GBS CPS-TT conjugate vaccines induce increases of fourfold or more in CPS-specific IgG in 80% or more of volunteers; maximum levels peak 4 to 8 weeks later and then decline gradually to approximately 50% of peak values 1 year after immunization (see Table 57.3). Limited data 2 and 5 years later demonstrate GMCs substantially higher than baseline and above the presumed protective levels for types Ia, Ib, II, and III in most conjugate vaccine recipients. In the absence of Phase III efficacy trials, two observations suggest that GBS glycoconjugate vaccine-induced CPS-specific IgG is protective. First, postvaccination serum concentrations as low as 0.5 μg/mL (Ia, Ib, and III) and 1.0 μg/mL (II and V) promote significant opsonophagocytosis of homologous strains in vitro (>1 $\log_{10}$ reduction) and although this activity declines over time, substantial functional activity is retained 18 to 24 months post immunization (Ia, III, and V).[77,78,80,81,88] Second, in case-control studies, similar concentrations in maternal serum samples at delivery are 90% protective against types Ia and III and 70% protective against type V EOGBS neonatal disease.[89] This strongly suggests that the immune response to GBS glycoconjugate vaccines is sufficient to induce durable protection, similar to other conjugate vaccines.[56]

SAFETY

Adverse Events

Candidate GBS CPS-TT glycoconjugate vaccines have been evaluated in more than 600 healthy adults. Each vaccine was well tolerated, and no vaccine-related serious adverse events occurred. The most common dose-dependent adverse effects reported were mild or moderate tenderness or swelling at the injection site in the highest-dose recipients. Systemic reactions consisting of low-grade fever, chills, headache, or myalgia were reported in only five volunteers (0.8%), and in almost all, these symptoms resolved in 24 to 36 hours. When a type III glycoconjugate vaccine was tested in 20 pregnant women, mild local reactions occurred in 5% of recipients.[87] No vaccine-related adverse event was noted in any infant.

PUBLIC HEALTH CONSIDERATIONS

Invasive GBS disease causes morbidity and mortality in pregnant women, neonates, young infants, and nonpregnant adults with underlying medical conditions, including elderly people. GBS infection also contributes to adverse pregnancy outcome including stillbirth.[26] The cost of treating these conditions is considerable. Only maternal peripartum disease and EOGBS can be prevented through IAP. Ongoing cases of EOGBS and LOGBS, cost, and concern for emergence of resistant GBS isolates suggest that IAP is an interim measure.

The health benefits of GBS vaccination were predicted in an analysis of potential chemoprophylaxis and/or GBS vaccination (adolescent, maternal, or postpartum) strategies, assuming an immunogenic multivalent GBS vaccine.[90] In this model, adolescent and maternal immunization strategies were superior to IAP. Maternal immunization strategies were more effective and projected to prevent 4% of preterm births, 61% to 67% EOGBS disease, and 70% to 72% of LOGBS disease. Maternal immunization is the only strategy that will reduce not only maternal and EOGBS infection, but also LOGBS.

Once safe and immunogenic GBS vaccines are developed commercially, appropriate regimens for their administration will be necessary. The regimen likely to have the most profound and immediate effect on human disease rates would be to vaccinate women in the early third trimester of pregnancy with a single dose of vaccine, thus preventing maternal and infant (EOGBS and LOGBS) disease.[87,90] Recent cost-effectiveness analysis of this strategy assuming a trivalent GBS conjugate (Ia, Ib, III) vaccine with 85% coverage in addition to IAP, predicted that an additional 899 cases of invasive infant GBS disease and 35 deaths would be prevented in the United States annually at a cost of US$91.31 per quality-adjusted life-year gained.[91] Surveys of pregnant and recently delivered women indicate that 79% to 83% would be accepting of such a strategy if it was accompanied by a provider recommendation, and as influenza and pertussis booster vaccines are already recommended in pregnancy, the platform for implementation exists.[92–95] However, such a regimen would not prevent GBS-associated maternal morbidity or preterm births earlier in pregnancy. An alternative strategy in the longer term may be to administer a priming GBS vaccine dose to young adolescent girls at 11 to 12 years of age with other recommended adolescent vaccines (i.e., tetanus, diphtheria, acellular pertussis [Tdap], meningococcal conjugate [MCV4], and human papillomavirus [HPV] vaccines) followed by a booster dose preconception as part of "preconceptional health" recommendations[96–99] or in the early third trimester of pregnancy. Further studies would need to define the optimal frequency of vaccination throughout the childbearing years and whether vaccination is required with each pregnancy. There are few data on immune response in nonpregnant adults with underlying medical conditions and elderly people, who account for ever more of the disease burden.[14,15,100] Given the increasing number of cases in this population caused by poorly encapsulated strains and the distinct difference in capsular types compared with those causing invasive perinatal disease, it is possible that vaccine constructs other than glycoconjugates will be needed for prevention (Baker C.J., personal communication, 2016).

FUTURE VACCINES

Efforts to develop GBS conjugate vaccines continue. The European Union's 7th Framework Program for Research and Technological Development funded the DEVANI project with the objective of developing GBS immunization strategies from 2008 to 2011.[101] A candidate GBS trivalent (Ia, Ib, III-CRM_{197}) glycoconjugate vaccine has been tested in Phase I and Phase II studies in pregnant and nonpregnant women, both HIV positive and negative, in Europe, Canada, United States, and Africa.[102] Although published data are limited, this candidate vaccine was safe, well-tolerated and appeared immunogenic when tested in 51 mother-infant pairs in Belgium and Canada. In 2015, after acquisition of Novartis Vaccines by GlaxoSmith-Kline, further development of this trivalent glycoconjugate vaccine was discontinued to concentrate on developing a glycoconjugate covering additional GBS CPS types. Also in 2015, Pfizer Inc. announced that it was exploring development of a multivalent GBS vaccine. It is likely that both companies will target infant GBS disease prevention using multivalent glycoconjugates that focus on maternal immunization, and that it will take many more years for new clinical trials to document immunogenicity, safety, and efficacy of these candidate vaccines.

Alternative strategies to develop GBS vaccines focus on GBS surface-expressed proteins as candidates themselves or

TABLE 57.4 GBS Vaccine Development

Target Antigen(s)	Approach	Candidate Vaccine	Correlate of Protection	Status
CPS	Conventional vaccinology	Multivalent glycoconjugate	Case-control studies of CPS IgG (μg/mL) in maternal sera; OPK; mouse protection[a]	Awaiting trials during pregnancy[b]
SURFACE PROTEINS				
C5a peptidase	Conventional vaccinology	C5a peptidase in PLGA microsphere	OPK; protection of mice from lethal injection, but not colonization	Unknown
α or β C protein	Conventional vaccinology	As protein carrier with CPS	Mouse protection	Unknown
Sip	Conventional vaccinology	Recombinant Sip	Mouse protection	Unknown
LrrG			Mouse protection	Unknown
Rib-α				Phase I trial
BibA	Reverse vaccinology		OPK; mouse protection	Unknown
Pilus 2a chimeric protein			OPK; mouse protection	Unknown

[a]Immunized dams → protection of pups from lethal GBS inoculum.
[b]Phase I and Phase II trials with monovalent CPS (Ia, Ib, II, III, V)-tetanus toxoid published.
BibA, GBS immunogenic bacterial adhesion (to human epithelial cells); CPS, capsular polysaccharide; GBS, group B β-hemolytic *Streptococcus*; LrrG, leucine-rich repeat protein; OPK, opsonophagocytic killing; PLGA, poly(lactide-co-glycolide); Rib-α, Rib protein combined with α-C protein; Sip, surface immunogenic protein.

as carrier proteins for multiple CPSs (Table 57.4). Examples are α- and β-C proteins (found in 50% and 10% of clinical isolates, respectively), C5a peptidase, rib protein, GBS immunogenic bacterial adhesion (BibA), and surface immunogenic protein (Sip). C5a peptidase is a cell-surface-localized serine protease that inactivates human C5a, a neutrophil chemoattractant produced during complement activation. The protein is a conserved, cell-surface–localized protein found in all GBS strains. Immunization of mice with purified SCPB/ScpB, derived from C5a peptidase, resulted in enhanced clearance of GBS from lungs of mice inoculated intranasally. Although this study used only a single GBS strain (the uncommon serotype VI), the results indicate the C5a peptidase construct might be a vaccine candidate, even if the antibodies produced did not inhibit the enzymatic activity of the surface-localized protein.

Another potential vaccine candidate is a well-conserved, cell wall–anchored protein called GBS immunogenic bacterial adhesion or BibA.[102] The *bibA* gene appears to be present in all GBS strains, and BibA binds human C4 binding protein and promotes the adhesion of GBS to human epithelial cells. Pups of BibA variant immunized pregnant mice survive lethal challenge by multiple GBS capsular types and antibodies to this moiety promote opsonophagocytosis in vitro.

Another possible candidate is a single-component protein vaccine based on a fusion of N-terminals of α-C and Rib, GBS-NN, which theoretically covers 95% of GBS CPS types. GBS-NN is in a Phase I trial in Northern Ireland.[103] The initial evaluation will investigate safety and dose escalation in 70 healthy, nonpregnant women and then enroll another 240 healthy, nonpregnant women to further evaluate safety and initial dose and schedule. It is possible that preliminary results will be available in mid 2017.

The genome sequences of eight GBS isolates have been analyzed and cloned.[104,105] This led to use of reverse vaccinology to identify 312 GBS surface proteins, and four of these in combination were highly protective against all circulating GBS serotypes in a mouse model of infection.[105] Protection correlated with antigen accessibility on the bacterial surface and with the induction of opsonophagocytic antibodies. GBS pili and other surface proteins also could be exciting carrier proteins with the potential of providing additional protection against virulent GBS strains.[28–31,106–108] Using structural vaccinology methods, the backbone subunit of pilus 2a, common to many CPS types, is another potential protein carrier. This backbone (BP-2a) is present in six immunogenically different but structurally similar variants. The three-dimensional structure of one of the variants has been demonstrated to elicit protective antibodies that specifically recognize one of the four domains that comprise the protein. A synthetic chimeric protein, constituted by the protective domain of each one of six variants, protects mice against lethal challenge with all type 2a pilus-carrying GBS strains.[109,110] Achievements in GBS vaccine development, albeit painfully slow, promise the advent of effective vaccines to at last decrease perinatal and adult GBS disease burden. Studies from Soweto, South Africa, demonstrating that GBS disease is related to high colonization and maternal antibody deficiency, strongly suggest that such GBS vaccines would significantly impact the global burden of GBS-associated morbidity and mortality.[111,112]

58 Tetanus Toxoid

Martha H. Roper,† Steven G.F. Wassilak, Heather M. Scobie, Alison D. Ridpath, and Walter A. Orenstein

Tetanus is unique among vaccine-preventable diseases in that it is not communicable. *Clostridium tetani*, the causative agent of tetanus, is widespread in the environment; many animals, in addition to humans, can harbor and excrete the organism and its spores. When spores of *C. tetani* are introduced into the anaerobic conditions found in devitalized tissue or punctures, they germinate to vegetative bacilli that elaborate toxin. The clinical presentation results from the actions of this toxin on the central nervous system (CNS). Many animal species besides humans are susceptible to the disease.

The clinical characteristics of tetanus were recognized as distinct early in human history because of the constancy and severity of the symptoms in animals and humans. A description of tetanus was found as early as 1550 BC in the medical papyri of ancient Egypt, and detailed descriptions were included in the writings of Hippocrates and other ancient Greeks.[1,2] The etiology of tetanus was unknown until 1884, when Carle and Rattone[3] demonstrated that injecting the contents of a pustule from a fatal human case into the sciatic nerve of a rabbit resulted in the typical symptoms of tetanus. The disease could subsequently be passed to other rabbits from infected nervous tissue. Inoculation of soil samples into animals also resulted in tetanus. Gram-positive bacilli were often noted in the exudate at the inoculation site but generally not in nervous tissue, leading Nicolaier[4] to hypothesize that a poison produced at the site of inoculation caused the nervous system symptoms. In 1886, spore-forming bacilli were observed in the exudate obtained from a human patient.[5] In 1889, the spores of *C. tetani*, in contrast to the vegetative organisms, were shown to survive heating and to germinate under anaerobic conditions; injection of pure cultures reproducibly caused the disease in animals.[6] After identification and purification of the toxin in 1890, repeated inoculation of animals with minute quantities of toxin led to the production of antibodies in survivors that neutralized the effects of the toxin.[7] Preparations of antibodies derived from animal sera, particularly from horses, became the first means to prevent and treat tetanus; efficacy was demonstrated in World War I by a sharp decline in tetanus cases among wounded soldiers once tetanus antiserum was introduced.[8,9] In 1924, these efforts culminated in the preparation of an anatoxin—a chemically inactivated toxin, now termed a toxoid—that induced active immunity against the disease before exposure.[10]

The impetus to prevent tetanus through immunization was the striking and highly fatal disease in both high and lower income nations, predominantly associated with injuries to otherwise healthy persons, and particularly during military conflicts. In the lower-income countries, tetanus in neonates continues to represent a substantial proportion of the health burden from tetanus. Prevention of tetanus is now almost universally achievable by use of highly immunogenic and safe toxoid-containing vaccines. Tetanus also can be prevented or modified by proper wound care, sterile surgical and obstetric practices, and use of exogenous antibody.

CLINICAL DESCRIPTION

Although the incubation period for tetanus varies from 1 day to several months after a wound, the majority of cases occur within 3 days to 3 weeks after inoculation of spores. In the United States during 1972 to 2001, the median interval between the injury and onset of tetanus was 7 days (range: 0 to 178 days) for 1191 nonneonatal cases with reported information. The time between injury and the onset of symptoms was 30 days or less for 97% of the cases, and 2 days or less for 10% of the cases.[11]

A direct relationship exists between the site of inoculation and the incubation period: the longest intervals occur after injuries farthest from the CNS; injuries of the head and trunk are generally associated with the shortest incubation periods.[12,13] The incubation period is inversely related to severity of illness[8,14–19] and has historically been considered one of the best prognostic indicators.[20,21] Incubation periods of 10 days or more tend to result in milder disease, whereas incubation periods within 7 days of injury tend to result in more severe disease.

Three clinical syndromes are associated with tetanus infection: (1) localized, (2) generalized, and (3) cephalic.[12] Localized tetanus, which is uncommon, consists of spasm of muscles in a confined area surrounding the site of the injury.[22,23] Painful contractions may persist for several weeks to months before gradually subsiding. Localized disease is thought to occur when transport of toxin produced at the site of the injury is restricted to the local nerves. The symptoms can be produced experimentally by simultaneously injecting toxin into a muscle and antitoxin into blood to prevent hematogenous dissemination.[13] Although localized tetanus per se is generally mild, with fatality rates of less than 1%, progression to generalized tetanus and its complications can occur.[22]

More than 80% of cases of tetanus are generalized. The most common initial sign is spasm of the muscles of mastication—trismus, or lockjaw—occurring in up to 90% of patients on presentation.[12,24,25] Spasm of the facial muscles produces a characteristic facial expression—*risus sardonicus*—consisting of raised eyebrows, tight closure of the eyelids, wrinkling of the forehead, and extension of the corners of the mouth laterally. Other early presentations of tetanus include pain and muscle spasm of the neck, shoulders, back, and abdomen. Dysphagia can be the initial symptom, particularly in the elderly.[26,27] Initially, spasms are triggered by external stimuli such as touch or sudden noises, but they occur spontaneously as the disease progresses. Sustained spasm of back muscles gives rise to the arched posture of opisthotonos. Generalized tonic seizure-like tetanospasms consist of sudden excruciating contraction of all muscle groups, resulting in opisthotonos, adduction at the shoulders, flexion of the elbows and wrists, and extension of the legs. Frank convulsions can occur in severely affected patients. Spasm of the glottis can result in immediate death. Patients exhibit generalized hyperreflexia; temperature elevations of 2°C to 4°C are often associated with severe spasms. Cognitive functions are not overtly affected.

Generalized tetanus is frequently accompanied by respiratory failure as a result of chest wall rigidity and spasm,

†Deceased.

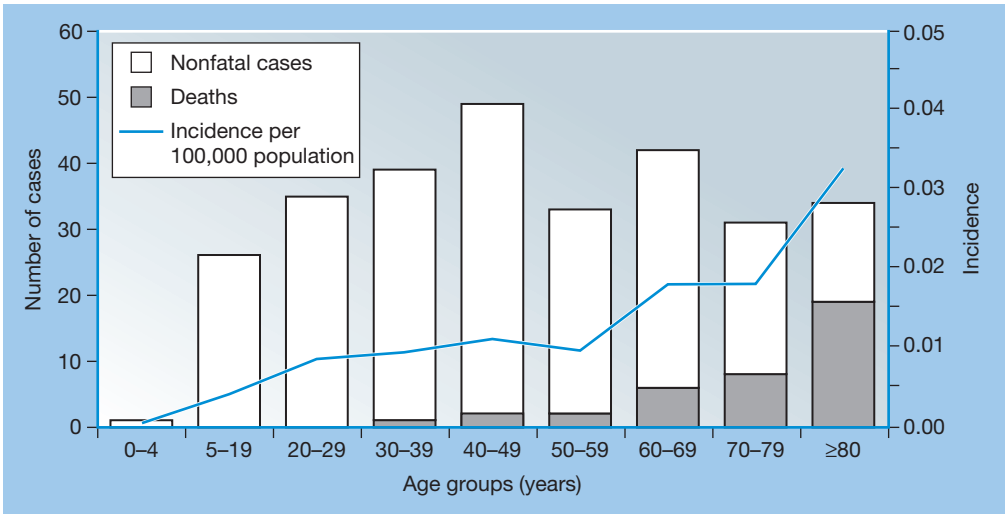

Figure 58.1. Number of reported cases of tetanus, survival status of patients, and average annual incidence rates by age group in the United States, 2000–09. More recent data show no change in trends. *(From Centers for Disease Control and Prevention, unpublished data.)*

diaphragmatic dysfunction, airway obstruction from laryngeal or glottis spasm, aspiration pneumonia, and fatigue.[1,12] Before the availability of effective medications to control spasms and mechanical ventilation, respiratory failure was the most common cause of death in patients with tetanus, and it continues to be so in lower income countries.[1,28,29] Tetanus also can be accompanied by severe autonomic nervous system abnormalities, usually developing several days to a week after symptom onset, which include labile or sustained systemic arterial hypertension, hypotension, flushing, diaphoresis, tachycardia, bradycardia, and arrhythmias.[1,30–35] Development of autonomic dysfunction carries a worse prognosis and has become the most common cause of death in countries where intensive care facilities and respiratory support are available.[1,36,37] Other complications associated with tetanus include vertebral and long bone fractures, dysphagia, traumatic glossitis, urinary retention, catheter-associated infections, pulmonary embolism, decubitus ulcers, and contractures. Long-term consequences—including prolonged muscle fatigue, hyperostoses and osteoarthritis, and difficulties with speech, memory, and mental capacity—have been documented but are uncommon.[38–41] Neonatal tetanus is a form of generalized tetanus occurring in the first month of life, most often as a result of an infected umbilical stump.[12,42,43] Symptoms begin 3 to 14 days after birth in approximately 90% of cases, but can occur from 1 to 28 days of age.[41,42,44–46] The predictable incubation period led several cultures to apply time-related names to the condition, such as "three-six disease" in China, "disease of the 7th day" in Latin America, and "8-day disease" in Scotland, the Pacific Islands, and other locations.[42,47–49] Illness begins with poor sucking and excessive crying in an infant with normal ability to suck in the first 2 days of life.[12,42,50,51] This is followed by variable degrees of trismus, difficulty swallowing, rigidity, and spasms. In survivors of neonatal tetanus, neurologic damage, including spastic paresis/paralysis and severe psychomotor retardation, as well as more subtle intellectual and behavioral abnormalities, has been reported in some studies when long-term sequelae have been assessed.[52–55]

The clinical course of generalized tetanus is highly variable. The disease frequently remains intense for 1 to 4 weeks and then gradually subsides. Case-fatality rates for reported cases of generalized tetanus have varied from 25% to 70% overall and approach 100% at the extremes of age.[18,19,41] With modern intensive care, mortality can be reduced to 10% to 20%[21,29,47,56–63]; however, high mortality persists where intensive care is limited.[64–68,68a] In the United States from 1972 to 2009, reported case-fatality rates declined from approximately 50% to 10% overall, but varied depending on age (Fig. 58.1) and immunization status (Centers for Disease Control and Prevention [CDC], unpublished data).[11,68–71] Higher case-fatality rates have been reported when tetanus results from intramuscular injection of quinine, or after deliveries and abortions.[41,42,72–74]

Cephalic tetanus is a rare manifestation of the disease generally associated with lesions of the head or face, especially in the distribution of the facial nerve and the orbits,[12,50] and with chronic otitis media.[75] The incubation period is usually 1 to 2 days after an acute wound. In contrast to generalized tetanus, which is associated with spasm, cephalic tetanus is manifested by atonic cranial nerve palsies involving nerves III, IV, VII, IX, X, and XII, singly or in combination. Nonetheless, trismus can be present. The disease may progress to generalized tetanus and has a similar prognosis if it does.[12,76]

BACTERIOLOGY

C. tetani is a gram-positive, spore-forming, motile, anaerobic bacillus.[77–80] Typically measuring 0.3 to 0.5 µm in width and 2 to 2.5 µm in length, the vegetative form often develops long filament-like cells in culture. Motility is produced by peritrichous flagellae coating the cell surface. With sporulation, *C. tetani* loses its flagellae and takes on the more characteristic drumstick-like appearance reflecting spore formation in the terminal position. *C. tetani* is a strict anaerobe that grows optimally at 33°C to 37°C; however, depending on the strain, growth can occur at 14°C to 43°C. It can be cultured in a variety of anaerobic growth media such as thioglycolate, casein hydrolysate, and cooked meat. Growth is enhanced in media supplemented with reducing substances at a neutral to alkaline pH. On blood agar, the organism produces characteristic compact colonies extending in a meshwork of fine filaments. Growth is usually accompanied by the production of gas and is associated with a fetid odor.

Sporulation depends on a variety of factors that include pH, temperature, and medium composition. Spores can be promoted at 37°C and in the presence of oleic acid, phosphates, 1% to 2% sodium chloride, protein, and magnesium.[77,78] In

contrast, acidification, high (≥41°C) or low (≤25°C) temperatures, glucose, assorted saturated fatty acids, antibiotics, and potassium inhibit spore formation. The germination of spores requires anaerobic conditions and is enhanced by the presence of lactic acid and chemicals toxic to cells.[80]

If not exposed to sunlight, *C. tetani* spores can persist in soil for months to years.[12,77,78] Spores are resistant to boiling and a variety of disinfectants.[12,81] Inactivation of spores requires 15 to 24 hours in a solution of phenol (5%), formalin (3%), chloramine (1%), or hydrogen peroxide (6%). Use of aqueous iodine or 2% glutaraldehyde at pH 7.5 to 8.5 kills spores within 3 hours; autoclaving at a temperature of 120°C and a pressure of 15 pounds per square inch destroys them within 15 to 20 minutes.[1,28,81]

The most common source of environmental exposure to *C. tetani* bacilli and spores is soil, where the organism is widely but variably distributed. It is difficult to compare studies of the distribution of the organism in nature because of differences in methodology.[82] Most studies suggest that viable spores are more common in soils with an alkaline pH and in nutrient-rich soils in warm, moist climates that could more easily support multiplication of the bacillus.[74,83] In the contiguous United States, however, a limited study in 1975 found spores in 30% of the samples without any apparent geographic or chemical influence on the distribution.[84]

Animals are also *C. tetani* reservoirs. Both herbivores and omnivores can harbor tetanus bacilli and spores in their intestines, disseminating the organism in their feces. Fecal carriage has been reported in 10% to 20% of horses and 25% to 30% of dogs and guinea pigs; fecal specimens from several other species, including sheep, cattle, and small mammals, also were found to contain *C. tetani*.[81,85] Attempts to quantify the frequency of human intestinal colonization have produced varied results ranging from 0% to 40%.[80,86–92] Rural residents tend to have higher rates of intestinal carriage than city dwellers. *C. tetani* spores have also been detected in street dust and the dust and air of surgical operating theaters.[92,93]

PATHOGENESIS

C. tetani produces two exotoxins: tetanolysin and tetanospasmin.[12,79,80] Tetanolysin is an oxygen-sensitive hemolysin related to streptolysin and the θ-toxin of *Clostridium perfringens*. It may play a part in establishing infection at the site of inoculation, but it has no other known role in pathogenesis of the disease.[94] Tetanospasmin, referred to as tetanus toxin, is the neurotoxin that causes the manifestations of tetanus. The toxin is a protein produced intracellularly during the logarithmic phase of bacterial growth and released on autolysis. The highly conserved genes for tetanus toxin and its transcriptional regulator are present on a plasmid.[95–97] Observed differences in *C. tetani* reference-strain toxigenicity are related to heterogeneity in the strains' constituent clones; lower toxigenicity results when there are mixtures of organisms with and without the plasmid.[98]

Tetanus toxin has an approximate molecular weight of 150,000 kDa and is synthesized as a single polypeptide prototoxin chain. When released by cell death, the prototoxin is cleaved by bacterial or tissue proteases into its active form, consisting of a 50,000-kDa light chain, the toxic domain, and a 100,000-kDa heavy chain with two domains related to membrane binding and translocation. The light and heavy chains are held together by a single disulfide bond; a second disulphide bond connects two heavy chain sites.[99–101] The three distinct domains of the toxin are related to the separate steps of neuron receptor binding, internalization, intraaxonal transport, membrane translocation, and target enzymatic activity. The carboxyterminal end of the heavy chain (HC, or fragment C) binds to receptor sites and is required for internalization by endocytosis[102]; the aminoterminal end (HN) of the heavy chain mediates intraaxonal transport and, in central interneurons, the translocation of the toxin molecule into the neuronal cytosol.[101,103,104] The light chain is an endopeptidase that is responsible for tetanospasm's specific toxic properties (discussed later).[101,105]

Tetanus toxin is one of the most potent known poisons on a weight basis because of its absolute neurospecificity and enzymatic function at the site of action.[105] As little as 1 ng/kg will kill a mouse; 0.3 ng/kg will kill a guinea pig.[106] The estimated minimum human lethal dose is less than 2.5 ng/kg.[106] Various species have different levels of responsiveness to the toxin: cats, dogs, birds, and poikilotherms are relatively resistant to its effects; mice, guinea pigs, monkeys, sheep, goats, and particularly horses are sensitive. Humeau and coworkers described evidence that these differences are the result of specific differences in toxin binding and neurotransmitter blocking activity.[107]

Infection usually begins with the inoculation of spores into wounds, accompanied by tissue injury, necrosis, and the anaerobic conditions necessary for spore germination and bacterial replication. Ionic calcium appears to increase local necrosis and the likelihood of *C. tetani* infection; its presence in soil contaminating wounds may enhance spore germination and bacterial replication.[108]

Transport of toxin from the infected site into the CNS is complex (Fig. 58.2). After extracellular release, toxin diffuses to neuromuscular junctions of α-motor neurons in adjacent muscle tissue or to the lymphatic system, which transports the toxin to the bloodstream, leading to systemic dissemination and widespread uptake.[12,109] The toxin gains entry into α-motor neurons via a double-receptor sequential binding process involving specific polysialgangliosides, and possibly glycoproteins, in lipid raft microdomains, followed by internalization by clathrin-mediated endocytosis.[104,110–117] Once internalized, toxin is transported by a specific retrograde axonal transport system to the motor neuron cell body at a rate of 3 to 13 mm/h.[105,115,118–121] The mechanism of its release into contiguous synaptic junctions is unclear.[105,111,115] Entry into adjacent inhibitory interneurons in the CNS occurs via synaptic vesicle recycling, whereby the toxin binds to synaptic vesicle membrane protein SV2 and is endocytosed in the synaptic vesicle lumen, and also by clathrin-mediated endocytosis and bulk endocytosis.[115,117,118,122–124]

Once inside an inhibitory neuron, the light chain is transferred to the neuronal cytosol by membrane translocation through a channel created in the vesicle membrane. Channel formation, and the conformational changes in heavy chain subdomains that are required for translocation, are still incompletely understood.[117,125] In the cytosol, the disulphide bond between the heavy and light chains is broken, freeing the light chain to begin its toxic enzymatic activity.[105,111,123,126] The light chain is a zinc endoprotease that cleaves peptide bonds in synaptobrevin, a synaptic vesicle protein necessary for vesicle fusion with the plasma membrane. Without intact synaptobrevin, synaptic vesicles accumulate at the nerve ending, unable to release their contents of the inhibitory neurotransmitters glycine or γ-aminobutyric acid (GABA).[105,127–129] With inhibition blocked, increased excitatory neuron baseline firing rates lead to muscle rigidity, followed by multiplication of unopposed excitatory impulses that cause characteristic tetanic spasms, and, less commonly at the cerebral level, convulsions.[1,12,101,130–132]

Tetanus toxin does not cross the blood–brain barrier[109]; neuronal transport is the sole means of entry into the CNS.[12,133–135] Transsynaptic transport of intact toxin allows transfer to inhibitory neurons in the spinal cord and wider

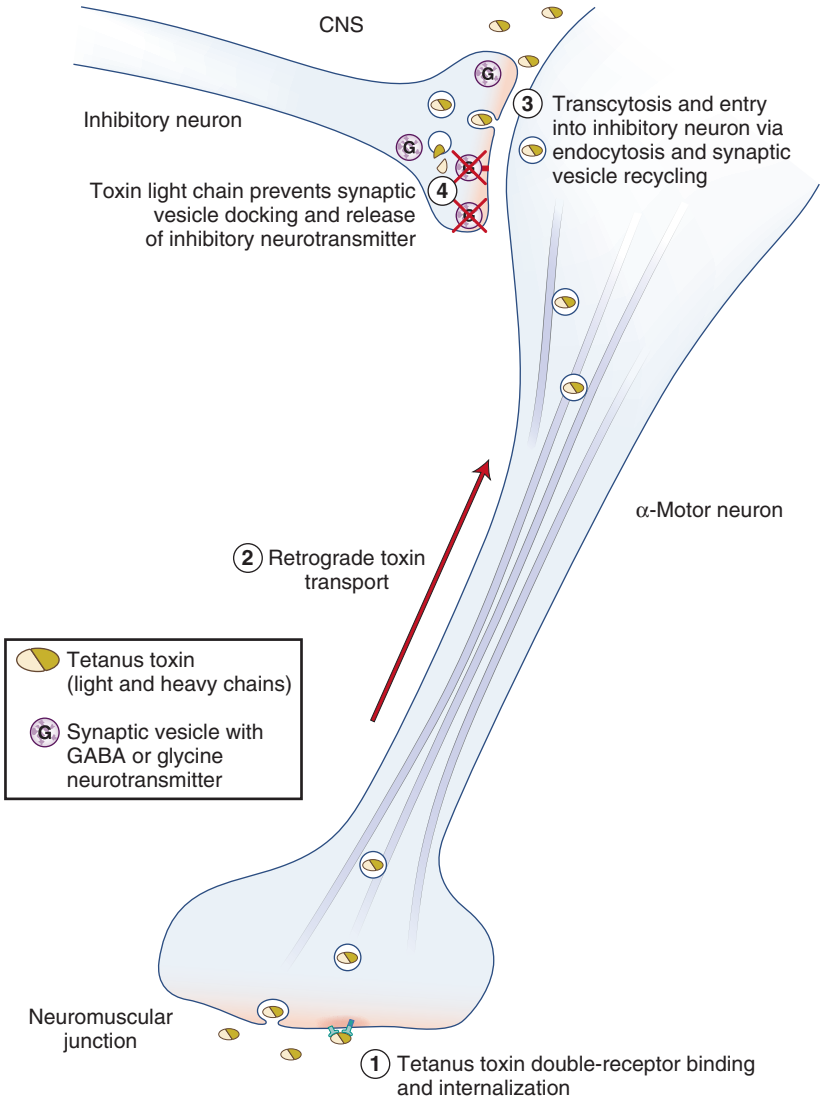

Figure 58.2. Route of tetanus toxin, from entry into an α-motor neuron to its site of action in an inhibitory neuron in the central nervous system (CNS). The steps are as follows: (1)Toxin binding with two specific receptors in the α-motor neuron membrane and internalization into the motor neuron. (2) Retrograde axonal transport of toxin to the motor neuron cell body. (3) Toxin release from the motor neuron, followed by entry into the inhibitory neuron via synaptic vesicle recycling, and also clathrin-mediated and bulk endocytosis. (4) Toxin translocation from the vesicles in which it entered the inhibitory neuron; the bond between heavy and light chains is then broken, freeing the light chain to cleave synaptobrevin, thereby preventing synaptic vesicle docking and release of inhibitory neurotransmitter. GABA, γ-aminobutyric acid.

dissemination in the CNS. Recovery may depend on new functional connections or toxin degradation.[136–138]

Tetanospasmin can act at the peripheral neuromuscular junctions, the spinal cord, the brain, and the autonomic nervous system.[12,30–33,104,131,132] With local tetanus, transport of toxin is from the neuromuscular junction of the affected muscle without hematogenous dissemination; the predominant effect is on spinal glycinergic inhibitory neurons.[1,139] In generalized tetanus, hematogenous dissemination of toxin allows more widespread uptake at neuromuscular junctions; the predominant effect is on the GABAergic supraspinal inhibitory neurons.[1] The clinical syndrome appears almost identical to strychnine poisoning, which acts by competitively binding to postsynaptic glycine receptors at the motor neurons.[140] Tetanospasmin also interferes with release of a variety of other neurotransmitters, including acetylcholine in peripheral somatic and autonomic nerves.[107,123] This accounts for autonomic dysfunction in cases of severe disease, flaccid cranial nerve palsy in cephalic tetanus, and peripheral muscle weakness, which often is masked by the more dramatic manifestations of the central inhibitory blockade. More detailed information on tetanus toxin can be found in recent reviews.[101,105,107,111,115,117,141]

DIAGNOSIS

The diagnosis of tetanus is established primarily on clinical grounds and secondarily supported by epidemiologic setting.[1,28,142] A history of a wound contaminated by soil or other material and the presence of a local skin infection are helpful in the diagnosis, although these criteria may not be present.[12] Bacteriologic investigations are frequently negative. Characteristic gram-positive bacilli, some with terminal or subterminal spores, occasionally may be seen in aspirates from the affected area, although anaerobic cultures of tissues or aspirates are usually not positive[57,143]; conversely, detection of the organism at a wound site does not confirm the clinical diagnosis.[1,144,145] Low or undetectable levels of circulating

antitoxin at the time of onset of symptoms are compatible with the diagnosis; however, there are a number of case reports in which moderately high levels of antitoxin were noted when the patient sought treatment.[146–153] Changes in antitoxin levels in convalescence are not reliably seen.[154] Given the mild nature of some presentations, electromyography has been suggested to aid in the diagnosis,[155] and elicitation of trismus by posterior pharyngeal stimulation ("spatula test") has been reported to help in clinical differentiation.[156]

The differential diagnosis depends on the clinical form of tetanus and the presenting symptoms. Cephalic tetanus may be confused with Bell palsy and trigeminal neuritis. However, cephalic tetanus often is accompanied by other cranial nerve symptoms, including dysphagia, and signs of trismus and nuchal rigidity.[12,50] Trismus has a variety of causes, including dental infection, tonsillitis, peritonsillar abscess, temporomandibular joint dysfunction, parotitis, and CNS disturbances other than tetanus. Patients with rabies can also have hyperreflexia; however, rabies is more likely to be associated with hallucinations, hydrophobia, mania, stupor, and a history of an animal bite, and it is unlikely to be accompanied by trismus. In addition, seizures with rabies are usually clonic, whereas tetanospasms are prolonged and tonic. Encephalitis is rarely associated with trismus and is much more likely to be accompanied by disturbances of consciousness than is tetanus. Because of nuchal rigidity, bacterial meningitis could be confused with tetanus. Stiff Person Syndrome, which is very rare, has been mistaken for tetanus (CDC, unpublished data).[1,157]

A variety of metabolic conditions and poisonings can resemble tetanus. Although muscle spasm may be seen with hypocalcemic tetany, it is not generally associated with trismus.[158] A determination of low serum calcium can confirm tetany. Strychnine poisoning mimics generalized tetanus.[140] However, such poisoning is characterized by (a) rare association with persistent trismus, (b) greater muscle relaxation between spasms, (c) normal body temperature, and (d) the presence of detectable strychnine in gastric contents or in urine. Phenothiazine toxicity may be associated with a variety of dystonias, including trismus. Detection of phenothiazines in the blood or amelioration by treatment with diphenhydramine confirms the diagnosis. Hysteria can mimic tetanus; however, hysterical patients usually relax during prolonged observation or when they are distracted, and they are more likely to display clonic rather than tonic spasms.[159]

Because of the distinctive presentation of neonatal tetanus, a postmortem history determining the nature and timing of symptoms, with verification that the child was normal at birth, permits accurate classification of tetanus as the cause of death with a high degree of probability.[160] The World Health Organization (WHO) defines neonatal tetanus as an illness occurring in a child who has the normal ability to suck and cry in the first 2 days of life, loses this ability between 3 and 28 days of life, and becomes rigid or has convulsions (see Chapter 76).[161]

TREATMENT

By the time a patient with tetanus presents for treatment, toxin has entered the nervous system, is circulating in the lymphatics and bloodstream, and is continuing to be produced by *C. tetani* at the site of infection. The purposes of tetanus therapy are: (a) to inactivate circulating toxin; (b) to prevent further toxin production by eliminating the organism; and (c) to give supportive care for the duration of the illness. General principles for use of human tetanus immunoglobulin (TIG) and pharmacotherapy are outlined here. Detailed information on treatment can be obtained from review articles and chapters.[1,28,61,130,162–167]

Patients with tetanus may initially have few symptoms and signs, but these will generally progress over subsequent days; in a substantial proportion of cases, the clinical status deteriorates quickly after hospital admission.[1,12] Although clinical scoring methods have been developed to predict prognosis and the need for aggressive management, these methods were derived empirically and have been used primarily in clinical research to stratify disease severity to balance treatment groups.[20,168] In addition, the scales were developed before major improvements were made in therapeutic interventions and mortality reduction. A tetanus severity score developed by Thwaites and associates was derived by logistic regression and found to be more specific and sensitive overall than other scales in their setting.[169] The primary indicators of rapid progression were age, time from first symptom to admission, entry site, and hemodynamic indicators on the first day.

