delaying infection to older ages. Although mumps vaccine is widely used in wealthier countries (combined with measles and rubella), it is not recommended in the basic Expanded Programme on Immunization schedule and thus mumps has not been influenced by vaccine in much of the world. Mumps notifications fell by more than 95% after introduction of the vaccine in the United States (it was licensed in 1967 and recommended universally for children in 1977), which is appreciably greater than the product of coverage and efficacy[64,81,82] and hence a clear indication of indirect protection.

The United Kingdom experienced a major post-honeymoon epidemic of mumps in 2004 to 2006 (more than 40,000 cases reported in 2005), concentrated among young adults,[83] reflecting the accumulation of susceptible persons in cohorts born too early to have received mumps vaccine (first dose introduced in 1988, and second dose [at school entry] introduced in 1996) and too late to have been exposed as children to extensive circulation of wild virus. A similar epidemic occurred in the United States in 1987 to 1994, 10 to 15 years after mumps vaccine was introduced nationally in 1977, and another in 2006. Each of these events illustrates the dynamic effect of vaccination leading to reduced incidence risk, to accumulation of susceptible persons, and to delayed epidemics in older age groups.

Because mumps vaccine is often given in combination with measles and rubella, there may be discussion of the possible implications of inclusion of mumps vaccines in association with any global effort to eradicate measles. This has received little attention to date.

Chickenpox (Herpes Varicella-Zoster Virus)

Herpes varicella-zoster virus is common in all human populations. Primary infection usually occurs in childhood and is manifested clinically as chickenpox. In common with many herpesviruses, varicella-zoster virus establishes a persistent "latent" infection, typically in the dorsal root ganglia, from which site it may recrudesce many years later to cause herpes zoster (shingles). Chickenpox is more severe in infants and adults than in children, and was responsible for some 11,000 hospitalizations and 100 deaths in the United States annually before the introduction of vaccination.[84] Because of this, varicella vaccine (a live attenuated virus) was introduced into the routine childhood immunization schedule in the United States in 1995, and its introduction is under consideration by several other countries. Surveillance data show a major decline in chickenpox incidence in the United States as a consequence of this program, including evidence for indirect protection among infants and adults, outside the vaccinated target age groups.[84,85]

Unlike immunity to variola, measles, rubella, and mumps viruses, immunity to varicella-zoster is not sterile following vaccination or natural infection, but it serves to suppress or to contain the persistent latent infection. Although it may provide some degree of protection against reinfection (or, better, superinfection), there is evidence that this protection wanes with time and that superinfections can occur.[86] This waning of naturally acquired protection is associated with increased risk of clinical episodes of herpes zoster. There is conflicting evidence over the extent to which exposure to children with varicella boosts immunity and reduces the risk of zoster in adults (see Chapter 61).[87,88] This has important implications.

Several authors have warned that reduction in the circulation of varicella virus, as a consequence of widespread vaccination of children, could lead to an increase in the incidence of herpes zoster.[89–91] This implies a perverse result—vaccination of one segment of a population (children) leading to reduced transmission and hence to reduced boosting of immunity, and ultimately to increased incidence of disease in another segment of society (adults). Although evidence for such an increase in zoster in the United States is inconsistent,[92,93] interest has turned to the possible need to vaccinate adults to artificially boost their immunity and prevent zoster in the absence of natural boosting. A trial has confirmed the efficacy of a zoster vaccine in adults older than 60 years of age (60% reduction in burden of illness).[94] This vaccine is now recommended for universal use starting at age 60 years in the United States[95] and for those 70 to 79 years of age in the United Kingdom.[96] A large-scale trial of a second-generation adjuvanted subunit herpes zoster vaccine demonstrated very high levels of protection, even in older age groups.[97]

The ecology of varicella-zoster virus and its related immunity (different levels of protection against infection and transmissibility in the presence or absence of boosting exposures) is complicated. Although the age distribution of chickenpox would suggest an R_0 of 8 to 10 in developed countries, this number should not be interpreted as implying an 85% to 90% herd immunity threshold for eradication, given that immunity is not sterile and zoster cases are infectious. It is now recognized that the immunity associated with varicella vaccine is not high, and that it wanes with time,[98] leading to a recommendation for two-dose schedules. Beyond this, the long-term risk of zoster associated with vaccine strains is still not clear. The situation will need close monitoring in the coming years to ensure an overall public health benefit from this intervention.[90] As a consequence of this uncertainty, several countries (e.g., the United Kingdom) still prefer to use varicella-zoster vaccine selectively—for example, in high-risk patients and healthcare workers, as well as the elderly[99]—although these policies may change if the U.S. policy proves successful and cost-effective in the long term.

Pertussis

Responsible for considerable morbidity and mortality in unvaccinated populations in the past, pertussis has been a target for routine vaccination programs in all countries for several decades. These programs have been successful in reducing greatly the burden of disease caused by pertussis, and there is good evidence of indirect protection, in terms of reduced disease risks among unvaccinated as well as vaccinated individuals.[100,101] The vaccines, schedules, and patterns of immunity have changed importantly in recent years.

The cyclical pattern of pertussis epidemics provides a classic example of mass action dynamics (compare Figs. 77.3, 77.4B,

and 77.4D).[102,103] Published estimates of the crude basic reproduction number for *Bordetella pertussis* range from 5 to 17 for developed countries in recent decades (see Table 77.2).[104] The higher values are similar to measles and imply a crude herd immunity threshold in excess of 90%, which is higher than most estimates of the protective efficacy of a complete course of any pertussis vaccine,[105,106] let alone that there is evidence of waning vaccine-derived protection[105,107] and of reinfections in adults.[108] Eradication of this infection is thus not possible by childhood vaccination alone.[109]

Immunity to pertussis is difficult to define, either in individuals or in populations. There is no good serologic correlate for protective immunity; and there are controversies over the effectiveness of available pertussis vaccines and the extent to which they protect better against disease than against infection.[105,106,110–112] Many industrialized countries have introduced acellular vaccines because of safety concerns with the older whole-cell vaccines, and several of these countries (e.g., United States, United Kingdom, Australia) subsequently experienced major resurgences of pertussis, apparently linked to more rapid waning of protection postacellular than post–whole-cell vacines.[102,105,108,113] Increased awareness of pertussis infections and reinfections in older individuals, and the recognition that protection induced by acellular vaccines is weaker and shorter lived than protection by whole-cell vaccines has led some countries to recommend routine (acellular) pertussis boosters for adolescents[114] and pregnant women.[115] Routine (acellular) pertussis boosters for pregnant women provides passive protection to young infants, in whom the disease is most severe.[115–120] This has been extended to selective vaccination of parents and others in contact with young infants, a strategy known as *cocooning*, yet another approach to manipulating the community distribution of immunity.[115,121,122]

Pertussis is thus another example of an infection for which the immunity profile in many populations has changed greatly in recent decades, from a predominance of immunity attributable only to natural infection and boosted by frequent reexposure (now restricted to older persons), to immunity attributable largely to killed whole-cell vaccines, which waned as natural reexposure became less frequent (in a high proportion of individuals born since 1950); and now, in wealthy countries, to immunity attributable largely to various acellular vaccines (in younger individuals). Each of these forms of immunity is likely to have different implications for protection against infection, disease, and infectiousness. The long-term implications of these changes are as yet unclear.

Diphtheria

Diphtheria was a major cause of morbidity and mortality in Europe and North America during the 19th century. Incidence fell from the early years of the 20th century, and the decline accelerated with introduction of widespread toxoid vaccination in the United States, the United Kingdom, and other countries during the 1940s. Because vaccination of less than 90% of children was associated with a more than 99.99% fall in disease, it might be argued that a herd immunity threshold was achieved. But a closer look reveals a complicated story of community protection.

Published estimates of a crude herd immunity threshold for diphtheria have ranged from 50% to 90%.[1] Estimates aside, the proportion of the population actually immune to diphtheria today is elusive. Vaccine coverage is difficult to define because it has varied over time, and because at least three doses are recommended, although one or two provide some protection. The protection against disease imparted by diphtheria toxoid vaccines has never been evaluated in formal trials, although observational studies provide estimates ranging from 55% to 90%.[123–125] Serologic studies show that vaccine-induced antitoxin titers decline with time, and that titers in some populations may be lower among persons born in recent decades, perhaps because they have not been boosted by exposure to natural infections.[126] Surveys done in industrialized countries have shown a wide range in prevalence of protective antitoxin levels among adults, from 29% to 80%, leading to recommendations that adults should receive booster doses of diphtheria vaccine.[126–129]

An important question concerning community protection against diphtheria relates to the nature of the immunity induced by toxoid vaccines, and how it may differ from infection-attributable immunity. In the sense that herd immunity implies indirect protection, it requires immunity against infection or against transmission. Given that diphtheria toxin is not a constituent of *Corynebacterium diphtheriae* per se, but exists as a consequence of bacteriophage infection, the immunity induced by toxoid vaccination may not provide protection against infection at all.[130] However, toxoid vaccines do protect against toxin-mediated disease, and transmission of the diphtheria bacillus is more efficient from clinical patients than from subclinical carriers[131]—thus the toxoid vaccines may protect against infectiousness and infection transmission, but not (or more than) against infection receipt ($P_t \gg P_i$, according to the logic of Eq. 9). This may have been an important contributor to the disappearance of diphtheria in vaccinated populations.

Skin and respiratory tract infections with nontoxigenic corynebacteria are common in many populations, in particular in the tropics, and these probably impart some cross-protection against infection with toxigenic *C. diphtheriae*.[132] Because this protection is independent of antitoxin, the emphasis on antitoxin antibodies in surveys of immunity to diphtheria may miss an important element in a community's protection against this disease.

Haemophilus influenzae Type B

Haemophilus influenzae type b (Hib) is a major cause of invasive bacterial disease in young children, with disease occurring at a median age of 18 months in northern Europe and Australia, before vaccine introduction, but as low as 6 months in developing countries with a high incidence of disease. Neonatal disease is extremely rare, but by 2 months children start to become susceptible. Although disease can occur at any age, in most of the world 85% to 90% of disease is in children younger than age 2 years. The absence of disease in the neonatal period is a result of maternal antibody, passed to the infant either transplacentally or via breast milk. As infant antibody levels fall, susceptibility rises, only to fall after 2 to 3 years as naturally acquired antibody levels rise associated with natural exposure. The source of these exposures is not entirely clear. Nasal carriage of Hib occurs in 4% to 12% of young children in unvaccinated communities and is the major source for transmission. Carriage also appears to provide immunity against disease. Interestingly, antibodies to *Escherichia coli* can be cross-reactive against Hib infection, although it is unknown whether these have any role in immunity to human infections.[133] What is clear is that immunity to Hib is conferred by antibodies to the polysaccharide capsule, which are specific for serotype b.

Polysaccharide-protein conjugate vaccines are immunogenic in early infancy, providing high protection (>90%) against invasive disease and some protection against carriage. The latter effect has been sufficient to reduce transmission and to provide appreciable indirect protection to nonvaccinated groups. This has been described in children too young to be vaccinated in Israel[134] and The Gambia,[135] and in those too

old to be vaccinated in Scandinavia.[136] This was responsible for substantial indirect effects demonstrated in the United States when the conjugate vaccine was introduced for children at 15 months of age, and in the United Kingdom where the vaccine was introduced in 1992 in infancy. In both settings, Hib disease fell to extremely low levels in all age groups. The United Kingdom was the only industrialized country to introduce Hib vaccine without a booster dose, having started with a catch-up campaign covering children younger than 5 years of age. After initially disappearing, Hib incidence increased in all age groups after 7 years. This indicates that, in the absence of the boosting effect of carriage, or a booster dose of vaccine, community immunity wanes.[137] Interestingly, while the United Kingdom was the only industrialized country to introduce Hib vaccine without a booster dose, the WHO has recommended that the vaccine be given without a booster dose. The Gambia, which was the first African country to introduce Hib vaccine in 1997 (in a three-dose schedule without a booster) recently reported a transient increase in cases, suggesting that, for this vaccine, a later booster might be required in similar settings.[138]

Streptococcus pneumoniae (Pneumococcus)

The pneumococcus is one of the most important pathogens of humans, causing more deaths in children than any other organism and probably a similar number of deaths in adults. Pneumococcal vaccines have been available for many years, but the poor immunogenicity of polysaccharide vaccines in infants, the importance and prevalence of noninvasive carriage in maintaining these organisms in populations, and the multiplicity of circulating serotypes raise special problems of community immunity.

There are nearly 100 immunologically distinct pneumococcal serotypes that cause disease in humans, but most are rare. Up to 23 serotypes have been included in polysaccharide vaccines, covering most disease-causing strains in adults, and the 13 serotypes incorporated in the largest conjugate vaccine currently available include most strains causing carriage or disease in young children. Pathogenicity varies with serotype, and different serotypes are more or less likely to affect different age groups, although all can cause disease in all age groups. To further complicate issues, the duration of carriage and the ability of a carriage episode to immunize an individual is also variable and dependent on age and serotype.[139]

The introduction of a seven-valent pneumococcal conjugate vaccine in the United States in 2000 had a dramatic impact. Although the substantial fall in infant invasive pneumococcal disease rates was as expected, it was associated with significant falls in pneumococcal disease among adults, more than doubling the overall benefits to the community.[140] The greater-than-expected protection accorded to U.S. adults by infant pneumococcal vaccination revealed the extent to which this infection was naturally transmitted from children to adults in this population. By 2007, rates of invasive pneumococcal disease caused by serotypes in the vaccine had fallen by 94% in all age groups.[141] A metaanalysis of 19 surveillance systems in industrialized countries confirmed the generalizability of this effect, with a mean reduction of vaccine-serotype invasive pneumococcal disease among adults of 75% to 83% 5 years after introduction of seven-valent vaccine. The benefit is enhanced by the fact that the vaccine includes, and has greatly reduced the appearance of, the five serotypes most associated with antibiotic resistance.[140,142]

Despite these powerful effects, wherever carriage has been studied, vaccination has not had a lasting effect on pneumococcal carriage prevalence overall, but has led to a reduction in the carriage of vaccine serotypes, with a compensatory rise in carriage of nonvaccine serotypes.[142,143] To a variable extent, there has also been an increase in disease associated with the replacement nonvaccine serotypes, and this has reduced the initial impact of the disease reduction by the vaccine in both children and adults.[142,144,145] The herd protection observed in adults in the general population indicates that either the replacement nonvaccine serotypes are less likely to cause disease in adults, or there are qualitative differences in carriage in vaccinated children, rendering them less likely to transmit the organism. Whatever the explanation, the net balance is beneficial in the majority of settings, despite variation in the magnitude of serotype replacement disease.[146] In the United Kingdom, after only 3 years of use of the seven-valent vaccine, serotype replacement forced authorities to move to a 13-valency preparation. The indirect effect of the 13-valent vaccine against disease in adults caused by the residual six serotypes has subsequently mirrored that of the seven-valent vaccine against the original seven serotypes.[147] The indirect effects of vaccine are so powerful that it is arguable they are sufficient for population control of disease, even among children. This, in turn, raises the question whether community immunity could be sustained, in a mature vaccine program, by a childhood schedule with fewer doses of vaccine, optimizing effectiveness against carriage.[148]

How all these effects will play out in low-income countries is unclear, but introduction of a 10-valent vaccine incorporating a catch-up campaign for children younger than 5 years of age in Kenya, was followed within 6 months by a sustained two-thirds reduction in carriage prevalence of vaccine serotypes among children younger than 5 years of age and among older children and adults.[149] Given the variety of epidemiological settings, patterns of circulating serotypes and comorbidities, especially HIV, it is difficult to predict whether indirect effects will enhance the direct effect of the vaccine (by generating community protection) or reduce it (as a consequence of serotype replacement).

Meningococcal Disease *(Neisseria meningitidis)*

Meningococcal disease is important everywhere, with different epidemiological patterns associated with different serotypes in different parts of the world. The introduction of conjugate meningococcal vaccines in recent years has provided some of the most spectacular evidence of the importance of community protection.

In the late 1990s, several high-income countries observed an increase in meningococcus type C (Men C) disease, with highest incidence in infants and teenagers. The United Kingdom's strategy (implemented in 1999–2000) was to introduce the newly licensed Men C conjugate vaccine into the infant schedule at 2, 3, and 4 months of age, with a single-dose catch-up campaign for those 1 to 18 years of age. This rapidly reduced the incidence of Men C disease across all age groups,[150,151] as well as nasopharyngeal carriage (which was only measured in teenagers[152]). Continuing surveillance demonstrated the long-term impact of the program.[150] This was all the more remarkable, given that the three-dose infant program seemed to offer only short-term protection (up to approximately 1 year).[151] The sustained reduction in incidence in the routinely vaccinated cohorts appeared to derive from the longer-term protection afforded by the one-dose campaign in the older cohorts, which presumably provided continued reduction in carriage.[153] In an attempt to maintain this community protection, the United Kingdom subsequently made two changes to its schedule: in each case, doses in infancy were dropped and replaced by doses later in life, initially in the second year of life but now also in teenagers. When The Netherlands introduced the Men C conjugate vaccine in 2002, it

also introduced a campaign for 1- to 18-year-olds, but did not vaccinate infants. Instead, the routine aspect of the program, which was put in place at the same time, consisted of a single dose at 14 months of age. High-quality surveillance over the first decade of the program confirmed the effectiveness of this strategy; with a 99% reduction in incidence in age groups eligible for vaccination and a 93% reduction in those that were not.[154]

Meningococcus serogroup A (Men A) has been the major cause of repeated, devastating meningococcal epidemics in the Sahel region of Africa (sometimes referred to as the "meningitis belt"), despite the widespread use of polysaccharide vaccines.[6] The situation has been altered dramatically by development and introduction of a conjugate Men A vaccine for Africa (MenAfriVac).[155] This vaccine has been rapidly rolled out across the meningitis belt in very large-scale campaigns that have led to the near elimination of Men A disease[156,157] and carriage.[158] The reduction in carriage has provided important indirect (or community) protection. For instance, in Burkina Faso, which was the first country to initiate a nationwide program, individuals 1 to 29 years of age were targeted for vaccination in 2010. In 2011 there was a 62% decline in the incidence of meningococcal meningitis (of any serogroup) in the targeted age groups, and a 55% reduction in those too old or young to be vaccinated.[156] In fact, in the year after the campaign only one case of Men A disease was identified from Burkina Faso—a 99.8% decline from the previous year.[156]

Tetanus

Clostridium tetani is not communicable between human hosts, and thus vaccination cannot lead to indirect protection in the sense implied in many definitions of herd immunity. Certainly, there is no threshold proportion of immune persons, below 100%, that can ensure total absence of tetanus from a community.

There is little doubt that the introduction of routine tetanus toxoid vaccination in the 1940s had an impact on trends and patterns of the disease. However, because the incidence of tetanus was declining prior to widespread vaccination, as a result of decreasing exposure (fewer people in contact with soil and animal feces, which are the main reservoirs of the tetanus bacillus), and because of the widespread use of tetanus toxoid in wound management, it is difficult to assess the extent to which routine prophylactic vaccination contributed to the decline in tetanus morbidity.

Despite the noncommunicability of *C. tetani* between people, there is a special sense in which vaccination does impart indirect protection. Antitetanus immunity of mothers is transmitted across the placenta, and two doses of toxoid during pregnancy can protect a woman's offspring against neonatal disease.[159] This is extremely important in that a major contributor to the public health importance of tetanus on a global scale is neonatal disease. In 1989, the World Health Assembly declared an initiative to "eliminate" neonatal tetanus (defined as less than one case of neonatal tetanus for every 1000 live births in each administrative district throughout the world). Although the initiative includes efforts to improve birth practices, it relies largely on provision of tetanus toxoid to girls and women in antenatal clinics. In this sense, the critical population for community immunity to tetanus consists of girls and women in their reproductive years. In developing countries with strong vaccination programs, the necessity for full tetanus toxoid vaccination during pregnancy should decline as more and more young women have received the vaccine in infancy. In this instance, the monitoring of community immunity may enable the winding back of an adult vaccination program in years to come.

Poliomyelitis

The issue of community protection against polioviruses is of particular importance today, because of the global polio eradication program. The subject is enriched by more than 5 decades of debate relating to different types of immunity induction by different types of polio vaccines.[160,161] Serologic surveys done long ago have been used to estimate the prevalence of immune persons in unvaccinated communities, suggesting that the basic reproduction number of wild-type polioviruses ranges from 2 to 20, implying crude herd immunity thresholds ranging from 50% to 95%, these numbers being inversely related to the level of hygiene.[161] Nevertheless, even this is far too simplistic.

The polio immunity discussion has focused upon the relative advantages of inactivated poliovirus vaccine (IPV) versus live oral poliovirus vaccine (OPV). Among the arguments favoring the live vaccines (in addition to low cost and ease of administration) has been the claim that they provide greater "herd immunity" than do IPVs, for two reasons. The first is that live vaccines impart greater intestinal (local, mucosal, immunoglobulin A–mediated) immunity, and hence impart greater protection against infection, than do the killed vaccines (which induce an immunoglobulin G response which is effective against tissue invasion and disease). The second is that OPV viruses are transmissible to contacts of vaccinees, and hence, in theory, one can immunize more people than are directly vaccinated.[162] This is a special property of the oral polio vaccines and may be responsible for substantial levels of indirectly acquired immunity in populations.[162] Both of these arguments are complicated by the fact that the effectiveness of OPV varies between different settings, being appreciably lower in tropical low-hygiene populations than in temperate high-hygiene populations, partly as a result of interference in the gut by various other enteric agents.[163] Furthermore, most of the traditional measures of vaccine effectiveness relate to protection against disease, whereas it is protection against infection, and against transmission, which are absolutely crucial for the eradication program, and it is known that seropositivity does not equate to solid protection against enteric infection. The importance of this distinction was exemplified in Israel in 2013–14, where environmental surveillance revealed extensive circulation of type 1 wild virus over more than a year, without a single clinical case.[164] This observation is in part a reflection of the low case-to-infection ratio of polioviruses, and the intensity of environmental surveillance in that country, but also, and importantly, by the fact that Israel had shifted from routine OPV to routine IPV in 2005, thus shifting its immunity profile from emphasis upon protection against infection toward protection against disease.[164]

Whereas OPV has been favored by the global program, it has two disadvantages. First, it causes paralytic polio in a small proportion of recipients and their contacts.[165] Because of this risk, most wealthy countries have shifted from OPV to IPV vaccines over the past 15 years, thus changing their population immunity profiles. Second, the transmissibility of OPV viruses is such that they can circulate by continued human to human transmission and revert to wild-type transmissibility and virulence. Such viruses, known as circulating vaccine-derived polio viruses have been responsible for outbreaks of clinical polio in more than 20 countries since their first recognition in 1999, typically in populations with poor hygiene and relatively low coverage of OPV, thus with relatively large numbers of individuals susceptible to infection.[166–168] The ultimate success of the global polio eradication initiative requires that transmission of these viruses, as well as the wild viruses, be stopped.

The eradication program is currently attempting to manipulate population levels of immunity to polioviruses on an

unprecedented scale. Given the complexities of low seroconversion post-OPV in tropical countries, and the fact that mucosal immunity is insufficient to completely stop infection with polioviruses, the strategy has been to keep vaccinating until wild virus is no longer found. This has entailed repeated massive OPV campaigns (up to 10 times per year, for children younger than 5 years of age, in northern India), producing the most heavily vaccinated populations in history.[169] At time of writing, this strategy has proven successful in terms of reducing wild virus cases to lowest ever numbers (only 37 cases in 2016). The global program is thus entering the "endgame."[170–172]

Because type 2 wild virus had not been seen for more than 15 years, type 2 OPV was withdrawn, globally, in April 2016, by substituting bivalent 1–3 OPV for trivalent OPV.[172] The main concern with this shift has been the need to ensure than type 2 vaccine-derived viruses do not continue to circulate, as they are known to cause vaccine-associated paralysis in rare circumstances and to revert toward wild-type transmissibility and virulence.[166–168] Thus all countries were requested to introduce at least one dose of (trivalent) IPV into their routine schedule by the end of 2015, in addition to continuing (bivalent) OPV.[172] IPV vaccines alone were sufficient to stop transmission of wild polioviruses in The Netherlands, Sweden, and Finland, but these countries have high levels of sanitation (and low herd immunity thresholds).[173,174] There is evidence that IPV can boost intestinal immunity in individuals with history of prior OPV[175]; but whether the introduction of IPV will be sufficient to raise community immunity levels high enough both qualitatively (i.e., in terms of mucosal immunity) and quantitatively (in terms of proportions of individuals) to stop circulation of type 2 vaccine-derived viruses in developing countries with poor hygiene standards and high herd immunity thresholds remains to be seen.

Rotavirus

Rotavirus is the commonest cause of severe diarrhea in infants and young children worldwide, estimated to cause 453,000 deaths in children younger than 5 years of age in 2008, 90% of these in low-income countries.[176] In the United States, before vaccine introduction, it principally affected children from 6 months to 4 years of age, and followed a marked seasonal pattern migrating from a winter peak in the Southwest to a spring peak in the Northeast, probably owing to differential birth rates and more rapid accumulation of susceptibles in the Southwest.[177]

Two oral live attenuated vaccines are in widespread use, one containing five strains given in three doses (RotaTeq), the other a monovalent vaccine given in two doses (Rotarix), from 6 weeks of age. The vaccines were efficacious against all episodes (74%) and severe episodes (85% to 100%) of rotavirus gastroenteritis in trials in United States, Finland, and Latin America.[178,179] After RotaTeq was introduced into the childhood immunization program in the United States in 2006, the seasonal rotavirus epidemic was delayed, shortened, and diminished in size,[180] and the rate of rotavirus-coded hospitalizations in children fell by 89%.[181] The average age at infection increased and the decline in the rate of rotavirus hospitalizations in infants and young children substantially exceeded the estimated vaccine coverage[182]; both features suggest that vaccination of infants had reduced virus transmission in the population. Although rotavirus vaccine was not given to older children, because of anxieties regarding the risk of intussusception, impact studies have demonstrated a reduction in the incidence of all-cause and rotavirus gastroenteritis hospitalizations among children too old to be vaccinated, and in adults, in the United States and other high-income countries following introduction.[183–185]

Rotavirus vaccine may induce herd protection by reducing infection among the infant population, who are at the center of transmission networks in the community, or by disseminating vaccine-type virus in stool leading to immunizing exposure among unvaccinated populations. To date there is no evidence of disease caused by vaccine strains. Dynamic models exploring indirect protection predicted an alternating pattern of yearly peaks among partially vaccinated populations, and this has subsequently been observed.[186] This emphasizes the need to evaluate impact over a longer time frame as, disconcertingly, disease rates may be higher in the second season after vaccine introduction than the first.[182]

Circumstances in low-income countries are different. Efficacy of the oral vaccines was estimated to be 39% to 56% in randomized controlled trials in several countries in Africa and South Asia.[187–190] The lower efficacy in these settings may be a consequence of higher titers of transplacental or breastmilk antibodies in infants, micronutrient deficiencies, interfering gut flora, intercurrent infections, or varying pathogenic strains. Rotavirus vaccine has now been introduced in several low-income countries. Although early evidence from Mexico is promising,[191] given their lower efficacy against disease (and presumably transmission) and the higher force of infection, it remains an open question whether current rotavirus vaccines will have an appreciable herd protection effect in low-income countries.

Influenza

Type A influenza viruses present yet another set of problems relating to immunity in the community. Given the genetic lability of these viruses, as manifested in periodic major (shift) and more frequent minor (drift) antigenic changes of their hemagglutinin and neuraminidase antigens, and their persistence in many different vertebrate species, there is no prospect of their total eradication. The large majority of humans have been infected by several antigenically different influenza viruses and thus have antibodies to a variety of hemagglutinin and neuraminidase epitopes; and the concept of herd immunity has been invoked as an explanation for the changing profile of influenza viruses in human populations and the successive disappearance of particular antigenic subtypes. The argument is that increasing proportions of the population immune to each individual influenza subtype, and varying degrees of cross-protection provided between subtypes, provide selective pressure favoring the spread of new antigenic variants. Although such a mechanism appears to fit the available evidence, it does not lend itself to precise numeric description and prediction because of the complicated immunologic relationships between virus subtypes, and the unpredictable nature of the antigenic changes of these viruses.

Influenza control by immunization is an important public health activity in all the wealthier countries. Much concern focuses on the threat of a global pandemic, attributable to some new shift strain of virus, but even without such an event, there is need for continuous control because of the changing antigenic nature of the viruses and their rapid spread, explosive epidemics, and serious impact in terms of hospitalization of infants, sickness absences among the employed adults, and mortality among the elderly.[192] Although the favored strategy of most countries has been to target high-risk groups, an alternative is to reduce community spread by concentrating on vaccination of schoolchildren, because transmission in crowded classrooms leads to rapid dispersal throughout the community and into the homes where susceptible adults reside. The effectiveness of this approach in providing a measurable degree of indirect protection to nonvaccinees in the community has been demonstrated under trial conditions in

Michigan,[193] Russia,[194] Texas,[195] and Canada.[196] Partly as a result of such evidence, different countries have recommended very different strategies. The United States recommends annual vaccination to all ages older than 6 months, but fails to achieve high coverage.[197] Ontario shifted to influenza vaccine to all ages in 2000, achieving marginally higher coverage than in the United States, a policy that has been supported by cost utility analysis of data through 2004.[198] In contrast, the United Kingdom now recommends annual vaccination to schoolchildren 2 to 16 years of age and the elderly and risk groups, based on a detailed evidence synthesis and modeling analysis.[199] Even more extreme, Japan for several years had a policy of vaccinating only schoolchildren. The Japanese strategy was unique in explicitly directing vaccination at one segment of the population (schoolchildren) to protect another (the elderly). Though this was national policy from 1962 and enforced by law between 1977 and 1987, the policy was discontinued in 1994 because of skepticism as to its effectiveness and public concern over adverse reactions to the vaccines.[200,201] The success of these different policies depends on several important parameters including demographic structure, contact rates between the various groups, coverage achieved and vaccine cost, as well as upon actual vaccine effectiveness and the indirect effects actually achieved.

Memories of the great Spanish influenza pandemic of 1917–20 continue to haunt the public health community. Concerns have been heightened over the past decade, first by the appearance of a highly pathogenic avian H5N1 strain carried by migrating birds and then the appearance of a new H1N1 swine virus which met the WHO's criterion of pandemic spread on June 11, 2009.[202] Rapid spread of influenza viruses is possible despite relatively low R_0 (on the order of 2) because of their short serial interval (3 or 4 days)—thus, three or four generations of influenza virus spread may occur in the same time as a single generation of measles. This rapidity of spread has important implications for the feasibility of developing, testing, producing, and administering vaccines at the scale required to control a new influenza strain. On the other hand, the low R_0 means that, in theory, the herd immunity threshold should be relatively low for influenza viruses (see Table 77.2).[18,19,203–205] Pandemic contingency planning in many countries includes a role for vaccines (e.g., targeted to essential service personnel or to schools) in an effort to reduce spread in the community, in addition to the use of antivirals and measures to reduce contact.[204,206] Longer-term strategic thinking includes recommendations for repeated (annual) routine vaccination of large segments of populations, perhaps with multivalent live attenuated vaccines, which may provide broader protection against influenza viruses than do inactivated vaccines.[195,207] The extent to which this would be beneficial in building up broad immunity against influenza virus antigens is unclear, but it would enhance influenza vaccine production and delivery infrastructure, which would be useful in implementing a vaccine response to a pandemic, if and when the need arises.[205]

Human Papillomaviruses

Humans are host to more than 100 different human papillomavirus (HPV) types, spread by different means and affecting different tissues. Most important for public health are several types spread predominantly by sexual contact, including high-risk oncogenic types 16 and 18, which are responsible for approximately 70% of cervical cancer (the second most common cancer of women worldwide), as well as many cancers of the anus, penis, and oral cavity, and types 6 and 11 that are associated with anogenital warts. Three vaccines are available: a bivalent vaccine that has been developed against types 16 and 18, a quadrivalent vaccine that also protects against types 6 and 11, and a nine-valent vaccine that also includes the rarer cancer-causing types 31, 33, 45, 52, and 58. Clinical trials and postimplementation surveillance studies show that the two- and four-valent vaccines offer good protection against persistent infection and precancerous stages,[208,209] although because of the long lag between infection and cancer there is no direct evidence of effectiveness against end-stage cancers. Both vaccines also appear to offer a degree of cross-protection against other high-risk types, such as types 31, 33, and 45,[209] and postvaccination surveillance from England even suggests that the bivalent vaccine may offer some protection against anogenital warts.[210] Many countries now recommend the routine use of these vaccines among (typically preadolescent) females. Some industrialized countries have also included catch-up programs up to 25 years of age as part of the introduction.

Two of the remaining controversies regarding these vaccines are whether they should be offered to boys, and whether the program should be extended to older women. Both of these issues hinge on indirect, or community protection. If an organism depends entirely on heterosexual contact, it can in theory be eliminated from a population by preventing infection of, or transmission by, a sufficient proportion of individuals of only one sex (e.g., females in the case of HPV 16/18 or 6/11). Thus, heterosexual men might be expected to benefit from vaccination of women, and older women might also benefit as the level of infection in their sexual network declines. There is growing evidence that this does, indeed, occur. Australia was one of the first countries to adopt HPV vaccination, introducing the quadrivalent vaccine for adolescent girls in 2007, with a catch-up (at lower coverage) for women up to 25 years of age. An analysis of national surveillance data found large (92%) declines in genital warts in women younger than 21 years of age, but also similar levels of declines in heterosexual males in the same age range (82%), even though they were not vaccinated.[211] Large declines in warts incidence were also observed in 21- to 30-year-old women and men. A recent systematic review and metaanalysis has lent weight to these findings.[209] The Australian study also made one further, important observation—no effect was seen in men who have sex with men—which led to the introduction of HPV vaccination of boys in Australia starting in 2013. Indeed, one of the arguments put forward for vaccinating all boys (as well as girls) is that it is not easy to target young men who have sex with men before they become exposed to the virus.

Policy decisions on the use of HPV vaccines are further complicated by the fact that these are among the most expensive current vaccines, coupled with the recognition that there will be a lag phase of many years (decades) before their introduction has a substantial effect in terms of cancer reduction, and the fact that there are alternative control approaches in place to reduce cervical cancer (large screening programs and associated surgical intervention). Several modeling studies that attempt to provide a rational basis on which to make decisions on the use of HPV vaccines are based on predicted impact and cost-to-benefit ratios associated with vaccinating males as well as females.[212,213] These models suggest that vaccination of males is in general not cost-effective under current circumstances, unless coverage in the female population is low (e.g., three-dose vaccine coverage <50% by age 12 years).[214] This is because females have a much higher burden of HPV-related disease than males, and so, other things being equal, it is much more cost-effective to raise coverage in girls than to start to vaccinate boys. Low coverage in the U.S. female population (only 32% with three doses among 13- to 17-year-olds in 2001) led the United States to recommend vaccination of males in 2011. Much more needs to be learned about the

natural history of the infections, in males as well as in females, before we can be confident of predictions of the long-term impact of HPV vaccination programs.

Tuberculosis (and Leprosy)

BCG vaccination is an important element in tuberculosis control in most countries of the world, and it raises still different questions about immunity at the population level. An appreciable proportion of the global human population—up to 32 % by some estimates[215]—is currently infected with *Mycobacterium tuberculosis*. As fewer than 10% of these infected individuals will ever manifest disease, this implies widespread immunity against tuberculosis disease. Although there is a consensus that it involves the T-cell compartment, the nature of this immunity is not well understood.

Even though BCG vaccines have been shown to reduce risks of disease, at least to some degree, in a large number of studies,[216] we have no measurable correlate of this protective immunity, and the most widely used measure of cellular immunity to the tubercle bacillus (i.e., delayed-type hypersensitivity to tuberculin) is associated with relatively high, rather than relatively low, risk of disease![217] This paradox arises because a high proportion of infections with the tubercle bacillus persist in the human host, and an appreciable proportion of all cases of disease reflect a breakdown of immunity in older, long-infected (and tuberculin-sensitive) persons. This breakdown of immunity may be attributable to several different factors, such as age or intercurrent disease, or, very importantly, to immunosuppression as a consequence of HIV infection. Several authors have commented that there is little evidence that BCG reduces infection risks in endemic communities, in part because most transmission is attributable to cavitary disease in older individuals,[218] whereas BCG's action is mainly against primary disease in younger individuals, which is less likely to be infectious (there is, however, a report of BCG's protection lasting for 50 years[219]). The argument is consistent with evidence that BCG works by preventing hematogenous spread of tubercle bacilli, thus against disease, rather than against primary infection itself,[220] but has recently been challenged by studies using in vitro assays with specific *M. tuberculosis* antigens, which suggest that BCG can reduce infection risks in child contacts of cases, by approximately 20 %.[221]

Despite the immense scale of BCG use over the past 50 years, its overall contribution to protection in endemic populations is unclear. Although there is indisputable evidence for its effectiveness in some populations, in particular against severe disease of childhood but also against pulmonary disease in young adults in northern temperate populations,[222] there is also indisputable evidence of the failure of some of the same BCG vaccines to provide any detectable protection against pulmonary tuberculosis in other populations, in particular in tropical environments.[223–225] The most likely explanation for these differences is that they reflect variations in exposure to different environmental mycobacteria in different parts of the world, the effect of which is either to obstruct or to mask any protection induced by BCG.[223,226] Among the lines of evidence are data from experimental animals and from human populations indicating that exposure to bacteria such as those of the *Mycobacterium avium-intracellulare* complex can induce a degree of cross-reactivity to tuberculin and can impart measurable protection against *M. tuberculosis*.[223] Related to this observation of cross-immunity is the fact that BCG provides variable, but substantial, protection (from 20% to 80% in different populations) against other diseases related to mycobacteria, in particular leprosy (*Mycobacterium leprae*), and it is one of the factors responsible for declines in leprosy in many parts of the world.[226,227] The mycobacteria thus provide examples of geographically variant, heterologous protective immunity, which acts differently against infection and different forms of disease, and is derived from environmental exposure, a group of vaccines derived from a bovine pathogen (*Mycobacterium bovis*), and different human pathogens. The overall picture is far from simple!

"Nonspecific Effects"

Most of the data and discussion of vaccine effects relate, understandably, to the target diseases against which the vaccines were designed. However, immunologists are aware of many examples of cross protection between different infections in animal models (e.g., BCG can protect mice against vaccinia virus)[227] and human vaccinologists can cite examples of vaccines acting beyond their target disease (an obvious example being BCG vaccine's protection against leprosy and its use in treating bladder cancer). Given that many vaccines contain a large number of antigens, let alone adjuvants, it should not be surprising that there are examples of vaccine effects on nontarget conditions. It is appropriate to consider the potential population implications of these nonspecific, or nontarget, effects of vaccines.

The subject is complicated by its very open-endedness and has a controversial history. Logic might lead to an expectation that nontarget effects would be most likely against closely related organisms (consistent with protection by BCG against *M. leprae*), but the complexity of vaccine antigens, of the immune system, of the human microbiome, and of the potential pathogens confronted in different environments is such that one may conceive a wide variety of possible effects. The controversy arises in part because the phrase "nonspecific effects" arose first in the context of a totally unexpected observation of apparent increase in all-cause mortality among (in particular female) recipients of high titer measles vaccines in trials done in the 1980s.[228] This observation led to discontinuation of research on these vaccines, but was never completely explained, and spawned a series of hypotheses attributing the observed effects not just to the measles vaccines but to their timing and sequence relationship to other vaccines, in particular diphtheria, tetanus, and pertussis.[229,230] Most of the studies were perforce observational, and many were open to criticism given that vaccinated and nonvaccinated individuals differ in many ways, and hence comparisons are open to bias. However a substantial body of data and methodological discussion has now accumulated which provides a basis for guiding more definitive research.

Much of the work on this subject has been done by Aaby and colleagues in West Africa, in particular in Guinea Bissau, thus under difficult conditions and in populations with high background rates of infectious disease morbidity and mortality. Because of the absence of diagnostic facilities in such populations, most of the studies have examined all-cause mortality as an outcome; thus mortality may be attributable to both target and nontarget diseases. Independent systematic review of this literature in 2014, supported by the WHO, provides evidence that (standard titer) measles and BCG vaccines are associated with reduced all-cause child mortality in several populations.[231] The effects look to be greater than can be explained in terms of prevention of measles or tuberculosis (range: 8% to 89% for BCG; 0% to 90% for measles). The extent of apparent protection varies considerably between populations, as might be expected, given not only many sampling factors but also the variation between infection exposures and hence causes of mortality between populations. For this reason it is inappropriate to provide single estimates of nonspecific protective effects.

A smaller body of work has examined possible nonspecific vaccine effects in wealthy countries. Analyses of linked data in Denmark have provided evidence that receipt of measles-mumps-rubella vaccine may be associated with low rates of hospital admissions for nontargeted infections and specifically for respiratory syncytial virus.[232,233] Interpretation of these findings is complicated by a longstanding argument over the extent to which measles disease is associated with, or can lead to, increased susceptibility to a variety of other infections, and hence whether an effect of measles-mumps-rubella vaccine or other nontargeted infections might be attributed indirectly to the prevention of measles per se.[234,235] This issue may become of importance in the future, if measles is ultimately eradicated, as there might be a discussion whether measles vaccination should be continued because of its potential "direct" protective effects on other ("nontarget") causes of morbidity and mortality.

The complexity of this subject, and attendant controversies have meant that it has not to date captured mainstream attention of the vaccine community. However, the accumulation of substantial data and recent independent systematic reviews mean that it is likely to be taken more seriously in future. Among various implications this means that there may be calls to consider the collection of data on all-cause morbidity and mortality effects of particular vaccines, and in assessment of different vaccine schedules, in the future.

DISCUSSION

This brief review reveals many complexities to the measurement and interpretation of immunity at the community level. Though not discussed in this chapter, the issues of vaccine coverage and effectiveness are obviously fundamental to protecting communities through vaccination programs. Maximizing coverage raises many practical problems relating to services, access, logistics, targeting, schedules, consent, enforcement, health education, and cost.[236] Increasing effort is now devoted to combatting antivaccine sentiment or "vaccine hesitancy," which is on the rise in many societies.[73] The definition and measurement of vaccine coverage are themselves complex issues, and are discussed elsewhere in this volume.

Beyond issues of coverage, to say that x% of a population has been vaccinated, or is "immune" to some infection can be misleading without detailed qualification of the nature of the immunologic states and the distribution of the various sorts of individuals in the population, in particular by age and area. For some infections, exemplified by measles, immunity to infection, to disease, and to infectiousness appear to be quite similar in nature and magnitude (although titers are lower postvaccination than after natural measles), but for many infections they are different. There are important differences between protection against infection, reinfection, carriage, disease, and infectiousness in varicella, pertussis, Hib, diphtheria, polio, HPV, and tuberculosis; immunity is not sterile in varicella and tuberculosis; heterologous immunity is important in influenza, diphtheria, and tuberculosis, and perhaps Hib; and both waning and boosting are important for natural or vaccine-derived immunity to many infections, including smallpox, varicella, pertussis, Hib, and pneumococcus. The step from description of immunologic states in individuals to their implications at the population level is also complex: serotype replacement occurs with both pneumococcus and influenza; vaccination of certain subsets of populations has important effects on risks in other subsets for rubella, pertussis, tetanus, varicella, pneumococcus, meningococcus, HPV, and influenza, and delayed post-honeymoon epidemics illustrate important temporal dynamics in measles, rubella, mumps, varicella, pertussis, and Hib. The acknowledgment of nonspecific or nontarget effects of vaccines introduces a considerable complexity that awaits further research.

Ironically, a major problem affecting the subject of community protection by vaccines is the word immunity itself, which too often is taken to mean solid protection against both infection and disease, thus overlooking the many subtleties of actual immune responses. These subtleties are likely to be even greater for some of the vaccines currently under development, for conditions such as malaria, HIV, and helminthiases, than for many of the vaccines in use today. The fact that these vaccines have been so difficult to develop reflects complexities in the biology of the target organisms and in the immune responses they generate. Distinctions between solid and partial immunity and between protection against infection, reinfection, carriage, disease, and transmissibility are thus likely to be particularly important for these new vaccines and will determine their overall effects in communities.[237–241]

Immunological mechanisms aside, the interpretation of measures of vaccine-derived protection in individuals can depend on the vaccine's distribution in populations. If vaccinated persons are clustered in community groups (as is often the case), then they benefit both directly, from individual receipt of the vaccine, and indirectly, from reduced transmission in their neighborhoods. In such circumstances, the vaccinated and unvaccinated groups are not equally exposed to infection, and crude measures of vaccine efficacy will overestimate the "immunizing" capacity of the vaccine among individual recipients.[105,242] This is a particular problem in observational studies of vaccines, but it also may affect trials in which randomization is by group and not by individual.[243–245] Related to this issue is the fact that cluster randomized trials provide a measure of overall benefit of vaccine distribution (including both direct and indirect effects), which may be appropriate in predicting overall impact and cost-effectiveness of a vaccine program.

This discussion has referred repeatedly to the *indirect protection* of nonimmune individuals brought about by the presence and proximity of immune persons. That such protection should occur is evident both intuitively and through theoretical argument, and it has been demonstrated repeatedly and convincingly in the context of many vaccination programs. Of the infections and vaccines discussed here, the only examples in which indirect protection has not been demonstrated are tetanus (though there is the argument relating to passive antibody transfer from mothers to their neonates) and tuberculosis (though the recent recognition that BCG can impart some protection against *M. tuberculosis* infection implies the possibility of some indirect effects[221]). In several examples, the indirect protection from vaccination has been obvious (e.g., smallpox, rubella, mumps, chickenpox, Hib, pneumococcus, meningococcus, diphtheria, influenza, HPV).

There are several important features to this indirect protection. One is that it applies to all individuals in the population containing the immune persons—including those too young to have been vaccinated, and those who may be still susceptible because of immune deficiency, or because they refused or otherwise failed to be successfully vaccinated, perhaps as a result of contraindications or lack of access to vaccination services or simple vaccine failure, or because their immunity has waned. Both pneumococcus and influenza illustrate how targeted vaccination of children can protect the elderly who are more susceptible to serious disease, and perhaps less able to respond to the vaccine. A second important point is that indirect protection is not a form of immunity; thus a person indirectly protected (shielded) from infection remains still susceptible, and may in fact contract infection at a later date and age. Under certain circumstances, this delay in infection may actually be hazardous for that person, or for society (e.g.,

with rubella or mumps, or perhaps polio). In this sense, indirect protection by vaccines is the opposite of a traditional approach, practiced in many societies, of exposing children to infectious cases of, for example, rubella or measles or chickenpox at a young age when they are most likely to contract a mild form of the disease. In addition, we have noted that indirect protection can have another potentially detrimental effect insofar as it may reduce boosting of immunity through repeated exposure to infection and may thereby lead to greater waning of immunity and increased susceptibility in older persons. This is a particular concern with regard to pertussis and perhaps varicella-zoster. In this context, an increase in one or another pattern of susceptibility in adults need not necessarily be detrimental to society—for example, if the use of vaccines in the young is sufficiently intense to greatly reduce transmission among the groups with the highest levels of contact, so that there is greatly reduced exposure among adults. However, such shifts in the age distribution of immunity and susceptibility are potentially hazardous and need to be monitored closely.

Appropriate comparisons between groups with different proportions of vaccinated individuals may allow estimates of both direct and indirect protection attributable to vaccines,[33,242] as shown in analyses of cholera vaccines in Bangladesh.[244] Despite the elegance of the methods, it is likely that measures of direct protection will be far more generalizable than are measures of indirect protection, given that the former depend only on the immunologic response of individual vaccine recipients, whereas the latter will be a function of the social and spatial distribution of vaccinated persons, and of social mixing patterns, which may differ greatly between populations. For example, the role of schoolchildren in community dispersal of influenza viruses (and hence in the indirect protection to adults that may be provided by their vaccination)[193–196,203] is a function of the age and family size distribution of the population (which determine what proportion of families have children in school) as well as the size and physical environment of the schools (a single, large, crowded school being more likely to serve as a distribution center for the community than a large number of small and well-ventilated schools).

This influenza example exemplifies one of several interesting and important ethical issues in community immunity: to what extent is it justifiable to protect—or even to increase risk in—unvaccinated individuals indirectly, by directly vaccinating and protecting other individuals (e.g., the vaccination of males against rubella)? What are the implications of such indirect effects for informed consent, or compulsion, or targeting of vaccines, or compensation of vaccinees should they suffer any adverse effects? To what extent can cost-effectiveness analyses incorporate such considerations? Children vaccinated with live attenuated influenza vaccines may be protected themselves, but under what circumstances is it justifiable to direct a program at them when the greater benefit (and perhaps even the intention) is to protect their grandparents? The fact that Japan's program to target schoolchildren with influenza vaccines was discontinued[200,201] gives one example of one nation's perception, at one point in time. These are among the difficult and important implications of the community effects of vaccination programs. They are addressed more fully in the chapters on economics, vaccine safety, legal issues and ethics within this volume.

Much of the literature on community, or herd, immunity to various infections emphasizes threshold proportions of immune persons that, if reached and sustained (e.g., by vaccination), should lead to progressive elimination of the infection from the population. Although such estimates (see Table 77.2) may provide a rough ranking of the levels of natural and vaccine- derived immunity required for control or eradication of these infections, they should not be accepted uncritically, as their validity depends on the various assumptions underlying their derivations, and even the most elaborate derivations typically omit important features of the immune response (e.g., implications of protection against infection, disease or infectiousness, or waning) and important features of the practical logistics and nonuniformity of real populations and of real vaccination programs. Although these thresholds are often referred to in the context of discussions of eradication targets, the practical experience of the major programs to date, as against smallpox, measles, and polio, has found them of little practical use. In addition, their relevance is mitigated by the fact that most public health programs aim at *control* rather than elimination or eradication of infections. Even if there is an eradication goal, the practical approach will not be to just attain some threshold, but to aim for and sustain the highest possible coverage, in theory 100%, because this will maximize the rapidity of the disappearance of the infection in question. Merely achieving a herd immunity threshold does not mean immediate disappearance of the infection; it only starts a downward trend.

Such caveats do not mean that herd immunity is not a valid concept. That indirect protection occurs is obvious, both in logic and in observation. Prevention of a communicable infection in any one person reduces by one the potential sources of infection— and hence the potential risk of infection—for that person's peers. That is indirect protection and a form of "herd effect."[246] The observation of apparent exceptions, small communities in which infections appear to be transmitted despite very high levels of vaccination coverage (e.g. because of chance or unusual clinical presentation or behavior or environmental circumstances), do not refute this principle,[247] just as the failure of a particular vaccination in some individual recipients need not refute an overall high effectiveness of a vaccine.

The herd immunity threshold concept provides an epidemiologic attribute with which to characterize particular infections. Although precision may not be possible because of population heterogeneities or because of variability in the immune status of individuals, and although they may be naïvely optimistic in practice, even crude estimates can be of use in giving a rough guideline for predicting the impact of a vaccination program and at least a hint as to the potential for eradication. As experience grows, and models become more sophisticated, we will come to appreciate better how the various subtleties of the immunology and epidemiology of different infections—for example, those attributable to the nature of the immune response and to the social structure of populations—imply greater or lesser biases in the estimates derived from simple models. The concept of a threshold is also useful in the context of teaching. It is part of the basic science of infectious disease epidemiology, and it provides an essential background for understanding the behavior of infections in populations.

The emphasis on elimination thresholds in the literature has distracted attention from important and complicated implications of changing patterns and levels of immunity in populations over time. A vaccination intervention entails a complex disruption of the previous natural balance, and it can destabilize epidemiologic patterns for many years. The introduction of an effective vaccination program among children may reduce infection incidence to such a degree that a large number of susceptible persons can accumulate among those born just too early to receive the vaccinations, and who thus escape both the natural infection and the benefits of vaccination. The accumulation of such susceptible groups may lead to changes in the age distribution of cases in subsequent years,

as has been described for many infections. Discussion of such changes is sometimes confused by presentation in terms of proportions of cases in different age groups, because it is possible for the proportion of (e.g., measles or pertussis) cases among adults to increase dramatically even though their absolute number decreases. Thus a shift to older cases need not necessarily be harmful overall. Prediction of such effects requires simulation with models that take into account differences in contact within and between age groups, using data such as generated in the POLYMOD-related projects.[248] The only way to develop convincing descriptions is by the accumulation of detailed analyses of age-specific data over time, preferably before and after vaccine interventions.

Although vaccines are given to increase levels of immunity in populations, we also need to consider immunity loss as an important issue. The loss of protective immunity may be attributable to waning of an immune response with time, which may in turn be a function of the nature and strength of the initial response, or to a reduction of boosting by natural exposures, as is important in contemporary trends in pertussis, Hib, and herpes zoster. Immunosuppression is also important in this regard, for the elderly and infirm and in particular as a consequence of HIV infection. HIV-attributable immunosuppression is a major force behind the global epidemic of tuberculosis today. Age itself is an important determinant of immune competence and status, and the increased numbers of older persons in many populations may lead to declines in overall levels of various aspects of immunity in many communities in the future. The mechanisms underlying the persistence of immunologic memory are poorly understood but of great importance to communities as well as to individuals.

The growth of vaccination programs and the recognition of the complexity of their implications highlight the importance of immunologic monitoring of populations. Only by accumulating such data will we ultimately be able to understand the dynamics of community immunity and the full effects of vaccine interventions and to optimize future interventions. Such monitoring should enable detection of accumulating pockets of susceptible persons, and hence the prediction of delayed epidemics such as have been observed after a period of vaccine program–attributable low incidence. The monitoring of increasing numbers of susceptible persons to measles in the United Kingdom in the early 1990s through routine serosurveillance, and the subsequent nationwide mass campaign, provides an example of effective monitoring and response—although, ironically, the omission of mumps antigen from the campaign allowed the massive resurgence of mumps in the United Kingdom starting in 2004.[68,83] Serosurveillance of antibody levels to rubella and diphtheria have also been used to plan immunization strategies, and such approaches are likely to increase in the future. Effective serosurveillance requires knowledge of appropriate humoral (preferably) or cellular correlates of protective immunity, such as we have for some vaccine-preventable diseases (e.g., measles and rubella) but not for others (e.g., pertussis and tuberculosis). Defining such correlates, and the development of appropriate assays for them, will be an important area of research in coming years.[249]

This review has avoided emphasis on any simple interpretation of herd immunity, instead accepting the varied uses of the term by different authors. This is in keeping with the first published use of the term, which posed the problem of "herd immunity" as the problem of how to distribute any given amount of immunity (e.g., antibodies, vaccinations) so as best to protect a population from disease.[8] The mechanisms will be several—direct protection of vaccinees against disease or transmissible infection, and indirect protection of nonrecipients by virtue of surreptitious vaccination, passive antibody, or just reduced sources of transmission and hence risks of infection in the community. The solutions likewise will depend on many factors—the nature of the population, the infection, the vaccine, and the health services. The population and the infection are generally given, the vaccine we may try to improve, but the distribution of that vaccine is up to the public health community. How to optimize that distribution for the betterment of society remains, in the broadest sense, the real problem of community protection.

Acknowledgment

The authors express their gratitude to Dr. Emilia Vynnycky for assistance with Figs. 77.4 and 77.5, and the editors for several helpful suggestions.

78 Economic Analyses of Vaccine Policies

Mark A. Miller and Bradford D. Gessner

Vaccination programs have greatly reduced morbidity and mortality worldwide. While new vaccines and the strategic use of existing vaccines offer the prospect of further reductions in disease, policy makers are often constrained by limited public health resources* and require assessments of a vaccine's value to justify and optimize its use. Newer vaccines tend to cost more than older products and those not under patent protection. Studies involving the integration of epidemiologic and economic data are critical to identify the most efficient use of public health resources, to optimize health benefits, and to help define research agendas.

Different quantitative techniques have been used to analyze policy decisions related to health outcomes, including those related to vaccine-preventable diseases. Economic analyses, such as **cost analysis**, **cost-benefit analysis**, **cost-effectiveness analysis (CEA)**, and **cost-utility analysis (CUA)** (Table 78.1), help estimate potential financial requirements and program impact for direct comparisons among vaccination strategies. A systematic assessment of policy options facilitates the creation of policies that are based on a set of established criteria and provides transparent accountability for the choices made.

These approaches share the characteristics of explicit delineation of possible alternatives, estimation of probabilities and costs associated with each of these alternatives, various health outcome metrics and values, and development of a summary statement of the implications of alternative courses of action. They also involve sensitivity analyses, in which estimated probabilities or costs are varied to determine how sensitive the conclusions are to particular variables.

Cost analysis is the basis of all economic studies because it quantifies the costs associated with a given intervention. The costs of the program may include, but are not limited to, vaccines, vaccine administration, efforts to address adverse events, and public education. Cost-benefit analysis is an extension of cost analysis that further accounts for the monetary benefits from a policy or program. Benefits are usually calculated as a function of the total cost of a disease in the presence and absence of an intervention. In a cost-benefit analysis, results are usually presented as ratios of the benefits from the intervention to the costs of conducting the program (B:C ratio) or the differences between the two, expressed as a net benefit (cost). By convention, the ratio is expressed as benefits to a cost of 1. If the B:C ratio is greater than 1.0, the intervention is considered to be cost saving, because 1.0 is the breakeven point at which costs and benefits are equal.

Because of the difficulties of assigning economic values for certain outcomes, such as averted deaths, or the macroeconomic impact of outbreaks, a full accounting for a cost-benefit analysis is challenging. However, because it can give a summary statement about whether the benefits of a program exceed its costs, irrespective of the character of the outcomes, it can be used to compare health programs with nonhealth programs. CEA and CUA are more useful for comparing different health programs and for avoiding the subjective valuation of intangibles such as death.

In CEA, results are presented in terms of the cost required to achieve a particular health outcome (Table 78.2). Usually no attempt is made to assign an economic value to a prevented death. In general, interventions are considered highly cost-effective (good buys) by financial authorities if the cost per year of life saved is less than or equal to the annual per capita gross domestic product (GDP), which can range from US$500 for low-income countries to greater than US$30,000 for high-income countries (the GDP per capita in the United States was US$47,400 in 2010).[1] The relative cost-effectiveness of a death prevented can depend on the age of the individual and the consequent number of years of life saved. For example, an intervention that prevented death at an early age is generally considered cost-effective even if the cost per death prevented is several times higher than the per capita GDP. By contrast, a public health intervention with the same cost per death prevented might not be considered cost-effective in an elderly person with fewer potential years of life saved. Ethical considerations are critical, because society must decide on the value of life-years saved at different ages.

CEA is particularly useful when there are several options to achieve a common outcome (e.g., delivering a second dose of measles vaccine as part of a campaign or as part of a routine schedule to prevent outbreaks). Despite its advantages, CEA is not useful when comparing investment in alternative health programs with disparate outcomes. In this situation, CUA is much more useful, because the units of measurement are standardized, albeit with subjective and therefore sometimes controversial, metrics.

CUA is a specific form of CEA in which health outcomes are reduced to a common denominator such as a quality-adjusted life-year (QALY)[2] or a disability adjusted life-year (DALY). The units of each of these outcomes are standardized through a process by which panels of ethicists, researchers, and decision makers weigh the value of different morbid states relative to full health for use in studies using either of these metrics. For example, a consensus group might find that two-thirds of a year living with full sight is equivalent to 1 year living with blindness, effectively equating the quality of the time spent with blindness as 67% of the quality of the time with full sight. The relative proportion of time preference with and without a specific condition allows the formulation of a common health metric unit that can offer direct comparisons of a variety of morbid conditions. There are more than 30 such health outcome metrics that integrate morbidity and mortality. Table 78.2 provides some examples of these metrics. A common metric calculated through CUA permits comparisons to be made among interventions aimed at diseases with diverse outcomes, such as death, acute illness, and prolonged disability. Although common outcome metrics facilitate comparisons of many health interventions, numerous subjective and ethical assumptions underlie their construct, and therefore they are not always easily interpreted (see Table 78.2).

*Although private consumers individually judge the value of prevention, this chapter focuses on the public sector.

TABLE 78.1 Examples of Economic Evaluations of Vaccine Policy and Their Derivation

Term	Definition
Cost analysis (CA)	Summation of vaccine program costs including vaccine, administration, adverse events, public health marketing
Cost-benefit analysis (CBA)	Computed as a benefit-to-cost (B:C) ratio equal to cost of prevented disease/ costs of program *or* net benefit equal to cost of prevented disease minus costs of program where prevented disease equals the difference in costs of disease (direct, indirect, and intangibles) without and with vaccine and costs of program equals the cost analysis
Cost-effectiveness analysis (CEA)	(Cost of program minus cost of prevented disease) divided by prevented health outcome
Cost-utility analysis (CUA)	(Cost of program minus cost of prevented disease) divided by standardized health metric

TABLE 78.2 Examples of Health Outcome Metrics[a]

Metric	Definition
Cases	An outcome may be stated as the number of cases that occur or are prevented by an intervention. It does not necessarily account for the various severity states of sequelae. One could further stratify the total number of cases by minor illness, hospitalizations, and long-term sequelae.
Deaths	Death may be easily quantified but defies an economic valuation. For this reason, CEAs are often used in health outcome assessments with deaths (or some variation) in the denominator.
Years of potential life	YPL is a refinement of the death metric performed by quantifying the total years of life lost or prevented from being lost. It integrates the difference in an expected life span of each person and the age at which a death occurs. YPL may be adjusted by discount and age weights to account for societal preference of time and years of productivity; there are considerable ethical considerations in the choice of a weighting scheme for different ages.
QALY or DALY	QALY and DALY are further refinements of the YPL metric that integrate mortality and morbidity states. Various health metrics have been developed to help quantify disease burden states to compare disparate health outcomes. QALYs and DALYs integrate mortality, the YPL, and a valuation of the disability from morbidity. They are calculated by adjusting the YPL by the time spent with various disabilities. These units may be discounted and contain an age-weighting factor. The weights are systematically defined and then used as standards for subsequent studies. They offer a common metric to compare many health outcomes.

[a]Any type of policy analysis requires a quantification of morbidity and mortality states. Although there is no universal consensus metric, attempts have been made to create a single unit to systematically quantify many diverse possible health outcomes.

CEA, cost-effectiveness analysis; DALY, disability-adjusted life-year; QALY, quality-adjusted life-year; YPL, years of potential life.

IMPORTANT CONSIDERATIONS IN QUANTITATIVE POLICY ANALYSIS

There are many decisions to be made in designing a quantitative policy analysis. Widespread variability in choices of parameters or metrics has made it difficult to make comparisons among many of the published studies. This variability has been criticized.[2] In the 1990s, a task force in the United States drew up suggested guidelines for carrying out cost-effectiveness studies of preventive services.[3] The journal *Vaccine* has published an editorial statement on the submission of economic evaluations of vaccines.[4] The U.S. Centers for Disease Control and Prevention (CDC) has published guidelines that are required to be followed to present any economic analysis to the CDC Advisory Committee on Immunization Practices (ACIP). Additionally, the World Health Organization (WHO) has published a guide for the standardization of economic evaluations of immunization programs.[3,4]

Economic models also may consider the indirect effects of immunization from the decrease of transmission (herd immunity).[5] As an example, the impact of immunization of U.S. infants with pneumococcal conjugate vaccine on the occurrence of pneumococcal disease in older, unvaccinated populations has been quite large.[6] Additionally, there has been increasing interest in providing different modelers with common data to assess the divergence and convergence of results and identify important nuances for consideration. This approach has been taken with respect to research focusing on rotavirus and human papillomavirus (HPV) vaccines and measles eradication.[7]

As a result of the increased levels of attention being given to the evidence base for new vaccine use, analytical tools and initiatives to assess new vaccine cost-effectiveness have been developed. The ProVac Initiative of the Pan American Health Organization is a notable example.[8] The Strategic Multi-Attribute Ranking Tool for Vaccines (SMART-Vaccines) has been developed to capture both quantitative and qualitative explicitly stated values to help make transparent decisions related to vaccine policy.[9] Many attributes, such as impacts on societal disruptions, macroeconomic considerations and development, may be considered. These tools can help National Immunization Technical Advisory Groups (NITAGs) assess available information and make a country-based and evidence-based decision on quantitative issues related to vaccines and immunization programs.[10]

Perspective

Individuals, healthcare systems, commercial vaccine manufacturers, and society at large all benefit from immunizations. Although the societal perspective theoretically captures all costs and benefits, the costs and benefits of a vaccination program clearly accrue to different budget lines. Results from any analysis would vary from each perspective[11,12] and should be explicitly stated.

Time Frame

Vaccines protect against diseases that would otherwise occur at a variable future time. While measles vaccine protects against childhood disease, hepatitis B or HPV vaccines can prevent liver and cervical cancer, respectively, in adults. Because a vaccine investment is made in a time frame different from the eventual benefit, economic analyses frequently discount future effects to take into account the implicit valuation that society has for health and financial costs and benefits over time. Even after accounting for inflation (which affects both costs and potential savings), there is an implicit difference in

the value of an event that occurs today versus one that occurs in the future. For example, it is generally thought that a child's death prevented today is worth more than a child's death prevented 50 years from now. Even though this is an ethical and subjective valuation, there is general agreement among economists to discount both costs and benefits at the same rate, typically from 3% to 10% per year, most often at the lower end of the range. Study results may be presented as both discounted and undiscounted to see the influence of this subjective assumption.

Disease Burden

Estimates of the potential impact of a vaccine on disease may be derived from surveillance data (usually an underestimate), extrapolations from other representative populations, vaccine clinical trials (e.g., vaccine probe studies),[13] or the results of mathematical models that simulate the natural history of microbes, infections, degrees of severity, and population mixing, among other variables. Analyses might need to be specific for age group, population and occupational group, risk of exposure (e.g., healthcare workers), and outcome, including the timing of the outcome (e.g., death in the next year vs death 50 years in the future). An understanding of the different rates of transmission of microbial agents is essential to appreciate the direct and indirect impact that vaccines can have on populations.

Measures Used for Health States

Outcomes (see Table 78.2) may be stated as the number of cases or deaths that occur or are prevented by an intervention. Years of potential life represents a refinement of the death metric that quantifies the total years of life lost or prevented from being lost. It integrates the difference in an expected life span of each individual and the age at which death occurs. QALYs, which measure the number of years of healthy life lived, or the currently used WHO metric, DALYs, which measure the years of healthy life lost, are further refinements of years of potential life that integrate a reduced valuation of various morbid states.

QALYs and DALYs are complementary concepts. Both metrics are derived from the product of the number of years lived and by the quality of those years. QALYs use utility weights of health states; DALYs use disability weights to reflect the burden of the same states. For example, if the utility of blindness is 0.67, the disability weight of blindness is 1–0.67 = 0.33. Disregarding age weighting and discounting, all other things being equal, a person who is blind for 50 years has 0.67 × 50 = 33.5 QALYs compared to 50 QALYs for a person with full sight. The condition of blindness contributed to 50–33.5 = 16.5 DALYs.[14] These metrics defy simplicity, are derived from many subjective inputs, and might not be readily understood by some policymakers; however, they offer a common metric to compare disparate health outcomes.

Economic Valuation of Health Outcome States

Direct and indirect costs and benefits are usually counted. Direct costs include those related to medical treatment and to administering the vaccine, including ancillary costs such as screening for target groups. Indirect costs include lost wages of those ill and/or their caregivers. Intangible costs, such as pain and suffering or death, are difficult to quantify; however, they may be implicitly valued as the denominator of a CEA or CUA (e.g., as cost per death prevented), allowing the reader to apply the reader's own value to the stated health outcome. An alternative valuation tool is the concept of willingness to pay, where individuals are asked what each would be willing to pay to achieve alternative health outcomes given different economic circumstances and probabilities. These collective responses are integrated with actual probabilities of risk to gauge individual or societal valuation of prevention.

Vaccine Program Characteristics

Vaccine effectiveness in the field, coverage, adverse effects, and the potential for indirect benefits to accrue to unvaccinated persons from decreased transmission are all program characteristics that should be accounted when evaluating the cost-effectiveness of vaccine initiatives. Fig. 78.1 shows a schematic model of a vaccine program. Each component has an associated cost or a benefit.

Sensitivity Analysis

Quantitative policy analysis provides the opportunity to evaluate the likely effects of different probabilities of events (or different costs) from those postulated in the base case analysis. This is particularly relevant when the value of a parameter used in an analysis is uncertain and must be estimated. Testing a range of values for an uncertain assumption or group of assumptions can help identify the variables to which the conclusion is most sensitive or robust. In turn, defining those variables' values can be the focus of further research.

EXAMPLES OF USES OF QUANTITATIVE POLICY ANALYSIS

In general, cost-benefit analysis, CEA, and CUA have shown that immunization is an excellent investment (highly cost-effective and often cost-saving) for older vaccines that have historically been recommended for the pediatric population. As Table 78.3, which summarizes selected studies of different vaccines, demonstrates, consideration of particular strategies in certain populations can show considerable variation,. With the advancement of computational capabilities, modeling software, the maturation of health economics applications to public sector health programs, and the expansion of the repertoire of new vaccines in recent years, the number of economic studies to evaluate vaccines has greatly expanded. Given that more than 1000 economic analyses have been published since the 1980s, we only present results of selected studies to highlight the relevant issues for consideration. Unless otherwise indicated, all costs are in U.S. dollars. A summary table of cost-effectiveness studies of other selected health interventions is included for reference (Table 78.4).[15,16]

Use of Models

Economic models are becoming more important to decision-making. A survey of NITAGs published during 2010 found that more than 90% considered financial aspects when issuing recommendations.[17] The United Kingdom and Australia NITAGs use the results of economic analysis as a criteria for public vaccine funding.[18] Vaccine recommendations by the WHO now routinely include data on economic impact. The Global Alliance for Vaccines and Immunization (GAVI) uses four categories of criteria and indicators to determine which vaccines it will support, one of which is cost and value as measured by total procurement costs, incremental in-country operational cost per vaccinated person, and procurement cost per death or case averted. From another perspective, vaccine manufacturers may consider the results of economic analyses when setting vaccine prices.

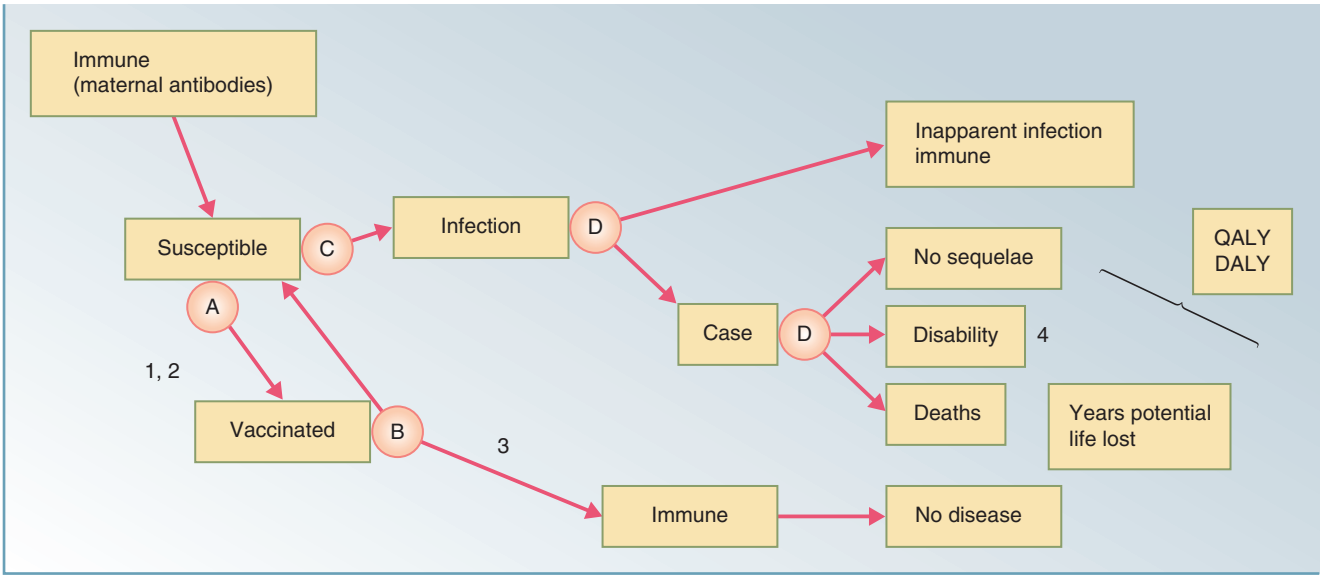

Figure 78.1. Simplified schematic of compartmental model of infectious disease transmission with a vaccine-preventable strategy. Each of the boxes represents a particular state of a vaccine-preventable disease. Assuming all persons are susceptible to infection after birth (following maternal antibody protection), there are variable probabilities for passage into another immunological state throughout the person's lifetime. These probabilities can be quantified to model the impact of a vaccination program on a birth cohort followed throughout life to quantify disease burden. *A,* Vaccination coverage rate (age specific and by dose). *B,* Vaccine efficacy by dose (effectiveness more relevant to account for herd effect). *C,* Age-specific rate of infection. *D,* Probabilities of progression to each outcome state. *1,* A screening program could be added here to help target vaccination efforts. *2,* Adverse event probabilities could be added here. *3,* Dose and possibly time dependent. *4,* Any number of mutually exclusive outcome states could be added here. DALY, disability-adjusted life-year; QALY, quality-adjusted life-year.