TIG should be given at the time of diagnosis to neutralize circulating toxin before it reaches the nervous system.[1,13,163] The optimal dosage of therapeutic TIG has not been established. When TIG became available in the 1960s, a dosage range of 3000 to 6000 units was chosen based on calculations of the quantity of immunoglobulin necessary to achieve antibody levels higher than those found to be minimally protective against the effects of tetanus toxin.[170] Despite the absence of evidence to support this choice of dosage range, 3000 to 6000 units of TIG given intramuscularly in a single administration was adopted as the standard for TIG therapy.[12] A retrospective analysis of tetanus cases reported in the United States from 1965 to 1971 subsequently suggested that a TIG dosage of 500 units is as effective as higher dosages in reducing mortality.[171] Similarly, the results of an observational study involving 236 patients with severe tetanus admitted to two hospitals from 1981 to 2001 also indicated that the reduction in TIG dose from 3000 to 6000 units to 500 units midway through the study did not appear to adversely affect patient outcome.[21] In addition to apparently being as effective as higher dosages, 500 units constitutes a smaller volume of antitoxin, thereby reducing the number of injections required when given intramuscularly and avoiding repeated painful spasm-inducing stimuli to the patient. Thus, a total dosage of 500 units of TIG is now commonly recommended,[1,136,163–166,172,173] although some authorities continue to prefer 3000 to 6000 units of TIG.[28,61,174,175]

Equine antitoxin can be given intravenously but is associated with serious allergic side effects such as anaphylaxis and serum sickness.[176–178] After intramuscular TIG administration, peak serum levels of antitoxin are achieved by 48 to 72 hours, a theoretical disadvantage of TIG, which, according to the product label, cannot be given intravenously in the United States.[179] Regardless, no evidence to date suggests that intravenous equine antitoxin is more efficacious than intramuscularly administered human TIG, and therefore equine antitoxin is not recommended when TIG is available.[180] Intravenous immunoglobulin (IVIg) has been proposed as an alternative to TIG when TIG is unavailable or when intramuscular injections must be avoided.[173,179,181,182] Although the quantity of tetanus antitoxin in IVIg produced by different manufacturers varies, it appears that commercial IVIg preparations contain sufficient antitetanus antibody to achieve protective antibody levels when given in dosages of 200 to 400 mg/kg.[179,182,183] IVIg is not licensed for this indication in the United States.

Use of intrathecal antitoxin for therapy has been controversial.[184,185] Systemically administered antibody does not cross the blood–brain barrier; intrathecal administration theoretically offers the possibility of neutralizing extracellular toxin in the CNS as it traverses synaptic spaces. This was supported by animal studies and early clinical series.[186,187] However, the

results of studies evaluating the benefits of intrathecal therapy are conflicting. The majority of published controlled trials with intrathecal administration of equine antitoxin or TIG to treat either adults or neonates reported failure to significantly decrease mortality.[185,187–190] However, even though many of these trials were limited in size, they did show a trend toward decreased mortality. Significantly decreased mortality, lowered by one-third to one-half, was demonstrated in six studies.[191–196] A metaanalysis of English-language studies by Abrutyn and Berlin in 1991 on the topic concluded that there was no net proven benefit, safety was not established, and well-designed controlled clinical trials were needed.[185] Subsequently, two randomized controlled clinical trials evaluating intrathecal TIG in adult patients with tetanus demonstrated significant improvement in clinical course and shortened duration[197,198] (as did some earlier trials[186,191]); the larger study demonstrated a trend toward decreased mortality and a clear reduction in treatment costs.[198,199] A 2006 metaanalysis of controlled clinical trials added these studies and concluded that intrathecal therapy is superior to intramuscular antitoxin alone in decreasing mortality[200]; inexplicably, the analysis did not include all studies used in the 1991 analysis and had other irregularities. Three newer studies again supported improved outcome with intrathecal therapy.[201–203] Because overall tetanus mortality has been decreasing over time as a result of improved medical care, evaluating the impact of individual therapeutic interventions on tetanus mortality is increasingly difficult and progressively less important. Although additional randomized controlled trials of sufficient sample size could provide definitive proof of decreased mortality, most studies suggest that intrathecal TIG can improve tetanus morbidity and mortality when given early in the course of disease. The added benefit of intrathecal therapy in reducing mortality, even if limited, may be more relevant to settings where critical care resources are scarce. Because TIG is not licensed for this indication and lacks clear benefit, intrathecal TIG use cannot be recommended in the United States.

All patients suspected to have tetanus should start or complete a primary series of vaccination with tetanus toxoid, or receive a booster dose, at the time of diagnosis. The quantity of toxin sufficient to produce disease is so minute that an immune response may not be elicited.[154] Relapsing or recurrent cases have been reported.[75,150,204–210]

When patients with tetanus have identifiable sites of ongoing infection, continued production of tetanus toxin may be prevented by careful surgical drainage or debridement,[211] and appropriate antimicrobial therapy. In the absence of active infection, the utility of antibiotics in treating tetanus is unclear,[1,28] but a study from Ghana demonstrated that when antibiotics were unavailable, mortality from tetanus increased.[65] In the past, penicillin administered for 5 to 10 days as procaine penicillin, 1.2 million units daily, or aqueous crystalline penicillin G, 4 million units daily divided (every 6 hours), was the antibiotic of choice to kill the vegetative form of the organism.[12] However, because penicillin is a central GABA antagonist and may potentiate the effects of tetanus toxin,[1,163] metronidazole given as 500 mg every 6 hours either intravenously or orally has been preferred more recently.[1] One controlled trial from Indonesia found significantly improved prognosis with use of metronidazole compared with penicillin[212]; another could not show differences in mortality, but did find reduced requirements for muscle relaxants and sedatives in patients randomized to metronidazole therapy,[28] and a third randomized controlled trial showed no advantage at all.[213] Thus, preference for metronidazole over penicillin may be more theoretical than real. Other antibiotics that are effective against *C. tetani* include macrolides, tetracyclines, and clindamycin.[1]

Meticulous supportive care is critical to the treatment of patients with tetanus.[57,58,184] To minimize spasms, the patient should be kept in a quiet, dimly lit room equipped to avoid sudden environmental stimuli, including loud noises. Pharmacologic treatment of hypertonicity and spasms depends on the severity of disease. The objective is to control spasms and increased tone without impairing voluntary movement, consciousness, or spontaneous respiration, if possible. Because tetanospasmin blocks GABA release from inhibitory neurons in the CNS, the ideal therapeutic agent would reverse or counteract this blockade.[1,130,163,214] Benzodiazepines such as diazepam are $GABA_A$ agonists that indirectly counteract the effects of the toxin.[1,167,215,216] Intravenous diazepam is generally given in dosages of 0.5 to 15 mg/kg per day.[143,217–220] Some clinicians use standard dosages administered every 2 to 8 hours; others give dosages at the time of spasms, using 5 to 10 mg as often as three times per hour or more.[12,58] Higher dosages may be used if the lower dosages fail; some adults require and tolerate dosages of more than 600 mg in 24 hours. Lorazepam is also effective and may be preferred because of its longer duration of action.[1] Midazolam given as a continuous infusion also has been effective and has the advantage of being free of propylene glycol, a preservative present in parenteral diazepam and lorazepam preparations that can produce lactic acidosis.[1,162,163]

Other muscle relaxants that have been used include dantrolene and intrathecal baclofen.[1,61,162,163,166,221,222] Propofol by continuous infusion has been used as an adjunct sedative to benzodiazepine therapy.[1,61,163,223] Magnesium sulfate, a presynaptic neuromuscular blocker, has also been used by some to control or reduce muscle spasms in generalized tetanus as well as manifestations of autonomic dysfunction (see later).[43,61,166,167,224–229] Short-acting barbiturates (secobarbital sodium and pentobarbital) can be used when diazepines are not available, bearing in mind they are more likely to result in respiratory depression and coma than benzodiazepines.[12,130,165] Chlorpromazine has also been used with and without benzodiazepine and barbiturate therapy.[12,28]

If conservative therapy fails to control muscle spasms, or if the patient has severe spasms compromising respiration, neuromuscular blockade with assisted ventilation is indicated. Vecuronium is now the agent of choice because it causes minimal autonomic instability; an alternative is atracurium.[1,61,130,163] Older agents can be used in their absence.[12,130] When neuromuscular blocking agents are used, sedation is still required to suppress consciousness and memory of the period of paralysis.[1,163]

Although effective in controlling spasms, the agents just discussed may not decrease the sympathetic overactivity that can complicate the course of tetanus and increase the risk of fatal outcome. Autonomic dysfunction should be treated with labetalol or morphine.[33,130,163,230–232] β-Blockers should not be given in isolation, because their use can result in unopposed α-adrenergic activity leading to severe hypertension. Other agents used for managing autonomic dysfunction include continuous intravenous magnesium sulfate, clonidine, and fentanyl.[61,162,167,224,226,227,233,234]

Acute respiratory failure is a common early complication of generalized tetanus. Respiratory decompensation in tetanus can be precipitous; close observation of patients early in the course is essential. Assisted ventilation may be required. Indications for tracheotomy include: likely prolonged mechanical ventilation, endotracheal tube exacerbation of upper airway spasm and inability to cough or swallow.[12,28,57,166,235]

Moderate or severe tetanus often results in high metabolic demands and a protein-catabolic state. Parenteral alimentation is sometimes required, best initiated early in treatment.[1,61,130,166,236,237] Other supportive measures include

prophylaxis for thromboemboli, gastrointestinal hemorrhage, and pressure sores.

EPIDEMIOLOGY

Incidence

The true public health impact of tetanus was largely unappreciated until the second half of the 20th century, despite its high mortality and dreadful symptoms. Possible reasons for the lack of recognition include the rural predominance of the disease, the occurrence of cases singly rather than in clustered epidemics, and the lack of compulsory reporting.[41,238] A 1966 review by Bytchenko of data reported to the WHO, supplemented by scientific publications from the 1950s, suggested overall tetanus mortality rates of two to three deaths per 100,000 population in Africa, Central and South America, and Asia, with rates as high as 25 to 100 per 100,000 in some countries and subnational areas.[74] He estimated a total of at least 50,000 annual tetanus deaths worldwide, but cautioned that this was likely to be a substantial underestimate.

A more accurate understanding of global tetanus burden came 20 years later when public health interest in tetanus, especially neonatal tetanus (NT), was spurred by the easy availability of inexpensive and highly effective tetanus toxoid vaccine. Before the 1980s, the incidence of NT in lower-income nations, based on reported disease, was estimated to be approximately 0.1 per 1000 live births.[74] Using hospital-based reporting, an estimate of 600,000 NT deaths worldwide was made for 1981, corresponding to approximately five NT deaths per 1000 live births.[239] However, because most NT cases were not brought to health facilities for treatment, a realistic assessment became possible only when community-based, house-to-house surveys of neonatal deaths were conducted in more than 40 countries in Africa, Asia, South America, and the Middle East. These surveys documented that actual NT mortality was far greater, with more than 50 deaths per 1000 live births in some areas.[41,44,240,241] Comparisons of survey data to reported data demonstrated that national NT reporting efficiencies were generally less than 5% in lower-income countries.[41,242,243] Using the survey results, global NT mortality was estimated to be approximately 1 million deaths per year in the early 1980s, corresponding to approximately 10 deaths per 1000 live births (Fig. 58.3).[42,244] At the same time, 310,000 to 700,000 non-NT cases with 122,000 to 300,000 deaths were estimated to occur in low- and middle-income countries, more than half in children.[245] In contrast, in high-income countries, only an estimated 2000 tetanus cases and 1000 resultant deaths occurred annually during that period.

A decline in tetanus incidence in higher-income countries began in the early 1900s. By the mid-1930s, many European countries had tetanus mortality rates of less than one per 100,000 population.[74] Factors that contributed to the decline included urbanization, mechanization of agriculture, adoption of aseptic surgical and medical techniques, hygienic childbirth and wound care practices, use of prophylactic tetanus antitoxin, and, ultimately, use of antibiotics.[41,74,245] However, in lower-income countries, tetanus continued to constitute a major health burden until tetanus toxoid was introduced into national immunization programs.

After more than 50 years of use of tetanus toxoid–containing vaccine in higher-income countries, and more than 30 years

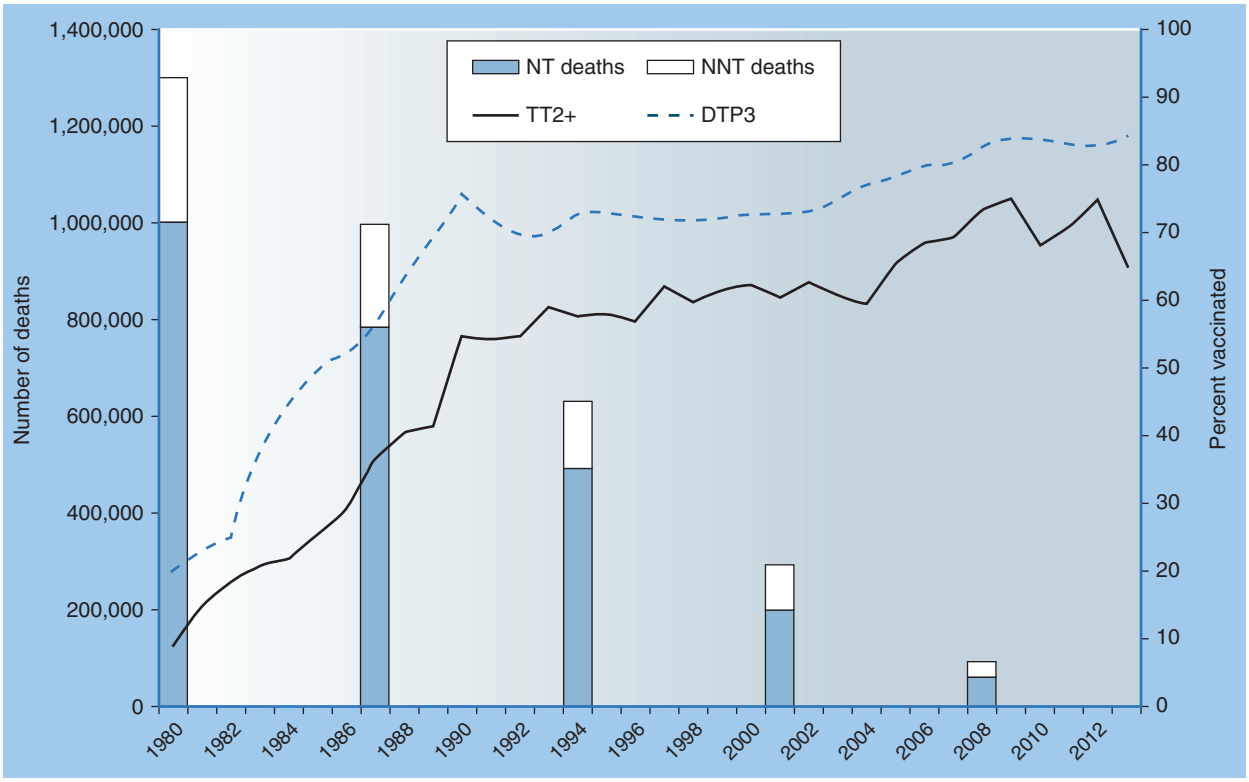

Figure 58.3. Estimated annual deaths from neonatal tetanus (NT) and nonneonatal tetanus (NNT), and coverage with combined diphtheria, tetanus toxoid, and pertussis-containing vaccine (DTP3) among children age 12 to 23 months and tetanus toxoid (TT)2+ (two or more TT doses) among pregnant women, 1980–2013. *(Vaccination coverage from the WHO/IVB [World Health Organization's Department of Immunization, Vaccines, and Biologicals] database, 2014. Estimated tetanus deaths from references 244, 245, 247, 249, 263, 795, and 804; World Health Organization, UNICEF, World Bank; State of the World's Vaccines and Immunization, Geneva, Switzerland, World Health Organization, 2002; and from M. Roper [unpublished data].)*

in lower-income countries, the number of tetanus cases and deaths has decreased dramatically (see Fig. 58.3).[246,247] The most recent estimates of total global tetanus (derived from different models and perhaps underestimated) are 66,129 deaths for 2012[248] and 58,900 deaths for 2013.[249] Fewer than 1000 of these tetanus deaths occurred in high-income countries. Total reported tetanus incidence rates for 2014 are less than 0.03 per 100,000 population in most European countries[250]; U.S. incidence from 2000 to 2012 was 0.01 per 100,000 population.[251,252]

Tetanus is also becoming rare in low- and middle-income countries with well-established immunization programs delivering both primary and booster tetanus toxoid doses.[247,253–255] For example, the 2006 incidence of tetanus in Thailand was 0.23 per 100,000 population, and in Brazil it is approximately 0.17 per 100,000 population; in both countries the rates are steadily declining.[256,257] Countries where primary immunization coverage has lagged, or where booster doses have not yet been introduced, still have incidence rates of one to two per 100,000 population (M. Roper, unpublished data). In such countries, tetanus still accounts for a significant proportion of hospital admissions and deaths.[62,258–262] Although global NT mortality has decreased by more than 90% since the 1980s,[263] 49,000 NT deaths were estimated to have occurred in 2013 (see "Public Health Perspective" later).[264]

Contemporary tetanus incidence estimates are still uncertain; reporting is little better now than in the 1950s. Many low- and middle-income countries report only NT cases, and NT reporting fractions are still low.[243,265–267] Even in developed countries, tetanus reporting efficiency is 60% or less[41,268–272]; in the United States, only 40% of tetanus deaths were reported in 1989,[268] and overall reporting was estimated to be less than 20%.[11] In the absence of reliable surveillance data, estimates of tetanus burden are generated by mathematical modeling.

Nonneonatal Tetanus

Prior to the availability of tetanus toxoid, the epidemiology of tetanus in a given area depended on the risk of infection with *C. tetani* and the availability of prophylactic tetanus antitoxin. The advent of widespread use of tetanus toxoid modified the distribution of disease, as has socioeconomic development in many parts of the world.

Sources of Infection

Acute wounds, particularly puncture wounds and lacerations, account for more than 50% of lesions associated with tetanus in most series (range: 47% to 82%). The severity of injury varies from superficial and trivial to extensive and deep; often, antecedent conditions are considered too minor to require medical attention. Burns, open fractures, abrasions, and excoriations also are commonly associated with tetanus.[11,17,74,273–277] Historically, tetanus was a dreaded consequence of war, with incidence rates on the order of two cases per 1000 injured troops[8,278]; similarly high rates were described in wounded civilians in Asia during World War II.[279] Large clusters of tetanus cases also have occurred in conjunction with natural disasters resulting in mass casualties,[166] including the 2004 tsunami in Aceh, Indonesia (106 cases, 20 deaths)[280,281] and the earthquakes in Pakistan (2005: 139 cases, 41 deaths)[282,283] and Indonesia (2006: 81 cases, ≥25 deaths).[281,284]

Tetanus also is associated with a wide variety of nontraumatic conditions, including chronic skin ulcers, abscesses, gangrene, dental infections, insect and animal bites, snake and stingray envenomations, and carcinomas.[11,41,71,73,277,285–287] In South Asia and Africa, otitis media is a common cause of tetanus in children, accounting for up to half of cases in some pediatric tetanus series.[73,201,210,277,288–292] Tungiasis (skin inflammation and secondary bacterial infection caused by *Tunga penetrans* flea infestation) is often associated with tetanus in Africa, South America, and the Caribbean, especially in children.[21,285,291,293,294]

Medical procedures, including surgeries and injections, were frequent causes of tetanus in high-income countries prior to the use of sterilized equipment, solutions, and dressings; they continue to account for a significant proportion of cases in lower-income countries.[74,261,273,295–299] Even vaccination, especially against smallpox, was associated with tetanus.[74,273,277] Intramuscular quinine injections are associated with especially high mortality, likely related to quinine-induced muscle necrosis that enhances bacterial growth and toxin production.[72,261,300] Tetanus associated with deliveries and abortions (maternal tetanus) has been a frequent cause of maternal mortality where unclean deliveries and abortions are common, accounting for up to 5% of maternal mortality.[43,74,301–303] Circumcision, both in the neonatal period and at older ages (male and female) has been associated with tetanus.[60,240,258,293,298,304–306] Tetanus also has been identified following voluntary male medical circumcision for HIV prevention.[307,307a,307b,307c] Traditional surgeries, such as uvulectomy, ear piercing, and ritual scarification, also are associated with tetanus.[41,60,74,298,308] In the United States, cases associated with body piercing and tattoos have been reported.[70,71,309,310] Injection drug use, long appreciated as a significant tetanus risk factor,[11,70,311–314] has accounted for 15% to 89% of tetanus cases in recent series from more affluent countries.[11,71,254,255,315,316] Substantial clusters have occurred in California and England in association with contaminated illegal drug supplies.[316–318] Failure to identify an antecedent wound or condition is not uncommon; up to 25% of tetanus cases in published series have no known associated cause (M. Roper, unpublished data).[74]

Seasonal and Geographic Distribution

Tetanus generally follows a seasonal pattern in temperate countries, with a midsummer peak that may reflect soil and spore conditions as well as agricultural and other outdoor activities associated with injuries during warmer months.[17,74,238,273,319,320] In tropical climates, tetanus tends to occur year round, although in some areas an increase in cases is seen during the wet season. Geographic distribution is uneven, with a higher incidence in lowland areas with a moist, warm climate and fertile soil, especially where land is used for cultivation or to pasture domestic animals,[9,80,321] although cases have been documented in desert environments.[322] High altitude has been associated with lower tetanus rates, although not consistently.[74,323] The highest rates of tetanus are found in rural communities, particularly those lying nearest the equator.[41,73,74]

Age and Sex Distribution

In the absence of vaccination, children were at highest risk of non-NT, accounting for 50% to 70% of all cases; age-specific incidence was highest in children younger than 10 years of age.[41,74,238,245,273,324] Despite the greater frequency of pediatric tetanus, mortality in children and adolescents was (and continues to be) substantially lower than in adults, ranging from 5% to 30% compared to 50% and higher in adults.[245,277,321,325] Second to pediatric disease, tetanus historically affected young adults, usually with a male predominance (2:1 or higher) except in societies where women are responsible for agricultural work and where septic deliveries and abortions are common.[74,326]

Vaccine Era

Tetanus has become rare wherever systematic use of tetanus toxoid has been implemented in large proportions of the population over many birth cohorts. In higher-income countries, cases predominate in the elderly who are most likely to be unvaccinated or undervaccinated.[11,41,58,59,245,269,272,325,327–331] Many countries have given tetanus toxoid to male military recruits since the 1940s, contributing to a female predominance among tetanus cases in older-age groups.[269,272,327,330,331] Other important risk groups are immigrants from countries with less-developed vaccination programs, persons with religious or philosophic objections to immunization, and injection drug users.[11,71,254,332,333] This distribution is remarkably consistent in higher-income countries, and is mirrored in population-based serosurveys that demonstrate highest susceptibility in the elderly, foreign born, and groups of vaccine objectors.[272,334–341]

In lower-income countries, coverage with three doses of DTP (diphtheria and tetanus toxoids and pertussis vaccine) in infancy and TT (tetanus toxoid) for pregnant and childbearing-age women has steadily improved (see Fig. 58.3); consequently, tetanus in young children is rare and is increasingly uncommon in women. Data from a longitudinal study of tetanus in a major medical center in Ho Chi Minh City, Vietnam, demonstrate this impact.[62] Vietnam has had high coverage with three doses of DTP (DTP3) since the late 1980s, exceeding 90% since the early 1990s; TT immunization for pregnant and childbearing-age women was widely implemented later in that decade. The age- and sex-specific pattern of tetanus admissions showed a small proportion of cases in children younger than 10 years of age (5.8%) and a 90% reduction in adult women over the study period (10% of cases in 1993; 1% in 2002), whereas tetanus in older children and adult men remained unchanged. The same pattern has been documented in other Asian and African countries: the most affected groups are persons in their 20s and 30s, with a male predominance as high as 12:1 (M. Roper, unpublished data).[258,342–345,307a] The few tetanus serosurveys available from lower income countries mirror this pattern: loss of protection is apparent in older childhood and, by adolescence and young adulthood, the prevalence of seroprotection is below 65% (often well below 50%), except among women who receive TT to prevent NT.[346–353,353a] Where booster doses in childhood and adolescence are used, the median age of patients with tetanus shifts to mid- and late adulthood and male predominance is modest.

Neonatal Tetanus

NT clusters in poor, rural, and disadvantaged communities where access to immunization is low, and where delivery conditions and postpartum cord care practices are unclean.[43,243] Studies in highly affected areas documented NT mortality rates as high as 50 to 110 per 1000 live births.[241,354–356] In community-based studies from the 1970s and 1980s, 23% to 72% of neonatal mortality was caused by NT; in 39% of the 46 surveyed countries, NT accounted for more than half of all neonatal deaths in at least one surveyed area.[41,44]

In contrast to the situation in the lower-income countries, NT rates in high-income countries prior to the use of TT were orders of magnitude lower. In Denmark, as hospital and clinic deliveries became increasingly common and aseptic practices became the norm, NT incidence fell from 0.79 per 1000 live births in the 1920s to less than 0.05 per 1000 live births by the mid-1960s.[357] Similarly, in the United States, NT mortality dropped from 0.64 per 1000 live births in 1900 to less than 0.02 per 1000 live births in the early 1950s.[48,320] Once tetanus vaccination became widespread in high-income countries in the second half of the 20th century, NT became exceedingly rare (see "Public Health Perspective" later).

Neonatal Tetanus Risk Factors

Roper and colleagues have reviewed documented NT risk factors in detail.[42] Increased NT risk is associated with home deliveries with unclean birthing surfaces, untrained birth attendants, lack of attendant hand washing, unclean tools used to cut the umbilical cord, and the use of traditional substances on the umbilical stump.[45,60,358–369] In Africa and South Asia, where animal dung was commonly used for postpartum cord care (to confer "strength" or "purity"), NT mortality was particularly high; when the practice was substituted with culturally acceptable cleaner alternatives, rates decreased dramatically.[370,371] Where domestic animals are prevalent, and especially if animals are kept close to or inside homes, NT is more common.[360,372,373] Use of dried cow dung as fuel may result in contamination of hands and substances placed on the umbilical stump.[374,375] Traditional surgeries or piercings are also associated with NT.[60,74,304,308,368]

Although immunization against tetanus per se is more effective in reducing NT mortality than deliveries performed by attendants trained in clean delivery practices in the absence of immunization, training of birth attendants reduces overall neonatal mortality resulting from tetanus and other infections.[356,362,370,376–379] Measures to prevent infection of the umbilical stump also have a powerful effect on reducing NT (and other neonatal infections).[370,371] Three case-control studies have indicated that the use of topical antibiotics at the time of delivery and in postnatal care decrease the risk of NT; antiseptics were also protective, while dry cord care in itself was not.[380–382] Recent systematic reviews of randomized, controlled trials evaluating the effect of chlorhexidine use on the umbilical stump in rural community settings in South Asia showed a 50% reduction in omphalitis and a 20% reduction in neonatal mortality.[383,384] The included trials were conducted in areas where maternal TT immunization coverage is high; thus impact on NT prevention per se could not be evaluated. Provision of clean delivery kits for home deliveries can have a positive impact on neonatal outcomes, even in the absence of trained birth attendants.[385,386] A systematic review of published studies on the effects of clean delivery and cord care practices on NT, neonatal sepsis and all-cause neonatal mortality underscored the difficulties in separating out and measuring the independent effects of specific hygienic obstetric and postnatal practices on the prevention of NT and other causes of neonatal death.[387] Based on the available evidence and a Delphi expert opinion exercise, it was concluded that clean delivery and postnatal practices are effective in preventing deaths from NT and neonatal sepsis and should continue to be promoted. Clean delivery practices can also reduce maternal tetanus and other forms of post-partum infections. China, a country that does not administer TT after childhood, eliminated maternal and NT* through near universal provision of clean delivery services.[388,389]

In many published community- and hospital-based studies, a male predominance in NT incidence has been observed (1.5:1 male-to-female ratio or higher).[41] However, this has not been a universal finding or, when found, is often minor and consistent with the known slightly higher frequency of male

*Elimination of maternal and neonatal tetanus is defined as an incidence of less than 1 NT case per 1000 live births in every district. See "Public Health Perspective" later.

births (~1.05 : 1).[42,360,369,379,390] Some authors attribute male NT predominance to culturally based differences in care seeking or recall bias resulting in better case/death detection in males.[42,44,364,391,392] Indeed, many of the higher ratios (up to 4 : 1) have been reported in hospital-based studies. Others propose a true male predominance in NT incidence and death attributable to sex-related differences in cord care practices and neonatal male circumcision,[240,304] or biologic differences, including later cord separation in males.[41,74,393]

Tetanus Epidemiology in the United States

Nonneonatal Tetanus

The epidemiology of tetanus in the United States illustrates patterns occurring in all high-income countries. Death certificate data from the early 1900s and national surveillance data starting in 1947 document a relatively constant decline in the annual rate of deaths from tetanus (Fig. 58.4). The decline accelerated somewhat in the mid-1920s with introduction of equine antitoxin for prophylaxis and treatment, as well as with improvements in living standards and medical care.[325] In 1947, when national reporting began, the incidence of reported cases was 0.39 per 100,000 population.[319] By 2000–09, overall incidence had declined to 0.01 per 100,000 population.[251] Declines in incidence occurred in all age groups (Fig. 58.5), with the greatest proportional reductions in infants and those older than age 60 years. There continue to be 25 to 37 tetanus cases per year reported through 2015, per the CDC (https://www.cdc.gov/mmwr/mmwr_nd/index.html). In the 1950s, more than one-third of the deaths from tetanus in the United States were among neonates and infants,[319,320] as compared with 2000–12, when there were only three infant cases (0.8% of 373 total cases; all NT), and more than 80% of tetanus deaths occurred among persons 60 years of age and older (CDC, unpublished data) (see Fig. 58.1). Tetanus in children and adolescents is now rare: in 2001–09, only 21 cases and no deaths occurred in those 1 to 19 years of age, corresponding to an incidence of 0.002 per 100,000 population. This trend has continued through 2012.[252] A review of neonatal and pediatric tetanus cases from 1992 to 2000 found that 85% of the children were unprotected because of parental religious or philosophic objection to vaccination[332]; homeschooling also has been identified as a risk for undervaccination and tetanus in children.[333]

Among all tetanus cases reported from 1972 to 2009, 52% were in males and the overall incidence of tetanus has been similar for males and females (0.022 per 100,000 and 0.019 per 100,000, respectively). However for all except the elderly (70 years of age or older), the incidence in males was higher than in females throughout the 37-year series, including 1.7 times higher in 2000–09 (0.13 vs 0.08 per 100,000). Among cases of tetanus in the elderly, women have predominated (64% of cases in 2000–09) with correspondingly higher incidence rates (0.42 per 100,000 vs 0.38 per 100,000 in elderly men) (CDC, unpublished data).[11,251] This pattern has persisted through 2014.

Serosurveys in the United States have demonstrated similar age- and sex-related patterns of immunity.[340,394–399] A national, population-based serosurvey of more than 18,000 people older than 5 years of age from 1988 to 1994 reaffirmed the heightened susceptibility in older ages.[340] Overall, 72% of the population 6 years of age and older had protective levels, falling from more than 90% in children 6 to 11 years of age to 31% in people 70 years of age or older.[340,398] At age 70 years, only 45% of men and 21% of women had protective levels of antibody to tetanus.[340] A similar pattern of lower levels of protective antibody with increasing age was identified in a 1990 to 2000 study of emergency department patients. Although protective levels were noted in 90% or more of

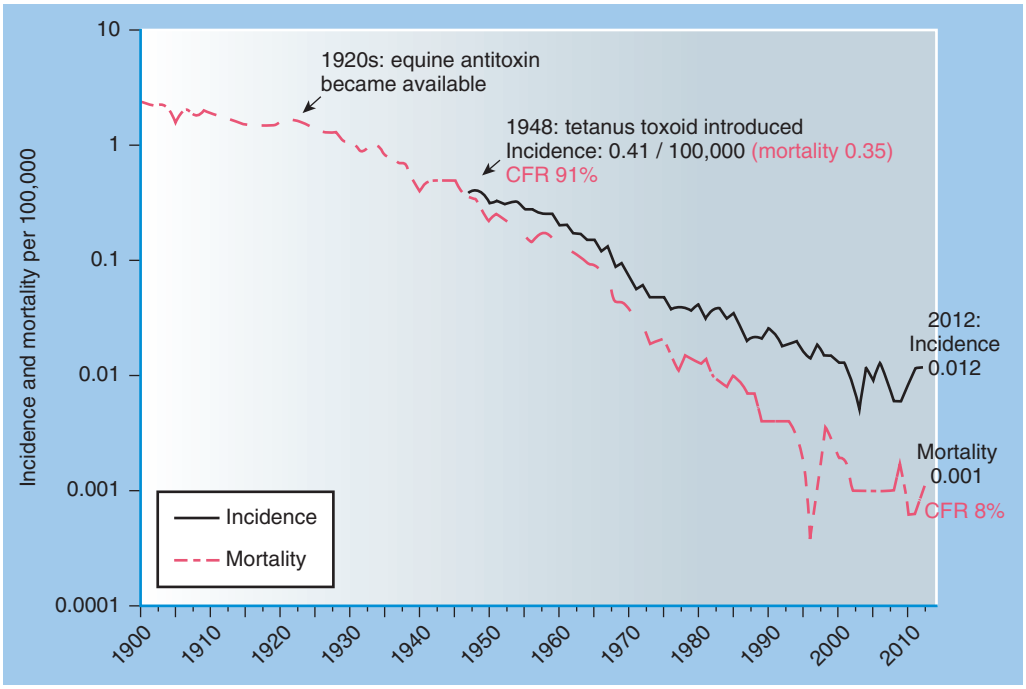

Figure 58.4. Mortality and incidence rates of tetanus reported in the United States, 1900–2012. Not all states reported deaths from tetanus until after 1932. Estimated rates shown are based on the population of the reporting states. National reporting of cases began in 1947 when widespread use of tetanus toxoid (TT) began. While tetanus mortality was declining prior to the availability of TT (see text), following its introduction, reduction in incidence, mortality, and case-fatality rates (CFRs) accelerated. *(From Centers for Disease Control and Prevention, unpublished data.)*

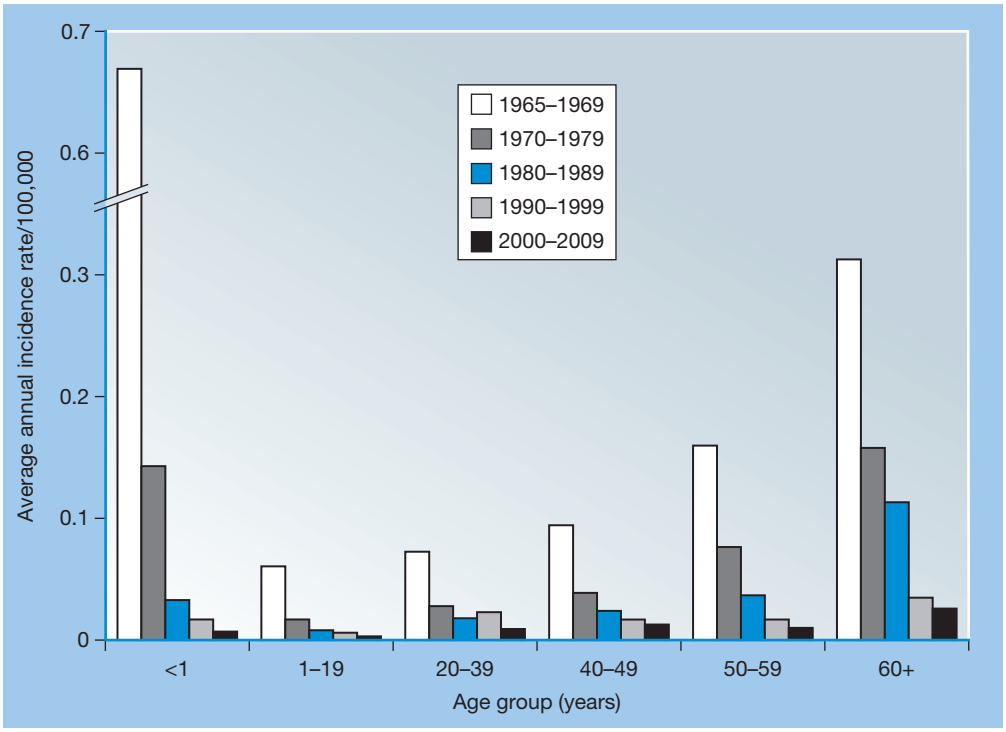

Figure 58.5. Age group–specific incidence rates of reported tetanus cases in the United States, 1965–2009. Data from 2010–12 show the same patterns seen in 2000–09. *(From Centers for Disease Control and Prevention, unpublished data.)*

patients up to 50 years of age, only 60% (both men and women) had protective antibody levels by age 70 years in that study population.[400]

Historically in the United States, tetanus was predominantly reported by states in the Southeast; incidence had a distinct peak during the summer.[17–19,319,320,325] In recent years, cases have been routinely reported from throughout the United States, and both geographic and climatic distinctions in incidence have been less apparent.[11,68–71]

In the 1950s, nonwhite people had an incidence of tetanus more than five times higher than that of whites.[319,320] By the 1990s, no substantial difference in incidence rates remained between whites (0.01 per 100,000 population) and nonwhites (0.01 per 100,000 population). However, the incidence in the Hispanic population (0.02 per 100,000 population) continues to be twice that of non-Hispanics (0.01 per 100,000 population).[11,252] Adult immigrants to the United States may be at substantially increased risk for tetanus compared with the rest of the population. A serosurvey involving 1988 patients seeking treatment at five major metropolitan emergency departments for wound care from 1998 to 2000 identified those born in Central and South America as being at significantly higher risk for nonprotective tetanus antitoxin levels.[400] Other studies in Washington, DC, Los Angeles, and New York City demonstrated increased tetanus risk in adult immigrants from Asia and Africa as well as the Americas.[397,401–404]

Clinical characteristics of non-NT cases are derived from available information on 2,012 cases reported from 1972 to 2009 (CDC, unpublished data).[11] Of 736 cases with clinical presentation reported, 88% were generalized, 12% were localized, and less than 1% were cephalic. Acute trauma of diverse severity was reported in 76% of the cases, including puncture wounds, lacerations, blunt trauma, crush injuries, burns, frostbite, surgery, gunshots, and animal bites or scratches. Seventeen percent were associated with chronic wounds and infections (e.g., skin ulcers, gangrene, abscesses, blisters, and cellulitis) or illegal injection drug use. Dental infections accounted for 0.5% of cases. Between 1987 and 2009 (when data on diabetes history were collected), patients with diabetes made up 13% of 882 cases reported and accounted for 29% of the tetanus deaths in that period. The estimated average annual incidence of tetanus among known diabetics[405] was 0.043 per 100,000 (0.061 per 100,000 among known diabetics older than 65 years of age). Patients with a history of injection drug use accounted for 10% of cases from 1990 to 2009; many had multiple subcutaneous abscesses from subcutaneous injections.[11,68–71] The steady decline in tetanus incidence among persons 20 to 39 years of age was interrupted in the 1990s by the resurgence in this cause of tetanus (see Fig. 58.5).[11,71]

Immunization histories were available for 986 (49%) of the tetanus cases reported from 1972 to 2009 (CDC, unpublished data): 163 (16%) had received at least a three-dose primary series of TT, and 62 (6%) reported that the last dose of TT was received less than 10 years before the illness.[71,251] Cases in previously immunized persons generally exhibit a milder clinical course and lower case-fatality rate than those in unimmunized persons.[406–408] Among the 163 patients who reported having had at least a three-dose primary series of TT, five deaths occurred (case-fatality rate: 3%); all of those five patients had received their last dose of TT 10 or more years before the onset of tetanus. All other deaths (526) occurred among 1849 patients with fewer than three doses of TT or with unknown vaccination history (case-fatality rate: 28%) (CDC, unpublished data).

Of the 514 patients from 1990 to 2009 with acute wounds and available medical history, 197 (38%) sought medical care for the injury; of these, 182 (92%) were eligible for TT prophylaxis with wound care, but only 79 (43%) received it (CDC, unpublished data). Prophylactic TIG was administered

to only eight (9%) of 91 patients for whom it was indicated. A review of U.S. cases reported in the 1980s and 1990s demonstrated that fewer than 60% of persons with injuries for which a tetanus booster was indicated received a dose during wound management.[409] Most patients in that series who sought medical care for the acute injury were also candidates for, but did not receive, TIG (see "Tetanus Prophylaxis in Wound Management" later). Similar findings were noted in a 2004 prospective study of wound patients treated in the emergency department of five academic medical centers: 58% of patients needing a TT dose were not vaccinated; only one of 504 patients for whom prophylactic TIG was indicated was actually given TIG.[400]

Neonatal Tetanus

In the United States, deaths from tetanus among infants declined from 0.64 per 1000 live births in 1900, to 0.07 per 1000 live births in 1930 and to 0.01 per 1000 live births by the 1960s.[48] Because tetanus among infants occurs almost exclusively in the neonatal period, tetanus in this age group has been used as a surrogate measure of neonatal disease in the United States. This decline reflected an increased prevalence of maternal immunity acquired through TT vaccination beginning in the late 1940s, as well as more hygienic birth practices, including hospital delivery. Monitoring of the incidence of tetanus among infants began in 1961; trends in incidence paralleled those in mortality. From 1967 to 1968, a precipitous decrease occurred in the incidence and mortality of reported tetanus among infants. This decrease corresponded to a sharp decline in cases reported from Texas following a rigorous vaccination campaign targeting high-risk mothers. After 1968, the incidence of tetanus among infants continued to decline but more gradually (see Fig. 58.5).

Of the 32 cases of NT reported in United States from 1972 to 2009, 28 (88%) were among infants born outside of a hospital. Nineteen of the cases (59%) occurred in Texas, which had fewer than 9% of U.S. births during that period. Only six mothers (19%) had a history of having received TT, and only one mother was reported to have received more than one dose of toxoid. Of the 28 infants with known outcome, 21 (76%) survived (CDC, unpublished data).

From 1985 to 2012, only six cases of NT have been reported in the United States: one each in 1989, 1995, 1998, 2001, 2011, and 2012 (CDC, unpublished data).[252,410–412] Three of the six mothers were foreign-born women who were undervaccinated or had unknown vaccine status; three were U.S.-born and declined tetanus vaccination on religious or philosophic grounds. In the well-documented 1998 case, the mother chose not to receive toxoid because of philosophic objection to vaccination. The infant was delivered in a hospital by cesarean section; at home, the umbilical stump was treated with a nonsterile, commercial clay powder thought to accelerate healing.[412] These cases highlight the importance of obtaining vaccination histories from all pregnant women, particularly those who are foreign-born, and of counseling women who decline vaccination about the risk of NT.

NATURAL IMMUNITY

There has been debate over whether humans can develop circulating antibody against tetanus in the absence of vaccination, an idea that is now considered discredited.[413] In the era before active immunization and standardization of the neutralization test, humans colonized with *C. tetani* were rarely and inconsistently found to have antibodies to toxin and other *C. tetani* antigens.[81,84,86,88] The majority of subsequent studies purporting to show "natural immunity" did not use an in vivo toxin neutralization assay, the definitive method of testing for biologically active antibody that correlates with clinical protection (see "Assessment of Immune Responses" later). Rather, using in vitro assays (e.g., enzyme-linked immunosorbent assay [ELISA] and passive hemagglutination), often with inappropriately low immunity thresholds, investigators reported that substantial proportions of allegedly unimmunized populations in Brazil, China, Ethiopia, India, Italy, Israel, Spain, the former Soviet Union republics, and the United States had detectable levels of antitoxin.[394–396,414–420] However, in most of these studies, detected antibody levels were 0.01 IU/mL or less, far too low to be distinguishable from nonspecific binding. "Naturally immunized" subjects failed to demonstrate the rapid rise in antitoxin characteristic of an anamnestic or "booster" response in the first week after administration of high-dosage TT (100 or 250 limit of flocculation [Lf]) in the one study assessing immunologic memory.[415] Also, the prevalence of seropositive people in these studies did not increase with increasing age as would be expected from a theoretically cumulative exposure.[413,414] Finally, vaccination histories were not confirmed and may have been inaccurate.[395,396,413,421]

PASSIVE IMMUNIZATION

Early researchers were able to prevent, modify, or treat tetanus in animal models using antitoxin prepared from large animals. The therapeutic dosages required were much larger than the prophylactic ones.[422] Passive immunization with equine tetanus antitoxin for treatment and for prophylaxis after wounds became common practice in World War I; data collected during the war provided evidence of prophylactic efficacy.[8,9,80,278] However, equine antitoxin is frequently associated with adverse reactions, including anaphylaxis and serum sickness.[176–178,423] As a means of decreasing the antigenicity of equine antitoxin for human use, proteolytic treatment was introduced to obtain cleaved Fab fragments with preserved neutralizing activity.[424] Further techniques to produce purified equine IgG antitoxin were developed, and a pasteurization step to reduce the risk of virus transmission has been tested.[425] Despite improvements in the quality of equine antitoxin, the passive immunity it confers is of limited duration. The half-life of refined equine antitoxin in humans is less than 2 weeks, and may be considerably less in previously sensitized persons.[425–427]

Human TIG was introduced in the early 1960s and was found to have a fairly constant circulating half-life of 28 days.[423,428] The frequency of local and systemic reactions associated with TIG is considerably lower than with equine antitoxin.[170,423] The greater safety and longer half-life of TIG has made it the preferred tetanus antitoxin for passive immunization. Even in the lower-income countries, TIG is beginning to replace equine antitoxin as it becomes more widely available, although the high cost of TIG compared with equine antitoxin precludes its use in many countries.[28,429] TIG is produced by cold-ethanol fractionation of the plasma of hyperimmunized adults. This preparation has been shown not to pose a risk of hepatitis transmission. It is distributed in 1-mL vials with 250 IU/mL. Recommendations for the use of TIG in patients with tetanus-prone wounds or conditions are given in "Tetanus Prophylaxis in Wound Management" later. TT is always given with TIG to induce long-lasting immunity in those with past exposure to toxoid, and to initiate active immunization in those without any prior exposure.[430–433]

Quantitation of the potency of antitoxin of animal or human origin has been standardized by comparison with an internationally standard antitoxin using fixed dosages of toxin. The international antitoxin unit defined in 1928 represented half the potency of the unit defined by the U.S. National

Institutes of Health (NIH). In 1950, the WHO reset the international standard unitage to agree with that of the NIH. Assay results before that time were generally reported in antitoxin units (or American units) per milliliter (AU/mL) using the NIH reference standard. Results using the current standard are reported as international units per milliliter (IU/mL). Before 1992, the only international reference antitoxin was of equine origin; in that year, the WHO Expert Committee on Biological Standardization established the first international standard for human anti-TIG.[434]

ACTIVE IMMUNIZATION: TOXOID

Early Approaches

The purification of tetanus toxin led to efforts to inactivate it chemically without eliminating immunogenicity. Initially, researchers used iodine trichloride. An early human challenge study and seroconversion studies supported the applied use of TT for prophylaxis in humans.[10] Later, formaldehyde emerged as the most convenient and efficient means of inactivation. In 1927, Ramon and Zoeller combined TT with diphtheria toxoid and demonstrated that there was no antigenic competition for immune responses; they also recognized NT as a disease to be prevented by immunization of pregnant women.[435] TT became commercially available in the United States in 1938, but was not widely used until the military began routine prewound prophylactic inoculation in 1941.

Toxoid Description

Currently, a high-yielding strain of *C. tetani* is cultured in liquid medium in large-capacity fermenters (up to 1000 L) to produce commercial toxoid. The medium, modified by Latham from that of Mueller and Miller, consists of a tryptic digest of casein, free of Berna and Witte peptones and other allergenic substances.[78,436] Media containing human blood group–specific substances, such as beef heart infusion broth, are specifically avoided. Data suggest that tetanus toxin production can be enhanced by bubbling nitrogen through the liquid media.[437] Extracellular toxin is harvested by filtration, purified, and detoxified for 4 to 6 weeks[438] or longer with 40% formaldehyde at 37°C. Some manufacturers detoxify the crude toxin before purification to enhance the safety of the production process.

In 1965, the WHO standardized the calibration of the potency of TT-containing vaccines and established the first international standard for TT, adsorbed, shortly after the establishment of the first international standard for TT, plain.[439] Comparison with a standard preparation using mouse bioassays allowed the establishment of international units of toxoid potency. The international standard assay was not adopted in the United States for licensure and lot standardization of TT content because of inconsistencies in results obtained from mouse assays.[440–442] The immune response in mice varies greatly depending on the mouse strain used.[441,442] In the United States, TT potency regulations require antitoxin induction of at least 2 IU/mL in the guinea-pig potency test which yields more consistent results than the mouse assay.[443,444] In late 2010, the fourth WHO international standard for TT, adsorbed, was approved.[445] The WHO now exclusively uses guinea-pig challenge assays for calibration.

In 1979, the WHO set the required potency standard for TT preparations at 30 IU per human dose. This was changed in 1982 to 40 IU per dose (60 IU in preparations of DTP).[446] Since 2003, WHO standards call for the potency of monovalent TT to be no less than 40 IU per 0.5 mL dose (determined in guinea pigs or in mice), and at least 40 IU (determined in guinea pigs) or 60 IU (determined in mice) per dose when TT is used in combination with diphtheria toxoid and whole-cell pertussis vaccine.[436,447–449] The Lf test is sometimes used as a surrogate measure of potency. Manufacturers of TT licensed in the United States indicate the quantity of toxoid in preparations by Lf content and the purity by Lf per milligram of protein nitrogen (pure toxoid has 3000 Lf/mg).[450] However, the Lf assay measures overall antigen content, which may not perfectly correlate with the level of antibody elicited. U.S. requirements for antigen content and potency for commercial TT products are discussed later (see "Dosage and Route" later).

WHO standards[436] apply as recommendations for commercial and governmental producers, and also serve as a requirement for supplies to United Nations agencies, including WHO and the United Nations Children's Fund (UNICEF).

Producers

In the 1970s to mid-1990s, local production of TT-containing products was common; in 1992, there were 63 producers of DTP/TT vaccines in 42 countries (WHO, unpublished data). The discovery of subpotent TT in use for NT prevention played a central historical role in the adoption of the 1992 World Health Assembly resolution that all vaccines used in national immunization programs should meet WHO requirements.[451–453] The effectiveness of maternal TT immunization in conferring protection against NT tetanus was well established by that time,[354–356,454–458] yet cases of NT were being reported in infants of vaccinated mothers.[149,151,359,413,459–462] A 1990 study in Bangladesh found the effectiveness of two doses of TT to be 45%; a small serosurvey supported those findings.[359] Subsequent testing at a WHO reference laboratory of TT samples from three consecutive lots produced in Bangladesh indicated no detectable potency. This prompted the WHO to review the quality-control procedures for commercial and state producers in 22 countries with a high NT burden. Only four had a functioning national control authority. Eighty lots of toxoid from 21 manufacturers were tested; 15 of the 80 failed to meet minimal potency standards.[451] Major efforts then were made to standardize the production of vaccines and to initiate and strengthen the biologics control authorities in the 22 countries. The volume of local products and producers decreased substantially as regulatory requirements to ensure vaccine quality were instituted. The regulatory requirements, and pre- and postqualification processes, developed by the WHO that are in place today ensure consistent effectiveness and safety for all vaccines procured by United Nations agencies.[453]

In the United States, TT is available in various combinations with diphtheria toxoid, acellular pertussis vaccine, and other antigens such as *Haemophilus influenzae* type b (Hib) conjugate vaccine, hepatitis B, and inactivated poliovirus vaccine. Similar preparations are available outside the United States. (See Chapter 15 for specific preparations and manufacturers.) Vaccine producers whose TT-containing products meet WHO requirements[436] and are prequalified, thus eligible for use by United Nations agencies, can be found on the WHO Immunization Standards website.[463]

Dosage and Route

As with other inactivated vaccines and toxoids, more than one dose of TT is required to confer protection and persisting immunity. When administering a primary series, there is no need to repeat doses if scheduled doses are delayed.

In North America, and universally when produced according to WHO recommendations,[436] TT preparations are given as 0.5-mL doses. Adsorbed toxoid is administered intramuscularly; fluid TT can be given subcutaneously. Either can be

given by jet injector. The toxoid content of commercial products is assessed by flocculation with standard antitoxin and measured in Lf units. This measure of toxoid protein content does not necessarily correspond to immunogenicity as measured by potency in guinea pigs. Adsorbed products available in the United States have a content of 2 to 10 Lf/dose. Potency, determined by measuring the amount of neutralizing antitoxin in serum pools from immunized guinea pigs must exceed 2 IU/mL.

Available Preparations

Whole-cell DTP, DTaP (diphtheria and TTs and acellular pertussis vaccine), and diphtheria and TTs (DT) are combinations used in infants and children younger than 7 years of age. Universal use of DTP/DTaP in infancy and childhood is recommended unless there are contraindications to pertussis vaccine, in which case DT is recommended.[173,464,465] In the United States, combination vaccines may be used when any component of the combination is indicated and if the other components are not contraindicated (see Chapter 15).

Products with reduced diphtheria toxoid content (2 to 2.5 Lf, compared with 6.7 Lf in pediatric preparations) are licensed for older children and adults. In the past, a combination of tetanus and diphtheria toxoid (Td) was used for persons 7 years of age and older in the United States. Since 2005, two Tdap products (reduced content of pertussis antigens and diphtheria toxoid) licensed for one-time use in adolescents and adults to boost immunity against pertussis as well as tetanus and diphtheria have been available.[466–469] (See Fig. 9.1 in Chapter 9 for details on recommendations and restrictions.[467]) Td or Tdap (tetanus, diphtheria, and pertussis) is preferred over single-antigen TT for tetanus prophylaxis in older children, adolescents, and adults under almost all circumstances because most persons in need of TT are likely to be susceptible to diphtheria.[466,468,469] In the United States, single-antigen TT is no longer available.

Adsorbed TT preparations are available with various precipitating salt adjuvants. In the United States, aluminum hydroxide, aluminum potassium sulfate, or aluminum phosphate is used as the adjuvant. These adjuvants induce an adequate immune response after fewer doses of toxoid than with the fluid preparation.[470] The primary immunization schedule for fluid toxoids requires four doses, whereas the adsorbed toxoid requires three. In NT prevention trials, three doses of fluid toxoid for pregnant women were necessary to achieve protective levels of antitoxin, as opposed to two doses of adsorbed toxoid.[471] In combined active–passive immunization, TIG does not substantially alter the response to adsorbed toxoid as it does with fluid toxoid.[428,433,472] Because fluid and adsorbed preparations are essentially equivalent with respect to the frequency of adverse events after immunization, adsorbed toxoid is preferred.[471,473] In the United States, Td preparations are available only as adsorbed products. Outside the United States, a calcium phosphate–adsorbed product is also available.[474] There is a theoretical but unproved possibility that calcium-adsorbed preparations may be associated with fewer reactions than the aluminum-adsorbed products.[475–477]

MenAfriVac (PsA-TT), a new Group A meningococcal conjugate vaccine with TT as a carrier protein, was designed to provide a tetanus booster dose in addition to immunization against meningococcal disease. Confirmation of its effectiveness is available.[478]

Constituents of Tetanus Vaccines

(See Chapters 5, 6, and 7 for more details on adjuvants and preservatives.)

According to WHO standards, the final bulk-purified lot of adsorbed TT should contain less than 0.2 mg/mL of free formaldehyde.[436] In the United States, regulatory requirements stipulate residual formaldehyde content of less than 0.1 mg per dose. In adsorbed products, amounts of precipitating calcium or aluminum salt adjuvant are also restricted. In the United States, a single human dose must contain less than 1.25 mg of aluminum. Preparations outside the United States may contain larger amounts of aluminum. Multiple-dose preparations of DTaP (and combinations), DT, Td, and TT products must contain an additive to prevent bacterial contamination; single-dose packaging does not require a preservative. Historically, mercury-containing thimerosal was the most common preservative, used in a final concentration of up to 0.1%, but more typically 0.01%. In response to concerns about mercury exposure from thimerosal raised in the 1990s, and to the 1999 U.S. Food and Drug Administration (FDA) call for eventual availability of thimerosal-free vaccines for infants and children, phenoxyethanol has been substituted as a preservative in preparations for children, usually to a final concentration of 0.01%. Currently, all DTaP, DT, and Tdap products used in the United States, and some preparations of Td, are either thimerosal-free or contain only trace residua from the manufacturing process (<0.00012%, corresponding to <0.3 μg of mercury per dose). Multiple-dose packaging includes 2-phenoxyethanol as a preservative, which is present in some single-dose preparations. Some Td products, TT fluid, and adsorbed multiple-dose preparations contain 0.0033% to 0.01% thimerosal as preservative, corresponding to 8.3 to 25 μg of mercury per dose. DTaP vaccines may also contain trace amounts of residual formaldehyde, residual glutaraldehyde, gelatin, and polysorbate 80.

Stability

Preparations should be stored at 2°C to 8°C and generally have a 2- or 3-year expiration date. The relative thermostability of tetanus vaccines make them less dependent on the cold chain than other immunobiologics. Ideally, higher ambient temperatures should be avoided, particularly for periods longer than 7 days, but exposure to ambient temperature for weeks does not substantially reduce the potency of the toxoid except at temperatures of 45°C or greater.[479] A recent study in rural Chad demonstrated that TT can safely be maintained in a "controlled temperature chain" at temperatures up to 40°C for 30 days or less without appreciable loss in potency.[352] However, TT exposed to 60°C is destroyed in 3 to 5 hours. Freezing can also reduce potency, particularly when the toxoid is adsorbed.[480,481] This effect is variable, but repeated freezing has been shown to reduce mean antitoxin response.[482] Adsorbed TT, whether monovalent or combined, can appear granulated after freezing has induced changes in the adsorbent, but granulation is not a reliable way to determine if the toxoid was previously frozen. The available data on temperature stability were reviewed in 1998,[483,484] with an update in 2006.[485]

RESULTS OF ACTIVE IMMUNIZATION

Assessment of Immune Responses

Active immunization confers immunity to tetanus by stimulating production of serum antitoxin. Primary immunization with TT also induces cellular immune responses (T-helper cell type 1, or type IV hypersensitivity) in 74% to 90% of recipients, which can be useful in assessing a person's capacity to mount an anamnestic response.[486] Intradermal skin testing

with TT is often used as a screen for anergy,[487–489] although false-positive reactions occur.[490]

In Vivo Assays

The gold standard for assessing a serologic immune response to TT is the in vivo toxin neutralization test, which measures biologically active antitoxin in serum.[420,471,491–493] (See "Serologic Correlates of Protection" later for a discussion of the relevance of antitoxin levels.) Neutralization tests are performed in mice injected with serial dilutions of test serum that have been preincubated with a lethal dose of tetanus toxin and standardized to a reference serum specimen. Toxin neutralization tests detect antitoxin titers as low as 0.001 IU/mL. This assay has been considered the most reliable and relevant because it assesses actual neutralization in a living host, although there is no universally accepted protocol.

In Vitro Assays

Because in vivo neutralization tests are time consuming and expensive, a variety of in vitro serologic tests have been developed. Among these are passive hemagglutination (PHA), ELISA, radioimmunoassays, immunofluorescent assays, latex agglutination, and a variety of methods using agar gel precipitation. The advantages and disadvantages of each technique have been reviewed.[413,494] In general, any of the in vitro techniques for tetanus antitoxin detection can be useful, provided that correlation with toxin neutralization has been confirmed. However, most in vitro assays have the important limitation that they do not discriminate between biologically active antibody and nonneutralizing antibody, leading to a lack of specificity that is most apparent at low antibody titers.[413] PHA and ELISA are currently the easiest to perform and the most commonly used in vitro techniques to determine tetanus antitoxin levels; the following discussion is limited to these two types of assays.

PHA techniques were the first widely used in vitro alternatives to neutralization assays.[420,494–500] Although results vary among PHA techniques, there is a good correlation with toxin neutralization at high and moderate titers of antibody. Consistency in testing among laboratories has been aided by the use of turkey erythrocytes in the assay.[494,498] However, PHA tests measure both immunoglobulin (Ig) G and IgM, perhaps preferentially IgM.[500] Only IgG has biologically relevant neutralizing activity.[491,501] Thus antibody detected at low titers by PHA, particularly those produced early in a primary immunization series, may not represent neutralizing antitoxin.[413]

The standard (indirect) ELISA measures antibody binding to tetanus toxin or toxoid that has been passively adsorbed to wells in microtiter plates (solid-phase antigen). Studies comparing the results of standard ELISA with neutralization assays in mice have demonstrated strong correlation between the two tests when ELISA titers are greater than 0.16 to 0.2 IU/mL; ELISA titers below that level significantly overestimate effective antibody concentrations.[413,502–508] Factors contributing to this lack of specificity include nonspecific antibody binding to contaminant proteins adhering to the surface of the test plate, detection of IgM in addition to IgG, and detection of antibody with little or no neutralization activity. Biologically inactive antibody can result from low avidity, asymmetric (monovalent) structure, or binding sites that recognize biologically unimportant epitopes, including those created on the toxin or toxoid molecules by the denaturing effects of solid-phase binding.[505,506,508–510] In reviewing serologic data for the licensure and regulation of TT-containing products in the United States, the FDA uses 0.1 IU/mL when determined by ELISA as the surrogate measure of the minimal level of protection.[511]

Several modifications to the standard ELISA have been used to overcome the problem of detecting biologically inactive antibody. In competitive-antigen ELISA, soluble toxin or toxoid antigen is mixed with the test serum solution, and the amount of antibody binding to soluble antigen is calculated. This assay produces results that correlate well with neutralization assays at titers as low as 0.004 IU/mL.[510,512] Another modification of ELISA that increases specificity at low antibody titers is toxin-binding inhibition. In this technique, a measured amount of toxin is preincubated with the serum specimen and subsequently exposed to antitoxin-coated plates to detect unbound toxin.[509,513,514] The most recent modification is the double-antigen ELISA, in which biotin-labeled toxin or toxoid is added to test serum that has been incubated in microtiter wells precoated with toxoid. In this assay, only antibody that is bound to both solid-phase antigen and the labeled soluble antigen is detected. The double-antigen method also shows good correlation with in vivo neutralization at antibody titers below 0.10 IU/mL.[515] Double-antigen ELISA has been recently applied in large serosurveys[272,341,516,517] and other studies.[351,518,519] Multiplex bead assays using tetanus toxoid have also been used in large serosurveys and have been shown to be accurate at detecting antibodies titers below 0.10 IU/mL.[353,519a]

A commercially available rapid test using fingerstick blood for tetanus antibody determination is discussed later in "Tetanus Prophylaxis in Wound Management." While efforts are under way to develop assays measuring tetanus antibody in oral fluid,[520] only serum assays reliably determine immunity to tetanus at present.

When reporting results of tetanus antitoxin tests, the assay method used should be stated, as well as the correlation with a neutralization assay, if known. Serosurveys to determine the prevalence of protective tetanus antitoxin in United States and Canadian populations have used standard ELISA to measure antitoxin levels. Protective immunity was defined as an antitoxin level greater than 0.15 IU/mL.[340,398,521] The use of this relatively high cutoff value underestimates the level of protection in the study populations because some people with lower antitoxin levels will be protected; however, use of a cutoff value substantially below 0.16 IU/mL would clearly overestimate the level of protection. The use of a more specific modified ELISA technique as discussed earlier may permit more accurate determinations of protective immunity against tetanus in future serosurveys.

Serologic Correlates of Protection

The minimal level of tetanus antitoxin needed to confer protection against tetanus is generally considered to be 0.01 IU/mL as measured by in vivo neutralization assay.[420,428,471,522] This cutoff level is based primarily on animal studies of the protective effects of active and passive immunization. A 1964 review by McComb of data on the reduction of tetanus in horses after homologous passive immunization found an absence of clinical tetanus in horses after injection of 1500 IU of antitoxin after acute injury (approximately 2.5 IU/kg), corresponding to a serum antitoxin level of 0.01 IU/mL.[428] These results were in agreement with earlier work showing that guinea pigs with serum antitoxin levels of 0.01 AU/mL or higher after active or passive immunization did not succumb to challenge with inocula of fixed lethal doses of *C. tetani* spores.[523] Of interest, although none of the guinea pigs with antitoxin levels of 0.01 AU/mL or higher died, 13% (with levels up to 0.5 AU/mL) developed mild, nonfatal tetanus; 7% with levels less than 0.01 AU/mL did not develop tetanus symptoms at all. As reviewed by Looney and coworkers, other animal studies of active immunization suggested incremental protection at 0.01 to 0.1 AU/mL.[524] The only experimental study in human

subjects was by Wolters and Dehmel, who immunized themselves with toxoid, achieving serum levels of 0.007 to 0.01 AU/mL, which allowed them to resist challenge with "two or three fatal doses" of tetanus spores. The actual challenge dosage is unknown.[525] Two observational studies of mothers immunized in pregnancy, and their newborns, suggested that an antitoxin level of 0.01 AU/mL was sufficient to protect infants from NT.[420,471] When standard in vitro assays are used, the minimal level of protection is taken to be 0.1 to 0.16 IU/mL,[413,510] while the 0.01 IU/mL cutoff can be used with modified ELISAs.

A number of reports describing cases of tetanus in neonates and adults with tetanus antitoxin levels of 0.01 IU/mL or higher challenge the assumption that an antitoxin level of 0.01 IU/mL (in vivo assay; 0.1 IU/mL for in vitro assay) is always protective.[146–148,150–153,526] Serum antitoxin levels detected at the time of presentation ranged from 0.15 to 25 IU/mL. The measurement of serum antitoxin levels in many of the reports was performed with in vitro methods that are known to overestimate the amount of neutralizing antibody present. In one study, the patient was shown to have a level of 0.2 IU/mL by ELISA but less than 0.01 IU/mL by neutralization assay.[150] Thus, in some of these cases, levels of biologically active antitetanus antibody may have been less than 0.01 IU/mL. However, a number of other patients had levels well above 0.01 IU/mL by neutralization assay.[146,148,151,152] Some of these patients had deep necrotic wounds. It is possible that, when large quantities of toxin are produced, a serum concentration of antitetanus antibody of 0.01 IU/mL or greater is insufficient to provide protection. Alternative explanations for these findings are that the wounds in these patients may have been sufficiently sequestered from circulating antitoxin, that toxin gained access to the nervous system before neutralization could occur, or that, in previously vaccinated persons, large dosages of tetanus toxin could lead to an anamnestic response before antitetanus antibody testing was performed. Nonetheless, these case reports suggest that protection at a 0.01 IU/mL level of antitoxin is not absolute.

Efficacy and Effectiveness

Tetanus Toxoid for Nonneonatal Tetanus

The early development of TT led to its use without the systematic safety and immunogenicity testing that is mandatory for licensure and WHO prequalification today. Some of the first data supporting the efficacy of active immunization with TT came from the self-experimentation by Wolters and Dehmel described above.[525] The first indisputable demonstration of the effectiveness of TT immunization came from its use in World War II. American troops were given a two- or three-dose primary immunization series plus postwound booster doses. Only 12 cases of tetanus occurred among 2.73 million wounded U.S. Army personnel on all fronts (0.44 per 100,000) compared with 70 of 520,000 wounded in World War I (13.4 per 100,000), and only four of the 12 had completed primary immunization.[527] Similarly, among British troops immunized with TT, tetanus incidence was four to nine per 100,000 wounded soldiers, with cases occurring predominantly in those who had evaded immunization, whereas in earlier conflicts, incidence was 22 to 147 per 100,000.[278]

Formal assessments of the efficacy of TT against non-NT conforming to the current standard of randomized controlled clinical trials have not been conducted. Instead, routine use of toxoid has been assumed to be highly effective on the basis of results of the studies on NT prevention presented in the next section, the impact that immunization programs have had on reducing both neonatal and non-NT, and the correlation of immunogenicity with protection.[356,420,471]

Tetanus Toxoid for Neonatal Tetanus

The success of TT in preventing tetanus during World War II inspired investigation into the possibility that immunizing pregnant women could prevent tetanus in their newborns. The first study to assess this possibility was a nonrandomized, controlled trial in New Guinea in 1959, that evaluated the effect of fluid TT administered during pregnancy on preventing NT. Vaccine efficacy for three doses was 94%; for two doses, 65%; and one dose of fluid toxoid had no effect.[355] A subsequent double-blind, randomized, controlled clinical trial in rural Colombia showed that two or three doses of TT administered to women of childbearing age protected their babies against NT for up to 4 years after immunization.[356] Control infants had an NT mortality rate of 78 per 1000 live births, whereas no NT cases occurred in the children of women who received at least two doses.