TABLE 78.3 Illustrative Examples[a] of Economic Analyses of Selected Childhood Vaccines

Reference	Type	Scope	Result	Comment
GENERAL				
Brenzel (2006)[27]	CEA	Global	Reviewed 30 studies; average cost to fully immunize a child with DPT, BCG, polio and measles vaccines US$22, ranging from US$8 (Tanzania, fixed site) to US$33 (Cameroon, national campaigns)	All costs adjusted to 1992 dollars (equivalents)
Miller (2000)[85]	CEA	Global	Country-specific analysis for vaccination against hepatitis B, *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and rotavirus. The global cost per life-year saved ranged from US$29 to US$150, with great variation by income and economic groups	Costs of vaccine were based on relative wealth of individual countries
Zhou (2005)[19]	CBA	United States	Benefit-to-cost ratios of 7 routine childhood immunization results in direct and societal benefit-to-cost ratios of 5.3 and 16.5, respectively	
BACILLE CALMETTE-GUÉRIN				
Trunz (2006)[31]	CEA	Global	At US$2–US$3 per dose, BCG vaccination costs US$206 (US$150–US$272) per year of healthy life gained	
CHOLERA				
Schaetti et al (2012)[290]	CEA	Zanzibar	During a mass vaccination campaign, the incremental cost-effectiveness of oral cholera vaccine compared to no vaccine was US$750,000 per death, US$6000 per case, and US$30,000 per DALY averted	Static model used
DENGUE				
Durham et al (2013)[277]	CEA	Brazil	Dengue vaccine estimated to be cost-effective at vaccination costs up to US$534 and cost-saving at costs up to US$207	Base-case assumption of 70% vaccine efficacy against all dengue combined

Continued on following page

TABLE 78.3 Illustrative Examples[a] of Economic Analyses of Selected Childhood Vaccines *(Continued)*

Reference	Type	Scope	Result	Comment
DIPHTHERIA–TETANUS–ACELLULAR PERTUSSIS				
Ekwueme (2000)[305]	CBA	United States	Benefit-to-cost ratios for acellular pertussis vaccine from a societal and healthcare system perspective were 27:1 and 9:1, respectively, but were marginally more expensive than whole-cell vaccine	Additional benefit of acellular vaccine is increased consumer confidence
GROUP B STREPTOCOCCUS				
Oster et al (2014)[297]	CEA	United States	Incremental cost-effectiveness of routine maternal immunization added to screening and intrapartum antibiotic prophylaxis would be US$91,321 per QALY gained	Base case assumed 85% coverage with vaccine cost of US$100 per person
HEPATITIDES A AND B				
CDC (2006)[63]	CEA	United States	Cost-effectiveness was estimated at US$173,000 per life-year gained and US$24,000 per QALY gained	Substantially more cost-effective when decreased transmission through herd effects are included
HUMAN PAPILLOMAVIRUS				
Jit et al (2015)[107]	CEA	Global	HPV vaccine cost-effective in 158 of 179 countries; vaccinating 58 million 12 year-old girls would prevent 690,000 cases of cervical cancer at a cost of US$4 billion	Model: Papillomavirus Rapid Interface for Modelling and Economics (PRIME). Assumed lifelong protection, vaccination presexual debut
Graham et al (2015)[120]	CEA	Canada	US$94.49 saved and 0.04 QALYs gained per vaccinated male age 12 years	Base case vaccine efficacy of 84%, coverage 50%
Laprise et al (2014)[106]	CEA	Canada	All 2- and 3-dose/girls only and girls+boys strategies had a cost-effectiveness ratio of <US$40,000/QALY gained; 2-dose/girls only had the lowest cost/QALY gained at US$7900–US$10,400	Incremental value of 3-dose girls only and 2-dose girls+boys varied depending on parameters; 3-dose girls+boys greater than US$100,000/QALY gained under most scenarios
INFLUENZA				
Skedgel et al (2011)[168]	CEA	Canada	Compared to vaccinating only pregnant women with comorbidities, the incremental cost-effectiveness of vaccinating all pregnant women was <US$40,000 per QALY gained	Net cost of universal vaccination was <US$10 per pregnant woman
MALARIA				
Seo et al (2014)[271]	CEA	Malawi	The incremental cost-effectiveness of adding RTS,S malaria vaccine to existing strategies (primarily bednets) was US$145 per DALY averted	The incremental cost-effectiveness was sensitive to vaccine's duration of protection
MEASLES				
Shepard (1994)[175]	CUA	Global	Vaccination results in US$17 per DALY, one of the most cost-effective health interventions in developing countries	
MEASLES-MUMPS-RUBELLA				
Hatziandreu (1994)[306]	CBA	United States	B:C ratio 16.3 for direct costs; 21.3 for total costs	Also considered B:C of individual components: measles 17.2, 17.2 for direct, total costs; mumps 6.1, 13.0; rubella 4.5, 11.1
NEISSERIA MENINGITIDIS				
Trotter et al (2002)[187]	CEA	England and Wales	The cost per life-year saved for an *N. meningitidis* serogroup C vaccination campaign was £6259; school-based campaigns were more cost-effective than vaccine delivered through physician practices	From healthcare provider perspective
Tu et al (2014)[200]	CEA	Canada	Over the lifetime of an Ontario birth cohort, *N. meningitidis* serogroup B vaccine would cost C$4.8 million per QALY gained	Baseline included 10-year duration of protection, vaccine cost of C$75/dose
PNEUMOCOCCAL (CONJUGATE)

TABLE 78.3 Illustrative Examples[a] of Economic Analyses of Selected Childhood Vaccines *(Continued)*

Reference	Type	Scope	Result	Comment
RESPIRATORY SYNCYTIAL VIRUS				
Meijboom et al (2012)[301]	CEA	Netherlands	Respiratory syncytial virus immunization with a 3-dose infant schedule would cost €34,142 per QALY gained	Over a full year and with 91% coverage, vaccination would prevent 1.5 deaths and 544 hospitalizations
TYPHOID (POLYSACCHARIDE)				
Carias et al (2015)[294]	CEA	Uganda	Over 3 years following a one-time vaccination campaign, typhoid vaccine would cost US$484 per DALY and US$341 per case averted	Results sensitive primarily to preventable disease burden and vaccine cost
VARICELLA AND ZOSTER				
Damm (2015)[255]	CEA, CBA	Various	Review of multiple studies one-dose varicella vaccination of young children would save 1.61 to 19.33 per unit spent; Zoster vaccine mostly cost-effective	Societal perspective; results dependent on importance of exogenous boosting

[a]These are examples of economic analyses are intended to illustrate the kinds of studies that have been done. The results of economic analyses will vary by methodology, the vaccine being used in a particular population, the characteristics of the population and the burden and epidemiology of vaccine-preventable diseases in that population, vaccine safety, effectiveness, potential for herd immunity, cost, and many other variables.

B:C, benefit-to-cost; BCG, bacille Calmette-Guérin; CBA, cost-benefit analysis; CDC, Centers for Disease Control and Prevention; CEA, cost-effectiveness analysis; CUA, cost-utility analysis; DALY, disability-adjusted life-year; DPT, diphtheria, pertussis, tetanus; HMO, health maintenance organization; HPV, human papillomavirus; QALY, quality-adjusted life-year.

TABLE 78.4 Selected Values of the Cost-Effectiveness of Traditional Clinical Preventive Services

Intervention	Median Cost/QALY (US$)
IMMUNIZATIONS AND CHEMOPROPHYLAXIS	
Immunizations and vaccinations	1500
Pharmaceuticals for asymptomatic persons (e.g., hormone replacement)	13,000
SCREENING TESTS	
Cardiovascular disease	3300
Neoplasms	18,500
Osteoporosis screening and treatment	13,000
Screening blood donors against pathogens	355,000
Other disease screenings	11,500
COUNSELING	
HIV risk behavior	1200
Cardiovascular disease risk	74,000
Presurgical autologous blood donation	730,000

QALY, quality-adjusted life-year.

Am J Prev Med. *2000;19(1):15–23; and Tengs TO, Adams ME, Pliskin JS, et al. Five-hundred life-saving interventions and their cost-effectiveness.* Risk Anal. *1995;15(3):369–390.*

Routine Childhood Immunization

A single study evaluated the economic impact of the routine U.S. childhood immunization schedule, including DTaP (diphtheria and tetanus toxoids and acellular pertussis vaccine), Hib (*Haemophilus influenzae* type b) conjugate vaccine, IPV (inactivated poliovirus vaccine), MMR (measles, mumps, rubella) vaccine, hepatitis B vaccine, and varicella vaccine. Routine childhood immunization with the seven vaccines was evaluated as cost-saving, with a societal B:C ratio of 16.5.[19]

Many studies have addressed immunization in developing countries using the vaccines against six diseases initially used in the WHO's Expanded Programme on Immunization (EPI): bacillus Calmette-Guérin (BCG) for tuberculosis (TB), DTP (diphtheria and tetanus toxoids and whole-cell pertussis vaccine), OPV (oral poliovirus vaccine), and measles. They generally demonstrate low costs per immunized child and favorable B:C ratios.[20–24] Studies published in 2000 in Ethiopia, Morocco, Bangladesh, and Côte d'Ivoire indicated a total cost of less than US$25 to fully immunize a child with basic EPI vaccines.[25,26]

The Disease Control Priorities Project estimates that increased coverage from 70% to 79% with the traditional EPI program in South Asia would cost US$8 per DALY averted and that a second opportunity for measles vaccination would cost US$1 to US$5 per DALY averted in sub-Saharan Africa.[27,28]

Bacillus Calmette-Guérin

BCG vaccine primarily prevents disseminated TB in infants and young children, but has little, if any, impact on disease transmission. Development of highly cost-effective strategies in industrialized countries based on case-finding and treatment have made BCG vaccination less competitive as an effective intervention against TB. Because BCG vaccination complicates identification of TB exposure, many countries have discontinued routine BCG vaccination. A B:C ratio of 0.13 for revaccination of schoolchildren was calculated in Japan and represented a very low level of cost-effectiveness. It was subsequently found that the cost of treating a case of pediatric TB in Japan was much lower than the cost of preventing cases through vaccination.[29,30]

In developing countries with high rates of childhood TB, BCG vaccination of infants might represent a better investment. In 2006, a metaanalysis and assessment of the cost-effectiveness of BCG vaccination to prevent childhood tuberculous meningitis and miliary TB concluded that BCG vaccination of infants in Southeast Asia, sub-Saharan Africa, and the western Pacific would cost US$206 per year of healthy life gained.[31]

Diphtheria, Tetanus, and Pertussis and Components

Although tetanus toxoid may be used as a single antigen, diphtheria toxoid is only used in combination with tetanus toxoid, and pertussis vaccine has only been used in combination with the two toxoids, as DTP. Results from economic analyses of single-antigen tetanus toxoid varied among the administration of toxoid to women who were pregnant (or were of childbearing age) to prevent neonatal tetanus, the mass immunization of the general population, and primary or booster vaccination among the elderly. In Haiti, a B:C ratio of 9 for communitywide tetanus immunization was estimated, with the primary benefit resulting from reductions in the occurrence of neonatal tetanus.[32] By contrast, primary immunization of the elderly in Canada was estimated to cost US$810,000 per year of life gained.[33] In the United States, it was estimated that decennial tetanus toxoid boosters would cost US$143,138 per year of life saved compared to US$4527 per year of life saved by application of a single booster at age 65 years.[34] Still, the decennial booster approach has been estimated to prevent four times as many cases as the single booster.

In the combined DTP vaccine, reductions in the direct costs of diphtheria were essentially equal to reductions in pertussis direct costs; however, diphtheria was the major contributor to total savings in indirect costs.[35] Cost-benefit analyses of pertussis vaccine use in the United States consistently show an excess of benefits over costs, even in the face of a dramatically increasing cost of vaccine.[36,37] Newer studies concentrated on the marginal improvement made by the pertussis component of combination vaccines. In many industrialized countries, acellular pertussis vaccines have replaced whole-cell vaccines, which were known to be the component of the combined vaccine most likely to be associated with adverse events. Vaccines that include acellular components of pertussis (available as DTaP) are more expensive than whole-cell vaccines (DTP) and may have an increased waning immunity.[38] There are, therefore, value trade-offs—increased consumer confidence in safer vaccines with possible higher coverage versus the need for additional doses to address waning immunity. In Germany, vaccination with acellular vaccines would be as cost-saving as the use of whole-cell vaccine if coverage could be raised by 7.5%,[39] but could require increased doses for adolescents and adults.[38] The efficacy and prices of different acellular and whole-cell vaccines vary greatly in many populations, which would require specific cost-effectiveness evaluations.

There is a rising incidence of pertussis in the United States, with a high proportion of cases occurring in adolescents and adults. Because of the lower rates of adverse events associated with acellular pertussis vaccines, ACIP has recommended use of Tdap (tetanus and reduced-dose diphtheria toxoids and acellular pertussis vaccine) in adolescents and adults.[40] A study has found that immunizing adolescents 10 to 19 years of age in the United States would be cost-saving.[41] Similar results were found in Canada.[42] Other studies have not found adolescent vaccination to be cost-saving, but have found it to be a good investment nonetheless. A boosting dose at 8 years or adolescence in The Netherlands[43] or adolescence in the United States would cost approximately US$4000 to US$22,000 per QALY saved, assuming various parameters of vaccine cost, waning immunity and quality of life.[44,45] Other studies have shown cost savings for vaccination in adults[46] including those older than 65 years of age.[47]

As DTP has become the platform for other combinations, numerous studies have been performed on the benefits and costs of the convenience of combinations with other antigens (hepatitis B, Hib, inactivated poliomyelitis vaccines). It was estimated that US$90 million to US$150 million per year could be saved in the United States by using combined whole-cell DTP-Hib or DTP–hepatitis B–Hib vaccines compared to using the vaccines separately.[48]

Haemophilus influenzae Type B

The original Hib vaccines used purified capsular polysaccharides effective in toddlers but not in infants. Nevertheless, their use was shown to be economically justified.[49] These vaccines have been replaced by conjugated polysaccharide vaccines, which have almost eliminated disease incidence in all countries that have introduced them into routine schedules. Owing to the greater cost of these vaccines compared to historically used vaccines, their initial evaluation was based on a single dose at 18 months.[50] In 1991, a breakeven price of US$7 was determined when the Hib vaccine is coadministered with DTP.[51] Numerous other economic studies have shown that a routine pediatric schedule with primary doses and a booster were cost-effective in a number of industrialized countries with higher vaccine costs.[51–60] All these studies justified introducing Hib vaccine without necessarily also accounting for the pain and suffering from sequelae and death from a preventable disease.

Developing countries have usually lagged in the introduction of novel vaccines. However, a study in Chile from 1993 showed that a three-dose regimen without booster at a vaccine cost of US$1 had a B:C ratio of 1.7.[61] After a study in Africa demonstrated the utility of Hib vaccine to prevent acute respiratory infections with radiographic evidence of alveolar consolidation or pleural effusion,[62] greater interest arose for their widespread use in developing countries.

Because of vaccine cost, quantification of disease burden in economic terms may be necessary in middle- and low-income countries to demonstrate the utility of its incorporation into routine schedules. A number of economic studies show Hib vaccine to be cost-effective at a vaccine price under US$2 to US$3,[63–65,66] with the exception in western Asia, where disease burden had not been well defined.[67] For many developing countries, the financial considerations for the national purchase of Hib vaccines had been daunting. However, cost-effectiveness studies helped justify to GAVI the benefits of financial support of Hib vaccine for the poorest countries,[68] with disease reduction results similar to wealthier nations. Donor support and improved communication through international initiatives has stimulated demand for the vaccines and increased the number of competing manufacturers, thus increasing vaccine supply, with a subsequent decline in price, which makes this vaccine more affordable to a wider population.

Hepatitis A

Hepatitis A vaccines were licensed in the late 1990s. At first, the widest use in many industrialized countries was in travelers to countries with high endemicity and in those whose behavior put them at higher risk (e.g., men who have sex with men). One study also found that vaccinating food service workers against hepatitis A could cost the health system US$13,969 per life-year saved.[69] The cost-effectiveness of adolescent hepatitis A vaccination in the 10 states in the United States with the highest incidence rates was also studied, with a cost of US$13,722 per life-year saved.[69] In the United States, routine immunization of 1-year-olds was recommended in the 17 states that had the highest incidence of hepatitis A beginning in 1999. Implementation of these recommendations was associated with dramatic declines in the incidence of hepatitis A in these states. In 2006, ACIP recommended universal immunization of children 12 to 23 months of age throughout the United States.[70] Nationwide immunization of 1-year-old

children in the United States was estimated to cost US$173,000 per life-year gained and US$24,000 per QALY gained.[70] In Australia, universal hepatitis A vaccination for infants and/or adolescents was found to have comparable cost-effectiveness compared with other preventive strategies.[71]

One study analyzed the epidemiologic and economic impact of using combined hepatitides A/B vaccination in all 1- to 15-year-olds or all 11- to 15-year-olds in Germany.[72] Although the strategy of vaccinating 11- to 15-year-olds was more cost-effective, it would only prevent one-third as many cases of hepatitis A and one-half the number of cases of hepatitis B as vaccinating all 1- to 15-year-olds. It was concluded that although vaccination of 1- to 15-year-olds was initially more expensive, it was nonetheless more beneficial in terms of epidemiologic impact.

In Catalonia, it was calculated that universal vaccination of preadolescents with combined hepatitides A/B vaccine had a B:C ratio of 2.58 compared to the previous program using hepatitis B vaccine alone.[73] A study in Canada similarly found cost savings if the current practice of vaccinating 9- and 10-year-olds against hepatitis B alone was replaced with a combined hepatitides A/B vaccine.[74] In Argentina and Chile, hepatitis A vaccination of all children at 12 and 18 months of age was found to be cost-saving.[75,76]

Hepatitis B

Hepatitis B poses a particular issue in economic evaluation because the primary benefits of vaccination are the prevention of chronic liver disease and death from cirrhosis or cancer, all of which typically occur many years after the age of vaccination.

Hepatitis B vaccines were relatively expensive when first licensed in the 1980s, prompting many evaluations to identify their most efficient use. Earlier studies considered screening strategies for targeting vaccine use to subpopulations that were at greatest risk for infection, such as healthcare workers, injection-drug users, and persons who were at risk for sexually transmitted diseases.[77,78] The relative costs of vaccination and screening and the prevalence of hepatitis B virus infection in the specific subpopulations studied were the most important determinants of outcomes. Early studies also addressed prenatal screening to identify the most efficient approaches for screening and passive and active immunization.[79–82]

As the cost of vaccines decreased, studies began to address the costs, benefits, and effectiveness of routine vaccination of various age cohorts, including infants and adolescents. Because vaccination is most easily delivered through an existing infant vaccination infrastructure, universal infant vaccination with hepatitis B vaccine has become a common practice, and the WHO has recommended universal infant immunization against hepatitis B since 1992.[83] Many analyses that take into account variations of vaccine price and prevalence of infection in different countries have been conducted.[84–86] Although a number of initial studies in developed countries in Europe determined that infant vaccination would not be cost-beneficial given the declining incidence,[87] studies in the United States,[88] United Kingdom,[89,90] Canada,[91] Switzerland,[92] Israel,[93,94] and Australia[95] have all found that universal infant vaccination was cost-effective.

In settings with higher incidence and prevalence, hepatitis B vaccination is more valuable. It was estimated that the cost to avert a death from liver cancer in The Gambia would be US$1200 to US$1500, using a 6% discount rate.[96] A B:C ratio greater than 40 from routine infant immunization was calculated in Jinan City, China.[97] In India, the cost-effectiveness results of hepatitis B vaccine use ranged from 1 year of life saved for less than one GDP per capita to 1 QALY saved for two times GDP per capita.[98,99] One study estimated a cost of US$47 per DALY averted as a result of infant immunization in Mozambique.[100] Before GAVI was established, hepatitis B and Hib vaccines were estimated to have a global cost per life-year saved of US$29 to US$150, with great variation by income and economic groups of countries studied.[85]

The most cost-effective strategy is not necessarily the best choice to address a particular health problem if it deals only with a limited part of the problem. Williams and colleagues found that the most cost-efficient use of hepatitis B vaccine in the United Kingdom would be to concentrate on high-risk populations. However, that would have only a small impact on the overall hepatitis B disease burden compared with the impact of a more costly universal infant or adolescent immunization strategy.[82] Additionally, experience indicates that vaccination efforts focused on high-risk persons may be more difficult to implement and achieve lower coverage rates than efforts directed at the entire population.

The economic implications of the use of hepatitis B vaccine changed with its presentation in combination with other vaccines. The incremental cost-effectiveness from combined Hib–hepatitis B vaccines in the United States compared to separate vaccines has been estimated at US$17,700 per life-year saved.[101] One study found that using combined DTP–hepatitis B–Hib vaccines in the EPI would be cost-effective compared to using them separately.[102] Subsequent studies with lower-cost and combination vaccines greatly improved the cost-effectiveness.[86]

Human Papillomavirus

The HPV vaccine, another cancer-prevention vaccine, has a number of similarities to the hepatitis B vaccine. Both involve two types of latency periods, the time between vaccination and potential infection to others and the prolonged interval between infection and severe manifestations of disease. Each prevents a sexually transmitted infection that has the potential to cause malignancy later in life, as well as less-severe events that occur earlier. Because the largest benefits accrue to both the patient and to society decades after vaccine administration, decisions pertaining to the optimal age of vaccination and discount rates of future benefits greatly affect economic analyses.

Quadrivalent and bivalent HPV vaccines protect against serotypes that are associated with 70% of cervical cancers, with an additional 10% to 15% coverage from the more recent nine-valent vaccine. Because HPV vaccine is specific to certain papilloma types, it does not obviate the need for routine cervical cancer screening, which covers a broader range of abnormal cervical pathology and papilloma types. Consequently, HPV vaccination could reduce the overall cost and frequency of screening if disease onset is delayed or terminated prematurely.[103,104] By contrast, if HPV immunization programs reduce screening utilization, it may reduce the impact of that prevention program. Because screening programs are integral to cervical cancer prevention programs regardless of vaccine introduction, the full benefit of these programs for secondary prevention should be included in economic models, although a recent analysis suggests this seldom occurs.[105] Beyond the issue of screening, a recent analysis concluded that most existing economic studies captured only a fraction of generated values, with data frequently lacking for productivity and patient and caretaker time and costs.[106]

A study using the Papillomavirus Rapid Interface for Modeling and Economics (PRIME) assessed cost-effectiveness for prevention of cervical cancer through vaccinating 12-year-old girls across 179 countries.[107] Assuming lifelong protection, the authors reported for a cohort of 58 million children a

reduction globally of 690,000 cancer cases and 420,000 deaths at a cost of US$4 billion. This equated to a cost per DALY averted less than the GDP per person in 87% of countries. A systematic analysis of GAVI-eligible countries found that at a vaccination cost of US$2 per dose, HPV vaccine would be cost-effective for all the poorest nations.[108] Numerous studies at the national level using different models have used favorable economic analyses as an aid to justify the expenditure for HPV vaccination in public programs, most of which have focused on HPV vaccination in combination with screening among 11- to 12-year-old girls.[103,104,109–111,112–116]

While a consensus exists on the efficiency of HPV vaccination in combination with screening for young girls, other issues remain to be resolved. Some studies found that vaccination of males adds little to vaccinating women alone.[109,117,118] However, other studies incorporating all HPV-related diseases found that vaccination of males may be cost-effective even at current vaccine prices, particularly when female vaccination coverage is low.[119–121] The utility of providing catch-up vaccination to older females (such as those <30 years of age) remains unknown, with results dependent on the assumption that vaccine has some effect for nonnaïve women.[122–124] Immunization of nontraditional high-risk populations to prevent anal cancer, such as men who have sex with men, also remains poorly evaluated, with some studies suggesting such an approach may be cost-effective.[125] Lastly, the benefit of more than two doses has been questioned.[106]

Different groups have reached different policy conclusions from the available data. In the United States HPV vaccination is recommended for universal administration to girls and boys at 11 to 12 years of age, with catch-up vaccination recommended for females through age 26 years and males through age 21 years with a permissive recommendation for males through age 26 years.[126–128] The WHO recommends a first priority of achieving high coverage with two doses spaced 6 months apart among females 9 to 13 years of age, with possible extension to older adolescents and young women as a secondary step; the WHO does not consider vaccination of males a priority.[129]

Influenza

Despite the frequently changing antigenic structure of the influenza virus and recent studies that have challenged the overall protective effects of influenza vaccines in the elderly,[130,131] the high annual attack rates of influenza and death rates among the elderly have historically been cited to justify expenditures to provide annual influenza immunization to persons older than 65 years of age and persons who are chronically ill. Newer pharmacoeconomic studies have concentrated on the expansion of vaccination efforts to other target age groups.

One of the earliest influenza cost-analysis studies assessed the cost of annual vaccination.[132] U.S. Congressional interest through the Office of Technology Assessment supported studies to evaluate federal funding of influenza vaccine. Assessments supported vaccine use in persons older than 64 years of age and in high-risk groups,[133] although they called for better epidemiologic data on transmission. In Australia, influenza vaccination was deemed a cost-effective intervention for healthy populations 45 to 64 years of age.[134]

The required annual vaccination needed to control disease caused by the dynamic evolution of influenza viruses has continuously challenged public healthcare systems. Economic analyses have been performed to assess administrative costs of annual programs that target various age groups and working populations. These analyses are undertaken from numerous perspectives, such as that of the healthcare system, society, or the employer. Newer studies have concentrated on recommendations that have expanded target groups to the pediatric population.

Because children are the primary force of transmission of influenza, increased attention has been placed on the desirability of vaccinating children both to protect them and indirectly protect high-risk groups, such as the elderly. Studies have focused on the vaccination of children 6 to 24 months of age. Vaccination of high-risk children was modeled to be cost-saving[135] compared to indiscriminate vaccination.[136,137] Vaccination of other age target groups modeled the cost-benefit analysis at 6 to 23 months, 6 to 59 months, and 5 to 14 years at various proportions of high-risk conditions.[138] The targeted vaccination of high-risk groups was universally cost-saving. Breakeven costs between US$45 and US$48 per administered dose were found for vaccinating the three age cohorts when these groups contained 10% high-risk children. In 2010, ACIP recommended annual influenza immunization of all people in the United States 6 months of age and older. Cost-effectiveness analysis shows this strategy costs twice as much as a targeted program but reduces influenza-related healthcare services by 52%.[139]

Influenza is unique among the vaccine-preventable diseases in that it requires annual revaccination; therefore, administration costs are highly relevant to economic analyses. Programmatic considerations in school-based programs greatly influenced the potential impact of group-based vaccination of healthy children; in school-based settings, US$35 per child was saved versus US$4 for individual-initiated programs from individual office visits.[140] These studies did not account for the indirect effects.

With the advent of health maintenance organizations, there has been a greater demand to justify vaccination programs from the provider's perspective. Although the effectiveness of vaccination programs to prevent hospitalizations for pneumonia and influenza is only 30%, vaccinating elderly persons saved US$1.10 for each person vaccinated. Furthermore, when groups were stratified, the net cost was only US$4.82 per vaccination for non–high-risk elderly persons, a negligible amount when pain and suffering are also taken into account.[141] Influenza vaccination in the elderly was found to be cost-saving when extended to other health outcomes, such as all hospitalized illness and mortality.[142,143] Although vaccination of elderly persons with high-risk conditions was found to be cost-saving, results for groups with fewer chronic conditions were more equivocal.[144,145] The paucity of randomized, controlled trials of vaccine efficacy in the elderly require cautious interpretation of these findings.

Because most of the estimated annual US$71.3 to US$166 billion (2003) in expenditures owing to influenza is attributable to lost productivity,[146] many economic studies on influenza control concentrate on younger, healthy workers. An average number of workdays missed owing to influenza-like illness by workers with work loss was valued at US$137 per person.[147] Algorithms that incorporate disease epidemiology, worker productivity, and economic cost allow the economic evaluation of influenza vaccination.[147] One study found a breakeven vaccination cost of US$16 when time lost from work exceeded 2.4 days per episode of influenza.[148] Some programs found that routine annual vaccination of healthy adults was cost-saving from the employee and employer perspectives,[149,150] but estimates are sensitive to many assumptions[151] as well as to the specificity and sensitivity of measured outcomes.[152] Vaccination was not always cost-saving, especially in seasons where the circulating virus differed from the vaccine strain.[153] In the United Kingdom, annual incidence rates as low as 2% still provided economic justification for influenza vaccination,[154] and in The Netherlands, many modeled scenarios

showed savings.[155] However, reviews of studies highlight the disparities of findings of vaccinating the healthy adult population, demonstrating the sensitivity of results to numerous assumptions.[156]

Influenza vaccine was also found to be cost-saving in a variety of settings in middle-income countries, including South Africa (seniors and healthy working adults),[157] Brazil (workers),[158] Mexico (elderly),[159] and Thailand (elderly),[160,161] but not in Hong Kong.[162]

The licensure of live attenuated influenza vaccines has led to their economic evaluation in children[163] especially as the cost differential with other influenza vaccines decreased.[164] For young healthy adults, the break-even cost of live attenuated influenza vaccines and its administration was between US$25.72 and US$58.92.[165]

The WHO has identified pregnant women as the highest priority target group for influenza immunization, based largely on studies in developed countries demonstrating an increased risk of hospitalization following infection with pandemic A(H1N1).[166] An economic analysis of vaccinating pregnant women against influenza in the United Kingdom showed this strategy would cost approximately US$35,000 per QALY gained with variation depending on whether vaccine provided protection over more than one season, whether vaccine protected infants as well as mothers, vaccine efficacy, and costs of hospitalization, outpatient visits, vaccine, and vaccine administration.[167] A Canadian study found vaccine to be cost-saving when targeted to pregnant women with comorbidities and cost-effective if delivered universally to pregnant women; compared to the UK study, an additional important factor in determining cost-effectiveness was duration of illness.[168]

A randomized clinical trial in Bangladesh found that influenza vaccine of pregnant women prevented a substantial amount of febrile respiratory illness and low birth weight birth among their infants.[169,170] A subsequent study in South Africa found an impact on mild illness, particularly among mother–infant pairs where the mother had HIV infection, but no impact on severe disease or birth outcomes.[171] Using reduction in infant outcomes to drive the economic argument for maternal immunization in developing country settings will depend on impact against severe outcomes rather than solely mild respiratory infection, the programmatic cost of delivering vaccine during pregnancy, and the impact of seasonality and trimester of vaccine receipt on vaccine efficacy.

Measles, Mumps, and Rubella

Measles, mumps, and rubella vaccines as individual antigens have repeatedly been shown to be cost-saving when administered to young children. The B:C ratio rises even higher when the vaccines are administered in combination because the costs of administration are substantially lower. For measles vaccine, the B:C ratio for a single dose is high; of particular interest, however, is whether the additional benefits derived from a second dose also outweigh the additional costs.

A 2004 study of a two-dose MMR program in the United States found it to be highly cost-saving, with B:C ratios of 14.2 and 26.0 for direct cost and societal perspectives, respectively. The incremental B:C ratio of the second dose showed ratios of 0.31 and 0.49, respectively.[172]

Measles is a major cause of death in developing countries, causing an estimated 139,300 deaths globally in 2010, with India accounting for 47% of the estimated mortality and the WHO African region for an estimated 36%.[173] In the Ivory Coast, the cost per death averted in 1986 was found to be US$479.[174] A 1994 study estimated the global cost of US$17 per DALY averted, an excellent buy.[175] Although a single dose of measles vaccine provides protection to approximately 80% to 95% of young children in developing countries, experience has shown that two doses are needed to provide the level of population immunity required to have a dramatic impact on measles mortality.[176] The second dose can be administered either by adding a second dose to the routine immunization schedule or by carrying out periodic campaigns (supplemental immunization activities) that can reach children who received the first dose as well as children who were missed by the routine immunization system. A study comparing the cost-effectiveness of supplementary immunization for measles in India concluded that supplementary immunization activities for measles are cost-effective but could not be considered superior to a second dose of measles in routine immunization.[177]

With the cost-effectiveness of measles, mumps, and rubella vaccines well established, attention is shifting to considerations of the cost-effectiveness of elimination or eradication strategies. In the English-speaking Caribbean, estimates have been made of the B:C ratio for a rubella-elimination initiative on top of the routine MMR immunization of 1 year olds. B:C ratios of 4.7 for Barbados,[178] 38.8 for Guyana,[179] and 13.3 for the entire Caribbean[180] have been calculated, with a cost of US$2900 per case of congenital rubella syndrome prevented. Analyses of the cost-effectiveness of global measles eradication have shown that eradication of measles would be a good economic investment; eradication would be more cost-effective than maintaining a very high level of measles control.[181]

Meningococcal Vaccines

Disease caused by *Neisseria meningitidis* historically has been addressed using polysaccharide vaccines against the four major serogroups A, C, Y, and W. With few exceptions, polysaccharide vaccines have not been used in routine schedules owing to perceived limitations of the duration of effectiveness, especially when administered during infancy, and thus this review will focus on newer polysaccharide-protein conjugate vaccines as well as subcapsular vaccines for serogroup B.

Because most vaccines are serogroup specific, the key epidemiologic feature for meningococcal vaccine is serogroup prevalence, which can differ dramatically. For example, serogroup A infections have vanished from developed countries without routine vaccination and several populations in Asia that have routinely used polysaccharide vaccines in children.[182,183] By contrast, the African meningitis belt has experienced seasonal endemic serogroup A disease combined with massive regional outbreaks every decade or so.[184] Moreover this region of Africa has experienced large outbreaks of X,[185] W,[186] and for the first time during 2015 in Niger serogroup C.

Studies have reviewed the cost-effectiveness of various strategies including routine coverage with monovalent meningococcal C[187–191] or tetravalent meningococcal ACYW conjugate vaccines.[192] In general, analyses were sensitive to age-specific incidence of disease, and therefore the cost-effectiveness is based on assumptions of the duration of immunity from the different formulations of these vaccines and the potential impact on the ecology of the different *N. meningitidis* serogroups. Monovalent serogroup A conjugate vaccine has successfully eliminated serogroup A outbreaks in the meningitis belt[193]; economic studies have not been done based on the assumption that control of massive disruptive epidemics in one of the world's poorest areas justified vaccine use.

The high societal fear of meningococcal meningitis has led to the development of serogroup C–specific conjugate vaccines for use in infancy and a tetravalent conjugate vaccine. Although the incidence of serogroup C disease is relatively

low, a number of nations have adopted routine vaccination, partially based on economic studies.[191] Specific serogroup C conjugate vaccines were introduced into the routine infant immunization scheme in the United Kingdom, with subsequent published analyses of their cost-effectiveness in various epidemiologic scenarios.[187] A review was conducted on the role of economic evaluations on decisions about the introduction of the conjugate vaccines in 21 countries.[191] A positive correlation was found between reported incidence rates of serogroup C meningococcal disease and the performance of economic evaluations. In The Netherlands, routine childhood vaccination at 14 months was estimated to cost €2200 to €2400 per life-year gained, and up to €17,700 per-life-year for catch-up compared to €147,000 for a vaccination program implemented during infancy.[190] In Canada, a three-dose program was modeled as most-effective, and a one-dose program with a vaccine cost of C$50 yielded US$23,000 per life-year gained.[189]

With the advent of the tetravalent meningococcal vaccine against types A, C, Y and W disease, there have been a number of assessments of its utility. Cost-effectiveness depends on local epidemiologic conditions. For the United States, for example, a catch-up and routine vaccination program for adolescents would prevent 48% of disease over a 10-year period at a societal cost of US$223,000 per case averted, approximately US$2.6 million per death prevented, and approximately US$88,000 per QALY at a cost per vaccinee of US$83.[194]

The economic case for use of serogroup B subcapsular vaccines remains controversial. A study from England concluded an infant vaccination program would be cost-effective at a cost of approximately US$15 per dose, rising to US$25 per dose assuming substantial impact on carriage as well as disease.[195] Despite this, the UK Joint Committee on Vaccination and Immunisation originally concluded four-valent serogroup B vaccine would not be cost-effective at any vaccine price.[196] This position was criticized as overemphasizing economic analyses rather than reduction in long-term suffering and death,[197,198] and was subsequently modified based on results using different model assumptions.[199] A later evaluation from Canada concluded an infant serogroup B immunization program was unlikely to be economically attractive.[200]

Pneumococcal Vaccines

As with influenza vaccination, the use of pneumococcal polysaccharide vaccine for the elderly and chronically ill has demonstrated a reasonable cost per QALY gained.[201–212] Additional assessments have also been made for children in developing countries[213] and healthy adults in the military.[214] Given different levels of age-specific incidence in healthy adults, one study found that this vaccine would be cost-effective at the minimal levels of vaccine effectiveness against pneumonia of 30% and 71% for ages 35 and 22 years, respectively.[215] With the advent of conjugate vaccines, more recent studies have concentrated on the cost-effectiveness of routine vaccination of pediatric populations.

A prelicensure study on the cost-effectiveness of the original seven-valent conjugate vaccine established a breakeven vaccine cost of US$46, where the expected treatment savings from routine use would offset the financial commitment to vaccinate the U.S. childhood population.[216] The manufacturer, who had a monopoly at the time, offered this vaccine to the public sector at this price. Although it was cost-effective for the United States at this cost, the vaccine was considered prohibitively expensive for many other populations in need. Likewise, at this cost, vaccination in other developed countries, such as The Netherlands,[217] Australia,[218] and Canada (with a B:C ratio of 0.57), was not cost-effective.[219] Given various economies and incidence rates in different populations, pneumococcal conjugate vaccine was considered to be cost-effective for Switzerland,[220] Spain,[221] the United Kingdom,[222] and Germany,[223] though often at the higher limits. In one review, cost-effectiveness ranged from US$26,000 to US$66,000 per QALY.[224]

Assessments that account for reduced transmission of the pathogen through herd effects provide a more favorable cost-effectiveness ratio.[225] Several reviews assessed the sensitivity of cost-effectiveness, mainly because of vaccine cost and whether societal perspectives were included.[226] The relatively high cost of this vaccine has led to the analysis of alternative strategies, such as reduced number of doses,[227] to justify its use. Nongovernmental organizations and public and private partnerships continue to work on demonstrating the utility of this vaccine for the public sector and to help with tiered pricing mechanisms so that a cost-effective intervention is also financially feasible for lower-income populations.

An example of the differences of the cost-effectiveness of the direct and indirect impact of vaccination was shown in a particular setting assessing the seven-valent pneumococcal conjugate vaccine. The direct cost was estimated at US$201,000 per life-year saved, and the indirect benefit of reduction of invasive pulmonary disease in the older population reduced this cost per life-year saved to US$10,400.[228,229]

The cost-effectiveness for this vaccine for resource-poor countries is more ambiguous. One analysis for The Gambia estimated that at a vaccine price of US$3.50 per dose, seven-valent pneumococcal conjugate vaccine would save a life at approximately threefold the national GDP, with uncertainty about type-specific circulating strains, replacement serotypes, and herd-immunity effects.[230] With the advent of additional valent vaccines and dynamic pricing and serotype distributions, the utility of any of these vaccine formulations should be assessed at the local level.

Poliomyelitis

A number of past analyses have favored the global eradication of polio, but they were based on assumptions that are no longer valid.[231,232] One study models the economic impact of various strategies and concludes that eradication, defined as the interruption of wild poliovirus transmission globally, is less costly and more effective than continued control.[233,234] However, the scenarios favoring eradication, defined as the cessation of wild-type virus transmission, assumed that during the posteradication period, vaccination with OPV could cease without replacement by IPV. This concept has been seriously challenged,[235–239] given the likelihood that poliomyelitis can reemerge.[240]

Taking into account the need for continued use of polio vaccines to ensure long-term control or sustained eradication, the CDC estimates the cost for eradication strategies is on the order of US$20 billion to US$23 billion through 2020 based on eradication of wild poliovirus by 2010.[241] One paper estimates a cost of US$31 billion,[242] given the generally accepted requirement to use currently supply-limited IPV for the foreseeable future,[238] but the cost would be offset by the savings from reducing the incidence of poliomyelitis from 1988 to 2035 compared to the preeradication era. Costs per DALY saved range from US$210 to US$1000 for low-income and low-middle income countries, respectively, to cost savings for upper-middle-income countries.

Economic assessments have been conducted on switching from OPV to IPV as natural disease is eliminated in populations. In the United States, an estimated B:C ratio of 6.1 was found for an OPV-only schedule, and a four-dose sequential IPV-OPV schedule had a ratio of 5.7.[35] One study found that

changing from an OPV-only schedule to an IPV-only schedule or a sequential IPV-OPV schedule would not be cost beneficial; the cost per case of vaccine-associated paralytic poliomyelitis averted was estimated at US$3.0 million and US$3.1 million for these options, respectively. The fact that the United States and other countries opted for IPV use with knowledge of these studies indicates the investment that the U.S. public health programs are willing to expend to avoid preventable adverse events in publicly mandated vaccine programs.[243]

A study found that introducing IPV into the Australian immunization schedule was not likely to be cost-effective unless it came in a combined vaccine with the IPV component price less than US$10.[244] Another analysis compared the cost-effectiveness of maintaining routine and intensive OPV use after eradication with that of switching to IPV use. It found that considering current costs of routine and intensive OPV use, adopting IPV to replace OPV will not increase the total global cost.[245]

As part of the strategy to eradicate polio, the WHO has recommended all countries introduce at least a single dose of IPV in the routine infant EPI schedule, followed by a switch from trivalent, serotype-2 containing OPV to a bivalent vaccine without OPV. Because of the widespread commitment to global eradication, this decision was made in the absence of short-term considerations of cost-effectiveness to individual countries and to the need of continued use of IPV for at least some unspecified period following eradication to guarantee sustained eradication.

Rotavirus

Rotavirus infection is nearly universal in infants, and it is a major cause of diarrhea around the world. Rotavirus vaccines have been licensed and recommended for universal use in the United States.[246] Earlier studies have found that rotavirus immunization in the United States would be a good investment, although not necessarily cost-saving.[247,248] A CDC study found that from a societal perspective, rotavirus vaccination would likely be cost-effective at a total cost per child of up to US$156 (approximately US$42/dose). At a cost of more than US$268 per child (approximately US$79/dose), a vaccination program would most likely have a net cost to society.[247]

A study from Finland found that the break-even cost for vaccine was equivalent to US$19.60.[249] A similar study from Australia estimated that rotavirus vaccination would be cost-neutral to the healthcare system at a vaccine price of US$19 and cost-neutral to society at a vaccine price of US$26.[250] In Vietnam, it was concluded that universal vaccination of infants at a vaccine cost less than US$7.26 per dose would be considered cost-effective by World Bank standards for low-income countries (i.e., <US$140/DALY).[251] The recent licensure of a low cost vaccine from Indian manufacturers holds promise for higher volume uptake at lower costs.[252]

The ubiquitous nature of rotavirus and high rates of medical expenditures for treatment might justify higher premiums for this vaccine where it is affordable and where the public sector is responsible for healthcare costs.[251] Economic considerations for use of this vaccine should take into account the lower efficacy and higher incidence of severe outcomes found in resource-poor settings.

Varicella

Varicella vaccination has generally not been shown to be cost-saving when only direct medical costs are considered. However, it is clearly cost-saving in developed countries when the indirect costs of lost income from caregivers are included in the analysis. Before licensure of the vaccine in the United States, a B:C ratio of 6.9 was estimated with a hypothetical vaccine, with most of the savings from indirect costs averted.[253] Another study estimated a B:C ratio of 2.0 for routine vaccination in the United States.[254] In the United States the B:C ratio was estimated to be 5.0, and the medical cost saved per life-year was around US$2500.[255] Scuffham and colleagues[256] estimated a B:C ratio of 2.8 for routine varicella vaccination in New Zealand; in Australia, routine varicella vaccination was not found to be cost-saving, considering direct medical costs alone. A B:C ratio of 1.6 was calculated for universal immunization of 15 month olds in Spain (including indirect costs).[257]

Although the varicella vaccine is effective, its effectiveness is not as high (or potentially as durable) as desired. Consequently, the ACIP has recommended that the immunization schedule include two doses of varicella-containing vaccine.[258]

Varicella vaccination of healthcare workers has also been studied. One study analyzed the experience with varicella exposures among hospital healthcare workers and found costs associated with furloughing susceptible workers and employing replacement workers were significantly higher than the cost to vaccinate all susceptible workers (B:C ratio = 3.0).[259] Vaccination of potentially susceptible healthcare workers could potentially result in net cost savings of US$59 per person.[260]

The long-term impact of universal varicella vaccination on the subsequent occurrence of zoster (shingles) is not clear. Some estimate an increase in zoster as a result of a decline in exogenous boosting of varicella zoster antibody titers owing to reduced circulation of varicella virus, although there might be a subsequent decrease in incidence of zoster once the vaccinated cohort ages.[261] A higher-titer varicella vaccine to prevent zoster (shingles) is effective,[262] has been licensed, and is now recommended for use in all persons 60 years or older in the United States.[263] A published economic analysis estimated a cost of less than US$100,000 per QALY gained if the unit cost of vaccination is less than US$200, the vaccine is administered before the age of 70 years, and vaccine efficacy lasts at least 30 years.[264]

Varicella vaccine has been combined with MMR vaccine as MMRV, which is widely used in the United States, presumably adding to its cost-effectiveness. The cost-effectiveness of a two-dose schedule of MMRV in young children compared to a single dose of varicella vaccine in adolescents in Germany showed it to be cost-saving.[265] However, evidence has shown that recipients of MMRV have a higher incidence of postvaccination febrile seizures than those who receive MMR and varicella separately (at the same visit) and has led the ACIP to suspend its preference for use of the combined MMRV vaccine for the first dose of vaccines.[266]

Malaria

While not currently licensed, the RTS,S vaccine against *Plasmodium falciparum* has completed Phase III studies, including a 4-year follow-up,[267–269] and as of July 2015 had received a positive scientific opinion from the European Medicines Agency.[270] For clinical malaria, and among children vaccinated at 5 to 17 months of age, these studies demonstrated a 36% overall reduction (range: 22% to 75% by transmission setting) with a booster and 28% without a booster (range: 18% to 66%); this corresponded to a reduction in cases of 1.8 and 1.4 per child vaccinated with and without a booster. Impact on severe disease was less, and overall was 0 at 48 months without a booster. Waning immunity occurred by 4 years in the absence of a booster. The latter issue is particularly problematic: a study from the Malawi RTS,S study site assessed cost-effectiveness relative to long-lasting insecticide-treated nets and concluded that vaccine would be highly cost-effective

across a wide range of assumptions, but was sensitive to immune duration.[271] Other considerations for economic analyses of malaria vaccines will include further assessment of earlier safety signals, optimal age of vaccination, and relative benefit of vaccine when integrated with other interventions with differing levels of coverage.[272]

Dengue

Two Phase III studies of a novel dengue vaccine have been completed, in Asia[273] Latin America.[274] Both of these studies found moderate vaccine efficacy against all virologically confirmed disease that was lowest for serotype 2, a large vaccine preventable disease incidence for mild disease, and a smaller vaccine preventable disease incidence—despite higher vaccine efficacy—for dengue hospitalization as the latter was relatively rare in the study population. Analyses conducted in advance of these pivotal results have shown that vaccine is likely to be cost-effective and in some circumstances cost-saving at vaccine costs up to approximately US$300[275–277] largely as a consequence of the massive costs of outbreaks.[278] Factors found to influence results include immune duration, vaccine cost, number of doses, vaccine efficacy based on serotype distribution in different settings, and the definition and accounting for costs of dengue outbreaks.

Specialized Vaccines

Adenovirus

Oral adenovirus vaccines had been used for 25 years in special populations (e.g., military recruits) before production was discontinued owing to regulatory issues relative to the manufacturer. Adenoviruses have historically contributed to the high burden of respiratory infections among military recruits. The resultant cessation of vaccination and the depletion of vaccine stores in 1999 led to a resurgence of adenovirus types 4 and 7 among military recruits.[279,280] This vaccine is an example of the fragility of vaccine supply and the economic situation of a single large purchaser (the U.S. military) and a single manufacturer. When commitments from the military to help update the manufacturer's production facilities could not be guaranteed, production was suspended, resulting in the need for costly expenditures to relicense the product. Had appropriate economic studies been done before this vaccine was discontinued, capital investments might have been justified to prevent cessation of production.

Studies have set out to examine the costs and benefits associated with reacquiring and using vaccines among military recruits, including the alteration of the vaccination schedule.[281] It was estimated that terminating the program would cost US$26.4 million and result in 12,370 cases of adenoviral acute respiratory disease. It was concluded that a seasonal program would be most cost-effective, preventing 7800 cases of acute respiratory disease and saving US$16.1 million in direct and indirect costs.[281] A similar study found that a seasonal vaccine program among naval recruits could save US$2.8 million and avert 4015 cases compared to a year-round program, which would prevent 4555 cases of acute respiratory disease and save the military US$2.6 million per year.[282] Economic reevaluations have reinforced the utility of adenovirus vaccines despite the increased funding that was needed to resume production.

Anthrax

Anthrax vaccines have long been used among humans and livestock in other countries, and in 1970, the U.S. Food and Drug Administration licensed the anthrax vaccine adsorbed (AVA; trade name BioThrax) for human use. In 1997, all military personnel were scheduled to receive anthrax vaccine. After anthrax bioweapon scares in 2001, ACIP supplemented their previous recommendations on anthrax vaccine use for the U.S. civilian population. Individuals at risk for repeated exposure to *Bacillus anthracis* were recommended to be given priority for preexposure vaccination. Despite being deemed to be safe and efficacious,[283] the use of anthrax vaccines and other prophylaxis and treatment strategies to protect against bioterrorist attacks remains controversial. Because the primary vaccination series entails six doses, postexposure vaccination does not seem feasible.

Two studies have set out to address the cost-effectiveness of various prevention and treatment strategies to reduce the mortality associated with a potential attack of aerosolized anthrax. One study found that in the case of an actual anthrax attack, three postexposure doses of anthrax vaccine and antibiotic therapy is the most effective strategy (0.33 life-year gained per person) and the cheapest strategy (US$355 saved per person) compared to vaccination alone.[284] The study concluded that in a preexposure or preattack scenario, a no-vaccination strategy would be cheaper than a vaccination scheme and would also provide marginally higher QALYs gained per person owing to the potential adverse effects of the vaccine.[284] These estimates are based on the probabilities of attack (1%) and the probability of exposure in the event of an attack (10%). The second study found that if an exposure was unlikely to occur or was small in scale, neither a vaccination nor an emergency surveillance and response program would be cost-effective.[245] Only if an attack was probable would the emergency surveillance and response system be more cost-effective than vaccination (US$73 versus US$29,600 per life-year saved).[285]

Cholera

The earliest economic studies regarding vaccines against cholera were geared toward their use as a preventive measure for travelers.[286] With the rise of endemic areas in Latin America during the 1990s, investigators have tried to justify the utility of routine vaccines against cholera by factoring in the potential prevention of macroeconomic trade disruptions.[287]

As in other vaccines against enteric diseases, the utility of cholera vaccines must be judged relative to other interventions designed to prevent and mitigate the effects of enteric infections, particularly improved water and sanitation and the use of oral rehydration therapy. A comprehensive CEA of cholera vaccination, which provided estimates for study sites in Mozambique, India, Bangladesh, and Indonesia, found that when the known immunological herd effect of cholera vaccination[288] is taken into account, all immunization programs in all four countries would be cost-effective.[289] Cholera outbreaks are difficult to predict and recent results emphasize the importance of incidence—as well as vaccine cost—in determining cost-effectiveness.[290] These results have been used to justify creation of a vaccine stockpile for outbreak control, but this stockpile is hampered by lack of a clear vaccination strategy.

Japanese Encephalitis

Japanese encephalitis is a mosquito-borne viral disease that is endemic throughout Asia and occasionally occurs as an epidemic. The death-to-case ratio in children is estimated at 10%; 37% of survivors can manifest subsequent neurologic disability. A live attenuated vaccine has been developed, and its impact as a routine childhood immunization in Bali, Indonesia, has been assessed. The conclusion was that routine vaccination of children in this setting was highly cost-effective.[291]

The Bill & Melinda Gates Foundation has invested in the development of a number of vaccines against arboviruses including Japanese encephalitis, dengue, and yellow fever. Furthermore, an inactivated Japanese encephalitis vaccine is available for travelers.

Typhoid

Three formulations of typhoid vaccine now exist: a parenteral Vi polysaccharide vaccine, Vi-conjugate, and an attenuated live oral vaccine. None have gained wide acceptance for community-based administration, perhaps owing to the underestimation of the burden of typhoid[292] attributable to factors such as limited healthcare access in high-burden communities, poor laboratory diagnostics, and failure to appreciate long-term sequelae. A cost-effectiveness study of use of Vi vaccination of all children 2 to 15 years of age in Kolkata, India; Karachi, Pakistan; North Jakarta, Indonesia; and Hue, Vietnam, found that the cost per DALY averted would qualify such vaccination as highly cost-effective in Kolkata, Karachi, and North Jakarta, but not in Hue, where the incidence of typhoid is substantially lower.[293] The newest Vi-conjugate holds the promise of offering long-term protection from infancy, and manufacturers are marketing this vaccine in Asia. A study in Uganda reported vaccine would be highly cost-effective when used in a typhoid endemic area.[294]

Yellow Fever

Live attenuated yellow fever vaccine has been available for decades and has been recommended for routine universal vaccination in yellow fever–endemic zones as well as for emergency outbreak control. A CEA for Nigeria indicated that for a single moderate-size epidemic, the cost-effectiveness of emergency mass immunization was twofold higher than that of a cumulative routine immunization (EPI) program. However, the EPI approach was more effective in preventing cases and deaths. In settings of epidemics occurring over successive years, the EPI approach was more cost-effective than emergency mass vaccination.[295]

Vaccines in Development

HIV/AIDS

The HIV/AIDS pandemic has been recognized as one of the largest public health threats over the last 30 years. Behavioral modification approaches and highly active antiretroviral therapies, along with other therapeutic modalities for the treatment of opportunistic infections, have contributed to primary and secondary prevention, but these are suboptimal and relatively costly. Therefore, the value of alternative means of control has become increasingly important, particularly the development of a preventive or therapeutic vaccine. As the quest for a vaccine against HIV/AIDS is pursued, increased attention will be given to the potential cost-effectiveness and financing of vaccines relative to and in conjunction with other control measures.[296] Economic analyses and estimations of effectiveness through modeling efforts are crucial in helping manufacturers and public health policy makers plan for market demand and for increased production capacity early in the development cycle.

Group B Streptococcus

Group B *Streptococcus* is a major cause of neonatal sepsis, pneumonia, and meningitis and thus in principle would be a good candidate for maternal immunization. A cost-effectiveness evaluation of a hypothetical group B *Streptococcus* vaccine in the United States found that immunization added to screening might prevent 899 cases and 35 deaths annually at a cost of US$91,321 per QALY gained.[297] In South Africa, risk factor based intrapartum antibiotic prophylaxis was estimated to prevent only 10% of cases, a figure that rose to 48% with the addition of a hypothetical vaccine.[298] Sensitivity analyses for these studies showed the importance of disease incidence, vaccine efficacy, and vaccine cost in determining the results.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a major cause of acute respiratory infectious disease and hospitalization in the pediatric and elderly population. However, documented case-fatality ratios are relatively low[299]; this latter feature may occur because critically ill children are less likely to receive diagnostic testing, thus underestimating mortality rates. An economic assessment of a hypothetical RSV vaccine emphasized the importance of mortality rates in determining economic utility.[300] In The Netherlands, and despite an estimation of 1.5 annual deaths averted, RSV vaccination in infants might be cost-effective but will depend on schedules, efficacy, inclusion of out-of-pocket expenses, and vaccine cost.[301] Similarly, two studies evaluated the potential utility of immunization programs targeting the elderly and both found that under some circumstances this might be an economically reasonable approach but depended on model values for RSV-associated mortality, life expectancy, determination of QALYs in the elderly population, and duration of immunity.[302,303]

OTHER ECONOMIC CONSIDERATIONS

Other economic considerations include the price of vaccines, their affordability, and the value placed on them. Traditional EPI vaccines have been relatively inexpensive in developed and in developing countries, reflecting lower prices of research, development, and production in the past and the fact that research and development costs have already been recovered. Newer vaccines are more expensive because of increased costs of development and production and of intellectual property rights. The question of how to make these vaccines available in developing countries has been addressed by a number of strategies, including tiered pricing and the creation of the GAVI, which provides grants to developing countries to purchase and administer newer vaccines. Seventy-two countries were originally eligible for GAVI support based on their annual per capita income of less than US$1000/year. Beginning in 2011, as a result of improvements in income, eligibility criteria were revised to require an annual per capita income of less than US$1500/year; 56 countries are now eligible. As of 2017, GAVI is supporting 12 vaccines.

The ultimate goal is for all countries to place a high enough value on vaccines to give them priority within their national budgets. This is particularly problematic as per capita public expenditure on health may be less than US$20/year, which was true in 13 countries in 2007.[304] Although the cost of fully immunizing all the children in the world will become increasingly difficult as the result of a mounting number of more-expensive vaccines, it remains an excellent investment of funding resources.[68]

CONCLUSION

Quantitative policy analysis techniques can support rational decision making in immunization by explicitly stating assumptions, costs, and benefits of different strategies and allowing, through sensitivity analysis, an indication of the

most important determinants of program outcomes. They are important tools to help evaluate competing options. When conducted appropriately, they help elucidate values, summarize data and knowledge gaps, and indicate the relative importance of epidemiologic and economic assumptions. Nevertheless, they are only tools and should not be the sole basis for making decisions about immunization policies or programs. Still, evidence from economic analyses have demonstrated immunizations as among the best investments in global health.

79 Regulation and Testing of Vaccines

Marion F. Gruber and Valerie B. Marshall

Vaccines are one of the most significant achievements of science and public health. As a result of successful vaccination programs and campaigns, many vaccine-preventable diseases are now uncommon in the United States. Vaccines for prevention of infectious diseases are regulated by the U.S. Food and Drug Administration (FDA) and the legal framework for regulation is derived from Section 351 of the Public Health Service Act and from certain sections of the federal Food, Drug, and Cosmetic Act (FD&C Act).[1,2] The FD&C Act defines drugs, in part, by their intended use as "articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease."[2] Thus, vaccines are a unique class of pharmaceutical products that meet the statutory definition of both a drug and biological product. Prophylactic vaccines differ from many other drugs and biologicals primarily in how they are administered to a large population, in particular, young healthy people to prevent rather than treat disease, their mechanism of action, and their risk/benefit profile. Although subject to the same regulations as other biological products, vaccines are inherently more difficult to develop, characterize, and manufacture than most pharmaceutical products. Current U.S. licensed vaccines are listed in Tables 79.1 and 79.2.

HISTORICAL PERSPECTIVE

Regulation of biologics has historically been initiated in response to issues of safety. Over time, legislative authorities have evolved to strengthen and modernize the regulation of vaccines and other biologics. Prior to 1902, manufacturing and product standards for biologics were not federally mandated. However, in 1902, the U.S. Congress passed an act to regulate the sale of viruses, serums, toxins, and analogous products (later referred to as the Biologics Control Act) following the deaths of 20 children who received contaminated products.[3] This Act authorized the Hygienic Laboratory of the Public Health and Marine Hospital Service to issue regulations that governed all aspects of commercial production of vaccines, serums, toxin, and antitoxins and similar products with the objective of ensuring their safety and purity. The regulations under this legislation contained the primary concepts for regulation of biologicals, such as labeling, mandatory facility inspections, and batch-certification guidelines. In 1930, the Hygienic Laboratory was reorganized, expanded, and renamed the National Institutes of Health (NIH).

In 1944, Congress recodified the 1902 Biologics Control Act as part of the U.S. Public Health Service Act (PHS Act) of 1944.[4] The PHS Act incorporated the 1902 Biologics Control Act into Section 351 of the PHS Act (42 U.S.C. 262). As with the 1902 Act, the 1944 PHS Act focused primarily on extensive control over manufacturing methods to ensure safety and purity. Unique to the 1944 PHS Act was Congress' explicit addition of the requirement that biologics manufacturers demonstrate potency as a measure of clinical usefulness. The PHS Act created the Laboratory of Biologics Control to facilitate testing and licensure of biologicals products and manufacturing establishments. After 1944, the authority of the Laboratory of Biologics Control was derived from Section 351 of the PHS Act and from certain sections of the 1938 FD&C Act. In 1948, the Laboratory of Biologics Control joined the NIH Division of Infectious Diseases and Division of Tropical Diseases to form the National Microbiological Institute (later renamed the National Institute of Allergy and Infectious Diseases). Administrative authority for regulation of biologics was originally granted to the National Microbiological Institute.

Although important regulations had been enacted to improve product safety, by the 1950s, the only legal requirement for vaccine licensing was submission of written protocols for vaccine production and safety testing to the Laboratory of Biologics Control. Regulations were dramatically expanded in 1955, when more than 200 cases of polio were attributed to incompletely inactivated polio vaccine manufactured by the Cutter Laboratories. As a result of the "Cutter Incident," administrative authority for the regulation of biologicals was transferred by Congress to the Division of Biologics Standards, a newly created division within the NIH. Regulations were strengthened that required more precise experimental testing to assess the safety of vaccines.

Congress passed the Consumer Safety Act of 1972 and transferred regulatory authority from NIH to FDA for the administration of the 1944 PHS Act. In 1972, the Division of Biologics Standards, which was charged with administering and enforcing Section 351 of the PHS Act, was transferred by the Secretary of Health, Education and Welfare to the FDA, and became the Bureau of Biologics. Once administrative responsibility for the regulation of biologicals was transferred from NIH to FDA, the FDA announced its intention to require that all new biologicals satisfy the additional standards of safety and efficacy mandated in the Drug Amendments Act of 1962. This resulted in the transfer of the regulations pertaining to biologics from Part 73 of Chapter I of Title 42 (USC §262) to Chapter I of Title 21 of the CFR. In 1982, the Bureau of Biologics was renamed the Office of Biologics Research and Review and combined with the Office of Drugs Research and Review to form the Center for Drugs and Biologics. In 1987, following a series of organizational changes within the FDA, the Bureau of Biologics was ultimately transformed into the Center for Biologics Evaluation and Research (CBER). A chronology of the development of the U.S. Biologicals Control Authority is summarized in Table 79.3 and outlined in Fig. 79.1.

FEDERAL LAWS AND REGULATIONS

Since its inception, the FD&C Act has been amended by Congress several times including the FDA Modernization Act (FDAMA) of 1997, the FDA Amendments Act (FDAAA) of 2007, and more recently, the FDA Safety and Innovation Act (FDASIA) of 2012.

Food and Drug Administration Modernization Act

Among other things, the FDAMA of 1997 included measures to modernize the regulation of biologics by synchronizing their review process with that of drugs and eliminating the requirement for an establishment license for biologics. Expedited approval mechanisms for life-threatening conditions also were authorized under FDAMA.[5]

TABLE 79.1 Bacterial Vaccines Currently Licensed in the United States

Vaccine	Manufacturer
Anthrax vaccine, adsorbed	Emergent Biodefense Operations Lansing, Inc.
BCG vaccine	Organon Teknika Corporation
Cholera vaccine, live, oral	Pax Vax Bermuda Ltd.
Diphtheria and tetanus toxoids adsorbed	Sanofi Pasteur, Inc.
Diphtheria and tetanus toxoids and acellular pertussis vaccine, adsorbed	Sanofi Pasteur, Inc.,[a] Sanofi Pasteur, Ltd., GlaxoSmithKline Biologicals
Diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed, hepatitis B (recombinant) and inactivated poliovirus vaccine combined	GlaxoSmithKline Biologicals
Diphtheria and tetanus toxoids and acellular pertussis adsorbed and inactivated poliovirus vaccine	Sanofi Pasteur, Ltd., GlaxoSmithKline Biologicals
Diphtheria and tetanus toxoids and acellular pertussis adsorbed, inactivated poliovirus and *Haemophilus influenzae* type b conjugate (tetanus toxoid conjugate) vaccine	Sanofi Pasteur, Ltd.
Tetanus and diphtheria toxoids, adsorbed	Massachusetts Public Health Biological Laboratories
Tetanus and diphtheria toxoids, adsorbed for adult use	Sanofi Pasteur, Inc., Sanofi Pasteur, Ltd.
Tetanus toxoid	Sanofi Pasteur, Inc.
Tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine, adsorbed	Sanofi Pasteur, Ltd., GlaxoSmithKline Biologicals
Haemophilus influenzae type b conjugate vaccine (meningococcal protein conjugate)	Merck Sharp and Dohme Corp.
Haemophilus influenzae type b conjugate vaccine (meningococcal protein conjugate) and hepatitis B (recombinant) vaccine	Merck Co., Inc.
Haemophilus influenzae type b conjugate vaccine (tetanus toxoid conjugate)	GlaxoSmithKline Biologicals, Sanofi Pasteur S.A.
Meningococcal (groups A, C, Y, and W-135), oligosaccharide diphtheria CRM_{197} conjugate vaccine	Novartis Vaccines and Diagnostics, Inc.
Meningococcal group B vaccine	Wyeth Pharmaceuticals Inc., Novartis Vaccines and Diagnostics, Inc.
Meningococcal groups C and Y and *Haemophilus influenzae* type b tetanus toxoid conjugate vaccine	GlaxoSmithKline Biologicals
Meningococcal (groups A, C, Y and W-135) polysaccharide diphtheria toxoid conjugate vaccine	Sanofi Pasteur, Inc.
Meningococcal polysaccharide vaccine, A, C, Y, W135 combined	Sanofi Pasteur, Inc.
Pneumococcal polysaccharide vaccine, polyvalent	Merck Co., Inc.
Pneumococcal 7-valent conjugate vaccine (diphtheria CRM_{197} protein)	Wyeth Pharmaceuticals Inc.
Pneumococcal 13-valent conjugate vaccine (diphtheria CRM_{197} protein)	Wyeth Pharmaceuticals Inc.
Typhoid vaccine, live oral, Ty21a	Berna Biotech
Typhoid Vi polysaccharide vaccine	Sanofi Pasteur S.A.

[a]License for the pertussis component of this product is held by the Research Foundation for Microbial Diseases of Osaka University (Aventis Pasteur Laboratories, Inc.).

Pediatric Research Equity Act

The Pediatric Research Equity Act (PREA) of 2003 amended the FD&C Act by adding Section 505(B) to address product development for pediatric subjects from birth to 16 years of age.[6] It requires that manufacturers submit a pediatric assessment with every application submitted under Section 505 of the FD&C Act or section 351 of the PHS Act for a new active ingredient, new indication, new dosage form, new dosing regimen, or new route of administration unless the applicant has obtained a waiver or deferral from the FDA. The pediatric assessment must contain data adequate to assess the safety and effectiveness of the drug or the biological product for the claimed indications in all relevant pediatric subpopulations and data to support dosing and administration for each pediatric subpopulation for which the product is safe and effective.

Food and Drug Administration Amendments Act

The FDAAA of 2007 includes 11 titles that added many new provisions to the FD&C Act.[7] It reauthorized and amended several drug and medical device provisions, and provided the FDA with additional responsibilities and new authorities. The provisions of FDAAA that have had a significant impact on the regulations of vaccines and the review process are contained in Title IV, the PREA, and Title IX, Enhanced Authorities Regarding Postmarket Safety of Drugs. The FDAAA reauthorized and revised the PREA, primarily to enhance FDA oversight and applicant accountability for the agreed-upon

TABLE 79.2 Viral Vaccines Currently Licensed in the United States

Vaccine	Manufacturer[a]
Adenovirus type 4 and type 7 vaccine, live	Barr Labs Inc.
Diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed, hepatitis B (recombinant) and inactivated poliovirus vaccine combined	GlaxoSmithKline Biologicals
Diphtheria and tetanus toxoids and acellular pertussis adsorbed and inactivated poliovirus vaccine	Sanofi Pasteur, Ltd., GlaxoSmithKline Biologicals
Hepatitis A vaccine, inactivated	Merck & Co., Inc., GlaxoSmithKline Biologicals
Hepatitis B vaccine, recombinant	Merck & Co., Inc., GlaxoSmithKline Biologicals
Hepatitis A vaccine, inactivated and hepatitis B (recombinant) vaccine	GlaxoSmithKline Biologicals
Haemophilus influenzae type b conjugate vaccine (meningococcal protein conjugate) and hepatitis B recombinant vaccine	Merck & Co., Inc.
Human papillomavirus (types 6, 11, 16, 18) recombinant vaccine	Merck & Co., Inc.
Human papillomavirus bivalent (types 16 and 18) vaccine, recombinant	GlaxoSmithKline Biologicals
Human papillomavirus 9-valent vaccine, recombinant	Merck & Co., Inc.
Influenza virus vaccine, trivalent, types A and B	Sanofi Pasteur, Inc., Novartis Vaccines and Diagnostics Ltd., GlaxoSmithKline Biologicals, ID Biomedical Corporation of Quebec, CSL, Ltd., Protein Sciences Corporation
Influenza A (H1N1) 2009 monovalent	Sanofi Pasteur, Inc., Novartis Vaccines and Diagnostics Ltd., ID Biomedical Corporation of Quebec, MedImmune Vaccines, Inc., CSL, Ltd.
Influenza virus vaccine, H5N1 (for national stockpile)	Sanofi Pasteur, Inc.
Influenza A (H5N1) virus monovalent vaccine, adjuvanted	ID Biomedical Corporation of Quebec
Influenza vaccine, adjuvanted	Novartis Vaccines and Diagnostics
Influenza virus vaccine, quadrivalent, types A and B	Sanofi Pasteur, Inc., GlaxoSmithKline Biologicals, ID Biomedical Corporation of Quebec, MedImmune Vaccines, Inc.
Influenza virus vaccine, intranasal	MedImmune Vaccines, Inc.
Japanese encephalitis vaccine, inactivated	The Research Foundation for Microbial Diseases of Osaka University
Japanese encephalitis vaccine, inactivated, adsorbed	Valneva Austria GmbH
Measles, mumps, and rubella virus vaccine, live	Merck & Co., Inc.
Measles, mumps, rubella, and varicella vaccine, live	Merck & Co., Inc.
Poliovirus vaccine inactivated, monkey kidney cell	Sanofi Pasteur, S.A.
Rabies vaccine	Novartis Vaccines and Diagnostics Ltd., Sanofi Pasteur, S.A.
Rotavirus vaccine, live, oral	GlaxoSmithKline Biologicals
Rotavirus vaccine, live, oral, pentavalent	Merck & Co., Inc.
Rubella virus vaccine, live	Merck & Co., Inc.
Smallpox (vaccinia) vaccine, live	Sanofi Pasteur Biologics
Varicella virus vaccine live	Merck & Co., Inc.
Yellow fever vaccine	Sanofi Pasteur, Inc.
Zoster vaccine, live	Merck & Co., Inc.

[a]These are the names of the license holders. Company names may be different.

pediatric assessments.[8] Of note, a new provision directed the FDA to establish the Pediatric Review Committee (PeRC), an internal review committee with pediatric expertise. This committee is required to provide consultation to FDA review divisions on all pediatric plans and assessments and on all deferral and waiver requests. Thus, early in the application review process the review team must assess whether PREA applies. If PREA applies, then a pediatric assessment must be presented to the PeRC.

Section 901 of Title IX of the FDAAA authorizes the FDA to require certain postmarketing studies and clinical trials for prescription drug and biological products approved under Section 505 of the FD&C Act or Section 351 of the PHS Act (42 USC §262). Section 901 of the FDAAA also created new Sections 505–1 and 505(o)(4) of the FD&C Act, authorizing the FDA, under certain circumstances, to require risk evaluation and mitigation strategies and safety-related labeling changes, respectively. The FDAAA also specifies adverse event reporting requirements for products with labeling changes that are a result of a pediatric assessment. Specifically, during the 12 months from the date that such a labeling change is made, all adverse event reports are reviewed by the FDA Pediatric Advisory Committee. Following review, the Pediatric Advisory Committee makes recommendations regarding whether

TABLE 79.3 Chronology of the Development of Biologic Control Authority

Year	Legislation Enacted	Existing Organization
1902	Biologics Control Act (Virus, Serum, Toxin Law) of 1902	Public Health Hygienic Laboratory
1930		Hygienic Laboratory renamed National Institutes of Health (NIH)
1937		Laboratory of Biologics Control (LBC) formed within NIH
1944	Enactment of U.S. Public Health Service Act (42 USC §§262, 263)	
1948		LBC incorporated into the National Microbiological Institute (later renamed the National Institute of Allergy and Infectious Diseases)
1955		Establishment of the Division of Biologics Standards (DBS) by the Surgeon General
1972		DBS transferred to FDA to become Bureau of Biologics (BoB)
1982–1983		BoB renamed Office of Biologics Research and Review (OBRR); joined with Office of Drugs Research and Review (ODRR) to form the Center for Drugs and Biologics (CDB)
1987		OBRR renamed Center for Biologics Evaluation and Research (CBER)
1997	Food and Drug Administration Modernization Act of 1997	
2007	Food and Drug Administration Amendments Act (FDAAA)	
2012	Food and Drug Administration Safety and Innovation Act (FDASIA)	

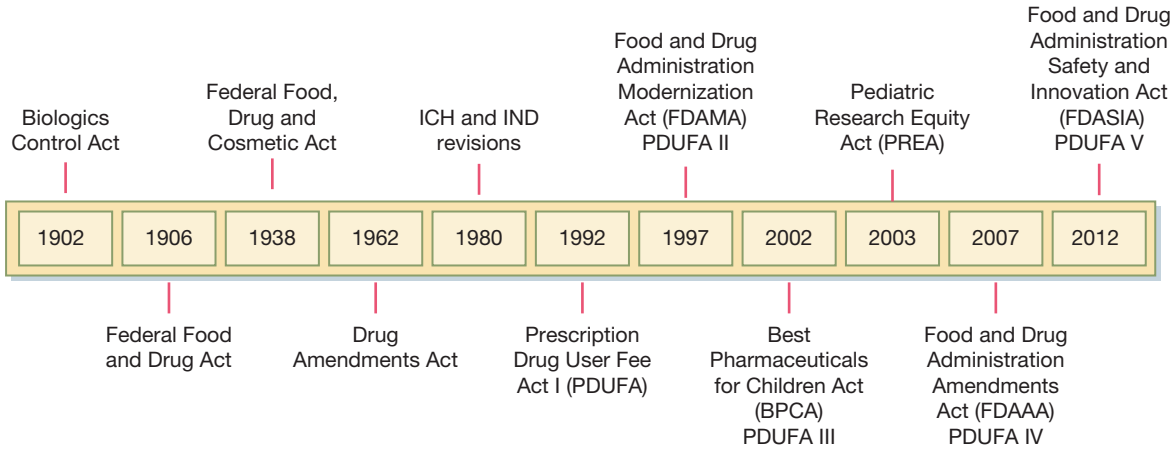

Figure 79.1. History of Food and Drug Law. ICH, International Council for Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use; IND, investigational new drug.

the FDA should take action in response to such reports and whether the current pharmacovigilance plan is adequate.

Food and Drug Administration Safety and Innovation Act

The FDASIA was signed into law in 2012 and expanded the FDA's authority by strengthening the agency's ability to safeguard and advance public health by promoting innovation, increasing stakeholder involvement in FDA processes, and enhancing the safety of the drug supply chain.[9] In addition to reauthorizing the prescription drug and medical device user fee programs, FDASIA established new user fee programs for generic drugs and biosimilar biological products. The provisions of FDASIA that impact the regulation of vaccines are contained in Pediatric Drugs and Devices (Title V) and Drug Approval and Patient Access (Title IX). Title IX expands the scope of products that qualify for accelerated approval and creates a new "breakthrough therapy" program, among other things (see below). FDASIA also revised PREA to include a provision that requires vaccine manufacturers to submit a Pediatric Study Plan early in the drug development process. This initial Pediatric Study Plan must contain an outline of the pediatric study or studies that the sponsor plans to conduct including, to the extent practicable, study objectives and design, age groups, relevant end points, and statistical approach, as well as any request for a deferral, partial waiver, or waiver. The FDA internal PeRC must be consulted for the review of the initial study plan, the agreed initial pediatric plan, and certain amendments to such plans. Both sponsors and the FDA must comply with prescribed timelines regarding submission, review, responses, and agreements reached

regarding the Pediatric Study Plan, which are also described in applicable FDA guidance.[10]

Prescription Drug User Fee Act

Of note, these amendments to the FD&C Act also renewed the Prescription Drug User Fee Act (PDUFA) that was first enacted in 1992, and authorized the FDA to collect user fees from companies. These fees enabled FDA to hire additional reviewers and support staff and upgrade its information technology systems. In return for these additional resources, the FDA agreed to certain review performance goals, such as completing reviews of new drug applications and biologics license applications (BLAs) and taking regulatory actions on them in predictable timeframes. These changes revolutionized the drug approval process in the United States and enabled FDA to speed the application review process for new drugs and biologics without compromising the FDA's high standards for demonstration of safety, efficacy, and quality. The PDUFA program has been reauthorized every 5 years, 1997 (PDUFA II), 2002 (PDUFA III), 2007 (PDUFA IV), and 2012 (PDUFA V). It includes the 5-year review performance goals for drug and BLAs, supplements and resubmissions, meeting management goals, clinical holds, major dispute resolution, special protocol question assessment and agreement, electronic applications and submissions, discipline review, and complete response letters.

FEDERAL REGULATIONS AND FOOD AND DRUG ADMINISTRATION GUIDANCE

The FDA's CBER is the national regulatory authority in the United States charged with the regulation of biological products including vaccines. The review of vaccine applications occurs among CBER's Office of Vaccines Research and Review, Office of Compliance and Biologics Quality, and Office of Biostatistics and Epidemiology. CBER's current legal authority for the regulation of vaccines derives primarily from Section 351 of the PHS Act and from certain sections of the FD&C Act. The statutes of the PHS Act are implemented through regulations codified in the Code of Federal Regulations (CFR). The CFR is published annually and contains all changes in regulations that have occurred during the previous year that were published in the *Federal Register*. Regulations are adopted in conformity with the Administrative Procedure Act.[11] Thus, before a regulation can be established, repealed, or revised, it must be proposed and published in the *Federal Register* with an invitation to all interested individuals or parties to comment within a prescribed time, commonly a period of 1 to several months. Once comments are received, they are evaluated and considered by the FDA before publication of the final regulation in the *Federal Register*.

Title 21 of the CFR, parts 600 through 680, contains regulations specifically applicable to vaccines and other biologicals. In addition, because vaccines meet the legal definition of a drug under the FD&C Act, manufacturers must comply with regulations for Current Good Manufacturing Practices (CGMPs) (parts 210 and 211). Table 79.4 summarizes the regulations applicable to vaccines and other biological products. These regulations cover not only the methods and establishment standards pertaining to the manufacture of a biological product to assure that the product is safe and meets the quality and purity characteristics that are claimed by the manufacturer, but also requirements for performing clinical trials (i.e., 21 CFR §312).

A single set of basic regulatory requirements applies to all vaccines, regardless of the technology used to produce them. The regulatory approval criteria contained in Title 21 CFR also apply to vaccines, regardless of their indication or intended target population. Section 351 of the PHS Act (42 USC §262) states that a BLA can be approved based on a demonstration that "…(a) the biological product that is the subject of the application is safe, pure, and potent; and (b) the facility in which the biological product is manufactured, processed, packed, or held meets standards designed to assure that the biological product continues to be safe, pure, and potent…"

Some of the more pertinent operational definitions for biologics contained in the statutes and 21 CFR are as follows:

- Section 351 of the PHS Act defines a biological product as any virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, or analogous product applicable to the prevention, treatment, or cure of diseases or conditions of human beings. Thus, vaccines clearly are regulated as biological products.
- Safety is defined as the relative freedom from harmful effect to people affected directly or indirectly by a product when prudently administered, taking into consideration the character of the product in relation to the condition of the

[b]Consists of Parts 600–680. Parts 606, 607, 640, 660 and 680 apply to blood, blood products, diagnostic test and allergenics.

DHHS, Department of Health and Human Services; FDA, Food and Drug Administration.

recipient at the time. Thus, the property of safety is relative and cannot be ensured in an absolute sense.
- Purity is defined as the relative freedom from extraneous matter, regardless of whether it is harmful to the recipient or deleterious to the product. Usually, the concepts of purity and safety coincide; purity most often relates to freedom from such materials as pyrogens, adventitious agents, and chemicals used in manufacture of the product.
- Potency is defined as the specific ability or capacity of the product, as indicated by appropriate laboratory tests or by adequately controlled clinical data obtained through administration of the product in the manner intended, to effect a given result. Potency, as thus defined, is equivalent to the concept that the product must be able to perform as claimed, and, if possible, this must correspond with some measurable effect in the recipient or correlate with some quantitative laboratory finding.
- Standards mean specifications and procedures applicable to an establishment or to the manufacture or release of products that are designed to ensure the continued safety, purity, and potency of biological products. The word standard is also used with a secondary meaning, usually in the sense of a reference preparation, such as a bacterial or viral antigen that can be used in evaluating potency or, in some cases, safety and purity.
- The regulations regarding biological products, in addition, define effectiveness as the reasonable expectation that, in a significant proportion of the target population, pharmacologic or other effects of the biological product, when administered under adequate directions for use and warnings against unsafe use, will serve a clinically significant function in the diagnosis, cure, mitigation, treatment, or prevention of disease in humans.
- CGMPs define a quality system that manufacturers use as they build quality into their products. The regulations outline the minimum manufacturing, quality control, and quality assurance requirements for the preparation of a drug or biological product for commercial distribution. For example, approved products developed and produced according to CGMPs are safe, properly identified, of the correct strength, pure and of high quality.

The FDA also periodically publishes various guidelines and guidance documents with regard to the manufacture and clinical evaluation of biologicals. These documents published by the FDA do not have the force of law, but are intended to provide useful and timely recommendations; Table 79.5 lists those applicable to vaccines. Guidance documents are particularly useful as a means for the FDA to provide recommendations that are current with areas of rapidly progressing science, and for specifying a degree of detail beyond what is included in the regulations. In the past few years, several FDA regulations and guidance documents have had a direct impact on the review of vaccines for licensure by the FDA, such as the "Guidance for Industry: Expedited Programs for Serious Conditions—Drugs and Biologics (2014)."[12] Some of these regulations and guidance documents evolved from an effort to streamline the regulatory process, while others—such as "Guidance for Industry: Clinical Data Needed to Support the Licensure of Trivalent Inactivated Influenza Vaccines (2007)", "Guidance for Industry: Clinical Data Needed to Support the Licensure of Pandemic Influenza Vaccines (2007)," "Guidance for Industry: Characterization and Qualification of Cell Substrates and Other Biological Material Used in the Production of Viral Vaccines for the Prevention and Treatment of Infectious Diseases (2010)," and "Guidance for Industry: Considerations for Developmental Toxicity Studies for Preventive and Therapeutic Vaccines for Infectious Disease Indications (February 2006)"—were written to facilitate the development of new vaccines with new technologies.[13–16] These documents are available at CBER's website.[17]

COLLABORATIONS BETWEEN THE FOOD AND DRUG ADMINISTRATION AND NATIONAL AND INTERNATIONAL PARTNERS

The FDA's CBER regulatory review staff consists of an internal multidisciplinary team of scientists, medical officers, and regulatory and public health professionals. To stay current on scientific advances and biotechnologies, the team is involved in a dynamic exchange of information with the outside scientific community through laboratory research and collaborations, participation in workshops and seminars, and engagement with national partners. The FDA also relies on the expertise of formal advisory committees, which include experts in the fields of vaccinology, microbiology, infectious diseases, immunology, biostatistics, epidemiology, and clinical trial design. In addition, CBER works closely with its counterparts in other U.S. government agencies within the Department of Health and Human Services and the U.S. Public Health Service (PHS), such as the National Vaccine Program Office, the Centers for Disease Control and Prevention (CDC), the NIH, and the Health Resources and Services Administration. The CDC is responsible, among its other duties, for epidemiologic surveillance of disease and for support of immunization programs. Its Advisory Committee on Immunization Practices makes recommendations for vaccine use. The Director of the National Vaccine Program Office coordinates vaccine efforts throughout the PHS and other governmental agencies. The NIH is responsible for conducting and providing funds for a wide variety of biomedical research. The Health Resources and Services Administration is responsible for managing the National Vaccine Injury Compensation Program. Other important collaborators inside the U.S. government involved in vaccine activities include the U.S. Department of Defense, and the Department of Veterans Affairs. Additionally, CBER works closely with its multilateral partners, notably the Pan American Health Organization and the World Health Organization (WHO), to provide assistance in regulatory capacity building. CBER has been very active in supporting the WHO's Developing Countries' Vaccine Regulators Network and the WHO's African Regional Office-led African Vaccine Regulatory Forum. As a WHO Collaborating Center, CBER contributes to a range of activities, including establishment of physical and written standards, implementation of WHO international standards, strengthening global regulatory systems, and serving as the National Regulatory Authority (NRA) of reference for WHO's vaccine prequalification program. CBER experts also contribute as members of several WHO Advisory Committees including the Global Advisory Committee on Vaccine Safety, the Polio Research Committee, the HIV Vaccine Advisory Committee, and the Expert Committee on Biological Standardization. CBER is an Essential Regulatory Laboratory in WHO's Global Influenza Surveillance and Response System. In addition, the FDA has confidentiality arrangements with many NRAs around the globe, allowing it to share information as part of its regulatory processes. These arrangements have strengthened interactions between the regulatory authorities and have contributed to improving the promotion and protection of public health globally.

MANAGED REVIEW PROCESS

The regulatory review in CBER incorporates a managed and integrated regulatory process that is continuous from

[a]Guidance documents are available at http://www.fda.gov/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/default.htm. They are also available at no charge from the Office of Communication, Training and Manufacturers Assistance, HFM-40, 1401 Rockville Pike, Rockville, MD 20852–1448.

discovery to postmarketing, and is designated as the Managed Review Process.[18] CBER's managed review process is designed to effectively review all regulatory submissions to reach informed evidence-based regulatory decisions to ensure safe and effective biological products. CBER uses a team-based approach with substantive involvement of discipline team leaders and management.

The Managed Review Process begins when a sponsor requests a pre–investigational new drug (IND) meeting that may result in the submission of an IND and, eventually, a BLA. The review process in CBER begins with an initial review of a submission for scientific content and compliance with the regulations. Members of a multidisciplinary review team are selected based on their expertise with the type of product and its method of manufacture. It is the responsibility of CBER's review component to evaluate submissions and recommend appropriate regulatory action to facilitate the approval of safe and effective biological products. The review includes an evaluation of chemistry, manufacturing, and controls information; the manufacturing facility and equipment; preclinical and clinical data on the safety, efficacy, pharmacology, and toxicology; the suitability of clinical trial design; and analysis of clinical data derived from such trials. In addition, reviewers monitor for conformance with FDA regulations in all phases of biological product development, including postmarketing. CBER scientists also perform research in the areas of statistical and epidemiologic analysis, clinical trial design, and chemistry, manufacturing and control specific to product issues, and contribute to policy development. Surveillance activities are performed to ensure that the safety of biological products is not compromised. These activities ensure the rapid availability and approval of safe and effective biological products.

MEETINGS WITH SPONSORS

The FDA encourages meetings with sponsors to the extent that they aid in the evaluation of the vaccine and in resolving scientific issues concerning the product. The general principle underlying the conduct of such meetings is that there should be free, full, and open communication about any scientific or medical question that may arise. Agreements reached at PDUFA meetings (e.g., pre-IND, IND, pre-BLA, and BLA meetings) are recorded in official minutes taken by FDA personnel and provided to the sponsor. They serve as a permanent record of any agreements reached. Detailed information on the conduct of regulatory meetings is described in 21 CFR §312.47.[19]

STAGES OF THE REGULATORY REVIEW OF VACCINE PRODUCTS

Premarketing Phase

The regulatory requirements for biological products cover the entire life-cycle of the product from the pre-IND stage, through the premarketing (consisting of the various IND phases and prelicensure) and postmarketing stages. The pre-IND stage consists of laboratory development, preclinical testing of candidate vaccines, and development of the manufacturing process. The clinical development of a new drug in the United States usually begins with a sponsor approaching the FDA for permission to conduct a clinical study with an investigational product through submission of an IND application form. These requirements can be found in the IND regulations.[20] Sponsors are encouraged to request a pre-IND meeting with FDA to discuss preclinical studies, clinical study design, and data requirements that require resolution prior to the initiation of clinical trials. In the application, the sponsor (a) describes the composition, source, and method of manufacture of the product and the methods used in testing its safety, purity, and potency; (b) provides a summary of all laboratory and preclinical animal testing; and (c) provides a description of the proposed clinical study and the names and qualifications of each clinical investigator. The FDA has a maximum of 30 days to review the original IND application and determine whether study participants will be exposed to any unacceptable risks. As part of the IND process, each clinical investigator files information describing the investigator's qualifications for performing clinical trials, details of the proposed study, and assurance that a number of conditions specified by the regulations will be met. A signed informed consent must be obtained from each study participant. Approval for the study must be obtained in advance from a local institutional review board. The regulations also cover the evaluation of the preclinical laboratory animal studies undertaken to support the use of the product in humans.

Investigational Phase

Only licensed vaccines may be shipped from one state to another; however, during the premarketing phase, interstate shipment of products for investigational use is allowed under the law and regulations. There are generally three separate phases in the clinical evaluation of experimental biologicals at the premarketing stage (Fig. 79.2). These phases may overlap, and the clinical testing may be highly iterative because

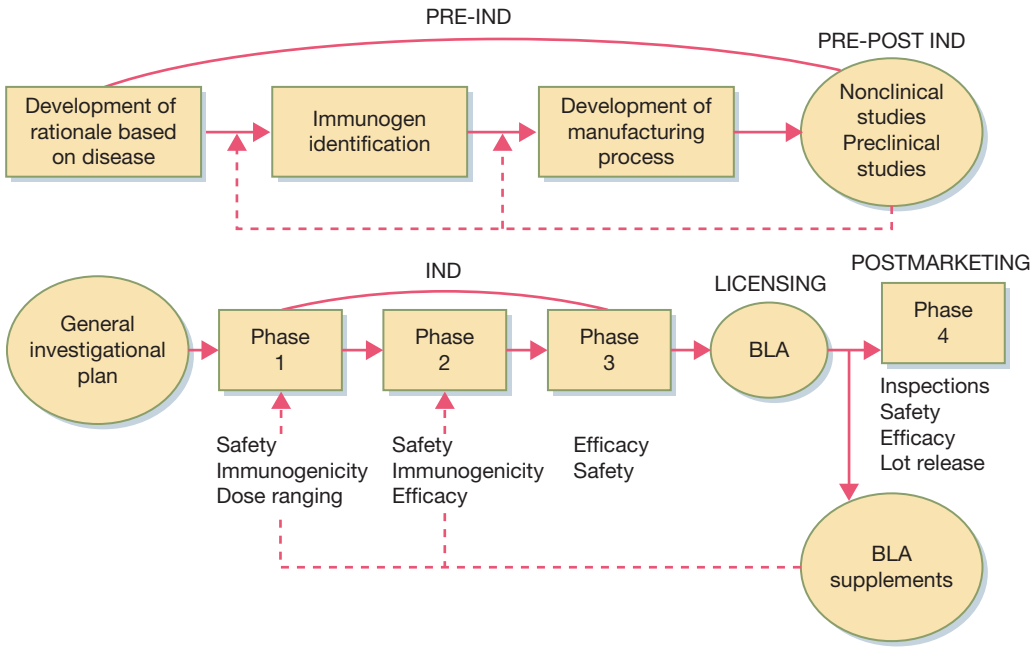

Figure 79.2. Sequence of key events in product development through the premarketing experimental investigational new drug (IND) and licensing phases and the postapproval marketing phase. Dashed lines indicate additional research/development submissions when significant changes are made in the product or its indications. BLA, biologics license application.

multiple Phase I or Phase II trials may be performed as new data are obtained. Phase I trials are intended primarily to provide a preliminary evaluation of safety and immunogenicity. These trials are typically conducted in a small number (e.g., 20 to 80) of closely monitored adult volunteers. If the ultimate target population for the vaccine is infants or young children, as is commonly the case, the product is usually evaluated in a stepwise progression from older to younger age groups down into the first year of life. Phase II studies can involve up to several hundred participants, are often randomized and well-controlled, and provide further information on safety and immunogenicity and optimal dose. In some cases, Phase II studies may provide preliminary data on the vaccine's activity against the infectious disease of interest. Phase III studies are large-scale trials to provide a more thorough assessment of safety as well as a definite assessment of efficacy.

The general considerations for clinical studies to support licensure of a vaccine include demonstration of safety, efficacy (immunogenicity may be sufficient in some cases), and evaluation of simultaneous administration with other licensed vaccines. Vaccine efficacy should be demonstrated, ideally in randomized, double-blind, well-controlled trials. The end points are product specific, and may be clinical disease end points or immune response end points if efficacy against clinical disease had been previously established and there are immune correlates or surrogates of that protection. In recent years, efficacy trials for various vaccines have involved a broad range in the number of study participants, from thousands to tens of thousands. This broad range is related to a number of interconnected variables such as study design and the incidence of the disease to be prevented. For example, clinical disease end point studies that are designed to demonstrate that a new vaccine is noninferior to an already existing product of the same type generally require larger numbers than one in which a new vaccine can be compared with a control that has no activity against the clinical disease. The incidence of the disease to be prevented in the study population is also important. As an example, a trial to show that pneumococcal seven-valent polysaccharide conjugate vaccine (PCV7) was successful in preventing a low incidence of invasive pneumococcal disease caused by the *Streptococcus pneumoniae* capsular serotypes included in the vaccine enrolled close to 40,000 children who were randomized equally to receive the pneumococcal conjugate vaccine or an unrelated control vaccine. In contrast, licensure of the pneumococcal 13-valent polysaccharide conjugate vaccine (PCV13) was based on noninferiority comparative studies to PCV7. Effectiveness of PCV13 was inferred from measuring anti-polysaccharide binding and functional opsonophagocytic antibodies because clinical end point disease efficacy studies were no longer feasible owing to the further decline of invasive pneumococcal disease as a result of introduction of PCV7 in the United States.

In some situations, human challenge studies have been conducted during early clinical development or in lieu of clinical trials in an endemic area. These studies served to demonstrate "proof of concept" of the vaccine early in clinical development (e.g., *Plasmodium falciparum* sporozoite challenge of malaria-naïve U.S. volunteers previously administered a candidate malaria vaccine). Human challenge studies may also be considered to demonstrate the efficacy of the vaccine. For example, the Agency convened the Vaccines and Related Biologics Products Advisory Committee (VRBPAC) to consider whether data from human challenge studies in U.S. subjects could be sufficient to demonstrate efficacy of a cholera vaccine in travelers to endemic areas who are at high risk for contracting the disease. In 1998, the VRBPAC agreed that human challenge studies could suffice to demonstrate efficacy of a cholera vaccine provided that studies were adequate and well-controlled and conducted under the provisions of good clinical practices.[21] In 2016, the FDA approved Vaxchora, a live, attenuated vaccine for the prevention of cholera in adults traveling to cholera-affected areas. Efficacy of Vaxchora was demonstrated in a controlled human challenge study in adult U.S. volunteers.

Safety is one of the most important considerations when evaluating new vaccines and modifications to currently

licensed vaccines. The initial responsibility for determining vaccine safety starts with clinical investigators and vaccine manufacturers. The FDA is responsible for assuring that clinical trials are done under good clinical practices, a requirement essential for the evaluation of safety data intended to support a license application. In general, when evaluating safety, one must compare the risk of the vaccine-preventable disease with the risk of the adverse event(s) potentially associated with the vaccine, and these may change over time. As an example, the reported association between Rotashield (rotavirus vaccine, live, oral, tetravalent, manufactured by Wyeth) and intussusception resulted in the additional requirement for the evaluation of the safety of RotaTeq (live, oral pentavalent human-bovine reassortant rotavirus vaccine, manufactured by Merck) with respect to intussusception. This clinical trial enrolled more than 70,000 infants divided equally between RotaTeq and placebo. The primary safety hypothesis was that the oral RotaTeq would not increase the risk of intussusception relative to placebo within 42 days of any dose. The intended target population should be taken into consideration in assessing the adequacy of the safety database. For routinely administered childhood vaccines in the United States, the target population would be the birth cohort in the United States (approximately 4 million/year). This is generally a healthy population, and a government body (e.g., state or local governments) may mandate vaccination. Common reactions can be studied adequately in hundreds of individuals, but many thousands will be required to define low-incidence adverse reactions.

For vaccines evaluated in clinical end point efficacy trials, a large safety database likely will derive from a double-blind, randomized, well-controlled efficacy study. However, for vaccines evaluated in immunogenicity end point studies, additional studies likely will be needed to obtain an adequate safety database. Additional controlled safety studies are often requested when the numbers of subjects included in the efficacy studies are deemed insufficient to provide adequate safety data. Safety studies may be unblinded if the number of injections, route of administration, or schedule differs between groups, in particular when infants and young children are involved. Phase II safety studies should provide data on common local and systemic reactions to the study vaccine. Phase II clinical development also should include immunogenicity and preliminary safety data on the concurrent administration of the study vaccine with other vaccines, if relevant. Phase III safety studies are designed to evaluate less common reactions, may be unequally randomized, and may have a simplified trial design for assessing less-common adverse events in large trials. If a vaccine is recommended on the same schedule as other routinely recommended vaccines, safety and immunogenicity data should be obtained in prelicensure studies to support simultaneous administration.

Licensing Phase

Following completion of IND studies demonstrating the safety and efficacy of the vaccine for a specific use and population the sponsor can submit a BLA to obtain a license for a new vaccine under section 351 of the PHS Act for commercial manufacture and distribution of the product. Prior to the submission of a BLA, a pre-BLA meeting with the FDA is strongly encouraged to discuss the sponsor's product development plan. For the FDA to provide sponsors with advice regarding the adequacy of information to support a BLA, the following information in advance of the pre-BLA meeting should be submitted, depending on the type of meeting: (a) an executive summary of the clinical studies to be submitted in the application; (b) a proposed format for organizing the submission, including methods for presenting the data; (c) information on the status of needed or ongoing studies; and (d) any other information for discussion at the meeting. The primary purpose of this exchange is to uncover any major unresolved problems; identify those studies that the sponsor is relying on as adequate and well-controlled to establish the product's effectiveness; identify the status of ongoing studies; acquaint FDA reviewers with the general information to be submitted in the BLA (including technical information); review methods used in the statistical analysis of the data; and discuss the best approach for the presentation and formatting of data in the application.

At the time that an applicant submits a BLA to the Director of CBER's Office of Vaccines Research and Review precise production methods and procedures should be defined, and the manufacturing process should be standardized. Critical information to be contained in the BLA include data derived from nonclinical laboratory and clinical studies that demonstrate that the manufactured product meets prescribed requirements for safety, purity, and potency. The BLA should contain information that supports compliance with standards addressing requirements for (a) organization and personnel; (b) buildings and facilities; (c) equipment; (d) control of components, containers, and closures; (e) production and process controls; (f) packaging and labeling controls; (g) holding and distribution; (h) laboratory controls; and (i) records to be maintained. Furthermore, a full description of manufacturing methods; data establishing stability of the product through the dating period; sample(s) representative of the product for introduction or delivery for introduction into interstate commerce; summaries of test results performed on the lot(s) represented by the submitted sample(s); specimens of the labels, enclosures, and containers; and the address of each location involved in the manufacture of the biological product should be included in the BLA.

An application for a biologics license is not considered as filed (or accepted by the agency for review) until CBER determines that it has received all pertinent information and data from the applicant. In this regard, CBER can refuse to file a BLA if it deems the submission to be incomplete. Additionally, the manufacturing facility must be inspection-ready at the time the BLA is submitted. The applicant is also required to include either an environmental assessment or a claim for categorical exclusion from the requirement to submit an environmental assessment or an environmental impact statement. Other components of the BLA review include product labeling, which describes the indications for use, contraindications, dosage and possible adverse effects; protocols for the manufacturing and testing of the number of product lots specified to establish the consistency of the process; and confirmatory testing results within CBER of samples of in-process material or product in final containers and conformance to existing regulations.

An internal CBER multidisciplinary committee performs the scientific review of the BLA. This process occurs for each BLA or supplement to a BLA in which significant changes are proposed. During the review, there are discussions and exchanges of correspondence between the sponsor and the CBER review committee concerning issues that may arise. During the FDA review of the BLA an announced prior approval inspection (PAI) of the manufacturing facility is performed. This inspection is designed as an in-depth review of the facilities, records, total production process, methods, equipment, quality control procedures, and personnel. With the implementation of the BLA process, changes have occurred in the scope of issues reviewed during the PAI. Instead of the manufacturer submitting detailed records with the BLA regarding studies on cleaning validation, monitoring data for

pharmaceutical-grade water, facility support systems (e.g., clean steam, compressed air, and building management systems), and other facility-related systems, a more detailed review of this type of data is done onsite during the PAI. PAIs tend to require longer periods of time for the FDA inspectors to be in the facility because of the increased scope of issues that are reviewed onsite. If licensure is denied following inspection for the original license application, reinspection will occur after receipt of assurance that all deficiencies that were the basis of the denial were corrected.

With the implementation of FDAAA (2007) and FDASIA (2012), in addition to completing the discipline reviews during the PDUFA V mandated timelines, the review committee must complete numerous additional tasks. These include, but are not limited to, review committee assignments, internal information exchange meetings, filing decisions, presentation of the application to the PeRC, midcycle review meetings and midcycle communication with the applicant, late-cycle meetings with the applicant, and presentation of planned or required postmarketing studies to an internal FDA safety committee.

After CBER reviews the entire package of information in the BLA, its advisory committee (the VRBPAC) and consultants, if needed, are asked to review and comment on the adequacy of the data to support safety and efficacy in the target population. The standards for safety and efficacy are relative; that is, the benefit-to-risk ratio of a biological product is considered. The VRBPAC's advice is considered in CBER's decision regarding licensure, and in developing recommendations for use to be given in the package insert. The committee may recommend additional studies to be performed either before or after approval. Once CBER determines that the data and information from the applicant are satisfactory and support the safety and efficacy of the product, the product is licensed.

Postmarketing Phase

If the manufacturer wishes to significantly modify the approved manufacturing process or directions for vaccine use, prior approval must be obtained from the FDA before these changes can be implemented. The applicant is required to submit an account of these changes to the appropriate license applications. Modifications to the manufacturing process may occur post licensure, such as scale-up or change in equipment to optimize the production process. Furthermore, clinical studies with the product also may be performed after licensure as the manufacturer seeks additional indications for product use (e.g., new target populations that would benefit from vaccination). For most new approvals, manufacturers may be asked to commit to completing specific postmarketing or so-called Phase IV studies, for example, to provide additional assessments of less-common or rare adverse events or further assess the duration of vaccine-induced immunity. These studies may also be designed to collect additional safety data in large numbers of vaccine recipients, as well as focus on issues that were identified during the prelicensure testing. Submission of status reports for certain postmarketing studies are required by regulation. In particular, this requirement for status reports pertains to postmarketing studies for clinical safety, efficacy and pharmacokinetics, and nonclinical toxicology to which an applicant committed in writing prior to licensure.[22]

Prior to FDAAA 2007, the FDA required postmarketing studies in the following situations (a) accelerated approvals for products approved under 505(b) of the FD&C Act or Section 351 of the PHS Act, respectively, which require postmarketing studies to demonstrate clinical benefit, (b) deferred pediatric studies, where studies are required under PREA, and (c) Animal Efficacy Rule approvals, where studies to demonstrate safety and efficacy in humans are required at the time of use. Under new Section 505(o) of the FD&C Act, the FDA is authorized to also require postmarketing studies or clinical trials at the time of approval or after approval if the FDA becomes aware of new safety information. Section 505(o)(3)(B) states that postmarketing studies and clinical trials may be required to (a) assess a known serious risk related to the use of the drug involved, (b) assess signals of serious risk related to the use of the drug, and (c) identify an unexpected serious risk when available data indicate the potential for a serious risk and when the adverse event reporting system is not adequate. The FDA has defined a clinical trial as any prospective investigation in which the sponsor or investigator determines the method of assigning treatment or other intervention to one or more human subjects. A study is all other investigations, such as investigations using humans, that are not clinical trials as defined above (e.g., observational epidemiologic studies), animal studies, and laboratory experiments. The FDA has issued guidance for industry to describe the type of studies and clinical trials that are required (Post Marketing Requirement [PMR]) under the FDAAA 2007, and those that will remain agreed-upon postmarketing commitments. A PMR describes all required postmarketing studies or clinical trials including those required under Accelerated Approval, PREA, the Animal Rule, and FDAAA. Examples of required studies are pharmacoepidemiologic studies designed to assess a serious risk, trials with a primary safety end point, preclinical studies investigating specific end organ toxicities, as well as pharmacokinetic studies in the indicated population at potential risk for high drug exposure that could result in toxicity. Studies that generally would not be considered required postmarketing studies or clinical trials are agreed-upon studies (postmarketing commitments) and include biologic quality studies (such as manufacturing, stability, and immunogenicity studies that do not have a primary safety end point), trials in which the primary end point is related to further defining efficacy, and pharmacoepidemiologic studies designed to examine the natural history of disease or background rates for adverse events. Since passage of FDAAA 2007, several new vaccines have been approved with either PMRs or postmarketing commitments. The FDA has the authority to monitor the progress of postmarketing studies or trials by requiring the applicant to submit an annual status report. Applicants are required to provide a timetable for study completion, a periodic status report on the status of the study including whether enrollment has begun, the number of participants enrolled, the expected completion date, and whether any difficulties in completing the study have been encountered.

ADVERSE EVENT MONITORING (POSTLICENSURE FOLLOW-UP)

The FDA is responsible not only for approving vaccines but also for monitoring their safety postlicensure. Because of the relatively small size of most prelicensure trials, rare adverse events are unlikely to be detected. Consequently, postlicensure or postmarketing surveillance (i.e., the continued monitoring of vaccine safety in the general population after licensure) is critical for identifying and evaluating rare or uncommon adverse events.

An adverse event refers to any untoward medical occurrence associated with the use of a drug in humans, whether or not considered drug related. The Vaccine Adverse Event Reporting System (VAERS) is a national system for passive surveillance of adverse events following vaccination. Established in 1990 as a result of the National Childhood Vaccine Injury Act of 1986, VAERS is administered jointly by the FDA and the CDC and, in recent years, has received more than

30,000 reports per year. The purpose of VAERS is to detect possible signals of adverse events associated with vaccines to help ensure the safety of U.S.-licensed vaccines. VAERS collects and analyzes information from reports of adverse events that occur after the administration of U.S.-licensed vaccines. Reports are submitted by healthcare providers, vaccine recipients or their parents or guardians, vaccine manufacturers, and other interested parties. FDA medical officers review all serious reports (defined as events that are fatal, disabling, or life-threatening; require or prolong hospitalization; result in congenital anomalies; require medical intervention to prevent such outcomes; or are deemed to be other medically important conditions). The VAERS system is not limited to routinely recommended pediatric vaccines; voluntary reports of adverse events occurring after administration of any vaccine are also accepted. FDA and CDC continually monitor VAERS reports for any unexpected patterns of adverse events.

Another important mechanism used by CBER to monitor adverse events is the Vaccine Safety Datalink, a collaborative effort between CDC's Immunization Safety Office and nine healthcare organizations. The Vaccine Safety Datalink uses electronic health data from participating sites and conducts vaccine safety studies based on questions or concerns raised from the medical literature and VAERS reports. When there are new vaccines that have been recommended for use in the United States, or if there are changes in how a vaccine is recommended, the Vaccine Safety Datalink will monitor the safety of these vaccines.[23]

INNOVATIVE SYSTEMS FOR EVALUATING VACCINE SAFETY POSTMARKETING

The FDA's Sentinel Initiative was launched in 2008 in response to a Congressional mandate in the FDAAA of 2007. The Sentinel Initiative aims to develop and implement a proactive system that will complement existing systems that the FDA has in place to track reports of adverse events linked to the use of its regulated products. It is a national electronic system that is transforming the FDA's ability to track the safety of drugs, biologics, and medical devices once they reach the market.[24] The Post-Licensure Rapid Immunization Safety Monitoring system (PRISM), a component of the FDA's Sentinel Initiative dedicated to vaccines, uses the FDA's Sentinel Distributed Database, which includes a population exceeding 178 million. PRISM monitors the largest U.S. general population cohort designated for active surveillance of vaccine safety by linking data from health plans with data from state and city immunization registries. The FDA structured PRISM as a program that includes specific vaccine evaluations. For example, several vaccines including a human papillomavirus vaccine, Gardasil, and two rotavirus vaccines, RotaTeq and Rotarix, were chosen for surveillance because their evaluations would benefit most from PRISM's large cohort size.

Postlicensure Manufacturing Changes

In 1997, the FDA published a Final Rule, Changes to an Approved Application, which amended 21 CFR §201.12 and §314.70 to simplify and categorize manufacturing reporting requirements for changes in testing methods, equipment, facilities, or personnel.[25] Proposed changes in manufacturing methods that have a substantial potential to have an adverse effect on the safety or effectiveness of the product may not become effective until notification is given of CBER's approval. The changed created the following categories: (a) those sufficiently significant with regard to safety, purity, potency, and effectiveness of the product to require preapproval of a supplemental application before product distribution; (b) those of lesser importance for which the manufacturer must provide notification 30 days before distribution of product made using the change; and (c) changes for which the manufacturer need only notify the agency by submission of an annual report. The guidance document, "Changes to an Approved Application: Biological Products" (1997), provides examples of changes that fall into these categories.[26]

Following approval, there is continued surveillance of the product and of the manufacturer's production activities. For most licensed vaccines, samples are submitted along with protocols for each lot prepared by the firm that provide the details of production and a summary of test results. Although not required by law or regulation, CBER often performs selected laboratory tests. The type and extent of confirmatory testing performed by CBER depend on several factors, such as the newness of the product or the difficulties that may have arisen with manufacture or use of the product. Release or rejection is based on a review of all test results, including those done by the manufacturer and those performed by CBER. Alternatives to official lot release are allowable under the provisions outlined for extensively characterized products having a track record of continued safety, purity, and potency.[27] A manufacturer must be able to produce a vaccine that repeatedly meets the standards for potency, purity, and stability of bulk and final container material while using a consistent process. Important factors to be considered are the nature of the product with respect to correlation between the measure of potency and biological activity and effectiveness. Surveillance samples and protocols may be required to be submitted to CBER at predetermined intervals.

Licensed establishments are inspected at least every 2 years. The purpose of the inspection is to determine whether licensed products are manufactured and tested as described in the license application and in accordance with applicable regulations. Manufacturers who fail to meet product standards or who are not in compliance with CGMPs may have their licenses suspended or revoked, depending on the nature of the potential health hazards created. The major issues observed during inspections can be categorized in three major areas: (1) process-related issues, (2) quality unit-related issues, and (3) facility- and production environment–related issues. Some examples of process validation issues include lack of documentation of time limits for major steps in the production process, lack of validation of rework or reprocessing steps in the manufacturing process, and lack of data to support in-process specifications. Quality unit-related issues include the appropriate reporting of out-of-specification results and process deviations (including adequate investigations into causes), appropriate documentation of product release, and adequate training of personnel. Facility and production monitoring concerns include controlling production environments by appropriately monitoring heating, ventilation, and air conditioning (HVAC) system performance and microbial quality (e.g., pressure differentials, appropriate sampling sites, and frequency of sampling). Other concerns pertaining to the facility include adequate cleaning, sanitization, storage, and changeover procedures for multiproduct areas and equipment. If the inspection team finds CGMP deficiencies in an already licensed facility, the team may remain in the facility until they have achieved an audit that provides confidence in the ability of the firm to reproducibly manufacture a safe and potent product.

Accelerating Availability of Vaccines and Pathways to Licensure

Mechanisms for providing earlier access to vaccines to prevent or treat severe and life-threatening illness have been developed.

These include fast-track development and the breakthrough therapy designation. The fast track program (Section 506(b) of FD&C Act) was added by FDAMA (1997) and amended by FDASIA (2012). It is designed to facilitate the development and expedite the review of new drugs and biologicals that are intended to treat serious or life-threatening diseases or conditions and for which nonclinical or clinical data are available that demonstrate the *potential* of the product to address unmet medical needs. A designation of a vaccine as fast track program provides the opportunity for frequent interactions of the applicant with the review team. The breakthrough therapy program (Section 506(a) of FD&C Act) was added by FDASIA of 2012. It applies to products for the treatment of serious or life-threatening disease or conditions for which preliminary clinical evidence indicates that the product may demonstrate substantial improvement on a clinically significant end point over available therapies. A sponsor may request a designation as a breakthrough therapy concurrently with, or any time after, submission of an IND. This new designation assists drug developers to expedite the development and review of new drugs with preliminary clinical evidence that indicates the drug may offer a substantial improvement over available therapies for patients with serious or life-threatening diseases. Breakthrough therapy designation provides for increased interaction with FDA to expedite the development and review of the application. In contrast to Fast Track designation, a breakthrough therapy designation requires evidence of substantial improvement over current treatments.

Products regulated by CBER are eligible for priority review if they provide a significant improvement in the safety or effectiveness of the treatment, diagnosis, or prevention of a serious or life-threatening disease. The FDA has 8 months to complete the review of a new BLA it designates as a priority, as opposed to 12 months for the completion of the review of a standard BLA submission.

Under the FDA's traditional approval pathway, a demonstration of vaccine effectiveness is based on a clinical disease end point (e.g., prevention of disease) or, alternatively, an accepted correlate of protection. In addition to these programs, the FDA's regulations provide for expedited pathways for licensure. Accelerated approval, 21 CFR §601.40, may be granted for certain biological products that have been studied for their safety and effectiveness in treating a serious or life-threatening disease or condition and that provide meaningful therapeutic benefit over existing treatments. Such an approval is based on adequate and well-controlled clinical trials establishing that the product has an effect on a surrogate end point that is reasonably likely to predict clinical benefit or on a clinical end point that can be measured earlier than irreversible morbidity or mortality that is reasonably likely to predict an effect on irreversible morbidity or mortality or other clinical benefit. Approval under this pathway is subject to the requirement that the sponsor study the biological product further, to verify and describe its clinical benefit, where there is uncertainty as to the relation of the surrogate end point to clinical benefit. Of note, the FDASIA of 2012 provided that evidence to support an end point is reasonably likely to predict clinical benefit to include "epidemiological, pathophysiological, therapeutic, pharmacologic, or other evidence developed using biomarkers, for example, or other scientific methods or tools." In other words, FDASIA expanded the scope of available end points that can be used to demonstrate that a product qualifies for accelerated approval, but do not affect the quantity and quality of evidence needed to demonstrate substantial evidence of effectiveness or safety.

Two vaccines to protect against meningococcal B diseases were licensed using the accelerated approval provisions and were designated breakthrough therapy. While the incidence of meningococcal serogroup B disease in the United States is low, outbreaks on several college campuses in the United States heightened concerns. Because of the diverse nature of meningococcal group B strains, as well as the low incidence of disease and the sporadic and unpredictable nature of an outbreak, clinical end point efficacy studies to support effectiveness of a serogroup B vaccine are not feasible. Given the public health concerns about meningococcal serogroup B disease in the United States, CBER agreed to provide breakthrough therapy designation and license two meningococcal group B vaccines, Trumenba and Bexsero, manufactured by Pfizer and GSK, respectively, under the accelerated approval regulations, 21 CFR §601 Subpart E. The Agency determined that it would be appropriate to use the accelerated approval pathway, basing approval on the ability of the vaccines to induce bactericidal antibodies, as measured by the human complement serum bactericidal assay, that are able to kill a panel of meningococcal group B strains that are representative of prevalent strains in the United States. The breadth of coverage of Trumenba and Bexsero against diverse meningococcal group B strains will be confirmed in subsequent clinical studies that examine the ability of the vaccine to induce bactericidal antibodies against a larger panel of meningococcal serogroup B strains representative of strains endemic in the United States.

In 2002, the FDA amended the biological products regulations to incorporate 21 CFR §601.90, Approval of Biological Products When Human Efficacy Studies Are Not Ethical or Feasible. This rule, referred to as the "Animal Rule," allows the use of animal efficacy data in lieu of human efficacy data when human challenge studies cannot be conducted ethically and field efficacy studies are not feasible because of infectious disease epidemiology (in the case of vaccines). In these situations, certain drug and biological products (e.g., vaccines) that are intended to reduce or prevent serious or life-threatening conditions caused by lethal or permanently disabling toxic chemical, biological, radiologic, or nuclear substances may be approved for marketing based on evidence of effectiveness derived from appropriate studies in animals and additional supporting data. Safety, pharmacokinetics, and immunogenicity data are still necessary in humans. Under the animal rule, the FDA licensure of a product for which safety has been established and the requirements of 21 CFR §601.60 have been met is based upon adequate and well-controlled animal trials, when results of these animal studies establish that the product is reasonably likely to provide clinical benefit to humans. The FDA can rely on the evidence from animal studies to provide substantial evidence of the efficacy of these products when:

1. There is a reasonably well-understood pathophysiological mechanism for toxicity of the chemical, biological, radiologic, or nuclear substance and its amelioration or prevention by the product.
2. The effect is demonstrated in more than one animal species that is expected to react with a response that is predictive for humans, unless the effect is demonstrated in a single animal species that represents a sufficiently well-characterized animal model (in other words, the model has been adequately evaluated for its responsiveness) in predicting the response in humans.
3. The animal end point is clearly related to the desired benefit in humans, which is generally the enhancement of survival or prevention of major morbidity.
4. The data or information on the pharmacokinetics and pharmacodynamics of the product or other relevant data or information in animals and humans is sufficiently well understood to allow selection of an effective dose in humans, and it is reasonable to expect the efficacy of the

product in animals to be a reliable indicator of its efficacy in humans.

The animal rule does not apply if the product can be approved based on standards described elsewhere in FDA regulations (e.g., accelerated approval based on surrogate markers or clinical end points other than survival or irreversible morbidity).

Emergency use authorization (EUA) is another regulatory mechanism by which the FDA can accelerate the availability of vaccines and other pharmaceutical products. Under an EUA, the FDA can authorize the use of an unapproved product or the unapproved use of an approved product when an emergency or a potential emergency exists. Section 564(b)(1) of the Federal FD&C Act was amended by the Project BioShield Act of 2004 to allow the Secretary of Health and Human Services (Secretary) to authorize the introduction into interstate commerce of a drug, device, or biological product intended for use in an actual or potential emergency. Before an EUA may be issued by FDA, the Secretary must declare an emergency justifying the authorization based on:

- A determination by the Secretary of Homeland Security that there is a domestic emergency or a significant potential for an emergency that involves a heightened risk of attack with a specified biologic, chemical, radiological, or nuclear agent or agents; or
- A determination by the Secretary of Defense that there is a military emergency or a significant potential for an emergency that involves a heightened risk of attack with a specified biologic, chemical, radiological, or nuclear agent or agents; or
- A determination by the Secretary of Health and Human Services of a public health emergency under section 319 of the PHS Act that affects or has the significant potential to affect national security and that involves a specified biological, chemical, radiological or nuclear agent or agents or a specified disease or condition that may be attributable to such agent(s).

Once the Secretary declares an emergency, the FDA can authorize the emergency use of a particular product if the other statutory criteria and conditions are met. Based on the particular circumstances, the process for authorization can be expected to range in duration from hours to days. The Secretary has delegated the authority to issue an EUA under Section 564 of the FD&C Act to the FDA Commissioner.

Vaccine Testing

Vaccines are tested during both the prelicensure and the postlicensure phases. Testing procedures are developed with the goals of controlling and minimizing the potential for product-related adverse events by taking into consideration the experience gained from the same or related products. As an example, for inactivated vaccines, a clear understanding of the kinetics of inactivation is critical. For live vaccines, attenuation must be stable both to avoid reversion to virulence and to avoid the vaccine becoming over attenuated and, as a consequence, less potent. For example, during the first decade of its widespread use, Yellow Fever 17D vaccine virus was serially propagated in eggs, as required to meet demand. However, it soon became obvious that the level of attenuation of the vaccine from one passage to the next could vary considerably. Some lots were excessively neurovirulent, especially in infants and young children, whereas successive lots might by chance be overattenuated and, consequently, not immunogenic. The WHO formulated a solution to this problem, which was to adopt a "seed-lot system" wherein the vaccine is prepared from a master seed virus at a specified passage number in eggs. Working seed virus is prepared by one passage of the master seed and is, in turn, used to generate all production lots. All 17D vaccines and all other live virus vaccines now adhere to a seed-lot system for manufacture.

The FDA requires that cell substrates and vaccine viral seeds used in production be appropriately selected and tested to ensure that they do not introduce any unintended risks. Current cell substrates used to manufacture licensed vaccines are primary avian cells (embryonated eggs or chick embryo fibroblasts), diploid cells, continuous cell lines (Vero and Madin-Darby canine kidney [MDCK]), as well as yeast and insect cells. Table 79.6 lists the cell substrates used in current U.S.-licensed vaccines. In 2010, the FDA published the guidance, "Characterization and Qualification of Cell Substrates and Other Biological Starting Materials Used in the Production of Viral Vaccines for the Prevention and Treatment of Infectious Diseases."[28] This document provides manufacturers of viral vaccines with guidance for the characterization and qualification of cell substrates, viral seeds, and other biological materials used for the production of viral vaccines for human use to assure that they meet the highest safety standards achievable using modern technology. Characterization of cell substrates should address certain general issues that might affect the safety and purity of vaccine products. For example, in the early 1960s, exogenous and endogenous contamination

TABLE 79.6 Cell Substrates Used in Current U.S.-Licensed Vaccines

		Vaccine	
Type	**Substrate**	**Live**	**Inactivated**
Animal tissues	Mouse brain Chicken eggs	 Influenza, yellow fever virus	Japanese encephalitis virus Influenza
Continuous cell lines (non-tumorigenic)	African green monkey cells (Vero)	Smallpox, rotavirus	Poliovirus, Japanese encephalitis virus
Diploid cells	Human MRC-5 cells Human WI-38 cells	Varicella, varicella-zoster Rubella, adenovirus types 4 and 7	Hepatitis A, rabies, poliovirus
Primary cell cultures	Chick embryo fibroblasts (CEFs) Madin-Darby canine kidney (MDCK) cells	Measles, mumps	Rabies Influenza vaccine
Insect cells	*Trichoplusia ni* *Spodoptera frugiperda*		Human papillomavirus Influenza vaccine
Yeast	*Saccharomyces cerevisiae*		Hepatitis B, human papillomavirus

of primary monkey kidney cells with simian virus 40 and chick embryo fibroblasts with avian leukosis virus were reported. Although chick embryo fibroblasts are still used for the production of viral vaccines, these cell substrates must be well-characterized and tested to assure absence of potentially infectious agents. Issues related to cell substrates have been discussed in a variety of forums.[29–31] Furthermore, if a vaccine is manufactured in a cell substrate that is derived from a tumor, or that has developed a tumorigenic phenotype through an unknown mechanism, it was considered to carry a higher theoretical risk of containing oncogenic substances such as oncogenic viruses and cellular DNA, derived from that cell substrate. This was the main reason tumorigenic cells or cells derived from human tumors had been considered unsuitable as cell substrates. However, at a 2012 meeting of the VRBPAC, experts recognized that cell lines derived from human tumor are an important tool for manufacturing of vaccines and could provide a wider repertoire of cell substrates for vaccine production.[30] They indicated that risk-mitigation strategies are the same for vaccines generated using human tumor-derived cell lines as for other cell substrates. A thorough characterization of the cell substrate with respect to adventitious viruses, which includes oncogenic viruses, should be done using new virus-detection technologies such as massively parallel sequencing, virus microarrays and broad-range polymerase chain reaction to complement existing assays. The manufacturing process should lower the amount and reduce the size of the DNA. Residual DNA for continuous nontumorigenic cells, such as low-passage Vero cells, should be limited to less than 10 ng/dose for parenteral inoculation and to less than 100 µg/dose for oral vaccines. Cells with tumorigenic phenotypes or other characteristics that give rise to special concerns may require more stringent limitation of residual DNA quantities and size to assure product safety.

The regulation of biologicals includes requirements for testing of licensed products (21 CFR §610). These tests include those for bacterial and fungal sterility, general safety, purity, identity, suitability of constituent materials and potency, thereby this specific testing performed may vary depending on the vaccine. For example, tests for potency may be based on studies of immunogenicity or, for some vaccines, protection from virulent challenge in laboratory animals. However, in vitro tests, including virus titration (e.g., live vaccines such as polio, measles, mumps, and rubella), antigen content (e.g., influenza and inactivated poliovirus vaccines), and biochemical and biophysical measurements (e.g., meningococcal conjugate vaccines) have been used.

Tests for purity are designed to determine that the product is free of extraneous material, except that which is unavoidable in the manufacturing process described in the approved license application. Tests for residual moisture and pyrogenic substances may also be included. Final-container material must be identified by a test specific for each product (e.g., neutralization of each of the components of live measles, mumps, and rubella vaccine with specific antisera). With regard to constituent materials, the manufacturer must ensure that all ingredients used in the product, such as diluents, preservatives, or adjuvants, meet generally accepted standards of purity. An adjuvant may not be used unless there is adequate proof that it does not adversely affect the safety or potency of the product.

Of note, the FDA periodically evaluates the appropriateness of testing requirements. An example is the general safety test (required under 21 CFR §610.11) used to detect extraneous toxic contaminants that may be present in the product in the final container from every final filling of each lot of the biological product. Technological advances have increased the ability of manufacturers to control and analyze the manufacture of many biotechnology-derived biological products. Thus, the FDA has published a final rule to remove this requirement.

In addition to the tests required by regulation, other tests tailored to the specific product may be required (e.g., neurovirulence testing and cell culture and animal tests for extraneous viruses). Once the product is licensed, the manufacturer's testing must be conducted according to the exact specifications in the manufacturer's license application, and the results of these tests must be within the specified prescribed limits.

Product Labeling and Advertising

Prescription drug labeling, also known as the package insert, package circular, or prescribing information, is the primary mechanism through which the FDA and drug manufacturers communicate essential, science-based prescribing information to healthcare professionals. Labeling provisions contained in 21 CFR §§201.57 and 201.56 require that prescribing information must summarize the essential information on the safe and effective use of the product; that information contained in the labeling must be accurate and not false and misleading; and that there must be no implied claims or suggestions for use if evidence of safety or effectiveness is lacking.[32] Whenever possible, data contained in labeling should be derived from human experience. In the United States, the FDA regulates the format and content of labels for product containers, cartons, and the package insert that accompanies the product. In January 2006, the FDA issued a final drug labeling rule, commonly referred to as the Physicians' Labeling Rule, amending the content and format of prescribing information for human drug and biologic products. The new format is intended to provide healthcare professionals with clear and concise prescribing information by reorganizing critical information into a streamlined format. Moreover, these revisions make it simpler for healthcare professionals to access, read, and use prescribing information, and enhance the safe and effective use of prescription drug products. New sections were added to the label, such as the Highlights section, which contains key benefit and risk information, and a table of contents for the full prescribing information. On December 3, 2014, the FDA issued the Pregnancy Lactation and Labeling Rule, which revises the content and format of the pregnancy subsection of labeling for prescription drugs and biologics (Sections 8.1 to 8.3 of the prescribing information). Previous regulations required that each product be classified under one of five pregnancy categories (A, B, C, D, or X) based on the risk of reproductive and developmental adverse effects or, for certain categories, such risk weighed against potential benefit. The most significant change proposed by the rule is the replacing of these letter risk categories with a narrative summary of the risks and benefits of using a drug during pregnancy, based on the available human and/or animal data and a discussion of the data. Additionally, the rule requires that prescription drug labeling include relevant clinical information to help healthcare providers make prescribing decisions and counsel women about the use of drugs during pregnancy and/or lactation.

The structured product labeling defines the content of human prescription drug labeling in XML format. It is a document markup standard approved by Health Level Seven and adopted by the FDA as a mechanism for exchanging product and facility information.[33] Structured product labeling documents contain both the content of labeling (all text, tables, and figures) for a product and additional machine-readable information (drug listing data elements). Drug listing data elements include information about the product (product and generic names, ingredients, ingredient strengths, dosage forms,

routes of administration, appearance, Drug Enforcement Agency schedule) and the packaging (package quantity and type).

During the BLA review, the agency considers the draft labeling and clinical studies submitted by the manufacturer, and the proposed indication for the licensed product, which is based on clinical data submitted by the sponsor demonstrating the safety and effectiveness of the product for its intended use and target population. Subsequently, significant changes in labeling, including new indications for use, new dosage forms or regimens, expanded patient populations who receive the product and additional information regarding safety and effectiveness, require manufacturers to submit a supplemental filing for review and approval by CBER. Unlike other product labeling, the promotional labeling and advertising are not subject to preclearance; however, they are monitored for misleading claims. These documents must also meet the standard of fair balance, that is, claims of efficacy are balanced with information about the product's safety.

Labeling changes are usually initiated by the manufacturer but may be initiated by CBER. Historically, manufacturers have had to obtain prior approval from CBER before the labeling changes were made. The changes to 21 CFR §601.12, mentioned previously, also apply to labeling changes and allow exceptions for a change that adds or strengthens a contraindication, warning, precaution, or adverse reaction; adds or strengthens instructions about dosage and administration intended to increase safe use; or deletes false, misleading, or unsupported indications for use or effectiveness claims. Under this regulation, a manufacturer could effect such changes and, at the same time, submit them and the supporting data to CBER without preapproval.

As described earlier, the FDAAA amended the FD&C Act by adding new Section 505(o) authorizing FDA to require and, if necessary, *order* labeling changes if the FDA becomes aware of new safety information that the FDA believes should be included in the labeling of the drug. Section 505(o)(4) of the FD&C Act imposes timeframes for application holders to submit and for FDA staff to review such changes, and gives the FDA new enforcement tools to bring about timely and appropriate safety labeling changes.

SPECIAL CONSIDERATIONS

Adjuvants

Strategies and approaches for the development and delivery of vaccine antigens have expanded over the last several decades, leading to a broad range of novel products comprised of purified subunit antigens or subunit proteins. These antigens may require the presence of adjuvants to enhance the immune response to the vaccine antigens, reduce the dosing frequency, induce cross-protective effects, direct the immune response and/or achieve antigen sparing. The number of investigational vaccines containing novel adjuvants evaluated in clinical trials has increased in recent years and some vaccines containing novel adjuvants have been licensed by the FDA. For example, the human papillomavirus vaccine manufactured by GlaxoSmithKline, Cervarix, contains AS04, an adjuvant system comprised of an aluminum hydroxide and monophosphoryl lipid A. GlaxoSmithKline's pandemic influenza vaccine, Q-Pan, contains AS03, an adjuvant system comprised of an oil-in-water emulsion.

The CFR defines adjuvants, together with ingredients, preservatives, and diluents as constituent materials (21 CFR §610.15).[34] These regulations state, "All ingredients…shall meet generally accepted standards of purity and quality" and that, "An adjuvant shall not be introduced into a product unless there is satisfactory evidence that it does not adversely affect the safety or potency of the product."

From a regulatory perspective, adjuvants are not considered active ingredients as defined in 21 CFR §210.3(b)(7) and vaccine adjuvants are not licensed separately.[35] It is the adjuvanted vaccine formulation, in toto, that is tested in nonclinical and clinical trials and licensed. There is a requirement that the adjuvanted vaccine formulation, as with any vaccine, must be both safe and effective, with its benefits outweighing the risks of adverse events that may occur. However, there is no explicit requirement for demonstrating the added safety and effectiveness of the adjuvanted vaccine formulation over that of the unadjuvanted vaccine formulation in comparative clinical trials.

The regulatory considerations for the nonclinical and clinical development of preventive vaccines, as well as pathways to licensure described elsewhere in this chapter, are largely also applicable to vaccines formulated with adjuvants. However, adjuvants can exhibit a range of properties that invoke complex immune responses, the mode of action is not always known or fully understood, and animal models that are relevant for evaluating both the safety and the efficacy of an adjuvant–antigen combination are frequently not available. Thus, there are some unique issues to be addressed during preclinical and clinical development of the adjuvanted vaccine formulation. A WHO guideline published in 2013 describes the nonclinical, quality, pharmacological, toxicological, and other information needed to support initiation of clinical trials with a vaccine combined with a novel adjuvant.[36]

In 2007, CBER published two guidance documents ("Guidance for Industry: Clinical Data Needed to Support Licensure of Pandemic Influenza Vaccines"[37] and "Guidance for Industry: Clinical Data Needed to Support the Licensure of Seasonal Inactivated Influenza Vaccines"[38]). Each of these documents discusses the development of adjuvanted inactivated influenza vaccines and notes that "[d]ata to support the safety of the adjuvanted formulation and added benefit over the unadjuvanted formulation must be submitted in the BLA…"[37,38] Sponsors were advised that "at an early stage of development, clinical data supporting the value of adding the adjuvant should be provided…"[37,38] The seasonal influenza vaccine guidance notes further that "[i]f an adjuvant is added to a licensed seasonal vaccine without antigen sparing effects…the immune response elicited by the adjuvanted formulation should be substantially better than that elicited by the unadjuvanted vaccine…"[38] As the FDA's experience with novel adjuvants has grown, the agency continues to reexamine guidance and engages with sponsors and applicants regarding the clinical development of adjuvanted vaccines.

Vaccine manufacturers should provide a rationale for the use of an adjuvant in the vaccine. The "added benefit" of an adjuvant may be defined as evidence of enhanced immune response, antigen-sparing effect, dose sparing, increased breadth of immune response, or superior clinical efficacy. Information to support the "added benefit" of the adjuvant may be derived from preclinical studies, for example, in vitro assays and/or proof-of-concept studies in animal models conducted prior to the initiation of clinical trials or early phase clinical trials. There is no regulatory requirement to demonstrate the "added benefit" of an adjuvant in clinical comparative Phase III effectiveness trials unless the applicant plans to make a claim of superiority of the adjuvanted product over unadjuvanted product.

The benefits from incorporating or adding an adjuvant to any vaccine formulation need to be balanced with the risk of adverse reactions. Adjuvants have their own pharmacological activity, which may affect both the immunogenicity and the safety of vaccines. Adverse reactions may include local

reactions such as pain, swelling, injection site necrosis, and granulomas. Systemic reactions may include nausea, fever, arthritis, as well as potential immunotoxic reactions. Unexpected, rare events may also occur. For example, during the H1N1 influenza pandemic in 2009–10, an increased risk of narcolepsy, a chronic neurological disorder caused by the brain's inability to regulate sleep–wake cycles normally, was observed in several European countries following vaccination with an AS03 adjuvanted, monovalent 2009 H1N1 influenza vaccine, Pandemrix.[39–43] The finding of narcolepsy in several European countries following vaccination with Pandemrix caused the European Medicines Agency to recommend restricting use of Pandemrix.[44]

Pandemrix was not licensed for use in the United States and no adjuvanted influenza vaccines were used in the United States during the influenza pandemic. The CDC published a study on a possible association between U.S.-licensed unadjuvanted 2009 H1N1 influenza vaccines, 2010–11 seasonal influenza vaccines, and narcolepsy.[45] The analysis included more than 650,000 people who received the pandemic influenza vaccine in 2009 and more than 870,000 people who received the seasonal influenza vaccine in 2010–11. The study found that neither vaccine was associated with an increased risk for narcolepsy. Additional studies including those conducted by the vaccine manufacturer will help discern whether this finding is attributable to the adjuvant, the H1N1 vaccine antigen, or both.

The safety of an adjuvanted vaccine formulation has to be demonstrated in adequate and well-controlled prelicensure safety studies. Safety information supporting licensure of an adjuvanted vaccine may include the safety experience obtained from domestic or foreign trials conducted using the adjuvanted vaccine formulation. In addition, safety experience with the same adjuvant formulated with other vaccine antigens may also contribute to the safety evaluation of the adjuvant. Early in clinical development (e.g., Phase I and Phase II clinical trials), supportive safety data may be derived by comparing the adjuvanted vaccine to a placebo or the unadjuvanted vaccine antigen, if feasible. Safety follow-up of human subjects administered vaccine with novel adjuvant is typically longer than for nonadjuvanted vaccines (e.g., 12 months rather than 6 months) and includes specific inquiries regarding symptoms consistent with autoimmune and neuro-inflammatory diseases. Furthermore, the safety database required to support licensure of a vaccine formulated with novel adjuvant may be larger than for unadjuvanted vaccines.

In summary, regulatory pathways supporting development and approval of vaccines formulated with novel adjuvants are similar to those for unadjuvanted vaccines. Efficient planning of the development pathway for any adjuvanted vaccine requires careful attention to preclinical testing, study design, dosing decisions, and safety monitoring. Although manufacturers are not required to demonstrate the "added benefit" of adjuvanted versus unadjuvanted vaccines in clinical comparative Phase III studies, manufacturers should provide a justification for including an adjuvant in the vaccine. Lastly, evaluation of safety of an adjuvanted vaccine needs to include special safety considerations.

Vaccines Against Global Infectious Diseases, Emerging Infectious Diseases, and Biothreat Agents

Immunization programs in the United States have been remarkably effective at reducing morbidity and mortality from the most common, naturally transmitted infectious diseases, such as polio, measles, and diphtheria. However, emerging infectious diseases (EIDs)—from pandemic influenza to novel pathogens like severe acute respiratory syndrome and Ebola, to biological threats that have the potential to be intentionally released into the general population by humans—also pose a threat to global public health. Vaccines will continue to be an important medical countermeasure against a broad range of infectious diseases from anthrax, smallpox, and influenza to newly emerging infectious diseases. Moreover, infectious diseases, such as tuberculosis and malaria present global public health challenges and increasing resistance to currently available treatments by common bacteria such as staphylococci, underscores the importance of the development of safe and effective vaccines.

The development of safe and effective vaccines to protect against global infectious diseases (e.g., tuberculosis, malaria, HIV/ AIDS), enteric diseases, and other neglected diseases of the developing world is of critical public health importance. Development and availability of such vaccines, particularly for use in the developing countries most affected by these diseases, will benefit U.S. and global health. In 2011, the FDA published a revised guidance document to assist sponsors in developing vaccines targeted against infectious diseases or conditions endemic in areas outside the United States. The FDAAA of 2007 revised the FD&C Act by adding Section 524, recognizing the importance of having products to treat and prevent tropical diseases that disproportionately affect poor and marginalized populations and for which there is no significant market in developed nations. Under Section 524, the Agency can grant priority review of applications under Section 505(b)(1) of the FD&C Act or Section 351 of the PHS Act for the treatment and prevention of specified tropical diseases, including tuberculosis, malaria, cholera, and "any other infectious disease for which there is no significant market in developed nations and that disproportionately affects poor and marginalized populations, designated by regulation by the Secretary." Consequently, this guidance provides general recommendations for regulatory pathways to use in the development of vaccines to protect against global infectious diseases for U.S. licensure and clarifies applicable regulations: (a) the FDA can license vaccines to protect against infectious diseases or conditions that are not endemic or have not been reported to occur in the United States; (b) the regulatory pathways to U.S. licensure for the development of vaccines to protect against infectious diseases that are not endemic or have not been reported to occur in the United States are the same as for vaccines to protect against diseases that are endemic in the United States; (c) a sponsor may submit data from clinical trials conducted outside the United States to support product licensure, (d) noting that the accelerated approval regulations may be used in appropriate cases; and (e) that when pivotal studies are conducted outside the United States, in some instances, it may not be necessary to conduct studies in the United States. This guidance also responded to the congressional mandate in Section 740 of the fiscal year 2010 Appropriation Act (Agriculture, Rural Development, Food and Drug Administration, and Related Agencies Appropriations Act, 2010, Public Law 111-80) by requiring the FDA to make recommendations on appropriate preclinical, trial design, and regulatory paradigms to prevent, diagnose, and treat rare diseases and neglected diseases.

The U.S. military has implemented vaccination programs to protect troops against several biological threats; however, the risk-to-benefit ratio for protecting civilians against agents of bioterrorism is more difficult to assess. As of this writing, there is one licensed smallpox vaccine in the United States, Sanofi Pasteur Biologics' ACAM2000. New smallpox vaccines are being developed under IND applications, with the goal to seek licensure, and new vaccinia immunoglobulin

preparations to treat certain complications of smallpox vaccination have been approved. There is one licensed anthrax vaccine in the United States, anthrax vaccine adsorbed (Emergent BioSolutions' BioThrax).

There are significant scientific and regulatory challenges associated with developing and testing new vaccines against EIDs and biothreat agents. Vaccines against EIDs are more likely to use novel technologies, and the science behind these technologies may be more complex; for example, use of novel cell substrates, the need to develop alternative potency assays, and the need to identify surrogate markers in humans or animals that predict vaccine effectiveness. To respond to this challenge, the FDA collaborates with interagency groups within the Department of Health and Human Services, such as the Biomedical Advanced Research and Development Authority, the CDC, and the NIH, as well as the Department of Defense and Department of Homeland Security to prepare for responding to an emergency. A committed, continuous investment in regulatory science is essential to producing medical countermeasures against public health threats. As noted in the *Public Health Emergency Medical Countermeasures Review*,[46] "Enhancement and ultimate application of updated regulatory science and scientific review capacity will help strengthen the MCM [medical countermeasure] regulatory process and thus streamline the MCM development process. [The] FDA will undertake a new initiative designed to focus on augmenting the tools used to assess the safety, efficacy, and quality of medical products, with a particular focus on MCMs, and to get them from concept through the approval process efficiently." An example of how the FDA's regulatory science efforts have assisted the agency in facilitating the licensure of vaccines against emerging diseases and biothreats is the successful public–private partnership during the 2009 H1N1 influenza pandemic, which resulted in the development and approval of safe and effective vaccines against the pandemic in record time. This included creating vaccine strains needed for vaccine manufacturing within weeks of the very first 2009 pandemic H1N1 influenza cases appearing, developing reagents and tests through international collaborations to measure the vaccine's potency, consulting the FDA's expert vaccine advisory committee to review the Agency's approach to approval of the 2009 H1N1 vaccine s as well as extensive in process quality control and product testing. Licensure of vaccines against the 2009 H1N1 influenza virus occurred in September 2009 based on the FDA's determination that standards to ensure the safety and potency of these vaccines had been met. In parallel to these efforts, NIH and vaccine manufacturers initiated clinical trials to determine the optimal vaccine dosage and number of doses needed to induce a protective immune response against pandemic 2009 H1N1 virus.

Another example illustrating collaboration both within the Department of Health and Human Services and between the Department and international partners is the response to the Ebola virus disease outbreak in West Africa in 2014–15 that caused more than 25,000 cases of Ebola virus disease and claimed the lives of more than 10,000 people, representing the most widespread epidemic of Ebola virus disease in history. To address this need, the FDA engaged with federal partners, sponsors of medical products, and international organizations to facilitate development of vaccines. To advance promising vaccine candidates to Phase I clinical trials to obtain preliminary human safety data, the FDA worked closely with manufacturers, clinical trial sponsors, and international regulators to rapidly assess product characterization data and protocols for these first human clinical trials and granted permission for the initiation of these Phase I studies in an expedited manner. Guidance provided by the FDA assured that these studies were conducted according to applicable regulations including the requirement for nonclinical testing and protection of human subjects. These efforts resulted in rapid availability of safety and immunogenicity data for the leading Ebola vaccine candidates, initiation of U.S. government–sponsored Phase III clinical studies to demonstrate the safety and effectiveness of these vaccines in individuals residing in outbreak areas, and collection of data supporting licensure of these products. To enable an initiation of these pivotal studies in an expedited manner, the FDA engaged in joint reviews with vaccine manufacturers, the WHO, regulatory agencies in Europe and Canada, and West African regulators to discuss study designs, ethical considerations, and required product information to reach international regulatory convergence, thus facilitating trial initiation. It is not always possible to test whether a vaccine or treatment will work against a new or emerging infectious disease, or against a biothreat, because the threat may be rare or even nonexistent at the time the vaccine or therapy needs to be developed. Moreover, many vaccines against EIDs and biothreats pose difficult challenges with regard to obtaining clinical efficacy data. For many of these infectious agents or toxins, human efficacy trials are not feasible because natural exposure no longer occurs (e.g., smallpox), occurs at a very low incidence, or occurs in an unpredictable manner. The animal rule described earlier (see "Accelerating Availability of Vaccines and Pathways to Licensure") is one regulatory mechanism that allows the FDA to address the challenges of obtaining clinical efficacy data for these products if the results of adequate and well-controlled animal studies establish that the product is reasonably likely to provide clinical benefits to humans.

Animal testing is often the only available option, but many diseases lack even good animal models, and animal studies are technically difficult to conduct and typically limited in size. Consequently, regulatory science is needed to develop and validate improved predictive models. Regulatory science can also support the identification and validation of surrogate measures of product efficacy. Biomarkers that predict efficacy are not yet available for most terrorism threats, emerging pathogens or major global infectious diseases. Efforts to develop, refine, and validate new biomarkers may lower development costs and improve and speed the development of safe and effective products for unmet public health needs.

In summary, for licensure, an EID vaccine product, just as for any product, must have an acceptable quality, safety, efficacy, and potency profile. Likewise, production and quality control also must be in compliance with CGMPs.

However, vaccines against EIDs and biothreats agents present unique issues for clinical development and evaluation by the FDA. Overall planning and coordination among the FDA and its national and international partners is necessary to move these products toward licensure and into distribution. FDA guidance and engagement with partners is critical to make sure these products can move from the future into the present.

CONCLUSION

The primary responsibility of NRAs is to ensure the quality, safety, and effectiveness of pharmaceutical products. The implementation of a strong regulatory system will facilitate these goals, which are especially critical for vaccines that are inherently more difficult to develop, characterize, and manufacture than most pharmaceutical products. The FDA has developed a managed review process that provides regulatory oversight through all phases of vaccine development. Advances across a wide range of scientific disciplines have enhanced the

prospects of developing new and better vaccines. Novel vaccine approaches such as recombinant vaccines and novel adjuvants and delivery systems pose regulatory challenges for NRAs. However, NRAs should be dynamic and flexible entities, as they strive to develop regulatory requirements to address the evolving science. Further, NRAs must be prepared to address public health emergencies that will require expedited approval mechanisms, such as biological terrorist events, pandemic influenza, and other EIDs.

Acknowledgments

I would like to acknowledge the employees in the Office of Vaccines Research and Review, Office of Biostatistics and Epidemiology, and the Office of Compliance and Biologics Quality/CBER for their assistance in the preparation of this manuscript.

80 Regulation of Vaccines in Europe

Falk Ehmann, Xavier Kurz, Marco Cavaleri, and Peter Arlett

Vaccines are complex biological medicinal products developed with increasingly sophisticated technologies. They can contain live infectious agents and many other ingredients. Because of the major individual and population benefits, immunization with certain vaccines is mandatory in many European countries, and any safety hazard could affect a large number of persons. In this context, regulatory authorities have the mandate to promote and protect public health by allowing use of safe and effective vaccines and by continuously assessing their benefit and risk profile after marketing authorization. These obligations are defined in two key European legislative texts, Regulation (EU) No. 726/2004 and Directive 2001/83/EC.

Many actors are involved in these activities: member states and their national competent authorities, public health institutions and national technical institutes including academia, and, at the European level, the European Commission in Brussels and the European Medicines Agency (EMA) in London. Another European agency established in 2004 through Regulation (EC) No. 851/2004, the European Centre for Disease Prevention and Control (ECDC), identifies, assesses, and communicates, in partnership with national health protection bodies across Europe, current and emerging threats to human health posed by infectious diseases. Since 1995, the EMA coordinates the scientific evaluation and supervision of medicines for use in the European Union, including vaccines; fosters scientific excellence in this activity; and makes scientific recommendations for marketing authorization of medicines to the European Commission.

MARKETING AUTHORIZATION

Marketing Authorization Procedures in the European Union

National Procedure

A national procedure applies when the manufacturer of a medicinal product or vaccine submits a marketing authorization application in a single member state where it intends to market the medicinal product or vaccine. This procedure for authorization of the product is the sole responsibility of the member states and is only possible if the concerned medicinal product does not fall within the mandatory scope of the centralized procedure.

A medicinal product may receive a marketing authorization that is valid in more than one member state in the European Union by one of two routes. These are the decentralized and the centralized procedures.

Decentralized Procedures

There are two decentralized procedures. In one, a marketing authorization application is submitted to more than one member state in parallel. In the other, a member state grants the first marketing authorization, which is then mutually recognized in the other concerned member states chosen by the manufacturer of the medicinal product or vaccine; this is the *mutual recognition procedure.* Such procedures are facilitated by the Co-ordination Group for Mutual Recognition and Decentralised Procedures—Human (CMDh), which meets at the EMA monthly.[1] The marketing authorization application submitted via one of these procedures (decentralized or mutual recognition) must be identical to the original marketing authorization application granted in the first member state, called the *reference member state.*

Centralized Procedure

European Union (EU) regulations define which medicinal products must go through the centralized procedure to receive a marketing authorization that is valid for the whole of the EU. In general, vaccines containing a new active substance outside any of the mandatory therapeutic indications defined in the Annex I of Regulation (EU) No. 726/2004[2] may follow the centralized procedure or the decentralized procedure. The centralized procedure is required for all medicinal products (including vaccines) developed by recombinant DNA technology, such as controlled expression of genes coding for biologically active proteins in prokaryotes (e.g., Cervarix) expressed in baculovirus and eukaryotes (e.g., Infanrix hexa), expressed in Vero human cell lines (e.g., Gardasil [human papillomavirus vaccine]), in yeast cell lines, and flu vaccines incubated in fertilized eggs. This includes transformed mammalian cells, or hybridoma and monoclonal antibody methods. This registration procedure must also be used if the concerned vaccine is considered to be an advanced therapy medicinal product or an orphan medicinal product pursuant to Regulation (EC) No. 141/2000.

The EMA and its Committee for Human Medicinal Products (CHMP) is responsible for evaluating the quality, safety, and efficacy of medicinal products submitted through this procedure. The CHMP consists of one member plus an alternate for each EU member state, one member each from Iceland and Norway (European Economic Area countries) plus their alternates, and five coopted members selected based upon their expertise and experience in evaluating medicinal products. The CHMP is assisted by a wide network of experts from all over Europe. The regulation allows the CHMP to establish working parties, such as the Vaccines Working Party and the Biologics Working Party, to draft guidance and advise the CHMP on specific aspects of product evaluation and supervision.

The scientific review of a marketing authorization application is performed to the highest scientific standards following a flexible timetable. The total duration to assess a marketing authorization application, draft and discuss reports, and adopt an opinion should not take more than 210 days. This duration can be shortened under certain conditions. Although the dossier submitted by the marketing authorization holder forms the basis for the evaluation of the benefits and risks of the vaccine, other sources of information, including those from the ECDC, national research institutions, including academia or the World Health Organization (WHO), might, in addition, be consulted to perform a scientific assessment. The result of the evaluation is a positive (favorable) or negative (unfavorable) CHMP opinion to recommend granting a marketing authorization for the medicinal product.

The CHMP may also consult the established vaccines scientific advisory group, possibly including additional ad hoc experts formed by leading experts in the relevant field and chosen based upon the content of the questions referred by the CHMP.[3] Scientific advisory groups assist the CHMP on specific questions, especially in cases where there is a divergence of scientific opinions.

Three types of positive opinions can be recommended by the CHMP: full marketing authorization, conditional marketing authorization, and marketing authorization under exceptional circumstances.

A full marketing authorization is adopted by the CHMP for a medicinal product for which a positive benefit-and-risk assessment has been concluded based on sufficiently comprehensive data.

A conditional marketing authorization may be recommended by the CHMP for certain categories of medicinal products and in certain situations; for example, to meet unmet medical needs and in the interests of public health, and where it is necessary to grant marketing authorizations on the basis of data that are less complete than is normal and therefore subject to specific obligations. The categories of products concerned should be medicinal products that aim to treat, prevent, or diagnose seriously debilitating or life-threatening diseases; medicinal products to be used in emergency situations in response to public health threats recognized either by the WHO or by the EU; or medicinal products designated orphans. Such conditional marketing authorizations are granted for 1 year, renewable until the specific obligations are fulfilled.[4]

The CHMP may recommend granting a marketing authorization under exceptional circumstances, subject to specific defined conditions, if the applicant can show that it is unable to provide comprehensive data on the efficacy and safety under normal conditions of use for one of the following reasons[5]:

- The indications for which the product in question is intended are encountered so rarely that the applicant cannot reasonably be expected to provide comprehensive evidence.
- In the present state of scientific knowledge, comprehensive information cannot be provided.
- It would be contrary to generally accepted principles of medical ethics to collect such information.

In all instances, the final opinion adopted by the CHMP is sent to the European Commission. If its standing committee's opinion is favorable, the commission issues a formal decision that serves legally as the EU marketing authorization, which is valid throughout the EU in all member states. Following the commission's decision, the EMA publishes the European Public Assessment Report after deleting commercially confidential information.[6]

The choice whether to follow the decentralized or centralized procedure lies with the applicant unless the vaccines fall under the mandatory scope of the centralized procedure as described above.

Preauthorization Evaluation of Benefit and Risk

In the context of a new drug application, the assessment of the benefits and risks must objectively reach a sufficient level of confidence that the quality, efficacy, and safety of the new medicinal product have been demonstrated. A marketing authorization may be refused if the therapeutic efficacy is insufficiently demonstrated or if the benefit-to-risk balance is not considered favorable.[7] This assessment should be based on the available tests and trials, which must be designed to determine the efficacy and safety of the product under normal conditions of use. The assessment should consider the perspectives of different stakeholders, in particular those of patients and treating physicians. Authorization decisions under the centralized procedure should be to the exclusion of economic and other considerations such as cost-effectiveness.

Data Requirements for New Vaccines

Efficacy

Protective efficacy studies ideally are presented for the authorization of new vaccines, but in some situations such studies are either not necessary or not feasible, such as in cases where use of immunologic data to predict protection against infection can be justified. Examples include cases such as the following:

- Immunologic correlates of protection against specific infections (e.g., diphtheria, tetanus) have been established.
- Estimation of protective efficacy is not feasible because the potentially preventable infectious disease occurs at a rate too low for a study to be performed in a reasonable period (e.g., brucellosis, Q fever).
- Efficacy studies are not feasible and no immunologic correlate of protection exists, but the likely efficacy of a vaccine may be estimated by comparison of immunologic responses with those seen in past studies of similar vaccines with proven protective efficacy (e.g., acellular pertussis vaccines).
- Efficacy studies are not feasible and there is no established immunologic correlate of protection or previous efficacy studies that might provide immunology data for comparison (e.g., anthrax).

In case a protective efficacy study is not performed, the applicant needs to provide a sound justification for the lack of such data. The protocols used for studies of protective efficacy should include a rationale for the choice of the study population and a detailed description of the methods used for diagnosing infection (e.g., clinically apparent or inapparent infections). In principle, validated methods should be used for diagnosis or for other evaluations (e.g., histology). Immunogenicity data to characterize the immune response to the vaccine and to support the development of specific posology need to be collected under all circumstances.

Guidelines with respect to quality, nonclinical and clinical development of vaccines are available on the EMA's website.[8]

Safety

Safety data should usually be collected after each dose of the vaccine. Because most adverse reactions to vaccines occur within the first few days after each dose, it is generally accepted to focus the collection of information on adverse events that occur within 5 to 7 days after vaccination (longer for live vaccines). In most cases, it is not reasonable to expect that the preauthorization database is sufficiently large to identify rare adverse events. As a minimum, the total data from preauthorization studies is usually sufficient to reliably determine the frequency of uncommon local and systemic adverse events that have an incidence of between one per 100 and one per 1000 vaccinated persons. Unless otherwise justified, the recommended minimum sample size should be at least 3000 subjects for new vaccines. Certain vaccines, such as those containing novel adjuvants, may have to provide additional evidence of their safe use.