Subsequent field assessments of the efficacy of two or more TT doses using data collected during NT mortality surveys demonstrated effectiveness of 70% to 100%.[413,456,457,528–533] A recent systematic review and metaanalysis concluded that immunization of pregnant or childbearing-age women with two or more doses of TT reduces NT mortality by 94% (95% confidence interval, 80–98%).[534]

Factors Associated With Reduced Effectiveness

A variety of factors have been associated with apparent TT failure in addition to the use of subpotent preparations (see "Producers" earlier). These include inaccurate or unverified histories of prior vaccination, use of inappropriately short intervals between doses,[483] and poor toxoid handling, particularly repeated freezing.[12,480–483] Immunosuppression can be associated with diminished response to vaccination or accelerated loss of protection (see "Immunization in Immunodeficiency" later). If tetanus antibody levels already are high, little or no additional antibody production is induced.[524,535–537] Dietz and colleagues[483] reviewed other factors that may affect the response to TT, including malarial infection, which can decrease the response; malarial chemoprophylaxis, which can enhance it; and malnutrition, which appears not to substantially affect induction of immunity.

TT prevention of NT depends on a mother's ability to produce antibody in response to vaccination, and normal transplacental antibody transfer to the developing fetus.[42] Substantial reductions in transplacental transfer of antitetanus IgG occur in the presence of hypergammaglobulinemia, maternal HIV infection, chronic placental malaria, and prematurity.[538–547] Where HIV infection, malaria, and premature births are common, the number of newborns without adequate protection against tetanus may be unexpectedly high despite immunization programs that are apparently functioning well. A final factor that may be at work in some apparent failures of TT to prevent NT is an unusually high amount of toxin production in heavily infected umbilical stumps that overwhelms normally protective amounts of maternal antitoxin. Case investigations are critical to determine whether the predominant cause of NT in a given area is vaccine failure or failure to vaccinate. Lack of adequate vaccination is a far greater cause of NT than is vaccine failure.

INDICATIONS FOR USE

Because of the success of active immunization in the military, ubiquitous *C. tetani* spore distribution, high tetanus case-fatality rates, and frequent reactions with and incomplete efficacy of equine antitoxin,[548] routine inoculation in childhood was recommended in 1944 by the American Academy of

Pediatrics (AAP). In the mid-1940s, TT was combined with diphtheria toxoid and pertussis vaccine, which permitted administration of all three antigens with a single injection of DTP. In 1951, the AAP recommended routine use of DTP in infancy and widespread use by practitioners began. Since that time, advisory groups in the United States, including the Advisory Committee on Immunization Practices (ACIP), have recommended that all people receive three or more doses of age-appropriate TT-containing vaccine followed by routine booster doses every 10 years.[173,464,549]

Administration to Infants and Children

In higher-income countries, primary tetanus immunization schedules consist of three doses of TT in the first year of life, often followed by a fourth dose approximately 6 months to 1 year afterward.[145,173,550–553] The recommended schedule in the United States includes a primary series at 2, 4, 6, and 15 to 18 months of age with DTaP, followed by booster doses at 4 to 6 years of age (DTaP), and 11 to 12 years of age (Tdap), with decennial Td boosters thereafter (see also Chapter 9, or the CDC website, https://www.cdc.gov/vaccines/acip/recs/index.html).[549,554]

The Expanded Programme on Immunization (EPI) of the WHO, with its emphasis on protection in early infancy, recommends an accelerated schedule for primary immunization in lower-income countries with doses at 6, 10, and 14 weeks of age.[449,555,556] Other accelerated schedules (doses at 2, 3, and 4 months, or at 3, 4, and 5 months) are used in some European countries[552] and elsewhere, and are discussed in more detail later (see also Chapter 44, Table 44.5). Because combination vaccine use in infancy is the norm, the schedule for tetanus immunization is tied to the immunization requirements for diphtheria toxoid, pertussis vaccines, and other included vaccines, which in turn are driven by epidemiologic risk. The diversity of national schedules in use today is based on varying exposure or mortality risks and available health resources.[553]

TT is one of the most potent immunizing agents used routinely in children. Protective levels can be obtained with schedules starting in the newborn period.[443,557–562] Premature infants have immune responses at a given chronologic age comparable to those of term infants.[561,563]

In contrast to the immunologic response to diphtheria toxoid, which may be impeded in the presence of passively transferred maternal antitoxin, the immune response to TT has historically been considered to be minimally inhibited by maternal antitoxin.[559,560,564–566] However, many of the studies examining potential inhibition of response to TT were performed at a time before most mothers were likely to be highly immune.[567] The vast majority of women of childbearing age in the United States today have previously been immunized and have received preschool, adolescent, and possibly additional booster doses; increasing numbers of adult women in the lower income countries have also been previously immunized in infancy and childhood, or in adult life. Studies in the United States have demonstrated that term infants who have high geometric mean titers (GMTs) of circulating tetanus antitoxin before immunization at 2 months of age have an adequate response to the three-dose series.[568–572] Edwards and colleagues[570] evaluated 13 candidate acellular pertussis (DTaP) vaccines (with a U.S. schedule of doses at 2, 4, and 6 months of age) and compared the serologic responses with a whole-cell DTP vaccine licensed in the United States. Before the first dose, GMTs varied from 1.11 to 7.43 IU/mL as measured by modified PHA. After the third dose, GMTs ranged from 3.09 to 22.51 IU/mL, again demonstrating that high preimmunization antitoxin titers in children of mothers vaccinated in pregnancy do not inhibit the induction of active immunity. Although the response to TT may be lower in infants with higher preexisting maternal antitoxin who receive an accelerated primary series, this appears to be clinically irrelevant; at 6 months after completing an accelerated schedule, mean titers are still well above the minimal level of protection.[573–575]

During the first year of life, the older a child is at the time of receipt of the third dose of TT, the higher the level of antitoxin produced. Brown and coworkers studied infants beginning immunization at 3 to 7 months of age who received three doses of DTP inoculated at 1- or 2-month intervals.[576] In general, regardless of interval, GMTs were higher in infants completing the schedule at older ages (21.2 to 29.1 AU/mL; in vivo neutralization assay) versus younger ages (13.5 to 24.0 AU/mL). However, these differences are probably of no clinical significance: all infants, regardless of schedule, had antitoxin titers much higher than 0.01 AU/mL for at least 12 to 18 months after completing the initial three-dose series (the lowest was 0.125 Au/mL), and both groups had comparable GMTs. Response to the booster dose was similar under all schedules tested (GMTs of 1.2 to 2.9 AU/mL), confirming that immunization against tetanus can begin at an early age with good results. More recent studies support the results of Brown and coworkers. In the United Kingdom, the routine schedule for DTP was changed in 1992 from three doses at 3, 4.5 to 5, and 8.5 to 11 months, to 2, 3, and 4 months.[557,575] Children vaccinated with the accelerated schedule (completed at 4 months of age) had only about one-sixth the GMT of tetanus antitoxin at approximately 8 weeks after the third dose, compared with children who completed immunization at the older age (0.522 vs 3.43 IU/mL, as assessed by radioimmunoassay). By 1 year after the third dose, the differences had narrowed (0.197 IU/mL for the accelerated schedule vs 0.341 IU/mL). No child with either schedule had levels less than 0.01 IU/mL. While combination vaccines containing acellular pertussis vaccine instead of the whole-cell formulation tend to induce lower responses to TT, the difference is not clinically relevant in populations that receive recommended booster doses.

Single doses of standard- or high-potency TTs have induced protective levels in some studies.[476,577–580] In general, however, a substantial proportion of subjects did not attain minimal protective levels of antibody; those subjects who did attain a level greater than 0.01 IU/mL had levels that only slightly exceeded this minimum, and long-term follow-up was lacking. Because most antibody induced by the first dose of TT is nonneutralizing IgM, and the avidity of neutralizing IgG antibodies increases with subsequent doses,[413] a minimum of two doses of standard-potency TTs is considered necessary to reach minimal protective levels of antitoxin during the first year of life.[443,581–585] Data collected in trials of DTP vaccines in the United States indicate that three doses may be needed in infants before production of substantial antitoxin takes place and persists.[568–570]

Recommended intervals between the first two or three TT doses are generally 1 to 2 months, and there appears to be little reason to prefer one interval over another with regard to tetanus antitoxin production. Data from Brown and colleagues indicated that, whereas infants vaccinated at 2-month intervals made higher levels of antitoxin than infants vaccinated at 1-month intervals, all groups of infants had similar GMTs at the time of reinforcing doses 12 to 18 months later.[576]

After the three-dose primary series during infancy, antibody levels tend to wane relatively rapidly.[565,575,576,586–588] Although children who receive three doses of vaccine at 1- or 2-month intervals have rarely lost protective levels of antibody 1 year after the last dose, reinforcing doses at this time (a fourth dose) leads to high levels of antitoxin production and protection through school entry.[565,568,575,576,585,587–591] The

WHO Pertussis Vaccine Position Paper notes that providing the fourth DTP dose (first booster) during the second year of life is preferred for optimal protection.[592]

In children older than 1 year of age, giving two doses at intervals of 1 to 2 months appears to induce protective levels of antitoxin that persist at least 6 to 12 months.[586] A third dose given 6 to 12 months after the first two is associated with a marked booster response and persistent high levels of antitoxin. Therefore, most immunization schedules for children older than 1 year call for three doses: either two doses separated by 1 to 2 months and a third dose 6 to 12 months later, or three doses at least 1 month apart.[551,593] However, when TT is combined with pertussis vaccine, which requires a minimum of three closely timed doses (4 to 8 weeks apart), a schedule similar to that for infants is often used, with the three doses given 1 to 2 months apart.

For tetanus protection in all age groups, the WHO recommends that, ideally, all children who begin immunization in infancy with DTP should receive at least three tetanus toxoid–containing vaccine booster doses, preferably in the second year of life, between 4 and 7 years of age, and between 9 and 15 years of age.[449,555,592,592a]

Administration to Adults

The immune response to TT appears to decrease with increasing age. In comparative studies, children generally develop higher levels of antitoxin than adults.[597] Despite the decrease in immunogenicity, the majority of adult vaccinees achieve and maintain protective levels of antitoxin for many years.[473,594] Most adult primary immunization schedules in use in the world today call for two doses 1 to 2 months apart, followed by a third dose 6 to 12 months later.[449,464,595,596] Some recommend three doses with a minimum of 1 month apart.[551]

After two doses 4 weeks or more apart, almost all adults produce antitoxin levels higher than 0.01 IU/mL (or 0.10 IU/mL by in vitro assay).[597] GMTs vary according to type of vaccine and schedule but in general are below 1.0 IU/mL. In one large-scale field trial in New Guinea, titers persisted at or above minimal protective levels for 40 months in 78% of adult women given two doses of aluminum phosphate–adsorbed vaccine, and for 54 months in 33%, although it should be noted the $AlPO_4$ adjuvant concentration was twice the maximum amount used today (2.5 mg).[454] Other studies, particularly in older adults, have confirmed that maintenance of antitoxin at or above minimal protective levels is short lived without a third dose.[421,598]

A third dose 6 to 12 months after the first two doses is associated with production of high levels of antitoxin (>5 IU/mL) that have long-term duration.[597] In the elderly, the immune response may be somewhat impaired. Only 77% of elderly subjects in one study had protective levels of antitoxin 8 years after a three-dose primary series.[421] Other investigators have also indicated a weaker immune response in elderly persons.[599–604] Nevertheless, in most adults, routine boosters every 10 years are sufficient to maintain immunity.[473,591,594,600]

In the United States, to reduce pertussis risk, the ACIP recommends that a single dose of Tdap be substituted for one of the recommended Td doses in the three-dose adult primary series, or as a booster dose (see Chapters 9 and 44, or the CDC website, https://www.cdc.gov/vaccines/acip/recs/index.html).[549,554]

Administration for Prevention of Maternal and Neonatal Tetanus

For previously unvaccinated women, a minimum of two doses of TT administered at least 4 weeks apart, with the last dose given at least 2 weeks before the estimated date of delivery, provides protective levels of antibody for well above 80% of newborns. The second dose is preferably given 4 or more weeks before delivery to ensure high maternal antibody levels and maximal transplacental antibody transfer.[42,413,579]

Early clinical trials found that the effects of a single maternal TT dose for NT prevention were limited, if any were observed at all.[355,356,420,577] Thus, data do not support sufficient protection against NT when only one dose of standard potency is administered in pregnancy.[413,457] The contrary findings of partial effectiveness of a single dose for up to 4 years from a long-term follow-up study of women in Bangladesh must therefore be held in some doubt.[605] The women's immunization histories were not confirmed and may have excluded TT doses actually received, and the findings were inconsistent with an earlier report from the same study site.[456]

The estimated duration of protection against NT from two maternal TT doses is up to 3 years for most recipients; after a third dose, protection lasts up to 10 years.[42,413,454] Efficacy above 80% and long-term protection are desired, so the WHO schedule of five properly spaced doses for previously unvaccinated women is designed to elicit high antitoxin titers during pregnancy to prevent maternal and NT (MNT) (Table 58.1; see "Duration of Immunity" later).[42,413,449,606]

In low- and middle-income countries where maternal and NT burden has been greatest, national EPI programs have been delivering routine immunization with TT-containing vaccine to infants, and in some countries booster doses to children, since the mid- to late-1970s. Many women now entering their reproductive years have thus received prior TT doses. A TT schedule that considers the woman's prior history of vaccination in infancy, childhood, and adolescence has been designed to avoid giving an excessive number of TT doses—a maximum of six doses is administered from infancy through the reproductive years to prevent NT (see Table 58.1).[413,449]

In the United States, Td has long been recommended for use in pregnancy for women who are not vaccinated, did not complete a primary series against tetanus, or received the last dose of Td-containing vaccine more than 10 years previously.[607] The ACIP now recommends that Tdap be given in the third trimester of every pregnancy between 27 and 36 weeks, or immediately postpartum, to reduce the risk of pertussis in young infants (see Chapter 44).[608] If more than one dose of tetanus-containing vaccine is indicated to complete a primary series, a combination of Td and Tdap should be used, with the Tdap dose given in the third trimester. Women requiring a third dose to complete the primary series should receive follow-up to ensure the series is completed.

Duration of Immunity

After each subsequent TT injection, antitoxin levels peak within 2 weeks, fall rapidly during 2 months, and then fall more gradually in the years following (Fig. 58.6).[413] A constant log-linear decline in antitoxin level has been described.[473,590,591,609] Data on long-term protection reviewed by Simonsen generally support long-lasting persistence of protective antitoxin levels but with the need for booster doses after a primary series throughout life.[610] In studies conducted in high income countries where infant immunization starts at 2 months of age or later, an acceptable immune response is achieved after booster doses of TT even when intervals of longer than 20 years have elapsed since the last dose, although the briskness and height of response and duration of protective antitoxin levels are somewhat dependent on the length of time since the primary vaccination.[519,524,590,600,609,611–613] Work from Cameroon raises concern that when a primary series is given on the accelerated EPI schedule (doses at 6, 10, and 14 weeks), immunologic

TABLE 58.1 WHO Recommendations for Routine Immunization With Tetanus Toxoid Vaccine[a]

	Primary Series: Age/Interval Between Doses[b,c]			Booster Doses[b]		
Age at First Dose	**Dose 1**	**Dose 2**	**Dose 3**	**Dose 4**	**Dose 5**	**Dose 6**
Infancy	6 wk (min) or at 1st contact	4 (min)–8 wk	4 (min)–8 wk by age 6 mo	2nd year of life, ≥6 mo after 3rd dose (min)	4–7 y	9–15 y
Childhood (1–6 y)	At 1st contact	2 mo	2 mo	≥6 mo after 3rd dose (min)	4–7 y ≥1 y after 4th dose (min)	9–15 y
Older children (≥7 y), adolescents, and adults	At 1st contact	2 mo	6–12 mo	≥1 yr after 3rd dose (min)	9–15 y ≥1 yr after 4th dose (min)	
Women of childbearing age/pregnancy (MNT prevention) with no previous immunization[d]	At 1st contact or as early as possible in pregnancy	6–8 wk (min, 4)[e]	6–12 mo or in next pregnancy[e]	≥1 yr after 3rd dose (min) or in next pregnancy[e]	≥1 yr (min) after 4th dose, or in next pregnancy[e]	
Women of childbearing age/pregnancy who have received 3 childhood DTP doses				At 1st contact or as early as possible in pregnancy	6–8 wk (min, 4)[e]	≥1 y (min) after 5th dose, or in next pregnancy[e]

[a]For the U.S. recommendations, see Chapter 9 or http://www.cdc.gov/vaccines/schedules/index.html.
[b]Vaccine used should be appropriate for age: DTP/DT for children ≤6 y; Td/TT for doses given to individuals age ≥7 y. For children aged ≥4 y, Td may be used and is preferred. From 7 years of age only Td combinations should be used.
[c]Individuals whose vaccination series has been interrupted should have the series resumed without repeating previous doses.
[d]For details on use of Td/TT for women of childbearing age who received DTP/DT/Td/TT in childhood or adolescence, see the sources below.
[e]If administered during pregnancy, optimally given in the third trimester, at least 2 weeks before due date.
DT, diphtheria and tetanus toxoids; DTP, diphtheria and tetanus toxoids and pertussis vaccine; MNT, maternal and neonatal tetanus; Td, tetanus and diphtheria toxoids adult formulation; TT, tetanus toxoid.
From WHO Recommendations for Routine Immunization: Summary Tables: http://www.who.int/immunization/policy/immunization_tables/en/index.html and Tetanus vaccines: WHO position paper – February 2017. memory may be lost if there are delays of 10 years or more before administering a first booster dose, necessitating a second booster dose to achieve desired antibody levels and duration of protection.[614] Further research is needed.

Studies in Denmark indicated that, after a three-dose primary series consisting of two doses separated by 1 month, followed by a third dose 9 to 12 months later, protective levels of antitoxin persisted in 96% of recipients for 13 to 14 years, and in 72% of recipients for more than 25 years.[589,609,610] For the Danish population, which had received toxoid of higher potency than that used elsewhere at the time, Simonsen and colleagues proposed a school-age booster after primary immunization and subsequent routine boosters at least every 20 years.[609]

A study in Sweden found that, after a series of three doses 4 to 6 weeks apart, antibodies at or above minimal protective levels were retained by 94% after 10 years.[615] An American study of children vaccinated at 2 to 15 years of age showed persistence in 91% of recipients for 7 to 13 years after a three-dose primary series 1 month apart without a reinforcing dose.[616] In U.S. children who received four or more doses of TT, none were found to have an antitoxin level below 0.08 IU/mL in the 90 months of follow-up.[591] A study from Finland found that, after 4 to 5 DTP doses in the first 4 years of life, a booster dose of Tdap at age 10 to 14 years protected more than 97% of individuals for up to 10 years.[616a] On the basis of this information and other studies with similar results, immunization advisory bodies in the United States have recommended that, after infant and childhood toxoid doses, boosters for routine, preexposure prophylaxis are needed no more frequently than every 10 years.[173,464]

The need for booster doses every 10 years has been questioned both because recent population-based serosurveys have supported duration of protective immunity for at least 20 years, if not substantially longer,[334,336,517,617,617a] and because few cases of tetanus, and even fewer associated deaths, are reported among people who received a primary series, regardless of whether they have received booster doses.[68–71,251,610,618–623] This low morbidity and mortality in vaccinated populations has occurred despite poor adherence to the recommendation for decennial boosters. In 2013, only 63% of adults in the United States reported having received a tetanus booster during the previous 10 years.[624] Proposed alternatives for the United States are that, after a primary childhood series and adolescent booster, no further routine assessment of tetanus immunization status should occur until the age of 30 or 50 years.[595,622,617a] TT prophylaxis in wound management would still be recommended. Gardner has argued that this alternative schedule is justified on the basis of excess adverse events attributed to TT use, and because this schedule could be more effectively monitored for compliance.[622] Some countries have revised their adult booster dose recommendations to reflect the longer expected duration of protection. For example, the United Kingdom recommends five doses of TT-containing vaccine delivered in infancy, childhood, and adolescence with no further boosters but rather TIG administration with wound care when indicated.[551,623] France has adopted an age-based approach, recommending adult booster doses at ages 25 years, 45 years, 65 years, and then every 10 years thereafter.[537,552]

Because medical care is not always sought for wounds that can result in tetanus, and tetanus boosters are not always administered for wounds and other conditions for which TT

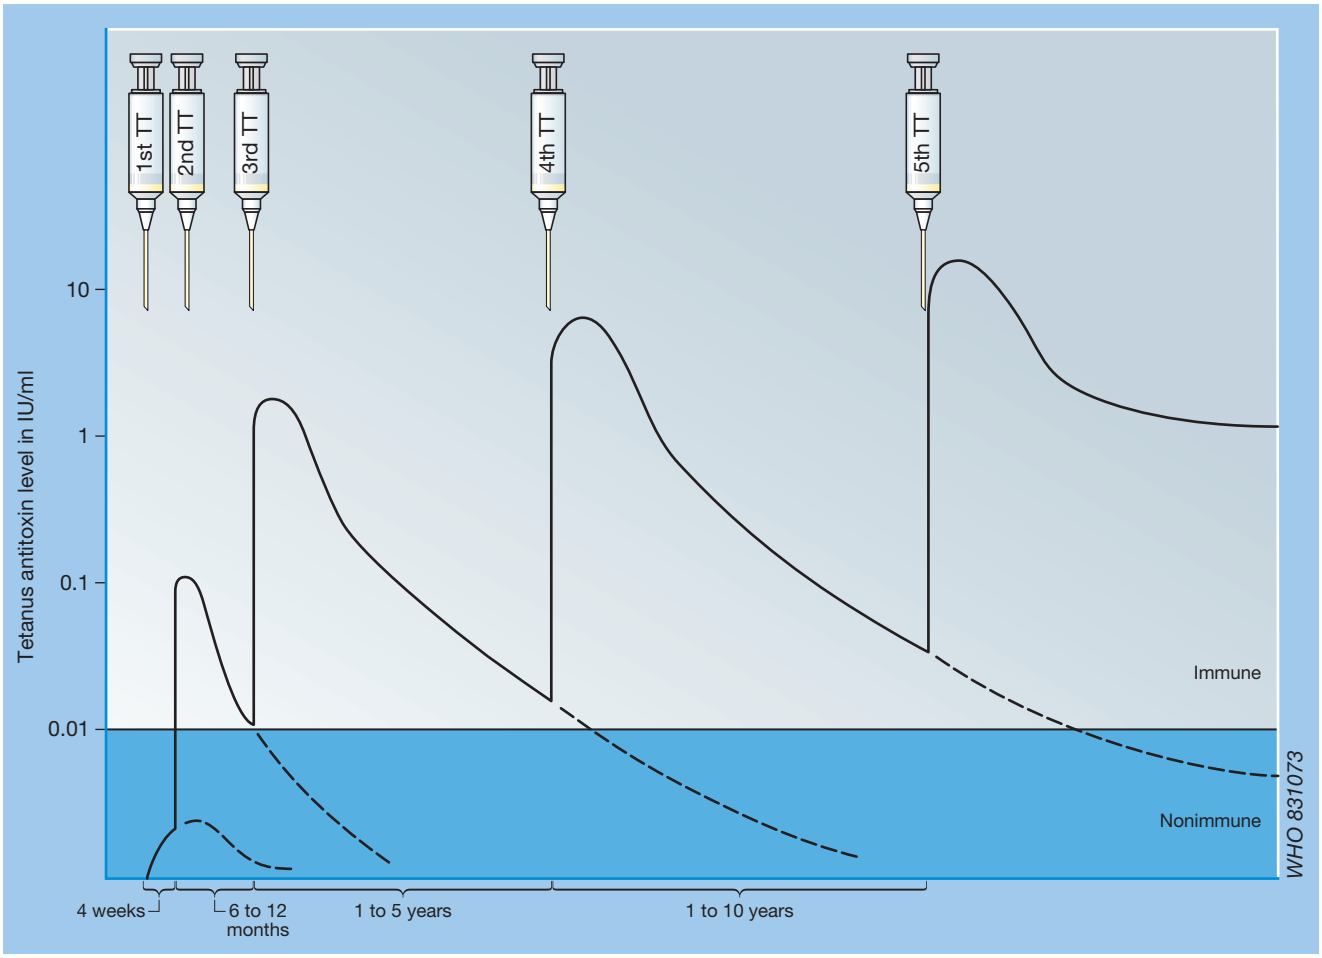

Figure 58.6. Antibody response to tetanus toxoid (TT). After five properly spaced doses, protection lasts at least 20 years and probably substantially longer for most recipients. (Threshold of protection of 0.01 IU/mL applies to values measured by in vivo neutralization or modified ELISA; for standard ELISA, the minimum level of protection is 0.10 to 0.16 IU/mL.) *(Modified from Borrow R, Balmer P, Roper MH. The immunologic basis for immunization. Module 3: Tetanus (update 2006). Geneva, Switzerland: WHO; 2007. Available at: http://apps.who.int/iris/bitstream/10665/43687/1/9789241595551_eng.pdf.)*

is indicated (see "Epidemiology" earlier), reliance on prophylaxis provided during wound care does not guarantee that those at high risk will be protected.[625] In addition, antibody response to a booster dose given at the time of wound care may not be sufficiently prompt to protect against an incubating infection.[413]

The most important rationale for the current recommendation of decennial adult tetanus boosters in North America has been to maintain serum antitoxin well above protective levels for nearly all members of the population who receive them. Although primary vaccination alone has an effect on disease severity, severe tetanus cases and deaths have been reported despite prior receipt of toxoid doses.[17,71,152,153,251,548,626] The consequences to population immunity of lack of compliance with the decennial booster policy are evident in population-based tetanus antitoxin serosurveys: the proportion of the population with antitoxin at or above minimal protective levels declines with increasing age, leaving substantial proportions of older age groups unprotected.[338,340,341] In addition, the elderly may not have as great or long-lasting a response to a single dose of toxoid as younger persons; a single booster dose at 50 years of age may not provide adequate protection,[394,421,601,603,604,627] although immunization histories in these studies were not generally verified, and some older "booster" recipients may have never received primary doses. The proportion of the unprotected in older age groups may be declining as increasing numbers of people who received childhood and adolescent immunization reach their later years.[400,517]

A cost-effectiveness analysis comparing the decennial booster strategy with that of a single booster in later life was performed by Balestra and Littenberg.[621] They estimated that decennial boosting prevented four times as many cases as a single booster at 65 years of age. They also estimated that decennial boosters were substantially less cost-effective—US$143,138 in 1993 dollars for every year of life saved with decennial booster, versus US$4527 with a single booster at age 65 years. However, the analysis did not take the costs of prophylactic tetanus boosters with wound care into account and may have overestimated the costs of complications after immunization, thereby overestimating the difference in cost between the two strategies.

The final consideration underlying the recommendation to give adults decennial boosters specifically with Td is the fact that diphtheria antitoxin levels decline more rapidly than tetanus antitoxin levels.[464,628] Given the greater health impact of decennial boosters, the ACIP has continued to recommend them.[136,173,596]

Immunization in Immunodeficiency

Because all TT-containing vaccines are inactivated, they are safe for use in immunocompromised persons, including those with congenital immunodeficiencies, HIV infection, hematologic or other malignancies, stem cell transplants or organ transplants, and chronic renal failure (CRF).[607,629,630] Most of these conditions are associated with reduced responsiveness to TT vaccination, shorter duration of protection, or both, although data are incomplete for some conditions.[630–649] Except for modified guidelines for stem cell transplant recipients and patients with CRF, general schedules for primary and booster vaccination with TT-containing vaccine are also recommended for persons with known or suspected immunodeficiency.[607,629,630] However, antitetanus antibody determinations to assess responses to vaccination and duration of protection may be indicated for immunocompromised persons to guide the use of supplemental TT doses.[643] See also Chapters 69, "Vaccination of Immunocompromised Hosts," and Chapter 70, "Vaccination of Human Immunodeficiency Virus–Infected Persons."

HIV and Tetanus Toxoid

Adults and infants infected with HIV generally respond to TT vaccination with increases in serum antitoxin levels, but antitoxin levels tend to be lower than in uninfected controls, particularly in those whose $CD4^+$ cell counts are less than 300×10^6/L.[518,543,630,632,633,635,650] Although most infants with perinatally acquired HIV infection respond normally to TT-containing vaccines, serologic responses to vaccination decline as HIV disease progresses.[634,635,651] The duration of tetanus antitoxin at or above minimal protective levels in HIV-infected patients is uncertain, although there is evidence that antibody levels are shorter lived than in those who are uninfected.[630,652,653] A 2010 review of immune responses in HIV-infected children on highly active antiretroviral therapy (HAART) concluded that immune reconstitution did not guarantee long-term protection. Children on HAART require monitoring and additional booster doses as indicated.[654] The same is quite likely true for adults on HAART: poor responsiveness to TT has been demonstrated in older subjects on HAART.[655] The AAP recommends that TIG be administered to HIV-infected patients with tetanus-prone wounds, regardless of history of tetanus immunization.[173] See also "Factors Associated with Reduced Effectiveness" earlier and Chapter 70.

Transplantation and Tetanus Toxoid

Vaccination recommendations for transplant patients differ for stem cell transplant recipients and solid-organ recipients. After stem cell transplantation, patients are initially severely immunocompromised and require reconstitution of immunity against vaccine-preventable diseases once their acquired immune system has matured.[656,657] Three doses of age-appropriate TT-containing vaccine are recommended; the doses should be given at 12, 14, and 24 months after transplantation.[638,656] There is evidence that vaccinating the stem cell donor 6 to 10 days before marrow harvest results in the transfer of antibody-synthesizing B cells and of antigen-specific T cells to the recipient, thereby conferring some protection during the first year after stem cell transplantation and augmenting the response to active immunization given during the second year.[638]

In contrast to the situation with stem cell transplantation, information about tetanus immunity and responsiveness to TT after solid-organ transplantation is sparse. Solid organ transplantation patients require lifelong immunosuppression to prevent organ rejection and to preserve allograft function, and are therefore at increased risk for infections. Children who undergo successful renal or hepatic transplantation appear to retain normal responses to TT despite immunosuppressive therapy.[658,659] Adult renal transplant patients also retain responsiveness to TT, although the level of antitoxin produced is significantly lower than in healthy controls.[639] Vaccination strategies vary among transplant centers, and sufficient information is not currently available to mandate a change in the formal recommendations for vaccination in solid-organ transplant recipients. Thus, the standard schedule for primary and booster TT vaccination continues to be recommended for both child and adult solid-organ transplant recipients.[638] See also Chapter 69.

Renal Failure and Tetanus Toxoid

CRF is associated with immune deficits caused by uremia-induced alterations in cell-mediated immunity and IgG_1 production.[639,658,660] Studies of adults with CRF, including those receiving chronic dialysis, demonstrate a variety of defects in responsiveness to TT. The proportion of patients with CRF with protective levels of tetanus antitoxin at baseline is lower than in healthy populations, as is the proportion of patients who seroconvert in response to TT.[639,640] Mean antitoxin levels produced by patients with CRF who respond to toxoid are lower than those produced by healthy controls, and the duration of protective immunity in patients with CRF is reduced.[639,641,642] More than one booster dose may be necessary to achieve protective antitoxin levels in adult patients with CRF, and boosters may be required more frequently than every 10 years to maintain protection. Monitoring antitoxin levels after vaccination and at periodic intervals thereafter is indicated in this population to direct individual vaccination strategies. In contrast to adults, children receiving hemodialysis for CRF have a normal initial response to vaccination with DTP, although the duration of protection has not been determined.[661] Most infants receiving peritoneal dialysis also have a normal response to routine DTP vaccination, maintaining antitoxin at or above minimal protective levels for 24 months.[662]

Adverse Events After Immunization

Whereas mild local reactions are relatively common after receipt of TT, more serious reactions, including neurologic and hypersensitivity reactions, are exceedingly rare.[663] The rates and severity of adverse events in recipients of TT are influenced by the number of prior doses and the level of preexisting antitoxin, perhaps the amount of toxoid in the dose, the type and quantity of adjuvant, the route of injection, the presence of other antigens in the preparation, and perhaps the presence of organomercurials used as preservative. Causality assessments of the role of TT in adverse reactions are complicated by the frequency with which it is given in combination with other antigens. Systematic reviews by the Institute of Medicine and the Agency for Healthcare Research and Quality concluded that evidence was adequate only to convincingly support a causal relationship between TT and anaphylaxis among the 16 potential serious adverse reactions examined.[663,664]

The most common adverse event after injection of TT is a local reaction. Local reactions are reported in 0% to 95% of recipients, depending on the definition. Most studies suggest that rates of local reactions increase with an increasing number of doses.[597,624,665,666] This occurred when annual boosters were given for wound management.[591] However, boosting with Tdap with every pregnancy is now recommended because of the risks of pertussis morbidity and mortality in the newborn

and the lack of apparent increased risk of local reactions when given to nonpregnant subjects as close as 4 to 5 years apart.[666a,666b] Studies on short intervals (i.e., within 21 days or ≤2 years) between administration of Td and Tdap or Tdap-inactivated polio vaccine in healthy, nonpregnant adolescents and adults found no serious adverse events.[666c,666d,666e] Among recipients of a booster dose of adsorbed toxoid, 50% to 85% experience pain or tenderness at the injection site, and 25% to 30% experience edema and erythema.[667–671] More severe local reactions characterized by marked swelling occur in fewer than 2% of vaccinees.[665,672]

Some investigators claim that increasing antigen content (Lf) increases local reactions, but there is no clear evidence of this.[665,666,673] However, higher levels of preexisting antitoxin are associated with higher rates of local reactions and with reactions of greater severity.[324,665–668,673–676] Persons who have a rapid immunologic response (within 4 days), suggestive of priming by past doses, have higher rates of local reactions than persons whose immunologic response is slower.[324,666,673,675,676] Massive local reactions, such as swelling from elbow to shoulder, have occurred most often in persons with a history of multiple booster doses of toxoid. Typically, these reactions began within 2 to 8 hours after toxoid administration in the deltoid. Serum antitoxin levels in these persons ranged from 2 to 160 IU/mL, manyfold higher on average than levels in persons without reactions, or in those with systemic adverse events.[673,677–680] The pathogenesis of massive local reactions is not fully understood. Preformed antibody apparently forms complexes with the deposited toxoid to induce an inflammatory response (i.e., Arthus reaction, or type III hypersensitivity).[677,680] Other undefined host factors are involved because the range of antitoxin levels in persons who exhibit this response is wide and includes levels seen in persons without such a response. In persons with a history of massive local reactions after TT, boosting with lower than standard doses of TT (e.g., 1 Lf) has been proposed by some researchers to lead to an adequate immune response without significant adverse events.[666,673,681] Antitoxin levels in such persons should be evaluated before booster doses are given to ascertain whether there is a need for additional doses. Most other severe local reactions can be prevented by avoiding unnecessary boosters of TT in wound management (see "Tetanus Prophylaxis in Wound Management" later).

There are conflicting reports as to whether aluminum adjuvants increase the incidence of local reactions compared with fluid toxoids.[470,667,668,676,682] Aluminum adjuvant in adsorbed products can theoretically invoke local inflammatory responses more frequently than fluid toxoid through adjuvant-induced complement activation and macrophage stimulation.[683] Histologic evidence suggests that aluminum hydroxide crystals may remain at the injection site after intramuscular injection of aluminum hydroxide–adsorbed vaccines in some persons, possibly creating local inflammation. However, the clinical implications of this finding, if any, are unclear.[684–686] Differences in study results could arise from manufacturing differences resulting in variable adsorption and adjuvant activity.[683] Alternatively, toxoid potency may have varied (with or without equivalent Lf content), a problem found in all comparisons of adverse events after TT administration. A 2004 systematic review found the quality of evidence from studies evaluating aluminum adjuvant–induced reactions to be low, but concluded that there was significantly more local erythema and induration in young children and more injection site pain in older children who received vaccines with aluminum adjuvant compared with fluid vaccine.[687] However, there was no evidence of increased serious adverse reactions, and the authors recommended that concerns about aluminum adjuvant be laid to rest.

The frequency of local reactions is increased when toxoid is administered subcutaneously rather than intramuscularly.[665] This is particularly true for adsorbed toxoid[688]; aluminum adjuvant can cause sterile abscesses when given subcutaneously.[683] Use of jet injectors, which deposit some toxoid in the subcutaneous tissue, results in twofold higher rates of edema at the administration site than intramuscular injection by needle.[689]

In the United States, TT is generally given in combination with diphtheria toxoid, with or without pertussis antigens.[145,173,607] (Adverse effects of diphtheria toxoid- and pertussis-containing vaccines are addressed in Chapters 19 and 44.) In some controlled trials, minor adverse events such as swelling or pain occurred more frequently after Td than after TT alone (Williams JJ, Ellingson HV. Field trial of commercially prepared diphtheria-tetanus toxoid: immunization reactions among recruits. Unpublished report to the Armed Forces Epidemiologic Board, 1954),[669] whereas other studies have not found a substantial difference in the rates of local reactions with Td compared with TT, or found that TT was associated with higher rates of local reactions than Td.[670,671,690] Increasing frequencies of large local reactions after use of DTaP vaccines have been observed; the pathogenesis of these reactions is not well understood but may be related in part to gelatin content.[691,692]

Reactogenicity data indicate that Tdap is well tolerated in older children, adolescents, and adults. In large, randomized, controlled trials evaluating a single booster dose of Tdap conducted in the United Kingdom and North America, the most commonly reported side effect was local injection site reaction in 5% to 78% of recipients. Other adverse events were mild and resolved without sequelae.[693] Comparative studies of Tdap preparations with Td indicate that although local reactions were more frequent in the groups receiving Tdap products, the increases were not of clinical importance (e.g., "any pain" occurred in 75% of recipients after Tdap, and in 72% after Td).[692] Tdap also is well tolerated when concurrently administered with other vaccines such as influenza and meningococcal vaccines.[694]

Up until 1999, the preservative used in U.S. preparations of TT was exclusively thimerosal. This mercury-containing compound has been linked to delayed-type hypersensitivity reactions in some people.[681,695] It is uncertain to what degree hypersensitivity to thimerosal influences local reactions when given intramuscularly. Reports have rarely linked reactions with an exaggerated delayed-type hypersensitivity response to TT itself.[677,696–698] No long-term effects of thimerosal use have been identified.[699] Nonetheless, concerns over exposure to mercury led the FDA to undertake a review of all medicinal products containing the metal, including vaccines. Similarly, the European Medicines Evaluation Agency's Committee for Proprietary Medicinal Products requested vaccine manufacturers to ultimately eliminate organomercurials as preservatives in their products.[700] In the United States, all DTaP and DT products administered to infants and children younger than 7 years of age are either thimerosal-free or contain trace amounts (see "Constituents of Tetanus Vaccines" earlier).[701,702] Other TT-containing products that are thimerosal free or contain only trace amounts are also available in the United States.

Systemic reactions after TT inoculation are less common than local reactions. Fever can accompany a local response, particularly when there is a marked local reaction or when antitoxin levels are high.[669,672,680] Uncommonly, persons with high antitoxin levels experience high fever and malaise without experiencing substantial local reactions, primarily after receiving booster doses of toxoid.[680] Clinically significant reactions are not substantially more frequent after receipt of Td than single-antigen TT[703,704]: booster doses of Td are associated with

fever in 0.5% to 7% of recipients, and temperatures above 39°C are rare (Williams JJ, Ellingson HV. Field trial of commercially prepared diphtheria-tetanus toxoid: immunization reactions among recruits. Unpublished report to the Armed Forces Epidemiologic Board, 1954).[669,672] Other systemic symptoms such as headache or malaise are reported less frequently than fever.[666,672] Lymphadenopathy also can occur after toxoid inoculation.[668,677] Comparative studies of Tdap and Td indicate that although local reactions, fever, and headache were significantly more frequent in the groups receiving Tdap products, the increases were not of clinical importance (e.g., fever after Tdap in 5% of recipients vs 3% after Td).[466,469,692,693]

Peripheral neuropathy, particularly brachial plexus neuropathy, has been reported to occur hours to weeks after TT administration.[705–712] These reports and laboratory findings have been reviewed.[712–714] Although anecdotal, the reports are consistent with neuropathy as a manifestation of immune complex disease similar to that occurring after equine tetanus antitoxin.[715] The Vaccine Safety Committee of the U.S. Institute of Medicine concluded in 1994 that there is evidence to support a causal association between TT and brachial plexus neuropathy.[714] The evidence was considered inadequate to accept or reject a causal relationship of TT with mononeuropathy. On the basis of two published case series from the Mayo Clinic of brachial plexus neuropathy that included cases after TT exposure,[710,711] the Institute of Medicine committee estimated that 0.5 to 1 case of brachial neuropathy per 100,000 recipients was attributable to TT within 1 month of immunization.[714] Given that this estimate was based solely on open case series that include six toxoid-exposed patients with unknown total immunization histories,[710,711] the calculated attributable risk may have been overestimated. Passive surveillance of events following immunization in the United States for 1991 to 2003 detected 49 verified reports of brachial neuritis occurring 0 to more than 60 days (median: 2 days) after administration of TT-containing vaccines (38 toxoid alone, 11 in combination). The ratio of reported cases to doses distributed was 0.69 cases per 10 million doses.[716] This strongly suggests that the true frequency of occurrence is much less than 0.5 to 1 case per 100,000 recipients.

There have been reports of at least 25 cases of Guillain-Barré syndrome (GBS) after TT.[705–708,714] One patient had relapsing GBS signs and symptoms after each of three injections of toxoid.[706] Although there may be a causal relationship between TT and GBS, the occurrence is rare and available evidence neither adequately supports nor excludes the association.[663,664] An estimate of the incidence of GBS after TT administration is 0.4 per million doses.[714] Population studies do not support a causal role for TTs in GBS. A study of 700,000 children who received DTP found a frequency of GBS after immunization that was similar to expected background rates.[717] After administration of TTs to an estimated 1.2 million children and adults, another study found a lower frequency of GBS after immunization than expected by chance alone.[718] The ACIP has recommended that GBS occurring less than 6 weeks after receipt of a TT-containing vaccine is a precaution for subsequent TT-containing vaccines.[550]

Other neurologic events, including seizures and acute encephalopathy, have been reported after TT or DT.[680,714,719,720] The data are insufficient to support a causal relationship with any of these other illnesses.[663,664,714] As is true with all immunizations, the occurrence of systemic symptoms soon after inoculation does not in itself indicate causation; the association may instead reflect an unrelated chance occurrence. A metaanalysis performed on case-control studies reported conflicting conclusions of the relationship of multiple sclerosis with tetanus immunization[721]; this analysis and additional reports suggest that TT administration may lower the risk of developing multiple sclerosis.[722,723]

TT occasionally induces an IgE response, particularly with aluminum-adsorbed toxoid.[475,724–726] Although true anaphylactic (type I hypersensitivity) reactions to purified TT are very rare,[714,727–729] the Institute of Medicine has concluded that evidence is sufficient to accept a causal relationship between TT and anaphylaxis.[664] Before 1942 in the United States, contaminating peptones from the culture media and silk fibers from the filtering process were present in toxoid preparations. Two cases of anaphylaxis were reported after administration of 61,000 doses (0.003%) of these vaccines.[730–733] In a large series using Air Force recruits in the early 1960s, serious allergic reactions attributable to toxoid occurred in 0.001%.[734] Passive surveillance in the United States from 1991 to 1995 for serious allergic reactions including laryngospasm, bronchospasm, or anaphylaxis yielded a rate of 1.6 serious allergic reactions reported per million doses of publicly distributed Td (CDC, unpublished data).

Skin testing has been suggested as an aid to assessing the risk of anaphylaxis with TT administration in persons with a history of hypersensitivity reactions after tetanus vaccine. However, skin tests are of limited benefit and confer some risk themselves.[681,735] In a study of Air Force recruits with a history of an anaphylactic reaction after a prior TT dose, an intradermal skin test was negative in 94 of 95. All recruits tolerated full-dose challenges of toxoid, suggesting lack of IgE-mediated hypersensitivity in the prior reaction. Positive skin test responses were found in study subjects who subsequently tolerated full-dose challenges.[681] However, in another study, anaphylaxis was reported in three of 200 persons undergoing skin testing who had a history of sensitivity; similar reports have been made by others.[729,735] Thus, undue weight should not be put on the results of the tests alone because of the lack of specificity,[736] and caution must be used if skin testing is performed.

When eliciting a history of allergic reactions to TT, attention should be paid to the details of the injection and the reaction. One potential problem with histories of reactions in older subjects is confusion between equine antitoxin and TT. An adverse reaction after a "tetanus shot" received before TT became widely available may suggest that equine antitoxin or another product was received. When the history is consistent with an immediate hypersensitivity reaction, testing for serum antitoxin level may be helpful to evaluate the actual need for a booster of toxoid. In the context of emergency wound care, such results are unlikely to be immediately available. In that case, skin testing before challenge could be attempted in a setting equipped to manage anaphylaxis (see Jacobs et al.[681] for the protocol).[681] If skin testing is not feasible, or is deemed imprudent, TIG can be used for immediate tetanus prophylaxis, and decisions about the approach to booster administration can be deferred until the results of serum antitoxin testing are available.

Simultaneous Administration With Other Vaccines

TT has been combined with diphtheria toxoid, pertussis vaccines (both whole cell and acellular), hepatitis B, inactivated poliovirus, and Hib conjugate vaccines without compromising the immune response or substantially enhancing adverse events associated with the tetanus component (see Chapter 15). Combination with whole-cell pertussis vaccines enhances the serologic response to diphtheria and TTs because of the adjuvant properties of whole-cell vaccines.

With the use of Hib–polyribosylribitol phosphate (PRP) polysaccharide conjugate vaccine covalently linked to TT (PRP-T), theoretical concerns were raised whether TT in the

conjugate vaccine could inhibit or enhance a response to TT. These concerns have not been shown to be clinically relevant. Initial antitoxin responses are slightly higher after simultaneous administration of DTP vaccines with PRP-T compared with DTP alone, but overall antitoxin levels are well above protective levels regardless of whether DTP is administered with PRP-T. Maternally acquired tetanus antitoxin does not interfere with the immune response to PRP-T.[737] PRP-T alone induces a tetanus antitoxin response that is substantial but lower than the response to TT;[738] thus, PRP-T vaccines cannot substitute for TT. Use of simultaneous PRP-T with DTP does not appear to increase the frequency of common adverse events and does not appear to differ in this respect from other Hib conjugate vaccines.[739] DTP combined with PRP-T vaccine in the same syringe is equivalent in immunogenicity and safety to DTP with PRP-T vaccine administered separately.[740,741]

Contraindications and Precautions

A careful history of possible adverse events is necessary because some patients may have confused equine antitoxin with toxoid. Conditions recognized by the ACIP and the Committee on Infectious Diseases of the AAP as contraindications to the use of TT include a history of severe hypersensitivity or a neurologic event after a prior dose.[173,464] The evaluation should distinguish between a neurologic illness, for which further doses are contraindicated, and other syndromes, such as syncope, for which they are not. When toxoid is contraindicated, TIG should be given if immune status is unknown and a wound occurs that is not clean and minor. TIG is not necessary for clean and minor wounds. Delayed-type hypersensitivity to thimerosal is not a contraindication to products containing this preservative because it would be manifested as a subcutaneous or cutaneous reaction without systemic effects.

Studies consistently fail to identify teratogenic or any other harmful effects when TT is given in pregnancy, with or without diphtheria toxoid and pertussis vaccine.[742–747] However, in settings where providers are confident that women will return for visits later in pregnancy, it may be prudent to delay immunization to the second trimester to minimize any concern of a perceived relationship with any observed birth defect.

TETANUS PROPHYLAXIS IN WOUND MANAGEMENT

All people seeking treatment for care of skin wounds or infections should be evaluated for tetanus prophylaxis. The lesion should be treated as medically indicated, including removal of foreign bodies, debridement of devitalized tissue, incision and drainage, and irrigation to prevent or eliminate an anaerobic environment and bacterial contamination.[211,748–751] The patient's history of TT immunization should be obtained, with attention to the number of prior doses as well as the interval since the last dose, bearing in mind that histories collected during emergency department and office visits may not be accurate, potentially overestimating protection among those claiming up-to-date status and underestimating protection in those whose histories suggest incomplete immunization.[400,752–758] The critical issue is to determine whether the person has completed a course of primary immunization; if that is in doubt, consideration must be given to administering TIG if warranted.

In the 1950s, a booster dose of toxoid was recommended for every wound if more than 1 year had elapsed since the last dose. The association of Arthus-type reactions with frequently repeated tetanus boosters, and a better understanding of the kinetics of antibody responses after booster administration, led to a reappraisal of this practice.[473,587,591,616,679] Table 58.2 summarizes the guidelines for the use of TT and TIG for tetanus prophylaxis in wound management based on the current recommendations of the ACIP.[173,464,549,751] Tdap should replace a single dose of Td in wound management for adults who have not previously received a dose of Tdap.[145,554,759,760]

TABLE 58.2 Summary Guide to Tetanus Prophylaxis in Routine Wound Management, United States

History of Adsorbed Tetanus Toxoid (Doses)	Clean, Minor Wounds		All Other Wounds[a]	
	Td[b]	TIG	Td[b]	TIG
Unknown or <3	Yes	No	Yes	Yes
≥3[c]	No[d]	No	No[e]	No[f]

[a]Including, but not limited to, wounds contaminated with dirt, feces, soil, saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, or frostbite (see text).
[b]For children age <7 y, Tdap (DT, if pertussis vaccine is contraindicated) is preferred to TT alone; whole-cell DTP may be used in other countries. For children age 7 to 9 y, Td is preferred to TT alone. Tdap is preferred to Td for persons age ≥10 y who have never received Tdap; Td is preferred to TT for persons aged ≥10 y who received Tdap previously or when Tdap is not available. (If TT and TIG are both used, Tetanus Toxoid Adsorbed rather than Tetanus Toxoid for Booster Use Only [fluid vaccine] should be used.)
[c]If only three doses of fluid toxoid have been received, then a fourth dose of toxoid, preferably an adsorbed formulation, should be given.
[d]Yes, if >10 years since last dose.
[e]Yes, if >5 years since last dose. (More frequent boosters are not needed and can exacerbate side effects.)
[f]Yes for persons with severe immunodeficiencies, including HIV infection.
DT, diphtheria and tetanus toxoids for pediatric use; DTP, diphtheria and tetanus toxoids and pertussis vaccine; Td, tetanus and diphtheria toxoids for adult use; Tdap, tetanus toxoid and reduced content diphtheria toxoid and acellular pertussis vaccine for adult use; TIG, tetanus immunoglobulin; TT, tetanus toxoid.
From Advisory Committee on Immunization Practices (ACIP): ACIP Vaccine Recommendations. Available at: http://www.cdc.gov/vaccines/acip/recs/index.html, and recommendations of the American Academy of Pediatrics in Tetanus (lockjaw). In: Kimberlin DW, Brady MT, Jackson MA, et al., eds. Red Book: 2015 Report of the Committee on Infectious Diseases. *30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:775–776.*

Although any wound can give rise to tetanus, clean wounds are considered to have a low likelihood of tetanus spore contamination and of developing the anaerobic and acidic conditions that promote spore germination. People with a history of three or more doses of toxoid but without detectable antitoxin develop detectable antibodies within 4 to 7 days after the receipt of a subsequent dose.[524,611,613,761,762] Thus, for people with clean wounds, a TT booster is recommended if the patient has received fewer than three doses of adsorbed toxoid in the past, or if more than 10 years has passed since the previous toxoid dose. TIG administration is not necessary. Except for the elderly and some immigrants, most people in the United States will have antitoxin at or above minimal protective levels before exposure (for groups more likely to be unprotected, see "Epidemiology" and "Duration of Immunity" earlier).

Wounds contaminated with dirt, feces, or saliva; deep wounds and punctures; and wounds with devitalized tissue, such as burns, frostbite, gangrene, and crush injures, are considered more likely to develop *C. tetani* infection and toxin production. Abscesses, cellulitis, chronic ulcers, and other wounds in patients with diabetes mellitus or illicit injection-drug use should also be considered "tetanus prone." Because antitoxin levels may have fallen to barely protective or to nonprotective levels in some patients after 5 years, the current

recommendation for patients with wounds that are other than clean and minor is to receive a dose of toxoid if more than 5 years have elapsed since the last dose.[145,173,549,591,751] In addition, patients who have received fewer than three prior toxoid doses, those whose vaccination histories are uncertain, and those with immunodeficiencies, including HIV infection (see "Immunization in Immunodeficiency" earlier) should receive prophylactic TIG for such wounds. When administered at a separate site, TIG does not interfere with the immune response to adsorbed TT.[428,433,472]

The dosage currently recommended by the ACIP and the AAP for prophylactic TIG is 250 IU given intramuscularly.[173,464] This dosage will provide antitoxin levels above 0.01 IU/mL beginning 2 to 3 days after administration and lasting for at least 4 weeks in almost all persons.[178,433,763–767] A concern that higher TIG doses are necessary to guarantee protection has led some authorities to recommend the range of 250 to 500 IU for wound prophylaxis.[163,751,768] The uncertainty about the optimal dosage for prophylactic TIG stems from reports of tetanus in people with circulating levels of antitoxin greater than 0.01 IU/mL (see "Serologic Correlates of Protection" earlier), and the report of fatal tetanus despite prophylactic administration of 250 IU of TIG.[769] Dosages of 400 to 500 IU may induce protective levels earlier than a dosage of 250 IU,[770] and may produce serum antitoxin levels of up to 1.0 IU/mL.[178,423,771] Because patients who receive prophylactic TIG do so in the context of professional wound care, they are less likely to develop tetanus, or tetanus infection with high levels of toxin. Thus, a TIG dosage of 250 IU is appropriate in most circumstances; however, if wound care has been delayed or if a wound appears to present a high risk of tetanus, the higher dosage of 500 IU may be considered.

Before TIG was widely available, antibiotics were used for tetanus prophylaxis in wound management as a substitute for, or as an adjunct to, equine antitoxin.[772] Smith and earlier researchers demonstrated the efficacy of prophylactic antibiotics in animal models[773]; however, efficacy superior or equal to that of antitoxin in the prevention of tetanus in humans was never proven.[774,775] Antimicrobials are not currently recommended for tetanus prophylaxis per se.[748,774] Instead, wounds should be observed for signs of infection and treatment should be initiated promptly if any infection occurs.

Reviews of tetanus cases reported in the United States from 1972 to 2009 demonstrated that many people who subsequently developed tetanus did not seek wound care or received less than the recommended prophylactic care when medical treatment was sought for wounds.[11,68–71,251,409] Several studies suggested that, when patients with wounds do seek care in the United States, substantial proportions (up to 96%) receive fewer prophylactic measures than recommended, whereas 8% to 17% receive Td, with or without TIG, when not indicated.[68,251,776–778] Failure to provide recommended prophylaxis was most common for patients who had not received primary immunization and who had tetanus-prone wounds—that is, for those in greatest need of appropriate prophylaxis.[400,776]

Failure to comply with recommended prophylactic guidelines has been described outside the United States as well.[758,779–782] A rapid immunochromatographic test that identifies tetanus antitoxin levels above 0.1 IU/mL has been evaluated for performance and cost-effectiveness in several emergency departments and outpatient travel and geriatrics clinics.[754–758,783–789] While specificity was very high, sensitivity ranged from 55% to 92%, with a median of 86%. Most false-negative tests occurred with lower antibody levels (between 0.1 and 0.5 IU/mL by standard ELISA), levels for which a tetanus booster would be reasonable.[780,786,788,789a] A more recent validation of tetanus rapid tests against in vivo neutralization assay showed a specificity of 1%, suggesting further validation studies are needed. Although use of the test could reduce errors in both over- and undertreating patients, the price is sufficiently high (and the cost of a tetanus booster is sufficiently low) that its cost-effectiveness may be limited to subgroups of patients, such as those younger than 65 years of age with tetanus-prone wounds for whom substantial unnecessary TIG administration could be averted.[756–758,783,787] Given that the major problem in appropriate prophylaxis is physician unfamiliarity with guidelines and the tendency to ignore them, substantial efforts are needed to educate healthcare providers and improve overall use of prophylactic measures before cost savings from a point-of-care rapid tetanus antibody test can be realized.

PUBLIC HEALTH PERSPECTIVE

Elimination of environmental exposure to *C. tetani* is impossible. However, TT is one of the most effective and safest biologics available, so the health burden of tetanus is almost completely preventable through routine immunization. Although advances have been made in the care of tetanus patients, tetanus remains a severe and lengthy disease with high mortality, especially for patients who do not have access to modern intensive care. It also is a very expensive disease: the average direct cost of care for tetanus patients in the United States from 1988 to 2001 was estimated to be US$84,000 (range: US$1700 to US$925,000 in 2005 dollars); the estimated total annual cost exceeded US$12.6 million.[11] In California, the median cost of hospital charges from 2008 to 2014 was US$166,259 (range: US$22,229 to US$1,024,672).[778] In France, the 2010 cost (direct and indirect) of a tetanus case was estimated to be €209,000 (about US$277,000 in 2010 dollars).[787] Data from Ibadan, Nigeria indicate that the cost of treatment for tetanus there was one to three times the average yearly income of the patients.[790]

Nonneonatal Tetanus Disease Control

In high-income countries, and those low- and middle-income countries that provide tetanus booster doses, the lowest seroprevalence of tetanus antitoxin and the highest incidence rates of tetanus disease are in the oldest age groups and in immigrants from countries with less-developed immunization programs (see "Epidemiology" earlier).[334–336,338,340,341,400,403,404,517,623] To achieve further progress in preventing tetanus in these more affluent nations, efforts are needed to increase compliance with national recommendations for primary immunization and booster doses, with particular attention to the elderly and foreign born.[595,596]

The WHO recommendations for use of TT-containing vaccine reflect the changing global picture of tetanus, with decreasing tetanus in neonates and young children and persistent burden in adolescents and adults, especially males (see "Epidemiology" earlier).[449] The recommendations now encompass tetanus prevention in all ages and both sexes (see Table 58.1). Because non-NT is beginning to predominate globally, the public health gains and reductions in tetanus-specific costs could be substantial if countries are able to phase in the recommended booster doses.

Maternal and Neonatal Tetanus Elimination

History of Neonatal Tetanus Elimination, 1974–1999

Efforts to decrease the incidence of NT in the lower-income countries began in earnest when the EPI was launched by the WHO in 1974; TT for women was among the original six recommended antigens. The WHO recommended NT prevention through training of traditional birth attendants to provide

clean delivery services and administration of TT to pregnant women.[606] Uptake of TT for women was slow compared with DTP for infants: reported administration of a second or higher dose of TT in pregnancy (TT2+) was 9% in 1980 and 26% in 1985, while coverage with DTP3 rose from 20% to 50% over the same period (see Fig. 58.3).[42]

The recognition in the 1980s of the enormous neonatal mortality caused by tetanus, coupled with the availability of an inexpensive and effective vaccine, led to the 1989 World Health Assembly resolution to eliminate NT worldwide by 1995.[791,792] The annual number of NT deaths at that time was estimated to be 787,000, or about six deaths per 1000 live births (see "Epidemiology" earlier).[792–794] The core strategies proposed by the EPI Global Advisory Group included rapidly increasing both the TT coverage for all women of childbearing age and the proportion of deliveries respecting the "three cleans" (clean hands, clean delivery surface, and clean cutting and care of the umbilical cord), adopting a "high-risk approach" to designate high-priority geographic or socioeconomic areas for elimination activities, and encouraging the adoption of NT incidence rate as a health indicator.[792]

In 1993, a specific definition for elimination of NT as a public health problem was adopted: less than one case of NT for every 1000 live births per year in all districts (third administrative level) of a given country.[242] Because the disease tends to cluster in hard-to-reach areas whose high disease burden may be obscured at the national or provincial level, elimination efforts had to be brought to the most remote and inaccessible communities to meet the intent of the World Health Assembly resolution.

Countries with relatively well-established health services and adequate internal resources made rapid progress toward NT elimination in the 1990s, principally by increasing routine use of TT in pregnancy. By 1996, reported TT2+ coverage had increased globally to 57%; the estimated number of global NT deaths dropped 44% to approximately 438,000; and 27 of the 90 countries that did not meet NT elimination criteria in 1990 had achieved that goal.[795] By 1999, an additional five countries attained elimination status; NT remained a public health problem in 57 countries.[796,797]

High-Risk Approach

The "high-risk" approach, initially pioneered in the Americas in the early 1990s, was instrumental in progress toward the global elimination goal.[42,242,792,795,796,798–803] The high-risk approach focuses available resources on districts or subdistrict areas with reported NT incidence of more than one case per 1000 live births or, if surveillance is unreliable, on areas where relevant EPI and Maternal and Child Health indicator data suggest substantial disease risk.[42,792] Once high-risk areas are identified, all women of childbearing age (usually 15 to 45 years of age) are targeted for TT immunization through mass campaigns (supplemental immunization activities [SIAs], or TT SIAs). Three rounds of immunization are performed to provide protection for up to 10 years. The immunization of all childbearing-age women circumvents limitations in access to routine maternal health services[241,804] and addresses tetanus after septic miscarriages, abortions and other wounds.[301,805] Because NT often clusters in areas consistently missed by routine services, the high-risk approach can reduce NT burden dramatically even though national-level indicators do not change appreciably (Fig. 58.7).[803]

Program Monitoring and Evaluation

To monitor the progress in TT delivery, the first programmatic indicator adopted was TT2+, the annual proportion of pregnant women who had received a second or higher dose of TT during pregnancy. At the outset of the program, few women in countries with significant NT burden had received prior immunization with TT, so immune protection was almost exclusively obtained from doses received in pregnancy. However TT2+ now often underestimates the true level of protection against MNT because TT-containing vaccine received in childhood, prior pregnancies, SIAs, and at other health encounters, is not usually taken into account. Thus, reported TT2+ coverage now underestimates the true proportion of women with protective antibody levels.[242,351,806–808]

An alternative indicator, protection at birth (PAB), was developed to improve the accuracy of monitoring program effectiveness for countries with high DTP1 coverage.[792,808] With the PAB method, health workers determine if infants coming for a first DTP dose were protected against tetanus at birth based on their mothers' full immunization history with TT-containing vaccine. An additional benefit of the PAB method is that mothers who are eligible for a TT dose can be immunized on the spot, thereby protecting future pregnancies. Although PAB is more reliable than TT2+, its relative complexity has prevented its routine use in most countries.[808]

PAB measurement can also be performed during nationally representative surveys investigating immunization coverage and other health indicators. A mother's cumulative TT immunization history is obtained and used to judge her immunity status at the time of her last delivery.[808,809] Although survey PAB measurement provides a more accurate measure of protection than TT2+, in populations where a high proportion of women received infant DTP doses and/or TT doses later in childhood, protection still will be underestimated because those doses are usually not taken into account.

Serosurveys have provided an immunologic assessment of the true protection of mothers and infants, and the correlation between maternal histories and actual protection.[353,512,543,807,810,811] A 1989 study in Burundi demonstrated good correlation of serologic protection with PAB estimated from maternal recall.[807] Similar studies in the Central African Republic in 1996 and Cambodia in 2012 showed that maternal history underestimated true protection: PAB by maternal recall was 74% and 83%, respectively, whereas seroprevalence of protective antitoxin levels (≥0.01 IU/mL, double-antigen ELISA) was 89% and 97% among parous women.[351,353]

Reliable surveillance for NT is the best method for monitoring program success. After implementing the high-risk approach, countries are encouraged to strengthen their NT surveillance systems to monitor intervention results and focus future activities on populations in greatest need. NT case investigations are performed to determine whether the case occurred as an isolated failure of the mother to access health services, or as a more systematic failure of the health system to provide immunization and clean delivery services to the community in which the case occurred.[161,797]

Maternal and Neonatal Tetanus Elimination Initiative: 2000 to Present

By 1999, progress toward NT elimination had slowed. Reported TT2+ coverage had stagnated at around 60% (see Fig. 58.7),[812] and the proportion of pregnant women with access to clean deliveries had not changed greatly since 1989, remaining well below 50% in many low-income countries.[42,796,797,813] Many of the 59* countries that had not achieved elimination faced

*The total number of high-risk countries increased from 57 to 59 when Timor Leste and South Sudan gained independence in 2002 and 2011, respectively.

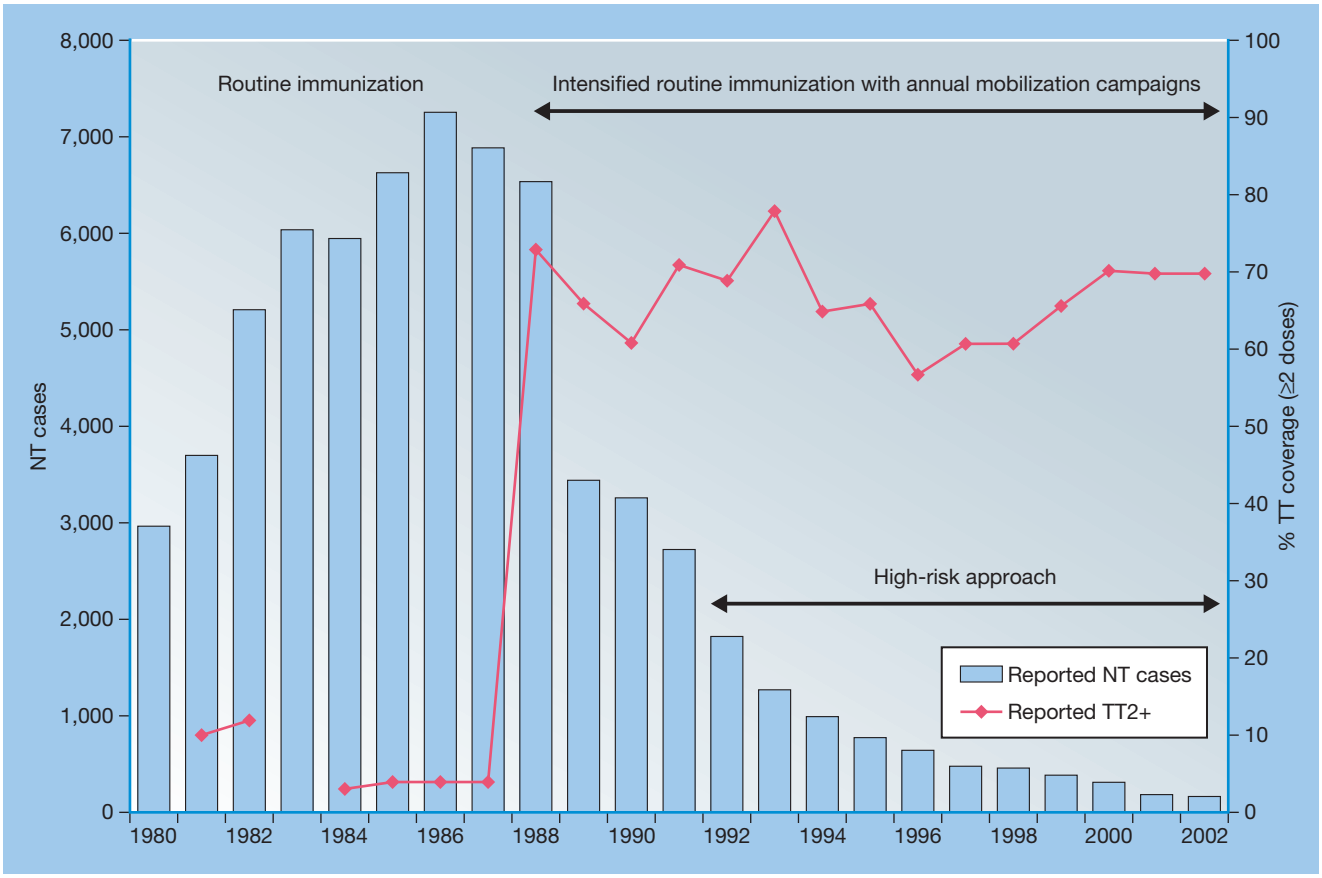

Figure 58.7. High-risk approach in Egypt. Tetanus toxoid (TT) supplemental immunization activities (SIAs) can produce a rapid reduction in neonatal tetanus (NT) cases and deaths when SIA coverage is high. Because SIAs target a limited number of communities with high NT burden, the reduction in NT incidence is often more dramatic than improvements seen in national-level TT or protection at birth coverage estimates. *(Modified from the World Health Organization's Department of Immunization, Vaccines, and Biologicals database and Expanded Programme on Immunization. Progress towards neonatal tetanus elimination, 1988–1994. The "high risk" approach: the WHO-recommended strategy to accelerate elimination of neonatal tetanus. Egypt. Wkly Epidemiol Rec.1996;71:33–36.)*

substantial health infrastructure weaknesses, ongoing civil unrest or conflict, and severely limited health budgets.[42,43,243]

In that context, UNICEF, the WHO, and the United Nations Population Fund forged a stronger partnership, with UNICEF taking the lead. Because maternal tetanus (tetanus during pregnancy or within 6 weeks of the end of pregnancy) shares the same risk factors and means of prevention as NT, the partnership amended the global goal to include elimination of maternal tetanus, with an operational target of 2005[243,796,797]; the program name was revised to the Maternal and Neonatal Tetanus (MNT) Elimination Initiative.[814] The traditional strategies of routine immunization of pregnant women, clean delivery and cord care practices, and effective NT surveillance continue to be promoted. Use of the high-risk approach was vigorously expanded using a more standardized method to identify high-risk areas requiring TT SIAs, and campaign achievements are closely monitored.[42,243,796,797,814]

Since 2000, 53 countries have used the high-risk approach, delivering at least two TT doses to more than 130 million women; 23 countries conducted TT SIAs in 2010 alone.[243,814] By the mid-2000s, reported TT2+ again began to rise, reaching 75% in 2009. A formal survey method was developed to accurately assess whether a country had met the definition of NT elimination.[815] If NT elimination has been achieved, elimination of maternal tetanus is assumed.[796] Since 1999, 41 of 59 countries at risk for MNT were validated as having eliminated MNT (Fig. 58.8). Among the remaining 18 countries, MNT elimination was confirmed subnationally for more than 90% of the populations of Ethiopia (except Somali Region), for the Philippines (16 of 17 regions) and for the Punjab province of Pakistan; many others also are nearing the validation process.[243,814]

A major impediment to program implementation in some countries has been dissemination of misinformation about the purpose of vaccination campaigns. Allegations that TT is a covert contraceptive or sterilizing agent disrupted immunization of adolescents and women in Cambodia, Cameroon, Kenya, Mexico, Nicaragua, Papua New Guinea, the Philippines, and Tanzania.[816–819] Such allegations, which circulate freely on the Internet, are based on suspicions and fears that the true aim of tetanus immunization is to reduce fertility. Because MNT prevention campaigns specifically target women of childbearing age, local populations are particularly vulnerable to these rumors if distrust of government or international agencies already exists. In areas where the fervor of public accusations has been extreme—leading to court injunctions or political posturing—the level of disruption has greatly affected women's, and even children's, immunization.[816–820] These accusations continue to circulate and must be combated with vigorous education campaigns involving credible community leaders in anticipation of problems.