Differences in the safety profile might be observed between certain subpopulations and also with consecutive doses during the immunization schedule. In these cases, it may be necessary

to obtain sufficient data to detect at least uncommon adverse events in various subsets before a marketing authorization could be granted, and the applicant should address these matters in adequately powered postmarketing studies.

Authorization Based on Limited Data

Special consideration is needed for clinical development of vaccines when protective efficacy studies are not feasible and when there is no established immunologic correlate of protection. This applies, for example, to vaccines intended to prevent rare infections that carry considerable morbidity and mortality, including by some pathogens that have the potential to cause widespread disruption to humanity in case of an epidemic or deliberate release.

In some cases, it is feasible to obtain some relevant data on protective efficacy from challenge studies in animal models. Immunologic correlates of protection might be established for very similar but not identical antigens that might be used in the meantime as a guide for likely efficacy. If possible, immunologic studies should focus on measuring functional immune responses. Taking the results of these and any other relevant investigations together, a presumptive risk-to-benefit relationship could be derived that might support authorization.

When authorization is based on limited data, it might not be possible to estimate the vaccine's effectiveness in the postauthorization period unless a natural epidemic or deliberate release occurs. In any case, it is likely that reliable data could be obtained only from national surveillance programs operated by public health authorities or those coordinated by the ECDC. Applicants are encouraged to work with public health authorities to develop plans that would allow collection of data on safety and efficacy if the opportunity arises (e.g., a significant outbreak or major epidemic). It is recommended to seek scientific advice when considering a marketing authorization application based on limited data.

SCIENTIFIC ADVICE AND AUTHORIZATION OF CLINICAL TRIALS

The EMA may provide pharmaceutical companies with scientific advice and protocol assistance; protocol assistance consists of scientific advice for companies developing medicines for orphan or rare diseases.[9] Advice may be requested at any stage of development of a medicinal product (e.g., before the submission of a marketing authorization application) or during the postauthorization phase. This is particularly useful when the development used by a company deviates from the available guidance or when relevant EU guidance does not exist. Scientific advice can be sought at any stage during product development and life-cycle and covers quality, nonclinical and clinical as requested.

The EMA scientific advice or protocol assistance procedure accepts questions related to clinical studies performed first in humans and questions related to clinical development plans and addresses them from a scientific point of view, adding a disclaimer clarifying responsibilities. Scientific advice can also relate to postauthorization monitoring of vaccines.

Requests for scientific advice are independent of the type of registration procedure followed for the marketing authorization. It has been shown that companies following EMA's advice are more likely to succeed with the authorization procedure, receive faster evaluation of the marketing authorization application, and have reduced risk of refusal of a marketing authorization.[10] For medicinal products for human use, scientific advice is given by the CHMP upon recommendation of the Scientific Advice Working Party. The advice is a preparatory act of the procedure, and it is not legally binding. The scientific advice can be followed or not by companies and regulators, and it does not ensure a favorable outcome for the marketing authorization application. The scope of this procedure can be very broad and can include questions regarding, for example, legal aspects of orphan medicinal products, a class of medicinal products, the use of scales in a therapeutic indication, or a risk-management plan. Scientific advice may be sought for products intended to be marketed exclusively outside the EU in cooperation with the WHO (see later discussion).

The EMA and the U.S. Food and Drug Administration cooperate to provide coordinated scientific advice. It is expected that this program will contribute to a common understanding of scientific issues, offer opportunities to optimize product development globally, and avoid unnecessary or divergent testing requests.

One goal of EMA's long-term strategy is to foster research and the uptake of innovative methods in the development of medicines. For this purpose, the multidisciplinary EMA Task Force on Innovation has been established as a discussion platform for early dialogue with applicants to proactively identify scientific, legal, and regulatory issues for emerging therapies and technologies and for borderline products that have characteristics belonging to diverse legal frameworks, such as medicines and medical devices.

The authorization of clinical trials is the responsibility of national competent authorities of EU member states in which the sponsor wishes to conduct the trial. The same applies for ethics committees. Guidance and legislation in relation to the conduct of clinical trials in Europe is described in volume 10 on clinical trials of the EudraLex.[11]

REQUIREMENTS FOR PEDIATRIC MEDICINAL PRODUCTS

The EU pediatric regulation (Regulation [EC] No. 1901/2006, as amended) was adopted in Europe to support the development, quality, and availability of medicines for children, promote ethical research in children, and ensure availability of information on the use of pediatric medicines.[12] This regulation also applies to vaccines used in children.

For new medicines (including vaccines) marketing authorization applications must include the results of studies conducted in the pediatric population in compliance with a pediatric investigation plan agreed upon between the EMA Pediatric Committee and the applicant. A pediatric investigation plan is also needed for a new pediatric indication, pharmaceutical form, or route of administration added to an existing authorized medicinal product in the EU. The pediatric investigation plan covers relevant clinical trials in the pediatric population, timelines to perform these, and measures proposed to obtain a pediatric indication; it also may propose an age-appropriate formulation in the target pediatric population. Deferrals to research may be granted when, for instance, development of the pediatric version is postponed until efficacy and safety have been demonstrated in adults. Waivers are granted when the Pediatric Committee does not consider specific pediatric development necessary or appropriate. When a pediatric authorization for a product is obtained for all EU member states and when the study results, whether positive or negative, are included in the product information, the medicine is eligible for a 6-month patent extension. Off-patent medicines developed specifically for pediatric use can also benefit from a marketing authorization for pediatric use with 10 years of data protection.

The EMA and the U.S. Food and Drug Administration cooperate and exchange information to foster the development of medicines for children.

MEDICINAL PRODUCTS INTENDED FOR MARKETS OUTSIDE THE EUROPEAN UNION

The CHMP may give a scientific opinion, in the context of cooperation with WHO, for evaluating certain medicinal products for human use intended exclusively for markets outside the EU. Examples of this so called *Article 58 procedure* include vaccines to be possibly used in the WHO Expanded Programme on Immunization, vaccines for protection against a WHO public health priority disease, and vaccines that are part of a WHO-managed stockpile for emergency response.[13] The procedures and requirements for the centralized procedure are applied in this case. The European Commission does not formulate a decision for a marketing authorization, but the Article 58 procedure does not exclude a future application for a marketing authorization in the EU. The CHMP assesses the quality, safety, and efficacy of the medicinal product applying the same scientific scrutiny and criteria as for an EU marketing authorization application using input from WHO experts and from observers from authorities from developing countries recommended by WHO as needed. This assessment is performed according to guidelines of the EU and International Conference on Harmonization or, if appropriate, to guidelines issued by WHO and other bodies. Different benefit-to-risk profiles of the product for the target population may be considered based on assumptions about possible conditions of use in the targeted country or region.

An Article 58 application may be assessed in parallel with a WHO prequalification procedure, in which case EMA collaborates with the WHO and interacts as necessary with relevant WHO expert advisory committees.

Following the CHMP opinion, the opinion holder is responsible for post opinion activities and life-cycle management as foreseen for products for which there is an EU authorization. A conditional opinion or an opinion under exceptional circumstances is applicable as well. New data are assessed by the CHMP in cooperation with the WHO, as appropriate. The opinion holder also ensures that suspected adverse reactions to a medicinal product that are brought to his attention are recorded and promptly reported to the competent authorities of the countries where the product is marketed according to their pharmacovigilance reporting obligations. Adverse reactions are also reported in the EU in compliance with applicable guidelines and standards. The CHMP may perform a benefit-to-risk review at any time and revise its scientific opinion after consulting the WHO.

RISK MANAGEMENT

Current European legislation requires applicants for a marketing authorization of a medicinal product to include in the application a detailed description of the risk-management system they will introduce. This system is described in Module V of the Good Pharmacovigilance Practices and is defined as "a set of pharmacovigilance activities and interventions designed to identify, characterize, prevent, or minimize risks relating to medicinal products, including the assessment of the effectiveness of those activities or interventions."[14] The description of a risk-management system takes the form of an EU risk-management plan.

An EU risk-management plan has two parts (Box 80.1). Part I includes a safety specification and pharmacovigilance plan. The safety specification summarizes what is known and not known about different aspects of the safety profile of the medicinal product at the time of authorization and thereafter at particular points of its life cycle. The plan helps identify important risks and important missing information that need to be addressed in a pharmacovigilance plan. Part II presents any risk-minimization activities deemed necessary for any of the identified risks. Vaccines are different from most other medicinal products in ways that influence safety considerations. Specific aspects to be addressed in the safety specification and pharmacovigilance plan of EU risk-management plans for vaccines have been provided in a specific good pharmacovigilance practices module focused on vaccine vigilance (Box 80.2).[15]

New EU legislation on pharmacovigilance has been operational since July 2012, and from that time all new EU risk-management plans must include the planning of efficacy and effectiveness studies as needed, as well as safety studies and risk-minimization planning. An important element of the new pharmacovigilance legislation is the possibility for regulatory authorities to impose to marketing authorization holders the conduct of postauthorization safety studies with the aim of identifying, characterizing, or quantifying a safety hazard; confirming the safety profile of the medicinal product; or of measuring the effectiveness of risk-management measures.[16] According to the new pharmacovigilance legislation, postauthorization efficacy studies can also be imposed in specific circumstances to marketing authorization holders.

POSTAUTHORIZATION EVALUATION OF BENEFITS AND RISKS

Postauthorization evaluation of the benefit-to-risk balance of vaccines is an ongoing process under the responsibility of marketing authorization holders and competent authorities (medicine regulatory authorities). The marketing authorization holder has the legal obligation to inform and submit any relevant changes to the data that were the basis for the original marketing authorization, in the form of relevant and, as appropriate, supported variations, in accordance with the EU Variation Regulation. This can lead to actions and communications on changes in the benefit-to-risk profile to public health institutions, healthcare professionals and patients.

Box 80.3 summarizes the roles and responsibilities for the benefit-and-risk evaluation for centrally authorized medicinal products. For the decentralized procedure, this activity is coordinated by the reference member states and the CMDh in case of points of disagreement raised by a member state. The responsibility for purely national procedures lies with member states.

The process of any benefit-to-risk evaluation includes taking the following steps:

- Promptly detect and share signals of possible unexpected adverse reactions.
- Confirm, quantify, and assess potential risks.
- Evaluate or reevaluate the benefits of vaccines, including any available data on effectiveness, duration of immunity, vaccination coverage, and public health impact.
- Improve the benefit-to-risk balance, such as by promoting correct use of the vaccine or close surveillance of vaccinated patients to detect early symptoms of severe adverse reactions.
- Evaluate the effectiveness of measures aiming to improve the benefit-to-risk balance.

A key component in this process is vaccine pharmacovigilance, defined as the set of activities for detecting, assessing, understanding, preventing, and communicating adverse events following immunization or of any other vaccine- or immunization-related issues.[17] To establish and maintain a pharmacovigilance system is a legal obligation of marketing authorization holders and member states, an important element being the recording and reporting by the marketing

BOX 80.1 Structure of the European Union Risk-Management Plan

Part I. Product Overview
Part II. Safety Specification
SI. Epidemiology of the indications and target population
SII. Nonclinical part of the safety specification
- Toxicity
- General pharmacology
- Drug interactions
- Other toxicity-related information or data

SIII. Clinical trial exposure
SIV. Populations not studied in clinical trials
SV. Postauthorization experience
- Action taken by regulatory authorities and/or marketing authorization holders for safety reasons
- Nonstudy postauthorization exposure
- Postauthorization use in populations not studied in clinical trials
- Postauthorization off-label use
- Epidemiological study exposure

SVI. Additional EU requirements for the safety specification
- Potential for harm from overdose
- Potential for transmission of infectious agents
- Potential for misuse for illegal purposes
- Potential for medication errors
- Potential for off-label use
- Specific pediatric issues

SVII. Identified and potential risks
- Newly identified safety concerns
- Recent study reports with implications for safety concerns
- Details of important identified and potential risks from clinical development and postauthorization experience
- Identified and potential interactions including food-drug and drug-drug interactions
- Pharmacological class effects

SVIII. Summary of the safety concerns
Part III. Pharmacovigilance plan
- Routine pharmacovigilance activities
- Additional pharmacovigilance activities
- Action plans for safety concerns with additional pharmacovigilance requirements
- Summary table of additional pharmacovigilance activities

Part IV. Plans for postauthorization efficacy studies
- Summary of existing safety data
- Table of postauthorization efficacy studies

Part V. Risk minimization measures
- Routine risk minimization
- Additional risk minimization activities
- Format of risk minimization plan(s)
- Evaluation of the effectiveness of risk minimization activities
- Summary of risk minimization measures

Part VI. Summary of activities in the risk-management plan by medicinal product
- Format and content of the summary of the risk-management plan
- Overview of diseases epidemiology
- Summary of treatment benefits
- Unknown relating to treatment benefits
- Summary of safety concerns.
- Summary of risk minimization activities by safety concern
- Planned postauthorization development plan
- Summary of changes to the risk-management plan over time

Part VII. Annexes to the risk-management plan

Modified from European Medicines Agency (EMA). Guideline on good pharmacovigilance practices (GVP). Module V–Risk management systems (Rev 1). 15 April 2014. Available at: http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2012/06/WC500129134.pdf

authorization holder of suspected adverse reactions. For authorized medicinal products, independent of the authorization procedure, notifications of adverse reactions received from healthcare professionals or patients, either spontaneously or through postauthorization studies, and adverse reactions identified from the worldwide published literature should be reported within defined timelines to Eudravigilance, a European database and data-management system of suspected adverse reactions for products authorized in the European Economic Area. For vaccines, cases of lack of efficacy should also be reported, in particular with a view to possible signals of reduced immunogenicity in a subgroup of vaccinees, waning immunity, and strain replacement.

Suspected adverse reactions should also be reported by marketing authorization holders in periodic safety update reports, which provide competent authorities with an update of the worldwide safety experience of medicinal products at defined points after authorization. This update includes a critical evaluation of the benefit-to-risk balance of the product in the light of new or changing information and ascertains whether further investigations need to be done and whether changes should be made to the marketing authorization and product information. For vaccines, the periodic safety update report also includes data of lack of efficacy. Periodic safety update reports should also be submitted immediately upon request from a competent authority and, for centrally authorized products, from the EMA.

Given the complexity of the benefit-to-risk evaluation of vaccines and the large number of aspects to be considered,[16] a broad range of expertise is needed in this process. In the EU this is made available by the Pharmacovigilance Risk Assessment Committee, the CHMP Vaccine Working Party, other CHMP working parties, vaccines scientific advisory group, and other ad hoc expert groups as needed.

To protect public health, it may become necessary to implement urgent measures, such as to recall or halt the distribution (quarantine) of (a) batch(es) of a vaccine because of a suspected batch-specific safety signal or defect. The principle of public health protection may be particularly relevant in certain situations (e.g., vaccines for healthy children, particularly in case of a localized incident). However, batch recall or quarantine may have a detrimental impact on the vaccination program itself, even if absence of association between the suspected batch(es) and the adverse events is later demonstrated, and thus may cause overall harm to public health. In situations where a batch-specific quality or safety issue has not been confirmed, measures other than recall or quarantine may be warranted initially while an investigation is ongoing (e.g., providing recommendations on patient surveillance and follow-up postvaccination). This may be considered when recall or quarantine may lead to vaccine supply shortages and alternatives are not widely available. Consequently, the Good Pharmacovigilance Practices Module P.I. on vaccine pharmacovigilance also includes recommendations to national

BOX 80.2 Aspects of the European Union Risk-Management Plan to Be Specifically Addressed for Vaccines

PART I. PRODUCT OVERVIEW

Type of vaccine and composition, manufacturing process (e.g., genetically engineered vaccine or novel concept); details of combined vaccines; any new technology or novel delivery systems; any immunogenic adjuvants, stabilizers, preservatives, excipients, and residual material from the manufacturing process.

PART II. SAFETY SPECIFICATION

SI. Epidemiology of the Indications and Target Population

Expected or observed (for vaccines already included into a vaccination program) impact of the vaccine on the epidemiology of the vaccine-preventable condition

SII. Nonclinical Part of the Safety Specification

Findings of preclinical testing related to the antigen, other vaccine constituents and residuals, and to interactions of vaccine components; vaccine-related quality aspects if relevant to safety

SIV. Populations Not Studied in Clinical Trials

Immune response in different age groups; risk to the fetus from vaccination of the mother with an inactivated vaccine; risks and immune response in immunocompromised individuals

SVI. Additional EU Requirements for the Safety Specification

Potential for Transmission of Infectious Agents. Potential for medication errors resulting from inappropriate handling or breakdown of the cold chain, the method of administration, noncompliance with the recommended vaccination schedule, product packaging and branding, circumstances of a mass vaccination, situations where several vaccines are marketed in a same country with the same indications

SVII. Identified and Potential Risks

Potential risks to be considered include waning immunity; those anticipated from experience with similar vaccines and vaccine ingredients; those associated with concomitant administration of several vaccines; potential interactions with medicinal products; syndromes closely resembling wild type disease, caused on rare occasion by some live attenuated vaccines; adverse events of special interest (AESIs).

SVIII. Summary of the Safety Concerns

Missing information to be considered include long-term duration of protection, waning immunity and need for (a) booster dose.

PART III. PHARMACOVIGILANCE PLAN

- Routine pharmacovigilance activities put in place for the surveillance of serious but rare adverse reactions, batch-related adverse reactions, identified and potential interactions, possible safety concerns identified with combined vaccines, AESIs, inappropriate use of vaccines and patterns of errors, cases of breakthrough infections, adverse reactions indicating a possible reversion to virulence. As part of the routine follow-up of adverse reactions, information should be collected on the vaccination schedule and route of administration; the vaccine and the diluent (including the batch number), batch release specifications in case of suspected quality defect, relevant comorbidities in the target population, including autoimmune disorders
- Additional pharmacovigilance activities may be needed to detect strain replacement phenomena; address patterns of shedding, transmissibility to contacts and effectiveness of the vaccine; establish evidence of safety for novel vaccines or for vaccines with a novel adjuvant; investigate clusters of adverse reactions
- Action plans for safety concerns with additional pharmacovigilance requirements
- Summary table of additional pharmacovigilance activities

PART IV. PLANS FOR POSTAUTHORIZATION EFFICACY STUDIES

- Summary of existing safety data
- Table of postauthorization efficacy studies

PART V. RISK MINIMIZATION MEASURES

- Routine risk minimization
- Additional risk minimization activities
- Format of risk minimization plan(s)
- Evaluation of the effectiveness of risk minimization activities
- Summary of risk minimization measures

Modified from European Medicines Agency (EMA). Guideline on good pharmacovigilance practices (GVP). Product- or Population-Specific Considerations I: Vaccines for prophylaxis against infectious diseases. 9 December 2013. Available at: http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2013/12/WC500157839.pdf.

regulatory authorities regarding elements to be taken into account when considering the recall or quarantine of vaccine batches for safety reasons.

In Europe, the ECDC may provide scientific advice on vaccine-related issues and measures that can affect vaccination programs and disease epidemiology. It may also help identify data sources for additional investigations based on linkage between vaccine exposure and health outcomes. For specific issues, specific expert groups may be established.

COMMUNICATION OF BENEFITS AND RISKS

Communication of the benefit-to-risk balance of vaccines needs careful consideration. Benefits in terms of protecting the public health may be difficult to convey, particularly if the incidence of the target disease is low. On the other hand, common and nonserious adverse events following immunization, such as fever or injection-site pain, can affect its acceptability. Uncertainty on potential rare and serious adverse reactions can further decrease public confidence in vaccination programs. Key elements of communication on vaccines therefore include factual information on what is known and not known about disease epidemiology, benefits and risks of the vaccines, and activities undertaken to address missing data and to minimize risks.[16]

In the European context, it is essential that consistent information with coordinated timelines be provided in all EU member states. EMA has a lead responsibility in preparing (in collaboration with the member state coordinator) communications on the benefits and risks of vaccines. The ECDC has a role in coordinating national communications regarding vaccination programs, which are the responsibility of member states, and disease epidemiology. Both EMA and ECDC have communication plans and provide information on their websites.

Among the available communication tools, direct communications to healthcare professionals are often used to reinforce safe and effective use of medicinal products, including vaccines, and are delivered directly to healthcare professionals by a marketing authorization holder or a competent authority.

BOX 80.3 Key Roles and Responsibilities of Partners Involved in the Postauthorization Evaluation of Benefit and Risk Evaluation and Decision-Making Process for Centrally Authorized Vaccines

MARKETING AUTHORIZATION HOLDER

- Establish and maintain a system to collect, collate, evaluate, and report pharmacovigilance data, including suspected adverse reactions and periodic safety update reports
- Respond to requests from authorities for additional information necessary for the evaluation of benefits and risks

MEMBER STATES

- Have in place national pharmacovigilance systems, including the provision for serious adverse reactions that have occurred on their territory to the agency and the marketing authorization holder
- Inform other partners of any relevant actions
- Identify and evaluate safety concerns and conduct evaluations of benefits and risks
- Implement European Commission decisions
- In case of urgent action needed to protect public health, suspend the use of the vaccine in the member state's territory and inform the agency and the European Commission of the basis of that action

EUROPEAN MEDICINES AGENCY

- Coordinate the pharmacovigilance system
- Monitor the legal obligations of the marketing authorization holders
- In agreement with the rapporteur, identify signals of possible unexpected adverse reactions or changes in severity, characteristics, or frequency of expected adverse reactions
- In agreement with the rapporteur, inform all involved parties of any safety concerns
- Coordinate the evaluation of data by the rapporteurs
- Communicate Committee for Medicinal Products for Human Use (CHMP) opinions to the European Commission

COMMITTEE FOR HUMAN MEDICINAL PRODUCTS RAPPORTEUR

- Evaluate safety concerns, adverse reactions, and benefit and risk data (e.g., periodic safety update reports and company reports) and obtain additional information as necessary
- Provide assessment reports to agreed-upon timetables for consideration by the Pharmacovigilance Working Party and CHMP, with proposals for appropriate action

PHARMACOVIGILANCE RISK ASSESSMENT COMMITTEE

- Evaluate potential signals arising from spontaneous reporting and other sources
- Evaluate emerging safety concerns at the request of the rapporteur
- Assess study protocols for imposed postauthorization safety studies (PASS) and provide advice to CHMP on nonimposed PASS
- Provide advice to the CHMP on safety, evaluations of benefits and risks, and actions necessary to minimize risk and maximize benefits

COMMITTEE FOR HUMAN MEDICINAL PRODUCTS VACCINE WORKING PARTY

- Provide advice to the CHMP on any vaccine-related issue

COMMITTEE FOR HUMAN MEDICINAL PRODUCTS

- Discuss the benefit-to-risk balance on the basis of the rapporteur's assessment report
- Formulate opinions

EUROPEAN COMMISSION

- Formulate decisions
- Enforce legal requirements and implementation of decisions by member states and marketing authorization holders

Modified from European Medicines Agency (EMA). Good pharmacovigilance practices. Available at: http://www.ema.europa.eu/ema/index.jsp?curl=pages/regulation/document_listing/document_listing_000345.jsp&mid=WC0b01ac058058f32c.

In general, an agreement between the marketing authorization holder and the competent authority is needed on the format and content of the information, the recipients, and the timetable.

CONCLUSION

Historically, many of the established vaccines have been nationally authorized by the EU member states. With the creation of the EMA to evaluate and monitor medicinal products in 1995, European legislation harmonized many aspects of the production, distribution, and use of medicinal products in the EU. This now supports a single EU-wide authorization for vaccines that could be made available for 500 million citizens. The CHMP evaluates new applications for vaccine marketing authorization, determines if the benefit-to-risk balance is positive or negative for the vaccine, and issues an opinion to the European Commission on whether to grant an EU-wide marketing authorization. Recent experience led to the authorization of new innovative vaccines such as pneumococcal, human papillomavirus, and (pandemic) influenza vaccines, resulting in major public health benefits.

One of the ongoing challenges in the regulation of vaccines in the EU is the disharmony of vaccination schedules among the member states. Efforts toward harmonizing vaccination schedules would favorably affect vaccine development and the harmonization of product information of vaccines authorized in the EU.

Information on adverse events that occur rarely, with delay, or in specific population groups can, under certain circumstances, only be detected after authorization. Therefore a European system is in place to detect, evaluate, minimize, and prevent if possible severe adverse events following immunization and any decrease of effectiveness that would affect the benefit-to-risk balance of the vaccine.

The authorization and surveillance of vaccines requires expertise from many actors: healthcare professionals, academic experts, vaccine manufacturers, regulatory authorities, public health institutions, and European agencies. It is through their efficient collaboration that public health benefits of vaccines will be maximized.

81 Regulation of Vaccines in Low- and Middle-Income Countries

Lahouari Belgharbi, Alireza Khadem Broojerdi, Carmen A. Rodriguez-Hernandez, and David J. Wood

The largest-ever epidemic of Ebola virus disease in 2014–15 triggered an unprecedented accelerated vaccine development process. Innovative clinical trial designs were successfully used to evaluate complex vaccine constructs[1] in countries with very limited regulatory resources and little or no experience in assessing vaccine clinical trial applications. Nevertheless, appropriate regulatory oversight was exercised in part because of the willingness of better-resourced regulatory agencies to provide peer-to-peer scientific support to the regulatory agencies in the affected countries. A key lesson learned from the 2014–15 Ebola virus disease epidemic is that regulatory preparedness for infectious disease threats needs to be strengthened in all countries, especially in low and middle-income countries (LMICs), and especially for regulation of vaccines.

Vaccines are manufactured in a subset (between 40 and 45) of the 194 Member States of the World Health Organization (WHO). They are used, without exception, in every Member State. A growing proportion of vaccines that are used to immunize the world's population are manufactured in LMICs. Appropriate regulatory oversight of vaccines in the developing world is critical not only to ensure the quality, safety and efficacy of vaccines used in national immunization programs in the country of manufacture but also to protect and enhance investments in the global immunization enterprise.

The WHO establishes international standards for the regulation of vaccines and assesses implementation of these standards. The functionality of National Regulatory Authorities (NRAs) in key vaccine-producing LMICs is improving, but further work is needed (e.g., to strengthen health systems to embed the gains made). The NRAs of LMICs that import vaccines are, in most cases, not resourced to provide specialist regulatory oversight of vaccines. The most appropriate strategy for such countries is to leverage the regulatory evaluations performed elsewhere. To assist these countries, the United Nations procures vaccines that have been prequalified by the WHO to be of assured quality. At the end of 2014, it was estimated that 64% of the global infant population was immunized with WHO prequalified vaccines. The key regulatory functions for this group of countries are to register vaccines; to monitor the safety of vaccines in use in the country; and to provide oversight of clinical trials of candidate vaccines. Networks of regulators are being developed to enhance the capabilities of LMICs to perform regulatory oversight for vaccines.

REGULATION OF VACCINES IN LOW- AND MIDDLE-INCOME COUNTRIES

Safe and effective vaccines are universally recognized as essential public health tools. Consistent production of safe and effective vaccines is difficult, and doing so at an affordable price even more so. Vaccines are regulated by pharmaceutical law and are among the most complex pharmaceuticals available today. Informed decision making for vaccines requires specialist regulatory expertise. Benefit-to-risk regulatory evaluations for vaccines requires an understanding of, first, biological production and quality control processes and, second, the implications (in the case of preventive vaccines) of administering products derived from living systems, often to very young infants, at a population scale. Regulatory authorities must always be ready to evaluate new information on potential or real risks and benefits of vaccines and change decisions as needed. Box 81.1 provides an example of the type of problem confronting regulators and how they have reacted to it.

LMIC vaccine manufacturers are an attractive option to supply the global market, but currently the potential of such suppliers is not fully realized. One obstacle is confidence in the quality of vaccines from such suppliers. The WHO has defined a program to strengthen national regulatory systems to address this concern. The aim is to ensure that the NRA in each producing country is functional against international standards for vaccine regulation. The functionality is assessed by WHO-led audits. Between 1997 and 2014 more than 100 assessments were conducted, including the NRAs of all vaccine-producing countries (Fig. 81.1).

Six functions are defined by the WHO for a NRA to provide comprehensive regulatory oversight of vaccines (Table 81.1).[4–8]

Comprehensive regulatory oversight should be in place in countries that manufacture vaccines. Regulatory systems in these countries should have a legal framework and a mandate to enforce the six regulatory functions recommended by the WHO. These functions are: (a) marketing authorization and facility licensing, (b) pharmacovigilance including adverse events following immunization (AEFI) surveillance, (c) NRA lot release, (d) laboratory access, (e) regulatory inspections, and (f) authorization and monitoring of clinical trials. However, for the majority of countries that import their vaccines, only a subset of regulatory functions need be in place. Stratification of the needed regulatory functions by source of vaccine has proved an effective and pragmatic strategy to guide countries of the level of investment that is appropriate to their context.

A "vaccine of assured quality" is defined as a vaccine that has been produced in a country with a functional NRA and has a positive benefit/risk evaluation for use in the target populations. The WHO recommends that 100% of vaccines that are used in national immunization programs are of assured quality.

VACCINES OF ASSURED QUALITY AND FUNCTIONALITY OF NATIONAL REGULATORY AUTHORITIES: GLOBAL STATUS AND TRENDS

Based on data available to the WHO, the proportion of doses of assured quality vaccines used in national immunization programs as of December 2014, reached 97%, as shown in Fig. 81.2. This contrasts with the situation in early 1990, when it is estimated that less than 50% of vaccines were of assured quality. Sustaining the gains made in vaccine-producing countries is constantly challenging, however. For example, a slight decrease was expected in early 2015 as one NRA was found in 2014 to be nonfunctional. The production from this country accounts for approximately 5% to 8% of the global vaccine

supply. The government of this country is committed to address the issues and the WHO expected the system to become functional again soon. A special capacity building and monitoring program was proposed to address this matter urgently.

Table 81.2 shows the status of NRA functionality in the area of vaccine regulation. Fig. 81.3 shows the trends for the implementation of the six specific regulatory functions for vaccines defined by the WHO. The majority of countries without a functional NRA use WHO prequalified vaccines in their national immunization programs.

BOX 81.1 Porcine Circoviruses and Rotavirus Vaccines as an Example of the Complexity of Vaccine Regulation

Rotavirus gastroenteritis is the most common cause of severe diarrheal disease in young children throughout the world, and rotavirus immunization is recommended by the World Health Organization (WHO). In 2010, researchers discovered porcine circovirus type 1 (PCV1) virus and DNA in one oral rotavirus vaccine (Rotarix) and fragments of DNA from PCV2 virus in another oral rotavirus vaccine (Rotateq). Regulatory authorities, academic virologists, and the vaccine manufacturers conducted investigations to understand this finding. The new data were used to conduct revised benefit-risk evaluations. Consensus emerged that the benefits of rotavirus vaccination for children far outweighed any known risk associated with use of vaccines that contained PCV or PCV DNA. The WHO recommended the continued use of Rotarix and RotaTeq for immunization programs, in particular in those parts of the world with elevated mortality of those younger than age 5 years that is associated with rotaviruses.[2] The lessons learned from this event have been codified by the WHO to provide guidance to regulators and the immunization community[3] should a similar event happen in the future.

WORLD HEALTH ORGANIZATION PREQUALIFICATION PROGRAM FOR VACCINES

Prequalification is a procurement term that refers to limiting a global public tender to fewer than the total universe of possible suppliers. Vaccine prequalification is a WHO-led activity with a primary purpose to ensure that the vaccines purchased by United Nations (UN) procurement agencies will be consistently safe and effective under conditions of use for national immunization programs.

The vaccine prequalification program (vxPQ) was formally put in place within the WHO in 1987 to provide advice to UN procuring agencies on the quality, safety, and efficacy of vaccines for purchase. As of this writing, 124 countries are served by the UN procurement system, 90 through the UNICEF Supply Division and 34 through the Pan American Health Organization's Revolving Fund. This accounts for approximately 64% of the total global infant population, which thus receives vaccines of assured quality. The list of prequalified vaccines published[9] on the WHO website is used also by non-UN agencies, by nongovernmental organizations that purchase vaccines, and by countries that procure their vaccines directly through international bidding processes. Its use is thus going beyond its primary aim of serving UN purchasing agencies having become a widely recognized "seal of quality."

Since its establishment in 1987, the procedure has been revised several times to introduce improvements and to adapt to upcoming needs.[10] The current version of the procedure

TABLE 81.1 Stratification of National Regulatory Functions According to Source of Vaccines Used in National Immunization Programs Within Countries

Functions	Sources of Vaccines as a Metric to Categorize Countries		
	Vaccines Provided by United Nations Agency	**Vaccines Self-Procured by the Country**	**Vaccines Produced by the Country**
A. National regulatory system[a]	X[b]	X	X
Function 1: Marketing authorization and licensing activities[c]	X	X	X
Function 2: Postmarketing activities, including surveillance of adverse events following immunization (AEFI)[d]	X	X	X
Function 3: Lot release[e]	Functions undertaken by national regulatory agencies (NRAs) in producing countries. The NRAs have been assessed by the WHO and objectively shown to appropriately implement the regulatory functions	X	X
Function 4: Laboratory access[f]		X	X
Function 5: Regulatory inspections[g]			X
Function 6: Authorization and monitoring of clinical trials[h]	X[i]	X[i]	X

[a]A national regulatory system requires a legal framework and a mandate to enforce the regulatory functions recommended by the WHO, plus a quality management system; strategic planning; adequate resources; a recall system; transparency; and conflict of interest provisions.
[b]X indicates a regulatory function that WHO recommends should be implemented by countries in each category.
[c]Marketing authorization and licensing activities includes provisions for registration and evaluation of products and facilities. The function covers import, export, and distribution activities.
[d]The postmarketing function includes capacity to detect and investigate significant vaccine safety issues and to take regulatory actions when needed.
[e]The lot release function requires the NRA to have a system for lot-to-lot review of each vaccine based, as a minimum, on independent review of a lot summary protocol provided by the manufacturer to allow release, against defined standards, of vaccines lots into the market.
[f]The laboratory access function requires that the NRA has a National Control Laboratory established to provide independent testing of vaccine lots submitted by the manufacturer. An operational agreement to use an external quality control laboratory is also acceptable.
[g]The regulatory inspection function means that the NRA has a system to conduct Good Manufacturing Practice (GMP) inspections and has the enforcement power to suspend or stop production in any vaccine manufacturing facility in the country, should the need arise.
[h]The clinical trials function means that there is provision for regulation of clinical trials consistent with WHO Good Clinical Practices (GCP), and enforcement power to take action if standards are broached.
[i]In countries that conduct clinical trials.

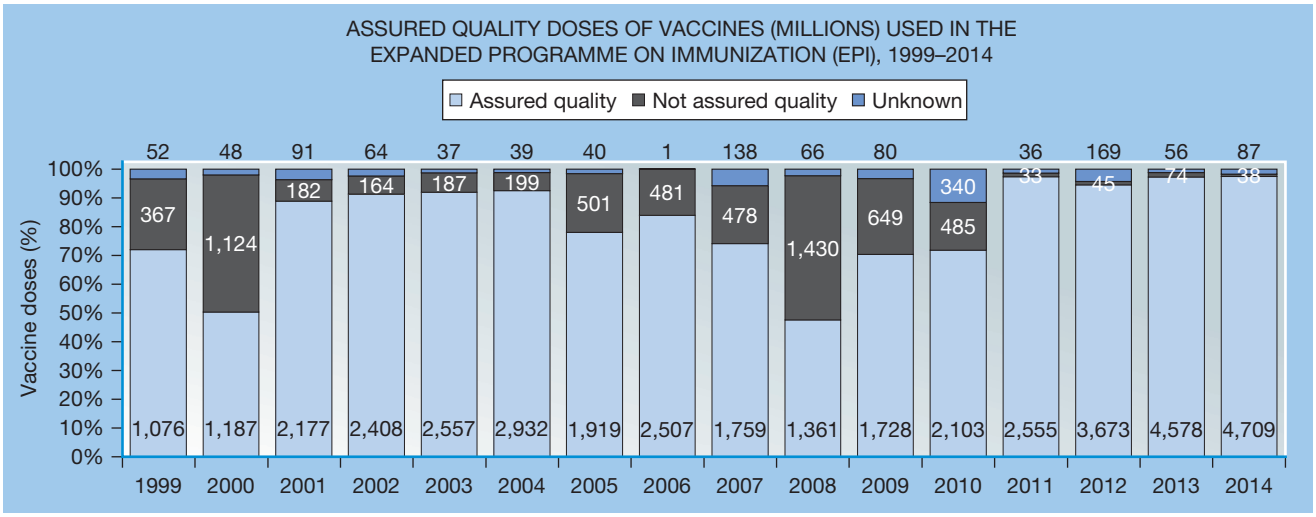

Figure 81.2. Assured quality doses of vaccines (millions) used in the Expanded Programme on Immunization (EPI), 1999 to 2014. *(Data from World Health Organization (WHO)/Essential Medicines and Health Products, as of May 2015. Doses of vaccines reported mainly from WHO/UNICEF Joint Reporting Form and WHO National Regulatory Systems Lot Release Database.)*

was established by the WHO Expert Committee on Biological Standardization.[11] Written standards developed by the WHO Expert Committee on Biological Standardization for individual vaccines define the quality specifications used by the program and are also key to developing technical specifications for the UN procurement tender documents.

The prequalification procedure includes a review of summary documentation on production and control of the specific vaccine under evaluation, proof of consistency of final product characteristics, proof of compliance with Good Manufacturing Practices (GMPs) (assessed through a site audit), and proof of adequate implementation of quality systems by the

TABLE 81.2 Status of National Regulatory Authority Functions in the Area of Vaccine Regulation, 2015[a]

Main Source of Vaccines	Number of Countries That Have Functional or Nonfunctional NRAs		
	Functional, N (%)	Nonfunctional, N (%)	Total
Producing	36 (83%)	7 (17%)	43
Procuring	20 (41%)	28 (59%)	48
United Nations agency	9 (9%)	94 (91%)	103
Total	**65**	**129**	**194**

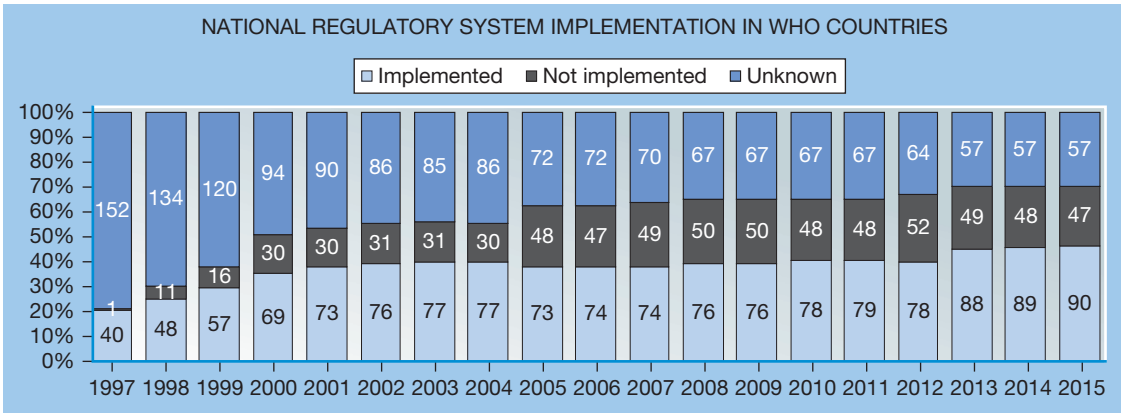
manufacturer. An important added value of the prequalification evaluation is its focus on the review of the product characteristics against the WHO-recommended standards as published in the WHO Technical Report Series and compliance with the UN tender specifications. The vxPQ review evaluates the programmatic suitability of product characteristics such as the vaccine presentation, stability profile in view of constraints in the cold chain in target countries, and preservative effectiveness for vaccines filled in multidose vials, among others. It ensures the relevance of the clinical trial data to the UN target population in the recommended schedules including co-administration with vaccines used in the national immunization programs in developing countries.

A vaccine can only be accepted for review for prequalification if the vaccine regulatory system in the country of manufacture has been assessed as functional by the WHO. The role of the national authority in the country of manufacture is critical not only in the stages prior to the submission—that is, marketing authorization for the vaccine—but also, and most importantly, for the ongoing regulatory oversight to ensure continuing quality of the vaccine if and when the vaccine gets prequalified. For example, release of the vaccine on a lot by lot basis by the NRA is an essential requirement of the UN tender, and provides the basis for distribution and use of the vaccine in the receiving countries. The release certificate by the NRA of the manufacturing country is the only evidence that the receiving country authorities have to ensure that the specific lots shipped to their country have been independently reviewed and cleared by the responsible NRA. GMP inspections (in accordance with internationally accepted standards, i.e., the WHO standard) conducted at regular intervals and monitoring of the efficacy and safety profile is also required to ensure the continuing quality of the prequalified vaccine. Similarly important is the regulation of variations by the NRA to ensure that the prequalified vaccine continues to meet the required standards of quality.

The prequalification program establishes collaboration agreements with the NRAs responsible for the national oversight of the prequalified vaccines to ensure that ongoing regulatory oversight is timely and adequately performed and that any important deviations or concerns regarding quality, safety or efficacy of the vaccines are promptly communicated to the WHO.

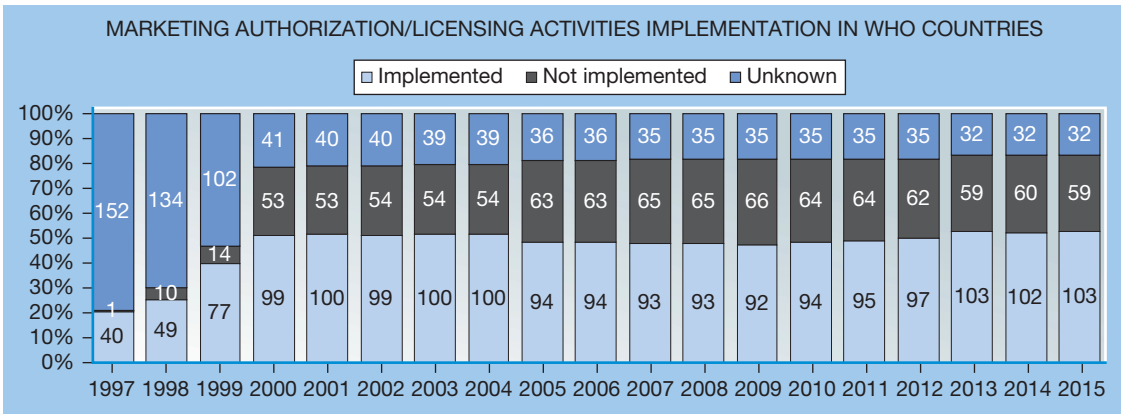
In the past, vaccines were first introduced in industrialized countries and years later reached less-developed countries as economies of scale allowed for a drop in price. This paradigm has significantly changed in recent years with the increased support from immunization stakeholders, including donors, to accelerate the introduction of priority vaccines in developing countries. This has proved challenging as some characteristics of vaccines designed for industrialized countries are not suitable for the conditions of immunization programs in developing countries. One example was that of a pneumococcal vaccine available in prefilled non-autodisable syringes. Vaccines supplied through UNICEF are required to be filled in vials, ampoules, or in autodisable injection devices.[12] The reason for this requirement is the need to prevent possible "reuse" of syringes in the field on one hand and, on the other hand, to secure effective destruction of syringes in countries without access to high temperature incinerators.

To address this issue a WHO guidance document describes the expected characteristics of vaccines for use in national immunization programs in developing countries, together with a process for the review of vaccine candidates which deviate from the expected characteristics.[13] Specifying programmatic characteristics in this way provides an incentive to vaccine developers and helps shape the market with respect to technical attributes of each vaccine for the benefit of poorer countries.



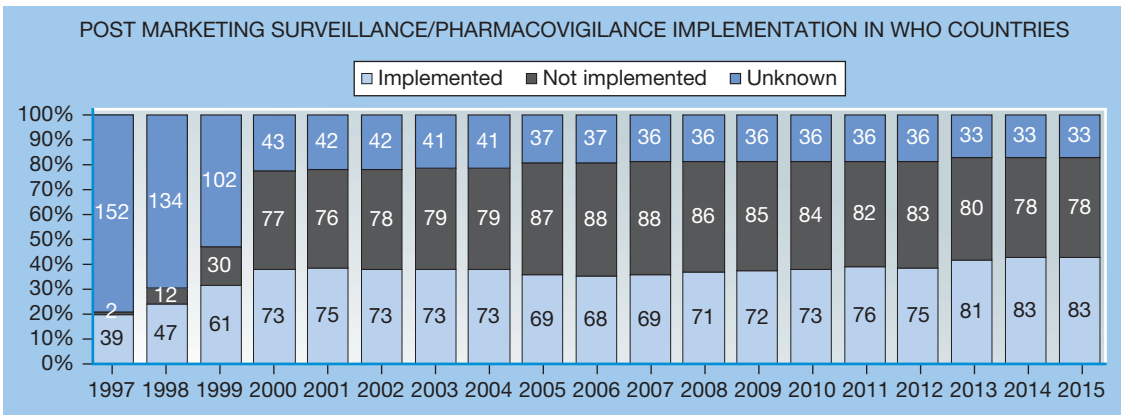
In line with the prequalification of vaccines, the WHO also prequalifies immunization devices relevant to the transport and storage of vaccines through its Performance, Quality, and Safety program. Its main objective is to provide countries with a selected set of products and tools to ensure the quality of vaccines through the supply chain as well as for the administration of vaccines. This work is done in close collaboration with partners through a multipartners' specification working group established in 2014 involving UNICEF, the Global Alliance for Vaccines and Immunization (GAVI), Programs for Appropriate Technology in Health, Clinton Health Access Initiative, and the Solar Electric Light Fund and supported by the Bill and Melinda Gates Foundation. It is recognized that developing countries are encountering a series of challenges in ensuring access to assured quality vaccines to the point of administration. The lack of reliable electricity, the ever increasing volume of vaccines to be transported and stored, the maintaining of storage temperature in the right range are examples of the difficulties countries are facing. To enhance the quality of equipment and facilitate the integration of innovative solutions, the Performance, Quality, and Safety program is developing target product profiles and product specifications against which products are evaluated by independent and accredited laboratories. For example, target product profiles have been published on solar direct-drive refrigerators and solar systems. Target product profiles have also been initiated for waterpack freezers, a freeze-safe cold box, a freeze-safe vaccine carrier, and a remote temperature monitoring system, all of which were expected to be developed in 2015. In 2014, the first long-term passive container was prequalified against new specifications. It can keep vaccines for more than 35 days without being recharged. As a result of this work, countries now have the choice between 258 prequalified products as of December 31, 2014 compared to 163 in 2010, corresponding to a 58% increase between 2010 and 2014.

INITIATIVES TO STRENGTHEN MEDICINES REGULATORY SYSTEMS IN DEVELOPING COUNTRIES FOR REGULATORY OVERSIGHT OF VACCINES

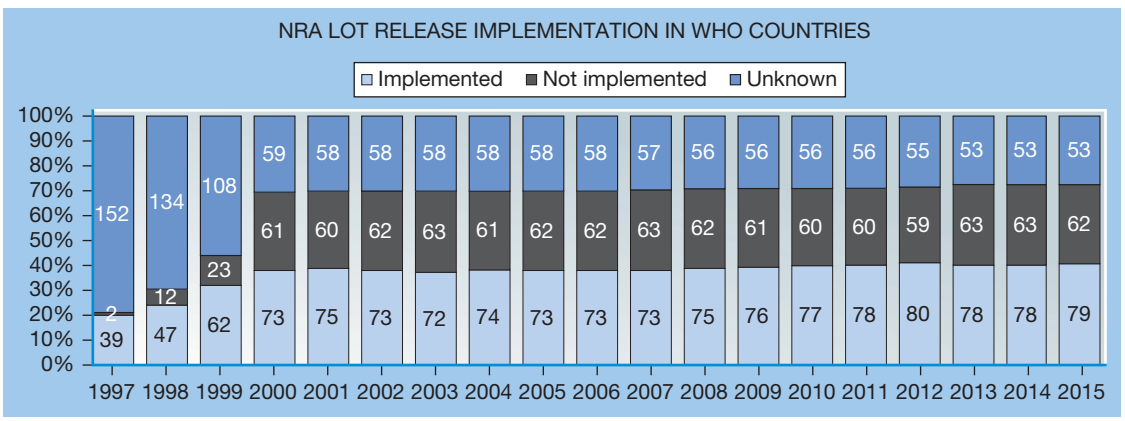


Five Steps for Capacity Building: Assessment and Institutional Development Program

The WHO has developed a five-step capacity-building program that relies on:



1. Benchmarks to objectively and reliably assess a national regulatory system for vaccines;



A

B

C

D

Figure 81.3. A, Trends in implementation of national regulatory systems for vaccines. The vertical axis is the percent of countries implementing a national regulatory system for vaccines. The denominator for 1997–99 is 190; for 2000–01 it is 191; for 2002–05 it is 192; and for 2006–10 it is 193. **B,** Trends in implementation of marketing authorizations/licensing activities for vaccines. **C,** Implementation of postmarketing/adverse events following immunization surveillance function for vaccines. **D,** Implementation of National Regulatory Authorities (NRA) lot release for vaccines.

Continued

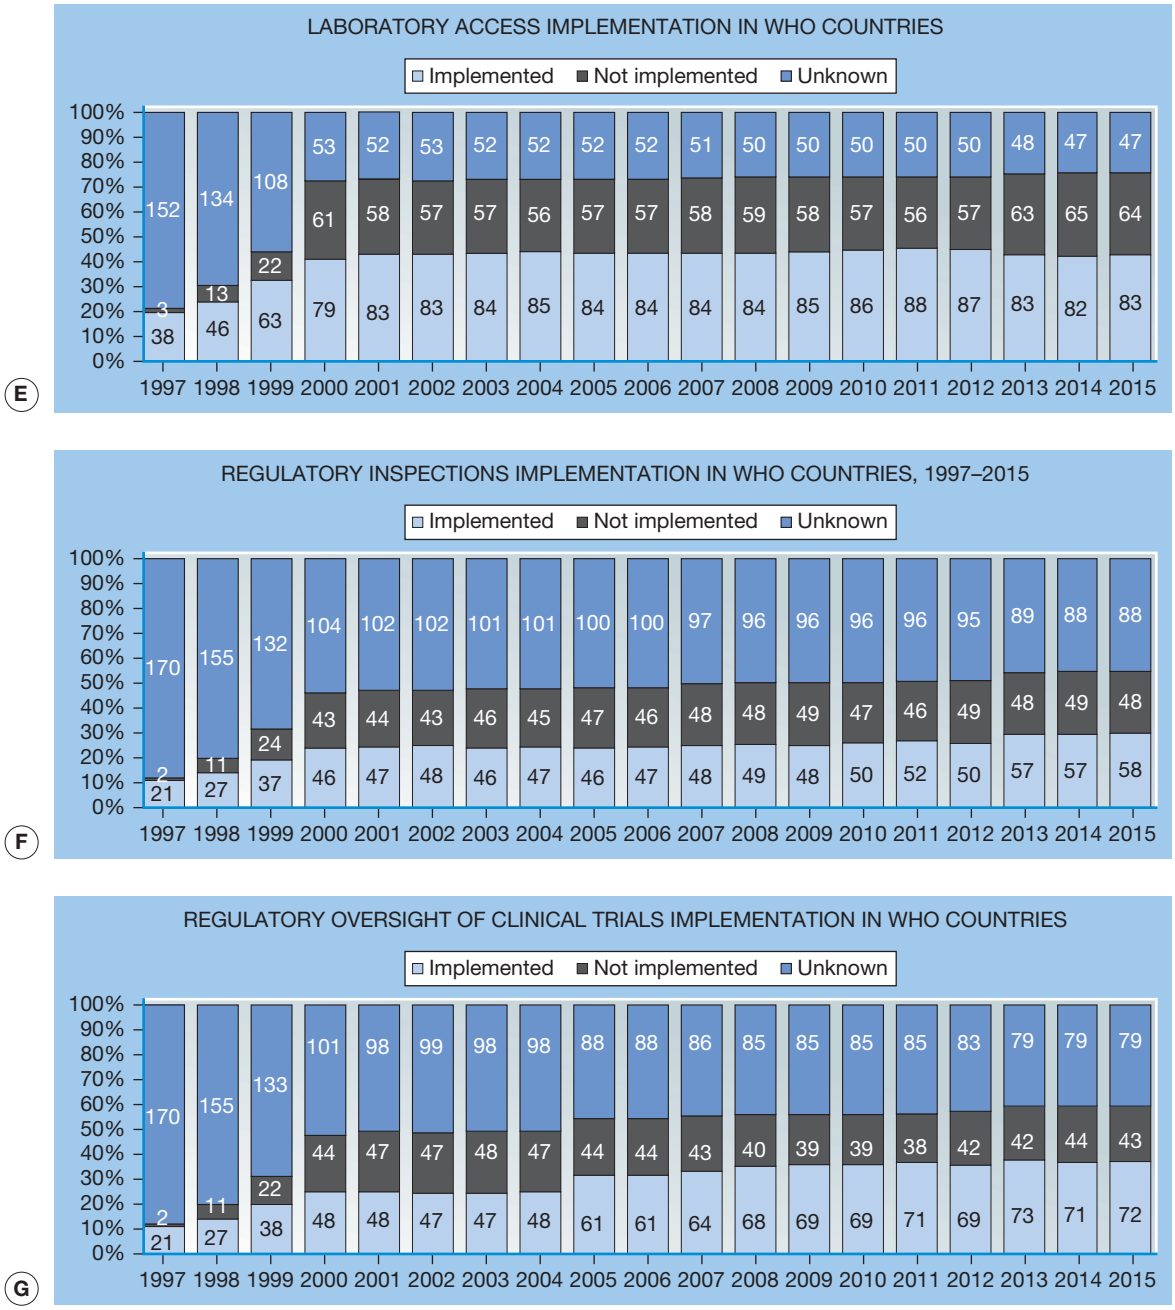


Figure 81.3, cont'd E, Implementation of laboratory access function for regulation of vaccines. **F,** Implementation of regulatory inspections functions for vaccines. **G,** Implementation of oversight of clinical trials for vaccines. *(Data from World Health Organization/Essential Medicines and Health Products, as of August 2015.)*

2. Assessment of a national regulatory system using the benchmarks, via computerized assessment tools for each regulatory function, with indicators and subindicators for each function;
3. Identification of gaps and development of an Institutional Development Plan (IDP) to address the gaps;
4. Provision of technical input and support through learning and training to build capacity in line with the needs identified through the IDP; and
5. Monitoring progress and re-assessment of the performance of the regulatory system.

World Health Organization Observed Audits: Enforcement of Good Manufacturing Practices

Adherence to GMPs during vaccine production is a key principle for consistent production of safe and effective vaccines. Robust regulatory inspections are thus critical. The WHO-observed audits have proved to be powerful tools to raise the competencies and enforcement power of the regulatory system and to guide countries to sustain their regulatory inspections function. In an observed audit, external regulatory experts, appointed by the WHO, monitor the local inspectors as they

perform a routine GMP inspection. Countries that have benefited from this exercise include China, Egypt, India, Indonesia, Iran, Senegal, Thailand, and Vietnam. The local inspectors receive feedback from the external experts on their performance and have an objective benchmark against which they, and the WHO, can measure progress.

Parallel Regulatory Review: Example of Vaccines Against Meningococcal Conjugate A and Japanese Encephalitis Vaccines

Another example of capacity building is the development of collaboration and sharing of information between two NRAs when assessing a vaccine for registration purposes. In this situation one NRA is a mentor that leads the process with its experts, and the second is a mentored NRA that receives advice. One example occurred during evaluation of the meningococcal A conjugate vaccine that was, subsequently, successfully introduced in the African meningitis belt countries.[14] The NRA of India was the recipient of the advice and the Canadian NRA provided its expertise to support this process. In this situation, the product was not intended for registration in Canada, and so the donor of the technical expertise did not derive direct benefit from the process. However, there were multiple indirect benefits. For example, the mentoring process and methods developed to support its implementation were subsequently used as a staff-development tool in the mentor NRA.

In a second example, parallel reviews were conducted for evaluation of a candidate Japanese encephalitis vaccine that had been submitted for registration in both Australia[15] and Thailand. The Thai Food and Drug Administration was technically supported by the Therapeutic Goods Administration from Australia. Each country retained the national prerogative whether to license, or not, the vaccine. The scientific data provided by the sponsor were evaluated by both countries, then discussed and used as a learning opportunity by the less-experienced regulator. In this case, the vaccine was subsequently registered in both countries.

Strengthening Oversight and Monitoring of Clinical Trials for New Vaccines

The responsibilities of the countries that are targets for clinical trials or introduction of new vaccines cannot be replaced by regulatory oversight from the country of manufacture. Although most Phase I clinical trials are done in the country of manufacture of the vaccine, some of the vaccines currently under development target diseases that are endemic in the developing world and Phase II and Phase III clinical trials will have to be conducted in countries where the disease is endemic. Often, these target countries have limited experience in regulatory oversight of vaccine clinical trials. Therefore, regulatory capacity in the areas of nonclinical product review and in protocol review for clinical trial testing needs strengthening.

An efficient approach to build capacity in the regulation of vaccine clinical trials is the use of existing networks of regulators and/or the establishment of new networks. As an example, WHO has worked with the established Association of Southeast Asian Nations (ASEAN) regulatory network to establish a "vaccine chapter," which represents a forum for collaboration in the area of vaccine clinical trial regulation. The WHO has also established two networks: the Developing County Vaccine Regulators Network (DCVRN) and a Regional Network in the African Region, the African Vaccine Regulatory Forum (AVAREF).

The DCVRN was established in September of 2004, its mission being to promote and support the strengthening of the regulatory capacity of NRAs of participating and other developing countries for evaluation of clinical trial proposals (including preclinical data and product development processes) and evaluation of clinical trial data through expertise and exchange of relevant information.[16] Nine countries constitute the DCVRN: Cuba, Brazil, China, India, Indonesia, Iran, Korea, South Africa, and Thailand.

Member countries aim to develop harmonized methodologies for evaluation of clinical trial applications and vaccine dossiers; to strengthen the ability of NRAs to conduct the evaluations; to establish open dialogue with multinational vaccine developers and manufacturers to discuss the development of novel vaccines; to ensure that developing country regulators keep up with internationally accepted requirements; and, to the extent possible, to guide other NRAs through regional initiatives.

The DCVRN operates through meetings twice a year and regular communications between meetings. The WHO's role as the Secretariat is to facilitate the participation of experts, vaccine developers, clinical trial sponsor institutions, and NRAs of manufacturing countries in scientific sessions. Examples of issues considered by the DCVRN include regulatory challenges relevant to the clinical evaluation of new vaccines including tuberculosis vaccines, vaccines against HIV/AIDS, human papillomavirus, rotavirus, typhoid, Japanese encephalitis, and dengue. This networking exercise provides member countries with the opportunity to share experiences and views, to exchange information and knowledge with other NRAs, to provide feedback to vaccine developers/manufacturers and trial sponsors, and to provide support to regional initiatives through sharing of regulatory procedures, funding of expert staff to support other countries, or taking a lead role in the facilitation of capacity building activities relevant to clinical evaluation of vaccines.

For regulatory oversight of vaccine clinical trials, there are challenges specific to certain regions. For Africa, AVAREF was conceived and established in 2006 as a "regional approach" to provide ongoing support for regulators in the region.[17] It is intended to serve as framework to ensure access to expertise for countries that have to make regulatory decisions for which they may not have the capacity/expertise and as a forum where countries can discuss with peers, strengthen the capacity of weaker countries, and identify the need for support and training.

AVAREF gathers representatives from NRAs and Ethics Committees from 23 countries identified as targets for clinical trials and introduction of novel vaccines. The objectives are to facilitate access to information on clinical development plans for priority vaccines in the region; provide a source of expertise to support countries in their regulatory review processes; identify the need for regulatory documents, training, and guidance; and foster collaboration with regulatory agencies of countries that produce vaccines that are clinically tested in Africa.

Some of the achievements of AVAREF include the development of model harmonized procedures for evaluation of clinical trial applications and regulatory monitoring of clinical trials.

AVAREF also established and tested the concept of joint reviews of protocols of clinical trials to be conducted in some member countries. Joint reviews take place between regulators of several countries targeted for trials of the same vaccine, with the agreement of sponsors and with participation of collaborating regulators with extensive experience in the review of clinical trial protocols and clinical trial data. Sponsors make simultaneous submissions to the target countries; these are independently reviewed in each of the countries who then

participate in the joint review exercise. During the joint reviews the assessors from target countries have the opportunity to discuss among themselves and to put forward consolidated questions to the sponsors and to request all the required clarifications or complementary information that may be needed. Regulators go back to their home countries with the necessary feedback to make informed and independent regulatory decisions.

Candidate malaria and meningitis A conjugate vaccines have been reviewed in this way. Experience showed that joint reviews were a very successful way to improve the quality of the review of clinical trials protocols.

AVAREF was particularly important as a platform in the public health emergency of the 2014–15 Ebola virus disease epidemic.[18] The platform was used to achieve progress in three areas: (a) presubmission discussions between the regulators and the clinical trial sponsors and vaccine manufacturers; (b) agreement on clinical trial approval processes; and (c) joint reviews, convened by WHO, of clinical trial applications. The outcomes were that ethical and regulatory approvals, conducted against international standards, were secured within 90 days for key vaccine studies.

The three networks, DCVRN, ASEAN, and AVAREF, have proven to be efficient as opportunities for interaction with advanced NRAs like the European Medicines Agency (EMA) and the U.S. Food and Drug Administration, who support these initiatives by actively participating and sharing their expertise with the network countries.

The role of networking as a platform to promote information exchange between regulators, harmonization of regulatory requirements and procedures, to identify gaps and training needs, to facilitate the development of guidelines as well as to provide technical support can be further exploited.

Technical Support and Learning Opportunities for Regulators From Developing Countries

Technical support for regulators from developing countries may be provided through multilateral or bilateral processes. WHO-led technical support is based on needs objectively identified during an NRA assessment. Using the outcome of the assessment for each of the regulatory functions, the regulators develop jointly with the independent assessment team the IDP. This plan provides detailed information on the gaps identified by the assessors and an initial proposal on ways to address them. The NRA assessment report and the IDP are shared with country authorities and, after endorsement by the authorities, the IDP becomes a tool to develop a targeted technical support plan.

A diversity of approaches can be used to provide technical support depending on the needs, such as participation in established global courses, or performance of tailor-made in country or subregional training activities, placements in centers of excellence for the specific field in question and/or by facilitating on site consulting.

Courses that become part of the set of approved WHO courses go through a proven process of effective course development. The WHO contracts a course development team to draft the course which includes both content and learning methods experts. The draft course is developed in modules concurrently with a manual with required technical information and guidelines for delivery aimed at fostering effective learning, as well as a participant's guide and reference and reading materials. Course materials are peer reviewed and cleared through a formal process.

The courses are selected both on the basis of identified needs and the potential to be developed and run effectively in a cost-effective manner. Some of the courses are conducted at established Global Training Centers or can be conducted as itinerant courses for regulators in one specific country or for a small group of neighboring countries with similar needs.

All WHO-approved courses are constructed in the form of learning modules with stated and measurable learning objectives. The courses include detailed procedures for monitoring progress daily and procedures for correcting identified weaknesses during the course. The modules are each evaluated through defined procedures as part of the course administration and following the course through additional tools and channels.[19] The WHO follows Kirkpatrick's *Four Level Evaluation* scheme.[20]

DCVRN members have developed a curriculum for training on regulatory inspections of clinical trials, to educate NRAs of developing countries. The material was further developed and finalized for delivery by the WHO. This is an example of contribution of one of the networks to the availability of global training materials.

Global learning events may not necessarily be the answer for a defined gap in a particular NRA assessment. In some cases, an in-country learning event designed on a custom made basis is required. However, in all cases, WHO ensures that design principles are properly defined and quality procedures are followed in development of the new material.

It is expected that the implementation of distance based e-learning will broaden the reach of current training activities significantly. The development of relevant e-learning curricula is a priority for the WHO.

Leverage of Regulatory Decisions Made Elsewhere: Expedited Review of Imported Prequalified Vaccines for Use in National Immunization Programs

Countries sourcing vaccines through UN agencies receive vaccines of "assured quality." Such vaccines have been appropriately licensed by the responsible regulatory authority and, in addition, have been reviewed by the WHO in the context of the prequalification evaluation. During the prequalification process, the WHO has specifically ensured that the vaccine meets the WHO recommendations, the UN tender specifications, and has closely reviewed the clinical data to ensure that they are relevant to the target population and compatible with the immunization schedules used in the receiving countries. The WHO has also checked that product characteristics—such as presentation, stability profile, and others—are suitable for use in developing country settings. Ongoing regulatory oversight is ensured by the responsible NRA through release of vaccines on a lot by lot basis, review of variations, regulatory inspections, and by the WHO through targeted testing of lots shipped to countries and monitoring of complaints and reports of AEFIs. In addition, the WHO reassesses all prequalified vaccines at regular intervals.

Under such circumstances, countries may opt to waive an additional comprehensive registration process. It may be more efficient to use available resources to focus on postmarketing activities such as the pharmacovigilance of the vaccines being used. Consequently, the WHO has developed a collaborative procedure for review of imported vaccines that have been prequalified.[21] The procedure allows for facilitated registration of vaccines included in the immunization program. The use of such a procedure allows for registration of all the prequalified vaccines used in the country in a short timeframe without disruption to the vaccine supply. Countries wishing to adopt this procedure are advised to ensure that their legislation includes provisions for waiving and/or accelerating regulatory

procedures. The WHO provides training to authorities of countries wishing to implement the procedure and additional support to ensure its effective implementation.

Consideration of the outcomes of assessments and inspections by trusted authorities substantially contributes to savings in regulatory resources and improvements in the quality of regulatory decisions, while retaining the prerogative of NRAs to conclude their assessment by sovereign decisions, which reflect their own judgement of the benefit-to-risk balance as it relates to their specific country situation and the legislation in place. Taking into consideration the regulatory decisions of other NRAs requires setting up a system that will permit:

- Identification of reference authorities whose regulatory decisions are based on acceptable standards and identification of documents associated with such regulatory decisions, which are relevant to the regulatory environment in the country wishing to rely on such decisions;
- Assurance that the product for which the decision has been taken by the reference NRA is identical to the product being assessed, or, if it is not identical, that a clear understanding exists of the differences between the products subjected to assessment in the two regulatory environments;
- Efficient use of available scientific expertise and human and financial resources to decide, with reasonable certainty, on the benefit-to-risk profile of an evaluated product when used in a given country;
- The choice by each NRA of the approaches that will make best use of the resources, workload, and competence of individual NRAs.

Approaches could range from completely independent data reviews and inspections to adoption of regulatory decisions of trusted authorities without any further scientific review. A pragmatic approach is to verify product identity and assess only those areas which relate to use of the product in the country concerned and where failure to comply with regulatory standards could pose health risks. In the other areas, the outcomes of trusted authorities may be adopted.

Enhanced collaboration and information exchange between NRAs and WHO/vxPQ benefits both partners. Subject to the agreement of the WHO prequalification holders concerned, NRAs have access to assessment outcomes that are not in the public domain and that have been prepared in conformity with the WHO recommended standards on which the "Procedure for prequalification of pharmaceutical products" and the "Procedure for assessing the acceptability in principle of vaccines for purchase by United Nations Agencies" are based. Such reports and other documents help NRAs to make their decisions and also assist in educating national regulatory staff. At the same time, feedback from NRAs on the information and documentation received from WHO/vxPQ under the Procedure allows WHO/vxPQ to improve its work and ensures that the outcomes of prequalification assessments are relevant to NRAs. As a consequence vaccinees benefit from this collaboration by gaining faster access to products that have been found acceptable in principle for procurement by UN agencies. Depending on available resources, participating authorities have the opportunity to participate in the assessment process and in inspections organized by WHO/vxPQ.

This collaborative procedure also benefits manufacturers of prequalified vaccines through faster and better harmonized regulatory approvals in participating countries. This Procedure, when combined with the "Collaboration Procedure with NRAs in inspection activities," alleviates the burden of additional national inspections on manufacturers.

FUTURE DIRECTIONS

Preventing Duplication of Effort

As NRAs become stronger, it is expected that the WHO prequalification program will implement a *risk-based approach* that will allow more reliance on NRAs. The prequalification process will be tailored according to factors such as the experience of the manufacturer and NRA, and to the level of risk that has been seen with similar products–for example linked to incidence of reported AEFIs, or to the experience of the vaccine producer in supplying prequalified products. In this way, the prequalification process will be focused more on novel vaccines. For this purpose products will be classified in one of the following three categories:

- *Category A*. High risk: products submitted by manufacturers with limited or no experience with the prequalification process or with the product in question, and/or the NRA is borderline with respect to functionality.
- *Category B*. Medium risk: manufacturer has at least one other prequalified vaccine and has experience with the product in question (although it is not prequalified), or manufacturer is new to the system but is supported by a joint venture with a well-established manufacturer, and NRA is functional.
- *Category C*. Low risk: Manufacturer is well established, more than one product prequalified, and may or may not have experience with product in question but has good research and development infrastructure. NRA is functional.

Products in categories A and B will be thoroughly assessed and monitored (as per current procedure). Products in category C will be subject to a lighter process with strong reliance on the NRA responsible for the product regulatory oversight.

The prequalification of new vaccines poses additional challenges from the regulatory point of view, in terms of implementation in immunization programs, since some of these vaccines are likely not to be used in the country of manufacture and therefore the responsible NRA would not have firsthand postmarketing surveillance data to monitor the performance of these newly introduced products in terms of safety and efficacy. To address the issue, the WHO is working on the establishment of a global network of sentinel countries, with strong postmarketing surveillance systems that would monitor the safety profile of recently introduced UN-supplied vaccines during a specified period (or significant number of doses administered) to increase the information on the postlicensure real-life safety profile of the product.

Strengthening Vaccine Safety Systems

Objective analyses performed by the WHO show that vaccine pharmacovigilance is one of the weaker regulatory functions (see Fig. 81.3C). The capacity of countries to detect and investigate significant vaccine safety events varies, not unexpectedly, with developmental status.

The relationship between functionality of the vaccine safety surveillance system and health expenditure also applies within the subset of LMICs.

As all countries use vaccines, these data indicate that, from a global strategic perspective, there are risks that vaccine safety events may be missed and thus inappropriately managed. Looking to the future, a global vision has been articulated that all countries are able to ensure effective vaccine safety monitoring and response so that unwanted vaccine reactions are minimized and public confidence in vaccination is maintained.[22] Three levels of engagement have been defined to realize this vision:

- Building capacity for effective vaccine safety monitoring so that all LMICs have at least a minimal capacity.
- Enhancing the level of vaccine safety activity in countries that manufacture vaccines and in early introducers of newly available vaccine so that these countries have the ability to carry out active surveillance and database studies.
- Fostering international collaboration and encouraging global strategic planning so that national systems are adequately supported, all vaccines are under adequate postmarketing surveillance and vaccine safety information is shared internationally.

It is proposed that minimal capacity at the country level encompasses both a vaccine safety monitoring structure and also appropriate managerial requirements embedded with the health system of the country.

The vaccine safety monitoring structure may consist of:

- A national system of spontaneous reporting with a national database of AEFI reports;
- A national AEFI advisory committee;
- A clear communication strategy for routine communication and crisis communication;
- A national vaccine pharmacovigilance center with designated staff collaborating with the WHO Programme for International Drug Monitoring;
- Links to external technical support if required.

The managerial requirements may consist of:

- A proper regulatory framework (with provisions for monitoring and management of AEFI);
- Clear lines of accountability identified for the conduct of vaccine safety work;
- A management plan that is periodically evaluated and revised to ensure continuous quality improvement in the conduct of national vaccine safety activities;
- A commitment to sharing information on vaccine safety with other countries.

Increased international as well as national resources are also required to bolster vaccine safety capacity. The international dimension includes setting standards such as for harmonized methodologies, case definitions and safety updates for prequalified vaccines; capacity building tools, such as a pool of experts to assist countries, international research groups working on vaccine safety issues, global rumor monitoring, and a global database of AEFIs; electronic tools, for example to enable rapid sharing of information on vaccine safety issues, and for case verification; quality improvement tools, such as best practice registry and performance indicators; and expert advice, particularly independent scientific advice on global vaccine safety issues. This latter function is already performed by the WHO Global Advisory Committee on Vaccine Safety.[23]

There will be many challenges to turning the vision into reality that will require sustained support and commitment from a variety of stakeholders.

Increasing and Sustaining Global Supply of Vaccines: Investing in Developing Countries as a Source of Affordable Vaccines of Assured Quality

Developing and emerging economy countries have a vaccine industry capable of manufacturing affordable vaccines of assured quality for global use. Currently, this capability is underused, limiting supply options for global projects. Expanding the supply base in a sustainable manner requires capacity building approaches and solutions that will vary from country to country. The common feature is that functionality of the NRA is the key to unlock the potential. As noted previously, functionality is assessed by WHO-led expert audits of the NRA. The audits result in an IDP to strengthen the NRA in areas where gaps are identified. The IDPs are effective tools to develop a roadmap with the government of the host country to address gaps, and to mobilize resources (internal and external) to support the necessary capacity building initiatives.

The concept of an IDP being used to inform a roadmap of capacity building against defined milestones, with regular review and feedback has been successfully applied in both China and India. In China, the concept enabled the Chinese NRA, the State Food and Drug Authority, to achieve functionality against WHO criteria on March 1, 2011. In India, the concept enabled the Indian NRA, the Central Drugs Standard Control Organisation, to regain functionality against WHO criteria in March 2009. The experience in India shows that functionality of key NRAs can go down as well as up, requiring special efforts to maintain status as functional and to continue to drive improvements.

On the manufacturing side, there are different challenges in each country. In China, there are more than 30 vaccine manufacturers that could apply for vaccine prequalification. This ranges from well-established manufacturers to new companies with research pipeline products. The feasibility of all these manufacturers reaching the standards needed for WHO prequalification remains to be seen. As these companies are new to UN supply, it is anticipated (from previous experience) there will be a steep learning curve. Tools to evaluate the viability of the manufacturers would therefore be useful, both to help prioritize applications to WHO prequalification, and also inform capacity building in the companies.

In India, there is a well-established industry that currently supplies the global market through UN procurement. However, in 2010 one major supplier of pentavalent vaccine was delisted from the WHO list of prequalified products.[24] This was because the manufacturer had introduced a series of changes into the production process, compared to the originally prequalified process, in an attempt to improve yields and to scale-up to meet increasing demand. This was done without commensurate scaling-up the quality management system to cope with the increased demands from increased production. Indicators that would provide early warning that a company is disproportionately scaling-up would provide a useful risk-mitigation tool. This could be implemented for key companies with strategically important contracts as identified by the UN procurement agencies. In addition to the quality management systems, it would also be important to closely monitor the capacity of key companies to respond to global vaccine safety issues, through having an adequately resourced postmarketing surveillance group.

Regulatory Pathways for Vaccines Manufactured in Developed Countries but Intended for Use in Developing Countries—Article 58

Medicinal products that are not intended for marketing in the European Community are not given a European marketing authorization and for those medicines that are no longer marketed in the European Union, the marketing authorization is not renewed. The lack of a marketing authorization in Europe could potentially impair the registration of such medicinal products in countries importing them that require registration in the country of origin. To avoid this European

law from becoming a barrier to access to medicines from European origin not intended for the European population, the EMA developed, in collaboration with the WHO, an alternative regulatory pathway ("Article 58") that allows the EMA to provide a "Scientific Opinion" on candidate medicines through an evaluation process that mimics the centralized procedure for registration of medicines.[25]

The scope of the procedure includes

- Vaccines used or of possible use in the WHO Expanded Programme on Immunization;
- Vaccines for protection against a WHO public health priority disease;
- Vaccines that are part of a WHO managed stockpile for emergency response;
- Medicinal products for WHO target diseases such as HIV/AIDS, malaria, tuberculosis, lymphatic filariasis (elephantiasis), trachoma, leishmaniasis, schistosomiasis, African trypanosomiasis (sleeping sickness), onchocerciasis (river blindness), dengue fever, Chagas disease, and leprosy.