Use of TT to prevent NT is highly cost-effective both when delivered as part of routine prenatal packages and when given in the context of SIAs.[243,821–827] It costs approximately

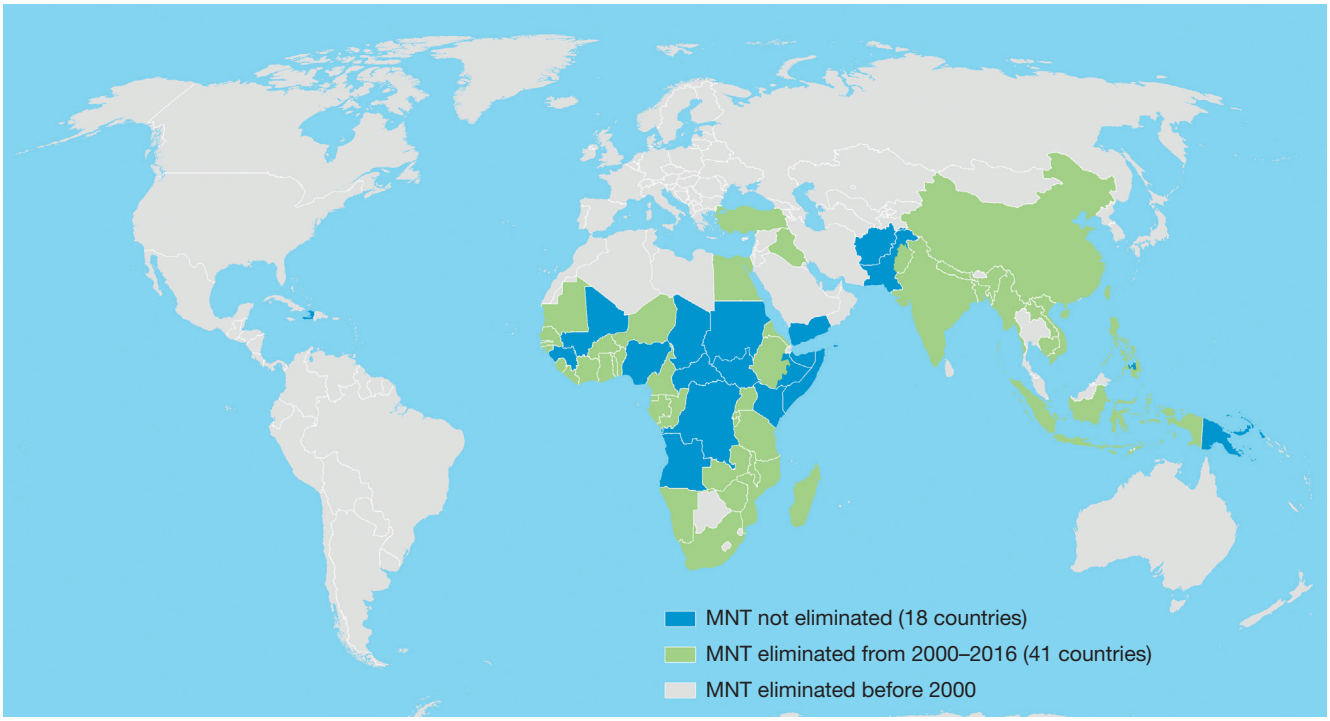

Figure 58.8. Global maternal and neonatal tetanus (MNT) elimination status by country, October 2016. MNT elimination is defined as <1 case of neonatal tetanus (NT) per 1000 live births in each district (third administrative unit) of a country. Formal validation of apparent elimination has been underway since 2000 (see text); most of the 18 countries that have not yet achieved elimination status are nearing that goal. Also shown are that 16 of 17 regions of the Philippines have validated MNT elimination, as has Ethiopia except for the Somali region, and Punjab province of Pakistan. *(From the World Health Organization. Maternal and Neonatal Tetanus (MNT) Elimination: The Initiative and Challenges. Available at: http://www.who.int/immunization/diseases/MNTE_initiative/en/.)*

US$2.00 to deliver three doses of toxoid by supplementary immunization.[534] A 2004 study using data from TT SIAs conducted in a rural district of Pakistan with a high NT burden confirmed current cost-effectiveness: the cost of three rounds of supplementary immunization was US$117 per averted death.[825]

Once countries achieve MNT elimination, ongoing support to health infrastructures is essential to continue and expand access to clean deliveries, to maintain high routine immunization coverage with TT for women and DTP for infants, and to introduce appropriate booster doses of TT-containing vaccine.[42,243,449,828] Use of school-based immunization strategies is proving to be an effective approach for delivering booster doses in many countries.[243,829,830] Enhanced NT surveillance and ongoing monitoring of immunization program quality indicators are necessary to identify areas of increased risk for MNT requiring targeted interventions to maintain elimination status.

59 Tickborne Encephalitis Vaccines

Joachim Hombach, Alan D.T. Barrett, and Herwig Kollaritsch

Tickborne encephalitis virus (TBEV) is a member of the genus *Flavivirus*, family Flaviviridae, which comprises approximately 70 viruses that cause many serious diseases, including dengue, Japanese encephalitis, West Nile virus neuroinvasive disease, and yellow fever. TBEV is one of the major human pathogenic flaviviruses, with disease being caused by three subtypes termed European or Central European (TBEV-Eu), Far Eastern or Russian Spring Summer encephalitis (TBEV-Fe), and Siberian (TBEV-Sib).[1] TBEV is the prototype member of the mammalian tickborne virus complex (previously known as the tickborne encephalitis [TBE] serocomplex), a group of genetically and serologically related viruses including Omsk hemorrhagic fever virus (OHFV), louping ill virus, Langat virus (LGTV), Kyasanur Forest disease virus (KFDV), Powassan virus, and Alkhumra virus. OHFV, KFDV, and Alkhumra virus are also associated with hemorrhagic fever, while Powassan virus and louping ill virus mostly cause subclinical disease with occasional cases of encephalitis. LGTV does not typically infect humans and appears to be naturally attenuated.

The manifestations of the European subtype were first described in 1931 by Schneider,[2] who reported a seasonal outbreak of meningitis in the district of Neunkirchen in Lower Austria. Shortly afterward, a similar outbreak was reported from the far eastern region of Russia. Beginning in 1939, a number of outbreaks were also reported in the European region. More recently, disease outbreaks in Siberia were related to the viral subtype, TBEV-Sib. In summary, the disease is now seen throughout most of Europe, except in the Southern regions, and in Russia, and Asia, corresponding to the distribution of Ixodid tick species, the chief vector of TBEV. The disease has also been referred to as spring-summer meningoencephalitis, central European encephalitis, Far Eastern encephalitis, Taiga encephalitis, Russian spring-summer encephalitis, biundulating meningoencephalitis, diphasic milk fever, Kumlinge disease, and Schneider disease.

TBEV is a major cause of neurological disease in humans living in endemic areas. According to a study conducted in 1958 prior to use of vaccine, 56% of all viral central nervous system (CNS) infections in Austria were caused by TBEV.[3,4] Before the start of the vaccination program, it was the most frequent CNS infection in adults, with several hundred hospitalizations reported each year.

During the last 25 years between 5000 and 12,000 clinical TBE cases have been reported annually worldwide. However, the number of cases of TBE is considered to be underreported, both in countries where the disease is well known and in regions where TBE is unrecognized. In addition, the increasing exposure of the mobility in people to the outdoor environment increases the risk of infection. Although there are several safe and effective vaccines available, TBE remains a growing public health problem in Europe and parts of Asia.

BACKGROUND

Clinical Description

Neurologic symptoms seen with TBE are similar to other forms of acute viral meningoencephalitis.[5] The clinical course of TBE can be either monophasic or biphasic. If biphasic, the disease starts with an influenza-like illness, followed by a few days of well-being, and then a second phase with neurological symptoms. While the biphasic course is typical for TBEV-Eu (72–87%) and TBEV-Sib (21%), the TBEV-Fe subtype is primarily a monophasic neurologic illness.[6–8]

After infection by an infected tick, there is an asymptomatic incubation period that lasts between 4 and 28 days, with most cases ranging between 7 and 14 days. The first stage of clinical illness, lasting for 1 to 8 days and corresponding to the viremic phase, is characterized by nonspecific influenza-like symptoms such as fatigue, headache, aching back and limbs, nausea, and general malaise. Temperatures generally rise to 38°C or higher. Very high initial temperatures have been reported, particularly in children.[9,10]

An afebrile interval then follows the first stage of TBE, lasting 1 to 20 days, with most patients being asymptomatic during this time. Then another sudden rise of temperature marks the beginning of the second stage of the disease. The clinical manifestations during this second stage are far more serious than during the first. In approximately 50% of cases there is CNS involvement in the form of meningitis with pleocytosis. Approximately 40% of cases have more-severe disease with signs of encephalitis, including paralysis, stupor, and pyramidal tract signs. Meningoencephalomyelitis, defined as neurological symptoms including spinal nerves, the most-severe form of the disease, occurs in approximately 10% of patients and is more common in older individuals.[10] In the paralytic forms of the disease, often seen in the region of the shoulder girdle, paralysis develops within 5 to 10 days after the remission of fever in the course of the second phase. Paralysis may progress for up to 2 weeks, followed by a tendency toward improvement. The overall risk of long-term sequelae increases with the severity of the neurologic symptoms.[10] One study showed that 80% of TBE patients with meningoencephalomyelitis did not fully recover within a 10-year follow-up period.[11]

Approximately 5% to 12% of patients require intensive care secondary to respiratory paralysis or serious disorders of consciousness.[9] Hospitalizations last between 3 and 40 weeks,[10] depending on the severity of the illness and long-term rehabilitation is required for approximately 20% to 30% of hospitalized patients.[11]

Not all persons infected with TBEV experience the monophasic or full biphasic spectrum of clinical disease. Seroconversion without obvious disease is common. On average, approximately 25% of infected persons develop clinical symptoms.[5] Differences in proportions have been reported by viral subtype and age. In children, the proportion of inapparent infection may be higher and normally results in seroconversion and establishment of immunity.[6,12]

Among those who develop clinical illness, 3% to 8% of TBEV-Fe patients, 21% of TBEV-Sib patients, and 72% to 87% of TBEV-Eu patients will experience the full biphasic course of disease; all other patients will experience the first phase of influenza-like illness only. In a minority of cases, the infection is inapparent during the first stage and the onset of clinical illness shows the characteristics of the second phase of the disease.[5]

Disease manifestations vary by age.[5,7–9,13] Older patients tend to have more-severe disease and suffer more neurologic sequelae, whereas in children asymptomatic infection is more common.[10] However, there are scattered reports of severe, even fatal cases in very young children.[14–19] In children and adolescents, meningitis rather than encephalitis is the predominant form of the disease. However, between 35% and 58% of hospitalized patients younger than age 15 years have long-term cognitive or neuropsychiatric sequelae, including sensory disturbances, ataxia, dysphasia, spinal nerve paralysis, hearing loss, concentration difficulties, memory impairment, and emotional instability.[5,7,13] Patients older than 40 years tend to have the encephalitic form of the disease, and those older than 60 years tend to have the most-severe disease, including paralysis and seizures, with the highest case-fatality rate.[5,10,20] In Austria, Germany, Sweden, Switzerland, and Lithuania, more than 50% of TBE cases are reported in people 50 years of age or older.[20] Thus, the elderly are a special target group for immunization.[12] In children younger than age 7 years, TBE tends to be less severe, with a lower probability of permanent sequelae.[10] However, a recent small-scale study suggests that children also have a significant risk of incomplete recovery.[21]

Although assessing clinical severity can be difficult when based on case reports from healthcare systems that differ in access to healthcare, case definitions, and diagnostic procedures, disease manifestations appear to differ by virus subtype.[5] The clinical course of TBEV-Sib in children is more severe than TBEV-Eu, with half experiencing encephalitis.[14] However, complete recovery from TBEV-Sib disease is reported in 80% of cases.[15]

The clinical presentation of TBEV-Fe differs from TBEV-Eu. TBEV-Fe presents more gradually, with a prodromal phase that includes fever, headache, anorexia, nausea, vomiting, and photophobia. These symptoms are followed by stiff neck, visual disturbances, and variable neurologic dysfunctions, including paresis, paralysis, sensory loss, and seizures. In a TBEV-Fe outbreak in Novosibirsk hemorrhagic manifestations in the form of gastrointestinal bleeding and local hemorrhages on mucosa and skin were observed.[16] It has been reported that only 25% of patients with TBEV-Fe will recover without sequelae.[15] Occasional chronic infections have also been reported.[22]

Besides age, the case-fatality rate of TBE appears to depend on the virus subtype. The case-fatality rates have been reported to be 1% to 2% in TBEV-Eu, 6% to 8% in TBEV-Sib, and up to 40% in TBEV-Fe.[5,8,12,17,18] However, the higher rates reported for TBE-Sib and TBE-Fe may be impacted by limited access to medical care or different healthcare seeking behavior of patients in the eastern TBE-endemic regions.[18]

A postencephalitic syndrome, with symptoms persisting beyond 3 months, has been described for all viral subtypes.[19,23] Chronic forms of TBE occur in 1% of cases caused by TBEV-Sib and have been verified by viral isolation.[5,22] Additionally, years after initial disease caused by TBEV-Fe or TBEV-Sib, rare cases of progressive neuritis and epileptic seizures have been described, but definitive proof of an etiological link to TBEV is lacking.[24]

Virology and Pathogenesis

The TBEV particle is icosahedral, approximately 50 nm in diameter, and consists of an electron-dense spherical nucleocapsid of approximately 30 nm in diameter, surrounded by a lipid bilayer. In sucrose density gradients, purified virus sediments at about 200S and bands after equilibrium centrifugation at a density of about 1.19 g/cm.[21] The viral genome is single-stranded, positive-sense RNA of approximately 11,000 nucleotides in length. The many strains of all three subtypes have been sequenced (including vaccine strains TBEV-Eu–Neudörfl, K23, and TBEV-Fe–Sofjin, TBEV-Fe–205, and TBEV-Fe–Senzhang).[25,26] There is 16% or less nucleotide variation between TBEV-Eu and TBEV-Fe subtypes and only 4% or less amino acid variation between the subtypes, including less than 2.2% amino acid variation between the different TBEV-Eu strains. Consequently, the three subtypes of TBEV are serologically closely related and vaccines against one subtype induce cross-protective immunity to all three subtypes (see below). Although initial studies suggested that the three TBEV subtypes were restricted to geographically distinct locations, phylogenetic studies demonstrate that the three subtypes of TBEV overlap geographically.

Mature virions are composed of three structural proteins: envelope (E), core (C), and membrane (M) proteins, with molecular weights of 55,15, and 8 kDa, respectively. The E protein is glycosylated and exists as 90 copies of a dimer orientated parallel to the viral surface as shown by x-ray crystallography.[27] A glycosylated precursor of the membrane protein (prM) is present in immature virus particles. The mature nonglycosylated M protein is derived by a furin-mediated cleavage from the precursor protein prM. C is the only protein constituent of the isometric nucleocapsid that contains the virion RNA. The virus RNA also encodes seven nonstructural (NS) proteins. The coding sequence of the positively stranded RNA is 5′-C-prM-E-NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5-3′. All viral proteins are encoded within a single open reading frame and the individual proteins are released from a precursor polyprotein by co-and posttranslational cleavage.[28] Structural elements of the E protein are involved in the binding of virions to cell receptors, receptor-mediated endocytosis, and low-pH–dependent membrane-fusion. The E protein contains the important antigenic determinants responsible for hemagglutination inhibition (HI) and neutralization. E protein epitopes induce protective immune responses in the infected host and monoclonal antibodies to these epitopes have been extensively studied.[29,30]

After the bite of an infected tick, the virus replicates in the dermal cells at the site of the bite. Then the virus is transferred through afferent lymphatic vessels to the regional lymph nodes where further replication occurs. The virus then spreads via the lymphatic system and the bloodstream, and invades susceptible tissues, including the reticuloendothelial system. There extensive viral replication occurs, leading to seeding of the CNS. High viral loads are required for the virus to cross the blood–brain barrier since the capillary endothelium is not easily infected. To evade host defenses, TBEV rearranges intracellular membranes to prevent recognition of double-stranded RNA (formed during virus replication) by cytoplasmic pathogen recognition receptors,[31] allowing an approximate 24-hour delay in interferon induction. The interferon response is further reduced by the NS TBEV protein NS5 that blocks JAK/STAT (Janus kinase–signal transducer and activator of transcription) signaling.[32,33] How TBEV enters the CNS is poorly understood but likely involves either crossing the blood–brain barrier via olfactory or autonomic neurons.[34] Animal models suggest that $CD4^+$ T cells may have a role in limiting the severity of TBE, while $CD8^+$ T cells seem to be mediators of immunopathology.[35,36]

Diagnosis

Because the clinical manifestations of TBE are nonspecific, TBE must be confirmed by laboratory techniques. In the initial viremic phase of the disease, the virus can be identified through inoculation of serum in a suitable cell line or in suckling mice.[37] However, polymerase chain reaction (PCR) technology has largely replaced such culture technologies for

virus identification.[38] With the onset of the second phase of the disease, the virus has been cleared from the blood and is also difficult to detect in cerebrospinal fluid.[39] Because the symptoms of CNS involvement are usually not observed until 2 to 4 weeks after the tick bite, antiviral antibodies are nearly always present at the time of admission to a hospital and can be detected readily by standard serologic tests. A recent TBEV infection can be confirmed by an increase in the HI titer, the neutralization titer (NT), or complement fixation titer, and by a decrease in HI titer after 2-mercaptoethanol treatment, suggesting the presence of immunoglobulin (Ig) M antibodies.[39] These tests are now used mainly for confirmatory purposes and have been largely replaced by rapid, sensitive, and reliable enzyme-linked immunosorbent assays (ELISAs) directed at the detection of IgM antibodies in the early phase of TBE. A four-layer ELISA system for the detection of TBEV-specific IgM has been developed that is extremely sensitive and prevents interference when high-titer, virus-reactive IgG antibodies for TBEV are present.[40] At an early stage after the onset of illness, TBEV-specific IgM can be detected in serum dilutions up to 1 : 10,000. However, in cases of other flavivirus exposures (e.g., vaccinations against yellow fever or Japanese encephalitis or following dengue virus infections), the use of a NT assay (e.g., rapid fluorescent focus inhibition test) is necessary to eliminate interference of flavivirus cross-reactive antibodies in ELISA and HI testing.[39,41] NT tests are only conducted in specialized laboratories with biosafety level 3 or 4 (depending on national requirements) and are not routinely available.[40] An alternative approach to diagnosis is the comparison of ELISA antibody titers in paired sera collected 14 days apart, where a fourfold or greater increase in titer is considered a confirmatory diagnosis. A high correlation has been demonstrated between the ELISA IgG units and the HI and NT titers, provided there was no other exposures to flavivirus antigens by natural infection or vaccination.[42,43] Standardized methods for serological and reverse-transcription PCR assays for European TBE have been published.[38,40]

Treatment

No specific therapy for TBE exists. Although reports of treatment with ribonuclease obtained from bovine pancreas[44] or with emetine[45] have been published, they are not generally accepted. Corticosteroids appear to hasten defervescence and improve subjective symptoms,[46] but also prolong the period of hospitalization.

Symptomatic treatment includes maintenance of water and electrolyte balance, provision of sufficient caloric intake, and the administration of analgesics, vitamins, antipyretics, and antiepileptics, as needed. Physiotherapy of paralyzed limbs is essential to prevent muscle atrophy.[10] Because person-to-person transmission of the virus has never been observed, there is no need to isolate patients with TBE. It is hoped that the improved knowledge of the structure of flavivirus proteins will soon lead to the development of antiviral agents.

EPIDEMIOLOGY

Incidence and Prevalence Data

TBEV is exclusively restricted to Europe and Asia, with the distribution of TBEV including almost the entire southern part of the nontropical Eurasian forest belt, from Alsace-Lorraine in the west to Vladivostok, and the northern and eastern regions of China to Hokkaido in Japan and some regions of the Republic of Korea (Figs. 59.1 and 59.2).[18,47] In the peak-year of 1996, more than 12,000 cases of TBE were reported from 19 European countries including Russia (Fig. 59.3 and Table 59.1). Although TBEV is found in valleys and nearby rivers with adequate habitats for ticks[47] rather than in higher altitudes, in recent years it has been reported from altitudes up to 2100 meters above sea level.[48–50] Geographically restricted foci with very high TBEV activity have also been reported.[47,51] TBEV prevalence varies from year to year,[52] possibly depending on microecological conditions such as humidity and temperature.[12]

In Europe, eight species of ticks have been identified that can transmit TBEV. *Ixodes ricinus*, the common castor bean tick, is the chief vector for the TBEV-Eu subtype and *Ixodes persulcatus* is the chief vector for the TBEV-Sib and TBEV-Fe subtypes. Other tick species have been associated with local TBE outbreaks in Siberia and the Far East. *I. ricinus* is found in much of Europe, extending to Turkey, northern Iran, and the Caucasus. *I. persulcatus* occurs mainly in eastern Europe, Russia, China, and Japan. The prevalence of TBEV in ticks has been shown to be as high as 21% in the District of Regen and 18% in the District of Freyung-Grafenau in southern Germany.[52] Other studies have reported the TBEV prevalence in ticks to be as high as 39%.[1,18,53–55] The distribution of TBEV subtypes is correlated to the distribution of tick species. In regions where both *I. ricinus* and *I. persulcatus* are present, TBEV subtypes cocirculate. However, the TBEV-Sib subtype has also been isolated from *I. ricinus*,[56] and the TBEV-Eu subtype has been found in *I. persulcatus*.[57]

The TBEV-Eu subtype is most prevalent in western, northern, and eastern Europe and European parts of Russia, but it has also been detected in Asian regions of Russia, such as Altai, eastern Siberia, and the northern Caucasus.[24,51,56,58] The TBEV-Sib subtype is prevalent in regions between Japan, the Baltic states, and Bosnia,[18,51,56,59] and may have replaced the TBEV-Fe subtype in several regions of Russia.[1,56] The TBEV-Fe subtype has been detected in regions between the easternmost Japanese and Russian islands and the Baltic states, including regions in China and Mongolia.[18,51,56]

Given the highly focal and variable proportion of infected ticks, there is no internationally accepted definition for when a region is considered endemic for TBE. According to Suess, regions with presence of TBEV or with locally acquired TBE cases (laboratory confirmed) in a 20-year period can be regarded endemic for TBE.[1] Dobler and associates expanded this definition to include TBE cases in animals and the presence of specific TBEV antibodies in wild animals and domestic animals with habitat fidelity.[47] Regions are suggested to be at high risk for TBE (e.g., Austria, Czech Republic) if more than five cases of TBE per 100,000 people occurred before widespread use of TBE vaccines.[47,18,60]

TBE vaccination coverage in Austria has been around 88% since 2007. However in the unvaccinated Austrian population, incidence rates of six per 100,000 population have been described, meaning Austria is highly endemic for TBE according to the definitions mentioned above.[61] Reporting systems often register the place where a person is diagnosed with TBE, which may differ from the place of infection. Therefore, reported cases may not always mirror the distribution of TBEV[47]; consequently, a travel history should be obtained from TBE patients.

Disease Surveillance and Reporting

TBE is an "emerging disease" because it is spreading to regions where TBEV had not been previously detected.[51] In the last few years, new foci of TBE cases have been identified in Austria, China, Denmark (mainland), Finland, Germany, Kazakhstan, Kirgizstan, Mongolia, Norway, Sweden, Switzerland, and Uzbekistan.[1,47,51] This may be the result of many different factors, including climate change, migration of populations to

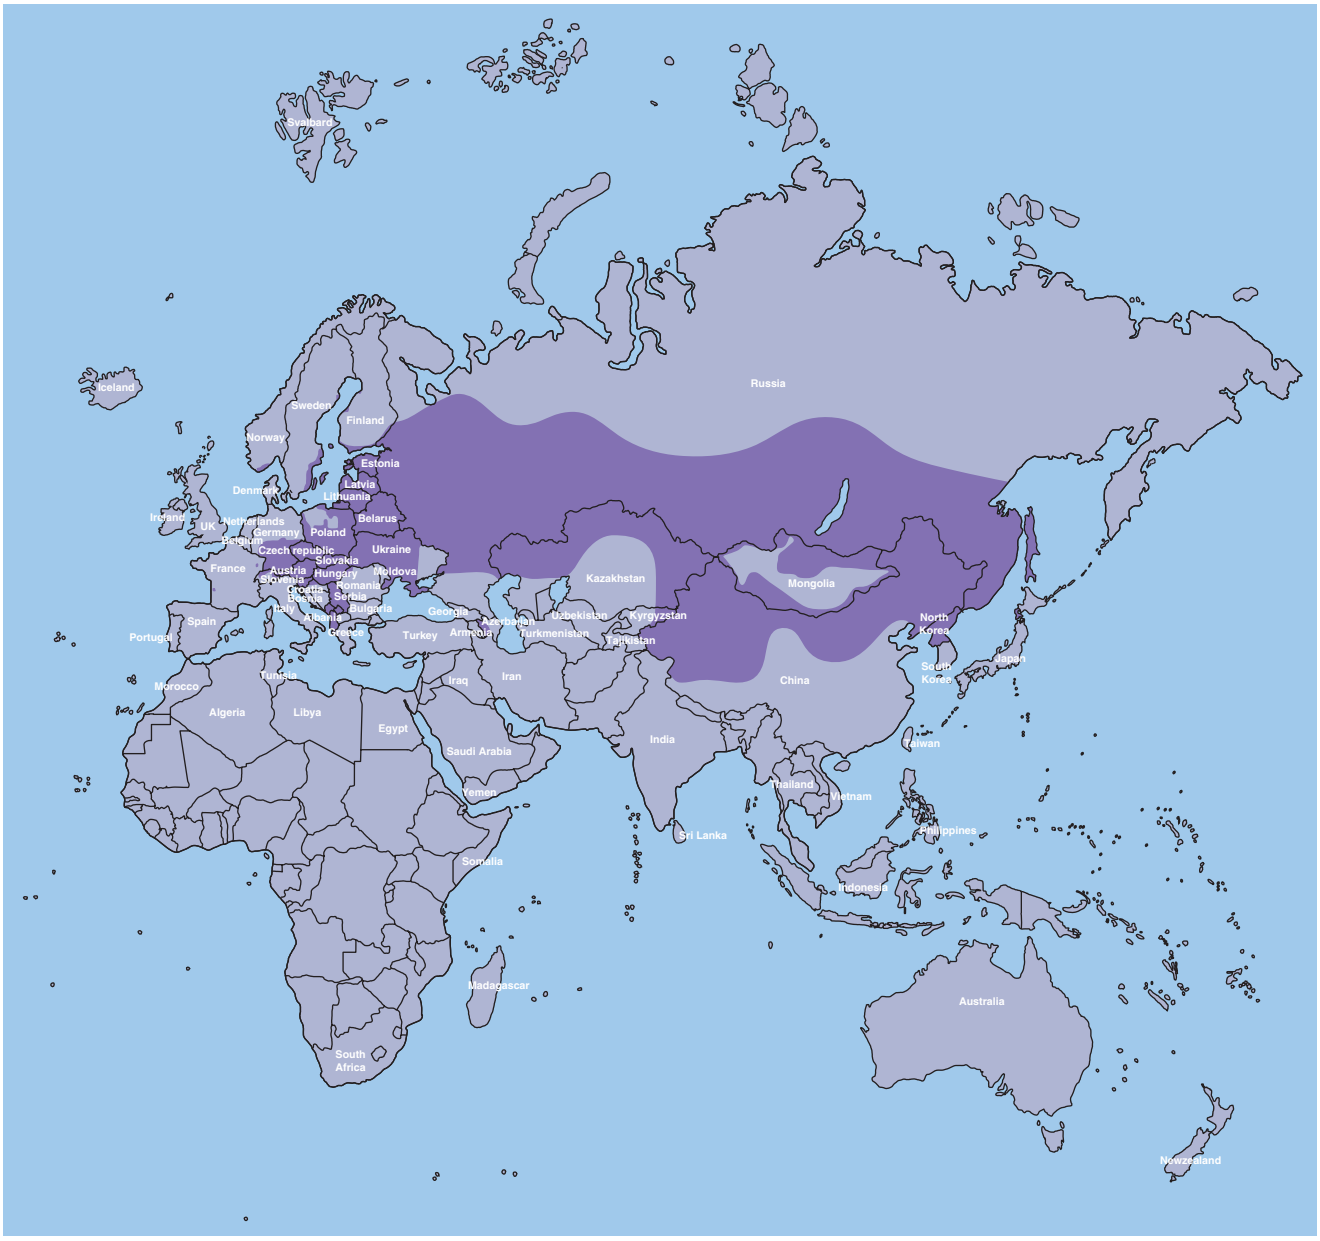

Figure 59.1. Geographic occurrence of tickborne encephalitis viruses in ticks, animals, and humans. *(From Dobler G, Gniel D, Petermann R, et al. Epidemiology and distribution of tick-borne encephalitis. Wien Med Wochenschr. 2012;162[11-12]:230–238.)*

suburban areas, changes in leisure habits, changes in agricultural practices, increased reforestation, and increased awareness and reporting.[18,51,62–65] Overall, awareness is limited in low-endemic countries and cases may not be diagnosed unless there is a clustering. Also, the disease is still not notifiable in countries without a dedicated surveillance system.[66] Furthermore, surveillance and reporting are hampered by the lack of an internationally harmonized case definition for TBE,[1,67] limiting the comparison of data from different countries. Data on TBE are collected by national institutions, reference laboratories, regional institutions, and the European Center for Disease Prevention and Control.[67,68] TBE surveillance is implemented in 20 European countries, 16 have mandatory reporting (see Table 59.1), and a case definition is in place in 10 countries (see Table 59.1).[47,68] Case definitions that include clinical symptoms and a laboratory confirmation are applied in the Czech Republic, Germany, and Hungary.[67] Since 1950 TBE is also a notifiable disease in Russia, although without a uniform case definition.[60] Table 59.1 lists the numbers of reported cases of TBE.

Risk Groups

A high percentage of detectable TBEV antibodies has been observed among high-risk groups, including persons working in agriculture and forestry, hikers, people engaged in outdoor sports, and collectors of mushrooms and berries. An increasing proportion of the population seems to be part of such recognized high-risk groups. In addition, increased tourism of nonvaccinated persons to central and eastern Europe exposes large numbers of people to significant risk of TBEV infection.[69] It is estimated that around 50 million travelers

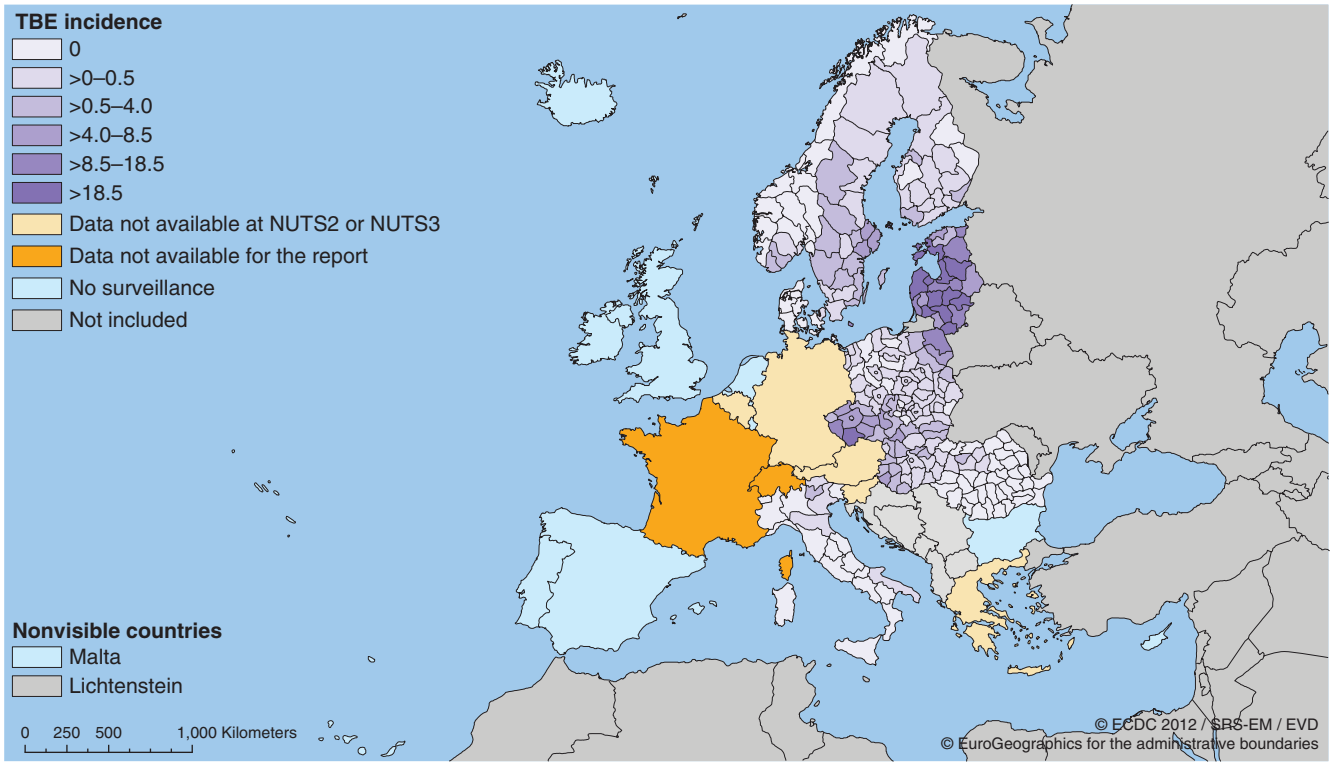

Figure 59.2. Tickborne encephalitis (TBE) average annual incidence rate per 100,000 inhabitants in the European Union (EU)/European Free Trade Association (EFTA) at lower administrative level NUTS (Nomenclature of Territorial Units for Statistics) 2 (Italy) or NUTS3 according to the European Centre for Disease Prevention and Control 2012. *(From European Centre for Disease Prevention and Control. Epidemiological Situation of Tick-Borne Encephalitis in the European Union and European Free Trade Association Countries. Stockholm, Sweden: ECDC, 2012.)*

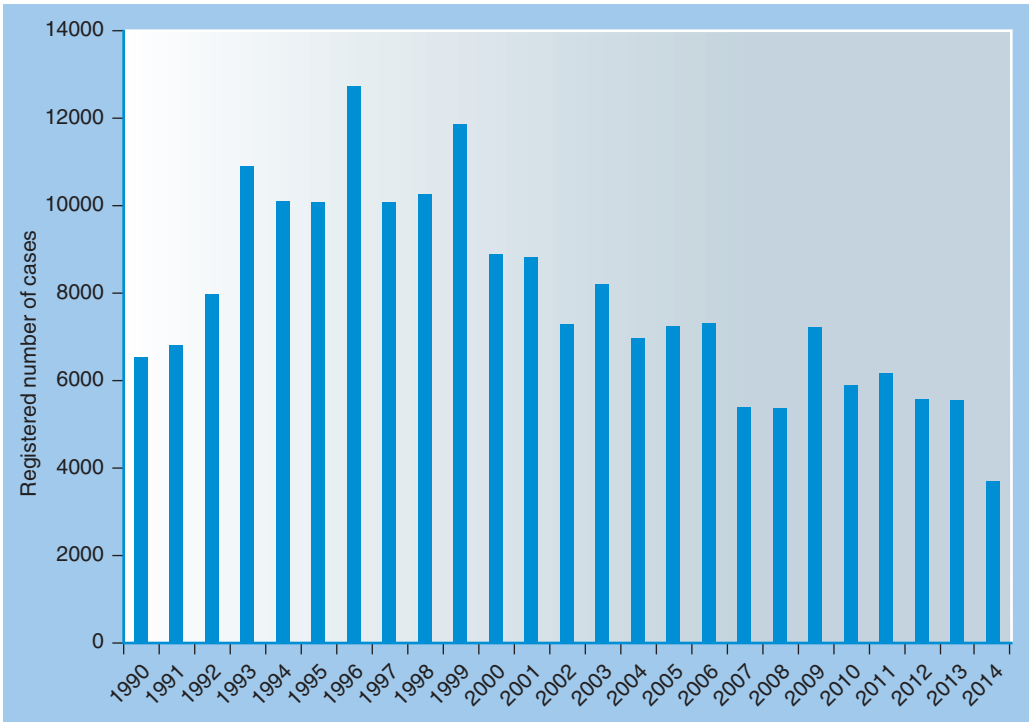

Figure 59.3. Registered number of cases of tickborne encephalitis (TBE) in Austria, Croatia, Czech Republic, Denmark, Estonia, Finland, France, Germany, Hungary, Italy, Latvia, Lithuania, Norway, Poland, Russia, Slovakia, Slovenia, Sweden, and Switzerland between 1990 and 2014 (2014: preliminary data) as of March 2015. *(Data courtesy Prof. J. Suess, Friedrich-Löffler-Institute, National Reference Laboratory for Tick-borne Diseases, Jena, Germany.)*

visit TBE-endemic regions every year.[70] The risk of contracting TBE in a highly endemic region has been calculated at one per 10,000 human-months during TBE season (April to October).[69] This risk of TBEV exposure was also highlighted in case studies of UK and U.S. citizens who contracted TBE during visits to Europe, Russia, and China.[71,72] The United States Centers for Disease Control and Prevention (CDC)[73] and the World Health Organization (WHO)[74] have on their respective websites recommendations for vaccination of travelers. However, implementation of such recommendations is limited by the availability of the TBE vaccines outside endemic regions.

Genetic factors have also been implicated in infection rates with persons having a mutation in the *CCR5* gene (CCR5Δ32)[75] and a wild-type *TLR3* gene reported to have an increased risk of TBE.[76]

Modes of Transmission and Reservoirs of Infection

TBE is a zoonotic disease, and ticks are the main vectors and reservoir hosts of TBEV in nature. Ticks become active at temperatures above 8°C and a relative humidity of 70% to 80%, explaining the seasonality of the disease and the suitability of Europe and Asia forested areas as habitats. Vertebrates serve as amplifying reservoir hosts of TBEV and the primary source of infection for ticks, thus forming a cycle of transmission. Small rodents, such as mice and voles, are believed to be prominent reservoirs, but also large mammals, such as roe, deer, and goat, may be involved.[8,77,78] Transovarial transmission of the virus as well as transstadial transmission have been described, when nymphs and larvae cofeed on the same host. Once infected, ticks carry the virus for life. TBEV is usually transferred to the host through the saliva of the infected tick. The virus can be transmitted to humans or other hosts by larvae, nymphs, and adult ticks. On humans, ticks attach themselves to the hair-covered portion of the head, ears, and the extremities. The epidermis is punctured with the chelicerae, and the hypostome is inserted. Because of the anesthetizing effect of the tick's saliva, the bite causes no pain and often passes unnoticed by the host, leading the victim to not recall having been bitten by a tick.

While the main route of TBEV transmission occurs through tick bites, there are reports from several European countries of occasional transmission through the alimentary route by means of ingestion of unpasteurized dairy products.[1] Goat, sheep, and cattle that are hosts for *I. ricinus* can be infected by TBEV, and raw milk from these animals collected during the viremic phase can be infectious to humans. More than 50 cases of TBE have been reported in Slovakia after consumption of cheese made from raw sheep milk,[79] and in Estonia an epidemic of TBE was linked to raw goat milk.[80] Unpasteurized milk and cheese were reported to be responsible for 64 cases of TBE in the Czech Republic between 1997 and 2008.[81] In an endemic region of Poland, reverse transcriptase–PCR demonstrated the presence of TBEV in the milk of more than 10% of the cows and more than 20% of the sheep and goats.[82] Although it has not been observed, human-to-human transmission is a theoretical possibility when blood from a viremic donor is transfused or when infected human milk is consumed by an infant.[12]

Significance as a Public Health Problem

In endemic areas, TBEV is one of the most important causes of viral meningitis/encephalitis and constitutes a major public health problem. As endemic regions are expanding, public health authorities should carefully monitor the situation in adjacent areas. Endemic locations are also expanding in altitude, up to 2100 meters above sea level.[50,83] On average, some 8000 cases of TBE are reported from European countries and Russia (see Table 59.1 and Fig. 59.3), although with significant year-to-year variation. Despite being a notifiable disease in the European Union since 2012,[66] the disease burden is believed to be significantly underestimated. Of note, even in the most severely affected areas, the disease is confined to certain foci, making it difficult to define at risk areas. Overall, more cases are being reported from males than females, which may reflect different risks of exposure. While TBE can affect all age groups, the age distribution of cases varies between endemic regions. For example, in the highly endemic region of western Siberia, most cases were reported in adults (20 to 49 years of age), with only 20% to 30% of cases reported in children younger than 14 years.[14] In contrast, among German TBE patients only 12% were children and a substantial proportion of the cases occurred in the elderly.[10] These epidemiological patterns may further change as life style and recreational activities evolve.

The burden of disease, including long-term sequelae, is not well defined. The disease tends to be relatively severe in adults and long-term sequelae from the disease are quite common in adult age groups. However, a significant risk of incomplete recovery also exists in children.

Ecological studies show that vaccination can have a profound impact on disease incidence. The WHO recently published a position paper on TBE vaccines,[18,84] recommending vaccination for whole populations in highly endemic areas (>5 cases/100,000/year) and vaccination of risk groups in low to moderate endemic areas (>0.5 cases/100,000/year).

Passive Immunization

An Ig concentrate containing specific γ-globulin against TBEV was previously used prophylactically or as a postexposure treatment; today, this approach is only used in Russia. As a number of cases of suspected antibody-mediated enhancement of infection were reported after use of TBE Ig in children,[85] these products were withdrawn from the European markets in the late 1990s. Although there was no conclusive evidence of enhancement of TBEV infection after use of Ig in humans and no such enhancement occurred in a mouse model,[86] postexposure treatment using TBE Ig is no longer recommended in most European countries.[87]

In Russia, on the other hand, passive immunization after tick bites is current practice in TBE endemic areas. Russian studies have reported that early application of TBE-specific Ig after tick bites can prevent clinical disease in approximately 80% of cases. This level of protection is achieved by timely administration of a single dose of 0.05 mL/kg body weight of TBE Ig with a titer of no less than 1 : 80.[88,89] Increasing the dose to 0.1 mL/kg or readministration of Ig provided no additional protective effect. Concerns have been raised in relation to the content of neutralizing antibody of some commercial preparations.[89]

ACTIVE IMMUNIZATION

History of Vaccine Development and Manufacture

In 1937, TBEV was discovered in the Far Eastern sections of the Union of Soviet and Socialist Republics (USSR) and the first candidate vaccine was generated as early as 1938.[90] Smorodintsev and coworkers developed a formalin-inactivated vaccine based on mouse brain infected with the strain Sofjin and administered it to forest workers in endemic regions.[91] Although mouse brain–derived vaccines were immunogenic

and effective, they frequently caused allergic reactions. Subsequently, in the 1970s the naturally attenuated mammalian tickborne flavivirus LGT virus was evaluated as a vaccine in clinical trials involving more than 600,000 volunteers in the former USSR. A high rate of adverse events involving the CNS (one in 18,570 volunteers) was observed and the clinical trials were stopped.[92]

Initial attempts to develop a vaccine against TBEV-Eu were made in Czechoslovakia in the 1960s.[93,94] The virus was grown in primary avian fibroblast cultures and formalin inactivated. It was shown to be an effective vaccine in a variety of laboratory animals and human volunteers.[95] In 1971, the Institute of Virology in Vienna, Austria, and the Microbiological Research Establishment in Porton Down, England collaborated to develop a formalin-inactivated vaccine based on the Austrian TBE strain Neudörfl. This strain was passaged in the brains of specific pathogen-free baby mice and grown for vaccine production on suspensions of primary specific pathogen-free chicken embryo cells. The vaccine virus was concentrated through centrifugation followed by inactivation with formalin and purification using hydroxylapatite chromatography. Aluminum hydroxide was added as an adjuvant. More than 400,000 people were vaccinated in Austria, and seroconversion rates of more than 90% after two vaccinations, as measured by the HI test, were documented.[96] However, despite its immunogenicity, local and systemic adverse events were common. Consequently, in a collaboration with Immuno AG, another purification step using continuous-flow zonal density-gradient centrifugation was added.[97] This resulted in a 90-fold increase in vaccine purity and a marked reduction in vaccine-associated side effects.[96] In 1999, the preservative thimerosal was removed from the final formulation, and in 2000 a production virus seed was generated that was free of both potential contaminating mouse brain protein and human serum albumin (HSA). Unexpectedly, the removal of HSA from the final formulation led to an increase in the rate of high fever in infants and small children, and a number of cases of febrile seizures were observed in children up to the age of 24 months. Subsequent animal studies suggested that HSA has an inhibitory effect on the production of tumor necrosis factor-α.[98] The HSA was reintroduced into the vaccine formulation in 2001, and thereafter there was a dramatic reduction in the rate of fever (FSME-IMMUN).[99] Immuno AG was purchased by Baxter Healthcare in 1996, and subsequently, the FSME-IMMUN vaccine was acquired by Pfizer in 2015.

A second Western European TBE vaccine, similar to FSME-IMMUN, was licensed in Germany in 1991 (Encepur, Chiron Behring, Marburg, Germany) and was subsequently introduced in a number of other European countries.[100] Chiron's vaccines were purchased by Novartis in 2005, and Novartis

vaccines were acquired by GlaxoSmithKline in 2015. The vaccine is based on the K23 TBEV-Eu virus strain, isolated in southern Germany. This strain, which has a nucleic acid sequence very similar to that of the Neudörfl strain,[25] was grown on primary chick embryo cells, inactivated by formaldehyde, and purified by continuous-flow density-gradient centrifugation. The vaccine then was stabilized with processed bovine gelatin and adsorbed onto aluminum hydroxide.[101] Formulations were available for both adults and children.[102] However, the first pediatric version of Encepur resulted in cases of immediate allergic reactions in rare cases.[103] A detailed evaluation suggested that these adverse events were most likely IgE-mediated reactions to the vaccine's polygeline stabilizer, a total of 38 cases were registered in the postmarketing surveillance between 1994 and 1997, a rate of approximately 2×10^{-5} doses distributed.[104] As a consequence, the first pediatric TBE vaccine was voluntarily withdrawn from all markets in early 1998. A new TBE vaccine formulation for children and adults was developed that contained an increased amount of sucrose, making the use of an additional protein-derived stabilizer unnecessary, and was commercialized as of 1999.[103,105]

Two chick embryo cell–derived, formalin-inactivated TBE vaccines have been developed and marketed in Russia. The vaccine TBE-Moscow is manufactured by the Federal State Enterprise of Chumakov Institute of Poliomyelitis and Viral Encephalitides (IPVE), using the TBEV-Fe prototype strain, Sofjin.[106] The second Russian vaccine, EnceVir, manufactured by Microgen, Tomsk, is based on the TBEV-Fe subtype strain 205.[107]

A TBE vaccine derived from the TBEV-Fe strain Senzhang is manufactured and marketed domestically in China by the Changchun Institute of Biological Products (CIBP).[108] This vaccine is produced in primary hamster kidney cells and then formalin inactivated. It uses HSA as stabilizer and aluminium hydroxide as adjuvant. Table 59.2 provides summary information on current TBE vaccines.

Producers

TBE vaccines are produced commercially by five manufacturers: Pfizer (Vienna, Austria), GlaxoSmithKline Vaccines (Marburg, Germany), IPVE (Moscow, Russia), Microgen (Tomsk, Russia), and CIBP (Changchun, China). GlaxoSmithKline and Pfizer use essentially the same process to produce the vaccine, the major differences being the use of different strains and the addition of different stabilizers. They also both provide adult (Pfizer, FSME-IMMUN; GlaxoSmithKline, Encepur) and pediatric (Pfizer, FSME-IMMUN Junior; GlaxoSmithKline, Encepur-Children) formulations for children older than 1 year. FSME-IMMUN is marketed as TicoVac in some

countries. Table 59.2 provides an overview of the excipients of the Western European and Russian vaccines. HSA is used as a stabilizer by Pfizer, IPVE, CIBP, and Microgen, whereas GlaxoSmithKline uses an increased amount of sucrose as a stabilizer. IPVE's TBE-Moscow was approved for use in adults in 1982 and has been administered to more than 25 million people in Russia and neighboring countries.[106] Microgen's EnceVir was licensed in the Russian Federation in 2001. Russian manufacturers do not offer specific pediatric formulations, and neither vaccine is licensed for use in children younger than 3 years. TBE-Moscow has been approved for use in children age 3 years or older since 1999. EnceVir had been administered to children 3 to 16 years of age, but in 2010 this was temporarily stopped by the Russian Ministry of Healthcare because of increased rates of febrile reactions. The Chinese CIBP vaccine is approved for those older than 3 years.

Vaccine Stability and Storage

FSME-IMMUN may be stored at 2°C to 8°C for 24 months (for prefilled syringes without needle attached) or for 30 months (for prefilled syringes with needle attached). Encepur and TBE-Moscow have shelf lives of 24 months and EnceVir of 36 months at this temperature. No stability data are available for the Chinese vaccine.

Vaccine Immunogenicity

All vaccines have been registered on the basis of their quality, immunogenicity, and safety, but no controlled trials with clinical efficacy end points have been conducted with any of the current TBE vaccines. Immunogenicity studies consistently show strong antibody induction after primary vaccination. A Cochrane Collaboration review published in 2009 summarized 11 randomized or quasi-randomized clinical trials involving a total of 8184 participants, including both children and adults. All vaccines (FSME-IMMUN and Encepur) gave seroconversion rates of more than 87%.[109]

Data on the immunogenicity of Encepur from eight clinical trials and postmarketing studies of 7500 subjects showed that following primary immunization, all subjects seroconverted or showed a fourfold increase in anti-TBEV antibodies.[103] The seroconversion rate (ELISA) of FSME-IMMUN was 98.5% and 100% after primary immunization of 412 children ages 1 to 15 years (pediatric dose); 96% in 64 vaccinees 12 to 15 years old (pediatric dose); and 98.2% in 57 vaccinees ages 16 to 35 years (adult dose).[110]

However, immunogenicity studies are not always directly comparable as different assay systems have been used for the various trials. Published FSME-IMMUN immunogenicity studies frequently measure TBEV-neutralizing antibodies or total IgG neutralizing antibodies against the homologous TBEV Neudörfl strain according to Adner and colleagues[111] or Holzmann and colleagues[42] or a commercially available ELISA kit (Immunozym FSME [TBE]-IgG, Progen Biotechnik, Heidelberg, Germany). Reported studies with Encepur measure neutralizing antibodies (NT assay) and total IgG antibodies (Enzygnost TBE, Dade Behring, Marburg, Germany) against the homologous K23 strain. Immunogenicity studies of the Russian vaccines have primarily used HI tests. While neutralizing antibodies against the E protein of the virion are believed to confer protection, no formal correlate of protection has been established for TBE and no internal reference reagents are available.[61]

All vaccines, except TBE-Moscow, have been tested using both conventional and accelerated schedules (Table 59.3). In the Cochrane review[109] four randomized controlled trials (RCTs) of the currently licensed western vaccines included 5063 children and adults who were followed up for 6 to 12 months for both serologic and safety data. All vaccines induced

seroconversion rates in the range of 92% to 100%, as measured by ELISA or NT, with seroconversion being defined by a NT of 1 : 10 or higher or a corresponding ELISA bridged to NT.[112–114] In a subsequent RCT, more than 95% of the enrolled 334 children achieved NTs of 1 : 10 or higher following two doses of either Encepur or FSME-Junior vaccine.[115] Similar immunogenicity was achieved with either conventional or rapid immunization schedules.[114]

The vaccines TBE-Moscow and EnceVir have been evaluated in two RCTs. In 2001–02, two studies of the Russian vaccines involving 200 adults each given two doses of vaccines showed that antibody titers of 1 : 80 or higher were detected in 84% and 93% of subjects, and with EnceVir, in 82% and 89% of the vaccinees following two doses, 2 or 5 months apart, respectively.[116,117] Similarly, an evaluation involving 325 individuals stratified into the age groups of 3 to 6 years, 7 to 14 years, and 15 to 18 years, after TBE-Moscow vaccine showed a fourfold or greater increase of HI-antibody titers in 96%, 93%, and 89% of subjects, respectively, compared to 84%, 97%, and 92% with EnceVir vaccine.[115] A newer randomized study compared the immunogenicity in adults of TBE-Moscow, EnceVir, FSME-IMMUN (new), and Encepur adults to TBEV-Fe.[118] Immunogenicity was measured at 2 to 5 months and again at 2 years following the administration of three doses of the respective vaccines. All vaccines induced neutralizing antibody against the TBEV-Fe subtype strain P-73. With TBE-Moscow, antibody was detected in 100% and 94% of the vaccinees after 2 to 5 months and 2 years, respectively. With EnceVir the corresponding figures were 88% and 84%, with FSME-IMMUN the figures were 88.2% and 78.1%, and with Encepur the figures were 100% and 100%.

No immunogenicity data have been reported for the Chinese vaccine.

Because different virus subtypes exist and sometimes coexist in the same TBE-endemic region, TBE vaccines need to provide cross-protective antibody responses. Owing to the high degree of antigenic similarity between TBEV subtypes, all currently marketed TBE vaccines are expected to provide good cross-protection against all TBE subtype viruses. Various studies with TBEV-Eu vaccines demonstrate cross-neutralization against TBEV-Eu, TBEV-Fe, and TBEV-Sib subtypes.[116,117,119] A systematic review of the immunogenicity of TBEV-Eu vaccines against TBEV-Fe and TBEV-Sib subtype viruses has been published[120] supporting robust cross-neutralization, except with one strain (TBEV-Fe P-69) showing a significantly lower level of neutralization.

It is well-documented that the capacity to mount immune responses against vaccines decreases with age, commonly labeled as immunosenescence, and this has been shown for TBE vaccines as well. Decreased postprimary and anamnestic antibody responses to TBE vaccine have been documented in individuals older than 50 years.[121] In contrast, there is no indication that antibody avidity decreases with age.[122] The need for booster doses will be addressed below.

Administration and Vaccination Schedule

Dosage and Route

Table 59.3 provides an overview of dosing schedules for Western European and Russian vaccines according to the respective product leaflets and WHO recommendations.[51] The standard immunization schedule for both Western European vaccines is similar, consisting of three immunizations administered intramuscularly, starting on day 0, the second dose given 1 to 3 months later, and a third dose is administered 5 to 12 months (FSME-IMMUN) or 9 to 12 months (Encepur) after the second one. The first booster is often recommended to be administered within 3 years, but there is overall little information available on the duration of protection post primary series. Consequently, national recommendations for booster vaccinations differ. In most countries, subsequent booster doses are recommended every 5 years for persons younger than 60 years and every 3 years for persons 60 years of age or older.[20,51,123] In Germany, booster doses every 3 years are recommended for persons 50 years of age or older. Booster doses are also recommended for Encepur recipients 50 years of age or older in some other countries by the respective national authorities. However, the Summary of Product Characteristics for Encepur recommends boosters every 3 years beginning at age 60 years. In Austria, TBE vaccination is routinely recommended for all individuals at least 1 year of age, and, in highly endemic regions such as parts of Carinthia, Styria or Upper Austria, children are vaccinated as early as 6 months of age as an off-label use.[51,124] Switzerland recommends a booster 10 years after primary immunization for all age groups.[125]

Accelerated immunization schedules are also available for persons requiring more rapid protection (e.g., when traveling to TBE-endemic areas or when the tick season has already begun). The rapid immunization schedule for Encepur consists of three immunizations administered on days 0, 7, and 21,[105,114,126] with a booster after 12 to 18 months. The rapid

immunization schedule for FSME-IMMUN allows a shortened interval for the administration of the second dose, that is, 2 weeks after the first dose, and a third dose to complete the primary vaccination program after 5 to 12 months.[127] Encepur is also licensed for a schedule with doses administered on days 0 and 14, with a third dose after 9 to 12 months.

The standard primary immunization schedule for both Russian vaccines is two doses administered 1 to 7 months apart with a booster 12 months after the second dose and every 3 years thereafter. A rapid immunization schedule for the emergency use of EnceVir prescribes the administration of the second dose 5 to 7 days after the first dose.[18]

For the Chinese TBE vaccine the vaccination schedule consists of two doses given 14 days apart and a booster that should be given right before the endemic season; no data, however, are available on boosting intervals.

Irregular Vaccination

The effectiveness of TBE vaccines are unaffected even by prolonged intervals between doses in the primary immunization schedule.[61,128] In a cohort study with more than 1100 persons who were vaccinated but deviated from the recommended schedule, the participants were administered a single booster up to 20 years after one, two, or three primary vaccinations.[129] The results of this study demonstrated that, independent of age of the vaccine recipient and of the interval to the last vaccination, an effective booster response was seen if two or three primary vaccinations were administered previously, even if the time intervals between doses were very prolonged.[129,130] Hence, there is no need to restart a primary vaccination series after an incomplete primary schedule or markedly delayed booster vaccination.

Duration of Immunity and Protection

A large number of studies have investigated the kinetics and seropersistence of antibodies after primary and booster doses of TBE vaccines.[131–136] Based on these data, immunization schedules have been proposed; however, there is no common practice on boosting intervals.[18] Table 59.3 lists the current dose schedules for each vaccine.

Several studies evaluated booster recommendations for FSME-IMMUN and Encepur and assessed the interchangeability of the two TBEV-Eu vaccines. The seropersistence of TBEV antibodies in adults 18 to 67 years of age was evaluated 2 and 3 years after primary vaccination (first two doses, FSME-IMMUN or Encepur; third dose, FSME-IMMUN) in a multicenter prospective study ($n = 347$).[137] Seropositivity rates 2 and 3 years after the primary vaccination were 96.8% and 95.4%, respectively, as determined by neutralizing antibody titers. Following the booster vaccination, seropositivity rates increased to 100%. Another study analyzed antibody titers before and after booster vaccination in subjects who had received their last FSME-IMMUN vaccination 3 to 7 years previously.[121] Before booster vaccination, antibody titers were significantly higher in subjects younger than 30 years compared with subjects 50 years of age or older. In addition, the response to a booster vaccination was significantly higher in the group younger than 30 years compared with subjects 50 years of age or older. However, there was no difference in booster responses in any of the age groups 50 years of age or older. NT were measured in 430 adults 2 to 10 years after the last vaccination to determine the seroprotection rate (SPR; defined as NT ≥1 : 10) over a longer period and to indicate age-specific differences in antibody persistence.[133,134,138] Subjects from this series of studies were given a booster dose of Encepur after having received a regular primary course of FSME-IMMUN at least 3 years before,[130,139] and SPR was evaluated from 2 to 10 years after the booster. Seroprotection was detected in 95.9%, 96.7%, and 93.8% of subjects after 2, 3, and 4 years, respectively. Geometric mean titers after 3 years were significantly lower in subjects 50 years of age or older, and were also significantly lower after 4 years in subjects 60 years of age or older. After 4 years, the proportion of subjects seroprotected dropped to 93.0% and 91.7% for people 50 to 60 years of age and 60 years of age, respectively. After 5 and 6 years, seroprotection was detected in 96% and 94%, respectively, of subjects younger than 60 years. For the group 60 years of age or older, the SPR dropped to 89% and 86% at 5 and 6 years, respectively, after the booster. Finally, 8 and 10 years after booster SPR was 86.8% and 77.3%, respectively, but age dependency became even more apparent: after 10 years the SPR was 83.9% in subjects younger than 50 years, but dropped to 66% in subjects older than 50 years.[133] These results indicate that seroprotection lasts considerably longer than the recommended boosting interval of 5 years in healthy volunteers, but there are variable responses by age. Data from a 5-year follow up of vaccinees 15 years of age or older after different (conventional, modified conventional, or accelerated) primary vaccination schedules also demonstrate long-term antibody persistence for 5 years.[140]

Most seroprotection data include subjects who were primed with TBE vaccines below the age of 50 years.[133,140] Data are limited for those older than age 50 years who are vaccinated for the first time, and only one study investigated the comparative primary immune response in older and younger subjects.[141] This study showed lower titers and earlier loss of neutralizing antibodies in those primed after the age of 50 years. However, the ability to boost was similar in both groups, indicating an adequate B-memory response, even in the older group of subjects.

During clinical development and the postlicensure period a number of studies were performed to evaluate differences between the licensed vaccines with respect to immunogenicity and seropersistence. However, head-to-head studies with Encepur and FSME-IMMUN are hampered by using different antibody assays and by the fact that the studies were sponsored by the manufacturers.[109,115,127,135,140,142,143] However, published data do not suggest relevant differences between the two TBEV-Eu vaccines, and they are regarded as equivalent.[51] For the two Russian vaccines data on immunogenicity and efficacy are limited and do not allow an assessment of equivalence.[118,144]

Cellular Immune Responses

Few data are available on the generation or role of T-cell responses in immunized persons, but it has been reported that immunization with inactivated TBE vaccine induces primarily a $CD4^+$ T-cell response with a very low induction of $CD8^+$ cells.[141,145] Recent immunological investigations of low-responders after TBE vaccination show that low cellular, humoral, and cytokine responses levels (interleukin-2 and interferon-γ) are correlated with each other.[146]

Correlates of Protection

Human antibody responses after vaccination differ from those seen after natural infection,[147] but in both situations, neutralizing antibodies against protein E are induced.[147]

According to the WHO, these neutralizing antibodies can be used as a surrogate marker for immunity.[18] As mentioned before, although a titer of 1 : 10 or higher is generally used to define seroprotection,[42] during the vaccine licensure procedure titers of 1 : 2 or greater were accepted as a correlate of

immunity.[123] A formal correlate of protection has not been established for TBE vaccines, and international reference reagents are lacking. Using ELISA titers as marker of protection, introduces a number of pitfalls, including cross-reactivity with other flaviviruses (antibodies deriving from infection or vaccination) and lack of a quantitative correlate of protection ("cutoff"). Thus, ELISA measurements are useful in screening but not in definitive assessments of immunity. HI tests do not offer advantages and are rarely used today.

Efficacy and Effectiveness of Vaccine

Although no controlled clinical efficacy trials have been performed, the public health impact of vaccination programs is well documented. In Austria, where TBE vaccines have been in use for more than 30 years, the protection rate can be calculated from both clinical and epidemiologic data (Fig. 59.4). The protection rate of the vaccines for the years 2000–06, when approximately 90% to 95% of TBE vaccines administered in Austria were FSME-IMMUN, was estimated to be approximately 99% in regularly vaccinated persons, with no statistically significant difference between age groups.[61] During this period, approximately 90% to 95% of TBE vaccines administered in Austria were FSME-IMMUN. A second analysis of effectiveness during the years 2010–11, when Encepur comprised approximately one-third of the vaccine used in Austria, showed very similar data: for regularly vaccinated persons effectiveness was between 98.7% (confidence interval [CI] 98.2–99.0; best case scenario for those with known vaccination status) and 96.3% (CI 95.5–97.0; worst case scenario for those with unknown vaccination status) and for subjects vaccinated with nonstandard schedules 92.5% (CI 90.3–94.3; best case scenario) and 91.3% (CI 88.9–93.3; worst case scenario), respectively, indicating a similar effectiveness over the years and for both vaccines.[128] Sensitivity analysis of best and worst case scenarios reflect the assumptions of vaccination status of those TBE with cases with unknown vaccination history.

Vaccine effectiveness after the second dose was high with no vaccine breakthroughs recorded in this group within the first year. However, a significantly lower effectiveness was calculated (≈96%) in persons not receiving the recommended schedule.[61,128] The risk of acquiring TBE was calculated to be increased three- to eightfold in persons receiving a nonstandard schedule, but potential confounders cannot be excluded. Nevertheless, the findings highlight the importance of adhering to the recommended vaccination schedule, in particular in relation to the primary series. Studies on breakthrough infections despite complete TBE vaccination[148,149] do not provide conclusive data if vaccine failures tend to increase with time after the last booster vaccination. Data also do not exclude the possibility that reported breakthroughs actually represent primary vaccination failures.[146]

It is estimated that approximately 4000 TBE cases and more than 20 deaths were prevented by vaccination in Austria between 2000 and 2011.[61,128] Since vaccine uptake is highest in endemic regions, exposure to TBEV is likely to be higher in the vaccinated population; therefore, effectiveness may, in fact, be even higher than calculated based on national coverage estimates. Impressively, whereas the incidence of TBE in Austria has declined markedly since the advent of generalized vaccination, that of neighboring Czech Republic, where only a small percentage of the population is immunized (16% in 2009) has actually increased.[128] A similar situation exists in Slovenia, with an incidence of 9.90 per 100,000 in 2007 and vaccination rates of only 12% in 2009.[83] The most affected region of Slovenia, which borders on Austria, reported a TBE incidence of 47 per 100,000 in 2006,[150] whereas the mean annual incidence rate in Austria from 2003 to 2007 was only 0.82 per 100,000, again suggesting that vaccination has an important impact on disease burden.[61]

A mass immunization program initiated in 1996 in the Sverdlovsk Region in Russia demonstrated the impact of the Russian TBE vaccines (TBE-Moscow, 80%; EnceVir, 6%; FSME-IMMUN, 12%; and Encepur, 2%). Using available data, this suggested that the incidence of TBE decreased from 42.1 per 100,000 in 1996, to 9.7 per 100,000 in 2000 and to 5.1 per 100,000 in 2006. Vaccine effectiveness was estimated to range from 62% in 2000 to 89% in 2006.[144]

Although vaccination is highly effective, rare cases of TBE have been reported after partial or complete primary

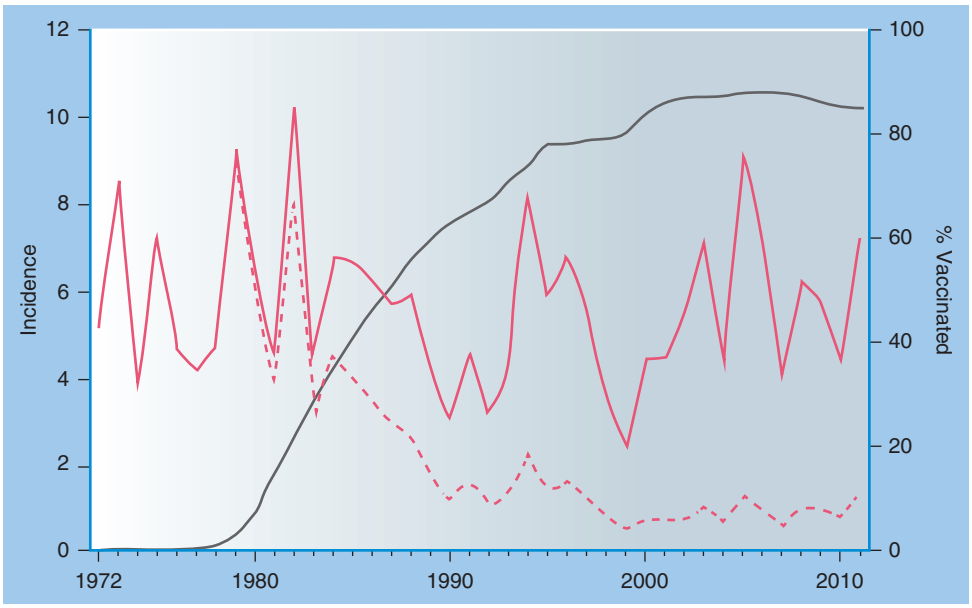

Figure 59.4. Tickborne encephalitis (TBE) incidence rate (cases/100,000 population/year) in Austria among vaccinated *(dashed red line)* and nonvaccinated populations *(solid red line)*, juxtaposed to the population vaccination coverage *(gray line)*. *(From Heinz FX, Stiasny K, Holzmann H, et al. Vaccination and tick-borne encephalitis, central Europe. Emerg Infect Dis. 2013;19[1]:69–76.)*

TBE vaccination, but not following booster immunization.[148,149,151,152] The majority of these breakthroughs occurred in persons older than age 50 years. Recent immunological investigations identified insufficient T-cell response as a possible mechanism of vaccine failure in a small proportion of primary vaccinees.[146]

Cross-Protection

There is good evidence that TBE vaccines protect not only against the homologous subtype, but also heterologous subtypes.[153] In vitro and in vivo studies demonstrate that vaccine-induced neutralizing antibodies are broadly cross-reactive and cross-protective.[118,154,155] There is no evidence that antibodies evoked by TBE vaccines provide cross-protection against other flaviviruses, although TBE prevaccinated subjects developed a significantly higher antibody response against Japanese encephalitis after vaccination with an inactivated Japanese encephalitis vaccine based on the attenuated SA-14-14-2 strain.[156]

Safety and Tolerability

Over the past decades, TBE vaccine formulations have been refined, significantly reducing vaccine reactogenicity. The currently available vaccines are considered to be safe with no serious adverse events reported.[18,109] Occasionally, however, fever and allergic reactions can occur. Following the standards of good clinical practice and extensive pharmacovigilance the excellent safety records of the two TBEV-Eu vaccines, FSME-IMMUN and Encepur, have been well documented. Little published data are available on the safety of the two Russian vaccines and almost no such information is available on the Chinese vaccine.[51] As with all intramuscularly administered vaccines, mild local reactions, such as redness, swelling, and local pain, may occur following TBE vaccination. Systemic adverse events after TBE vaccines include headache, fatigue, malaise, muscle pain, joint pain, and fever, and are more frequent after the first vaccination.