An Article 58 Scientific Opinion follows the same rules and requirements as a marketing authorization for Europe. In addition, the procedure includes participation of observers from the WHO vaccines prequalification program (when the vaccine is expected to be also prequalified) and it includes participation of WHO-designated experts and NRAs from countries targeted for use of the candidate vaccines. EMA will focus the review of clinical data in the target population in the user countries. This focused review by EMA allows the WHO to consider the streamlining of the prequalification evaluation when this is requested by the manufacturer. It is expected that countries procuring vaccines directly through international tenders will also recognize the EMA Scientific Opinion as an equivalent to the registration in Europe.

82 Vaccine Safety

Frank Destefano, Paul A. Offit, and Allison Fisher

During the past 100 years, pharmaceutical companies have made vaccines against diphtheria, tetanus, pertussis, polio, measles, mumps, rubella, varicella, hepatitis A, hepatitis B, *Haemophilus influenzae* type B (Hib), pneumococcus, meningococcus, rotavirus, and human papillomavirus, among others (Table 82.1). As a consequence, the number of children in the United States killed by pertussis decreased from 8000 each year in the early 20th century to fewer than 20; the number paralyzed by polio decreased from 15,000 to 0; the number killed by measles decreased from 3000 to 0; the number with severe birth defects caused by rubella decreased from 20,000 to 0; and the number with meningitis and bloodstream infections caused by Hib decreased from 25,000 to fewer than 100.

Vaccines have been among the most powerful forces in determining how long we live.[1] However, the landscape of vaccines is also littered with tragedy. In the late 1800s, starting with Louis Pasteur, scientists made rabies vaccines using cells from nervous tissue, including animal brains and spinal cords. Although the vaccine prevented a uniformly fatal infection, it also caused seizures, paralysis, and coma in as many as 1 of every 230 people who used it.[2–5]

In 1942, the military injected hundreds of thousands of American servicemen with a yellow fever vaccine. To stabilize the vaccine virus, scientists added human serum. Unfortunately, some of the serum came from people unknowingly infected with hepatitis B virus. As a consequence, 330,000 soldiers were infected with hepatitis B, severe disease developed in 50,000, and 62 died.[6–9]

In 1955, five companies made Jonas Salk's new formaldehyde-inactivated polio vaccine. However, one company, Cutter Laboratories of Berkeley, California, failed to completely inactivate poliovirus with formaldehyde. Because of this failure, 120,000 children were injected with live poliovirus; 40,000, developed mild polio, 200 were permanently paralyzed, and 10 died. It was one of the worst biological disasters in American history.[10]

Vaccines have also caused uncommon but severe adverse events not associated with production problems. For example, acute encephalopathy after whole-cell pertussis vaccine,[11,12] Guillain-Barré syndrome (GBS) after swine flu vaccine,[13] paralytic polio following live attenuated oral polio vaccine,[14] anaphylaxis following several different vaccines,[15] severe or fatal viscerotropic disease following yellow fever vaccine,[16] and intussusception following rotavirus vaccine,[17–19] are problems associated with the use of vaccines, albeit rarely. As vaccine use increases and the incidence of vaccine-preventable diseases decreases, vaccine-related adverse events become more prominent (Fig. 82.1). Even unfounded safety concerns can lead to decreased vaccine acceptance and resurgence of vaccine-preventable diseases, as occurred in the 1970s and 1980s as a public reaction to allegations that the whole-cell pertussis vaccine caused encephalopathy (Fig. 82.1). Recent outbreaks of measles, mumps, and pertussis in the United States are important reminders of how immunization delays and refusals can result in resurgences of vaccine-preventable diseases.[20–22]

METHODS OF MONITORING IMMUNIZATION SAFETY

Because vaccines are given to healthy children and adults, a higher standard of safety is expected of immunizations compared with other medical interventions. Tolerance of adverse reactions to pharmaceutical products (e.g., vaccines, contraceptives) given to healthy people—especially infants and toddlers—is substantially lower than to therapeutic agents (e.g., antibiotics, insulin) used to treat illness.[23] This translates into a need to investigate the possible causes of much rarer adverse events after vaccinations than would be acceptable for other pharmaceutical products. For example, severe side effects are essentially universal for cancer chemotherapy, and 10% to 30% of people receiving high-dose aspirin therapy experience gastrointestinal symptoms.[24]

Safety monitoring is performed both before and after vaccine licensure, with slightly different goals based on the methodological strengths and weaknesses of each step.[25–28] Although the general principles are similar irrespective of country, the specific approaches may differ because of the organization of immunization services and the level of available resources.[29]

Prelicensure Evaluations of Vaccine Safety

Vaccines, similar to other pharmaceutical products, undergo extensive safety and efficacy evaluations in the laboratory, in animals, and in phased human clinical trials before licensure.[30,31] Phase I trials usually involved smaller numbers of subjects and are able to detect only extremely common adverse events. Phase II trials generally enroll several hundred people in each vaccine arm, as in the comparative infant diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine trials,[32] and provide data on the impact of antigen content, number of vaccine components, vaccine formulation, effect of successive doses, and profile of common reactions. These data can inform the choice of the candidate vaccines for Phase III trials.[33,34] Sample sizes for Phase III vaccine trials are often based on efficacy considerations, and resultant safety data are dependent on the sample size (approximately 10^2 to 10^5) and the duration of observation (often <30 days).[33] Typically, only observations of rates of common local and systemic reactions (e.g., injection site swelling, fever, fussiness) are feasible. The experimental design of most clinical trials includes a control group (a placebo or an alternative vaccine) and the detection of adverse events by researchers who are "blinded" to which vaccine the patient received. This allows relatively straightforward inferences on the causal relationship between most adverse events and vaccination.[35]

Several ways of enhancing prelicensure safety assessment of vaccines have been developed. One of these ways includes the Brighton Collaboration (www.brightoncollaboration.org), which was established to develop and implement globally accepted standard case definitions for assessing adverse events following immunizations.[36] Without such defined standards, it was often difficult, if not impossible, to compare and

contrast safety data across trials. The Brighton case definitions for each adverse event are further arrayed by the level of evidence provided (insufficient, low, intermediate, and highest); therefore, they also can be used in settings with fewer resources (e.g., studies in less-developed settings or postlicensure surveillance). For example, in the large multisite Phase III infant DTaP trials, definitions of high fever across trials varied by temperature (39.5°C vs 40.5°C), measurement (oral vs rectal), and time (measured at 48 vs 72 hours).[37] This was unfortunate because standardized case definitions had been developed in these trials for efficacy but not for safety, even though the safety concerns provided the original impetus for the development of DTaP.[38,39]

There has been a greater recognition of the need for much larger safety databases before licensure. Because of pragmatic limits on the sample sizes of prelicensure studies, there are inherent limitations to the extent to which they can detect very rare, yet real, adverse events related to vaccination. Even if no adverse event has been observed in a trial of 10,000 vaccinees, one can only be reasonably certain that the real incidence of the adverse event is no higher than one in 3333 vaccinees.[40]

TABLE 82.1 Maximum and Number of Cases Reported in 2004: Morbidity From Vaccine-Preventable Diseases Events, United States

Disease	Maximum Cases (Year)	Cases Reported in 2014	% Change
Smallpox	206,939 (1921)	0	–100
Diphtheria	894,134 (1941)	1	>–99
Measles	152,209 (1968)	667	>–99
Mumps	265,269 (1934)	1223	–99
Polio (paralytic)	57,686 (1952)	0	–100
Congenital rubella syndrome	20,000[a] (1964–65)	1	>–99
Haemophilus influenzae type b	25,000[a]	306	–98

[a]Estimated because no national reporting existed in prevaccine era.

Thus, to be able to detect an attributable risk of one per 10,000 vaccinees (e.g., such as the approximate risk found for intussusception in the postlicensure evaluation of the simian–human reassortant rotavirus vaccine, RotaShield vaccine), a prelicensure trial of at least 30,000 vaccinees and 30,000 control subjects is needed. Both second-generation rotavirus vaccines (the bovine human reassortant vaccine, RotaTeq, and the attenuated human rotavirus vaccine, Rotarix) were subjected to Phase III trials that included at least 60,000 infants.[41,42] While these trials were adequately powered to detect intussusception at the rate seen with RotaShield, they were not adequately powered to detect the rates ultimately seen with either RotaTeq or Rotarix. In addition, the cost of such large safety trials could limit the number of vaccine candidates that could be studied.[43]

Postlicensure Evaluations of Vaccine Safety

Because reactions that are rare, delayed, or which occur in only certain subpopulations may not be detected before vaccines are licensed, postlicensure evaluation of vaccine safety is critical. Historically, this evaluation has relied on passive surveillance and ad hoc epidemiologic studies, but, more recently, Phase IV trials and preestablished large, linked databases have enhanced the capabilities to study rare adverse events after specific immunizations.[35] Such systems may detect variation in rates of adverse events by manufacturer[44,45] or specific lot.[46] More recently, clinical centers for the study of immunization safety have emerged as another useful infrastructure to advance our knowledge about safety.[47]

In contrast with the methodological strengths of prelicensure randomized trials, however, postlicensure observational studies of vaccine safety pose a formidable set of methodological difficulties.[48] Confounding by contraindication is especially problematic for nonexperimental designs. Specifically, persons who do not receive vaccine (e.g., because of a medical contraindication) might have a different risk for an adverse event than vaccinated persons. Therefore, direct comparisons of vaccinated and unvaccinated children are often inherently confounded, and teasing out these confounding issues requires understanding of the complex interactions of multiple, poorly quantified factors.

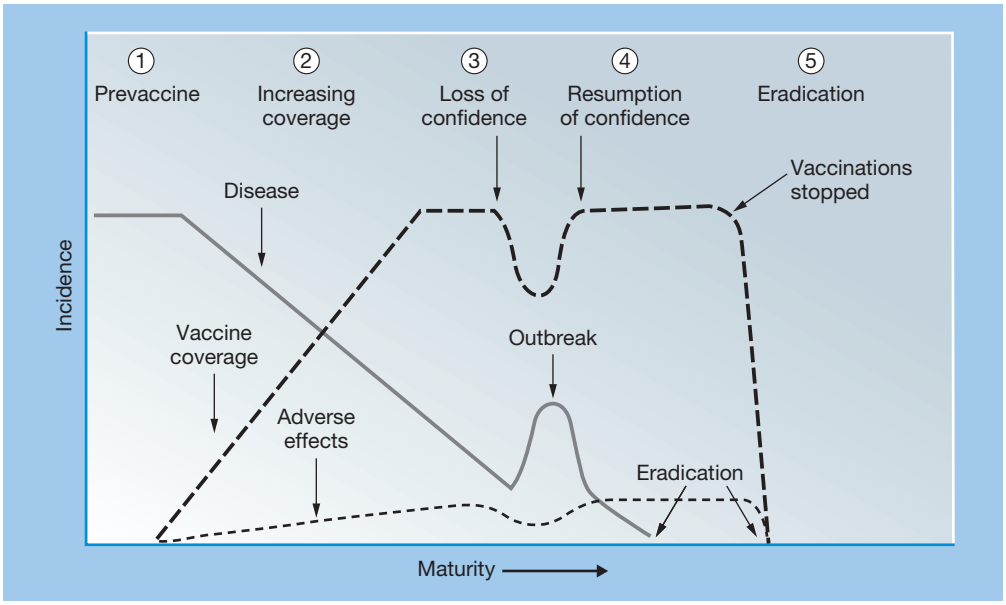

Figure 82.1. Evolution of immunization program and prominence of vaccine safety.

Passive Reporting Systems, Including the Vaccine Adverse Event Reporting System

Informal or formal passive surveillance or spontaneous reporting systems (SRSs) have been the cornerstone of most postlicensure safety monitoring systems because of their relative low cost of operations.[49–51] The national reporting of adverse events following immunizations can be done through the same reporting channels as those used for other adverse drug reactions,[51] as is the practice in France,[52] Japan,[53] New Zealand,[54] Sweden,[55] and the United Kingdom,[56] or with reporting forms or surveillance systems different from the drug safety monitoring systems, as is the practice in Australia,[57] Canada,[58,59] Cuba,[60] Denmark,[61] India,[62] Italy,[63] Germany,[64] Mexico,[65] The Netherlands,[66] Brazil,[67] and the United States.[68] Vaccine manufacturers also maintain SRSs for their products and they forward reports to appropriate national regulatory authorities.[30,65]

In the United States, the National Childhood Vaccine Injury Act of 1986 mandated that healthcare providers report certain adverse events after immunizations.[69] The Vaccine Adverse Events Reporting System (VAERS) was implemented jointly by the Centers for Disease Control and Prevention (CDC) and the U.S. Food and Drug Administration (FDA) in 1990 to provide a unified national focus for collection of all reports of clinically significant adverse events, including, but not limited to, those mandated for reporting.[68]

The VAERS form permits narrative descriptions of adverse events. Patients and their parents—not just healthcare professionals—are permitted to report to VAERS, and there is no restriction on the interval between vaccination and symptoms that can be reported. Report forms, assistance in completing the form, answers to other questions about VAERS, and additional information about the reported reactions, including whether or not the patient recovered, are available on the VAERS website (vaers.hhs.gov). Web-based reporting and simple data analyses are also available.

A contractor, under CDC and FDA supervision, distributes, collects, codes (currently using the Medical Dictionary for Regulatory Activities), and enters VAERS reports into a database. Reporters of selected serious events are contacted by trained clinical staff on report receipt and are sent letters at 1 year after report receipt to provide additional information about the VAERS report, including the patient's recovery. Approximately 30,000 VAERS reports are now received annually, and these data (without personal identifiers) are also available to the public (at vaers.hhs.gov and at wonder.cdc.gov/vaers.html).

Several other countries also have substantial experience with passive surveillance for immunization safety. In 1987, Canada developed the Vaccine Associated Adverse Event reporting system,[59,70] which is supplemented by an active, pediatric hospital–based surveillance system that searches all admissions for possible relationships to immunizations (Immunization Monitoring Program-Active [IMPACT]).[71] Serious Vaccine Associated Adverse Event reports are reviewed by the Advisory Committee on Causality Assessment consisting of a panel of experts.[72] The Netherlands also convenes an annual panel to categorize reports, which are then published.[66] The United Kingdom and most members of the former Commonwealth use the yellow card system, whereby a reporting form is attached to officially issued prescription pads.[50,55] Data on adverse drug events (including vaccine) from several countries are compiled by the World Health Organization (WHO) Collaborating Center for International Drug Monitoring in Uppsala, Sweden.[73]

With so many different passive surveillance systems that collect information on various medical events following vaccination, standardized definitions of vaccine-related adverse events are optimal. Implementation of similar standards across national boundaries has been advanced by the International Conference on Harmonization[74] and the Brighton Collaboration.[36]

Because VAERS is the only surveillance system covering the entire U.S. population with data available on a relatively timely basis, it is the major means available to currently detect possible new, unusual, or extremely rare adverse events. For example, in 1999, passive reports to VAERS of intussusception among children vaccinated with RotaShield was the first postlicensure signal of a problem,[75] leading to epidemiologic studies that verified the association.[17,76] Similarly, initial reports to VAERS of a previously unrecognized serious yellow fever vaccine–associated neurotropic disease[77] and viscerotropic disease[78,79] have since been confirmed elsewhere.[80] Because of the success in detecting these signals, there have been various attempts to automate screening for signals using SRSs reports. New tools developed for pattern recognition in extremely large databases are beginning to be applied.[81] These include empirical Bayesian data mining to identify vaccine-event adverse event combinations that are reported more frequently following a specific vaccine than following all other vaccines combined.[82]

Despite the aforementioned uses, SRSs for drug and vaccine safety have a number of major methodological weaknesses. Underreporting, biased reporting, and incomplete reporting are inherent to all such passive systems, and potential safety concerns might be missed.[83–85] Some increases in adverse events detected by VAERS might not be true increases, but instead might be the result of increases in reporting efficiency or vaccine coverage. For example, an increase in GBS reports was noted in VAERS shortly after the introduction of a new meningococcal conjugate vaccine (MCV4) in 2005, but a larger study conducted in five U.S. health plans with more than 1.4 million MCV4 vaccinations found no increased risk of GBS.[86] As another example, pending litigation resulted in the filing of a large number of VAERS reports claiming that vaccines caused autism.[87,88]

Perhaps the most important methodological weakness of VAERS, however, is that it does not contain the information necessary for formal epidemiologic analyses. Such analyses require calculation of the rate of the adverse event after vaccination and a comparison rate among unvaccinated persons. The VAERS database provides data only for the number of persons who may have experienced an adverse event following immunization and, even then, only in a biased and underreported manner. VAERS lacks data on the denominator of total number of people vaccinated and the corresponding data on number of cases and denominator population of unvaccinated people. Sometimes reporting rates can be calculated by using VAERS case reports for the numerator and, if available, doses of vaccines administered (or, if unavailable, data on vaccine doses distributed or vaccine coverage survey data) for the denominator. These rates can then be compared with the background rate of the same adverse event in the absence of vaccination, if available. Because of underreporting, however, VAERS reporting rates will usually be lower than the actual rates of adverse events following immunization.

A higher proportion of serious events, such as seizures, that follow vaccinations are likely to be reported to VAERS than milder events, such as rash, or delayed events requiring laboratory assessment, such as thrombocytopenic purpura after measles-mumps-rubella (MMR) vaccination.[83] The reporting efficiency or sensitivity of SRSs can sometimes be estimated if an independent source of cases of specific adverse events following immunization is available to conduct capture-recapture analyses.[89]

Formal evaluation has been limited by the quality of diagnostic information on VAERS reports, especially whether a serious event reported to VAERS has been diagnosed accurately. Of 26 cases reported to VAERS in which GBS developed after influenza vaccination during the 1990–91 season, and for which hospital charts were reviewed by an independent panel of neurologists blinded to immunization status, the diagnosis of GBS was confirmed in only 22 (85%).[90] Intussusception was verified in 88% of VAERS reports filed after Rotashield vaccination.[75] Clinical reviews of VAERS reports submitted following 2009 H1N1 influenza vaccine were able to verify 56% of possible GBS reports and 42% of reports of possible anaphylaxis.[91] Clinical review verification rates were similar for VAERS reports following human papillomavirus (HPV) vaccination: 57% for GBS and 38% for anaphylaxis.[92]

These studies highlight the often crude nature of signals generated by VAERS and the difficulty in ascertaining which potential vaccine safety concerns warrant further investigation. The problems with reporting efficiency and potentially biased reporting and the inherent lack of an adequate control group limit the certainty with which conclusions can be drawn. Recognition of these limitations in large part has helped stimulate the creation of more population-based methods of assessing vaccine safety.

Postlicensure Clinical Trials and Phase IV Surveillance Studies

To improve the ability to detect adverse events that are not detected during prelicensure trials, some recently licensed vaccines in developed countries have undergone formal Phase IV surveillance studies on populations with sample sizes that have included as many as 100,000 people. These studies usually have included cohorts in managed care organizations (MCOs) supplemented by diary or phone interviews. These methods were first used extensively after the licensure of polysaccharide and conjugated Hib vaccines.[93–95] Large postlicensure studies on safety and efficacy have also been conducted for several other vaccines, including those for DTaP,[38] varicella, and herpes zoster,[96,97] as well as for less-frequently used vaccines, such as Japanese encephalitis vaccine.[98]

Large Linked Databases, Including the Vaccine Safety Datalink. Historically, ad hoc epidemiologic studies have been used to assess signals of potential adverse events detected by SRSs, the medical literature, or other mechanisms. Some examples of such studies include the investigations of poliomyelitis after inactivated[10,99] and oral[100] polio vaccines, sudden infant death syndrome (SIDS) after diphtheria-tetanus-pertussis (DTP) vaccination,[101–104] encephalopathy after DTP vaccination,[105,106] meningoencephalitis after mumps vaccination,[107] injection-site abscesses after vaccination,[108] and GBS after influenza vaccination.[13,90,109] The Institute of Medicine (IOM) has compiled and reviewed many of these studies.[11,110,111]

Unfortunately, such ad hoc studies are often costly, time-consuming, and limited to assessment of a single event or a few events or outcomes. Given these drawbacks and the methodological limitations of passive surveillance systems (such as described for VAERS), pharmacoepidemiologists turned to large databases linking computerized pharmacy prescriptions (and later immunization records) and medical outcome records.[85] These databases include defined populations such as members of MCOs, single-provider healthcare systems, and Medicaid programs. Such databases cover enrollee populations numbering from thousands to millions, and, because the data are generated from the routine administration of the full range of medical care, underreporting and recall bias are reduced. With denominator data on doses administered and the ready availability of appropriate comparison (i.e., unvaccinated) groups, these large databases provide an economical and rapid means of conducting postlicensure studies of safety of drugs and vaccines.[112–116]

The CDC initiated the Vaccine Safety Datalink (VSD) project in 1990[113] to conduct postmarketing evaluations of vaccine safety and to establish an infrastructure allowing for high-quality research and surveillance. Several MCOs or integrated healthcare systems in the United States, comprising a population of more than 9 million members, participate in the VSD. Each site prepares computerized data files using a standardized data dictionary containing demographic and medical information on their members, such as age and sex, health plan enrollment, vaccinations, hospitalizations, outpatient clinic visits, emergency department visits, urgent care visits, and mortality data, as well as additional birth information (e.g., birth weight) when available. Other information sources, such as medical chart review; member surveys; and pharmacy, laboratory, and radiology data are often used in VSD studies to validate outcomes and vaccination data. There is rigorous attention to the maintenance of patient confidentiality, and each study undergoes institutional review board review.

The VSD project's main priorities include evaluating new vaccine safety concerns that may arise from the medical literature,[11,110] from VAERS,[76,117] from changes in immunization schedules,[118] or from introduction of new vaccines.[94,95] The creation of frequently updated data files has enabled the development of near real-time postmarketing surveillance for newly licensed vaccines and changes in vaccine recommendations. Many studies have been performed within the VSD project,[116] including general screening studies of the safety of inactivated influenza vaccines among children and of thimerosal-containing vaccines; and disease-specific investigations, including studies investigating autism, multiple sclerosis, thyroid disease, acute ataxia, alopecia, rheumatoid arthritis, asthma, diabetes, and idiopathic thrombocytopenic purpura following vaccination.

Among these advantages, a few caveats are appropriate. Although diverse, the population in the MCOs currently in the VSD project is not wholly representative of the United States in terms of geography or socioeconomic status. More important, because of the high coverage attained in the MCOs for most vaccines, few nonvaccinated control subjects are available. Therefore, VSD studies often rely on risk-interval analyses (e.g., to study the question of whether outcome "x" is more common in period "y" following vaccination compared with other periods) (Table 82.2).[119] This approach, although powerful for evaluating acute adverse events, has limited ability to assess associations between vaccination and adverse events with delayed or insidious onset (e.g., autism). The VSD project also cannot easily assess mild adverse events (such as fever) that do not always come to medical attention.[113] Finally, because vaccines are not delivered in the context of randomized, controlled trials, the VSD project may not be able to successfully control for confounding and bias in each analysis,[120] and inferences on causality may be limited.[121]

Despite these potential shortcomings, the VSD project provides an essential, powerful, and cost-effective complement to ongoing evaluations of vaccine safety in the United States.[115,116] In view of the methodological and logistic advantages offered by large-linked databases, the United Kingdom and Canada also have developed systems linking immunization records with medical files.[71,112] Certain countries, such as Sweden and Denmark, have the capability to conduct important

TABLE 82.2 Example of Method for Risk-Interval Analysis of Association Between a Universally Recommended Three-Dose Vaccine and an Adverse Event

1. Define biologically plausible risk interval for adverse event after vaccination (e.g., 30 days after each dose).

2. Partition observation time for each child in the study into periods within and outside of risk intervals, and sum respectively (e.g., for a child observed for 365 days during which 3 doses of vaccine were received, total risk interval time = 3 × 30 person-days = 90 person-days; total non-risk interval time = 365 – 90 = 275 person-days).

0————————-x= = = =————-x= = = =————————x= = = =———//———->|

Birth Dose 1 Dose 2 Dose 3 365 days

3. Add up (a) total risk interval and nonrisk interval observation times for each child in the study (Person-Time Observed; for mathematical convenience, example below uses 100 and 1000 person-months of observation), and (b) adverse events occurring in each time period to complete 2 × 2 table (for illustration, example below uses 3 and 10 cases):

Vaccinated in Risk Interval	Adverse Event: Yes	Person-Time Observed (mo)	Incidence Rate
Yes	3	100	0.03
No	10	1000	0.01
TOTAL	13	1100	

Incidence rate adverse event vaccinated = 3/100 = 0.03
Incidence rate adverse event unvaccinated = 10/1,000 = 0.01
Relative rate vaccinated: unvaccinated = 0.03/0.01 = 3.0
Probability finding is the result of chance: <5/100
Conclusion: There is a threefold increase in risk for developing the adverse event within the 30-day interval after vaccination compared to other time periods.

vaccine safety assessments by linking data across national registries.[122–124]

Clinical Centers, Including the Clinical Immunization Safety Assessment Centers. More recently, the immunization safety infrastructure has been augmented by tertiary clinical centers, such as were first developed in certain regions in Italy[47] and Australia.[125,126]

In the United States, the CDC's Clinical Immunization Safety Assessment (CISA) Project was established in 2001 to address unmet vaccine safety clinical research needs. CISA is a national network of vaccine safety experts from the CDC, seven medical research centers, and subject-matter experts. The CISA mission is to improve understanding of adverse events following immunization at the individual patient level. CISA serves as a vaccine safety resource providing expert consultation on clinical vaccine safety issues and with its partners conducts studies to identify risk factors and preventive strategies for vaccine adverse events, particularly in special populations.[28] The CISA investigators bring in-depth clinical, pathophysiological, and vaccinology expertise to assessing causal relationships between vaccines and adverse events,[127] and to understanding the pathogenesis of adverse events following vaccinations. The CISA investigators have published a standardized algorithm for evaluating and managing persons who have suspected or definite immediate hypersensitivity reactions such as urticaria, angioedema, and anaphylaxis following vaccines.[128] Some of the studies undertaken by CISA include an assessment of extensive limb swelling after DTaP,[129] a study of the usefulness of irritant skin test reactions for managing hypersensitivity to vaccines,[130] the clinical evaluation of patients with serious adverse events following yellow fever vaccine administration,[131] and evaluation of vaccine safety among children with inborn errors of metabolism.[132,133] New understanding of the human genome, pharmacogenomics, and immunology hold promise for future CISA studies and may make it possible to elucidate some of the biological mechanisms of vaccine adverse reactions, which, in turn, could lead to the development of safer vaccines and safer vaccination practices, including revaccination when indicated.[134]

SAFETY OF MASS IMMUNIZATION CAMPAIGNS

In mass-immunization campaigns during which many people are vaccinated in a short time, it is critical to have a vaccine safety monitoring system in place that can detect potential safety problems early so that corrective actions can be taken as soon as possible.[135] Mass-immunization campaigns are often conducted in developing countries, which poses a particular challenge of ensuring injection safety.[136] In any setting in which large numbers of immunizations are being administered, more adverse events will coincidentally occur following immunization. Thus, it is important to have background rates available of expected adverse events to allow rapid evaluation of whether reported adverse events are occurring at a rate following immunization that is higher than would be expected by chance alone. The resources devoted to mass vaccination campaigns also provide opportunities to enhance existing immunization safety monitoring systems or to establish a system if none exists and these may lead to long-term improvements in immunization safety monitoring beyond the specific mass immunization campaign.

The response to the 2009 H1N1 influenza pandemic involved probably the largest and most intense immunization safety monitoring effort ever undertaken in the United States and internationally. The emergence of a novel influenza A (H1N1) virus prompted the development of 2009 influenza A (H1N1) monovalent vaccines. The FDA licensed the first 2009-H1N1vaccines in September 2009. With potentially hundreds of millions of people expected to be vaccinated, adverse events were anticipated to occur in some recently vaccinated people. To address the question of whether the vaccine could be causing the adverse events, background rates for several adverse events were developed.[137] To rapidly detect any unforeseen safety problems, the federal government implemented enhanced postlicensure 2009-H1N1 vaccine safety monitoring,[138] including in VAERS and VSD. A new collaboration was initiated that also performed rapid ongoing analyses similar to VSD and included the databases of several large health insurance plans, the Department of Defense, Medicare, and the Veterans Administration. In addition, active case

finding for GBS was conducted in 10 areas of the United States with a combined population of approximately 50 million people. Initial safety data were provided by VAERS, which found that the adverse event profile after 2009-H1N1 vaccine in VAERS (>10,000 reports) was consistent with that of seasonal influenza vaccines.[91,138] Combined results from the U.S. monitoring systems found 1.6 excess cases of GBS per 1 million vaccinations, which is similar to the increased risk found with some seasonal influenza vaccines.[139]

Similar efforts to intensely monitor the safety of influenza A (H1N1) 2009 vaccines occurred in other countries, primarily in North America, Europe, and Australia, but also included the development of new immunization safety monitoring systems in countries such as Taiwan[140] and a multicountry study of GBS.[141] These extensive international safety monitoring activities and collaborations represented an unprecedented commitment to ensuring the safety of influenza A (H1N1) 2009 vaccines, as well as a model for how we might improve tracking of safety for all vaccines going forward.

WEIGHING THE EVIDENCE AND ASSESSING CAUSALITY

A central function of vaccine safety monitoring and assessment activities is to determine if particular adverse events following immunization are caused by a vaccine. This determination is important in guiding immunization policy and individual care and possibly compensation decisions. Causality assessment may be performed at the individual or population level. Epidemiologic studies provide measures of risk on a population level, but they do not provide evidence that a particular vaccine caused an adverse event in a particular individual. It is often not possible to infer causality in individual cases of adverse events following immunization, except in certain special situations. Circumstances in which a causal association in individual cases can reasonably be inferred include: (a) local reactions at a vaccine injection site; (b) immediate hypersensitivity reactions (in absence of other exposures); (c) recurrence–same adverse event recurs in same individual following repeat exposure to same vaccine; (d) isolation of vaccine virus (from typically sterile site), as, for example, Urabe mumps vaccine and aseptic meningitis; and (e) a unique clinical syndrome, such as vaccine-associated paralytic polio.

More general causality assessments rely on weighing different pieces of evidence using criteria such as strength of association, consistency of findings, temporal relationships, potential biases, and possible biological mechanisms. In the United States, the most authoritative assessments of causality have been conducted by the IOM, whose findings have been particularly influential in compiling the vaccine injury table of the National Vaccine Injury Compensation Program. The IOM has conducted three comprehensive reviews of adverse effects of vaccines,[111,142,143] as well as several focused reviews of specific vaccine safety topics. As highlighted in Table 82.3, the adverse reactions for which there is strong evidence of a causal association with recommended childhood vaccines in the United States are few and tend to occur rarely. Newer vaccines and certain other vaccines, however, were not covered in the latest IOM review in 2012. This gap was addressed by a systematic review of the literature commissioned by the Agency for Healthcare Research and Quality.[144] That review identified a few additional adverse events where the evidence favors a causal association, including rotavirus vaccines and intussusception, pneumococcal conjugate vaccine and febrile seizure, hepatitis A vaccine and purpura, and varicella vaccine and thrombocytopenic purpura.

In addition to identifying causal associations, IOM reviews have also been influential in clarifying particularly controversial issues where the evidence does not favor a causal association. These include pertussis vaccines and SIDS,[145] vaccines and autism,[146] hepatitis B vaccine and multiple sclerosis,[147] and vaccines and type 1 diabetes.[148]

TABLE 82.3 Vaccines and Adverse Events for Which Evidence Favors a Causal Association

Vaccine(s)	Adverse Event	Source	Rate Per Million Doses
Tetanus toxoid, pertussis, measles, mumps, rubella, inactivated polio vaccine, hepatitis B, varicella, influenza, meningitis, human papillomavirus	Anaphylaxis	VIT, IOM 2012	1–2[a]
Pertussis (whole cell)	Encephalopathy/encephalitis	VIT	<1[b]
Measles-mumps-rubella (MMR)	Encephalopathy/measles inclusion body encephalitis	VIT, IOM 2012	Case reports only
MMR	Febrile seizures	IOM 2012	333[b]
MMR	Transient arthralgia, women & children	IOM 2012	~5% (postpartum women); <1% (children)
Measles	Thrombocytopenic purpura	VIT	33[b]
Rubella	Chronic arthritis	VIT	Unknown[c]
Varicella	Vaccine strain dissemination	IOM 2012	Case reports
Any vaccine	Injection-related syncope, deltoid bursitis	IOM 2012	Case reports

VACCINE SAFETY CONTROVERSIES AND MISCONCEPTIONS

Unfortunately, vaccine safety issues have increasingly taken on a life of their own outside of the scientific arena—arguably to society's overall detriment. In particular, various chronic diseases (and their advocates) in search of a simple cause, for which immunizations—as a relatively universal exposure—have made all too convenient a hypothesized link. Case studies of some of these controversies are discussed in the following sections.

Whole-Cell Pertussis Vaccine Causes Permanent Brain Damage

In 1974, Kulenkampff and coworkers[149] reported a series of 22 cases of children with mental retardation and epilepsy following receipt of the whole-cell pertussis vaccine. During the next several years, fear of the pertussis vaccine generated by media coverage of this report caused a decrease in pertussis immunization rates in British children from 81% to 31% and resulted in more than 100,000 cases and 36 deaths from pertussis.[150] Media coverage of the Kulenkampff report also caused decreased immunization rates and increased pertussis deaths in Japan, Sweden, and Wales.[150]

However, many subsequent, excellent, well-controlled studies found that the incidence of mental retardation and epilepsy following whole-cell pertussis vaccine was similar in vaccinated children to that in children who did not receive the vaccine.[151–156]

Deaths Following Vaccination: Temporal Association Versus Causality

When a death occurs shortly following vaccination, there might be a natural tendency to question if the death was caused by the vaccine. Suspected associations of deaths with vaccination can have a negative impact on vaccination programs even when investigations do not find any evidence of a direct causal relationship. For example, when a combination pentavalent vaccine replacing the diphtheria-tetanus-whole-cell pertussis (DTwP) vaccine or DTwP-hepatitis B vaccine was introduced into Sri Lanka, India, and Vietnam in 2008–10, deaths were reported among a small number of vaccine recipients prompting authorities to suspend the use of these vaccines.[157] In 2010, an HPV demonstration project in India was suspended in response to demands from advocacy groups when four deaths occurred following receipt of HPV vaccine.[158] In December 2013, the deaths of 17 infants following hepatitis B virus vaccine made by a manufacturer in China generated widespread media and public interest, leading to a temporary suspension of the vaccine.[159] Investigations in all these examples found that the deaths were not caused by the vaccines.

Historically, SIDS has garnered the greatest concern with respect to a possible association with vaccination. In the mid-1980s, the antivaccine group Dissatisfied Parents Together raised the notion that the whole-cell pertussis vaccine could cause SIDS. In the early 1990s, when the hepatitis B vaccine was recommended for routine use in newborns, a popular television news program raised the question of whether vaccines could cause SIDS. SIDS peaks between 2 and 3 months of age, a time when infants are receiving a relatively large number of recommended vaccinations; thus, it would not be unexpected to observe a coincidental close temporal relationship between vaccination and SIDS. SIDS deaths in the United States have been declining since the early 1990s for a variety of reasons, including recommended changes in sleeping position.[160] This downward trend in SIDS has also been observed in SIDS reports submitted to VAERS.[161] Considerable evidence supports the notion that vaccination is not causally associated with SIDS,[162–165] including an IOM review in 2003 that rejected a causal association between the whole cell pertussis–containing vaccine and SIDS and between exposure to multiple simultaneous vaccines and SIDS.[145]

More recently, the misconception of mistakenly attributing temporally related events as causal was highlighted in the U.S. multistate measles outbreak of 2014–15. Early on, unsubstantiated claims of deaths caused by the MMR vaccine appeared on the Internet.[166–168] These claims were largely based on publicly available VAERS data. VAERS, however, is a voluntary reporting system that accepts any submitted report of an adverse event without judging whether it was caused by a vaccination. Any claims of cause and effect with respect to deaths following vaccination based on VAERS reports should be interpreted with caution. When the complete VAERS reports and accompanying medical records, autopsy reports, and death certificates were reviewed by FDA and CDC physicians, no concerning patterns were detected to suggest a causal relationship with MMR vaccination.[169,170]

With rare exceptions (e.g., anaphylaxis), the evidence does not suggest a causal relationship between vaccination and death. In addition to the 2003 review of SIDS, a previous IOM review of death reports in VAERS concluded that the vast majority of reported deaths were coincidental and not causally related to vaccination.[171] A newer VSD study of more than 13 million vaccinated persons compared rates and causes of death in the vaccinated study population to the general U.S. population. The death rate 1 or 2 months following vaccination was lower than that in the general U.S. population and the causes of death were similar,[172] providing persuasive evidence that vaccinations are not associated with an increased risk of death.

Vaccines Cause Cancer

Simian virus 40 (SV40) was present in monkey kidney cells used to make the inactivated polio vaccine, live attenuated polio vaccine, and inactivated adenovirus vaccines in the late 1950s and early 1960s. Later, investigators found SV40 DNA in biopsy specimens obtained from patients with certain unusual cancers—mesothelioma, osteosarcoma, and non-Hodgkin lymphoma—leading some to hypothesize a link between vaccination and the subsequent development of cancer.[173] However, genetic remnants of SV40 were present in cancers of people who had or had not received contaminated polio vaccines; people with cancers who never received SV40-contaminated vaccines were found to have evidence for SV40 in their cancerous cells; and epidemiologic studies did not show an increased risk of cancers in people who received polio vaccine between 1955 and 1963 compared with people who did not receive these vaccines.[173] Taken together, these findings do not support the hypothesis that the SV40 contained in polio vaccines administered before 1963 caused cancers.

Several studies have evaluated the possible relationship between vaccination and leukemia. The findings from these studies indicate that MMR, DTaP, diphtheria and tetanus toxoids–adult (Td), Hib, hepatitis B, and polio vaccines are not associated with childhood leukemia.[174–177]

Safety of the Immunization Schedule and Simultaneous Vaccinations

One hundred years ago, children received one vaccine—smallpox. Today, children receive 14 vaccines routinely.

Although some vaccines are given in combination, infants and young children could receive more than 20 shots and three oral doses of vaccines by 2 years of age, including as many as five shots at one time.[178–181] A prevalent concern is that little is known about the safety of the recommended immunization schedule as a whole. Parents have expressed the opinion, for example, that too many vaccines are given to children at too young an age and that early childhood immunization overwhelms the immune system. These sentiments reflect concern about the number, frequency, and timing of recommended vaccines rather than about the specific properties of particular vaccines.[178,182–184]

In response to this public concern, the IOM, in 2012, convened a committee to examine stakeholder concerns and scientific evidence regarding the safety of the recommended childhood immunization schedule, and to identify study settings, designs, and methods that would be appropriate to rigorously address this issue.[185] The IOM committee concluded that, although few published investigations had specifically examined the safety of the recommended childhood schedule as a whole, the accumulation of available evidence indicated that the current U.S. immunization schedule is safe. That evidence was based in part on concomitant use studies required by the FDA prior to licensure of a vaccine. Concomitant use studies determine whether new vaccines alter either the safety or immunogenicity profile of existing vaccines that will be given at the same time as the new vaccine and whether existing vaccines alter the safety or immunogenicity profiles of the new vaccine.

Although we have witnessed a dramatic increase in the number of vaccines routinely recommended for infants and young children, the number of immunogenic proteins and polysaccharides contained in vaccines has declined (Table 82.4). The decrease in the number of immunogenic proteins and polysaccharides contained in vaccines is attributable to discontinuation of the smallpox vaccine and advances in the field of protein purification that allowed for a switch from whole-cell to acellular pertussis vaccine, and recombinant DNA technology that allowed for the relatively easy manufacture of single protein vaccines.

A practical way to determine the capacity of the immune system to respond to vaccines is to consider the number of B and T cells required to generate adequate levels of binding antibodies per milliliter of blood.[186] Calculations are based on the following assumptions:

1. Approximately 10 ng/mL is likely to be an effective concentration of antibody directed against a specific epitope.
2. Approximately 10^3 B cells/mL are required to generate 10 ng of antibody/mL.
3. Given a doubling time of approximately 0.75 days for B cells, it would take approximately 7 days to generate 10^3 B cells/mL from a single B-cell clone.
4. Because vaccine-specific humoral immune responses are first detected approximately 7 days after immunization, those responses could initially be generated from a single B-cell clone per milliliter.
5. One vaccine contains approximately 10 immunogenic proteins or polysaccharides (see Table 82.4).
6. Each immunogenic protein or polysaccharide contains approximately 10 epitopes (i.e., 10^2 epitopes per vaccine).
7. Approximately 10^7 B cells are present per milliliter of blood.

Given these assumptions, the number of vaccines to which a person could respond would be determined by dividing the number of circulating B cells ($\approx 10^7$) by the average number of epitopes per vaccine (10^2). Therefore, a person could theoretically respond to approximately 10^5 vaccines at one time. This is probably a conservative estimate for several factors, including consideration of only vaccine-specific B-cell responses and ignoring the dynamic nature of the immune system. For example, a study of T-cell population dynamics in HIV-infected persons found that adults have the capacity to generate approximately 2×10^9 new T lymphocytes each day.[187] Although the quantity of new B and T cells generated each day in healthy people is unknown, studies of HIV-infected persons demonstrate the enormous capacity of the immune system to generate lymphocytes when needed.

TABLE 82.4 Year of Introduction and Number of Immunogenic Proteins and Polysaccharides Contained in Selected Vaccines

Vaccine	Year of Introduction	Number of Proteins or Polysaccharides or Both
Smallpox[a]	1796	198
Rabies	1885	5
Diphtheria[b]	1923	1
Pertussis (whole cell)[a]	1926	~3000
Tetanus[b]	1927	1
Yellow fever	1936	11
Influenza[b]	1945	10
Polio (inactivated)[b]	1955	15
Polio (live, attenuated)[a]	1961	15
Measles[b]	1963	10
Mumps[b]	1967	9
Rubella[b]	1969	5
Hepatitis B[b]	1981	1
Haemophilus influenzae type b (conjugate)[b]	1990	2
Pertussis (acellular)[b]	1991	2–5
Hepatitis A[b]	1995	4
Varicella[b]	1995	69
Pneumococcus (conjugate)[b]	2000	8
Meningococcus (conjugate)[b]	2005	5
Rotavirus[b]	2006	16
Human papillomavirus[b]	2006	4

Vaccines Weaken the Immune System

Infection with wild-type viruses can cause a suppression of specific immunologic functions. For example, infection with wild-type measles virus causes a reduction in the number of circulating B and T cells during the viremic phase of infection and a delay in the development of cell-mediated immunity.[188,189] Similarly, wild-type measles virus infection can cause long-term loss of memory B and T cells, resulting in an increased mortality from other infections.[190] Downregulation of cell-mediated immunity by wild-type measles virus probably results from downregulation of the production of

interleukin-12 by measles-infected macrophages and dendritic cells.[188] Taken together, the immunosuppressive effects of wild-type measles virus account, in part, for the increase in morbidity and mortality from measles infection. Similarly, the immunosuppressive effects of infections with wild-type varicella virus[191] or wild-type influenza virus[192] cause an increase in the incidence of severe invasive bacterial infections.

Live viral vaccines replicate (albeit far less efficiently than wild-type viruses) in the host and, therefore, can mimic events that occur after natural infection. For example, measles, mumps, or rubella vaccines can significantly depress reactivity to the tuberculin skin test,[193–199] measles-containing vaccines can cause a decrease in protective immune responses to varicella vaccine,[200] and high-titered measles vaccine (Edmonston-Zagreb strain) can cause an excess of cases of invasive bacterial infections in developing countries.[201] All these phenomena are explained by the likely immunosuppressive effects of measles vaccine viruses. However, current vaccines (including the highly attenuated Moraten strain of measles vaccine) do not seem to cause clinically relevant immunosuppression in healthy children. Studies have found that the incidence of invasive bacterial infections following immunization with diphtheria, pertussis, tetanus, bacille Calmette-Guérin (BCG), measles, mumps, rubella, or live attenuated poliovirus vaccines was not greater than that found in unimmunized children.[202–206]

Vaccines Cause Autoimmunity

Mechanisms are present at birth to prevent the development of immune responses directed against self-antigens (autoimmunity). T- and B-cell receptors of the fetus and newborn develop with a random repertoire of specificities. In the thymus, T cells that bind strongly to self-peptide–major histocompatibility complexes die, while those that bind with a lesser affinity survive to populate the body. This central selection process eliminates strongly self-reactive T cells, while selecting for T cells that recognize antigens in the context of self–major histocompatibility complex. In the fetal liver, and later in the bone marrow, B-cell receptors (i.e., immunoglobulins) that bind self-antigens strongly are also eliminated. Therefore, the thymus and bone marrow, by expressing antigens from many tissues of the body, enable the removal of the majority of potentially dangerous autoreactive T and B cells before they mature—a process termed *central tolerance*.[207]

It is not simply the presence of autoreactive T and B cells, however, that result in autoimmune disease. Autoreactive T and B cells are present in all people because it is not possible for every antigen from every tissue of the body to participate in the elimination of all potentially autoreactive cells. A process termed *peripheral tolerance* further limits the activation of autoreactive cells.[208,209] Mechanisms of peripheral tolerance include: (a) antigen sequestration (antigens of the central nervous system, eyes, and testes are not regularly exposed to the immune system unless injury or infection occurs); (b) anergy (lymphocytes partially triggered by antigen but without costimulatory signals are unable to respond to subsequent antigen exposure); (c) activation-induced cell death (a self-limiting mechanism involved in terminating immune responses after antigen is cleared); and (d) inhibition of immune responses by specific regulatory cells.[210–213]

Thus, the immune system anticipates that self-reactive T cells will be present and has mechanisms to control them. Any theory of vaccine causation of autoimmune diseases must take into account how these controls are circumvented. As discussed subsequently, epidemiologic studies have not supported the hypothesis that vaccines cause autoimmune diseases. This is consistent with the fact that no mechanisms have been advanced to explain how vaccines could account for all the prerequisites that would be required for the development of autoimmune disease.

At least four key conditions must be met for development of autoimmune disease. First, self-antigen–specific T cells or self-antigen–specific B cells must be present. Second, self-antigens must be presented in sufficient amounts to trigger autoreactive cells. Third, costimulatory signals, cytokines, and other activation signals produced by antigen-presenting cells (such as dendritic cells) must be present during activation of self-reactive T cells. Fourth, peripheral tolerance mechanisms must fail to control destructive autoimmune responses. If all these conditions are not met, the activation of self-reactive lymphocytes and progression to autoimmune disease are not likely.

Evidence That Vaccines Do Not Cause Autoimmunity

Rigorous epidemiologic studies of infant vaccines and type 1 diabetes found that measles vaccine was not associated with an increased risk for diabetes; other investigations found no association between BCG, smallpox, tetanus, pertussis, rubella, or mumps vaccine and diabetes.[214] Specifically, a Canadian study found no increase in risk for diabetes as a result of receipt of BCG vaccine.[215] In a large 10-year follow-up study among Finnish children enrolled in an Hib vaccination trial, no differences in risk for diabetes were found among children vaccinated at 3 months of age (followed later with a booster vaccine) and children vaccinated at 2 years only or with children born before the vaccine trial. The weight of currently available epidemiologic evidence does not support a causal association between currently recommended vaccines and type 1 diabetes in humans.[216–218]

The hypothesis that vaccines might cause multiple sclerosis was fueled by anecdotal reports of multiple sclerosis following hepatitis B immunization and two case-control studies showing a small increase in the incidence of multiple sclerosis in vaccinated persons that was not statistically significant.[219–221] However, the capacity of vaccines to cause or exacerbate multiple sclerosis has been evaluated in several excellent epidemiologic studies.[222–226] Two large case-control studies showed no association between hepatitis B vaccine and multiple sclerosis,[223] and found no evidence that hepatitis B, tetanus, or influenza vaccines exacerbated symptoms of multiple sclerosis.[224] Other well-controlled studies also found that influenza vaccine did not exacerbate symptoms of multiple sclerosis.[225–227] Indeed, in a retrospective study of 180 patients with relapsing multiple sclerosis, infection with influenza virus was more likely than immunization with influenza vaccine to cause an exacerbation of symtpoms.[227]

A 2009 review also showed that, with the possible exception of the swine flu vaccine in 1976, influenza vaccines are not a definite cause of GBS and that any possible increased risk following vaccination is outweighed by a higher risk following natural influenza infection.[228]

Vaccines Cause Allergies and Asthma

Allergic symptoms are caused by soluble factors (e.g., immunoglobulin E) that mediate immediate-type hypersensitivity; production of immunoglobulin E by B cells is dependent on release of cytokines such as interleukin-4 by T-helper type 2 (Th2) cells. Two theories have been advanced to explain how vaccines could enhance immunoglobulin E–mediated, Th2-dependent allergic responses. First, vaccines could shift immune responses to potential allergens from T-helper type 1 (Th1)-like to Th2-like.[229] Second, by preventing common prevalent infections (the "hygiene hypothesis"), vaccines

could prolong the length or increase the frequency of Th2-type responses.[230,231]

Although all factors that cause changes in the balance of Th1 and Th2 responses are not fully known,[232] it is clear that dendritic cells have a critical role. For example, adjuvants (e.g., aluminum hydroxide or aluminum phosphate ["alum"] contained in some vaccines) promote dendritic cells to stimulate Th2-type responses.[233,234] Adjuvants could cause allergies or asthma by stimulating bystander, allergen-specific Th2 cells. However, vaccine surveillance data show no evidence for environmental allergen priming by vaccination.[235] Furthermore, local inoculation of adjuvant does not cause a global shift of immune responses to Th1 or Th2 type.[236,237]

The other hypothesis advanced to explain how vaccines could promote allergies is that by preventing several childhood infections (the hygiene hypothesis), stimuli that evolution has relied on to cause a shift from the neonatal Th2-type immune response to the balanced Th1–Th2 response patterns of adults have been eliminated.[230,231] However, the diseases that are prevented by vaccines constitute only a small fraction of the total number of illnesses to which a child is exposed, and it is unlikely that the immune system would rely on only a few infections for the development of a normal balance between Th1 and Th2 responses. For example, a study of 25,000 illnesses performed in Cleveland, Ohio, in the 1960s found that children experienced six to eight infections per year in the first 6 years of life; most of these infections were caused by viruses such as coronaviruses, rhinoviruses, paramyxoviruses, and myxoviruses—diseases for which children are not routinely immunized.[238] Also at variance with the hygiene hypothesis is the fact that children in developing countries have lower rates of allergies and asthma than children in developed countries even though they are commonly infected with helminths and worms—organisms that induce strong Th2-type responses.[239]

Evidence That Vaccines Do Not Cause Asthma

Although some relatively small early observational studies supported the association between whole-cell pertussis vaccine and development of asthma,[240] newer studies suggest otherwise. A large clinical trial performed in Sweden found no increased risk,[241] and a very large longitudinal study in the United Kingdom found no association between pertussis vaccination and early- or late-onset wheezing or recurrent or intermittent wheezing.[242] Two studies from the VSD project have also lent data to this controversy. In one study of 1366 infants with wheezing during infancy, vaccination with DTP and other vaccines was not related to the risk of wheezing in full-term infants.[243] In another study of more than 165,000 children, childhood vaccinations were not associated with an increased risk for developing asthma.[244] Finally, a study from Finland also suggested that children with a history of natural measles were at increased risk for atopic illness. Such findings run contrary to the hypothesis that the increase in atopic illnesses seen in several countries is a consequence of the reduction in wild measles resulting from immunizations.[245]

A separate concern is whether inactivated influenza vaccination may exacerbate asthma in children with preexisting asthma. Results of studies examining the potential associations between administration of inactivated influenza vaccine and various surrogate measures of asthma exacerbation, including decreased peak expiratory flow rate, increased use of bronchodilating drugs, and increase in asthma symptoms, have yielded mixed results. Most studies, however, have not supported such an association.[246] In fact, after controlling for asthma severity, acute asthma exacerbations were less common after inactivated influenza vaccination than before,[247] and inactivated influenza vaccination seems to be associated with a decreased risk for asthma exacerbations throughout influenza seasons.[248] Several more recent studies have also shown a lack of correlation between receipt of vaccines and the development of asthma.[249–252]

Vaccines Cause Autism and Other Developmental Disabilities

Probably one of the most contentious issues in recent years has been speculation that vaccines cause autism. Autism is a chronic developmental disorder characterized by problems in social interaction, communication, and responsiveness and by repetitive interests and activities. Although the causes of autism are largely unknown, family and twin studies suggest that genetics has a fundamental role.[253] In addition, overexpression of neuropeptides and neurotrophins has been found in the immediate perinatal period among children later diagnosed with autism, suggesting that prenatal or perinatal influences or both have a more important role than postnatal insults.[254] However, because autistic symptoms generally first become apparent in the second year of life, some scientists and parents have focused on the role of MMR vaccine because it is first administered around this time. Concern about the role of MMR vaccine was heightened in 1998 when the *Lancet* published a study based on 12 children that proposed an association between the vaccine and the development of ileonodular lymphoid hyperplasia, nonspecific colitis, and regressive developmental disorders (later termed by some as "autistic enterocolitis").[255] Among the proposed mechanisms was that MMR vaccine present in the intestinal tissues caused bowel problems, leading to the malabsorption of essential vitamins and other nutrients and eventually to autism or other developmental disorders. Concern about this issue led to a decline in measles vaccine coverage in the United Kingdom and elsewhere.[256] Significant concerns about the validity of the study included the lack of an adequate control or comparison group, inconsistent timing to support causality (several of the children had autistic symptoms preceding bowel symptoms), and the lack of an accepted definition of the syndrome.[257] Subsequently, population-based studies of autistic children in the United Kingdom found no association between receipt of MMR vaccine and autism onset or developmental regression.[258,259] Soon after publication of the *Lancet* article that ignited the controversy,[255] two ecologic analyses found no evidence that MMR vaccination was the cause of apparent increased trends in autism over time[260,261]; in addition, two other studies found no evidence of a new variant form of autism associated with bowel disorders secondary to vaccination.[262,263] Several newer studies also refuted the notion that MMR vaccine caused autism.[264–269] Perhaps the most powerful study involved younger siblings where the older child had autism; in this study, receipt of MMR vaccine did not increase the risk of autism in the younger child.[270]

Because of the level of concern surrounding this issue, the CDC and the National Institutes of Health requested an independent review by the IOM.[271] The Immunization Safety Review Committee appointed by the IOM to review this issue was unable to find evidence supporting a causal relationship at the population level between autistic spectrum disorders and MMR vaccination, nor did the committee find any evidence of biological mechanisms that would support or explain such a link. In February 2010, the *Lancet* retracted the 1998 article.[272]

The mercury-containing preservative, thimerosal, has also been suggested to possibly increase the risk of autism. Mercury is a naturally occurring element found in the earth's crust, air, soil, and water. Certain types of bacteria in the environment

can change inorganic mercury to organic mercury (methylmercury). Methylmercury makes its way through the food chain in fish, animals, and humans. At high levels, it can be neurotoxic. Thimerosal, however, contains ethylmercury, not methylmercury. Studies comparing ethylmercury and methylmercury suggest that they are processed differently; ethylmercury is broken down and excreted much more rapidly than methylmercury. Therefore, ethylmercury is much less likely than methylmercury to accumulate in the body and cause harm.

The FDA Modernization Act of 1997 called for the FDA to review and assess the risk of all mercury-containing food and drugs. This led to an examination of mercury content in vaccines. Public health officials found that infants up to 6 months old could receive as much as 187.5 μg of ethylmercury (thimerosal) from vaccines, a level that exceeded recommended safety guidelines for methylmercury from the Environmental Protection Agency, but not levels recommended by the FDA or the Agency for Toxic Substance Disease Registry.[273] Consequently, the United States began transitioning to a childhood vaccine schedule free of thimerosal as a precautionary measure.[274] Currently, only the multidose influenza vaccine contains preservative quantities (i.e., 25 μg per dose) of thimerosal.

Several pieces of biological[275] and epidemiologic evidence indicate that thimerosal does not cause autism. Importantly, several large epidemiologic studies have compared the risk of autism in children who received vaccines containing thimerosal with children who received vaccines without thimerosal or vaccines with lesser quantities of thimerosal; none of the studies found an increased risk of autism associated with thimerosal-containing vaccines.[276–281] The IOM has reviewed these studies and concluded that evidence favored rejection of a causal association between thimerosal in vaccines and autism.[111,282] Denmark, a country that abandoned thimerosal as a preservative in 1991, actually saw an increase in the disorder beginning several years later. In the United States, all childhood vaccines with thimerosal as a preservative (except multidose influenza vaccine) passed their expiration date by 2003 and were no longer available in the United States; nonetheless, autism prevalence increased in the subsequent years.[283]

The hypothesis for why vaccines might cause autism has continued to shift. In 1998, the concern was that the MMR vaccine caused autism. The following year, the concern shifted to include the fear that thimerosal in vaccines caused autism. As data continued to be generated showing that both of these concerns were ill founded, the hypothesis shifted again—this time to include the fear that too many vaccines given too soon caused autism. To address this concern, a CDC study published in 2013 compared the number of antigens from vaccines during the first 2 years of life in a group of children with autism and matched controls without autism. The results showed that the total amount of antigen from vaccines received was the same between children with autism and those who did not have autism.[284]

Related to concerns about autism, the possibility that vaccines could cause other developmental disabilities, such as speech problems or learning difficulties, has also been evaluated. Several studies have evaluated a possible association between exposure to thimerosal in vaccines and neurodevelopmental problems and have found no consistent increased risk.[285–287] The total number of vaccines and vaccine antigens has also not been found to have a relationship with neurodevelopmental problems. Smith and Woods compared children who had received vaccines according to the CDC/American Academy of Pediatrics schedule with children who were not vaccinated, only partially vaccinated, or received vaccines on a delayed schedule, noting no difference between the two groups in neurodevelopmental outcomes.[288] A separate analysis found no association between the number of antigens in vaccines and neurodevelopmental outcomes.[289]

Aluminum in Vaccines Is Harmful

Aluminum salts have safely been used to adjuvant vaccines since the 1930s. However, by the mid-2000s, parents became concerned that aluminum in vaccines might be harmful. Indeed, high levels of aluminum can cause osteomalacia, anemia, or encephalopathy, typically in preterm infants or infants with absent or severely compromised renal function who are also receiving high doses of aluminum from other sources (e.g., antacids).[290] Studies show that children who receive aluminum-containing vaccines have serum levels of aluminum that are well below the toxic range.[291–293]

A specific concern that has been raised about aluminum adjuvants is their possible relationship to macrophagic myofasciitis, a condition consisting of a variety of complaints along with findings in muscle biopsies of minute lesions that contain aluminum salts.[294,295] The WHO Global Advisory Committee on Vaccine Safety has reviewed the evidence regarding macrophagic myofasciitis on several occasions and concluded that aluminum salts can be found in cells at an injection site of an aluminum-containing vaccine, but associated systemic symptoms related to that finding have never been scientifically proven.[296]

Formaldehyde in Vaccines Is Harmful

Formaldehyde has been used in vaccines to detoxify bacterial toxins (i.e., diphtheria toxin, tetanus toxin, pertussis toxins) and to inactivate viruses (i.e., poliovirus). Because formaldehyde at high concentrations can cause mutational changes in cellular DNA in vitro,[297] some parents have become concerned that formaldehyde in vaccines might be dangerous. However, because formaldehyde is a product of single-carbon metabolism, everyone has formaldehyde that is detectable in serum.[298] Indeed, the level of formaldehyde in the circulation is approximately 10-fold more than would be contained in any vaccine.[299] Also, people exposed to high levels of formaldehyde in the workplace (e.g., morticians) are not at greater risk of cancer than people who are not exposed to formaldehyde.[300] Finally, the quantity of formaldehyde present in vaccines is at least 600-fold lower than that necessary to induce toxicity in experimental animals.[301]

Vaccines Contain DNA From Aborted Human Fetuses

Two cell lines, MRC-5 and WI-38, both derived from elective abortions performed in Europe in the early 1960s, have been used as cell substrates in vaccine manufacture. Four vaccines continue to require the use of these cell lines: varicella, rubella, hepatitis A, and one of the rabies vaccines. Human fetal cells were valuable in vaccine research because they support the growth of many human viruses and are sterile; they were first used at around the time that researchers found that primary monkey kidney cells were contaminated with SV40 virus.

Some religious groups have become concerned about the use of cells originally obtained from elective abortions. However, the Catholic Church and other religions have deemed vaccines made using these cells worthy of continued use, despite their origins.[302,303]

SAFETY OF HUMAN PAPILLOMAVIRUS VACCINE

Concerns about safety have been a primary reason for not initiating HPV vaccination.[304] The WHO has noted that a

number of national immunization programs have experienced loss of confidence in their HPV vaccination programs as a result of negative publicity from perceived safety issues.[305] The postulated safety problems have included cerebral vasculitis, complex regional pain syndrome (CRPS), postural orthostatic tachycardia syndrome, and autoimmune diseases.[305–307] The suggestion that HPV vaccine could cause fatal cerebral vasculitis was raised in case reports that hypothesized that inflammation could be related to HPV L1 gene DNA fragments in the vaccine.[308,309] The FDA, however, determined that small amounts of HPV DNA fragments are to be expected as a result of the vaccine manufacturing process and do not represent a safety concern.[310] Moreover, the autopsy findings in the reported cases did not reveal evidence of inflammation and thus do not support a diagnosis of cerebral vasculitis. Concerns about CRPS have been limited to a few case reports in Japan that received considerable media attention.[311] Similar cases have not been reported from other countries. An expert review committee in Japan determined that information was not adequate to make a definitive diagnosis of CRPS in many of the reported cases and a causal relationship to vaccination could not be established.[312] A review by the European Medicines Agency concluded that the evidence does not support a causal association between HPV vaccines and CRPS or postural orthostatic tachycardia syndrome.[313]

Safety monitoring in the United States and internationally support the safety of HPV vaccine. In the United States, a review of VAERS found that reports of syncope and venous thromboembolism (VTE) were higher following HPV4 when compared to other vaccines. Continued monitoring in VAERS has not identified any new or unexpected safety concerns.[314] A population-based study of HPV4 safety from the VSD found no statistically significant increased risks of GBS, stroke, VTE, appendicitis, seizures, syncope, allergic reactions, or anaphylaxis.[315] A manufacturer-sponsored postlicensure safety assessment of HPV4 did not identify any major safety concerns except for an elevated relative risk of Hashimoto thyroiditis; however, further investigation of the temporal relationship and biological plausibility by the safety review committee revealed no consistent evidence for a safety signal for autoimmune thyroid conditions.[316] A national registry linkage study from Denmark found that HPV4 did not increase the risk of VTE.[317] A large population-based cohort study conducted in Denmark and Sweden analyzed more than 696,000 doses of HPV4 among females[318] and found no consistent evidence supporting causal associations with several autoimmune and neurologic conditions or VTE. A case-control study in France found no increased risk of several autoimmune outcomes (idiopathic thrombocytopenic purpura, central demyelination, GBS, connective tissue disorders, type 1 diabetes mellitus, and autoimmune thyroiditis) following HPV vaccination.[319] An analysis of national data from Sweden and Denmark covering 4 million women, including nearly 800,000 who had received HPV4, found no increased risk of multiple sclerosis or other demyelinating diseases following HPV4 vaccination.[124] Arguably, the HPV vaccine has been subjected to greater scrutiny postlicensure than most other vaccines.

NARCOLEPSY ASSOCIATED WITH AS03-ADJUVANTED PANDEMIC H1N1 INFLUENZA VACCINE

During the 2009 H1N1 influenza pandemic, GlaxoSmithKline's AS03-adjuvanted 2009 monovalent H1N1 influenza vaccine Pandemrix was used extensively in Europe and in other countries worldwide, although not in the United States. In August 2010, public health agencies in Sweden and Finland announced that they had received reports of narcolepsy after vaccination with Pandemrix.[320,321] Narcolepsy is a chronic central nervous system disorder characterized by excessive daytime sleepiness.[322] Its incidence is highest during the teen years,[323] but many individuals with narcolepsy are not diagnosed until several years after the onset of symptoms.[324] An increased risk of narcolepsy in Pandemrix-vaccinated compared with unvaccinated children and adolescents was found in Finland,[325] Sweden,[326] Ireland,[327] and Norway,[328] as well as in England [329] and France.[330] A case-control study that pooled data from eight European countries found an overall increased risk, although not in all countries.[331] Some European countries also reported an increased risk after vaccination in adults up to age 40 years, although the risk was smaller than the risk among vaccinees younger than 20 years of age.[326,330] A case-control study from Quebec of the Canadian AS03-adjuvanted vaccine, Arepanrix, found a small increased risk of narcolepsy, mainly in individuals younger than 20 years old, but a possible confounding effect of influenza infection could not be ruled out.[332] No increased risk of narcolepsy was found in a VSD study of the nonadjuvanted 2009 H1N1 pandemic influenza vaccines that were used in the United States.[333] Although no signals have been identified in SRSs,[334] risk of narcolepsy associated with MF59 adjuvanted vaccines has not been evaluated in formal epidemiologic studies. Questions remain about possible biological mechanisms and whether the association between Pandemrix and narcolepsy is confounded by other potential exposures or systematic biases, including publicity around the identified association.[331,335] Newer studies suggest that the issue may be more related to the influenza vaccine and not the adjuvant.[336] This is more fully discussed in Chapter 68.

Vaccine Risk Communication

Disease prevention with vaccination, especially if it requires continuous near-universal compliance, is a formidable task. In the preimmunization era, vaccine-preventable diseases such as measles and pertussis were so prevalent that the risks and benefits of disease versus vaccination were readily evident. As immunization programs successfully reduced the incidence of vaccine-preventable diseases, however, an increasing proportion of healthcare providers and parents have little or no personal experience with vaccine-preventable diseases. In contrast, some degree of personal discomfort, pain, and worry is generally associated with each immunization. In addition, parents searching for information about vaccines on the Internet are likely to encounter sites that encourage vaccine refusal or emphasize the dangers of vaccines alongside information from reputable sources.[337,338] Similarly, the media may sensationalize vaccine safety issues or, in an effort to present "both sides" of an argument, fail to provide perspective.[339,340] For reasons discussed earlier, there may be uncertainty if vaccines are associated with rare or delayed adverse reactions if only because the scientific method does not allow for acceptance of the null hypothesis; consequently, one cannot prove that a vaccine never causes a particular adverse event, only that an adverse event is unlikely to occur by a certain statistical probability.

The combination of these factors may affect parental beliefs about immunizations. Although the majority of parents support immunizations, surveys have found that many parents have concerns or misconceptions[180–182] that could erode their confidence in vaccines.[178] Within this context, the art of addressing vaccine safety concerns through effective risk communication has emerged as an increasingly important skill for managers of mature immunization programs and healthcare providers who administer vaccines.

Risk Perception

The science of risk perceptions and risk communications, which was developed initially for technology and environmental arenas,[341] can also be applied to immunizations.[342] For scientists and other experts, risk tends to be synonymous with the objective probability of morbidity and mortality resulting from exposure to a particular hazard.[343] In contrast, research shows that laypersons may have subjective, multidimensional, and value-laden conceptualizations of risk.[344] Individual people can vary in their perception of the magnitude of risks; studies show that various factors such as sex, race, political worldviews, emotional affect, and trust are associated with risk perception.[345] Risk perception factors such as involuntariness, uncertainty, lack of control, and high level of dread can lead to a heightened perception of risks.[346] All these can be seen as associated with childhood immunizations. Moreover, these factors are referred to as "outrage" factors in the risk communication literature. Outrage can lead to a person responding emotionally and can increase further the level of perceived risk.[346]

People care not only about the magnitude of risks, but also how risks are managed and whether they participate in the risk-management process.[347] In medical decision making, this has resulted in a transition from more paternalistic models to increasing degrees of shared decision making.[348] Some have argued that a similar transition also should occur with immunizations.[349] One study,[350] however, found that physicians who introduced vaccines using a participatory approach were more likely to encounter resistance compared to those who introduced vaccines as a presumptive or default choice. Furthermore, immunization is unlike most other medical procedures in that the consequences of the decision affect not only the individual person, but also others in society. Because of this important distinction, many countries have enacted immunization laws that, in part, are meant to limit an individual person's right to infect others. Without such mandates, persons may attempt to avoid the risks of vaccination while being protected by the herd immunity resulting from others being vaccinated.[351] Unfortunately, the protection provided by herd immunity may disappear if too many people avoid vaccination, resulting in outbreaks of vaccine-preventable diseases.[352,353] Debates in the United States, where such laws are created and enforced at the state level, have focused on whether philosophical (in addition to medical and religious) exemptions to mandatory immunizations for school entry should be more or less restrictive, and what standards for claim of exemption are needed.[349,354,355] For example, in 2015, California removed all nonmedical exemptions to school-entry vaccination requirements beginning in the 2016–17 school year.[356] Thus, vaccine risk communications should not only describe the risks and benefits of vaccines for individuals, but also should include discussion of the impact of individual immunization decisions on the larger community.

Factors That Can Influence Parental Vaccine Acceptance

Vaccination coverage among infants and young children in the United States has been consistently high, suggesting that vaccination as recommended by medical and public health professionals is still the norm.[357] However, high national coverage can mask variation at the local level.[358] Uneven distribution of undervaccinated individuals can mean a greater likelihood of disease outbreaks if exposed. One consequence of the success of vaccines is that an increasing number of parents and clinicians have little or no personal experience with or knowledge of many of the diseases that vaccines prevent. Thus, vaccine-preventable diseases often are not perceived as a real threat by parents.[359,360] Moreover, increasingly parents want to be fully informed about their children's medical care[361]; consequently, merely recommending vaccination may not be sufficient. Stories in the media highlighting adverse events (real or perceived) may also cause some parents to question the safety of vaccines.

Apart from the media attention on vaccine safety issues, several factors can shape parents' vaccine attitudes in the present environment of a low incidence of vaccine-preventable diseases. Some of these factors are: (a) depth of information needed, (b) timing of information given, (c) information sources and social media, (d) personal experience, and (e) general health literacy. An understanding of these factors and a proactive approach to vaccine education may prevent future concerns from escalating into widespread refusal of vaccines, with a consequent increased incidence of vaccine-preventable diseases. Each of these factors is discussed in more detail below.

Depth of Information

There is an association between information and vaccine acceptance. One study found that while 67% of parents agreed that they had access to enough information to make a good decision about immunizing their children, 33% of parents disagreed or were neutral.[362] Parents who disagreed they had enough vaccine information had negative attitudes about immunizations, healthcare providers, immunization requirements and exemptions, and trust in people responsible for immunization policy. Moreover, a larger percentage of parents who reported they did not have access to enough information about vaccines also had several specific vaccine concerns compared with parents who were neutral or agreed they had access to enough information.[362] It may be that when there is a void of accurate, trusted information, doubts about vaccines arise and misinformation is more readily accepted.

By using the principle of audience segmentation (partitioning a population into segments with shared characteristics), a survey study identified five parent groups that varied on health and immunization attitudes, behaviors, information sources, and demographics: Immunization Advocates (33.0%), Go Along to Get Alongs (26.4%), Health Advocates (24.8%), Fencesitters (13.2%), and Worrieds (2.6%).[363] It is important to recognize that parents vary in the amount and depth of information that they need to make decisions about vaccines, and that health communicators should take this into account when developing educational materials.

Timing of Information

Vaccine Information Statements (VISs) are typically given to parents the day their child is scheduled for immunization.[364–366] This often places the parent in a conflict situation of reviewing the VIS or attending to a frightened or upset child. Not surprisingly, studies have shown that parents would rather receive such information in advance of the first vaccination visit.[364,366–368] Suggested earlier times for vaccine education include prenatal clinic visits and just after delivery in a hospital.[369] A national survey indicated that 80% of providers said that a preimmunization booklet for parents would be useful for communicating risks and benefits to parents.[365]

Information Sources and Social Media

The majority of parents (84%) report receiving immunization information from a physician.[178] Furthermore, most parents,

including those who have concerns about vaccines, consider their child's doctor to be an important influence in their vaccination decision and report a high level of trust in their vaccine advice.[370,371] Thus, having a physician who engenders trust providing immunization information and who is available to listen and answer questions is the optimal situation from the public health perspective. If trust in a child's physician is low, parents may be drawn to other, less-credible sources of information.

Even though parents may have a number of sources of vaccine information other than a physician (e.g., family, friends), it is also important to consider the rise in social media use when discussing sources of information and influence regarding vaccine decisions. Online social media platforms, such as Facebook and Twitter, promote the two-way exchange of information and ideas, as opposed to the one-way information presentation of traditional Internet sites.[372] Although it remains to be seen how much of an influence social media interactions will have on parents' vaccine beliefs and behaviors, research to date points to both the potential importance of new technologies for engaging parents with accurate and timely information, as well as the potential for dissemination of myths and misinformation among parents' online social networks.[373]

Personal Experience

When a child experiences an adverse event following receipt of a vaccine, it often raises the question, "Was this vaccine necessary?" To the parent, it may seem that the risks of the vaccine are greater than the risks of not getting the vaccine. Parents who sought medical attention for any of their children owing to an apparent adverse event following immunizations (6.9%) not only expressed more concern about immunizations, but also were more likely to have a child who lacked one or more doses of three high-profile vaccines compared with parents who reported that none of their children had experienced an adverse event following immunization.[374] Two scenarios were seen as plausible. It may be that parents who were already concerned about vaccines before their child began the vaccination schedule sought medical attention for minor side effects (e.g., fever) or nonrelated problems. It is also possible that an apparent adverse event following immunization that resulted in parents seeking medical attention for their child caused the parents' perception of vaccines to become more negative. Both possibilities may result in parents declining future vaccines for their children. It is also important to note, however, that a physician's personal experience, with both vaccinations and vaccine-preventable diseases, can also be influential in helping reluctant parents understand the importance of on-time vaccination.[375] Education and descriptions of vaccine-preventable diseases may also help parents balance the perceived risks of vaccines with the risks of vaccine-preventable diseases.[376]

Health Literacy

There is a wide gap in the level of health literacy across the U.S. population, and this gap emphasizes the need for tailored information. The need for tailored information applies to all areas of health, including childhood immunizations. Immunization educational materials aimed at a "one-size-fits-all" audience are not likely to satisfy all parents' needs.[377] Tailoring should also take into account the need to avoid technical jargon and instead use a plain language approach to communication, regardless of the literacy level of the intended audience. Resources such as CDC's Clear Communication Index[378] can help assess the clarity of educational materials.

Evaluating and Addressing Vaccine Safety Concerns: Role of Healthcare Practitioners and Public Health Professionals

Empathy, patience, scientific curiosity, and substantial resources are needed to address concerns about vaccine safety. Although each evaluation of a vaccine safety concern is in some ways unique, some general principles may apply to most cases. As with all investigations, the first step is objective and comprehensive data gathering.[43] It is also important to gather and weigh evidence for causes other than vaccination. For individual cases or clusters of cases, a field investigation to gather data firsthand may be necessary.[108,379] Advice and review from a panel of independent experts also may be needed.[90,380,381] Causality assessment at the individual level is difficult at best; further evaluation via epidemiologic or laboratory studies may be required.[382] Even if the investigation is inconclusive, such studies can often help maintain public trust in immunization programs.[383]

In the United States, written information about the risks and benefits of immunizations developed by the CDC has been required to be provided to all people vaccinated in the public sector since 1978.[384] The National Childhood Vaccine Injury Act requires every healthcare provider—public or private—who administers a vaccine that is covered by the Act to provide a copy of the most current VIS to the adult vaccinee or, in the case of a minor, to the parent or legal representative, each time a dose of vaccine is administered.[385] Healthcare providers must note in each patient's permanent medical record the date printed on the VIS and the date the VIS was given to the vaccine recipient or the recipient's legal representative. VISs are the cornerstone of provider–patient vaccine risk–benefit communication. Each VIS contains information on the disease(s) that the vaccine prevents, who should receive the vaccine and when, contraindications, vaccine risks, what to do if a side effect occurs, and where to go for more information. Current VISs can be obtained from the CDC's National Center for Immunization and Respiratory Diseases[386] and are available in a number of languages other than English from the Immunization Action Coalition (www.immunize.org). An increasing number of resources that address vaccine safety misconceptions and allegations also have become available, including websites, brochures, resource kits, and videos (Table 82.5). Some studies have been conducted to assess the use and effectiveness of such materials[364,365,387–389]; however, more research in this area is needed.

Immunization programs and healthcare providers should anticipate that some members of the public may have deep concerns about the need for and safety of vaccines. Some may refuse certain vaccines and a few may reject all vaccinations. In the United States, less than 1% of young children have received no vaccines; a number that has been consistent for the past several years according to the National Immunization Survey.[357] However, surveys have estimated that anywhere from 13% to 39%[181,390,391] of parents have intentionally delayed or refused one or more recommended vaccines, depending on the population studied and the definition of delay and refusal used. Acceptance of this practice among physicians is associated with younger physician age, highlighting the importance of physicians' understanding of the risks of vaccine delay and refusal among their patients.[392] An understanding of vaccine risk perceptions and effective vaccine risk communication are essential in responding to misinformation and concerns. Healthcare professionals are also in the best position to help all parents provide evidence-based comfort measures to children to reduce acute pain and anxiety associated with vaccines.[393] It is also important to convey to those who refuse recommended vaccines that their decision is not without risk,

and that they (or their children) are vulnerable to a vaccine-preventable disease and its possible consequences.

Importance of Educating Parents Concerned About Vaccines

It is important not to assume that just because most parents are having their children immunized that they will continue to do so.[394] While the host of factors contributing to parents' decisions to have their children immunized (e.g., need for information, experience with adverse events) might remain stable for some time, it is possible that one or more factors may change so that some parents perceive the risks of vaccines to be greater than the risk of disease. This would then push the parents above a theoretical "unacceptability threshold" in which they would choose not to have their children immunized with one or more vaccines. One study[181] found that many parents whose children were fully vaccinated were "at risk" for vaccine delay or refusal based on their concerns about the safety or necessity of vaccines. Furthermore, vaccination is not a one-time, all-or-nothing decision, but rather an ongoing series of choices over time.

Averting the future possibility of outbreaks of vaccine-preventable diseases will take a concerted effort by healthcare and public health professionals to educate and better communicate with parents concerned about immunizations. In guidance for clinicians, the American Academy of Pediatrics does not recommend physicians remove nonvaccinating families from their practice, but it does give them permission to do so.[394a] Instead, American Academy of Pediatrics suggests that pediatricians should listen carefully and respectfully to parents' immunization concerns, factually communicate the risks and benefits of vaccines, and work with parents who may be concerned about a specific vaccine or having their child receive multiple vaccines in one visit.[395] Providers can make a huge impact on vaccine acceptance, resulting in a cascading effect in which providing information can increase trust and increasing trust can lead to greater acceptance of and confidence in vaccines. For healthcare providers to be able to optimally fill this important role, however, two related issues need to be addressed. The first is the need for quality communication courses and training in medical schools and residencies and training programs for medical and public health professionals regarding vaccine safety.[396–398] The second is for MCOs and medical insurance companies to adequately reimburse physicians for health education. Lack of reimbursement to physicians has been noted as a barrier to implementation of behavioral treatments for health issues such as heart disease[399] and smoking.[400] It is important to note that studies show that education programs can be a cost savings to healthcare systems.[401,402] We live in a world already benefiting from vaccines that exist, and there is the promise of more vaccines to come. The challenge we have now is to make sure that the promise is not lost because we did not present the benefits and risks of vaccines in a meaningful way acceptable to the public.

FUTURE CONSIDERATIONS

An optimal immunization safety system requires rigorous attention to safety during prelicensure research and development; active monitoring for potential safety problems after licensure; and clinical research and risk-management activities, including risk communication, focused on minimizing potential vaccine adverse reactions. Prelicensure activities form the foundation of vaccine safety. Rapid advances in biotechnology are leading to the development of new vaccines,[403] and novel delivery technologies, such as DNA vaccines and new adjuvants, are being developed to permit more antigens to be combined, reducing the number of injections.[404,405]

In the prelicensure evaluation of new vaccines, the trend is likely to continue to conduct larger Phase III trials enrolling tens of thousands of participants. Although such larger trials are helpful in identifying more rare adverse events, even these larger trials may not be large enough to detect increased risks of rare events. For example, the RotaTeq and Rotarix preclinical trials identified no increased risk of intussusception in studies that enrolled more than 60,000 infants.[41,42] Subsequent much larger postlicensure safety monitoring studies, however, identified statistically significant increased risks on the order of approximately one to five per 100,000.[18,19,406,407]

The attributable risks were less than that found for RotaShield (approximately one per 10,000), and, because the benefits of rotavirus vaccines clearly outweighed the small risk of intussusception, no changes were made to the vaccine recommendations.

Although technological advances and more thorough evaluation of safety before vaccines are licensed should lead to the development of safer vaccines, there will continue to be a need for comprehensive postlicensure safety monitoring systems. Combined with the difficulties associated with identifying rare, delayed, or insidious vaccine safety problems in prelicensure studies,[35] the well-organized consumer activist organizations,[408] Internet information of questionable accuracy,[337,338] media eagerness for controversy,[339,409] and relatively rare individual encounters with vaccine-preventable diseases virtually ensure that vaccine safety concerns are unlikely to go away. The existence of a robust vaccine safety monitoring system is essential for providing assurance of the safety of currently marketed vaccines and for rapidly identifying and responding to potential safety problems. Currently, SRSs, such as VAERS, serve as the frontline systems for the early identification of vaccine safety problems. Such systems could be improved if reporting were more complete. Application of web-based and text messaging technologies could make reporting easier and more accurate and also enable more active follow-up of vaccinated persons.[410] Alerts built into electronic medical record systems[411] could also improve reporting to VAERS, as could linkages with immunization registries. Some of these advances will be particularly important to enable monitoring vaccine safety in mass vaccination campaigns during which vaccinations may be administered primarily outside of the traditional healthcare system.

An optimal vaccine safety monitoring system must also include a mechanism or infrastructure to rapidly conduct formal epidemiologic evaluations of potential safety problems identified from SRSs or other sources. In the United States, this function is primarily served by the VSD project. The diffusion of electronic health records and the capability to link records across data systems (such as large health insurance claims databases and immunization registries) may allow the expansion of the population that could be included in postlicensure epidemiologic evaluations of vaccine safety. For example, the FDA Sentinel Initiative has a goal to develop a national electronic system covering 100 million people for monitoring the postlicensure safety of drugs and other medical products, including vaccines.[412]

For adverse reactions that are established as caused by vaccines, clinical and laboratory research is essential for determining the biological mechanisms of the adverse reaction, which, in turn, could lead to the development of safer vaccines. Clinical research is also essential for the development of protocols for safer vaccination, including revaccination of persons who have previously experienced an adverse reaction. Advances in genomics and immunology hold particular promise for elucidating biological mechanisms of vaccine adverse reactions and the development of possible screening strategies for persons who may be at high risk for an adverse reaction.

The need for comprehensive postlicensure monitoring of vaccine safety can be expected to grow with the development of new vaccines and as vaccines are increasingly used in populations that may have different susceptibilities to vaccine adverse events, such as immunocompromised individuals and pregnant women. Vaccination in pregnancy is unique in that it can affect the pregnant woman, the developing fetus, and the newborn infant. Pregnant women, however, are usually excluded from prelicensure clinical trials, making postlicensure monitoring key for evaluating safety of maternal immunizations. Currently in the United States, only two vaccines are routinely recommended for all pregnant women, inactivated influenza and combined tetanus, diphtheria and pertussis (Tdap) vaccines,[413,414] although other vaccines recommended for women of reproductive age are sometimes administered during pregnancy when the need arises. Evidence indicates that influenza and Tdap vaccines are safe when administered during pregnancy.[415–418] Safety data, however, are more limited on vaccination in the first trimester of pregnancy and for repeat Tdap vaccination at short intervals. Safety monitoring will also be important when anticipated new vaccines, such as group B streptococcus, respiratory syncytial virus vaccines,[419,420] and possibly meningococcal vaccines are introduced for use in pregnancy.

Scientific data are essential in the monitoring and evaluation of vaccine safety, but scientific evidence alone often is not sufficient to provide reassurance about the safety of a vaccine. Although immunization levels of U.S. children are high, a sizable fraction of parents do not have their children fully immunized, and concern about vaccine safety is the leading reason for underimmunization. These concerns persist despite the scientific evidence that vaccines do not cause autism or a host of other conditions that have been alleged to be caused by vaccines, such as asthma, diabetes, and autoimmune diseases. Thus, it is critically important that public health agencies, medical organizations, and other influential authorities continue to focus on the safety of vaccines and assure public confidence by providing clear, consistent messages on vaccine safety concerns; supporting effective and transparent vaccine safety monitoring systems and research activities; providing review and recommendations by respected independent expert groups on vaccine safety controversies; and engaging advocacy groups in constructive and open dialogue about their vaccine safety concerns. Although the efforts of government, medical, and other authorities are important, it is healthcare providers who have the greatest influence in determining the acceptance of vaccines by individual people. Even among parents who believe that vaccines may not be safe, most will have their children vaccinated if they have a trusting relationship with an influential healthcare provider. Thus, development of tools and strategies that can assist healthcare providers in effectively communicating with their patients on the risks and benefits of vaccines will continue to be important.

In low- and middle-income countries (LMICs) there is a need to establish minimal vaccine safety monitoring capabilities, such as SRSs, and the capability to rapidly investigate vaccine safety problems and effectively communicate the findings of the investigations. Concerns about vaccine safety can adversely impact immunization efforts, as happened in Vietnam and other countries when newly introduced pentavalent vaccines were falsely believed to have caused infant deaths.[157] An increasing number of vaccines are being introduced and used in LMICs, some are primarily for use in these settings.[421–423] A majority of LMICs, however, have nonexistent or limited vaccine safety monitoring capabilities.[424] In 2012, WHO led the development of the Global Vaccine Safety Blueprint[424] to set forth guidance on establishing and strengthening vaccine safety monitoring systems in LMIC settings. The possibilities for conducting enhanced safety monitoring, particularly with the large-scale introduction of new vaccines, was demonstrated with meningococcal A conjugate vaccine in sub-Saharan Africa.[425] Continued development of LMIC vaccine safety monitoring infrastructures will be needed with the introduction of new vaccine products, such as an adjuvanted malaria vaccine,[426] and viral vector dengue[427] and Ebola virus vaccines.[428] Mass immunization campaigns, during which millions of people receive parenteral immunizations over a period of days,[429] pose substantial challenges to ensuring injection safety,[430] especially given concerns about inadequate

sterilization of reusable syringes and needles, recycling of disposable syringes and needles, and cross-contamination resulting from the current generation of jet injectors.[431] The WHO has promoted the use of safer autodisposable syringes and disposal boxes.[432]

Vaccines are among the most successful and cost-effective public health tools for preventing disease and death. However, like all medical interventions, vaccines are not completely without risk of side effects or other adverse outcomes. A timely, credible, and effective monitoring system, coupled with prompt action in response to identified safety problems, is essential to preventing adverse effects of vaccination and to maintaining public confidence in immunizations. Because immunizations are typically administered to healthy people and are often recommended or mandated to provide societal and individual protection, vaccines must be held to a very high standard of safety. Vaccine safety monitoring and research should optimally be able to detect potentially very small levels of increased risk, especially for adverse events that can result in death or permanent disability. The ultimate goal of such research, including the application of new developments in biotechnology, is to develop safer vaccines and vaccination practices.

83 Legal Issues

Emily Marcus Levine, Andrea Sudell Davey, and Avril Melissa Houston

This chapter reviews liability for vaccine injuries historically; the rationale, development, and implementation of the National Vaccine Injury Compensation Program (VICP); and the program's current status. The first part of the chapter discusses the development of the law in the United States until 1986, the year of the passage of the National Childhood Vaccine Injury Act of 1986 (NCVIA). Later sections discuss the administration of the VICP, reported decisions relating to liability for the production and administration of vaccines after 1986, and current developments in the area of vaccine injury liability and compensation.

VACCINE LIABILITY BEFORE 1986

To understand the decisions that were rendered in cases filed against vaccine manufacturers and administrators before 1986, it is important to understand the nature of products liability law as it was evolving in that era. Before the early 1980s, manufacturers were not held liable for the harm associated with a product unless it failed to comply with the standards of manufacturing or care implemented by similarly situated manufacturers. Usually, vaccine manufacturers sued by consumers would prevail because they used customary practices and complied with statutes and regulations and because of the doctrine of the *learned intermediary,* discussed later.

This standard began to change when, in 1965, the American Law Institute introduced the concept of "strict liability" in its *Restatement (Second) of Torts*. Although the principles embodied in this *Restatement* were not applied uniformly to lawsuits against vaccine manufacturers and administrators, they served as guiding principles in the field and were viewed by many as significant emerging legal doctrines.

Under the *Restatement*'s doctrine of strict liability, a manufacturer who sold a product in a defective condition that made the product unreasonably dangerous was subject to liability for harm caused to the user or consumer even if the manufacturer exercised all possible care in the preparation and sale of the product.[1] A product was deemed defective if it was in a condition not contemplated by the ultimate consumer, which made it unreasonably dangerous to the consumer.[2] Although the doctrine of strict liability lowered the burden required to find manufacturers liable for the harm caused by their products, the authors of the *Restatement* recognized that some products were, by their nature, "unavoidably unsafe," and determined that such products should not be deemed unreasonably dangerous under the doctrine of strict liability.[3] Thus, products such as vaccines, which necessarily entail some risks (risks considered reasonable given their benefits to the community), were not deemed defective or unreasonably dangerous so long as they were properly prepared and accompanied by adequate warnings.[4] Consequently, vaccine manufacturers and administrators were generally not held liable for harm caused by their products before 1986, so long as these requirements of proper preparation and adequate warnings were satisfied.

The risk of liability created by the requirements to properly prepare vaccines and provide adequate warnings is important. If, for instance, a lot of vaccine was defective and caused disease in recipients because the disease-causing agent was not sufficiently inactivated or because of contaminants, the manufacturer could be liable, whether or not the defect could be shown to be the manufacturer's fault. This happened with early lots of Salk poliovirus vaccine, and there were numerous and substantial recoveries by persons who acquired polio from the vaccine.[5] As another example, if a physician administered a vaccine when it was contraindicated (e.g., administered Sabin oral poliovirus vaccine [OPV] to a child known to be immunodeficient or administered a second dose of diphtheria and tetanus toxoids and whole-cell pertussis [DTP] vaccine after a child had a severe adverse reaction to the first), the physician could be liable if the adverse consequence risked by violating the contraindication occurred. Furthermore, if a physician administered a vaccine without warning the patient of the risks, the physician could be liable if the risks occurred.

Despite the limits on liability imposed by general doctrines of products liability law in cases concerning adverse reactions from vaccines, certain judicial decisions in the pre-1986 era imposed liability even when the vaccines were properly made and administered. These cases, which were a significant impetus to the enactment of the NCVIA, can be divided into three categories: the *Reyes* decision, the swine flu litigation against the government, and the 1980s decisions.

Reyes v Wyeth Laboratories,[6] decided in 1974 by the United States Court of Appeals for the Fifth Circuit, held a manufacturer of OPV liable to a child who contracted paralytic poliomyelitis after being administered the vaccine. The decision broadened the potential liability faced by manufacturers in the context of mass vaccination efforts.

This case articulated an exception to the learned intermediary doctrine. Under the general rule, a manufacturer of prescription medicines, including vaccines, is obliged to provide warnings concerning the product to the healthcare provider (the learned intermediary), but has no duty to directly warn the user of the product of its associated risks. This doctrine is based on the assumption that the medical professional makes an individualized medical judgment with respect to the risks and benefits of a particular drug or vaccine and a particular patient. The Reyes decision narrowed this general rule, holding that, when a manufacturer can reasonably be said to be aware that the product (i.e., the vaccine) will be administered in such a way that no personalized medical advice will be provided (e.g., in the context of a public health department's immunization effort in which the patient had no direct contact with a physician), the manufacturer is responsible for providing warnings directly to patients or ensuring that such warnings will be given.

In Reyes, the manufacturer shipped the vaccines to the Texas Department of Public Health, accompanied by the Food and Drug Administration (FDA)-required package inserts containing warnings concerning the possible consequences of the vaccine. The Texas Department of Public Health sent the vaccine to the county health department without ensuring that the warnings would actually be given to vaccine recipients (or their parents). The nurse who administered the vaccine to the child in this case did not warn the parents of the minute risk that a recipient or contact could contract the disease. Although the Reyes Court determined that OPV was not unreasonably dangerous per se, it concluded that the vaccines were

unreasonably dangerous as marketed and that the manufacturer breached its duty because it was aware that the vaccine could result in a particular danger, knew or had reason to know that the vaccine would be administered in circumstances in which vaccine recipients might not be counseled by learned intermediaries (i.e., in mass vaccine clinics), and failed to provide warnings or ensure that such warnings were provided to vaccine recipients.

The next development in the area of vaccine liability involved the swine flu vaccine. In the spring of 1976, leading epidemiologists predicted that the United States could be afflicted the following winter with a strain of influenza that could lead to a pandemic similar to the catastrophic outbreak of 1918.[7] The lack of prior immunity raised fears that many people who contracted the disease would die or have serious illnesses. This prediction led the government to recommend a campaign to immunize almost all American adults.[8,9]

The Reyes decision caused manufacturers to refuse initially to provide the swine flu vaccine to the government. In addition, manufacturers, concerned about other unforeseen risks of liability in a program this large, did not want to accept any liability for the vaccines. As a result, the Swine Flu Act was passed.[10] This law required vaccine recipients who believed they had been injured to sue the federal government, which served as a substitute defendant for vaccine manufacturers. The swine flu program was a considerable success as a matter of effective public health mobilization, insofar as the vaccine was successfully produced, distributed, and administered to more than 45 million people in a few months. However, vaccination was suspended when the feared swine flu epidemic had not yet appeared and suspicions arose that there might be an association between the vaccine and Guillain-Barré syndrome (GBS).[11] Numerous claims concerning GBS were filed under the Swine Flu Act, many of which relied on a Centers for Disease Control and Prevention (CDC)-sponsored study that showed a statistically significant increase in the risk of GBS in the 10 weeks after immunization compared with the risk in unvaccinated people. The government accepted liability for all cases of GBS with onset falling within this period. The government did not agree to accept liability for cases of GBS falling outside this time interval or for other illnesses. The defense of this litigation resulted in more than 100 judicial opinions, which generally shielded manufacturers and administrators from liability by relying on the Swine Flu Act. However, some courts wrote opinions in the *Reyes v Wyeth* tradition that imposed increased liability for the federal government based on a theory of inadequate warning, for example, *Unthank v United States*[12] and *Petty v United States*,[13] in which the federal government was found derivatively liable for a manufacturer's failure to provide plaintiffs with adequate warnings covering the risks of the swine flu vaccine.[14]

The efforts of plaintiffs to establish common law, strict tort liability on the part of vaccine manufacturers (i.e., the manufacturer is liable even if adequate warnings are given and the vaccine is produced and handled in full compliance with FDA regulations) seemed to increase after *Reyes* and the swine flu episode. In the 1980s, plaintiffs achieved some notable successes. For example, in *Johnson v American Cyanamid Co.*,[15] the father of a vaccinated child who claimed to have contracted polio through contact with his child sued the manufacturer and administrator of the OPV. The jury found the vaccine manufacturer liable and imposed a $10 million damages award. The Kansas Supreme Court reversed the jury's verdict and award, determined that there was no manufacturing or design defect, and concluded that the manufacturer's warning was adequate. The court did not resolve whether the vaccine administrator might have been liable for failing to warn the parents of the vaccine's risk had this claim been pursued.

In *Toner v Lederle Laboratories*,[16] a jury returned a verdict of over $1.1 million for a recipient of a DTP vaccine who claimed that the vaccine caused transverse myelitis, a condition that had never been shown scientifically to be caused by any available DTP vaccine. The plaintiff's theory was that the vaccine caused transverse myelitis, that the defendant could have marketed a safer vaccine (a vaccine once marketed by another manufacturer that was withdrawn from the market in the 1970s), and that the manufacturer's failure to make a safer version of the vaccine was negligent. The verdict was appealed to the United States Court of Appeals for the Ninth Circuit, which referred the issues to the Idaho Supreme Court. The Idaho Supreme Court affirmed the jury's verdict that the manufacturer's design of DTP was negligent.

The results reached in these cases are notable and underscore the fear of liability by vaccine manufacturers and healthcare professionals.

NATIONAL CHILDHOOD VACCINE INJURY ACT

The *Reyes v Wyeth* decision and its progeny were followed by the withdrawal of a number of pharmaceutical houses from vaccine production and an increase in the price of vaccines.[14]

The litigious atmosphere of the 1980s and the sharp decrease in the number of vaccine manufacturers had an adverse impact on the research and development of new and safer vaccines. Before a vaccine is marketed and before a manufacturer has a possibility of reaping any profit, the FDA requires the manufacturer to prove that the vaccine is safe and effective. Meeting this burden is costly, and the investment cannot be recovered until the vaccine is marketed. The costs and logistics associated with administering a new vaccine enough times in prelicensure clinical trials to detect rare adverse side effects are high. A manufacturer's inability to accurately estimate its risk of liability and, therefore, the effect of this potential liability on its profit margin translated into limited commercial incentives to develop new vaccines.

During this period, the nation's children were at risk. The American Academy of Pediatrics and the American Medical Association were concerned about the continued availability of vaccines and the possibility that physicians were at risk for liability. At the time, it was common for plaintiffs to join the pharmaceutical company and the administering physician in a complaint, claiming that the physician did not adequately disclose the risk associated with the vaccine. At least one state (North Carolina) enacted legislation protecting participants in the delivery of vaccines from liability and authorizing compensation to injured vaccinees.[17] In the end, the NCVIA of 1986[18] was compromise legislation fought for by parents and physicians with some backing of industry and trial attorneys, but with little support from the Administration.

NATIONAL VACCINE INJURY COMPENSATION PROGRAM

Purpose and Goals

The VICP, established by the NCVIA, was authorized by Congress to address a variety of public policy needs.[19,20] As explained in the NCVIA's legislative history and repeated in many court decisions, two significant concerns led to the enactment of this legislation. First, concerns about the instability and unpredictability of the childhood vaccine market (based on several factors, including litigation and whether affordable product liability insurance was available) led Congress to determine that a new system was required to stabilize the childhood vaccine market, considered essential to the nation's public health. Second, Congress recognized that

persons injured by childhood vaccines should receive fair compensation and determined that the tort system used at the time to provide such compensation was inadequate.[21]

Congress addressed these issues by creating the VICP, a federal "no-fault" system under which awards can be made to vaccine-injured persons quickly, easily, and generously. Persons injured through the receipt of a vaccine after the effective date of the legislation generally are required to file claims with the VICP before they are allowed to bring a civil suit against vaccine manufacturers or administrators. Although the statute is entitled the "National Childhood Vaccine Injury Act," eligibility for compensation extends to children and adults. Rules of evidence, discovery, and other legal procedures are relaxed to accelerate the compensation process. Petitioners in VICP proceedings need not demonstrate negligence on the part of a vaccine manufacturer or administrator, thus the no-fault designation. Petitioners with eligible claims must exhaust their remedies within the VICP before filing lawsuits against vaccine manufacturers or administrators. To do so, a petitioner must withdraw his or her petition from the VICP (if the Court of Federal Claims fails to issue a decision or enter judgment within the time periods provided for in the NCVIA) or reject the judgment entered (whether or not compensation was awarded).

In addition to the establishment of the VICP and the imposition of liability protections, the NCVIA established sweeping vaccine safety provisions and created a more prominent vaccine safety role for the federal government. The NCVIA included a mandate for the reporting of certain adverse events. Healthcare providers and vaccine manufacturers are required to report the occurrence of any event set forth in the Vaccine Injury Table (VIT) (Table 83.1) and any contraindicating reaction to a vaccine that is specified in the manufacturer's package insert.[22] The report must state the symptoms and manifestations of the illness or injury, how long after administration of the vaccine such symptoms occurred, and the manufacturer and lot number of the vaccine administered. These reports are to be made to the Vaccine Adverse Event Reporting System. Other vaccine safety mandates include record keeping by vaccine administrators (documenting the date of vaccine administration, the manufacturer and lot number, and the name and address of the administrator) and development and dissemination of risk-to-benefit information materials (known as Vaccine Information Statements) by the Secretary of Health and Human Services (HHS). The NCVIA also required certain studies, conducted by the Institute of Medicine (IOM), of vaccine adverse events.

The NCVIA also established two advisory panels, the Advisory Commission on Childhood Vaccines (ACCV)[23] and the National Vaccine Advisory Committee (NVAC).[24] The NCVIA mandates that the ACCV include as members equal numbers of health professionals, members of the public (including legal guardians of children injured by vaccines), and attorneys (including a representative of persons injured by vaccines and a representative of vaccine manufacturers). The ACCV makes recommendations to the Secretary of HHS on changes to the VIT and other issues related to the administration of the VICP. The NVAC has much broader responsibilities, including the authority to recommend ways to achieve optimal prevention of disease through changes related to vaccine research, development, delivery, safety, and efficacy. The NVAC makes recommendations to the HHS Assistant Secretary for Health.

Although the NCVIA was landmark in design and scope, numerous amendments to the initial legislation were enacted. Funding of the VICP, not provided for in the original legislation, was authorized by Congress in early 1987.[25] Additional protections for manufacturers defending claims filed by persons after exhausting their remedies under the VICP also were written into the law at this time. These included the statutory bars to actions based on plaintiff allegations of vaccine misdesign or inadequate warning of risk, two common tort theories pursued in the 1980s, and the elimination of punitive damages unless gross negligence in vaccine production was proven.[26] At the same time, the provision requiring claimants to pursue their claim through the VICP before filing a tort claim against manufacturers was expanded to include healthcare providers, a protection that was not offered by the original act. Subsequent legislation in 1993 permanently reauthorized the VICP and provided a mechanism for adding new vaccines and for the Secretary of HHS to modify the VIT.[27] Vaccines recommended by the CDC (usually on recommendation by the Advisory Committee on Immunization Practices) for routine administration to children would be added to the VICP. As described below, a statutory amendment passed in 2016 expanded the VICP's coverage to include vaccines recommended by the CDC for routine administration to pregnant women. Congress also would have to enact an excise tax as a necessary step before coverage could begin.

Text continued on p. 1608

TABLE 83.1 Vaccine Injury Table[a]

In accordance with section 312(b) of the National Childhood Vaccine Injury Act of 1986, title III of Public Law 99-660, 100 Stat. 3779 (42 U.S.C. 300aa-1 note) and section 2114(c) of the Public Health Service Act, as amended (PHS Act) (42 U.S.C. 300aa-14(c)), the following is a table of vaccines, the injuries, disabilities, illnesses, conditions, and deaths resulting from the administration of such vaccines, and the time period in which the first symptom or manifestation of onset or of the significant aggravation of such injuries, disabilities, illnesses, conditions, and deaths is to occur after vaccine administration for purposes of receiving compensation under the Program. Paragraph (b) of this section sets forth additional provisions that are not separately listed in this Table but that constitute part of it. Paragraph (c) of this section sets forth the qualifications and aids to interpretation for the terms used in the Table. Conditions and injuries that do not meet the terms of the qualifications and aids to interpretation are not within the Table. Paragraph (d) of this section sets forth a glossary of terms used in paragraph (c).

Vaccine	Illness, Disability, Injury or Condition Covered	Time Period for First Symptom or Manifestation of Onset or of Significant Aggravation After Vaccine Administration
I. Vaccines containing tetanus toxoid (e.g., DTaP, DTP, DT, Td, or TT)	A. Anaphylaxis	≤4 hours
	B. Brachial neuritis	2-28 days (not less than 2 days and not more than 28 days)
	C. Shoulder injury related to vaccine administration[b]	≤48 hours
	D. Vasovagal syncope[b]	≤1 hour

Continued on following page

TABLE 83.1 Vaccine Injury Table[a] *(Continued)*

Vaccine	Illness, Disability, Injury or Condition Covered	Time Period for First Symptom or Manifestation of Onset or of Significant Aggravation After Vaccine Administration
II. Vaccines containing whole cell pertussis bacteria, extracted or partial cell pertussis bacteria, or specific pertussis antigen(s) (e.g., DTP, DTaP, P, DTP-Hib)	A. Anaphylaxis B. Encephalopathy or encephalitis C. Shoulder injury related to vaccine administration[b] D. Vasovagal syncope[b]	≤4 hours ≤72 hours ≤48 hours ≤1 hour
III. Vaccines containing measles, mumps, and rubella virus or any of its components (e.g., MMR, MM, MMRV)	A. Anaphylaxis B. Encephalopathy or encephalitis C. Shoulder injury related to vaccine administration[b] D. Vasovagal syncope[b]	≤4 hours 5-15 days (not less than 5 days and not more than 15 days) ≤48 hours ≤1 hour
IV. Vaccines containing rubella virus (e.g., MMR, MMRV)	A. Chronic arthritis	7-42 days (not less than 7 days and not more than 42 days)
V. Vaccines containing measles virus (e.g., MMR, MM, MMRV)	A. Thrombocytopenic purpura B. Vaccine-strain measles viral disease in an immunodeficient recipient Vaccine-strain virus identified If strain determination is not done or if laboratory testing is inconclusive[b]	7-30 days (not less than 7 days and not more than 30 days) Not applicable ≤12 months
VI. Vaccines containing polio live virus (OPV)	A. Paralytic polio In a non-immunodeficient recipient In an immunodeficient recipient In a vaccine associated community case B. Vaccine-strain polio viral infection In a non-immunodeficient recipient In an immunodeficient recipient In a vaccine associated community case	 ≤30 days ≤6 months Not applicable ≤30 days ≤6 months Not applicable
VII. Vaccines containing polio inactivated virus (e.g., IPV)	A. Anaphylaxis B. Shoulder injury related to vaccine administration[b] C. Vasovagal syncope[a]	≤4 hours ≤48 hours ≤1 hour
VIII. Hepatitis B vaccines	A. Anaphylaxis B. Shoulder injury related to vaccine administration[b] C. Vasovagal syncope[b]	≤4 hours ≤48 hours ≤1 hour
IX. Haemophilus influenzae type b (Hib) vaccines	A. Shoulder injury related to vaccine administration[b] B. Vasovagal syncope[b]	≤48 hours ≤1 hour
X. Varicella vaccines	A. Anaphylaxis[b] B. Disseminated varicella vaccine-strain viral disease Vaccine-strain virus identified If strain determination is not done or if laboratory testing is inconclusive[b] C. Varicella vaccine-strain viral reactivation[b] D. Shoulder injury related to vaccine administration[b] E. Vasovagal syncope[b]	≤4 hours Not applicable 7-42 days (not less than 7 days and not more than 42 days) Not applicable ≤48 hours ≤1 hour
XI. Rotavirus vaccines	A. Intussusception	1-21 days (not less than 1 day and not more than 21 days)
XII. Pneumococcal conjugate vaccines	A. Shoulder Injury Related to Vaccine Administration[b] B. Vasovagal syncope[b]	≤48 hours ≤1 hour
XIII. Hepatitis A vaccines	A. Shoulder injury related to vaccine administration[b] B. Vasovagal syncope[b]	≤48 hours ≤1 hour
XIV. Seasonal influenza vaccines	A. Anaphylaxis[b] B. Shoulder injury related to vaccine administration[b] C. Vasovagal syncope[b] D. Guillain-Barré syndrome[b]	≤4 hours ≤48 hours ≤1 hour 3-42 days (not less than 3 days and not more than 42 days)
XV. Meningococcal vaccines	A. Anaphylaxis[b] B. Shoulder injury related to vaccine administration[b] C. Vasovagal syncope[b]	≤4 hours ≤48 hours ≤1 hour
XVI. Human papillomavirus (HPV) vaccines	A. Anaphylaxis[b] B. Shoulder injury related to vaccine administration[b] C. Vasovagal syncope[b]	≤4 hours ≤48 hours ≤1 hour
XVII. Any new vaccine recommended by the Centers for Disease Control and Prevention for routine administration to children, after publication by the Secretary of a notice of coverage	A. Shoulder injury related to vaccine administration[b] B. Vasovagal syncope[b]	≤48 hours ≤1hour

TABLE 83.1 Vaccine Injury Table[a] *(Continued)*

(b) Provisions that apply to all conditions listed.
  (1) Any acute complication or sequela, including death, of the illness, disability, injury, or condition listed in paragraph (a) of this section (and defined in paragraphs (c) and (d) of this section) qualifies as a Table injury under paragraph (a) except when the definition in paragraph (c) requires exclusion.
  (2) In determining whether or not an injury is a condition set forth in paragraph (a) of this section, the Court shall consider the entire medical record.
  (3) An idiopathic condition that meets the definition of an illness, disability, injury, or condition set forth in paragraph (c) of this section shall be considered to be a condition set forth in paragraph (a) of this section.

(c) Qualifications and aids to interpretation. The following qualifications and aids to interpretation shall apply to, define and describe the scope of, and be read in conjunction with paragraphs (a), (b), and (d) of this section:
  (1) Anaphylaxis. Anaphylaxis is an acute, severe, and potentially lethal systemic reaction that occurs as a single discrete event with simultaneous involvement of two or more organ systems. Most cases resolve without sequela. Signs and symptoms begin minutes to a few hours after exposure. Death, if it occurs, usually results from airway obstruction caused by laryngeal edema or bronchospasm and may be associated with cardiovascular collapse. Other significant clinical signs and symptoms may include the following: Cyanosis, hypotension, bradycardia, tachycardia, arrhythmia, edema of the pharynx and/or trachea and/or larynx with stridor and dyspnea. There are no specific pathological findings to confirm a diagnosis of anaphylaxis.
  (2) Encephalopathy. A vaccine recipient shall be considered to have suffered an encephalopathy if an injury meeting the description below of an acute encephalopathy occurs within the applicable time period and results in a chronic encephalopathy, as described in paragraph (d) of this section.
    (i) Acute encephalopathy.
      (A) For children less than 18 months of age who present:
        (1) Without a seizure, an acute encephalopathy is indicated by a significantly decreased level of consciousness that lasts at least 24 hours.
        (2) Following a seizure, an acute encephalopathy is demonstrated by a significantly decreased level of consciousness that lasts at least 24 hours and cannot be attributed to a postictal state—from a seizure or a medication.
      (B) For adults and children 18 months of age or older, an acute encephalopathy is one that persists at least 24 hours and is characterized by at least two of the following:
        (1) A significant change in mental status that is not medication related (such as a confusional state, delirium, or psychosis);
        (2) A significantly decreased level of consciousness which is independent of a seizure and cannot be attributed to the effects of medication; and
        (3) A seizure associated with loss of consciousness.
      (C) The following clinical features in themselves do not demonstrate an acute encephalopathy or a significant change in either mental status or level of consciousness: Sleepiness, irritability (fussiness), high-pitched and unusual screaming, poor feeding, persistent inconsolable crying, bulging fontanelle, or symptoms of dementia.
      (D) Seizures in themselves are not sufficient to constitute a diagnosis of encephalopathy and in the absence of other evidence of an acute encephalopathy seizures shall not be viewed as the first symptom or manifestation of an acute encephalopathy.
    (ii) Exclusionary criteria for encephalopathy. Regardless of whether or not the specific cause of the underlying condition, systemic disease, or acute event (including an infectious organism) is known, an encephalopathy shall not be considered to be a condition set forth in the Table if it is shown that the encephalopathy was caused by:
      (A) An underlying condition or systemic disease shown to be unrelated to the vaccine (such as malignancy, structural lesion, psychiatric illness, dementia, genetic disorder, prenatal or perinatal central nervous system (CNS) injury); or
      (B) An acute event shown to be unrelated to the vaccine such as a head trauma, stroke, transient ischemic attack, complicated migraine, drug use (illicit or prescribed) or an infectious disease.
  (3) Encephalitis. A vaccine recipient shall be considered to have suffered encephalitis if an injury meeting the description below of acute encephalitis occurs within the applicable time period and results in a chronic encephalopathy, as described in paragraph (d) of this section.
    (i) Acute encephalitis. Encephalitis is indicated by evidence of neurologic dysfunction, as described in paragraph (c)(3)(i)(A) of this section, plus evidence of an inflammatory process in the brain, as described in paragraph (c)(3)(i)(B) of this section.
      (A) Evidence of neurologic dysfunction consists of either:
        (1) One of the following neurologic findings referable to the CNS: Focal cortical signs (such as aphasia, alexia, agraphia, cortical blindness); cranial nerve abnormalities; visual field defects; abnormal presence of primitive reflexes (such as Babinski's sign or sucking reflex); or cerebellar dysfunction (such as ataxia, dysmetria, or nystagmus); or
        (2) An acute encephalopathy as set forth in paragraph (c)(2)(i) of this section.
      (B) Evidence of an inflammatory process in the brain (central nervous system or CNS inflammation) must include cerebrospinal fluid (CSF) pleocytosis (>5 white blood cells (WBC)/mm[FN3] in children >2 months of age and adults; >15 WBC/mm3 in children <2 months of age); or at least two of the following:
        (1) Fever (temperature >= 100.4 degrees Fahrenheit);
        (2) Electroencephalogram findings consistent with encephalitis, such as diffuse or multifocal nonspecific background slowing and periodic discharges; or
        (3) Neuroimaging findings consistent with encephalitis, which include, but are not limited to brain/spine magnetic resonance imaging (MRI) displaying diffuse or multifocal areas of hyperintense signal on T2-weighted, diffusion-weighted image, or fluid-attenuation inversion recovery sequences.
    (ii) Exclusionary criteria for encephalitis. Regardless of whether or not the specific cause of the underlying condition, systemic disease, or acute event (including an infectious organism) is known, encephalitis shall not be considered to be a condition set forth in the Table if it is shown that the encephalitis was caused by:
      (A) An underlying malignancy that led to a paraneoplastic encephalitis;
      (B) An infectious disease associated with encephalitis, including a bacterial, parasitic, fungal or viral illness (such as herpes viruses, adenovirus, enterovirus, West Nile Virus, or human immunodeficiency virus), which may be demonstrated by clinical signs and symptoms and need not be confirmed by culture or serologic testing; or
      (C) Acute disseminated encephalomyelitis (ADEM). Although early ADEM may have laboratory and clinical characteristics similar to acute encephalitis, findings on MRI are distinct with ADEM displaying evidence of acute demyelination (scattered, focal, or multifocal areas of inflammation and demyelination within cerebral subcortical and deep cortical white matter; gray matter involvement may also be seen but is a minor component); or
      (D) Other conditions or abnormalities that would explain the vaccine recipient's symptoms.

Continued on following page

TABLE 83.1 Vaccine Injury Table[a] *(Continued)*

(4) Intussusception.
  (i) For purposes of paragraph (a) of this section, intussusception means the invagination of a segment of intestine into the next segment of intestine, resulting in bowel obstruction, diminished arterial blood supply, and blockage of the venous blood flow. This is characterized by a sudden onset of abdominal pain that may be manifested by anguished crying, irritability, vomiting, abdominal swelling, and/or passing of stools mixed with blood and mucus.
  (ii) For purposes of paragraph (a) of this section, the following shall not be considered to be a Table intussusception:
    (A) Onset that occurs with or after the third dose of a vaccine containing rotavirus;
    (B) Onset within 14 days after an infectious disease associated with intussusception, including viral disease (such as those secondary to non-enteric or enteric adenovirus, or other enteric viruses such as Enterovirus), enteric bacteria (such as Campylobacter jejuni), or enteric parasites (such as Ascaris lumbricoides), which may be demonstrated by clinical signs and symptoms and need not be confirmed by culture or serologic testing;
    (C) Onset in a person with a preexisting condition identified as the lead point for intussusception such as intestinal masses and cystic structures (such as polyps, tumors, Meckel's diverticulum, lymphoma, or duplication cysts);
    (D) Onset in a person with abnormalities of the bowel, including congenital anatomic abnormalities, anatomic changes after abdominal surgery, and other anatomic bowel abnormalities caused by mucosal hemorrhage, trauma, or abnormal intestinal blood vessels (such as Henoch Scholein purpura, hematoma, or hemangioma); or
    (E) Onset in a person with underlying conditions or systemic diseases associated with intussusception (such as cystic fibrosis, celiac disease, or Kawasaki disease).

(5) Chronic arthritis. Chronic arthritis is defined as persistent joint swelling with at least two additional manifestations of warmth, tenderness, pain with movement, or limited range of motion, lasting for at least 6 months.
  (i) Chronic arthritis may be found in a person with no history in the 3 years prior to vaccination of arthropathy (joint disease) on the basis of:
    (A) Medical documentation recorded within 30 days after the onset of objective signs of acute arthritis (joint swelling) that occurred between 7 and 42 days after a rubella vaccination; and
    (B) Medical documentation (recorded within 3 years after the onset of acute arthritis) of the persistence of objective signs of intermittent or continuous arthritis for more than 6 months following vaccination; and
    (C) Medical documentation of an antibody response to the rubella virus.
  (ii) The following shall not be considered as chronic arthritis: Musculoskeletal disorders such as diffuse connective tissue diseases (including but not limited to rheumatoid arthritis, juvenile idiopathic arthritis, systemic lupus erythematosus, systemic sclerosis, mixed connective tissue disease, polymyositis/determatomyositis, fibromyalgia, necrotizing vasculitis and vasculopathies and Sjogren's Syndrome), degenerative joint disease, infectious agents other than rubella (whether by direct invasion or as an immune reaction), metabolic and endocrine diseases, trauma, neoplasms, neuropathic disorders, bone and cartilage disorders, and arthritis associated with ankylosing spondylitis, psoriasis, inflammatory bowel disease, Reiter's Syndrome, blood disorders, or arthralgia (joint pain), or joint stiffness without swelling.

(6) Brachial neuritis. This term is defined as dysfunction limited to the upper extremity nerve plexus (i.e., its trunks, divisions, or cords). A deep, steady, often severe aching pain in the shoulder and upper arm usually heralds onset of the condition. The pain is typically followed in days or weeks by weakness in the affected upper extremity muscle groups. Sensory loss may accompany the motor deficits, but is generally a less notable clinical feature. Atrophy of the affected muscles may occur. The neuritis, or plexopathy, may be present on the same side or on the side opposite the injection. It is sometimes bilateral, affecting both upper extremities. A vaccine recipient shall be considered to have suffered brachial neuritis as a Table injury if such recipient manifests all of the following:
  (i) Pain in the affected arm and shoulder is a presenting symptom and occurs within the specified time-frame;
  (ii) Weakness;
    (A) Clinical diagnosis in the absence of nerve conduction and electromyographic studies requires weakness in muscles supplied by more than one peripheral nerve.
    (B) Nerve conduction studies (NCS) and electromyographic (EMG) studies localizing the injury to the brachial plexus are required before the diagnosis can be made if weakness is limited to muscles supplied by a single peripheral nerve.
  (iii) Motor, sensory, and reflex findings on physical examination and the results of NCS and EMG studies, if performed, must be consistent in confirming that dysfunction is attributable to the brachial plexus; and
  (iv) No other condition or abnormality is present that would explain the vaccine recipient's symptoms.

(7) Thrombocytopenic purpura. This term is defined by the presence of clinical manifestations, such as petechiae, significant bruising, or spontaneous bleeding, and by a serum platelet count less than 50,000/mm[FN3] with normal red and white blood cell indices. Thrombocytopenic purpura does not include cases of thrombocytopenia associated with other causes such as hypersplenism, autoimmune disorders (including alloantibodies from previous transfusions) myelodysplasias, lymphoproliferative disorders, congenital thrombocytopenia or hemolytic uremic syndrome. Thrombocytopenic purpura does not include cases of immune (formerly called idiopathic) thrombocytopenic purpura that are mediated, for example, by viral or fungal infections, toxins or drugs. Thrombocytopenic purpura does not include cases of thrombocytopenia associated with disseminated intravascular coagulation, as observed with bacterial and viral infections. Viral infections include, for example, those infections secondary to Epstein Barr virus, cytomegalovirus, hepatitis A and B, human immunodeficiency virus, adenovirus, and dengue virus. An antecedent viral infection may be demonstrated by clinical signs and symptoms and need not be confirmed by culture or serologic testing. However, if culture or serologic testing is performed, and the viral illness is attributed to the vaccine-strain measles virus, the presumption of causation will remain in effect. Bone marrow examination, if performed, must reveal a normal or an increased number of megakaryocytes in an otherwise normal marrow.

(8) Vaccine-strain measles viral disease. This term is defined as a measles illness that involves the skin and/or another organ (such as the brain or lungs). Measles virus must be isolated from the affected organ or histopathologic findings characteristic for the disease must be present. Measles viral strain determination may be performed by methods such as polymerase chain reaction test and vaccine-specific monoclonal antibody. If strain determination reveals wild-type measles virus or another, non-vaccine-strain virus, the disease shall not be considered to be a condition set forth in the Table. If strain determination is not done or if the strain cannot be identified, onset of illness in any organ must occur within 12 months after vaccination.

TABLE 83.1 Vaccine Injury Table[a] *(Continued)*

(9) Vaccine-strain polio viral infection. This term is defined as a disease caused by poliovirus that is isolated from the affected tissue and should be determined to be the vaccine-strain by oligonucleotide or polymerase chain reaction. Isolation of poliovirus from the stool is not sufficient to establish a tissue specific infection or disease caused by vaccine-strain poliovirus.

(10) Shoulder injury related to vaccine administration (SIRVA). SIRVA manifests as shoulder pain and limited range of motion occurring after the administration of a vaccine intended for intramuscular administration in the upper arm. These symptoms are thought to occur as a result of unintended injection of vaccine antigen or trauma from the needle into and around the underlying bursa of the shoulder resulting in an inflammatory reaction. SIRVA is caused by an injury to the musculoskeletal structures of the shoulder (e.g. tendons, ligaments, bursae, etc.). SIRVA is not a neurological injury and abnormalities on neurological examination or nerve conduction studies (NCS) and/or electromyographic (EMG) studies would not support SIRVA as a diagnosis (even if the condition causing the neurological abnormality is not known). A vaccine recipient shall be considered to have suffered SIRVA if such recipient manifests all of the following:
   (i) No history of pain, inflammation or dysfunction of the affected shoulder prior to intramuscular vaccine administration that would explain the alleged signs, symptoms, examination findings, and/or diagnostic studies occurring after vaccine injection;
   (ii) Pain occurs within the specified time-frame;
   (iii) Pain and reduced range of motion are limited to the shoulder in which the intramuscular vaccine was administered; and
   (iv) No other condition or abnormality is present that would explain the patient's symptoms (e.g. NCS/EMG or clinical evidence of radiculopathy, brachial neuritis, mononeuropathies, or any other neuropathy).

(11) Disseminated varicella vaccine-strain viral disease. Disseminated varicella vaccine-strain viral disease is defined as a varicella illness that involves the skin beyond the dermatome in which the vaccination was given and/or disease caused by vaccine-strain varicella in another organ. For organs other than the skin, the disease must be demonstrated in the involved organ and not just through mildly abnormal laboratory values. If there is involvement of an organ beyond the skin, and no virus was identified in that organ, the involvement of all organs must occur as part of the same, discrete illness. If strain determination reveals wild-type varicella virus or another, non-vaccine-strain virus, the viral disease shall not be considered to be a condition set forth in the Table. If strain determination is not done or if the strain cannot be identified, onset of illness in any organ must occur 7- 42 days after vaccination.

(12) Varicella vaccine-strain viral reactivation disease. Varicella vaccine-strain viral reactivation disease is defined as the presence of the rash of herpes zoster with or without concurrent disease in an organ other than the skin. Zoster, or shingles, is a painful, unilateral, pruritic rash appearing in one or more sensory dermatomes. For organs other than the skin, the disease must be demonstrated in the involved organ and not just through mildly abnormal laboratory values. There must be laboratory confirmation that the vaccine-strain of the varicella virus is present in the skin or in any other involved organ, for example by oligonucleotide or polymerase chain reaction. If strain determination reveals wild-type varicella virus or another, non-vaccine-strain virus, the viral disease shall not be considered to be a condition set forth in the Table.

(13) Vasovagal syncope. Vasovagal syncope (also sometimes called neurocardiogenic syncope) means loss of consciousness (fainting) and postural tone caused by a transient decrease in blood flow to the brain occurring after the administration of an injected vaccine. Vasovagal syncope is usually a benign condition but may result in falling and injury with significant sequela. Vasovagal syncope may be preceded by symptoms such as nausea, lightheadedness, diaphoresis, and/or pallor. Vasovagal syncope may be associated with transient seizure-like activity, but recovery of orientation and consciousness generally occurs simultaneously with vasovagal syncope. Loss of consciousness resulting from the following conditions will not be considered vasovagal syncope: organic heart disease, cardiac arrhythmias, transient ischemic attacks, hyperventilation, metabolic conditions, neurological conditions, and seizures. Episodes of recurrent syncope occurring after the applicable time period are not considered to be sequela of an episode of syncope meeting the Table requirements.

(14) Immunodeficient recipient. Immunodeficient recipient is defined as an individual with an identified defect in the immunological system which impairs the body's ability to fight infections. The identified defect may be due to an inherited disorder (such as severe combined immunodeficiency resulting in absent T lymphocytes), or an acquired disorder (such as acquired immunodeficiency syndrome resulting from decreased CD4 cell counts). The identified defect must be demonstrated in the medical records, either preceding or postdating vaccination.

(15) Guillain-Barré Syndrome (GBS).
   (i) GBS is an acute monophasic peripheral neuropathy that encompasses a spectrum of four clinicopathological subtypes described below. For each subtype of GBS, the interval between the first appearance of symptoms and the nadir of weakness is between 12 hours and 28 days. This is followed in all subtypes by a clinical plateau with stabilization at the nadir of symptoms, or subsequent improvement without significant relapse. Death may occur without a clinical plateau. Treatment related fluctuations in all subtypes of GBS can occur within 9 weeks of GBS symptom onset and recurrence of symptoms after this time-frame would not be consistent with GBS.
   (ii) The most common subtype in North America and Europe, comprising more than 90 percent of cases, is acute inflammatory demyelinating polyneuropathy (AIDP), which has the pathologic and electrodiagnostic features of focal demyelination of motor and sensory peripheral nerves and nerve roots. Another subtype called acute motor axonal neuropathy (AMAN) is generally seen in other parts of the world and is predominated by axonal damage that primarily affects motor nerves. AMAN lacks features of demyelination. Another less common subtype of GBS includes acute motor and sensory neuropathy (AMSAN), which is an axonal form of GBS that is similar to AMAN, but also affects the sensory nerves and roots. AIDP, AMAN, and AMSAN are typically characterized by symmetric motor flaccid weakness, sensory abnormalities, and/or autonomic dysfunction caused by autoimmune damage to peripheral nerves and nerve roots. The diagnosis of AIDP, AMAN, and AMSAN requires:
      (A) Bilateral flaccid limb weakness and decreased or absent deep tendon reflexes in weak limbs;
      (B) A monophasic illness pattern;
      (C) An interval between onset and nadir of weakness between 12 hours and 28 days;
      (D) Subsequent clinical plateau (the clinical plateau leads to either stabilization at the nadir of symptoms, or subsequent improvement without significant relapse; however, death may occur without a clinical plateau); and,
      (E) The absence of an identified more likely alternative diagnosis.

Continued on following page

TABLE 83.1 Vaccine Injury Table[a] *(Continued)*

(iii) Fisher Syndrome (FS), also known as Miller Fisher Syndrome, is a subtype of GBS characterized by ataxia, areflexia, and ophthalmoplegia, and overlap between FS and AIDP may be seen with limb weakness. The diagnosis of FS requires:
(A) Bilateral ophthalmoparesis;
(B) Bilateral reduced or absent tendon reflexes;
(C) Ataxia;
(D) The absence of limb weakness (the presence of limb weakness suggests a diagnosis of AIDP, AMAN, or AMSAN);
(E) A monophasic illness pattern;
(F) An interval between onset and nadir of weakness between 12 hours and 28 days;
(G) Subsequent clinical plateau (the clinical plateau leads to either stabilization at the nadir of symptoms, or subsequent improvement without significant relapse; however, death may occur without a clinical plateau);
(H) No alteration in consciousness;
(I) No corticospinal track signs; and
(J) The absence of an identified more likely alternative diagnosis.

(iv) Evidence that is supportive, but not required, of a diagnosis of all subtypes of GBS includes electrophysiologic findings consistent with GBS or an elevation of cerebral spinal fluid (CSF) protein with a total CSF white blood cell count below 50 cells per microliter. Both CSF and electrophysiologic studies are frequently normal in the first week of illness in otherwise typical cases of GBS.

(v) To qualify as any subtype of GBS, there must not be a more likely alternative diagnosis for the weakness.

(vi) Exclusionary criteria for the diagnosis of all subtypes of GBS include the ultimate diagnosis of any of the following conditions: chronic immune demyelinating polyradiculopathy (CIDP), carcinomatous meningitis, brain stem encephalitis (other than Bickerstaff brainstem encephalitis), myelitis, spinal cord infarct, spinal cord compression, anterior horn cell diseases such as polio or West Nile virus infection, subacute inflammatory demyelinating polyradiculoneuropathy, multiple sclerosis, cauda equina compression, metabolic conditions such as hypermagnesemia or hypophosphatemia, tick paralysis, heavy metal toxicity (such as arsenic, gold, or thallium), drug-induced neuropathy (such as vincristine, platinum compounds, or nitrofurantoin), porphyria, critical illness neuropathy, vasculitis, diphtheria, myasthenia gravis, organophosphate poisoning, botulism, critical illness myopathy, polymyositis, dermatomyositis, hypokalemia, or hyperkalemia. The above list is not exhaustive.

(d) Glossary for purposes of paragraph (c) of this section—

(1) Chronic encephalopathy.

(i) A chronic encephalopathy occurs when a change in mental or neurologic status, first manifested during the applicable Table time period as an acute encephalopathy or encephalitis, persists for at least 6 months from the first symptom or manifestation of onset or of significant aggravation of an acute encephalopathy or encephalitis.

(ii) Individuals who return to their baseline neurologic state, as confirmed by clinical findings, within less than 6 months from the first symptom or manifestation of onset or of significant aggravation of an acute encephalopathy or encephalitis shall not be presumed to have suffered residual neurologic damage from that event; any subsequent chronic encephalopathy shall not be presumed to be a sequela of the acute encephalopathy or encephalitis.

(2) Injected refers to the intramuscular, intradermal, or subcutaneous needle administration of a vaccine.

(3) Sequela means a condition or event which was actually caused by a condition listed in the Vaccine Injury Table.

(4) Significantly decreased level of consciousness is indicated by the presence of one or more of the following clinical signs:
(i) Decreased or absent response to environment (responds, if at all, only to loud voice or painful stimuli);
(ii) Decreased or absent eye contact (does not fix gaze upon family members or other individuals); or
(iii) Inconsistent or absent responses to external stimuli (does not recognize familiar people or things).

(5) Seizure includes myoclonic, generalized tonic-clonic (grand mal), and simple and complex partial seizures, but not absence (petit mal), or pseudo seizures. Jerking movements or staring episodes alone are not necessarily an indication of seizure activity.

(e) Coverage provisions.

(1) Except as provided in paragraph (e)(2), (3), (4), (5), (6), (7), or (8) of this section, this section applies only to petitions for compensation under the program filed with the United States Court of Federal Claims on or after February 21, 2017.

(2) Hepatitis B, Hib, and varicella vaccines (Items VIII, IX, and X of the Table) are included in the Table as of August 6, 1997.

(3) Rotavirus vaccines (Item XI of the Table) are included in the Table as of October 22, 1998.

(4) Pneumococcal conjugate vaccines (Item XII of the Table) are included in the Table as of December 18, 1999.

(5) Hepatitis A vaccines (Item XIII of the Table) are included on the Table as of December 1, 2004.

(6) Trivalent influenza vaccines (Included in item XIV of the Table) are included on the Table as of July 1, 2005. All other seasonal influenza vaccines (Item XIV of the Table) are included on the Table as of November 12, 2013.

(7) Meningococcal vaccines and human papillomavirus vaccines (Items XV and XVI of the Table) are included on the Table as of February 1, 2007.

(8) Other new vaccines (Item XVII of the Table) will be included in the Table as of the effective date of a tax enacted to provide funds for compensation paid with respect to such vaccines. An amendment to this section will be published in the Federal Register to announce the effective date of such a tax.

[a]As of early March 2017, scheduled to be effective March 21, 2017. See 82 Fed. Reg. 6294 (Jan. 19, 2017); 82 Fed. Reg. 11321 (Feb. 22, 2017).
[b]Newly added injury.

In addition to the general statute of limitations, the statute provided for 8 years' retroactive coverage for claimants alleging injuries from a newly added vaccine and for injuries added to the VIT for existing vaccines, with a 2-year window in which to file after addition of coverage. These changes ensured that the Vaccine Act's liability protections and compensation under the VICP would be extended to new categories of vaccines recommended for children.

Structure and Process

The VICP is administered by HHS in conjunction with the U.S. Department of Justice (DOJ), and the Office of the Special Masters, U.S. Court of Federal Claims. Vaccines designated by the CDC for "routine administration to children" and subject to an excise tax are covered by the program. As of March 2017, these included vaccines against 16 diseases: *Haemophilus*

influenzae type b (Hib), diphtheria, tetanus, pertussis, measles, mumps, rubella, polio (inactivated poliovirus vaccine [IPV] and OPV), hepatitis A, hepatitis B, rotavirus, varicella zoster virus (VZV), all seasonal influenza, meningococcal, pneumococcal (pneumococcal conjugate vaccines, e.g., PCV13), and human papillomavirus (HPV). As of December 2016, vaccines recommended by the CDC for routine administration to pregnant women and subject to an excise tax are also covered by the program. As of March 2017, this has not resulted in any additional categories of vaccines under the program.

The VICP created two classes of claims: claims involving vaccinations given before October 1, 1988 ("pre-1988") and claims involving vaccinations administered on or after October 1, 1988 ("post-1988"). Pre-1988 claims were optional but had to be filed by January 31, 1991, and all were fully adjudicated by 2005. Post-1988 injury claims must first be filed under the VICP. Under the general filing deadline, post-1988 injury claims must be filed within 36 months after the first symptom appeared following vaccination. Death claims must be filed within 24 months of the death and within 48 months after the onset of the vaccine-related injury from which the death occurred. The NCVIA provides for up to 14 months from the filing date for the court to issue a decision, subject to extension.

Petitioners, through an attorney or on their own, file a petition with the court, which begins the review and adjudication process. Petitions (claims) are filed against the Secretary of HHS as respondent on behalf of the government. The court assigns the petition to one of eight special masters, who are lawyers handling cases only in the VICP. Supporting documents required by the NCVIA include medical records and affidavits of the parents (or other family members) regarding the vaccination and resulting injury or death. Expert witness reports may also accompany the initial filing. Proceedings are expedited by eliminating formal civil discovery and rules of evidence in favor of a more informal process. Court rules provide for regular telephone status conferences with both parties and informal review and fact determinations by the special master before a hearing, should one be needed. These relaxed rules seem to encourage and facilitate settlements.

Once the claim is filed, HHS assigns it to one of its medical reviewers, who reviews the documents. The VICP medical staff reaches a recommendation on the petitioner's entitlement to compensation, which is then forwarded to the court through the DOJ attorney assigned to the case. Pediatric and adult subspecialists sometimes assist VICP staff in reaching a recommendation on eligibility and testifying about vaccine causation in hearings.

Petitioners can establish medical eligibility for compensation in one of three ways. First, petitioners can prove that a condition listed on the VIT occurred in the prescribed interval meeting the table requirements (and that there is not greater evidence of an alternative cause or "factor unrelated"). Second, petitioners can prove that the vaccine actually caused the injury if the injury does not meet all the requirements (e.g., time frame) for a VIT condition or the injury is not listed on the VIT. A third option is showing that the vaccine significantly aggravated a preexisting medical condition. It is worth noting that a factor unrelated must be a condition of known cause and not "idiopathic." In addition to satisfying one of these three elements, petitioners must also show there were continued effects for longer than 6 months, except in the case of a vaccine-related death, or that the injured person required "inpatient hospitalization and surgical intervention" as a result of the vaccine injury.

VICP medical staff's recommendations are predominantly based on the contemporaneous medical records rather than the affidavits of family members, which are often generated months to years following the alleged injury. Eligibility for compensation is recommended if the VICP staff finds that the records fulfill the requirements of the NCVIA. At the same time, the DOJ determines whether the petition meets the legal requirements for an award. The criteria are detailed and require that each petition contain several elements before the special master can have jurisdiction over the matter (Table 83.2). The court nearly always concurs with a determination by the government that petitioners are entitled to compensation, thereby obviating the need for a hearing. The cases not conceded by HHS often proceed to a hearing before a special master, at which point both sides present testimony, including expert witnesses for each party. In some cases, the court may find the testimony of family members more persuasive than contemporaneously recorded events or give greater weight to the initial diagnosis of the treating physician over determinations made on subsequent clinical evaluations. Therefore, notwithstanding the HHS position, it is not uncommon for the special master to award compensation after an entitlement hearing. In addition, today a significant number (83%) of petitions are resolved between the parties by settlement, based on both parties' perception of their exposure to the risk of an adverse decision. A "litigative risk settlement" is not an admission by the United States or the Secretary of HHS that the vaccine caused the petitioner's alleged injuries, and, in settled cases, the court does not determine that the vaccine caused the injury. A settlement, therefore, cannot be characterized as a decision by HHS or by the court that the vaccine caused an injury. Claims may be resolved by settlement for many reasons, including consideration of prior court decisions; a recognition by both parties that there is a risk of loss in proceeding to a decision by the court making the certainty of settlement more desirable; a desire by both parties to minimize the time and expense associated with litigating a case to conclusion; and a desire by both parties to resolve a case quickly and efficiently.

Once entitlement to compensation is conceded, the special master determines that the petitioner is entitled to compensation, or the parties agree to settle a claim, the DOJ and the petitioner work to reach agreement on the amount of compensation (damages). The level of compensation is often based on life care plans that evaluate the health of the injured person and the person's future needs.

The government and petitioner often use informal negotiations under the guidance of a special master to resolve entitlement and damages issues. Alternative dispute resolution is being increasingly used to avoid holding a hearing. Compensation for injured minors or incompetent persons is usually in the form of a lump sum payment and an annuity designed to provide a lifetime stream of benefits. This includes unreimbursable costs for vaccine-related goods and services from the date of injury, lost wages,[28,29] and pain and suffering (up to $250,000).[30] A benefit of $250,000 is available for eligible death claims. The Court of Appeals for the Federal Circuit has expanded the availability of damages, holding that an eligible petitioner's estate that established vaccine-related injuries and vaccine-related death is entitled to recover a death benefit and provable compensation for medical expenses, lost wages, and pain and suffering of the decedent.[31] "Reasonable" attorneys' fees generally are paid whether or not petitioners are successful in obtaining compensation if the claim was brought in good faith and on a reasonable basis. Punitive damages and awards to others in the family for loss of companionship are not allowed.

Appeals of special master decisions can be made to a judge of the United States Court of Federal Claims and then to a three-judge panel of the United States Court of Appeals for the Federal Circuit. Only twice has a Federal Circuit decision

TABLE 83.2 Legal Requirements Under the National Vaccine Injury Compensation Program

REQUIREMENTS FOR PROPER FILING
Must be properly filed with Department of Health and Human Services and U.S. Court of Federal Claims
Must be filed by proper person as petitioner:
Person who sustained vaccine-related injury; or
Legal representative of minor or individual who sustained vaccine-related injury or death
Must contain:
Affidavit; and
Medical and vaccination records, and, if applicable, death certificate and autopsy (or identification of any unavailable records and reasons for unavailability)
Must be filed within the statute of limitations:
Injuries: within 36 months of first symptom/manifestation of onset (or significant aggravation) of vaccine-related injury; or
Deaths: within 24 months of vaccine-related death and within 48 months of date of first symptom/manifestation of onset (or significant aggravation) of injury from which death resulted; or
Table revisions: if the Vaccine Injury Table revision makes person who was previously ineligible to seek compensation eligible or significantly increases likelihood of person obtaining compensation, such person may file petition within 2 years of effective date of revision so long as vaccine-related injury/death did not occur more than 8 years before date of revision
NATURE OF THE ALLEGATION
Must involve covered vaccine listed in the Vaccine Injury Table or included within the Vaccine Injury Table's general category of vaccines recommended by the CDC for routine administration to children or to pregnant women once excise tax is passed
Must involve proper relationship between injured person and covered vaccine:
Injured person either received covered vaccine;
Or in the case of polio, injured person contracted polio from another person who received oral polio vaccine
Must involve proper place vaccine was administered:
Injured person receiving covered vaccine must have been in United States or its trust territories, unless:
Person was U.S. citizen serving abroad as member of armed forces or employee of United States or dependent of such a citizen
Vaccine manufactured in United States and person returned to United States within 6 months after date of vaccination
Injured did not receive covered vaccine but contracted polio from another person who received oral polio vaccine, and must have been citizen of United States or a dependent of such a citizen
TO OBTAIN COMPENSATION
Must prove compensable injury/death by preponderance of the evidence:
Sustained Table injury or died from covered vaccine and first symptom/manifestation of onset occurred within time period set forth in the Vaccine Injury Table; or
Sustained Table condition or died from covered vaccine and first symptom/manifestation of onset of condition did not occur within time period set forth in the Vaccine Injury Table; or
Sustained any condition not set forth on Table from covered vaccine
Must show residual effects:
Suffered residual effects/complications of vaccine-related injury for more than 6 months after vaccine's administration; or
Died from administration of the vaccine; or
Received inpatient hospitalization and surgery as result of vaccine-related injury
Factor unrelated to administration of the vaccine that caused injury/death must not be shown (by preponderance of evidence)
Must not have previously filed Vaccine Injury Compensation Program claim for same vaccine administration
Must not have previously collected award/settlement of civil action for damages for vaccine-related injury/death
Must elect to accept Court of Federal Claims' judgment to receive compensation awarded

advanced to the next level of appeal, the Supreme Court (see *Shalala v Whitecotton* and *Sebelius v. Cloer* in "Vaccine Injury Compensation Program Cases Since 1986" later).

Implementation and Program Experience

Table 83.3 shows the numbers of claims filed under the VICP by vaccine type and year of administration. Data pertaining to claims filed with the VICP refer to the first vaccine named in each petition. Additional information and data that is updated periodically are available on the webpages for the ACCV[32] and the VICP.[33] This table includes hundreds of vaccines given during the 1950s and 1960s, with the oldest case dating back to 1918 for a death alleged to be associated with the pertussis vaccine. The program processed many claims that were otherwise barred from the tort system by a state statute of limitations. Statutory deadlines have twice brought large numbers of claims during a short period, the first occurring when more than 4000 pre-1988 claims were filed during a 6-month period from 1990 to 1991; in the second, more than 300 hepatitis B virus (HBV) vaccine claims were filed in August 1999 to meet the 2-year deadline for filing of retroactive claims after HBV was added to the VIT (effective August 6, 1997). Given that approximately 118 million doses of seasonal influenza vaccines are distributed annually (personal communication with the Centers for Disease Control and Prevention [CDC], August 4, 2014), it was to be expected that the addition of influenza vaccines in 2005 prompted a large influx of claims. Although fewer than 200 influenza claims were filed by the 2-year deadline for newly added vaccines in July 2007, the number of influenza claims filed annually has increased steadily since that time. Since 2007, more than 3200 influenza claims have been filed.

Starting in late 2001, thousands of claims were filed alleging autism (or autism spectrum disorder) resulting from the thimerosal (a type of mercury) preservative included in certain vaccines or the measles, mumps, and rubella (MMR) vaccine, which has never contained thimerosal. Table 83.4 shows the number of cases submitted to the VICP through February 27, 2017, including the number of cases pending, adjudicated, or dismissed and the dollars awarded.[34] Many pre-1988 cases were dismissed by the court on grounds of

TABLE 83.3 National Vaccine Injury Compensation Program Claims by Year of Administration and Vaccine Type as of February 27, 2017[a,b]

Year of Administration	DTP, DTaP, P, Tdap (and various combinations)	DT, Td, TT	MMR, MMRV, MR, M	Rubella	OPV	IPV	Hep B	VZV	HIB	RV	PCV	Hep A	Influenza	MCV, MPSV	HPV	Total

[a]The total number of claims filed in the VICP was 17,856 as of February 2017. This number reflects the claims represented on this table, in addition to 5,434 claims that were unspecified as to vaccine type (most filed as part of the Omnibus Autism Hearing) or to date of administration, and claims for vaccines not covered by the VICP.

[b]Data pertaining to claims filed with the VICP refer to the first vaccine named in each petition.

DT, diphtheria and tetanus toxoids-pediatric; DTaP, diphtheria, tetanus toxoids, and acellular pertussis; DTP, diphtheria, tetanus, and pertussis; HepA, hepatitis A; Hep B, hepatitis B; HPV, human papillomavirus; IPV, inactivated polio vaccine; M, measles; MCV, meningococcal conjugate vaccine; MMR, measles, mumps, and rubella; MMRV, measles, mumps, rubella and varicella; MPSV, meningococcal polysaccharide vaccine; MR, measles and rubella; OPV, oral polio vaccine; P, pertussis, PCV, pneumococcal conjugate vaccine; RV, rotavirus; Td, diphtheria and tetanus toxoids-indicated for persons 7 years or older; Tdap, tetanus, diphtheria, and acellular pertussis; TT, tetanus toxoid; VICP, National Vaccine Injury Compensation Program; VZV, varicella-zoster virus.

TABLE 83.4 Status of the National Vaccine Injury Compensation Program as of February 27, 2017[a]

	Vaccines Administered Before October 1, 1988	Vaccines Administered on or After October 1, 1988	Total
Claims filed	4,259	13,676	17,935
Claims adjudicated	4,259	11,918	16,177
Compensable	1,187	4,087	5,274
Dismissed	3,072	7,843	10,915
Awards paid	1,187	4,085	5,272
Compensation (millions)	$863	$2,499	$3,362
Attorneys' fees/costs (millions)[b]	$38	$215	$253
Total outlays (millions)	$901	$2,718	$3,619

[a]Compensable cases include cases settled by the parties in which no finding of table injuries or causation was reached.
[b]Includes fees/costs for compensated claims, dismissed claims, and interim fees/costs.

legal or medical insufficiency. Some plaintiffs, given the opportunity to obtain additional records, later refiled. Most of the larger awards include an initial lump sum payment with the remainder going toward purchase of an annuity. Overall, the majority of submissions (30%) allege pertussis-containing vaccines–related effects owing to the large number of pre-1988 filings. The remaining claims break down as follows: 12% from seasonal influenza vaccine; 7% from measles-containing vaccines, given alone or in any combination; 4% from hepatitis B-containing vaccines vaccine; 2% from tetanus-containing vaccines (excluding those containing pertussis); 2% from OPV; 2% from IPV; 2% for HPV vaccines; and 1% or less each for Hib, pneumococcal conjugate, rotavirus, hepatitis A virus (HAV), meningococcal, rubella, and VZV vaccines.

A better barometer of the recent VICP experience is reflected in the percentages by vaccine type filed during the 5-year period from fiscal years 2012 through 2016. A breakdown of 3,449 nonautism claims shows influenza vaccines predominate at 65%, followed by pertussis-containing vaccines (e.g., DTaP alone or in various combinations, Tdap) at 15%, MMR (3%), HPV (5%), HBV (2%), tetanus-containing vaccines (2%), and the remaining vaccines all less than 2%. Although percentages vary by vaccine, overall, injuries account for 93% of claims and deaths the remaining 7%.

As VICP adjudications continued into the mid-1990s, attention focused on the Vaccine Injury Compensation Trust Fund. Excise tax levels for the original seven vaccines covered by the NCVIA were based on the estimated numbers and cost of claims that each would generate. By 1996, the trust fund had exceeded anticipated needs, with $1 billion in holdings and annual receipts totaling $140 million, against peak outlays in the $35 to $42 million range. With passage of the Taxpayer Relief Act of 1997, the vaccine excise structure was revised, setting a 75-cents-per-"dose" (disease prevented) rate on all covered vaccines under the program. This federal excise tax funds the VICP. (At the end of 2014, the trust fund balance was $3.5 billion,[35] with more than $304 million in receipts from excise tax collections and interest on investments against awards totaling $223.4 million.)[34]

VACCINE INJURY COMPENSATION PROGRAM CASES SINCE 1986

Without question, the biggest controversy (and challenge) in adjudicating cases filed in the VICP has been determining vaccine causation. The legislative history underlying the NCVIA noted the lingering controversy about what is and is not vaccine-caused, with a recognition that the scientific understanding on these issues would evolve. For the first 8 years after the VICP was created, the vast majority of petitions filed alleged a VIT injury ("Table claims"), which confers the presumption that the injury, significant aggravation, or death, were vaccine-related. A VIT-based adjudication was straightforward: A petition would usually allege that the injured person experienced the signs and symptoms described in the VIT, as defined by the Qualifications and Aids to Interpretation (QAIs), within a VIT time frame, regardless of whether these allegations were substantiated or contradicted by the medical record. Accordingly, in the earlier years of the VICP, the special masters and the courts concentrated almost exclusively on developing a body of law establishing the quality and quantity of evidence needed to prove an injury included on the VIT. Since then, and partly because of regulatory amendments to the VIT that more precisely reflected the science of vaccine injury causation than did the original statutory VIT, the majority of petitions have shifted to allege injuries not found on the VIT ("off-table claims"), in which petitioners are required to prove that the vaccine actually caused the injury.

Most special masters place more weight on the medical records most contemporaneous to the vaccination than on contradictory evidence assembled later, after memories fade or when litigation is contemplated.[36] In circumstances in which the contemporaneous medical records are contradictory or do not exist, the special masters rely on the credibility of the family and the expert witnesses to determine whether a VIT injury occurred. The appellate courts give deference to special masters' credibility determinations, as long as they were not arbitrary or capricious.[37]

The courts also have addressed questions concerning whether special masters must strictly apply and interpret the definitions in the QAIs, which accompany the VIT. In *Hellebrand v Secretary of Department of Health and Human Services*[38] and *Hodges v Secretary of Department of Health and Human Services,*[39] the U.S. Court of Appeals for the Federal Circuit found that because special masters have wide latitude in adjudicating claims, they are not required to apply the QAIs in a mechanical manner; rather, they have reasonable discretion when applying them.

Shalala v Whitecotton[40] is the landmark Table injury case regarding the meaning of "significant aggravation" under the statute. Significant aggravation is important in VICP cases because if the onset of signs or symptoms following vaccination is not the first evidence of the alleged vaccine-related condition, to receive compensation, the petitioner must prove that the vaccine significantly aggravated a condition present before vaccination. The NCVIA defines significant aggravation as "any change for the worse in a preexisting condition which results in markedly greater disability, pain, or illness accompanied by substantial deterioration of health."[41] According to the legislative history, an example would be a child whose seizure frequency increased from one per month before vaccination to one per day after vaccination.[42] The special master in *Whitecotton* denied compensation on the basis that the child was born with a brain disorder that was responsible for the encephalopathy that appeared after receipt of the third DTP vaccination. The Court of Federal Claims agreed, but the U.S. Court of Appeals for the Federal Circuit reversed the

decision based on a different interpretation of "first symptom or manifestation of onset," writing that "first" did not necessarily mean that other clinical signs could not appear before vaccination.[43] The U.S. Supreme Court unanimously reversed the Federal Circuit's decision, finding that the Federal Circuit misread the NCVIA. However, Justice O'Connor, in a concurring opinion, noted that the Federal Circuit opinion did not address the issue of significant aggravation of a preexisting condition, but instead only addressed the issue of "first symptom or manifestation of onset." The case was remanded to the Federal Circuit, which set forth a test for Table injury-significant aggravation claims, specifying that the special master must (a) assess the person's condition before the administration of the vaccine, (b) assess the person's current condition, and (c) determine if the person's current condition constitutes a significant aggravation of the person's condition before vaccination within the meaning of the statute; and, if the special master determines there has been a significant aggravation, then the special master must (d) determine whether the first symptom or manifestation of the significant aggravation occurred within the period prescribed by the VIT for the injury.[44] Although *Whitecotton* involved a Table injury, the courts have applied the significant aggravation test in off-Table claims.[45,46]

A clarification of the fourth step of the *Whitecotton* test was announced in *Gruber v Secretary of Department of Health and Human Services.*[47] The Court of Federal Claims clarified that the special master, in determining the first symptom or manifestation of onset of the significant aggravation, must take into account the preexisting condition. The court found that the definition of the term *significant aggravation* should more properly be understood as "any change for worse in *[the allegedly aggravated Table injury]* which results in a markedly greater disability, pain, or illness accompanied by substantial deterioration in health." Furthermore, the court indicated that the four-step test articulated in *Whitecotton* does not merge the significant aggravation and sequelae inquiries. Rather, to obtain compensation for sequelae, a petitioner must establish that the aggravation of the Table injury caused them, without reliance on any Table presumption.

The parameters of the *factor unrelated* defense also have been tested. Under the NCVIA, if petitioners show proof of a Table condition occurring within the specified time, they are entitled to a presumption of vaccine causation unless the government can show greater evidence of an alternative cause or factor unrelated. The U.S. Court of Appeals for the Federal Circuit generally used a strict interpretation when it applied the NCVIA's definition of the term: A factor unrelated may not include "any idiopathic, unexplained, unknown, hypothetical, or undocumentable" condition.[48] However, the Federal Circuit has considered whether the government was required to specifically identify a virus it alleged was a factor unrelated. In *Knudsen v Secretary of Department of Health and Human Services,*[49] the Federal Circuit held that so long as the government could prove that the petitioner did in fact have a viral infection, the government need not identify the type of viral infection with specificity. More recently, in the consolidated appeal of *Stone v. Secretary of Department of Health and Human Services* and *Hammitt v. Secretary of Department of Health and Human Services,*[50] the Federal Circuit reiterated prior precedent and found that special masters may consider evidence of a factor unrelated in examining the record as a whole to determine whether or not petitioners have met their burden of proof in establishing a prima facie case.

The original NCVIA allowed the Secretary of HHS to modify or amend injuries listed in the VIT, which was originally included in the statute, and QAIs (see "Modifying the Vaccine Injury Table" later) by regulation.[51] In petitions filed after the first set of VIT changes took effect, the focus of most claims changed from proving a VIT injury to proving that the injury was caused-in-fact by the vaccine. This shift occurred for several reasons. First, HHS removed residual seizure disorder and shock collapse from the VIT. Second, the QAIs for encephalopathy were revised so they more accurately reflected the medical view of significant acute and chronic neurologic injuries, instead of the normal, transient side effects common to some childhood vaccines.[52]

Third, although additional conditions have been added to the "original" vaccines, few of the new vaccines added to the VIT in recent years have had associated VIT injuries (Table 83.5). Since 1997, only three conditions were added for the nine "new" vaccines. Some of these conditions were subsequently removed from the VIT given that they were no longer applicable based upon changed circumstances. Fourth, and arguably most significantly, the licensure of acellular pertussis vaccines for primary use in infants and the transition to an IPV-only schedule all but eliminated DTP vaccine and OPV filings, the former of which comprised a significant percentage of alleged injury and death claims.

Current cases, therefore, establish a challenge for the special masters and the courts to strike an appropriate balance between (a) denying compensation of claims based merely on a temporal relationship between the injury and the vaccine and a lack of apparent alternative causes and (b) the need to fulfill the VICP's mandate to provide compensation "generously" and "fairly," even in the absence of full scientific knowledge about potential vaccine adverse events. Early in the history of the VICP, the court determined in *Grant v Secretary of Department of Health and Human Services* that causation-in-fact was shown when there is "proof of a logical sequence of cause and effect showing that the vaccination was the reason for the injury. A reputable medical or scientific explanation must support this logical sequence of cause and effect."[53] The U.S. Court of Appeals for the Federal Circuit clarified this issue somewhat by holding that the scientific evidence need not rise to the level of being a scientific certainty.[49] Still, there were questions. For example, special masters considered whether animal studies could be used, how much weight should be given to case reports, and whether the petitioner had to rely on any published or peer-reviewed evidence in pursuing a VICP claim.[54,55]

The standard of proof for causation-in-fact has been adjusted and clarified over time. In *Shyface v Secretary of Department of Health and Human Services,*[56] the U.S. Court of Appeals for the Federal Circuit found that the petitioners need not show that the vaccination was the sole or even the predominant cause of the injury or condition. Rather, the petitioner need only show that the vaccination was at least a "substantial factor" in causing the condition and was a "but for" cause. In *Althen v Secretary of Department of Health and Human Services,*[57] the court held that petitioner's burden was to show by preponderant evidence that the vaccine brought about her injury by providing: "(1) a medical theory causally connecting the vaccination and the injury; (2) a logical sequence of cause and effect showing that the vaccination was the reason for the injury; and (3) a showing of proximate temporal relationship between vaccination and injury." The decision held that there is no requirement that petitioners provide scientific literature to support their theory of causation—medical opinion or medical records can suffice under the law. The court stated that while the case involved "a sequence hitherto unproven in medicine, the purpose of the NCVIA's preponderance standard is to allow the finding of causation in a field bereft of complete and direct proof of how vaccines affect the human body." It further stated that, "close calls regarding causation are resolved in favor of injured claimants."

TABLE 83.5 National Vaccine Injury Compensation Program Summary of Modifications to the Vaccine Injury Table and Qualifications and Aids to Interpretation

Effective Coverage Date	Vaccine	Table Changes	Qualifications & Aids to Interpretation Changes	Federal Register Citation
3/10/1995	DTP and DTaP	*Removed*— Hypotonic-hyporesponsive episode *Removed*— Residual seizure disorder *Changed onset interval*— Anaphylaxis and anaphylactic shock (24 hours to 4 hours)	*Added*— Definition for anaphylaxis and anaphylactic shock *Revised*— Definitions of encephalopathy (or encephalitis) and residual seizure disorder	Fed Registr. 1995;60:7678—(FR)
	DT, Td, or TT	*Removed*— Residual seizure disorder *Changed onset interval*— Anaphylaxis and anaphylactic shock (24 hours to 4 hours)	*Added*— Definition for anaphylaxis and anaphylactic shock *Revised*— Definitions of encephalopathy (or encephalitis) and residential seizure disorder	Fed Registr. 1995;60:7678—(FR)

	Added—Varicella (VZV)	*Added*— No condition specified, [onset interval: not applicable]		Fed Registr. 1997;62:7685—(FR) Fed Registr. 1998;63:25777—(FR) Public Law: 105-34

TABLE 83.5 National Vaccine Injury Compensation Program Summary of Modifications to the Vaccine Injury Table and Qualifications and Aids to Interpretation *(Continued)*

Effective Coverage Date	Vaccine	Table Changes	Qualifications & Aids to Interpretation Changes	Federal Register Citation
10/22/1998	*Added*—Rotavirus (RV) *to the New Vaccines Category*			Public Law: 105-277
	Added—Rotavirus (RV) *as a distinct vaccine category*	*Added*—No condition specified, [onset interval: not applicable]		Fed Registr. 1999;64:40517—(FR)
12/18/1999	*Added*—Pneumococcal conjugate (PCV-7) *to the New Vaccines Category*			Fed Registr. 2001;66:28166—(FR) Public Law: 106-170
8/26/2002	*Added*—Rotavirus (RV) –rhesus based	*Added*—Intussusception, [onset interval: 0–30 days]		Fed Registr. 2002;67:48558—(FR)
	Removed—Haemophilus influenzae type b (Hib) [polysaccharide]	*Removed*—Early-onset Hib disease	*Removed*— Definition for early-onset Hib disease	Fed Registr. 2002;67:48558—(FR)
	Added—Pneumococcal conjugate (PCV-7) *as a distinct category*	*Added*—No condition specified, [onset interval: not applicable]		Fed Registr. 2002;67:48558—(FR)
			Removed— Definition for residual seizure disorder	Fed Registr. 2002;67:48558—(FR)
12/01/2004	*Added*—Hepatitis A (HAV) *to the New Vaccines Category*	*Added*—No condition specified, [onset interval: not applicable]		Fed Registr. 2004;69:69945—(N) Public Law: 108-357
7/01/2005	*Added*—Trivalent influenza (TIV, LAIV) *to the New Vaccines Category*	*Added*—No condition specified, [onset interval: not applicable]		Fed Registr. 2005;70:19092—(N) Public Law: 108-357
2/1/2007	Added—Meningococcal (MCV4, MPSV4) and human papillomavirus (HPV) to the New Vaccines Category	*Added*— No condition specified, [onset interval: not applicable]		Fed Registr. 2007;72:19937 Public Law: 109-432
11/10/2008	Removed—Rotavirus (RV)–live, oral, rhesus-based	*Removed*—intussusception		Fed Registr. 2008;73:59528—(IFR)
7/22/2011	*Added*—Hepatitis A, trivalent influenza, meningococcal, and human papillomavirus vaccines *as distinct categories*	*Added*—No conditions specified, [onset intervals: not applicable]		Fed Registr. 2011;76:36367—(FR)
11/12/2013	*Added*—All vaccines against seasonal influenza to the New Vaccines Category	*Added*—No condition specified, [onset interval: not applicable]		Fed Registr. 2012;78:67369-01–(N)
7/23/15	*Added*— No new vaccines	*Added*— intussusception	*Added*— intussusception	80 Fed Registr. 35848 (June 33, 2015)—(FR)
3/21/17	*Added*— Seasonal influenza vaccines *as a distinct vaccine category* *Removed*—Trivalent vaccines *as a distinct vaccine category (now included in seasonal influenza vaccines category)* *Modified*— haemophilus influenza type b polysaccharide conjugate vaccines category changed to haemophilus influenza type b vaccines	*Many injuries added*—See Table 83.1	*Multiple definitions changed or added*—See Table 83.1	82 Fed Registr. 6294 (Jan. 19, 2017)—(FR); 82 Fed. Registr. (Feb. 22, 2017)—(FR)

The following parenthetical abbreviations found within the Federal Register Citation column—(FR), (N), and (IFR)—indicate final rule, notice, and interim final rule, respectively.

The Federal Circuit expanded the *Althen* holding in *Capizzano v Secretary of Department of Health and Human Services,*[58] in which it criticized the special master for inadequately considering the opinions of treating physicians. The court held that "medical records and medical opinion testimony are favored in vaccine cases, as treating physicians are likely to be in the best position to determine whether 'a logical sequence of cause and effect show[s] that the vaccination was the reason for the injury.'"

The Federal Circuit continues to refine the body of law regarding causation-in-fact. In *Walther v Secretary of Department of Health and Human Services,*[59] the Federal Circuit clarified that when the petitioner has proven all three *Althen* prongs, the petitioner is not required to eliminate other potential causes to prevail. With regard to the nature of the petitioner's evidence, in *Andreu v Secretary of Department of Health and Human Services,*[60] the Federal Circuit noted that in proving a medical theory of causation, the petitioner is neither required to rely on epidemiologic studies nor to show that the theory has general acceptance in the medical community. When petitioners offer medical literature or epidemiologic evidence, it is not to be evaluated through the lens of a laboratorian, but instead from the vantage point of the preponderance standard.

Most notably in *Andreu*, however, was the decreased level of deference given to the special master's credibility findings. Under prior case law, the Federal Circuit asserted that it is not its role "to reweigh…whether the special master correctly evaluated the evidence" or to "examine the probative value of the evidence or the credibility of the witnesses," because "these are all matters within the purview of the fact finder." The Federal Circuit in *Andreu* rejected the special master's credibility findings of the petitioner's expert witness, remarking that special masters may not cloak their evaluation of the evidence in the guise of a credibility finding. However, in *Moberly v Secretary of Department of Health and Human Services,*[61] the Federal Circuit renewed its deference to special masters and reasserted that special masters are expected and entitled to make reliability and credibility determinations of expert witnesses. Moreover, although petitioners are not required to offer proof in the form of epidemiologic studies or well-established medical experience, it does not mean that special masters are precluded from assessing the reliability of testimony from expert witnesses. This approach was reaffirmed by the Federal Circuit in *Porter v. Secretary of Department of Health and Human Services and Rotoli v. Secretary of Department of Health and Human Services,*[62] in which the Federal Circuit found that a Court of Federal Claims judge incorrectly read *Andreu* to prohibit a special master from using credibility determinations to reject a petitioner's theory of causation. Instead, the court averred, the Federal Circuit has "unambiguously explained" in previous opinions that special masters are expected to consider the credibility of expert witnesses in evaluating Vaccine Act claims. In litigating these difficult, fact-intensive, causation-in-fact cases, several special masters have indicated that a more expeditious resolution could be obtained by combining several cases in a consolidated or "omnibus" proceeding. As of this writing, numerous consolidated and omnibus proceedings have been initiated, and several have concluded. The results of some of these proceedings (e.g., hepatitis B vaccine and demyelinating diseases) have been controversial given the scientific literature.[63–65]

One such omnibus proceeding involved tuberous sclerosis complex (TSC), a genetic disorder characterized in many cases by classical skin lesions, growths (tubers), and other structural changes in the brain, causing seizures and mental retardation. Many of the claims alleging seizure onset within a VIT time frame were litigated as a group to determine whether DTP vaccine significantly aggravated the preexisting tuberous sclerosis complex condition. Based in part upon advances in magnetic resonance imaging in the 1990s,[66,67] the presiding special master ruled that the number and presence of tubers in the cerebral cortex, not the timing of DTP vaccination, ultimately determines clinical outcome. The special master's decision denying compensation was affirmed on appeal in *Hanlon v Secretary of Department of Health and Human Services,*[68]*Turner v Secretary of Department of Health and Human Services,*[69] and *Flanagan v Secretary of Department of Health and Human Services.*[70]

By far the omnibus proceeding that has garnered the most scrutiny is the omnibus autism proceeding. Interest and concern about vaccines and autism started with the publication of a 1998 case series by Wakefield and colleagues[71] in the *Lancet* suggesting that MMR vaccine was associated with autism. Little attention was paid in the United States until the following year when a congressionally mandated FDA review of mercury in biological products showed some vaccinated infants were receiving ethylmercury in excess of one federal safety guideline established for methylmercury, the more extensively studied form of organic mercury. Attention then became focused on thimerosal, an ethylmercury compound used for decades in the formulation of many routinely administered childhood vaccines to prevent bacterial and fungal contamination.[72] In the early 2000s, individual and class action lawsuits were filed in state courts alleging autism or autism spectrum disorder caused by thimerosal-containing vaccines and/or the MMR vaccine (which does not contain the preservative).[73] As noted below, the plaintiffs often argued that they were not required to subject to the NCVIA's exhaustion requirements with respect to claims concerning thimerosal. Multiple large, well-controlled epidemiologic studies all failed to find an association between thimerosal-containing vaccines and autism.[74–77] The IOM concluded in its 2004 report that the body of scientific evidence favors rejection of a causal relationship between MMR and thimerosal-containing vaccines and autism.[78] A 2012 IOM report reiterated the same conclusion for MMR vaccine and autism, and did not again examine thimerosal-containing vaccines as part of its review.[79]

The VICP began receiving claims alleging autism or autism spectrum disorder caused by MMR or thimerosal-containing vaccines in late 2001. As the number of claims grew to nearly 5000, the Office of the Special Masters established the omnibus autism proceeding to adjudicate the cases in a consolidated manner.[80]

The petitioners put forth six test cases to represent two separate theories of causation. Under the first theory ("Theory 1"), petitioners argued that MMR vaccine and thimerosal-containing vaccines cause autism. Under the second theory ("Theory 2"), petitioners argued that thimerosal-containing vaccines alone cause autism. The Office of the Special Masters conducted extensive evidentiary hearings, reviewing 939 medical articles, 50 expert reports, and testimony from 28 experts. The hearings produced more than 5000 pages of transcripts and 7000 pages of posthearing briefs. The three presiding special masters issued decisions in favor of the government in all six cases with respect to both theories.[81–86] Petitioners appealed the three Theory 1 cases to the Court of Federal Claims, without success.[87–89] Petitioners further appealed two of the three Theory 1 cases to the Court of Appeals for the Federal Circuit.[90,91] In both cases, the Federal Circuit ruled in favor of the government, upholding the lower determinations that petitioners had not proven their theory of causation by a preponderance of the evidence. Petitioners did not pursue appeals in the Theory 2 cases.[92]

In 2011, the Federal Circuit issued an *en banc* decision holding that the Vaccine Act's statute of limitations begins to

run on the date of occurrence of the first symptom or manifestation of onset of the injury, reversing a lower court decision that concluded the limitations period does not run until the medical community at large understands and recognizes a causal relationship between the vaccine and the injury.[93] Overruling prior precedent, the Federal Circuit also held that equitable tolling applies to the Vaccine Act. Equitable tolling is a principle of law stating that the statute of limitations shall not bar a claim in cases in which the petitioner, despite due diligence, could not or did not discover the injury until after the expiration of the limitations period. However, finding that equitable tolling under the Vaccine Act because an unawareness of a causal link between an injury and the administration of a vaccine is unavailable, the court declined to apply equitable tolling in the petitioner's case. The issue of whether attorneys' fees and costs were available in this untimely filed case was appealed to the U.S. Supreme Court, which affirmed the judgment of the Federal Circuit, finding that a person whose petition under the VICP is dismissed as untimely may recover an award of attorneys' fees and costs if certain requirements are satisfied.[94]

MODIFYING THE VACCINE INJURY TABLE

The Secretary of HHS has the authority to modify or amend injuries listed in the VIT (and QAIs) in consultation with the ACCV and after opportunity for public comment. Such changes apply only to cases filed after the effective date of the changes. In 1993, Congress provided a mechanism for the Secretary to add to the VIT "new" vaccines recommended by CDC for routine administration to children based on the effective date of the excise tax for that vaccine.[27] Table 83.5 summarizes changes to the VIT through March 2017.

Separate efforts by the VICP to modify the initial statutory VIT and QAIs began with publication of the two congressionally mandated IOM reviews in 1991 and 1994, respectively.[95–98] With a few exceptions, the approach by the VICP was straightforward: If the IOM concluded that there was evidence that a condition was "causally related" to a covered vaccine, it was added to the VIT or left on the VIT. However, if there was no proven evidence of an association, that condition was removed. Publication of final rules in 1995 and 1997 setting forth these modifications was the final step in a 3- to 4-year process for each set of changes involving ad hoc scientific panel reviews by the NVAC, mandatory ACCV reviews, and a 180-day public comment period, including a public hearing.

The first set of changes, effective March 10, 1995, was the most controversial. Hypotonic-hyporesponsive episode and residual seizure disorder were removed as covered conditions under DTP vaccines, and the definitions of encephalopathy and residual seizure disorder were modified in the QAIs.[52] At that time, the only exception in using the IOM conclusions to guide changes to the VIT was encephalopathy/encephalitis under DTP vaccine, which had been proposed for removal but was left in the Table in response to advice from the ACCV. The ACCV recommended that claims of acute encephalopathy of unknown etiology within 3 days of DTP vaccination should continue to receive a presumption of causation but that the definition in the QAIs needed to be more clinically precise. A subsequent 1994 analysis by the IOM[99] of a 10-year follow-up to the British National Childhood Encephalopathy Study tried to answer, but fell short of answering, the ultimate question of whether DTP vaccine causes permanent brain damage,[100] even though many investigators over time had failed to find a link based on epidemiologic and other scientific evidence.[101–107] The changes to the VIT and the QAIs for DTP have proved controversial and have been a topic addressed at congressional oversight hearings.

For the most part, DTP injury claims were filed on behalf of children and adults with chronic encephalopathy of unknown cause manifesting as developmental delay or the onset of seizures during the first year or two of life. Overall, no specific cause is ever determined for as many as 40% of the cases, with most thought to be caused by migrational abnormalities of fetal brain development or metabolic or "genetic" conditions not identifiable by current technology.[108] For petitioners to successfully pursue a VIT claim, the designated condition and time frame must be satisfied, and, if so, there must be insufficient evidence of a factor unrelated to the vaccine, which has to be of known cause and not idiopathic.

As for seizures, nearly half of the early DTP filings involved the initial onset of seizures in an otherwise healthy infant. Significant numbers of seizure claims were being compensated using the statutory version of the VIT originally put into law. Often the fever commonly associated with DTP vaccine would serve as the triggering event for the onset of seizures in a child predestined to have epilepsy. Alternatively, a Table seizure condition would be found in a child with cryptogenic (idiopathic) infantile spasms if the onset of myoclonic seizures was within 3 days of DTP vaccination. This resulted in compensated cases despite controlled epidemiologic studies showing the condition to be non–vaccine-related.[95,96]

Claims alleging death caused by DTP vaccine also proved challenging in the program's early years. Approximately half were attributed to sudden infant death syndrome (SIDS), with compatible histories and forensic findings in accordance with the 1989 National Institutes of Health consensus definition.[109] However, because the cause of SIDS remains unknown, these cases were initially viewed as "idiopathic" by the court and could not be used by the government to prove that a factor unrelated to the vaccine caused the death. Furthermore, based on testimony concerning events preceding the death, the court sometimes concluded that an encephalopathy or hypotonic-hyporesponsive episode was present before death and awarded compensation. More recently, however, the Federal Circuit has said that special masters may consider evidence of SIDS in weighing the strength of the petitioner's case.[110]

The second set of changes to the VIT proved far less controversial and was based, in large part, on the 1994 IOM report covering the five remaining original VICP vaccines, as well as Hib, HBV, and VZV vaccines, which were also added to the VICP because all were recommended by the CDC for routine administration to children. The other modifications, effective March 24, 1997, included the addition to the VIT of thrombocytopenia for measles-containing vaccines and brachial neuritis for tetanus-containing vaccines, the removal of residual seizure disorder under MMR vaccines, and the creation of a provisional or placeholder category on the VIT for vaccines newly taxed and satisfying the CDC recommendation requirement.[111] Only after notice to the public on publication in the *Federal Register* would the newly added vaccine have a separate and distinct listing on the VIT, including the addition of a Table condition when appropriate.

As with the 1995 rulemaking, proposed VIT changes developed by the Secretary paralleled the IOM conclusions for or against causation with two exceptions: the Secretary did not add GBS following OPV and following tetanus-containing vaccines. The IOM's OPV conclusion was based largely on a Finnish study following a national OPV campaign.[112] A subsequent U.S. study (therefore not considered by the IOM) showed no evidence of an increase in GBS following OPV administration.[113] Further doubt was cast when one of the Finnish study's coauthors wrote a letter noting that it was not their intention to claim that OPV was causally related to GBS because the data could be interpreted more than one way.[114]

The question of GBS and tetanus-containing vaccines was even more difficult to decide. The IOM conclusion was based on case reports, particularly of one person who experienced three episodes of GBS, each within weeks following tetanus vaccination. The fact that he had other non–vaccine-related episodes made him immunologically unique. Population studies, in contrast, showed no evidence that GBS incidence is higher in people receiving tetanus vaccine compared with the background rate.[97,98] Because there was no evidence of increased incidence overall, it was thought that petitions involving GBS following tetanus-containing vaccines should continue to require proof of causation, and, therefore, GBS should not be added to the VIT.

Since 1997, the VIT has been modified further (see Table 83.5). The general category of rotavirus vaccines was added effective October 21, 1998,[115] following licensure of RotaShield, a tetravalent rhesus-based rotavirus vaccine. RotaShield was subsequently withdrawn from the market by the manufacturer in October 1999, after epidemiologic studies confirmed an association between the vaccine and cases of intussusception, a potentially life-threatening bowel obstruction that occurs in infants.[116–118] In July 2002, a final rule was published adding intussusception as a listed injury to the VIT under a second category of rotavirus vaccines (i.e., live, oral, rhesus-based).[119] In addition, pneumococcal conjugate vaccines were made a separate and distinct category on the VIT. The second category of rotavirus vaccines (i.e., live, oral, rhesus-based), with the associated injury of intussusception, was removed from the VIT, effective November 10, 2008.[120] This was a technical change, since the 3-year filing deadline for all such claims had long since passed given that the RotaShield vaccine was withdrawn from distribution in the United States in 1999. The general category of rotavirus vaccines with "no condition specified" was not affected.

Beginning in 2004, hepatitis A and trivalent influenza, meningococcal (conjugate and polysaccharide) and HPV vaccines were added to the VIT in the placeholder category for "new" vaccines recommended by CDC for routine administration to children.[121–123] However, the vaccines were subsequently moved to separate and distinct categories in the VIT, effective July 22, 2011.[124] On November 12, 2013, all seasonal influenza vaccines (e.g., quadrivalent influenza vaccines) were added to the VIT in the placeholder category for "new" vaccines.[125] Subsequent to the licensure of two new rotavirus vaccines in 2006 and 2008, new evidence from postmarketing studies suggested intussusception was causally associated with Rotarix and RotaTeq, although much more rarely than had been the case with RotaShield.[154–156] Effective July 23, 2015, intussusception was added to the VIT as an injury for the rotavirus vaccines.[125a]

The 2012 IOM review reported the results of its reviews concerning the evidence with respect to causal associations between 12 VICP-covered vaccines (in various combination) and 158 adverse events.[79] After release of the 2012 IOM report, medical staff at the Health Resources and Services Administration (HRSA) and the CDC reviewed the IOM conclusions as well as other medical and scientific literature not contained in the IOM report. Based primarily on the IOM's review, the work of nine HHS workgroups that reviewed the IOM findings, and consideration of the ACCV's recommendations, a final rule to substantially revise the VIT was published on January 19, 2017.[125b] As of early March 2017, this rule was scheduled to go into effect on March 21, 2017.[125c]

The 2017 final rule included numerous revisions to the VIT. It added two injuries, Shoulder injury-related vaccine administration (SIRVA) and vasovagal syncope, which were found by the IOM to be associated with the injection of a vaccine rather than the components of a particular formulation of vaccine. Thus, the final rule included SIRVA and vasovagal syncope as injuries for all injected vaccines on the VIT. Further, the rule revised the QAI for anaphylaxis and added it as an injury for the varicella, seasonal influenza, meningococcal, and HPV vaccines based on the IOM's findings that the scientific evidence convincingly supports a causal relationship. Additionally, stemming from the IOM's findings, the final rule added vaccine-strain measles viral disease in an immunodeficient recipient to the VIT as an injury for vaccines containing the measles virus, and disseminated vaccine-strain viral disease and varicella vaccine-strain viral reactivation as injuries for varicella vaccines.

Following the recommendation of the ACCV, the final rule also added the injury of GBS to the VIT for seasonal influenza vaccines. The IOM found the evidence inadequate to accept or reject a causal relationship between seasonal influenza vaccines and GBS. However, studies have demonstrated a causal association between some nonseasonal influenza vaccines—the monovalent 2009 H1N1 vaccine and the 1976 swine flu vaccine—and GBS. To date, the H1N1 antigen has been included in all seasonal influenza vaccines beginning with the 2010–11 flu season. Acknowledging that seasonal influenza vaccine formulations, unlike other vaccines, include multiple antigens that change from year to year, and enhanced surveillance activities to detect the incidence of GBS that occurred during the 2009 H1N1 pandemic may not occur with each virus strain change, the ACCV recommended that the Secretary add GBS to the VIT consistent with one of the ACCV's Guiding Principles: where there is credible evidence to both support and reject a change to the VIT, the change should, whenever possible, be made to the benefit of petitioners.

Finally, the final rule included many organizational and structural changes to the VIT and QAI designed to increase clarity and scientific accuracy. For example, it added definitions for terms that had previously been on the VIT or QAIs but were undefined, such as encephalitis and immunodeficient recipient; it updated some of the QAIs to address certain changes in scientific nomenclature; it streamlined the VIT with the deletion of redundant wording; and it changed the category of "trivalent vaccines" to "seasonal influenza vaccines" to cover all seasonal influenza vaccines, including trivalent influenza vaccines, in one category.

MEDICAL REVIEW OF CLAIMS

Most claims filed under the VICP had some clinical outcome in temporal relation to vaccination that varied from the expected side effects of crying, fever, and local swelling to much more serious acute and chronic illness. The claims represent a database of possible vaccine-related events, although only a small percentage of serious outcomes were thought to be caused by vaccines after VICP medical staff review. Some of the more relevant allegations are reviewed here.

Diphtheria, Tetanus, and Pertussis Vaccines

DTP/DTP-Hib Vaccines

Of the thousands of petitions filed for DTP and DTP-Hib vaccines, 84% of them reported outcomes that occurred after the primary series of immunization in children younger than 12 months. In 1997, the CDC recommended that diphtheria, tetanus, and acellular pertussis (DTaP) be used for all doses in the childhood immunization schedule.[126] Prior to that time 33% of all claims associated with the DTP vaccine alleged an injury of seizure disorder (including epilepsy and infantile spasms). Another significant category was the 34% of claimants who reported an injury of encephalopathy. Six percent of claims were related to mental retardation/developmental delay.

Approximately 42% of claims alleging DTP-related death stated that the death was related to SIDS. The next most frequent diagnostic category for alleged death cases involved the 27% of patients with reported encephalopathy followed by the 12% of those who reported the occurrence of a seizure disorder. Approximately 30 deaths were allegedly the result of anaphylaxis.

Approximately 682 DTaP (and any combination of DTaP vaccines) claims had been filed by February 2017, which make up approximately 5% of filings from 2012 to 2017, and 4% of claims overall. While similar types of neurologic conditions have been alleged to be caused by the acellular pertussis vaccine, these are reported in far fewer numbers than the whole-cell DTP product (207 cases of encephalopathy and 17 cases of seizures). Postmarketing surveillance of serious adverse events following DTaP continues to confirm the better safety profile versus the whole-cell product.[127,128] Tetanus, diphtheria, and pertussis (Tdap) claims also comprised 9% during the same 5-year period, with alleged injuries similar to those seen with other tetanus-containing vaccine claims.

Tetanus-Containing Vaccines

Claims involving tetanus-containing vaccine not including a pertussis component (i.e., diphtheria and tetanus toxoids–pediatric [DT], diphtheria and tetanus toxoids–adult [Td], or tetanus toxoid [TT]) comprise 2% of filings overall. Brachial neuritis (17%), a condition listed on the VIT, is the most frequently alleged or documented condition. After that come GBS (16%), encephalopathy (3%), and seizure disorders (2%). Nearly all (90%) are adult vaccine recipients. Litigating GBS claims has been particularly challenging. Few were decided before the 1994 IOM report which concluded that tetanus-containing vaccines could cause GBS if the onset was within 5 days to 6 weeks following immunization.[97,98] In one case in which compensation was not provided, the court found that, although Td can cause GBS, one could not conclude that it did cause GBS in any particular case. The decision was appealed but was affirmed by the U.S. Court of Appeals for the Federal Circuit.[129] In a subsequent report, the IOM concluded that the evidence is inadequate to accept or reject a causal relationship between tetanus containing vaccines and GBS.[79] From 2012–17, approximately 46% of these claims have been compensated on the basis of a litigation risk settlement.

Measles-Mumps-Rubella Vaccines

Overall, MMR-containing vaccines are implicated in 7% of claims, most of which are events associated with immunization during the second year of life. Natural measles infection is known to cause acute encephalopathy/encephalitis and 24% of claims were filed alleging this injury, a VIT condition with a prescribed onset of 5 to 15 days following vaccination. Although the IOM found the evidence to be "inadequate" to determine whether measles vaccine can cause acute encephalopathy, there is some evidence of clustering of encephalopathy/encephalitis cases whose onset is 8 to 10 days following measles-containing immunization, based on an analysis of 48 VICP claims.[130] Only rarely are biological markers demonstrated to support a genetic, metabolic, or vaccine cause. In only one VICP case was cerebrospinal fluid measles antibody, a biological marker for measles causation, found in a previously healthy 2-year-old girl who received the first dose of MMR and varicella vaccine.

There were several other injuries that were alleged in VICP cases following the receipt of MMR-containing vaccines (e.g., seizure disorders). Another common filing alleged that MMR vaccine caused thrombocytopenic purpura (5%), a VIT condition with prescribed onset of 7 to 35 days following vaccination.

Claims alleging injury from rubella vaccine comprise 1% of claims overall. Most (75%) are filed on behalf of adults. Twenty-four percent of claims filed alleged that arthritis or rheumatoid arthritis developed after rubella immunization. Although 13% to 15% of susceptible (serology-negative) women may experience transient arthritis after the currently used rubella vaccine, with a higher percentage (up to 40%) reporting some type of musculoskeletal complaint, it is less clear what role, if any, the vaccine has in causing recurrent or chronic arthropathy (i.e., arthralgia or arthritis).[95,96]

Based on the 1991 IOM finding that chronic arthritis may be caused by rubella vaccine, a special master held a hearing to determine criteria necessary for proof of causation. Following the special master's publication of these guidelines, the VICP added chronic arthritis to the VIT in the 1995 final rule[52] and incorporated several of the court's criteria in the 1997 final rule.[111] The main difference between the criteria adopted by the VICP and those adopted by the court has been the latter's willingness to compensate arthralgia, a subjective symptom that is difficult to assess, unlike observable signs of arthritis. Additional research published since the IOM report, including retrospective case reviews and a prospective double-blind study, has produced mixed results. If rubella vaccine does cause chronic arthropathy, it would seem that the incidence is rare.[131–133] The most recent IOM report also concludes that the evidence supports a causal relationship between MMR vaccines and transient arthralgia in women and children. However, this report also concluded that the evidence is inadequate to support or refute a causal relationship for chronic arthritis in women, chronic arthropathy in women and children, as well as arthropathy in men.[79]

Varicella Vaccine

Varicella vaccine, which was licensed in March 1995, became a covered vaccine in August 1997, after enactment of the excise tax. By February 2017, the VICP had received at least 98 claims in which varicella vaccine was administered alone. The group comprised 38 children between 12 and 18 months of age, 39 older children, and 19 adults. Neurologic conditions were the predominant injury category (e.g., encephalopathy/encephalitis GBS, and seizures), followed by hematologic disorders (e.g., thrombocytopenia), ear, nose, and throat disorders (e.g., hearing loss), and other conditions. Various neurologic disorders have been reported to be associated with primary VZV (wild-type) infections, including meningoencephalitis, encephalitis, transverse myelitis, and acute cerebellar ataxia.[134] Vasculitis and acute cerebellar ataxia also have been reported following receipt of varicella vaccine.[135] Most of these conditions were reflected in the claims filed. The vaccine-strain genotype by polymerase chain reaction was identified in skin lesions of two persons.[136] Since 2012, 17 measles-mumps-rubella-varicella (MMRV) and 26 VZV claims have been filed, reflecting a shift to the combination product following licensure in 2005.[137]

The revised VIT added syncope and SIRVA as well as disseminated varicella vaccine-strain viral disease.

Hepatitis B Virus Vaccine

More than 740 hepatitis B–containing vaccines (e.g., HBV, HAV-HBV, Hib-HBV) vaccine claims have been filed as of February 2017, which represent 2% of all VICP claims. Claims alleged the following categories of injuries: encephalopathy/encephalitis (4%), GBS (4%) and various arthritic conditions

(4%). Vaccine recipients ranged in age from birth to 69 years, with 47% pediatric claims (younger than 18 years), of which 24% were for children younger than 2 years.

In general, there are no serious adverse events linked to the recombinant vaccine other than acute anaphylaxis.[97,98] In April 2002, the IOM Vaccine Safety Review Committee published its findings regarding HBV vaccine and neurologic disorders. The IOM concluded that there is evidence against a causal relation between HBV vaccine and multiple sclerosis and relapse, and insufficient evidence for other central or peripheral nervous system demyelinating conditions.[65]

In 2012, the IOM revised its previous conclusions and stated that the current evidence was inadequate to accept or reject a causal relationship between hepatitis B vaccines and the onset or relapse of multiple sclerosis among children and adults, and affirmed the conclusion that inadequate evidence exists to support or reject a causal relationship for other central or peripheral nervous system demyelinating conditions.[79] Approximately 37% of all the HBV vaccine claims were filed in 1999 before the 2-year window for filing retroactive claims expired. Working with the DOJ and the two petitioners' counsel who filed the majority of these cases, the court agreed to group the claims into diagnostic categories as a means of managing the large volume. After many years of attempting to convene an expert panel to deal with the constellation of cases and matrix of various injuries, the court abandoned the concept, and the cases were reassigned in early 2006 to three newly hired special masters. As a result, the claims are increasingly being assessed individually, not necessarily in relation to other claims involving similar allegations of injury.

In addition to individual hearings, there have been several omnibus proceedings using test cases with similar diagnoses to help move the backlog of claims.

A special master in the Hepatitis B–Neurological Demyelinating Omnibus Proceeding[138] ruled that HBV vaccine can cause transverse myelitis,[138] GBS,[139] multiple sclerosis,[140] and chronic inflammatory demyelinating polyneuropathy.[141] However, another special master ruled differently,[142] consistent with the government's position based on scientific evidence.[143–145] Another consolidated hearing resulted in the special master ruling that the HBV vaccine did not aggravate petitioner's type 1 diabetes mellitus.[146] In another proceeding, the special master ruled that the petitioners never offered a medical theory causally connecting the thimerosal contained in HBV vaccine to sudden death.[147] Finally, a split decision on appeal followed the special master's decision in five cases involving allegations of HBV and autoimmune hepatitis. In this proceeding, the same theory was offered and the same experts testified, but the facts of each of the cases were presented separately, and the special master wrote a separate decision on each of the cases. The special master ruled in favor of HHS in all five cases, but only two were affirmed on appeal by the Court of Federal Claims.[148,149] Ultimately, HHS appealed two of the three cases reversed by the Court of Federal Claims to the U.S. Court of Appeals for the Federal Circuit, which reversed the Claims Court's findings and remanded with instructions that a decision be entered affirming the special master's denial of compensation.[62]

Since 1999, some claims outside the aforementioned groupings have been adjudicated with varied results. Aside from anaphylaxis or anaphylactic shock, the only condition listed on the VIT for HBV vaccine, all HBV claims are being adjudicated on a causation-in-fact basis.

Polio Vaccines

Polio vaccine–related claims totaled approximately 460 of the pre-1988 case filings. IPV is a killed virus vaccine and, if properly manufactured, is not associated with paralytic poliomyelitis. It is reasonable to expect that some persons acquired natural poliomyelitis in temporal relationship to receipt of IPV, particularly if only one or two doses were given. The 1955 Cutter incident, in which an estimated 260 cases of paralytic poliomyelitis were attributed to residual live virus in the vaccine, is well documented.[150] No similar instances of killed vaccine–related poliomyelitis were publicly identified, although there is evidence that at least one lot of Wyeth vaccine given during this same period had infective amounts of live virus.[151] Of 278 IPV claims, nearly all (97%) have been dismissed by the court, with none being found to be secondary to Cutter vaccine administration. Only 13 claims are for vaccines administered since 1979, when the last indigenous case of wild poliovirus transmission occurred in the United States.[152]

OPV claims were approached much differently because paralytic polio is known to be a rare complication in vaccine recipients and in contacts and, therefore, is listed in the VIT. More than half (73%) of the claims alleged an injury of poliomyelitis. Naturally, it is difficult to know which cases were actually vaccine-related when polio was present in the community. Of the 308 claims filed alleging OPV-related injury (or death), 158 were compensated and 150 were dismissed.

Rotavirus Vaccine

Claims alleging intussusception from the rhesus-based rotavirus vaccine (RotaShield) started appearing in 2000. Some claims filed before the final rule adding intussusception as a VIT condition were compensated on a causation-in-fact basis, a burden that was made easier with epidemiologic studies confirming an association.[116–118] Once epidemiologic studies confirmed an association between rotavirus vaccine and intussusception in the first 2 weeks after immunization, HHS began the process for revising the VIT. A 2002 final rule added intussusception to the VIT under a second category of rotavirus vaccines (i.e., live, oral, rhesus-based), with an onset interval of 0 to 30 days following immunization.[119] The wider interval was chosen to provide a generous presumption of causation. Once intussusception was added to the VIT, petitioners otherwise barred under the general statute of limitations benefited from a presumption of causation in claims involving intussusception and had 8 years of retroactive coverage from the effective date of the VIT change, with a 2-year window in which to file their claims.

Ironically, the benign outcome of most cases of intussusception proved challenging for the VICP. Until October 2000, the NCVIA required all claimants to establish that the residual effects of an injury persisted for more than 6 months after vaccination or that a death occurred.

Because most patients with intussusception recover completely within days, some petitioners might be denied compensation under that standard. However, the Children's Health Act of 2000 amended the NCVIA to permit payment of compensation in claims in which the effects of the injury last less than 6 months if the petitioner demonstrates that the vaccine-related illness, disability, injury, or condition "resulted in inpatient hospitalization and surgical intervention."[153] Thus, under current law, infants who experienced intussusception following a rotavirus vaccine and did not have residual effects for more than 6 months qualified for compensation if their injury resulted in inpatient hospitalization and surgery.

With licensure of two new rotavirus vaccines in 2006 and 2008, the program once again began receiving claims alleging intussusception. At the time of publication, new evidence from postmarketing studies suggested intussusception was

causally associated with Rotarix and RotaTeq, although much more rarely than had been the case with RotaShield.[154–156] On July 24, 2013, HHS published a Notice of Proposed Rulemaking seeking comments about its proposal to add the injury of intussusception to the VIT for rotavirus vaccines.[157]

Since the beginning of the program, 79 injury claims had been filed, 43 of those alleged an injury of intussusception. Of all the claims that have been adjudicated, 51 received compensation and were dismissed.

Hepatitis A Virus Vaccines

HAV vaccines were added to the VICP in 2004. Since then, fewer than 1% of nonautism claims filed alleged injury from HAV vaccine. Petitioners ranged in age from 0 to 70 years, with approximately 55% younger than age 18 years. No patterns in claimed injuries emerged, which included liver-related conditions (hepatitis), neurologic disorders (seizure disorder, acute disseminated encephalomyelitis, transverse myelitis, GBS), and various immunologic conditions. The majority of cases heard before the court have been dismissed.

Meningococcal Vaccines

Meningococcal polysaccharide and conjugate vaccines were added to the VIT on February 1, 2007. Fewer than 1% of claims filed since then have alleged injury from these vaccines, and none involved the polysaccharide product. More than one third of the claimants had at least one other vaccine coadministered. The majority of MCV4 claims involved demyelinating conditions, with GBS found in nearly 26% of claims. Other demyelinating disorders found were transverse myelitis, chronic inflammatory demyelinating polyneuropathy, and multiple sclerosis.

Of the 43 claims that have been adjudicated, 84% have received compensation. A report by the CDC in 2006 suggested a small increase in the risk of GBS among meningococcal conjugate vaccine recipients.[159] However, two large unpublished postlicensure safety studies presented to the Advisory Committee on Immunization Practices in June 2010 found no evidence of increased GBS risk following vaccination.[160] The most recent IOM report found that the evidence was inadequate to determine a causal relationship between meningococcal vaccine and GBS.[79]

Influenza Vaccines

Trivalent influenza vaccines (TIV [trivalent inactivated influenza vaccine], LAIV [live attenuated influenza vaccine]) were added to the VICP in July 2005. In 2013 all seasonal influenza vaccines, including the quadrivalent influenza vaccines, were added to the VIT. Since July 2005, approximately 51% of the total VICP claims filed allege an influenza vaccine injury, with increasing numbers being filed each year. Moreover, since 2007, nearly 76% of VICP claims filed are for adults, which is a decided shift from the first 15 years of the program when most claims were filed on behalf of children.

As of February 2017, 3301 petitions had been filed claiming an injury caused by an influenza vaccine. Only 6% were for petitioners younger than 18 years of age. GBS comprised 36% of the claims. In fact, claims alleging GBS are now the most common vaccine injury claim filed annually. Other demyelinating conditions made up a significant portion of influenza claims, which included transverse myelitis, chronic inflammatory demyelinating polyneuropathy, and acute disseminated encephalomyelitis. The remaining claims involved various allegations, such as encephalopathy, seizures, brachial neuritis, and a range of neuromuscular conditions.

After medical review, it was found that more than 380 claims involved a shoulder injury related to vaccination, an injury apparently from the unintentional injection of antigenic material into synovial tissues resulting in an immune-mediated inflammatory reaction. A case series of 13 VICP cases is described in a 2010 report.[161] Most of these claims were conceded by HHS.

No specific injury related to influenza vaccine is listed in the VIT, and HHS has concluded that certain claims have demonstrated injury compensation by a preponderance. Such claims included anaphylaxis,[162] syncopal episodes resulting in severe injuries, and shoulder injury related to vaccine administration. However, it is not uncommon for influenza claims to receive compensation on the basis of a litigation risk settlement (76%) because of the evolved causation standard.

A new challenge faced the VICP after increased rates of GBS were detected following the 2009–10 monovalent influenza pandemic campaign. A metaanalysis of the Vaccine Safety Datalink, Emerging Infections Program (an active population-based surveillance program), and Post-Licensure Rapid Immunization Safety Monitoring programs that analyzed data from 23 million people who were vaccinated with the influenza A (H1N1) 2009 monovalent vaccine found that the 2009 H1N1 inactivated vaccine (a vaccine not included in the VICP) was associated with a small increased risk of GBS within 6 weeks of vaccination.[163] This excess risk is equivalent to 1.6 excess cases in the 6 weeks after vaccination per million people vaccinated. A separate program within HHS is responsible for alleged injuries or deaths related to use of the monovalent product and vaccines against pandemic influenza (see the discussion of the Countermeasures Injury Compensation Program [CICP] in "Related Liability Protection and Compensation Schemes" later). Incorporation of the H1N1 pandemic virus into the seasonal influenza vaccine first occurred with the 2010–11 trivalent vaccine and this strain has been included in seasonal formulations since. Presently, there is no scientific evidence demonstrating that current formulations of the seasonal influenza vaccine, which contain the H1N1 virus, can cause GBS.[79,164,165] However, the degree of surveillance needed to detect an increased risk of approximately one case per million vaccinations, as was seen with the monovalent 2009 H1N1 vaccine, is unlikely to be routinely performed as the strains in the flu vaccines change from year to year. Nonetheless, numerous studies have been conducted to determine whether a possible association between seasonal influenza vaccines and GBS exists, and almost all have not shown any causal relationship.

Human Papillomavirus Vaccines

HPV vaccines were added to the VICP in February 2007. By February 2017, 345 had been filed. The majority of injury claims alleged neurologic injuries, such as GBS, transverse myelitis, and acute disseminated encephalomyelitis. Other neurologic categories included headaches and seizures. There were also significant numbers of claims alleging rheumatologic disorders, including rheumatoid arthritis, systemic lupus erythematosus, and fibromyalgia. One hundred thirteen cases received compensation and of those, 13 injury claims were resolved through a concession of entitlement by HHS. Of the claims that were conceded, the majority of claims (54%) involved injuries resulting from a syncopal episode, one involved complex regional pain syndrome, and one claim involved an injury from the injection process or shoulder injury related to vaccine administration.[161]

There were 14 claims of HPV vaccine–related death. All were adolescents and young adults ages 11 to 21 years. Evidence demonstrating a relationship between the vaccine and

the subsequent death was lacking. Seventy-three percent of claims had been adjudicated by February 2017.

ISSUES OF INTEREST

During the last two decades, the greatest challenge to the VICP has been adjudicating causation-in-fact claims. This depends heavily on the availability of credible and timely scientific evidence. Only through a comprehensive vaccine adverse event surveillance and research program can causal versus coincidental reactions following vaccination be distinguished. Rotavirus vaccine causing intussusception is an example of how epidemiologic research led to expedited compensation once intussusception was found to be vaccine-related. At the same time, safety studies allow for the debunking of erroneous theories of vaccine causation, assisting the court in dismissing claims not shown to be vaccine-related. The creation of IOM committees to perform independent, expedited scientific reviews of current and emerging vaccine safety hypotheses (see discussion of the IOM Immunization Safety Review Committee in Chapter 80) have been an important step in ensuring continued evaluation of the safety of vaccines.

Ten reports issued from 2001–13 have been helpful to HHS and the court in clarifying the current scientific literature on vaccine adverse events.[167] At the same time, securing adequate funding for vaccine safety research overall remains one of the greatest challenges at a time of budget deficits and competing priorities for vaccine program funding. In 2008, the Health Resources and Services Administration engaged the IOM to establish a new IOM committee to review the medical and scientific literature to assess the causal relationship, if any, between 78 adverse events (158 adverse event–vaccine combinations) and 12 VICP-covered vaccines. The consensus report was released in August 2011 and included a lengthy discussion of each adverse event–vaccine combination, as well as a discussion of its approach in assessing vaccine causation generally.[79] The report may result in additional modifications to the VIT by the Secretary.

Criticism by petitioners and their attorneys led to oversight by Congress in the VICP's early years. Government Accountability Office (GAO) reports issued in 1999 and 2000 addressed the VICP process and trust fund, respectively.[168,169] The VICP adjudication process was judged to be easier than the traditional tort system, but not as streamlined as Congress had originally intended. Moreover, although there seemed to be a scientific basis for the VIT changes made by HHS, the GAO found some inconsistencies in applying results of the IOM reviews. The trust fund and its huge, ever-increasing size was the focus of the second effort by GAO. Potential solutions varied depending on stakeholder perspective, with petitioners wanting more claims compensated by decreasing the burden of proof, vaccine companies wanting the federal excise tax reduced to lessen cost, and researchers calling for a portion of incoming revenues annually to pay for vaccine safety research and surveillance. In the end, the GAO's only recommendation was that HHS publish a clear method for future changes to the VIT to help ensure that such changes are perceived as fair.

It should be noted that guidance regarding recommending changes to the VIT has been provided. The HHS National Vaccine Plan recommends updating the VIT in response to evolving science.[170] In 2006, the ACCV adopted principles that should guide their recommendation of changes to the VIT: (a) the VIT should be scientifically and medically credible, and (b) where there is credible scientific and medical evidence to both support and to reject a proposed change to the VIT, the change should, whenever possible, be made to the benefit of the petitioner. [171]

The GAO issued another report in 2014 that examined the adjudication process time, changes to the VIT, and how the balance of and spending from the Trust Fund have changed.[172] It was found that claims filed since 2009 were resolved within 1 to 2 years and that the majority of compensated claims (80%) were resolved through a negotiated settlement. It was also noted that although six new vaccines had been added to the Table since 1999, additional covered injuries associated with these vaccines had not been added, which means that each petitioner must demonstrate that the administered vaccine did, indeed, cause their alleged injury. Finally, it was found that the income to the Trust Fund exceeded the expenditures. The GAO made no recommendations. However, the GAO did conclude that HHS's outreach efforts would be important to ensure that potential petitioners are aware of the program.

Concerns that helped lead to the creation of the VICP (e.g., fears regarding liability and the availability of compensation in relation to adverse events resulting from products) have surfaced with regard to vaccines not covered by the VICP (because they are not routinely administered to children) and to other countermeasures used to prevent and treat particular diseases.

Some interested parties have suggested adding more selective-use vaccines to the VICP, such as pneumococcal polysaccharide, used primarily in adults. An NVAC review in 1996 found little evidence at that time to support the need, based on a lack of liability concerns by manufacturers and healthcare providers.[173]

In more recent years, the issue of maternal immunization (or vaccines administered to pregnant women) has received significant attention. For some time, certain stakeholders have pointed to the need to cover pregnant women for vaccines in development to prevent respiratory syncytial virus, cytomegalovirus, and group B streptococcal infections, which cause significant morbidity and mortality in very young infants.[174–176] A wide variety of parties has cited liability concerns as a key barrier to licensure of new vaccines for maternal immunization Maternal immunization has raised several complex issues under the NVCIA. One concern was that new categories of vaccines intended exclusively for pregnant woman could not be covered by the NVCIA (which extends the statute's liability protections and permits compensation under the VICP). Beyond vaccines included on the original statutory VIT, such coverage could extend only to those recommended by the CDC for routine administration to children and subject to an excise tax. Other concerns were raised with respect to categories of vaccines covered under the NVCIA that are administered to pregnant women (DTaP vaccines and seasonal influenza vaccines), such as the NCVIA's requirement that to be eligible for compensation, a person must have "received" a covered vaccine (putting aside a narrow category for persons who contracted polio from persons who received the OPV) and a requirement that only one petition may be filed per vaccine administration. No binding court decision resolved these issues.

The issue of maternal immunization generated significant interest, partly given the significant public health benefits that could be achieved with new categories of vaccines for pregnant women. In 2013, the ACCV recommended that the Secretary work to expand coverage under the VICP to include vaccines recommended for routine administration to pregnant women (and not specifically recommended for routine administration to children) and support eligibility to pursue compensation for injuries sustained by a liveborn infant whose mother receives a vaccine while the infant is in utero. In 2014, the NVAC released a report, "Reducing Patient and Provider Barriers to Maternal Immunization," recommending that the

Assistant Secretary for Health support efforts to address the issue of in utero injuries allegedly incurred following maternal immunization within the VICP.

On December 2016, the 21st Century Cures Act made changes to the NVCIA in connection with vaccines administered to pregnant women and claims concerning injuries alleged to have occurred in utero.[176a] First, the 21st Century Cures Act added a new category of vaccines to the NVCIA's coverage: vaccines recommended by the CDC for routine administration to pregnant women and subject to an excise tax. While no vaccines fell within this category as of March 2017, this amendment ensures that vaccines designed for administration in pregnant women (perhaps for the protection of their later-born children) could be covered vaccines under the VICP and trigger the NVCIA's related liability protections. Second, the 21st Century Cures Act amended the Vaccine Act to provide that if the vaccination of a pregnant woman leads to injuries both in the woman and in her later, live-born child, claims could be pursued with respect to both alleged injuries in the VICP. Finally, the law now provides that claims may be filed within the VICP on behalf of live-born children alleging injuries alleged to have been sustained in utero as a result of maternal immunization and that vaccine administrators and manufacturers will be afforded the NVCIA's related liability protections, issues that were unresolved prior to this legislation.

RELATED LIABILITY PROTECTION AND COMPENSATION SCHEMES

Despite the successful global eradication of smallpox in 1980, terrorist attacks in 2001 led to concerns that terrorists might have access to the smallpox virus and might attempt to use it against Americans. As part of President Bush's plan to protect the American population from the threat of a smallpox attack, liability protections were enacted to protect covered persons in relation to their involvement in the federal smallpox vaccination campaign. Covered persons included manufacturers of smallpox vaccines, healthcare entities, and healthcare providers under whose auspices the vaccine was administered and state and local governments, including first responders. The liability protections[177,178] were meant to ensure that the smallpox vaccine and other related smallpox countermeasures were available, if necessary, to protect the public health.

Under the liability provisions, no lawsuit for liability for injuries or deaths arising out of the administration of a smallpox vaccine or other smallpox-covered countermeasure named in a declaration could be maintained against covered persons. Instead, such claims had to be pursued against the United States as a substitute defendant. Such claims were to proceed under the Federal Tort Claims Act, which requires plaintiffs to demonstrate negligence or another cognizable tort. Although these liability protections were broad, they were subject to certain limitations. For example, if a covered person failed to cooperate with the government in the defense of a claim, the government would not be liable for any damages resulting from that person's act or omission. Also, if the United States made a payment on a claim that was based on bad acts or omissions by a covered person (e.g., gross negligence), the United States was entitled to recover funds from the covered person.

These liability protections were triggered in January 2003, when the Secretary issued a declaration concluding that a potential bioterrorist incident made advisable the administration of particular smallpox countermeasures (including smallpox vaccines, products designed to prevent or treat smallpox, and products designed to control or treat adverse events from smallpox vaccination).[179] The Secretary recommended that certain categories of persons (including first responders and members of approved smallpox response teams), receive the covered countermeasures.

As a companion to these liability protections and as incentive for the targeted persons to receive smallpox countermeasures, Congress authorized the Secretary to establish the Smallpox Vaccine Injury Compensation Program (SVICP) to provide medical, lost employment income, and death benefits to eligible persons (including smallpox vaccine recipients; persons who came into contact with a vaccinated person or with another person with whom the vaccinated person had contact, known as "vaccinia contacts"; and the estates and survivors of otherwise eligible deceased persons).[180] Among the eligibility requirements, requesters had to demonstrate an injury that resulted from a covered countermeasure. Like the VICP, requesters could demonstrate this by showing that the injured person sustained an injury included in an injury table promulgated by HHS within the table time frame or by demonstrating that the person's injury was actually caused by the vaccine or other covered countermeasure. Unlike the VICP (in which claims are litigated in court), the SVICP was a purely administrative program operated by the HHS. Persons eligible to file SVICP claims had to exhaust their remedies with this program before filing any action against the United States. We are not aware of any post-SVICP claims filed against the United States. A total of 64 persons applied for benefits with the SVICP, and 19 persons received compensation. The SVICP is no longer operational and was terminated in 2008 owing to a lack of funding, among other factors. The smallpox vaccine is now a covered countermeasure under the CICP, discussed below.

More recently, concerns about a potential pandemic and the possibility that the threat of liability would inhibit manufacturers from producing vaccines and other countermeasures needed to prevent or treat a pandemic or other emergency event (and would inhibit healthcare professionals and others from distributing and administering such countermeasures) led to the enactment of the Public Readiness and Emergency Preparedness Act (PREP Act), within the Department of Defense Appropriations Act, in 2005.[181] The PREP Act offers extremely broad liability protections to manufacturers and other persons and entities (e.g., distributors, program planners, administrators) for all claims of loss resulting from the creation, distribution, and administration of certain products if the Secretary issues a declaration determining that a disease or other health condition or threat constitutes a public health emergency or that there is a credible risk that the disease, condition, or threat may in the future constitute such an emergency and recommending that particular countermeasures should be administered or used. In such a declaration, the Secretary must explain his or her findings and the parameters of the attendant liability protections, including the category of diseases or conditions for which the Secretary recommends the administration of the covered countermeasure, the applicable periods, the pertinent population or populations, and the applicable geographic areas.

A very narrow exception to these liability protections allows an exclusive federal lawsuit against a covered party if the plaintiff can prove that the party engaged in willful misconduct and that such misconduct caused death or a serious physical injury. "Willful misconduct" is defined very broadly as an act or omission taken intentionally to achieve a wrongful purpose, knowingly without factual or legal justification, and in disregard of a known or obvious risk that is so great as to make it highly probable that the harm will outweigh the benefit.[182] The PREP Act provides that this standard is more stringent than any form of negligence or recklessness. Other defenses are also available.

The Secretary invoked the liability protections of the PREP Act through a series of declarations published beginning in 2008.[183,184] These declarations extend to several countermeasures meant to prevent or treat pandemic influenza and other unrelated countermeasures (those relating to anthrax, botulism, smallpox, acute radiation syndrome, and Ebola virus). Although vaccines against pandemic influenza A viruses and influenza A viruses with pandemic potential are covered by one of these declarations, seasonal influenza vaccines administered annually are excluded (and are subject to the NCVIA and the VICP). Covered countermeasures include several vaccines and other countermeasures (e.g., antibiotics, antivirals).

The PREP Act provides for the establishment of a program to provide compensation to certain covered persons who sustain serious physical injuries (or death) as a result of a covered countermeasure designated under a declaration of the Secretary. This program, which was established in 2010, is known as the CICP. The structure of and benefits available under this program are very similar to the SVICP. Like the SVICP, the CICP is an exclusively administrative program run by the HHS. In addition, requesters for benefits must satisfy the requirements for a condition listed on a countermeasures injury table or prove that a covered countermeasure caused a specific injury. Under the CICP, the Secretary must rely on compelling, valid, reliable medical and scientific evidence to add injuries to an injury table or to determine that a countermeasure caused a specific injury. The regulations governing the CICP, including any tables of injuries, are codified at 42 CFR part 110.[185] As of February 2017, 475 requests had been filed with the CICP, nearly all (86%) alleging injury from the 2009–10 H1N1 pandemic influenza vaccine. The remaining 14% involved antiviral drugs, anthrax vaccine, and smallpox vaccine, as well as other ineligible items.

We are aware of two cases filed against covered persons under the PREP Act. *Parker v St. Lawrence County Public Health Department*[186] arose from a pandemic influenza vaccine clinic held by a county public health department at a school pursuant to a Secretarial declaration issued under the PREP Act. At the clinic, a kindergartner was administered a vaccine by mistake even though her parents did not consent to the vaccination. The child's mother filed an action alleging that the administration of the vaccine without parental consent was negligence and resulted in a battery of her daughter. A New York appellate court dismissed the claim, concluding that the mother's state law claims for negligence and battery were preempted by the PREP Act's liability protections.

In *Kehler v. Hood, et al.*,[187] the plaintiff alleged that his wife suffered transverse myelitis as the result of a pandemic influenza vaccine administered pursuant to a PREP Act declaration. The plaintiff sued a doctor and her employing hospital, alleging that they were negligent in failing to obtain the patient's informed consent and consult with a specialist prior to the vaccine administration. The defendants brought third-party product liability/failure to warn claims against the vaccine manufacturer. The federal district court dismissed the claims against the manufacturers as barred by the PREP Act (given that willful misconduct was not alleged) and remanded plaintiffs' remaining claims to state court for further consideration.

VACCINE LIABILITY SINCE 1986

The passage of the NCVIA in 1986 did not mark an immediate decline in the number of reported vaccine liability decisions in state and federal courts (largely owing to the length of time until cases reach a final, reported resolution and the fact that retrospective claimants had until January 1991 to file claims with the VICP). However, since 1992, the number of reported vaccine liability cases has declined sharply. This decrease in reported cases suggests that most VICP petitioners have chosen not to pursue traditional tort litigation after the VICP process.

There are few reported federal and state court cases in which a claimant filed a traditional tort claim against a vaccine manufacturer or a vaccine administrator after being denied compensation under the VICP. In many of these cases, the courts concluded that the claims must be dismissed as barred by the applicable statute of limitations (e.g., state statute of limitations) because the underlying VICP claim was time-barred or because the plaintiffs failed to file a timely VICP claim within the limitations period.[188–195] Other reported post-VICP cases address other issues. In one case, a state court dismissed a medical malpractice action filed against a vaccine administrator by a pre-1988 petitioner because of the petitioner's acceptance of a VICP award.[196]

There are very few reported cases of vaccine injury or death lawsuits being pursued outside of the VICP.

As a general rule, as long as petitioners properly exhaust their remedies under the VICP, they may pursue civil actions against vaccine administrators and manufacturers. The NCVIA imposes certain limitations on post-VICP claims that may be filed against vaccine manufacturers. No such protections exist for vaccine administrators. Until recent years, these post-VICP limitations on civil actions filed against vaccine manufacturers attracted little attention.

However, one such limitation was brought into the spotlight as different interpretations of its language led to a post-VICP case, concerning a seizure disorder alleged to be the result of a DTP vaccine that was decided by the U.S. Supreme Court, *Bruesewitz v Wyeth*.[197] The NCVIA provides that "[n]o vaccine manufacturer shall be liable in a civil action for damages arising from a vaccine-related injury or death associated with the administration of a vaccine after the effective date of this part if the injury or death resulted from side effects that were unavoidable even though the vaccine was properly prepared and was accompanied by proper directions and warnings."[198] The issue before the Supreme Court was whether, in post-VICP litigation, this provision prohibits claimants from bringing "design defect" claims against manufacturers in civil court. In these claims, the plaintiff alleges that the design of the vaccine was defective; a safer alternative design was available; the manufacturer failed to design its vaccine in conformity with the safer alternative; and as a result, the claimant was injured.

Before the U.S. Supreme Court's decision, lower courts had differed in their interpretations of this language. The Supreme Court of Georgia concluded in *American Home Products Corp v Ferrari* (a thimerosal–neurologic damage claim) that design defect claims could proceed on a case-by-case basis until a court determined that the particular vaccine was unavoidably unsafe.[199] The U.S. Court of Appeals for the Third Circuit reached a different result, in *Bruesewitz v Wyeth*.[200] In that case, family members filed a petition with the VICP arguing that their child sustained a seizure disorder as the result of a DTP vaccine. After their VICP claim was dismissed, the family filed a design defect claim against the vaccine manufacturer in civil court. On appeal, the Third Circuit dismissed their claim, concluding that the statutory language preempted all post-VICP design defect claims against vaccine manufacturers.

Given the split in judicial interpretations and the significance of the issue, the Supreme Court granted the family's petition for certiorari to clarify whether this provision of the NCVIA preempts all design defect claims in post-VICP litigation filed against vaccine manufacturers. Many stakeholders filed amicus briefs on both sides, emphasizing the significance

of the Supreme Court's anticipated ruling.[201] The federal government filed an amicus brief arguing that the NCVIA preempts all design defect claims against vaccine manufacturers in post-VICP litigation.[202] During oral argument, the federal government emphasized the significant public health implications of the case and the important role of the government in ensuring that licensed vaccines are safe and effective.

In an opinion delivered by Justice Scalia, the U.S. Supreme Court held that the NCVIA preempts design defect claims against manufacturers in civil court.[197] The plain text of the statute suggests that a vaccine's design is not open to question in a tort action. In addition, the structure of the NCVIA reinforces the interpretation that design defect claims are preempted: The NCVIA provides for comprehensive federal agency improvement of vaccine design and for federally prescribed compensation as an alternative means for achieving the aims of design defect tort suits.

Beyond the issue of any limitations on design defect claims, the NCVIA addresses "duty to warn" claims with respect to vaccine manufacturers (but not administrators) by providing that "[n]o vaccine manufacturer shall be liable in a civil action for damages arising from a vaccine-related injury or death associated with the administration of a vaccine after the effective date of this subpart solely due to the manufacturer's failure to provide direct warnings to the injured party."[203]

Before the *Ferrari* and *Bruesewitz* cases arose, the largest development in non-VICP vaccine litigation had been an upsurge in cases, beginning in 2001, in which parents alleged that covered vaccines (the MMR vaccine, which never contained the preservative thimerosal, and/or childhood vaccines containing thimerosal) caused their children's autism. Plaintiffs argued that they were not required to exhaust their remedies within the VICP based on their argument that the preservative thimerosal was an adulterant. This argument hinged on the NCVIA's definition of a "vaccine-related injury or death," which excludes any injury or death associated with an adulterant or contaminant intentionally added to a covered vaccine.[204] The federal government's position, filed in one of these cases, was that thimerosal was not an adulterant because it was part of the vaccine formulation when the products were licensed and approved for use by the FDA.[205] Courts held that such claims must be filed with the VICP and all remedies there exhausted before any such claim may be brought outside the program.[206,207] Thus, unless a claim fits within one of the limited statutory exceptions (see "Other Situations in Which Suits Are Not Barred by the National Childhood Vaccine Injury Act" later), it must be filed with the VICP before tort remedies can be pursued.

Several cases were also filed in state court in New Jersey alleging that a contaminant in the OPV (simian virus 40 [SV40]) caused cancerous tumors.[208] Manufacturers argued that the SV40 was not "intentionally added" to the vaccine and, thus, that jurisdiction should be before the VICP. A decision that the statutory exception did not apply was upheld on appeal.[209]

Risk to Healthcare Professionals

Civil actions against healthcare providers are rare, and few have been pursued since the VICP was modified to cover vaccine administrators, because claimants must go through the VICP before filing most actions against a vaccine administrator. However, if a claimant were to reject the VICP decision, the claimant might file a tort action against the healthcare provider on such grounds as failure to adequately warn, negligent vaccine administration, or negligent postvaccination care.

Other Situations in Which Suits Are Not Barred by the National Childhood Vaccine Injury Act

The NCVIA covers only the losses sustained by the injured person; thus, all loss of companionship claims by the parents, children, or spouse of an injured person are not compensable. Family members may file these so-called derivative claims in state court, if they can be pursued in court under state law, but the claims will be successful only if the plaintiff can prove that the underlying injury or death was related to the vaccine and prove a theory of liability. The NCVIA makes inadmissible in such subsequent litigation any finding of fact or conclusion of law in a VICP case, as well as the VIT.[210] Up until 2001, with the thimerosal litigation, families rarely filed such claims. The issue first came to light in *Schafer v American Cyanamid*.[211] The husband and daughter of a woman who contracted vaccine-related polio filed a claim for loss of consortium and emotional distress in state court after the woman accepted a VICP award. The case was removed to federal court, and a federal appellate court found that the plaintiffs' claim was not precluded by the family member's acceptance of a VICP award. The Court of Federal Claims' interpretation of the NCVIA was consistent with the Schafer holding.

In *Abbott v Secretary of Department of Health and Human Services*,[212] a young man's mother filed a state wrongful death claim against a healthcare provider alleging that the provider negligently left her son unattended in the bathtub. The young man had a seizure in the tub and drowned. Ms. Abbott filed the state claim as mother of the decedent and accepted a settlement from the healthcare provider. The mother later filed a VICP claim as administrator of her son's estate alleging that the death was a sequela of a vaccine-related seizure disorder. The U.S. Court of Appeals for the Federal Circuit concluded that the previous settlement covered only damages for injuries to the son's beneficiaries. The mother received an award under the VICP as a representative of her son's estate. Other civil litigation related to autism claims was filed by plaintiffs. These cases included class action lawsuits filed on behalf of the parents, children, or spouses of the injured person seeking their own damages for loss of companionship or consortium or services and loss of earnings. Other lawsuits sought the costs of medical monitoring to determine whether thimerosal-related injuries would develop in the future, generally alleging $1000 or less in damages.[213] Because the plaintiffs sought $1000 or less per person to pay for "medical monitoring" (i.e., future tests to determine if a child is developing an injury), plaintiffs argued they were not covered by the NCVIA because it exempts claims seeking $1000 or less.[214,215] By 2006, all medical monitoring lawsuits had been dismissed.[216]In *Cook v Children's Medical Group*,[217] parents claimed that a vaccine administrator fraudulently concealed their child's vaccine-related injury, and, as a result of this concealment, the time for filing a VICP claim had passed. The Supreme Court of Mississippi held that the parents' claim against the administrators for fraudulent concealment and breach of fiduciary duty could continue in state court (because it was not the subject of the NCVIA), but that any claim on behalf of the child for his vaccine-related injuries was subject to exhaustion of remedies under the VICP.

INTERNATIONAL COMPENSATION PROGRAMS

Nineteen industrialized countries provide some form of compensation for injuries (or deaths) following vaccination.[218,219] Germany and France were the first to institute programs in the 1960s, followed by Austria, Denmark, Japan, New Zealand, Sweden, Switzerland, United Kingdom, and Northern Ireland in the 1970s; Taiwan, Finland, United States, and Quebec

(Canada) in the 1980s; Italy, Norway, and Republic of Korea in the 1990s; and Hungary, Iceland, and Slovenia since 2000. A variety of factors led to the establishment of such programs, including concerns about liability and vaccine adverse events, concerns about the vaccine supply, and a belief that governments have a responsibility to persons injured by properly manufactured and administered vaccines used in public health programs. Most are managed administratively through the national government, including decisions on eligibility and the amount of compensation.

Eligibility may depend on several factors, including the category of vaccine (e.g., recommended, compulsory) administered. Some programs are part of larger no-fault compensation schemes. Because few vaccine-related injuries have a clinical or laboratory marker, proving actual causation can be difficult. Causation decisions are usually based on the preponderance or "more likely than not" standard. All countries have a threshold severity of injury or disability requirement, and nearly all provide coverage for medical costs, noneconomic damages (pain and suffering), all usually proportional to the injury, and death benefits. No compensation programs outside the United States reimburse attorneys' fees and costs. Funding is generally from the national treasury, with some programs receiving support from other governmental entities or vaccine manufacturers. Two countries fund the programs with a vaccine tax (Taiwan and the United States).

Interest has been expressed in expanding vaccine injury compensation to the developing world (Clements CJ, Oleja S, Fife P. Vaccine injury compensation: an international perspective. Unpublished data, 2006).

THE POWER TO COMPEL VACCINATION

U.S. courts generally have been deferential to public health judgments that mandatory vaccination is required in particular circumstances. In *Jacobson v Massachusetts,*[220] the U.S. Supreme Court upheld a Massachusetts statute authorizing each local board of health to require vaccination of the inhabitants "if, in its opinion, it is necessary for the public health or safety." Under this authority, and responding to a partial outbreak of smallpox, the city of Cambridge required all residents to receive the smallpox vaccination. Although children whose physicians determined that such vaccination was medically contraindicated were exempted from this requirement, such an exemption was not available for adults. Jacobson, who explained that he suffered adverse reactions to the vaccine as a child, refused vaccination and was fined. The Supreme Court rejected Jacobson's argument that the Massachusetts law was constitutionally invalid, holding that the law was a reasonable and proper exercise of the state's police power to protect the public health and safety. The court determined that the Massachusetts legislature was entitled to rely on the commonly held belief (maintained by high medical authority) that vaccination was a preventive of smallpox and was not compelled to commit such a public health and safety matter to the final decision of a court or jury. This case is significant because the Supreme Court recognized the importance of vaccination and deferred to the authority of state lawmakers to develop and impose vaccination requirements on the public. The Supreme Court's 1922 decision in *Zucht v King*[221] had the effect of upholding the authority of the city of San Antonio to issue an ordinance requiring all persons attending public schools or other places of education to first present certificates of vaccination, thereby permitting mandatory vaccination requirements for school attendance. The lawsuit was filed on behalf of a child who refused to be vaccinated and was excluded from a public school and a private school for failure to have the certificate. Although there had been no epidemic of smallpox in San Antonio in *Zucht*, in contrast to the circumstances in *Jacobson*, the Supreme Court in *Zucht* affirmed the validity of a preventive vaccination mandate for a disease not in circulation.[222]

Decisions of contemporary courts continue to be supportive of mandatory vaccination requirements and often cite *Jacobson* in deciding lawsuits challenging immunization mandates. In *Maricopa County Health Department v Harmon,*[223] a health department issued an emergency rule barring unimmunized children from attending school because of an outbreak of measles in the county. The health department sought an injunction excluding unimmunized children from school. The trial court granted the injunction, and the appellate court affirmed. The court rejected the families' argument that the health department had no authority to exclude children unless there had been a confirmed case of measles in the particular school, concluding that the health department had the authority to exclude children even in the absence of a serologically confirmed case.

Contemporary vaccination laws are not as sweeping as the law involved in *Jacobson.* States generally require that children receive certain recommended vaccines to attend schools and childcare centers. There is variation among state laws as to which vaccines are required for school entry. These laws are dynamic and often incorporate new vaccines. The CDC's National Immunization Program maintains a website with current information on state immunization requirements for attendance in schools and childcare centers, together with information on exemptions permitted under these laws.[224] The CDC also maintains websites with data about vaccination coverage.[225,226] Currently, all states allow some form of a medical exemption, approximately one-third of states allow philosophical exemptions, and nearly all allow religious exemptions.[227, 228]

In recent years, particularly in the wake of the measles outbreak in California in 2015 and concerns about the rates of exemptions in certain communities, state legislatures have devoted substantial attention to school immunization requirements, as well as the exemptions available to such requirements. The issue has received particular attention in California, which passed a law in 2012 requiring consultation with a healthcare practitioner about the risks and benefits of immunization as a requirement for personal belief exemptions.[229] In a signing statement, the then governor of California directed the Department of Public Health to allow for a separate religious exemption on the form, even though it was not provided for by law, so that "people whose religious beliefs preclude vaccinations will not be required to seek a healthcare practitioner's signature."[230] The governor's authority to unilaterally change the bill in this manner has been questioned.[231] More recently, on June 30, 2015, the governor of California signed a controversial law eliminating personal and religious exemptions to the State's vaccination requirements.[232] The law applies to pupils in public or private schools and daycare centers, but not to children who are home-schooled. The law retains a single exemption that permits a parent or guardian to file a written statement by a licensed physician "to the effect that the physical condition of the child is such, or medical circumstances relating to the child are such, that immunization is not considered safe, indicating the specific nature and probable duration of the medical condition or circumstances, including, but not limited to, family medical history, for which the physician does not recommend immunization" and exempting such child from the vaccination requirements "to the extent indicated by the physician's statement." In a signing statement, the governor of California noted scientific evidence concerning the benefits of vaccination and that the law, after considerable debates and amendments, "explicitly provides an

exception when a physician believes that circumstances—in the judgment and sound discretion of the physician—so warrant."[233] Students already enrolled in schools or facilities whose families previously objected to immunizations may continue to attend covered schools and facilities until they enter covered grade spans (i.e., kindergarten, seventh grade), at which time they must satisfy the law's immunization requirements. The law permits the State Department of Public Health to subject vaccines against additional diseases beyond those already listed by statute to the law's immunization requirements, but only if exemptions are allowed for both medical and personal beliefs. The law permits a child to be excluded from a school or daycare center if there is good cause to believe that the child has been exposed to a covered disease and documentation proving immunization against such disease is not submitted. Oregon adopted a law permitting religious or philosophical exemptions only after parents either reviewed the risks and benefits of immunization with a physician or completed a vaccine education module.[234]

In 2016, many bills were pending in state legislatures proposing removing existing exemptions, proposing altering existing exemptions (e.g., requiring physician counseling about the risks and benefits of vaccination for exemptions), or proposing new exemptions.

The laws that require vaccination before school entry are congruent with the grant program operated by the U.S. Public Health Service.[235] If a state or local government participates in that federally funded immunization program, it must, among other requirements, have a "plan to assure that children begin and complete their immunizations on schedule" and a "plan to systematically immunize susceptible children at school entry through vigorous enforcement of school immunization laws."[236]

Although all states allow medical exemptions to school immunization laws, the scope and application of these laws vary by state.[224,237, 238] In a case concerning medical exemptions, the Wyoming Supreme Court held that the state of Wyoming's Health Department could waive state immunization requirements for a particular child if such vaccination was medically contraindicated for that child but that the Department exceeded its authority in requiring a child or the child's physician to provide a reason for such a contraindication.[239]

Many states have granted persons exemptions from mandated vaccination requirements based on religious or personal beliefs. Parents have filed numerous lawsuits challenging the fact that states did not allow religious and/or personal exemptions or challenging the scope or application of the specific exemptions. In a case in which a mother challenged the constitutionality of a West Virginia law that allowed no religious exemptions, a federal judge concluded that states need not provide religious exclusions from their compulsory immunization laws.[240] Although the court in *Brown v Stone*[241] struck a religious exemption from a state statute on the grounds that it violated the Equal Protection Clause of the Fourteenth Amendment (by requiring most school children to be vaccinated while exposing them to the hazards of associating with nonvaccinated children subject to a religious exemption), most courts have recognized that states may allow religious exemptions. The courts have focused on the scope of such exemptions. For example, in *McCarthy v Boozman*, a federal district court judge found unconstitutional an Arkansas law that granted religious exemptions to the state's school immunization requirements only to persons who were members or adherents of a church or religious denomination recognized by the state but not to others whose objections to immunization were also grounded in sincere religious beliefs.[242] The judge found that the religious exemption section of the Arkansas law violated the U.S. Constitution, noting that the primary effect of this exemption provision was to "inhibit the earnest beliefs and practices of those individuals who oppose immunization on religious grounds but are not members of an officially recognized religious organization." An appeal was mooted when the Arkansas legislature broadened the law to encompass philosophical and religious exemptions.[243]

In another case, a New York agency sought a court order to immunize foster children over the objections of their foster mother. Applying New York law, the judge considered the nature of the foster mother's objections to determine whether they were religious or philosophical. Although the foster mother conceded that the tenets of her religion did not necessarily preclude vaccination, she argued that her interpretation and strict adherence thereto did. Finding that the foster mother's opposition to immunization was rooted in genuine and sincerely held religious beliefs, the judge determined that she qualified for New York's religious exemption and denied the agency's request for a court order directing the immunization of the foster children.[244]

In another case, the U.S. Court of Appeals for the Second Circuit upheld a lower court's determination that the constitutional rights of a mother, who failed to demonstrate that she sincerely held religious objections to immunizations, were not violated by the school district policy requiring persons requesting religious exemptions to complete individualized questionnaires concerning the nature of their objections.[245] Based upon the language in state law, the Wyoming Supreme Court held that the state was not authorized to hold hearings to judge the sincerity of a parent's religious beliefs before a religious waiver to state immunization requirements would be granted.[246] In a recent case, a federal appellate court dismissed the plaintiffs' claims that a New York immunization law requiring vaccination for school entry (subject to medical and religious exemptions) was unconstitutional. The court also dismissed the parents' challenge to a state regulation allowing unvaccinated children to be excluded from public school based on outbreaks of vaccine-preventable diseases.[247]

In another case, a federal trial court denied a mother's application for a preliminary injunction against a local department of education to admit her unvaccinated child to school under a religious exemption, finding that the objections articulated by the mother had a medical, and not a religious, basis.[248] In a similar case, a federal appellate court upheld a decision that parents failed credibly to demonstrate that they held genuine and sincere religious beliefs that prohibited vaccinations for their child, as required to establish religious-based exemption from the state's immunization requirement.[249]

In another case, a federal appellate court held that West Virginia has a compelling interest in requiring children to be vaccinated before allowing them to attend public school and that a child's rights were not violated when her request for a medical exemption was denied. The court concluded that the state's immunization statute, which did not include a religious exemption, was not facially invalid under the federal Constitution.[250]

Another set of cases concerns the rights of parents and vaccination requirements in the context of guardianship issues. In one case, the Supreme Court of Oregon concluded that the Department of Human Services, which had been named the legal custodian and guardian of eight siblings, held the power to approve their immunization. The parents of the eight children raised religious objections. The court concluded that the ability to assert a religious exemption did not apply, given that the Department had acquired custody and guardianship over the children.[251] A federal district court reached a similar conclusion. In that case, custody of a plaintiff's minor children had been awarded to the local county. While in the county's

care, the children were vaccinated by order of a juvenile court. Plaintiff alleged that this was a violation of her First Amendment rights, as she objected to the vaccinations on religious grounds. The court concluded that such vaccinations did not violate plaintiff's constitutional rights, noting that local authorities may constitutionally mandate vaccinations, that the right to practice religion does not include parental liberty to expose the community or a child to communicable disease, and that states are not required to provide a religious exemption from compulsory immunization.[252]

In another case arising from a child protective proceeding, the plaintiff appealed from a ruling that she had neglected her child and that the Administration for Children's Services could direct that her child be immunized. A New York appellate court upheld a lower ruling that the plaintiff was not entitled to a religious exemption from the law's vaccination requirements because she failed to prove that her opposition to immunization stemmed from genuinely held religious beliefs.[253]

In the *Matter of Christine M.*,[254] a state court held that it was child neglect for an otherwise responsible parent to refuse to permit his 2-year-old child to be vaccinated for measles during a measles outbreak in New York City absent a demonstration of sincere grounds for a religious exemption. However, the court refrained from ordering immediate vaccination on the grounds that the vaccination would be required when the child entered school and that the measles outbreak had ended by the time of the decision. Another court case arose from a disagreement between the parents of a child whether the child should be immunized. The mother did not want her child to be immunized (based on her family's medical history and her research about the safety of vaccines) and sought the exclusive authority to make this determination for the child. After obtaining the input of a physician, the trial court ruled that the child should be immunized, consistent with the father's desire. The Texas appellate court affirmed this ruling, concluding that the trial court did not violate the mother's constitutional and statutory rights to raise her child and ruling that the physician's opinion constituted sufficient evidence to support the trial court's order.[255]

There are no federal governmental vaccination requirements for the general adult population in the United States. However, certain segments of the adult population (e.g., college students and healthcare professionals) may be subject to particular vaccination requirements imposed by schools or employers. Members of the armed forces are also required to receive vaccines in certain circumstances. In one case, military personnel subject to orders to receive the anthrax vaccine brought an action against the FDA, the HHS, and the Department of Defense, challenging the FDA's determination that the anthrax vaccine was effective against inhalation anthrax and seeking temporary and permanent relief from Department of Defense's anthrax vaccination program. A federal court granted the defendants' motion to dismiss, finding in part that the FDA did not act arbitrarily or capriciously, that the agency applied its expertise and found that the vaccine was effective for immunization against anthrax, and that service members challenging the Department of Defense's anthrax vaccine requirements lacked standing to bring that claim.[256]

State and employer vaccination mandates for healthcare workers have garnered significant attention in recent years.[257] In *Ritterband v Axelrod*,[258] a New York trial court upheld health department regulations that required hospital employees and medical staff to have current rubella immunizations, finding unpersuasive a staff physician's argument that the vaccination requirement was a violation of the Fourth Amendment protection against unreasonable searches and seizures and a violation of his privacy. More recently, several provider groups sought a temporary restraining order to prevent the enforcement of a New York State regulation requiring healthcare workers with direct patient contact to get the pandemic H1N1 and seasonal influenza vaccines. The regulations permitted medical exemptions only for medical contraindications.[259] A state court judge granted a temporary restraining order against the application of the regulation to New York State healthcare workers, and the governor announced the suspension of the influenza shot mandate for healthcare workers because of vaccination shortages before the order could go into effect. Thus, the lawsuit was dismissed as moot by the New York Supreme Court.[257]

In another case, a hospital required all employees to receive the influenza vaccine (unless the hospital granted an exemption based upon CDC guidance). A benefits coordinator refused vaccination based on her medical and family history and the recommendation of a physician. Because she was not granted an exemption, the employee was fired and applied for unemployment. Such benefits were only available if the coordinator was not fired for cause. The court determined that the hospital's policy was reasonable, but that the employee's refusal to comply under the circumstances was also reasonable. Thus, the former coordinator was entitled to unemployment benefits.[260]

In another case, a hospital required all healthcare workers to receive the influenza vaccine, but permitted exceptions for medical or religious reasons (and persons receiving such exemptions were required to wear a face mask). A nurse who refused the vaccination on secular philosophical grounds (but wore a face mask) was fired. She challenged a decision denying her unemployment benefits and an appellate court in New Jersey found that she was entitled to such benefits because she did not commit misconduct. The court based its finding in part upon the fact that the employer's policy was not based on solely public health grounds, given that it permitted religious exemptions and concluded that her behavior did not undermine her ability to perform her job as a nurse.[261]

SUMMARY, CONCLUSIONS, AND FUTURE IMPLICATIONS

Our nation's experience with the public's perception concerning immunization and other countries' experiences with the same issue make clear that uncertainty and fear often come together when information is lacking. Although most parents seem to believe in the wisdom of vaccination and use their healthcare providers as a key source of guidance in decision making, immunization must never be taken for granted. Although the federal and state immunization programs, together with the VICP, have done a remarkable job of ensuring that our nation's children will be vaccinated against dangerous diseases and although a national surveillance system and several IOM reports confirm the general safety of immunizations given routinely in this country, public perceptions concerning the risks of vaccines remain an important challenge for vaccine administrators to address. Given the outcome of the omnibus autism proceedings, the VICP was shown to have been able to adequately address this phenomenon. Finally, the ability of the VICP to successfully fulfill its mandate and to further its statutory purposes seems strong, particularly given the near-universal consensus among the VICP's stakeholders (i.e., physicians, manufacturers, lawmakers, attorneys, and members of the public, including parents of injured children) that a successful national immunization program can be achieved only with a compensation program and liability safeguards in place. Recent experiences with legislation enacted in preparation for a potential smallpox attack or the emergence of a pandemic flu or other public health emergencies

have emphasized the necessity of providing clear liability protections and fair compensation to ensure the success of vaccination programs across the United States.

The VICP has largely satisfied the public policy imperatives driving passage of the NCVIA in 1986. First, persons found to have sustained vaccine-related injuries (through a presumption of causation under the Table or by demonstrating causation for off-table claims) receive generous compensation in a streamlined process. Second, the availability of compensation under the NCVIA has generally given plaintiffs a sufficient incentive to abandon the pursuit of tort remedies against vaccine manufacturers and administrators.

Claims against vaccine manufacturers are significantly reduced compared with the litigation manufacturers faced at the inception of the VICP. Although claims against healthcare providers are more difficult to track, there is no indication that their liability experience is any different from that of manufacturers. Until the new wave of court cases pertaining to autism, few cases alleging vaccine-related injuries were filed outside the VICP in recent years. The reduction in the number of such civil actions can largely be explained by the fact that the NCVIA requires petitioners to file for compensation under the NCVIA before pursuing outside litigation for alleged vaccine-related injuries or deaths. With regard to post-1988 claims, petitioners have two options once the VICP process is concluded: (a) accept the court's judgment and the compensation awarded (if any); or (b) reject the court's judgment, with the option of pursuing a civil action in state or federal court (under limitations set forth in the NCVIA). most VICP petitioners, even petitioners who were not awarded compensation under the VICP, have chosen the former option. Even among the small number of VICP petitioners who have chosen the latter option (a group consisting almost entirely of persons who were not awarded compensation under the VICP), most have chosen not to pursue further civil remedies. The fact that most VICP petitioners choose to accept the court's judgment and forgo additional civil litigation can largely be explained by the VICP's generous compensation awards, which are devised in an effort to create a lifetime stream of benefits for the injured party, and the general understanding that the VICP imposes a lesser burden on litigants than that imposed in traditional civil litigation. One remarkable feature of the VICP is that all petitioners, including petitioners for whom compensation is denied, receive attorneys' fees and costs so long as their claims were brought in good faith and on a reasonable basis. A new challenge facing the VICP is the proper standard for judging causation-in-fact claims, an issue that is certain to generate a lively debate among the VICP's stakeholders and to result in an increasing number of judicial opinions as new alleged vaccine-injury relationships are examined.

The reported decisions are consistent with the conclusion that vaccine manufacturers and administrators are generally shielded from any significant liability risk. However, the protection is not absolute. Because the NCVIA does not preclude a person who is otherwise ineligible to file a claim under the VICP (e.g., family members of injured persons) from pursuing civil litigation, liability exposure remains a possibility in states where such suits may be brought. However, the Supreme Court decision in *Bruesewitz v Wyeth*, holding that injured claimants are prohibited from bringing design defect claims against vaccine manufacturers in civil court, clarified the scope of the Vaccine Act's liability protections.

A measure of the success of the VICP is the development and administration to children of new vaccines to prevent childhood diseases. Since the creation of the VICP, the following vaccines have been recommended for routine administration to children by the CDC and included in the VICP's coverage: HBV, HAV, Hib, varicella, rotavirus, pneumococcal conjugate, seasonal influenza, meningococcal, and HPV. That since creation of the VICP such vaccines have successfully traversed the long, arduous licensing process to become routinely administered vaccines demonstrates that the scientific community is able to develop innovative vaccine products to combat childhood diseases under the current system. Moreover, recent statutory changes that resolved issues of liability protections and compensation with respect to adverse events and vaccines administered to pregnant women, and expanded the coverage of the NVCIA to vaccines recommended by the CDC for routine administration in pregnant women, but not children, show that the VICP continues to be seen as a successful means of resolving thorny liability issues while making compensation available to those who sustained adverse events.

Another benefit of the VICP has been that liability concerns no longer lead to destabilization of the marketplace. The market experienced some vaccine supply shortages from 2000 to 2015,[262–264] but such shortages did not seem attributable to liability factors.[265] Although many new vaccines are relatively expensive (reflecting the manufacturers' need to recoup the costs of research and development), vaccine prices today seem to reflect public and private sector purchase trends and the effects of inflation, rather than including significant funds to address liability concerns or repercussions. Thus, the existence and general success of the VICP in meeting the public policy objectives underlying the NCVIA have led to a current system in which innovative vaccine products and technologies are developed, the vast majority of American children are immunized against a growing number of diseases that pose a threat to their health, and the small number of persons who sustain adverse events as the result of such immunizations are able to receive appropriate compensation through the VICP.

Despite its successes, the VICP has been criticized for several perceived weaknesses. For example, one criticism is that the liability protections provided by the NCVIA are not absolute (e.g., persons with claims of $1000 or less need not pursue claims under the VICP, vaccine manufacturers and administrators may be liable if a person exhausts his or her remedies in the VICP and then opts to pursue civil litigation outside of the VICP).[265] Another criticism is that the VICP extends only to certain vaccines, rather than to all vaccines. Thus, for vaccines that are not covered by the VICP (e.g., vaccines against Lyme disease, vaccines recommended only for adults), the NCVIA's expedited no-fault process and attendant liability protections are unavailable. The NCVIA's statute of limitations (for injuries, 3 years after the date of the first symptom or manifestation of onset of the injury) also has been criticized. Because this period begins running from the first symptom rather than from diagnosis or any attribution to vaccines, some believe the NCVIA's statute of limitations is particularly unfair as applied to certain illnesses with early manifestations that may be subtle. The fact that claims for damages sustained by persons close to an injured person (e.g., loss of consortium claims by an injured party's spouse) cannot be pursued in the VICP has been criticized.

The compensation limits for pain and suffering as well as for death have also been criticized. In the original Vaccine Act enacted in 1986, the benefit cap for pain and suffering ($250,000) and the death benefit cap ($250,000) were established and have remained unchanged. It has been recommended that these caps be increased to account for inflation.[266] The conflict inherent in litigation may also be seen as a weakness of the VICP when compared with other compensation programs that are purely administrative. Depending on one's vantage point, some of these perceived weaknesses may be seen as strengths (e.g., that the liability protections afforded by the NCVIA are not absolute may be seen as a weakness by persons who see vaccines as an important but vulnerable part

of the public's health but as a strength by injured parties who want to file suit against persons who they believe are responsible for the damages sustained).

Finally, a judicial program such as the VICP is not an ideal system for reaching complicated decisions about whether vaccines are causing particular injuries. Petitioners alleging injuries that meet the requirements of the VIT need not demonstrate to the court that a VICP-covered vaccine caused their injuries to receive compensation. Instead, it is presumed that the vaccine was the cause of the injury unless another cause is proven. Moreover, the majority of VICP cases today are resolved by settlement, in which the court does not determine that the vaccine caused the injury. Despite this, opponents of vaccines may erroneously refer to the number of cases compensated and the amount of money awarded under the VICP as proof that vaccines cause harm.

An increasing focus has been given to the issue of vaccine safety during recent years. Effective vaccine risk communication is imperative and must include a recognition of the difficult and confusing nature of risk assessment and decision making for some vaccines.[267] Such communication is particularly critical now, at a time when most parents do not have an independent recollection of the devastation caused by the infectious diseases prevented by childhood vaccines. Interwoven into vaccine safety awareness are the issues of state mandates for immunization and state-provided exemptions. Vaccination levels among American children remain remarkably high and of vaccine-preventable diseases, generally low. Courts generally continue to uphold the states' police powers to mandate immunization for school entry, while allowing them to provide exemptions for medical, religious, or philosophical reasons. However, the measles outbreak of 2015[268] has contributed to ongoing discussions regarding the value of public health to reduce/eliminate preventable disease versus the rights of individuals to refuse vaccines.[269] In fact, since the outbreak began, at least 16 states have introduced legislation address exemptions to immunizations.[270]

Immunizations have been hailed as one the 10 greatest public health achievements of the 20th century because of their success in eradicating or substantially minimizing the diseases they are targeting within the American population.[271] It has been estimated that between 1924 and 2012, more than 100 million cases of serious diseases were prevented by childhood vaccinations.[272] With waning vaccine-preventable disease, vaccines may be viewed as a routine nuisance procedure to prevent diseases that few, including most young physicians, have actually experienced. In this setting, it is only natural that people will choose to avoid risk when the benefit is not readily apparent and to demand safer products. However, outbreaks of measles and pertussis in 2012 to 2015 have reignited the debate between the value of immunizations versus personal choice.[269,273,274] Medical experts and public health officials must remember that an effective vaccination program can be successful over the long term only if its purposes and methods are well understood by both healthcare personnel and society. The importance of transparency in explaining the vaccination process, risks, and benefits cannot be overstated in helping to maintain an effective vaccination program.

Acknowledgments

We thank the following persons for their assistance in preparing the manuscript: Sarah Atanasoff, MD, Terry Dalle-Tezze, MD, Narayan Nair MD, Ward Sorensen, and Carole Marks from the VICP, HHS; David Benor, JD, Kevin Malone, JD, Christopher Frisina, and Ashley Woolard from the Office of the General Counsel, HHS.

84 Ethics

Arthur L. Caplan and Jason L. Schwartz

Vaccines present a spectrum of novel ethical considerations compared with those associated with other medical interventions. Central to these differences are the role of vaccines in disease prevention rather than treatment, the concurrent interest of vaccination policy in improving the health of both communities and individuals, and the focus on children in many vaccination programs. Formal discussions of ethical issues related to vaccination once concentrated principally on aspects of clinical research and specific topics regarding vaccine safety and financing. Recent events, such as outbreaks of vaccine-preventable diseases, increases in parental vaccine hesitancy and refusal, and the 2014–15 Ebola outbreak, demonstrate the value and importance of a more comprehensive and sustained examination of vaccine ethics. Such an approach offers important insights into all aspects of the vaccine life cycle, from the earliest stages of research through deployment in national and global immunization programs.

ETHICAL ISSUES UNIQUE TO VACCINATION

Ethics of Prevention Versus Ethics of Treatment

Unlike pharmaceuticals and most other medical interventions, vaccines are intended to prevent disease rather than to treat it. The ethics of prevention differ greatly from the ethics of treatment. Chief among these differences are the disparate meanings and interpretations of "risk" in each context.

When treating disease, risks are largely confined to two broad categories: the risks associated with a particular intervention and the risks of doing nothing. These risks are weighed against the potential benefits of a specific treatment and compared with the risk-to-benefit profiles of potential alternatives. Decision making is invariably complicated by the uncertainty associated with any assessment of risks and benefits. Nevertheless, every treatment decision is made based on the evaluation of all options in light of the risks and potential benefits of each, compared with the consequences of doing nothing.

When aiming to prevent disease by means of vaccination, assessing the risk of inaction is more challenging. Here, the physiological consequences of a disease in an individual person must be considered *in addition to* the specific likelihood of acquiring that disease. As a result of successful vaccination programs, the incidence of many vaccine-preventable diseases is extremely low in the United States and other wealthy countries. This complicates efforts to convey the continued necessity of vaccines to parents, many of whom may have never seen or experienced the diseases being prevented. Globally, the risk of diseases is subject to wide geographical, national, and occupational variability. In all cases, high rates of vaccination among communities are widely credited with preserving the low incidence of many vaccine-preventable diseases.[1]

The benefit of high vaccination rates highlights a key difference between the ethics of treatment and the ethics of prevention. Prevention, specifically the prevention of infectious diseases through vaccination, has important implications for individual people and communities. While considerations relative to justice and the allocation of scarce resources have ethical relevance to some treatment decisions, rarely are they primary factors in how care is delivered.

As a form of prevention, vaccination requires juxtaposing individual autonomy against societal best interests. These values are often in alignment, but for some, they present competing arguments regarding the decision to vaccinate. Central to this debate is herd protection, the indirect benefits that result from high vaccination rates in a community and provide additional protection to vaccinated and unvaccinated individuals alike. For some parents or patients, the benefits of vaccination may be seen as being outweighed by the associated risks and costs, however small or unlikely they may be. This is a particularly possible scenario for vaccines against diseases that have virtually disappeared in wealthy countries partly as a result of successful vaccination programs. Those choosing not to be vaccinated would still benefit at least somewhat through herd protection, creating the potential ethical problem of benefiting as a "free rider."

Free riders are those who knowingly share in the benefits of social programs such as vaccination without personally assuming any risks, burdens, or costs, such as the risk of adverse events or the time and expense required to receive vaccines. Numerous vaccine-preventable disease outbreaks among unvaccinated persons suggest that personal reliance on herd protection is often inadequate.[2,3] Such decisions also increase the overall risk of vaccine-preventable disease in communities, particularly for their members too young to receive a vaccine or unable to do so because of medical contraindications. Those who knowingly benefit from the actions of others without sharing in the burden or cost of providing that benefit act in an unethical manner.

Target Populations and the Routinization of Vaccines

The significance of healthy children as the largest target population for vaccines cannot be overstated. Young children are ethically vulnerable because they cannot exercise their own autonomy to mediate issues of risk and benefit. With a majority of vaccinations in the United States and other countries recommended for children in the first 24 months of life, vaccine recipients are typically among the most ethically vulnerable of populations. Attention by vaccine stakeholders to vaccine-related risks, whether confirmed or alleged, is understandably heightened with respect to children, as is the importance of the potential benefits of routine, on-time vaccination. While striving to make decisions that are in a child's best interests, parents and guardians must navigate a sea of at times conflicting information related not only to vaccines, but also to all aspects of their child's medical care.[4–6] Widely publicized claims by critics of vaccines questioning the safety and value of vaccinations have added to the challenges faced by parents striving to make responsible and informed decisions about their children's health.

Ironically, communication efforts may be hampered as a result of how routine childhood vaccination has become in large parts of the world. Amid competing demands on healthcare providers' time, efforts to explain the continued importance of vaccination to parents may suffer. Absent unique

concerns raised by parents or providers, communication about vaccines may be left instead to a few short questions and answers or reliance on government-required printed information statements.[6] The routinization of vaccines is amplified by state laws in the United States requiring vaccination against many diseases as a condition of school or daycare attendance. This atmosphere of familiarity partially explains the widespread alarm generated by reports of vaccine-related safety concerns, regardless of whether the concerns are confirmed, alleged, or simply a matter of rumor.

ETHICAL CONSIDERATIONS IN THE VACCINE LIFE CYCLE: AN OVERVIEW

While the preceding discussion highlights some of the unique attributes of vaccines and vaccine decision making, their research, development, and regulation are similar in form and function to those of pharmaceuticals and other medical interventions. The following sections provide an overview of relevant ethical considerations at various stages of the vaccine life cycle, a period that begins with the earliest basic research and extends through licensure and all dimensions of national and international vaccine production and distribution programs.

Research and Development

The successful development of new discoveries increasingly relies on collaborations among academic scientists, government researchers, small biotechnology firms, and large, multinational vaccine manufacturers. Although financial support for this work has traditionally come from a combination of commercial investment and government-sponsored research awards, philanthropic groups and public–private partnerships have become increasingly active supporters of vaccine development, particularly for disease targets that lack large potential markets (and thus profitability) in wealthy countries.

Such a diverse group of research entities and funders all but assures a collection of differing research priorities, objectives, and measures of success. While all contributors share the general aim of developing safe and effective vaccines, conflicts may arise regarding how best to achieve this goal.[7] If unchecked, such conflicts could impede progress toward novel vaccines, waste limited financial resources, and fail to respect the contributions of human research subjects. Large research partnerships have the potential to advance public health in ways that would occur much more slowly, if at all, if attempted by individual entities. While respecting their obligations to shareholders, boards, or other overseers, all contributors to vaccine research and those who invest in their work should remain keenly aware of the morally distinguishing ability of their work to save lives, prevent suffering, and greatly improve global health.

Research partnerships become even more ethically complex when they include clinical research in developing countries. This is especially important as vaccine development efforts increasingly target diseases common in developing countries, often through collaborations in which Western researchers have a leading role. These activities bring needed expertise and capabilities to countries often lacking robust medical research infrastructures and stable health systems, even before considering the potential direct benefits successful new vaccines may bring. During this research and development process, local researchers and health ministries ought to be involved in a meaningful way in all aspects of clinical research taking place in their countries. The benefits of such relationships are many. For example, they may provide additional knowledge and training for local health officials, expertise that could benefit communities long after research has concluded. Meaningful contributions from local officials also create an additional layer of protection to ensure that the generosity of volunteers is not exploited by research that very often would have been deemed unethical had it been proposed for populations in wealthy countries.

No topic related to vaccine research has generated more controversy on ethical grounds than the designs of clinical trials, particularly those in developing countries.[8–12] As an example, one prominent and ongoing debate for nearly 20 years has centered on HIV vaccine trials in developing countries, particularly the level and duration of care that ought to be provided to research subjects who become infected during trials.[13–18] Options range from lifelong treatment with the latest in antiretroviral medications—the norm in many developed countries but highly uncommon elsewhere—to whatever the typical treatment is in the country where the trial took place. Such a level of care is often well below that of the research sponsors' home countries. It may be nothing. Because of the significant consequences of this debate to the feasibility of future research, attempts at reaching consensus on the question of which standards should prevail have largely failed.[13,15] This longstanding and still unresolved debate provides a useful example of the value of robust discussions of ethical considerations *before* controversies develop and decisions cannot be undone.

Vaccine development can never be immune from the twin pressures of personal advancement and corporate profitability. Nevertheless, the world community is best served by vaccine research programs that match these concerns with a continued acknowledgment of the enormous suffering that can be averted by vaccines and respect for the individual people and communities volunteering to assist in clinical research.

Finally, concern for justice requires that the populations in which a vaccine candidate is studied mirror as closely as possible the groups expected to receive the licensed product. The use of mentally handicapped children as primary sources of vaccine research subjects in the 1950s and 1960s exemplifies how this principle was violated in the past.[19] These children often lived in overcrowded institutions with sanitary conditions that placed them at increased risk for the diseases for which potential vaccines were being tested. New vaccines would have been particularly valuable to these children, who also provided a convenient, accessible study population for researchers.

However, mentally handicapped children in state institutions are among the most vulnerable of populations, for whom clinical research is ethically appropriate only in extremely limited circumstances and always with strict oversight. In pursuit of vaccines that would benefit society broadly, the past use of these children as a primary study population often violated this fundamental and timeless tenet of research ethics.

Today, the opposite extreme has become common. Manufacturers have a strong disincentive to include among their research subjects members of potentially high-risk populations, such as pregnant women or children with intellectual disabilities. Without complete data on safety and efficacy in all populations to whom a vaccine will be administered, patients, parents, and policymaking bodies have inadequate information on which to base their decisions regarding vaccination in these groups. The vaccine research and regulatory communities should remain aware of past exploitation of vulnerable research subjects but strive to conduct clinical research in ways that protect subjects while providing as complete a picture as possible of a vaccine's safety and efficacy profile.

Licensure and Safety Monitoring

Vaccines are subject to oversight and regulation by a variety of entities in every country where they are available.[20] It is initially determined whether a new vaccine should be licensed, and if so, the populations for whom it should be recommended. In the United States, these responsibilities belong to groups within the Food and Drug Administration (FDA) and the Centers for Disease Control and Prevention (CDC), respectively. For the life of the vaccine thereafter, activities are undertaken by these groups in collaboration with its manufacturer to monitor its safety and efficacy.[20,21] These processes have generated considerable controversy in recent years, threatening public confidence in vaccination.[22] As the success of vaccination programs depends on earning and maintaining public trust, there are several points in vaccine regulation at which ethical considerations are relevant to public policy.[9,23]

A primary concern of critics of vaccine policy in the United States is the potential for conflicts of interest among government advisors and researchers who have ties, financial or otherwise, to vaccine manufacturers. The very nature of vaccine development presents unique challenges in avoiding even the appearance of a conflict. Any researcher working on novel vaccine candidates *must* eventually partner at some point with industry owing to the infrastructure needed for large-scale clinical testing and development. To exclude all such researchers for this reason would be to forfeit a wealth of expertise and wisdom on vaccine science and policy, ignoring internationally respected leaders in vaccine science.

However, the importance to vaccination programs of maintaining public trust demands that those contributing to policy exercise particular caution and care regarding their professional and financial relationships. Most advisory bodies have clear policies regarding the disclosure of potential conflicts of interest.[24,25] Even when confident that financial relationships would have no impact on their actions, individuals should remain highly attentive to how such interests might affect the manner in which the decisions to which they contribute may be perceived. Transparency, minimization of personal gain, divestiture, and disclosure are crucial principles that work to counteract the perception of conflict of interest influencing decision making.

Public attention to conflicts of interest among policymakers and their expert advisors is often linked to reports of vaccine safety concerns. The public health and regulatory communities should respond vigorously to reports of vaccine-associated adverse events, even if they initially seem unlikely. Passive surveillance programs, such as the Vaccine Adverse Event Reporting System in the United States, are valuable tools in this effort, but their limitations as hypothesis-generating mechanisms should be clearly and repeatedly conveyed to the public and the media.[26] Emerging patterns of possible safety problems should be explored thoroughly, with the results of these analyses promptly communicated to the public. Even when evidence suggests that a reported safety concern is unfounded, experience shows it is unlikely that any such assurance will allay the worries of all. Nevertheless, open, expeditious, and objective examinations of possible vaccine-associated safety concerns are essential to maintaining overall confidence in vaccination programs and their oversight.[22,27]

It is known that a small number of persons will genuinely be harmed as a result of vaccines. Because vaccination benefits communities, victims are entitled to compensation for their suffering in these rare cases. In the United States, the Vaccine Injury Compensation Program is the principal mechanism for resolving such issues.[28] By means of a no-fault system with funds collected via a tax on every vaccine dose, the system provides compensation without exposing manufacturers to substantial legal and financial risk.

This program has faced scrutiny in recent years regarding how claims are resolved and the scope of its coverage. The Omnibus Autism Proceeding and the case of *Bruesewitz v Wyeth* heard by the U.S. Supreme Court in 2010 represented challenges to aspects of the federal government's system for identifying and compensating vaccine-related injuries.[29,30] In the Omnibus Autism Proceeding, theories that the measles-mumps-rubella vaccine and the vaccine preservative thimerosal could, individually or in tandem, cause autism in vaccine recipients were extensively examined and unequivocally rejected by the special masters who evaluate claims for compensation. *Bruesewitz v Wyeth* affirmed the primary role of the federal Vaccine Injury Compensation Program, not state laws or civil proceedings, in assessing vaccine-related adverse events. Given the concomitant challenges of compensating victims fairly, accurately distinguishing correlation from causation regarding adverse events, and ensuring that manufacturers remain committed to developing and manufacturing vaccines, the current design of the Vaccine Injury Compensation Program is a generally fair way of resolving these ethical obligations.[31]

Vaccine Supply, Access, and Financing

The highly publicized influenza vaccine shortage in 2004 and many other shortages for recommended childhood vaccines underscore the vulnerability of vaccine supply worldwide.[32,33] With limited manufacturers and often only a single licensed product available in a country, vaccines are highly susceptible to large fluctuations in supply and availability owing to unforeseen events.[34–36] In the United States, CDC stockpiles of recommended vaccines are maintained to provide a temporary buffer in case of production or supply problems, but these efforts provide only limited protection.[37,38]

A spectrum of economic and business considerations helps explain why many manufacturers have left the vaccine market and why the remaining manufacturers are not eager to develop new products to compete with older vaccines that, in general, are able to meet demand.[34,35] Finding incentives to increase the number of vaccine manufacturers and to encourage development of new vaccines for common diseases would help ensure a more resilient vaccine supply landscape that is better insulated against the shortages that have become increasingly common.

Even when vaccine supplies are adequate, vaccination rates reflect many of the same racial and ethnic disparities in access present throughout medicine.[39,40] While the underlying causes of these conditions are debated, several programs seek to eliminate vaccine cost as an obstacle to childhood vaccination in the United States, most notably the Vaccines for Children program for uninsured and underinsured children.[41] Established in 1994, this entitlement program makes vaccines recommended by the CDC's Advisory Committee on Immunization Practices available free of charge to children in these groups. The size and cost of the program has grown with additions to the recommended vaccination schedule, especially since the 1990s; in 2016, its annual budget surpassed $4 billion.[42]

With respect to private health insurance in the United States, under the Affordable Care Act, new insurance plans must provide coverage for any vaccine recommended for routine use in children or adults by the Advisory Committee on Immunization Practices.[42] No copayment, coinsurance, or deductible can be required from the insured patient. This provision for vaccines is part of a spectrum of preventive services required of new private insurance plans. According to the

Institute of Medicine, an estimated 11 million children and 59 million adults had private insurance that did not adequately cover costs related to immunization prior to the passage of the Affordable Care Act, a shortcoming that the law is quickly correcting.[43]

In comparison with children and insured adults, uninsured adults in the United States face far greater financial obstacles to vaccination. With an increasing number of vaccines recommended for adults but no program similar to Vaccines for Children, the affordability of vaccines for uninsured adults remains a substantial challenge. Federal funding through the Section 317 program to state and municipal grantees has long provided some assistance in this area, but the available funds have long been outstripped by the needs in this area, all the more so as the adult vaccination schedule has also expanded in recent years.[41] Federal and state governments, in collaboration with vaccine manufacturers, should identify strategies that would reduce these financial obstacles to adult vaccination. The laudable patient assistance programs organized by several vaccine manufacturers may provide a foundation for more expansive efforts in this area.

Vaccination Requirements, Hesitancy, and Refusal

Governments worldwide use a variety of approaches to promote high vaccination rates among their citizens.[41,44–46] The United States is generally unique in its reliance on federal recommendations coupled with state school-entry vaccination requirements as central contributors to the success of vaccination efforts. While specific requirements vary among states, all require that children receive a series of vaccinations as a condition of attending public schools or state-licensed daycare facilities.[47] Every state allows for exemptions based on medical grounds, and nearly all also accept religious or philosophical reasons, although not every state includes all three types of exemptions.[48]

No topic related to vaccine ethics in the United States is the subject of more public scrutiny and, at times, controversy than state vaccination requirements. The debate reflects not only the common tension in public health policy between individual (or parental) autonomy and the public good, but also questions over the role and extent of government intervention to protect the well-being of children. Requirements promote vaccination for individual children, while also striving to limit the potential transmission of diseases among communities to the greatest extent possible. School-entry requirements have long been seen by public health officials as essential to maintaining vaccination rates sufficiently high to preserve herd protection, particularly when other vaccine education and promotion efforts have failed.[49] The high vaccination rates associated with herd protection offer benefits against vaccine-preventable diseases to all members of a community, including those too young to receive vaccines, those unable to do so because of medical contraindications, and those who were vaccinated but did not generate the typical, adequate immune response needed for personal protection.

For those whose views on medical ethics are guided by the primacy of patient autonomy, it is understandable why U.S. vaccination requirements are so contentious. However, few contemporary ethical models place autonomy absolutely above all other considerations. Instead, respect for autonomy is typically one of several factors that should be examined in light of other relevant considerations as part of ethical deliberation and decision making. There is a compelling argument that the lives saved and suffering prevented by vaccination outweigh the potential infringement on personal autonomy created by school mandates. While one may be free to make medical decisions that place one's own health at risk, one may not jeopardize the health of others, a consequence of low vaccination rates within a community. Even in an autonomy-oriented culture such as the United States, there are ethical reasons to place some limits on individual choice.

An ethically preferable scenario would be maintaining current high rates of vaccination without needing the force of mandates to do so. Absent evidence that this is attainable in the United States, the current policy is sound. Mandates serve as a "safety net," a valuable tool to call attention to the importance of vaccines and help direct government and public health resources to vaccination efforts.[47] Exemption policies provide a ready alternative in nearly all states for persons whose personal beliefs do not coincide with protecting their child against vaccine-preventable disease to the greatest extent possible or with promoting public health in their communities. Combined with incomplete enforcement by state health departments or local school districts, current policies fall far short of true compulsion. They are, instead, best understood as presumptive or default approaches to vaccination.

Even though national rates of nonmedical exemptions remain quite low, recent trends—particularly clusters of voluntarily unvaccinated individuals in some communities—are of deep concern to advocates of vaccination.[50] Recent outbreaks of vaccine-preventable diseases, particularly the 2015 measles outbreaks in the United States, prompted calls to reevaluate the compromise reflected in the current approach to vaccination requirements and exemptions.[51] Proposals to eliminate nonmedical exemptions entirely—as has been the case for many years in West Virginia and Mississippi—have been debated in numerous states, and passed in California in 2015. Other proposals have sought to preserve such exemptions but to impose additional administrative burdens to make them more difficult to obtain, an approach shown in states with similarly rigorous procedures to successfully reduce the rate of nonmedical exemptions.

Although a principled and persuasive argument can be made for the elimination of all nonmedical exemptions, some advocates of vaccination worry that a potential public backlash and resulting challenges in enforcement might lead to such reforms actually doing more harm than good to vaccination rates and vaccination programs overall. The experiences of states like California that move to eliminate exemptions should be watched closely to assess whether these hypothesized concerns are or are not realized as new policies are approved and implemented.

These various proposals to restrict or eliminate exemptions all reflect the increasingly clear and ethically defensible assessment that current policies in this area place unvaccinated children and their communities at an unacceptable, elevated risk of preventable disease. At the same time, these legislative approaches to ensuring high vaccination rates must be viewed as part of a comprehensive education and promotional effort that aims to grow and sustain the widespread foundation of public support that remains in the United States. This confidence in the value of vaccination is reflected in high vaccination rates in young children long before they are likely to encounter school or daycare requirements, and it persists despite discouraging trends in vaccine hesitancy and refusal among a small, but growing minority.

A related issue is how physicians and other healthcare providers should respond to parents who desire an alternate approach to vaccination than the evidence-based recommendations developed by public health and medical authorities, such as the schedule in the United States developed by the CDC, the American Academy of Pediatrics, and other medical professional organizations.[4,52] At issue has been whether physicians should decline to care for children whose parents wish

to delay or omit some or all recommended vaccines. Advocates of this view believe it would clearly signal physicians' unambiguous position on the importance of on-time vaccination, and it would reduce the theoretical risk unvaccinated children would pose to other patients in waiting rooms. Critics, including the American Academy of Pediatrics in a longstanding policy statement, believe dismissal of patients in this context should be reserved for the very rare circumstance when conflicts between the views of the physician and parents present a profound impediment to the provision of care to the child.[52] In nearly all other circumstances, the American Academy of Pediatrics recommends continuing to provide care, in hopes that a growing relationship of dialogue and trust between physicians and parents may lead to a changed position over time. Otherwise, children of parents who delay or decline vaccines may be left without advocacy and find themselves cared for by physicians who are willing to accept any (or no) approach to vaccination, a harmful outcome for those children and their communities alike.[4]

SPECIAL TOPICS IN VACCINE ETHICS

Healthcare Providers

Healthcare providers have a twofold role in the success of disease-prevention efforts through vaccination. Considerable evidence points to the importance of recommendations from physicians and other providers as being among the most effective ways to influence the perceptions and decisions of parents regarding vaccines, particularly parents with reservations or questions.[53] Amid conflicting information and contentious debates about the safety, effectiveness, and value of vaccines, healthcare providers can help patients (or parents or guardians) make sense of the science and evidence so often obscured by unproven allegations and anecdotal evidence. Doing so effectively requires sustained attention by providers to new information about vaccines—particularly vaccine safety—and the time and willingness to engage parents with concerns or uncertainty.

Healthcare providers can also demonstrate the value of vaccination by ensuring that they are personally up-to-date on recommended vaccines. Beyond the symbolic value of this action, vaccination of providers protects patients, particularly in hospital settings where diseases like influenza are easily transmitted.

Maintaining high vaccination rates against seasonal influenza among healthcare providers has proven to be a considerable challenge, despite the vaccine being recommended for this group since 1981.[54] A variety of programs, including those involving incentives for compliance and appeals to professional duty, have generally failed to yield adequate vaccination rates, prompting an increasing number of healthcare facilities to mandate annual influenza vaccination as a condition of employment.[55] In light of the consistent failure of voluntary approaches to improve influenza vaccination rates among healthcare workers, mandatory vaccination policies, which now exist in more than 600 hospitals and nursing homes throughout North America, are an appropriate response.[56] This is particularly true in light of the increased susceptibility to infection among many patients in hospitals and related settings.

Vaccination in the Developing World

Special ethical considerations related to vaccines in the developing world extend beyond the research issues discussed previously. A particular challenge is ensuring that new vaccines are introduced against diseases that are most prevalent or most severe in those nations but uncommon or mild in developed countries. Owing to the limited profitability of such vaccines, manufacturers are often reluctant to invest in these efforts, with occasional exceptions for diseases relevant to national security or biodefense.[57,58] Much of the remaining work, at both early and late stages of development, is therefore supported by private philanthropies, nonprofit entities, and public–private partnerships. These efforts should continue to be encouraged so that the benefits of vaccination may be more equitably distributed among all populations. For vaccines developed by corporate manufacturers, work should continue to develop financing arrangements that ensure that existing products are available to populations in developing countries that in many cases stand to benefit most from them.

When organizing vaccine distribution programs, particular respect should be paid to cultural traditions and social customs specific to communities in the developing world. In locations where healthcare infrastructures are radically different from those of wealthy countries, successful vaccination efforts depend on embracing these differences, valuing the input of community leaders, and striving to develop programs that gain widespread support.

Finally, efforts should be undertaken to better understand the concept of consent in the context of developing world vaccination programs. Informed consent in the strict Western sense may not always be attainable, nor may it be a reasonable expectation owing to the varying structures of communities and families present throughout the world. However, vaccination efforts should remain faithful to the spirit of informed consent, with those administering vaccines taking steps, as appropriate, to ensure that surrogates offer consent for recipients and that local and international ethics committees closely supervise research when individual informed consent is weak.

Eradication Campaigns

The global eradication of smallpox, certified by the World Health Organization in 1980, remains one of the foremost achievements in the history of public health.[59,60] By means of a coordinated, extensive vaccination campaign, a disease that had been the cause of untold suffering and death for centuries was effectively eliminated. The successful eradication of smallpox added to the enthusiasm for other eradication campaigns against vaccine-preventable diseases, including those then already underway and others hypothesized at the time. This enthusiasm has continued, despite as yet insurmountable challenges in adding additional diseases to the list of those eradicated.

Measles and polio have long been among the most prominent targets of eradication efforts, and eradication is now mentioned as a target for malaria, a disease for which a partially effective vaccine recently has been developed.[61,62] In recent years, most attention has been directed toward the potential eradication of polio, a goal that seems tantalizingly close in light of the limited number of identified cases (considerably below 500/year for several years) and the three countries where the disease remains endemic—Afghanistan, Pakistan, and Nigeria.[63] The unique characteristics of poliovirus have presented significant challenges for the potential eradication of the disease, despite laudable attention and enormous investment in the effort, much of it supported by philanthropies including The Bill and Melinda Gates Foundation and Rotary International.[64] Horrific attacks on polio vaccination workers in both Pakistan and Nigeria have added a human toll to the already considerable costs and challenges of the continued pursuit of polio eradication.[65] A rare but very serious adverse event, vaccine-associated paralytic poliomyelitis, associated with the oral polio vaccine that has long been central to

polio eradication efforts in developing countries presents still further questions regarding the ethics of eradication.

The obstacles and risks related to the continued pursuit of polio eradication have prompted some observers to suggest that a better overall strategy for global health is to maintain current levels of control while redirecting the sizable resources (both financial and personnel) currently going toward polio eradication campaigns to the many other causes of preventable morbidity and mortality worldwide.[66] A necessary and important debate has ensued among scientists, ethicists, and global health scholars.[67,68] The symbolic significance of disease eradication carries an allure that may not necessarily coincide with evidence-based approaches to global health policy. Because global health resources are limited, policymakers and funding sources should ensure that attention is directed to the prevention and treatment strategies that will prevent the most suffering and thereby do the most good.

Vaccines and Public Health Emergencies

Concerns about anthrax or smallpox bioterror attacks in the aftermath of September 11, 2001; preparedness efforts in the early 2000s for an avian influenza pandemic and the subsequent pandemic caused by a novel strain of H1N1 influenza in 2009–10; and a series of emerging or reemerging infectious diseases including severe acute respiratory syndrome and Ebola have all called attention to the critical role that the development and deployment of vaccines can play in responding to public health and global health emergencies.

The 2009–10 H1N1 influenza pandemic provided a real-time test of global preparedness and planning for a potential influenza pandemic. While much of this planning had focused on the threat of H5N1 (avian) influenza, those preliminary activities served as a valuable foundation for the response to H1N1 influenza. Vaccines were central to those planning and response efforts.[69–72] Within weeks of the identification of a potential pandemic strain of influenza in April 2009, the process of developing seed stocks for an eventual vaccine began.[73] The total time required to produce the first doses of vaccine adhered fairly closely to the long-predicted estimate of 6 months. By the time vaccine was widely available in late 2009, public interest had waned, in part a result of a growing understanding of the relatively modest severity of the virus.

Despite having overall impacts well below some of the most dire forecasts, the 2009–10 H1N1 influenza pandemic was still a significant cause of infection, illness, and death worldwide, particularly among children. It thereby provided valuable knowledge and experience that will inform subsequent planning and response activities for public health emergencies for which vaccines may be available, including potential pandemics and acts of bioterrorism. Among the topics that have received scrutiny are the communication of accurate information about the severity of threats amid uncertainty, the efficiency of vaccine development and the need for greater production capacity and novel technologies, the adequacy of testing and postlicensure safety surveillance, the development of appropriate prioritization strategies, the structure of financing and distribution systems, and the allocation of vaccine to countries in the developing world. As these retrospective analyses are translated into plans for subsequent public health emergencies, public health officials should aim above all to ensure that vaccination programs are designed to maximize benefits and minimize risks fairly among communities, populations, and nations.

As demonstrated in 2009, the urgency that follows the arrival of public health threats makes thoughtful discussion of these topics in real-time all but impossible, making it all the more important to engage in public deliberation and planning well in advance of public health emergencies. In particular, it is necessary to achieve and maintain public consensus on the rules that will govern allocation and rationing. Unless the rules are widely perceived as fair—arrived at by reasonable, open procedures—and just—helping persons at greatest risk while maximizing the public good—response plans are unlikely to gain acceptance.

Similar evidence of the challenges of debating complex scientific, public health, and ethical aspects in the midst of an unfolding health emergency was shown in the response to the 2014–15 Ebola outbreak concentrated in West Africa. Many of these issues pertained to aspects of the response unrelated to vaccines, such as the quarantines and travel bans endorsed by some elected officials in the United States despite a consensus among the scientific community that they were at best unnecessary, if not outright harmful to the response.[74] However, questions also arose regarding how to strike the appropriate balance between rigorously evaluating the safety and effectiveness of potential Ebola vaccines and urgently responding to what, in late 2014, was an unprecedented and out-of-control health crisis in the affected countries. At issue was how to design trials that would provide valid data regarding those vaccines without imposing undue delays on the availability of vaccines (or, similarly, pharmaceuticals) that had at least some potential to aid in the response.

With valuable coordination from the World Health Organization, the global community quickly debated the relative merits—both scientific and ethical—of randomized controlled trials versus other designs, as Ebola vaccine candidates that had received limited attention and investment for years were quickly accelerated into clinical testing.[75,76] Proponents of randomized controlled trials noted that those methods would provide the strongest, clearest evidence of the safety and effectiveness of any vaccine.[75] Advocates of alternative designs—such as nonrandomized approaches, stepped-wedge designs, and others—believed that the magnitude of an unfolding public health emergency necessitated novel approaches that would make potentially valuable interventions available as quickly as possible to as many people as possible, goals to which randomized designs may not be best suited.[76,77]

By early 2015, large-scale clinical trials of multiple vaccines were ready to commence, incorporating both randomized trials and alternative approaches. However, the apparent waning of the outbreak in the countries most severely affected by Ebola by spring 2015 made it likely that the trials might not provide clear evidence of the effectiveness of the vaccines. Such evidence, invaluable to the use of Ebola vaccines to prevent and respond to future outbreaks, may now have to be inferred from other sources such as animal studies or immune response analyses.

While the global community should be commended for the frank and highly engaged discussion regarding the testing and use of unlicensed interventions as part of the Ebola response, the experience again underscores the value of proactive deliberation on issues related to research methodology and ethics in response to public health emergencies. Also, that Ebola vaccine development languished for years because of a lack of investment from public or private sources and the absence of an obvious commercial market provides further evidence for the need to pursue novel strategies to accelerate vaccine research for diseases that have been neglected by the traditional development pathways unless and until a crisis emerges.[78]

THE FUTURE OF VACCINE ETHICS

The study of ethical issues in vaccination has received increasing attention in recent years, but there still have been relatively

few concentrated attempts at broad exploration. Those attempts to examine vaccine ethics at a level larger than a single topic or debate have produced valuable results and can serve as models for future efforts.[79,80] A need continues to exist, however, for the creation of frameworks and key principles for ethical decision making throughout the vaccine life cycle. Such work would move us closer to solutions or consensus for many of the questions raised in this overview. These efforts would do far more good if they occur proactively, long before controversies or crises surface.

Advances in vaccination are attributable to gains in scientific knowledge, breakthroughs in research, and the creation of sound public health policy, among many other factors. Ultimately, however, the success of vaccination depends on maintaining widespread public trust, without which vaccination programs cannot succeed.[23] Preserving trust requires an unwavering awareness that the remarkable societal benefits of vaccination ultimately involve individual people who are entitled to respect, in a broad sense, that manifests itself at every point in the vaccine life cycle. By remaining sensitive and responsive to the consideration of ethical challenges, vaccination is best positioned to add to its history of public health triumphs.

APPENDIX Websites and Applications for Mobile Devices With Information About Immunization

Deborah L. Wexler, Teresa A. Anderson, and Mary R. Quirk

Note: Since the sixth edition of *Vaccines* was published, many organizations have begun offering social media features and applications (apps) for mobile devices in addition to their websites. This edition of the appendix includes some of these resources.

CENTERS FOR DISEASE CONTROL AND PREVENTION (CDC) WEBSITES

National Center for Immunization and Respiratory Diseases (NCIRD)

- www.cdc.gov/vaccines

NCIRD is an interdisciplinary immunization program that brings together vaccine-preventable disease science and research with immunization program activities. Its website provides information about vaccine-preventable diseases, the benefits and risks of immunization, vaccine licensures, Advisory Committee on Immunization Practices (ACIP) recommendations, Vaccine Information Statements (VISs), and vaccine supply issues, as well as educational resources for the public and healthcare professionals.

ACIP is composed of 15 experts in fields associated with immunization who provide guidance on the control of vaccine-preventable diseases. ACIP recommendations are available at: www.cdc.gov/vaccines/acip.

- CDC vaccine schedules app: https://itunes.apple.com/us/app/cdc-vaccine-schedules/id875273858?mt=8

Morbidity and Mortality Weekly Report (Weekly Publication)

- www.cdc.gov/mmwr
- Twitter: https://twitter.com/DrNancyM_CDC
- *MMWR Express* app: https://itunes.apple.com/us/app/mmwr-express/id868245971?mt=8

Influenza

- www.cdc.gov/flu

CDC's influenza website includes information for healthcare professionals and the public on influenza prevention, clinical and laboratory diagnosis, treatment, surveillance, and issues for specific groups as well as educational tools.

- Twitter: https://twitter.com/CDCFlu
- CDC Influenza app: https://itunes.apple.com/us/app/cdc-influenza-flu/id577782055?mt=8
- CDC FluView app: https://itunes.apple.com/us/app/fluview/id507807044?mt=8

Immunization Safety Office (ISO)

- https://www.cdc.gov/vaccinesafety/iso.html

ISO identifies possible vaccine side effects, conducts epidemiological studies to determine whether an adverse event is caused by a vaccine, helps determine the appropriate public health response to vaccine safety concerns, and communicates the benefits and risks of vaccines.

National Center for HIV/AIDS, Hepatitis, STD, and Tuberculosis Prevention (NCHHSTP)

- www.cdc.gov/nchhstp

NCHHSTP is responsible for public health surveillance, prevention research, and programs to prevent and control HIV, hepatitis, other sexually transmitted diseases, and tuberculosis.

- Viral hepatitis information: www.cdc.gov/hepatitis
- Human papillomavirus virus (HPV) information: www.cdc.gov/hpv
- Twitter: https://twitter.com/DrMerminCDC and https://twitter.com/DrDeanCDC

Traveler's Health

- wwwnc.cdc.gov/travel

This website provides health information on specific travel destinations, information on disease outbreaks, and ACIP vaccination recommendations for travelers of all ages.

- Twitter: https://twitter.com/cdctravel
- CDC's TravWell app: https://itunes.apple.com/us/app/cdc-travwell/id969599694

OTHER U.S. GOVERNMENT IMMUNIZATION-RELATED WEBSITES

Centers for Medicare & Medicaid Services (CMS)

- www.cms.gov

CMS is the agency responsible for administering programs such as Medicare, Medicaid, and the State Children's Health Insurance Program. A key section is "Immunizations" (www.cms.gov/Medicare/Prevention/Immunizations/index.html), which includes links to pay rates, billing instructions, FAQs for healthcare professionals, and best practices.

- Twitter: https://twitter.com/cmsgov

Dale and Betty Bumpers Vaccine Research Center (VRC)

- https://www.niaid.nih.gov/about/vrc

VRC, part of the National Institute of Allergy and Infectious Diseases, was established to facilitate vaccine development research.

Department of Defense: Defense Health Agency Immunization Healthcare Branch

- www.health.mil/vaccines

This website provides access to current immunization program information for the U.S. Department of Defense

and the military services as well as disease and vaccine information.
- Twitter: https://twitter.com/dha_ihb

Department of Health and Human Services (HHS)

- www.vaccines.gov

HHS maintains this website for the public; it includes information about how to find and pay for vaccination services.
- HHS influenza public website: https://www.vaccines.gov/diseases/flu/

Food and Drug Administration (FDA), Center for Biologics Evaluation and Research (CBER)

- www.fda.gov/BiologicsBloodVaccines

CBER is the part of the FDA responsible for ensuring the safety, efficacy, purity, and potency of vaccine products. Information on currently licensed vaccines and their manufacturers is available at: www.fda.gov/BiologicsBloodVaccines/ucm121134.htm.
- Twitter: https://twitter.com/fdacber

National Vaccine Injury Compensation Program

- www.hrsa.gov/vaccinecompensation

This program, enacted by Congress, is a no-fault alternative to the tort system for resolving claims resulting from adverse reactions to recommended childhood vaccines. The site includes information on how to make a claim.

National Vaccine Program Office (NVPO)

- www.hhs.gov/nvpo

NVPO, which resides within HHS, has responsibility for coordinating and ensuring collaboration among the many federal agencies involved in vaccine and immunization activities. The website provides publications and reports on vaccine preventable diseases and information on vaccine safety, vaccine coverage, immunization laws, immunization registries, and reports by the National Vaccine Advisory Committee (NVAC).

Vaccine Adverse Event Reporting System (VAERS)

- http://vaers.hhs.gov

VAERS is a postmarketing safety surveillance program that collects information about adverse events that occur after the administration of U.S.-licensed vaccines. This website provides a nationwide mechanism by which adverse events following immunization can be reported, analyzed, and made available to the public.

STATE AGENCIES AND PROGRAMS

State Immunization Websites

- www.immunize.org/states

This Immunization Action Coalition (IAC) website provides access to all state immunization program websites.

State Immunization Coordinators

- www.immunize.org/coordinators

This IAC website provides access to the names and phone numbers of state and territory immunization program managers, hepatitis B coordinators, adult viral hepatitis prevention coordinators, and Vaccines for Children coordinators.

State Mandates on Immunization and Vaccine-Preventable Diseases

- www.immunize.org/laws

This IAC website provides vaccination mandate information for child care facilities, schools, colleges, and long-term care facilities. CDC also maintains a website related to requirements and laws at: www.cdc.gov/vaccines/imz-managers/laws/index.html.

INTERNATIONAL IMMUNIZATION-RELATED WEBSITES

Bill & Melinda Gates Foundation

- www.gatesfoundation.org

The Bill & Melinda Gates Foundation is dedicated to improving the quality of life for individuals around the world by partnering with organizations to identify issues, find answers, and drive change in the areas of poverty, health, and education. Its Vaccine Delivery Program works to ensure that existing life-saving vaccines are introduced into countries where people need them most and supports innovation to develop new vaccines, as well as new delivery technologies and approaches.
- Vaccine Delivery Program: www.gatesfoundation.org/What-We-Do/Global-Development/Vaccine-Delivery
- Twitter: https://twitter.com/gatesfoundation

Edward Jenner Society

- www.edwardjennersociety.org

The mission of the society is to engage, support, and sustain the professional goals and interests of vaccinologists around the world and to perpetuate the memory of Dr. Edward Jenner.

End Polio Now

- www.endpolio.org

This website documents Rotary International's work in the area of global polio eradication.
- Twitter: https://twitter.com/EndPolioNow

Gavi, the Vaccine Alliance

- www.gavi.org

Gavi is an international organization created in 2000 to improve access to new and underused vaccines for children living in the world's poorest countries. Gavi brings together the public and private sectors with the shared goal of creating equal access to vaccines for children.
- Twitter: https://twitter.com/gavi

Global Polio Eradication Initiative

- www.polioeradication.org

The fight to end polio is led by this organization, which includes Rotary International, UNICEF, CDC, WHO, the Bill & Melinda Gates Foundation, and governments of the world.

International Vaccine Access Center (IVAC)

- www.jhsph.edu/research/centers-and-institutes/ivac

The Johns Hopkins Bloomberg School of Public Health established IVAC to increase access to life-saving vaccines and serve as a source of international vaccine policy information and analysis.

Measles & Rubella Initiative

- www.measlesrubellainitiative.org

The Measles & Rubella Initiative is a global partnership committed to ensuring no child dies from measles or is born with congenital rubella syndrome.

- Twitter: https://twitter.com/MeaslesRubella

Pan American Health Organization (PAHO)

- www.paho.org/english/ad/fch/im/Vaccines.htm

PAHO is an international public health agency working to improve health and living standards of the countries of the Americas.

- Twitter: https://twitter.com/pahowho

PATH

- www.path.org

PATH is a nonprofit organization that works to enable communities to break long-standing cycles of poor health throughout the world. Its Vaccine Resource Library (www.path.org/vaccineresources) offers a variety of documents and links on vaccine-preventable diseases and topics in immunization, including training materials in multiple languages.

- Twitter: https://twitter.com/VaxResources

Safe Injection Global Network (SIGN)

- www.who.int/injection_safety/sign/en

SIGN is a voluntary coalition of stakeholders aiming to achieve safe and appropriate use of injections throughout the world. The website includes resources to assist in developing and managing national injection policies.

Shot@Life

- http://shotatlife.org

Shot@Life, a project of the United Nations Foundation, empowers American citizens to champion vaccines as one of the most cost-effective ways to save the lives of children in developing countries.

- Twitter: https://twitter.com/shotatlife

Viral Hepatitis Prevention Board (VHPB)

- www.vhpb.org

This independent, international, multidisciplinary group of experts works to focus attention on the importance of viral hepatitis and on how to prevent it. Access fact sheets, reports, and articles from the website.

World Health Organization (WHO)

- www.who.int

WHO is the policy vehicle for global public health recommendations. Some of WHO's vaccine-related websites include:

- Index of WHO's vaccine and immunization information pages: www.who.int/topics/vaccines/en
- WHO Department of Immunization, Vaccines and Biologicals: www.who.int/immunization/en
- WHO position papers on vaccines: www.who.int/immunization/policy/position_papers/en

Global Advisory Committee on Vaccine Safety (GACVS)

- www.who.int/vaccine_safety/committee/en

GACVS consists of international vaccine experts who investigate vaccine safety issues of potential global importance. GACVS reports are available at: www.who.int/vaccine_safety/committee/reports/en.

Strategic Advisory Group of Experts on Immunization (SAGE)

- www.who.int/immunization/policy/sage/en

SAGE was established by the director-general of the World Health Organization in 1999 to provide guidance on the work of WHO. SAGE is the principal advisory group to WHO for vaccines and immunization.

Vaccine Safety Net (VSN)

- www.who.int/vaccine_safety/initiative/communication/network/vaccine_safety_websites/en/

VSN is a project aimed at improving global dissemination of reliable web-based vaccine safety information. The VSN newsletter is available at: www.who.int/vaccine_safety/initiative/communication/network/vaccine_safety_websites/en/index3.html.

Immunization Surveillance, Assessment and Monitoring

- www.who.int/vaccines/globalsummary/immunization/scheduleselect.cfm

This web page provides immunization statistics and schedules for individual nations.

- WHO position papers on vaccines: www.who.int/immunization/documents/positionpapers/en

ENGLISH LANGUAGE RESOURCES FROM NON-U.S. ORGANIZATIONS

Immunize Canada

- www.immunize.cpha.ca

This national nonprofit program offers vaccination information and resources for parents and patients.

Canadian Paediatric Society's "Caring for Kids"

- www.caringforkids.cps.ca/handouts/immunization-index

This section of this professional society's website provides information for parents about immunization.

Department of Health, United Kingdom of Great Britain and Northern Ireland

- www.gov.uk/government/collections/immunisation

This website is the official source of immunization information for health and social care professionals in the United Kingdom from the National Health Service. The following National Health Service website is targeted toward parents and patients: www.nhs.uk/Conditions/vaccinations/Pages/vaccination-schedule-age-checklist.aspx.

Health Canada, Immunization & Respiratory Infections Division

- www.phac-aspc.gc.ca/im

This website includes general information on immunization and vaccine safety as well as Canadian-specific material.

Immunise Australia Program

- www.immunise.health.gov.au

The website of the Australian government's immunization program provides information for healthcare professionals, patients, and parents.

ORGANIZATIONS WITH IMMUNIZATION-RELATED WEBSITES

317Coalition

- www.317coalition.org

The 317 Coalition, an alliance of more than 100 U.S. organizations, advocates for increased 317 funding from Congress to ensure that underinsured children and uninsured adults have access to recommended vaccines.

Alliance for Immunization in Michigan (AIM)

- www.aimtoolkit.org

The AIM website provides a toolkit of practical immunization resources for healthcare professionals and the public.

American Academy of Family Physicians (AAFP)

- www.aafp.org

AAFP provides immunization information to providers at: www.aafp.org/online/en/home/clinical/immunizationres.html.

American Academy of Pediatrics (AAP)

- www.aap.org

AAP provides immunization information to pediatricians and parents at www2.aap.org/immunization.

AAP has several apps, including the AAP *Red Book* app (included with a subscription) and *AAP News*: https://www.aap.org/en-us/Pages/Get-the-AAP-Mobile-App.aspx.

American College of Obstetricians and Gynecologists (ACOG)

- www.acog.org

ACOG's Immunization for Women website provides information for obstetricians and gynecologists and their patients at: www.immunizationforwomen.org.

- ACOG app: www.acog.org/ACOGapp

American College of Physicians (ACP)

- www.acponline.org

ACP provides information related to adult immunization at: https://www.acponline.org/clinical-information/clinical-resources-products/adult-immunization.

American Nurses Association (ANA)

- www.nursingworld.org

ANA maintains a website devoted to immunization topics, including a newsletter, at www.anaimmunize.org.

American Pharmacists Association (APhA)

- www.pharmacist.com

APhA's online Pharmacist Immunization Center (www.pharmacist.com/immunization-center) is a key resource for pharmacist immunizers that delivers news, tools, and resources.

Association of Immunization Managers (AIM)

- www.immunizationmanagers.org

AIM, a national organization that represents state and territory immunization managers, was created to enable them to work together to effectively prevent and control vaccine-preventable diseases and improve immunization coverage.

- Twitter: https://twitter.com/aim_iz

Association for Prevention Teaching and Research (APTR)

- www.aptrweb.org

APTR is an interprofessional association of health promotion and disease prevention educators and researchers. The website includes a number of online immunization training programs.

Center for Vaccine Awareness and Research, Texas Children's Hospital

- www.texaschildrens.org/vaccine

This organization provides online vaccine education resources for patients and healthcare professionals and is currently conducting National Institutes of Health-funded research on vaccines for pregnant women.

Every Child by Two (ECBT) and Vaccinate Your Baby

- www.ecbt.org and www.vaccinateyourbaby.org

ECBT works on reducing morbidity and mortality in children through timely immunization. The Vaccinate Your Baby website features information for parents. A related ECBT blog (Shot of Prevention) is updated for providers and parents: www.shotofprevention.org.

- Twitter: https://twitter.com/everychildby2

EZIZ Training, California Department of Public Health

- www.eziz.org

EZIZ is the e-learning website for the California Vaccines for Children Program. EZIZ offers unique resources and free online training related to vaccine storage and handling and administration.

Group on Immunization Education (GIE)

- www.immunizationed.org

GIE is part of the Society of Teachers of Family Medicine. The group's website provides immunization information for healthcare professionals and educators, including free smartphone apps and computer software for the childhood and adult immunization schedules.

HealthMap Vaccine Finder

- http://vaccine.healthmap.org

HealthMap Vaccine Finder is a free, online service where users can search by zip code for locations that offer immunizations. This service is maintained by a team of researchers, epidemiologists, and software developers at Boston Children's Hospital.

- Twitter: https://twitter.com/healthmap

History of Vaccines

- www.historyofvaccines.org

The History of Vaccines website was created by The College of Physicians of Philadelphia and explores the role of immunization in the human experience and examines its continuing contributions to public health.

- Blog: www.historyofvaccines.org/blog
- Twitter: https://twitter.com/historyvaccines

Immunization Action Coalition (IAC)

- www.immunize.org, www.vaccineinformation.org, and www.immunizationcoalitions.org

IAC publishes a wide array of immunization information for healthcare professionals and their patients at www.immunize.org, including hundreds of free downloadable CDC-reviewed print materials at www.immunize.org/handouts. IAC offers free subscriptions to two quarterly periodicals, *Needle Tips* and *Vaccinate Adults*, and a weekly email news service, *IAC Express*, at: www.immunize.org/subscribe. IAC provides translations of CDC's Vaccine Information Statements (VISs) in more than 30 languages at: www.immunize.org/vis. A second website, www.vaccineinformation.org, provides reliable immunization information to patients and parents and includes an extensive video library. IAC's third website, www.immunizationcoalitions.org, provides resources and support for immunization coalitions.

Ask the Experts, a collection of more than 1000 Q&As answered by CDC vaccine experts, can be found at: www.immunize.org/askexperts.

- Twitter: https://twitter.com/ImmunizeAction

National Academy of Medicine (NAM)

- www.nationalacademies.org/hmd

The mission of the IOM is to advance and disseminate scientific knowledge to improve human health. The Institute provides objective, timely, authoritative information and advice concerning health and science policy.

Institute for Vaccine Safety (IVS)

- www.vaccinesafety.edu

Based at the Johns Hopkins University, IVS is committed to investigating vaccine safety issues and providing timely and objective information on vaccine safety to healthcare professionals, journalists, and parents.

Institute for Safe Medication Practices National Vaccine Errors Reporting Program (VERP)

- http://verp.ismp.org

The Institute for Safe Medication Practices, a nonprofit national patient safety organization, launched VERP in collaboration with the California Department of Public Health. VERP is a place where healthcare professionals and patients can report vaccine errors confidentially. By collecting and quantifying information about these errors, ISMP will be better able to advocate for changes that could reduce the likelihood of vaccine errors in the future.

- Twitter: https://twitter.com/ismp1

Medscape

- www.medscape.org/infectiousdiseases

Medscape offers free continuing education activities, including vaccine topics, for physicians and other healthcare professionals. There is no charge for this service, but you must register.

- Twitter: https://twitter.com/medscape
- Medscape app: https://itunes.apple.com/app/medscape/id321367289

Medical Assistants Resources and Training on Immunization (MARTi)

- www.marti-us.org

MARTi provides medical assistants with access to practical immunization information as well as training opportunities.

- Twitter: https://twitter.com/martidotorg

National Adult and Influenza Immunization Summit (NAIIS)

- www.izsummitpartners.org

NAIIS, dedicated to addressing and resolving adult and influenza immunization challenges, is a national network of more than 130 public and private sector organizations that is cosponsored by CDC, NVPO, and IAC. NAIIS sponsors an annual meeting and ongoing work groups that operate throughout the year.

National Association of County and City Health Officials (NACCHO)

- www.naccho.org

NACCHO is the national organization representing local health departments. Its website offers a number of toolkits related to immunization.

National Association of School Nurses (NASN)

- www.nasn.org

NASN's website includes immunization resources, including position papers and continuing education opportunities: www.nasn.org/ToolsResources/Immunizations.

National Conference of State Legislatures

- www.ncsl.org/research/health/school-immunization-exemption-state-laws.aspx

NCSL collects data from all 50 states about religious and philosophical exemptions from school immunization requirements and provides links to specific statutes (if available).

National Foundation for Infectious Diseases (NFID)

- www.nfid.org

NFID is a nonprofit organization dedicated to research, education, prevention, and treatment related to infectious diseases. The website features sections on many vaccine-preventable diseases, including resources for healthcare professionals and patients.

- Twitter: https://twitter.com/nfidvaccines

PKIDs (Parents of Kids With Infectious Diseases)

- www.pkids.org

PKIDs offers information and resources for parents looking for support services, counseling, referrals, and information concerning infectious diseases in children.

- Twitter: https://twitter.com/pkids

Sabin Vaccine Institute

- www.sabin.org

The Institute promotes rapid scientific advances in vaccine development, delivery, and distribution worldwide via vaccine research and development, academic support, and public awareness. The Institute houses the International Association of Immunization Mangers (IAIM).

IAIM provides a forum where immunization managers can discuss and exchange best practices, build and support international and regional networks of immunization managers, and improve their technical and leadership capacity.

- IAIM website: www.sabin.org/programs/vaccine-advocacy-education/international-association-immunization-managers
- Twitter: https://twitter.com/sabinvaccine

ShotbyShot

- http://shotbyshot.org

A collection of stories from people who have been affected by vaccine-preventable diseases, sponsored by the California Immunization Coalition.

- Twitter: https://twitter.com/ShotbyShotorg

Vaccine Education Center at The Children's Hospital of Philadelphia (VEC)

- http://vec.chop.edu/service/vaccine-education-center

VEC provides reliable, up-to-date information about vaccines, including videos and tear sheets on vaccines and vaccine concerns for healthcare professionals to use with patients and parents. The Center also sponsors the Parents PACK program, where parents can get answers to questions or subscribe to an email newsletter: www.chop.edu/centers-programs/parents-pack. Healthcare professionals can sign up for updates here: vec.chop.edu/professionals/vaccine-healthcare-providers/home.html.

Vaccine Facts and Policy (VFAP)

- www.vaccinefactsandpolicy.org

VFAP is a partnership of the Association of Immunization Managers, George Washington University, and the Immunization Action Coalition. The website includes extensive information about many major topic areas related to state immunization law and policy: demographics and rates, fiscal environment, law and policy, strategies and initiatives, and the structure of immunization programs. The site is searchable by state and by topic.

Vaccine Investigation and Online Information Network (VIOLIN)

- www.violinet.org

VIOLIN is a searchable online database of vaccine-related research data collected and curated at the University of Michigan. The website launched in 2007 and now contains information on more than 3000 vaccines/vaccine candidates.

Voices for Vaccines (VFV)

- www.voicesforvaccines.org

VFV is a parent-run member organization that provides clear, science-based information about vaccines and vaccine-preventable diseases. It provides the public with opportunities to join regional and national discussions about the importance of vaccination. VFV is a project of the Task Force for Global Health.

ORGANIZATIONS WITH DISEASE-SPECIFIC WEBSITES

Hepatitis

Asian Liver Center (ALC)

- http://liver.stanford.edu

ALC at Stanford University addresses the high incidence of hepatitis B and liver cancer in Asians and Asian Americans through outreach and education, advocacy, and research. ALC's website includes resources for healthcare professionals and patients, including brochures in many Asian languages.

CDC's Viral Hepatitis website

- www.cdc.gov/hepatitis

Hepatitis B Foundation (HBF)

- www.hepb.org

HBF is a national nonprofit organization dedicated to the global problem of hepatitis B and to finding a cure and improving the quality of life for people affected by hepatitis B. The website content is provided in 10 languages and also features an expert speakers forum.

- Twitter: https://twitter.com/hepbfoundation

National Task Force on Hepatitis B, Focus on Asian and Pacific Islander Americans

- www.hepbtaskforce.org

The Task Force brings together scientists, healthcare professionals, and nonprofit organizations in an effort to eliminate hepatitis B–related mortality and morbidity.

National Viral Hepatitis Roundtable (NVHR)

- www.nvhr.org

NVHR is a coalition of many public, private, and voluntary organizations dedicated to reducing the incidence of infection, morbidity, and mortality from viral hepatitis in the United States through strategic planning, leadership, coordination, advocacy, and research.

Human Papillomavirus (HPV)

American Sexual Health Association's National HPV & Cervical Cancer Prevention Resource Center

- www.ashasexualhealth.org/stdsstis/hpv

This website includes information about HPV and personal stories and support for infected persons. The National Cervical Cancer Coalition (NCCC), part of ASHA, is dedicated to helping women who are affected by HPV and cervical cancer. It advocates for cervical health by promoting prevention through early vaccination and testing. NCCC's website is www.nccc-online.org.

CDC's HPV website

- www.cdc.gov/hpv

Influenza

Childhood Influenza Immunization Coalition (CIIC)

- www.preventchildhoodinfluenza.org

CIIC seeks to address and improve the low influenza immunization rates among children.

Families Fighting Flu (FFF)

- www.familiesfightingflu.org

FFF is a nonprofit organization made up of families who have experienced the loss of a child to influenza or who have had a child experience severe medical complications from influenza. The organization's mission is to reduce pediatric morbidity and mortality due to influenza by raising awareness about the importance of getting all children vaccinated against this disease.

- Twitter: https://twitter.com/famfightflu

Meningitis

Meningitis Angels

- www.meningitis-angels.org

Meningitis Angels is a nonprofit organization of survivors and families of meningitis victims. It offers information and support to families affected by meningitis.

- Twitter: https://twitter.com/MeningitisAngel

National Meningitis Association (NMA)

- www.nmaus.org

NMA is a nonprofit organization founded by five parents whose children died or have long-term disabilities from meningococcal meningitis. NMA advocates for meningitis disease awareness and prevention.

Rotavirus

Rotavirus Vaccine Program

- www.path.org/projects/rvp.php

A PATH affiliate, the Rotavirus Vaccine Program's mission is to reduce child morbidity and mortality from diarrheal disease by accelerating the availability of rotavirus vaccines appropriate for use in developing countries.