Safety data on FSME-IMMUN, after vaccination of more than 13,500 subjects of all age groups (>1 year of age) in both Phase II and Phase III clinical studies and postmarketing studies, show no safety concerns.[110,112,113,127,137,143] Typically, mild local reactions include redness, itching, and local injection site pain. Table 59.4 summarizes the relevant data from the Summary of Product Characteristics. There is evidence that HSA, when used as a stabilizer in the vaccine, is influencing the frequency of fever reactions. Experimental data,[98] as well as clinical reports of a HSA-depleted vaccine formulation,[124] suggest that HSA is associated with decreased fever reactions. HSA is hypothesized to suppress tumor necrosis factor-α production after vaccination.[98] However, it remains unclear why Encepur (see "Encepur" below), which does not contain HSA, is not associated with febrile reactions.

Postmarketing surveillance of FSME-IMMUN, including almost 42 million doses administered, indicates a rate of severe adverse events of 1.6 per 10,000 doses administered (spontaneous reports, not checked for causality).[123] An additional postmarketing study of general practitioners conducted by the Institute for Vaccine Safety of the Austrian Green Cross evaluated more than 25,000 vaccinations (85% vaccinated with FSME-IMMUN). A total of 107 adverse events of any severity were reported, including 69 (64.5%) in toddlers up to 2 years of age. In this study, 63 cases of fever were reported, 75.8% of which were in children after the first vaccination. The fever exceeded 40°C in only three cases.[157]

Encepur

Data from Encepur reveal a very similar picture for product safety based on RCTs, postmarketing studies, and regulatory documents in subjects ages 1 to 76 years (see Table 59.4).[105,114,158,159] Transient pain at the injection site, general malaise, myalgia, and headache were most commonly reported (>10% of vaccinees); redness and/or swelling at the injection site, flu-like symptoms, nausea, and arthralgia were observed in 1% to 10% of vaccinees. Transient fever, mostly low grade, was comparable to the rates after FSME-IMMUN administration.

Based on reports after the administration of more than 30 million doses of the licensed formulation of Encepur between 2002 and 2009, including pediatric and adult doses, the rate of serious adverse events was 1.9 per 10,0000 doses, a comparable safety profile to that of FSME-IMMUN.[51]

TABLE 59.4 Safety and Reactogenicity of Encepur and FSME-IMMUN

Probability	≥1/10	≥1/100 <1/10	≥1/1000 <1/100	≥1/10.000 <1/1000	Not Known
FSME-IMMUN First: *n* = 3512 Second: *n* = 3477 Third: *n* = 3277	Local reaction at injection site: redness, swelling, induration	Headache, nausea, myalgia, arthralgia, malaise, fatigue	Lymphadenopathy, vertigo, vomiting, fever (only exceptionally >39°C)	Acute allergic reactions; somnolence, diarrhea, abdominal pain	Aggravation of autoimmune disease; visual impairment, photophobia, meningismus, epilepsy, encephalitis, neuritis; tachycardia; urticaria, pruritus, exanthema; flu-like symptoms, weakness, edema
Encepur (pooled data from clinical studies and postmarketing surveillance)	Transient pain at injection site; general malaise, myalgia, headache	Redness, swelling at injection site; flu-like symptoms; nausea, arthralgia	Arthralgia and myalgia (neck)	Granuloma at injection site; lymphadenopathy, neuritis-like symptoms; diarrhea; systemic allergic reactions like urticaria, dyspnea, bronchospasm, hypotension	Extremely rare: Guillain-Barré syndrome

Data from summary of product characteristics.

Thus, both clinical studies and pharmacovigilance from the vaccine manufacturers indicate that the TBEV-Eu vaccines have an acceptable safety and tolerability profile. According to safety grading of the WHO, there is no causal association of these vaccines with serious adverse reactions.[160]

For the vaccines EnceVir and TBE-Moscow, there are no published large-scale, randomized, controlled trials from which to assess safety. Small-scale studies report low rates of adverse events and reactogenicity in children and adults.[99,106,161] Comparing the safety of immunization with TBE-Moscow vaccine and FSME-IMMUN (old formulation used before 2000) in children between 7 and 17 years of age, fever was reported more frequently with TBE-Moscow vaccine, but the differences were not significant.[107] Available data from post-marketing surveillance of the two Russian vaccines did not identify any serious adverse events.[162,163] According to the Russian National Regulatory Authority, TBE-Moscow vaccine and EnceVir are both safe and well tolerated, and their manufacturing is in accordance with WHO requirements.[18,123] However, no documentation on the quality assessment and control of the two Russian vaccines has been found. More recently, some lots of EnceVir were associated with high fever and acute allergic reactions in up to 19% of the vaccinees, particularly in children. These lots were withdrawn by the manufacturer, and the vaccine is currently not indicated for immunization of individuals younger than 17 years.[51]

No safety data have been found for the Chinese vaccine.

Contraindications and Precautions

Persons with acute inflammatory disorders that require treatment should not be vaccinated until at least 2 weeks after full recovery. Allergies to components of the vaccines constitute contraindications (listed in Table 59.2). Nonsevere allergy to egg protein does not usually constitute a contraindication to TBE vaccination. However, persons with such allergies should be vaccinated only under appropriate supervision. It has been speculated that previous exposure to other flaviviruses could affect TBE vaccination. Such problems are difficult to study because of cross-reactive flavivirus antibodies. Interestingly, although vaccination with TBE vaccine also enhances the immune response to an inactivated Japanese encephalitis vaccine,[156] there is no evidence of cross-protection between Japanese encephalitis and TBE. Pregnancy does not constitute a contraindication for the two TBEV-Eu vaccines.

Public Health Considerations

Even though no formal vaccine efficacy or effectiveness studies have been conducted for TBE vaccines, there is ample evidence of the public health impact of immunization, as discussed previously. The most striking data have been obtained from Austria, where TBE vaccination campaigns were initiated in the 1980s and reliable epidemiological data are available since 1972. Reported disease incidence dropped from 5.7 per 100,000 cases (range, 3.9–9.0) to 0.9 per 100,000 cases (range, 0.6–1.3) in parallel with increase in vaccination coverage with 85% to 88% of the population having received at least one dose of vaccine (see Fig. 59.4).[128] The findings are corroborated by the higher disease incidence in a neighboring country that did not introduce vaccine at population level.

Very few studies have been published on the economic burden of TBE disease. However, it is obvious that in regions with high disease prevalence, the disease has high costs to both individuals and society, particularly in those with long-term neurological sequelae. One study suggested that, as a result of widespread vaccination from 1991 to 2000, savings related to patient care, lost productivity, and early retirement amounted to 828 million Austrian Schilling or US$80 million.[164] These estimates would depend on the vaccine price, disease incidence, vaccine uptake, and booster vaccine policies.[18]

With the exception of Austria, no country currently has a universal vaccination recommendation (Table 59.5). The majority of endemic countries have issued recommendations targeting populations at risk, including those in endemic regions and with occupational exposure. As pediatric TBE cases tend to be less severe, some countries limit their recommendations to older age groups. Reimbursement regulations vary, but in many countries TBE vaccination is an out-of-pocket expenditure. In addition, many countries have issued vaccination recommendations for travelers to endemic regions.

In 2011, the WHO published a position paper on TBE vaccination.[18] The recommendation acknowledged the complexity of risk assessment, given highly variable risk patterns. The WHO recommends vaccination of all age groups in areas of high prevaccination disease incidence, defined as an incidence of 5 or more cases per 100,000 population per year. In lower-incidence areas, TBE vaccination should be confined to populations with a particular risk of exposure. The WHO also notes the significant knowledge gaps that exist in relation

TABLE 59.5 Vaccination Recommendations

Country	Recommendation Status
Austria	Universal recommendation older than age 1 yr
Bulgaria	No policy
Croatia	For highly endemic areas and occupational exposure
Czech Republic	For highly endemic areas and occupational exposure
Estonia	Recommended, but reimbursed only if occupational exposure
Germany	Recommended for endemic districts
Finland	Recommended for endemic region
Hungary	Recommended and reimbursed
Latvia	Recommended, mostly not reimbursed
Lithuania	Recommended, but not reimbursed
Norway	Recommended for high-risk populations, not reimbursed
Poland	Recommended for high-risk populations, not reimbursed
Romania	No policy
Russia	Recommended at regional level
Slovenia	For highly endemic areas and occupational exposure
Slovakia	For highly endemic areas and occupational exposure
Sweden	Recommended for highly (>1 year of age) and moderately (>3 years of age) endemic districts
Switzerland	Recommended for all endemic districts, >6 years of age
Turkey	No policy

From Zavadska D, Anca I, André F, et al., Recommendations for tick-borne encephalitis vaccination from the Central European Vaccination Awareness Group (CEVAG). Hum Vaccin Immunother. *2013;9(2):362–374; and European Centre for Disease Prevention and Control (ECDC).* Epidemiological Situation of Tick-Borne Encephalitis in the European Union and European Free Trade Association Countries. *Stockholm, Sweden: ECDC, 2012.*

to booster requirements,[165] and encourages research to better define booster needs and cost-effectiveness of immunization programs. The WHO also recommends the vaccine for travelers planning on outdoor activities in endemic areas during the period April to November.[74]

Other Disease-Control Strategies

Adequate clothing should be used to make skin access more difficult for ticks. Repellents containing 20% or more of *N*,*N*-diethyl-3-methylbenzamide (DEET) provide protection for several hours, and clothes can be treated with permethrin.[167] Skin should be checked daily for the presence of ticks, and ticks should be removed using fine-tipped tweezers. It is important to note that ticks may transmit other diseases, particularly Lyme disease (also termed borreliosis). Swiss authorities estimate that some 9000 cases of borreliosis and 105 cases of TBE occurred in Switzerland in the year 2014.[168] No vaccines are available against these bacterial infections, but they can be treated with antibiotics, although long-term sequelae have been described.

Related and Future Vaccines

In addition to the TBE vaccines described above, there is also a vaccine against KFDV that is manufactured and licensed in India. Originally, this was a formalin-inactivated mouse brain vaccine, but this was replaced in approximately 1990 with a formalin-inactivated chick embryo fibroblast-derived vaccine given as two doses, 28 days apart, with an initial booster at 6 to 9 months and subsequent boosters every 5 years.[169] The effectiveness of the two-dose vaccine was estimated as 93.5%; however, the duration of protective immunity is unclear.

Although there are licensed vaccines against TBE and KFDV, other members of the mammalian TBE serogroup are pathogenic and the question of cross-protection of vaccines is important. To date there have been no clinical trials to evaluate cross-protection against Omsk hemorrhagic fever, Kyasanur Forest disease, and anaplastic lymphoma kinase viruses. However, there have been some mouse studies investigating cross-protection. Neutralization tests performed on sera from OHFV-and TBEV-infected mice showed that neutralizing antibodies are cross-protective. The geometric mean titers of antibodies against TBEV and OHFV from TBEV-Fe strain Sofjin-infected mice were similar. The FSME-IMMUN TBE vaccine provided 100% protection against OHFV infection. Furthermore, 86% of FSME-IMMUN or Encepur TBE vaccinees seroconverted against OHFV following a three-dose vaccination regimen, and the geometric mean titers of neutralizing antibodies against OHFV were comparable to those against TBEV.[170]

All current TBE vaccines consist of purified, inactivated, whole-virus particles. A number of candidate TBE vaccines using recombinant or live attenuated technology are at various stages of development. Candidate chimeric live attenuated TBEV vaccines have been developed by replacing the prM and E genes of dengue type 4 (DENV-4) virus with the corresponding genes of TBEV-Fe strain Sofjin.[171] Another chimeric candidate TBEV vaccine was based on the antigenically distinct LGTV (LGTV prM and E genes in a DENV-4 backbone). A single dose of either of these chimeric vaccines was efficacious in protecting monkeys against wild-type LGTV challenge.[172] The chimeric LGT/DEN-4 vaccine candidate was subsequently shown to be safe in a Phase I clinical trial.[173] However, low levels of viremia were detected in one subject, and antibody responses to TBEV were poor. In a later report, this vaccine candidate was shown to replicate to moderate titers in the CNS of monkeys, causing pathological lesions in two and illness in one of four animals.[174] Further studies on a TBEV/DEN-4 vaccine candidate reported the introduction of defined mutations in several regions of the viral genome (E, NS5, and 3′NCR) that have led to improved attenuation in mice and arthropods, which represent the natural vector for the two wild-type viruses.[175,176] It was also shown that neurovirulence of the TBEV/DEN-4 chimera could be reduced by insertion into the viral genome of target sequences for cellular microRNAs expressed in the CNS.[177]

A number of promising experimental recombinant subunit and nucleic acid vaccines were reported in the 1990s and in the first half of the last decade,[30,145,178–181] but there have been no published follow-up data or registered clinical trials for the majority of these proposed vaccine candidates. Finally, a novel TBE vaccine candidate, RepliVAX-TBE, is currently being developed,[182] using a replication-defective flavivirus platform (or single-cycle replicating vaccine), RepliVAX. Attenuation is achieved by a deletion in the capsid gene that prevents replication; thus, the vaccine is generated in helper cells that supply this protein in *trans*.[183] RepliVAX-TBE based on a West Nile virus backbone (RV-WN/TBE; the prM and E genes were of TBEV-Eu strain Hypr) multiplied efficiently, was highly immunogenic and efficacious in a mouse model, and highly immunogenic in Rhesus macaques after a single dose, inducing a significantly higher humoral immune response when compared with three doses of the licensed FSME inactivated TBE vaccine. This study also showed that candidate live chimeric yellow fever vaccine strain 17D/TBE, dengue 2/TBE, and LGTV strain E5/TBE vaccines were not sufficiently attenuated to be vaccine candidates.

Acknowledgments

We kindly acknowledge the technical contributions from Dr. Maria Paulke-Korinek, Institute of Specific Prophylaxis and Tropical Medicine; Center for Pathophysiology, Immunology and Infectiology; Medical University of Vienna, and the sharing of data from Prof. Jochen Süss, Institute of Bacterial Infections and Zoonoses Friedrich Löffler Institute, Jena. We also thank Prof. Bjarne Bjorvatn, Center for International Health, University of Bergen, Norway, and Dr. Kirsten Vannice, Initiative for Vaccine Research, WHO, for critically reviewing the manuscript.

60 Tuberculosis Vaccines

Willem A. Hanekom, Thomas R. Hawn, and Ann M. Ginsberg

Bacille Calmette-Guérin (BCG) is currently the only licensed vaccine available against tuberculosis (TB). The vaccine has been given to over 4 billion people; yet, TB still poses a major public health threat globally.[1] One-third of the world's population is thought to be infected with *Mycobacterium tuberculosis*, while 10.4 million new cases of TB disease, causing 1.4 million deaths, occurred in 2015.[1] Drug-resistant forms of disease, difficult and expensive to treat, are emerging and are associated with high morbidity and mortality.[1] Intervention in the TB pandemic requires optimal delivery of BCG, antimicrobials, and diagnostics. In settings where these current tools could be delivered optimally, the decline in TB incidence has been approximately 5% per year, compared to the global average decline of 1.5% per year.[2,3] Even at decline of 5% per year, the World Health Organization (WHO) Stop TB Partnership goal of achieving a disease incidence of 20 cases per 100,000 per year by 2030 is not achievable.[4] New tools are needed; among these, a vaccine that is effective in preventing adult forms of pulmonary TB is likely to have the greatest impact.[5,6] The ability of the current TB vaccine, BCG, to prevent pulmonary disease is variable, as the vaccine mainly protects infants and young children against disseminated forms of TB (see below).

TUBERCULOSIS—A BRIEF OVERVIEW

History and Epidemiology

TB has probably been the leading cause of death in Europe and the United States in recorded history.[7] The earliest known cases of TB were discovered in Egyptian mummies dating from 4000 to 2000 years BC where evidence of spinal disease was uncovered.[8] Recent studies analyzing global distribution and variability among *M. tuberculosis* strains suggest that the pathogen migrated out of Africa with humans during the Neolithic period and may have coexisted with humans for up to 70,000 years.[9,10]

In 1882, Koch identified the tubercle bacillus as the cause of TB.[11] The discovery that TB is an infectious disease led to four successive disease control approaches.[7] First, a sanatorium movement was established in Europe in 1854 and in the United States in 1882, and remained in place until after the advent of antimicrobial therapy against TB. This intervention included exposure to fresh air and sunlight in a community setting. Other intervention during this period included ordinances to improve sanitation and housing. The second development was pasteurization of cow's milk, which virtually eliminated human disease caused by *Mycobacterium bovis*, the most common cause of TB in animals. Third, the BCG vaccine was developed in the early 20th century in France (see below). Finally, antimicrobials against TB were developed, including streptomycin, first used in the 1940s, followed by isoniazid and rifampin, which were introduced in the 1950s and 1970s, respectively. These anti-TB drugs would be used both to treat established disease and to prevent progression of latent *M. tuberculosis* infection to active disease. The cornerstone of TB control for the past 5 decades in the United States has been a combination of targeted screening, chemotherapy, and contact investigation of persons potentially exposed to patients with TB disease.

It is worth noting that TB disease incidence declined in Europe and the United States long before the availability of chemotherapy and without use of BCG.[12] The decrease in incidence was associated with industrialization, urbanization, and an accompanying rise in socioeconomic status.

Today, the global burden of TB disease remains high, with an estimated 10.4 million incident cases and 1.4 million deaths in 2015 (Fig. 60.1).[1] Despite these numbers, substantial progress in TB control has been made in all regions of the world over the past 20 years. The United Nations Millennium Development Goal target of halting and reversing the rise in TB incidence globally by 2015 was met: between 2000 and 2013, global incidence was reduced by 1.5% per year.[1,13] The STOP TB Partnership's target of halving mortality attributable to TB from 1990 to 2015 was reached in three of six WHO regions; globally, mortality fell by 45% in the period up to 2013.[1]

Adolescents and adults between the ages of 15 and 54 years account for the vast majority of cases of TB disease,[1] and those with pulmonary disease are responsible for the transmission of TB. Modeling studies show that interruption of transmission would be the most effective intervention in the TB epidemic.[5] In contrast to adolescents and adults, children with TB do not commonly spread the pathogen, a consequence of the paucibacillary nature of their disease. Therefore, many TB vaccine developers are now focusing efforts on developing vaccines for delivery to adolescents and adults as a priority.[6] In contrast, the current TB vaccine, BCG, targets infants and works best in infant and childhood populations (see below). Ultimately, novel TB vaccine strategies should address all populations at risk, including, for example, the elderly, whose contribution to the Western Pacific Rim region burden of TB disease is increasing.[1]

The HIV epidemic has compounded challenges of meeting TB control targets: globally, approximately 13% of TB cases occur in HIV-infected persons.[1] HIV infection leads to increased susceptibility to TB disease, and complicates treatment, because of drug interactions between TB and HIV medications, and immune reconstitution inflammatory syndrome.[14] Novel vaccines would also need ultimately to be effective in HIV-infected persons if the burden of disease is to be prevented.

The rise of multidrug resistant (MDR) TB poses a global health threat. The WHO estimated that there were 480,000 new cases of MDR TB globally in 2013.[15] Extensively drug-resistant and totally drug-resistant strains of *M. tuberculosis* have now been isolated from patients, compounding efforts to control TB even more.[16] Drug-resistant disease needs to be treated for prolonged periods, and the total cost of care is manyfold higher than for drug-sensitive TB. Even in countries where drug-resistance rates are low, managing these forms of the disease may absorb a major portion of TB control budgets.[17] The situation clearly calls for new tools, of which novel, better vaccines would be particularly attractive. *M. tuberculosis* drug-resistance patterns are not likely to be a factor in vaccine efficacy.

BACTERIOLOGY

All members of the genus *Mycobacterium* share the property of acid-fastness, which is related to mycolic acid components of

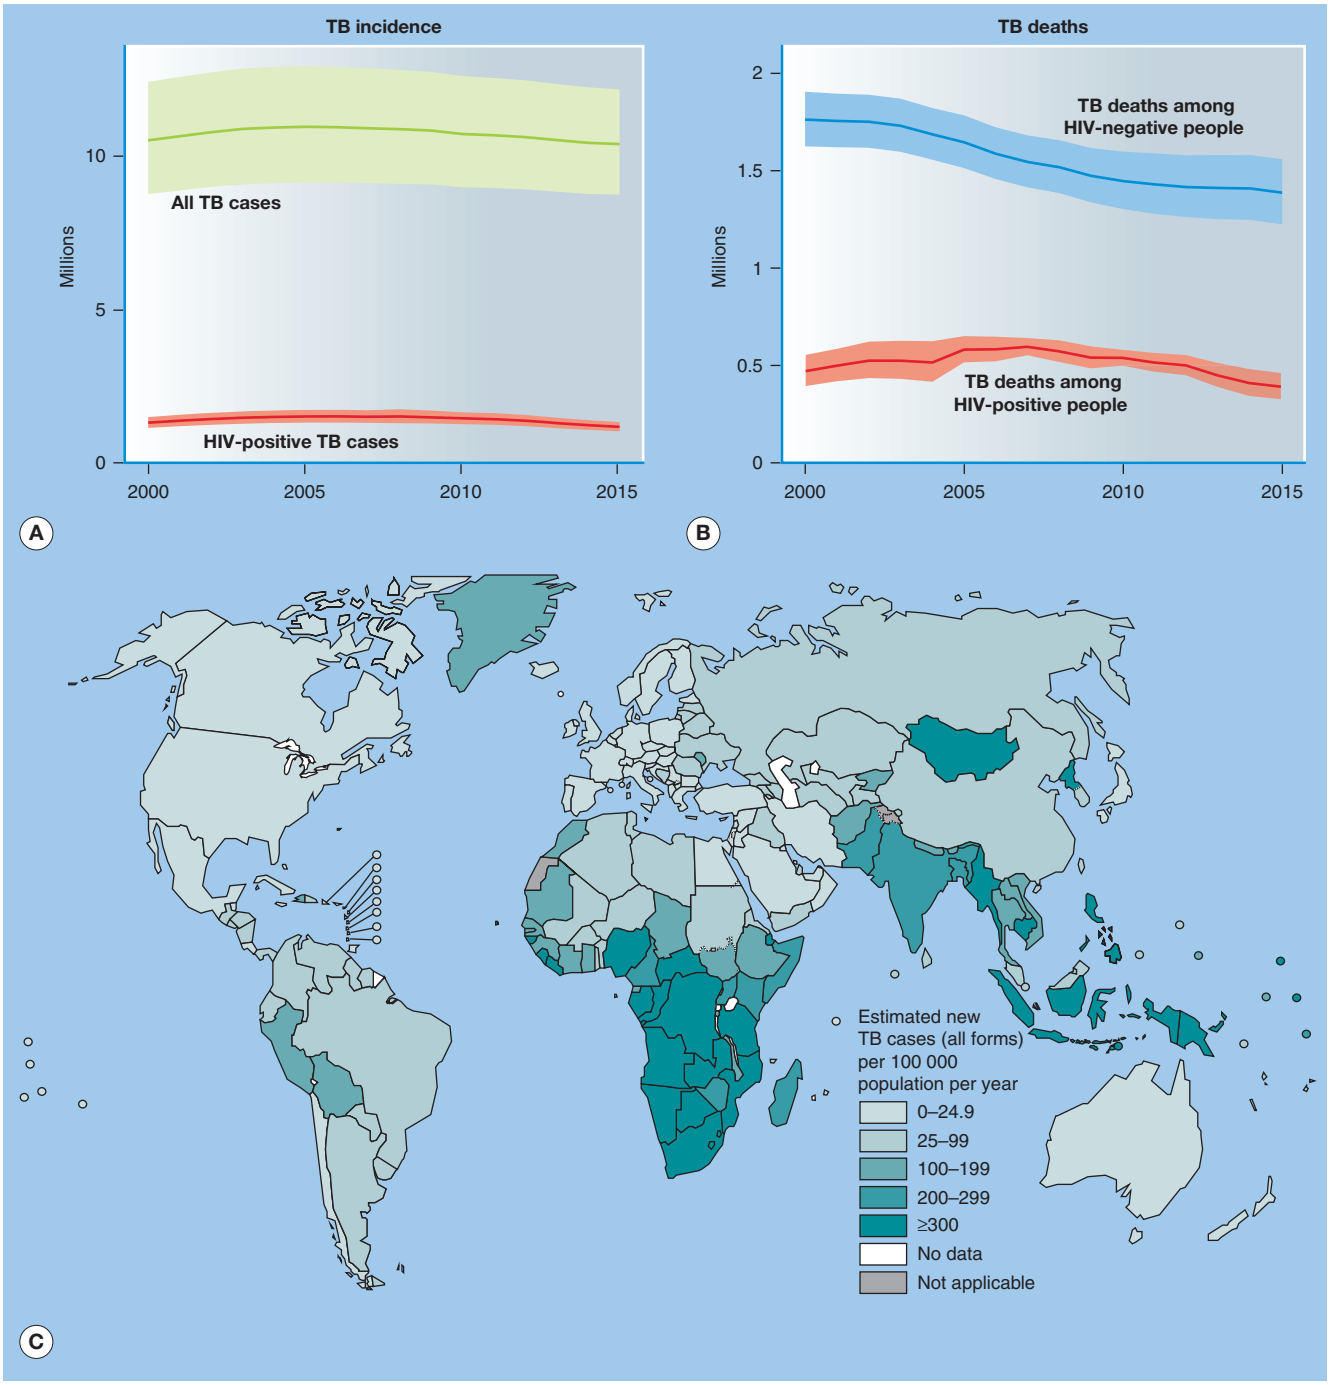

Figure 60.1. Changes in (A) global incidence of and (B) mortality from tuberculosis (TB). C, Incidence rates of TB disease in 2013 in countries from around the globe. *(From World Health Organization. Global Tuberculosis Report 2016. Geneva, Switzerland: WHO; 2016.)*

a complex cell wall. Each species has a unique pattern of mycolic acid composition.[18] Nine species—*M. tuberculosis*, *Mycobacterium africanum*, *Mycobacterium canetti*, *M. bovis*, *Mycobacterium caprae*, *Mycobacterium pinnipedii*, *Mycobacterium microti*, *Mycobacterium mungi*, and *Mycobacterium orygis*—share 99.9% similarity at the nucleotide level and have identical 16S ribosomal RNA sequences, and are classified together as the *M. tuberculosis* complex. These strains share growth characteristics and biochemical reactions, and can each cause clinical TB disease in humans and other mammals.[19,20] *M. bovis* causes TB in cattle and other animals, primarily, but can cause disease in humans who have extensive contact with infected animals or who drink animal milk that contain the pathogen. Veterinary control programs have all but eliminated *M. bovis* disease in the United States, but human infection still occurs in some countries.[21]

Approximately half of the approximate 3,800 open reading frames of the *M. tuberculosis* genome are involved in fatty acid metabolism. A major effort is ongoing to determine whether lipid components could be used in future vaccines against TB[22] (see below). Most new vaccines in clinical testing contain immunodominant protein antigens, including early secretory antigen target-6 (ESAT-6) and culture filtrate protein-10 (CFP-10) (see below). These antigens belong to the so-called RD1

region, which also contains the secretory apparatus for transport of ESAT-6 and CFP-10 to the cell surface to mediate host cell membrane disruption and bacterial release, thereby promoting cell-to-cell infection.[23,24] Importantly, the RD1 region is missing in BCG. Other important protein families, some of which have been incorporated into novel vaccines, include mycolyl transferases (Ag85 family), which play a role in building and stabilizing the cell wall by anchoring units of mycolic acid, and major chaperonins such as DnaK, GroEL, GoeES, and α crystalline. Recent studies have expanded our understanding of the breadth of antigens that stimulate T-cell responses in humans[25]; many novel CD4 and CD8 immunodominant epitopes[26] have been discovered with screening strategies. Interestingly, many of these belong to the PE/PPE group of antigens, which appear to have immunomodulatory and virulence properties.[27] Functional attributes of many *M. tuberculosis* proteins remain unknown. In addition, it is not known which particular antigens are critical for protection against TB. Rather, the lack of variation of immunodominant antigens in *M. tuberculosis* strains across the globe in the face of possibly tens of thousands of years of immune pressure suggest that responses to these components may even hold evolutionary advantage to the pathogen.[28]

Nontuberculous mycobacteria (NTM) were discovered shortly after Koch's identification of the tubercle bacillus, but were recognized as human pathogens only in the 1940s, approximately 20 years after the first use of BCG.[29] NTMs are a group of more than 140 species and are found worldwide, often in soil and water reservoirs.[30,31] The most ubiquitous species are those of the *Mycobacterium avium–intracellulare* complex. Although environmental mycobacteria rarely cause disease, immunologic effects on humans may modulate the course of *M. tuberculosis* infection. In addition, NTM interactions may partially explain variability in efficacy induced by BCG (see below).

PATHOGENESIS

TB is spread by adolescents and adults with cavitary lung disease who release the pathogens into the air, largely through coughing. Approximately 35% of contacts of a patient will become infected following inhalation of *M. tuberculosis*; proximity and duration of exposure are important determinants of infection. Only a small fraction of exposed persons resist infection, as demonstrated by their having persistently negative tuberculin skin tests (TSTs) or interferon-γ release assays (IGRAs).[32] These individuals may have an innate alveolar macrophage response to *M. tuberculosis* that resists initial infection or rapidly clears the bacillus before a T-cell response develops.

Upon inhalation, once in the lung, the bacilli bind to receptors on macrophages and other myeloid cells, such as monocytes, dendritic cells, and neutrophils, resulting in detection by the innate immune system.[33,34] Several phagocyte receptors mediate this detection, including toll-like receptors (TLRs: TLR1/2/6/8/9), Nod-like receptors (NLRs: NOD2), C-type lectin receptors (CLRs: CLEC4E or Mincle), mannose receptor (MR), dendritic cell-specific intracellular adhesion molecule-3 (ICAM-3)-grabbing non-integrin (DC-SIGN or CD209), and DNA sensors (STING).[35–38] In animal models, inoculation with tubercle bacilli first causes inflammation of the lung interstitium, with local tissue damage and histamine and prostaglandin release. Infected macrophages secrete tumor necrosis factor, which causes local tissue cells to release chemokines. Leukocytes are attracted, including neutrophils and T cells. T cells migrate to the lung following sensitization in regional lymph nodes by dendritic cells that have migrated to this compartment. A so-called TB primary complex visible on roentgenography consists of a local infiltrate in the lung as well as enlarged regional lymph nodes, both caused by cellular accumulation.

The onset of specific T-cell immunity greatly alters the pathogenic picture. The incubation period between when tubercle bacilli enter the body and the development of cutaneous delayed type hypersensitivity, a hallmark of the T-cell response, is most often between 3 and 8 weeks. During this time, a granuloma is formed at the site of infection. This granuloma, the pathognomonic histopathologic feature of the infection, contains a center of macrophage-derived cells with an outer ring of lymphocytes. The granuloma may contain the infection through encapsulation, or may break down leading to caseous necrosis with the subsequent local spread of mycobacteria. It is also thought that systemic spread of the tubercle bacilli to multiple organs occurs early in the pathogenesis of the infection.

Only 10% of untreated infected persons will develop TB disease, with approximately 50% of these individuals developing disease within 2 years of infection—so-called primary progressive disease. TB disease may also occur much later in life, by reactivation and growth of live bacilli contained within contained granulomas. This so-called secondary, postprimary, or adult-type disease is often associated with a temporary decline in T-cell immune status, associated with aging, cancers, poor nutrition, or other forms of immune compromise. In settings where TB is endemic, primary disease drives the epidemic. In this setting, exogenous reinfection may occur in persons previously infected and play a role in manifestation of clinical disease. As epidemic disease control advances, the relative contribution of postprimary, endogenous reactivation TB becomes greater.

There is evidence that a primary *M. tuberculosis* infection imparts a degree of protection from disease resulting from secondary exogenous infection. Studies from the preantibiotic era in areas with high TB rates compared active TB disease rates in those with or without original primary *M. tuberculosis* infection (as indicated by positive skin test reactivity). A metaanalysis of 18 studies with an aggregate sample size of 19,886 individuals estimated that individuals with latent *M. tuberculosis* infection (positive skin test reaction) had a 79% (95% confidence interval [CI], 70–86%) lower risk of developing active TB disease after reinfection when compared with uninfected individuals.[39] Other studies have had similar findings.[40–42] Together, these studies suggest that humans can acquire partial immunity to TB disease from natural exposure, and that understanding this protection may hold clues to successful vaccination against TB.

The immunologic mechanisms that control *M. tuberculosis* disease remain incompletely understood.[43] CD4 T cells are indispensable and act by producing T-helper type 1 (Th1) cytokines, including interleukin (IL)-2 and interferon (IFN)-γ, to activate infected macrophages for control of the pathogen. Animal studies show that CD8 T cells may also contribute, either through cytokine production or cytotoxic activity. In addition to effector responses, a host response characterized by immune mechanisms to control excessive inflammation may be important.[44] An optimal vaccination response would therefore not necessarily be a quantitatively greater T-cell response. To date, the immunological correlates of protection against *M. tuberculosis* infection and/or TB disease have not been identified.[45] Although identification of correlates of protection against TB is not possible until completion of a placebo-controlled trial of a protective vaccine, some clues have emerged from prospective studies of BCG-vaccinated infants or of other persons at risk of TB disease. A prospective study of infants vaccinated with BCG at birth, where a control arm of unvaccinated infants was not possible, showed that classical CD4 and CD8 T-cell responses induced by BCG and

measured 10 weeks after vaccination did not differ between infants who ultimately developed TB disease and whose who did not develop TB disease in the first 2 years of life.[46] These results suggest that host responses that are essential may not be sufficient for protection against TB. In another study, *M. tuberculosis*–infected South African adolescents were enrolled and followed for 2 years to identify those who developed TB disease and those who did not.[47] Examination of blood collected prior to development of disease revealed a 16-gene expression signature of risk. The signature predicted tuberculosis progression with a sensitivity of 66.1% (95% CI, 63.2–68.9%) and a specificity of 80.6% (79.2–82.0%) in the 12 months preceding tuberculosis diagnosis. The risk signature was validated in various independent African cohorts. Although further analysis of the character of the host response associated with disease risk is needed, these results represent a step toward better understanding of correlates of protection against TB.

During thousands of years of coevolution with humans, *M. tuberculosis* has evolved multiple strategies to evade or modulate a host response. The bacillus employs phagolysosome modification and inhibition of apoptosis (and promotion of bacillus survival) of innate cells,[48] for example. The pathogen also induces cellular trafficking to the granuloma to allow expansion of the number of cells available for infection to increase its survival.[34,49–51] After infection, T-cell responses to the pathogen are delayed; a positive skin reaction does not develop for approximately 6 weeks.[52,53] A similar delay in T-cell immune responses is observed in mice, which has been associated with delayed transport of bacilli from the lung to the draining lymph node.[54,55] Antigen-specific T cells often fail to recognize and eradicate *M. tuberculosis*-infected macrophages.[34,56] There are several possible mechanisms underlying impaired killing of bacilli, including a protected cellular niche for the pathogen during the first week that prevents recognition,[57] inhibition of IFN-γ activated pathways in macrophages,[58–60] and the development of excessive regulatory T-cell response,[61] which may dampen effective immune responses.

Successful vaccination against TB will require induction of immunity that is critical for protection, while, at the time of exposure to *M. tuberculosis*, circumvent the pathogen's ability to inhibit innate and adaptive host responses, and allow inflammation of an optimal character and magnitude. One possible approach would be to pursue a vaccine goal of prevention of *M. tuberculosis* infection, rather than disease.[62] Advantages would include circumvention of delayed T-cell induction by the pathogen, if CD4 T-cell or other effector cell responses were present at the time of exposure. Second, the kinetics of killing of *M. tuberculosis*-infected macrophages may be altered in acutely infected cells, compared with those with chronic infection. If T cells produced IFN-γ to activate macrophages immediately after infection, clearance of the bacillus may be more likely because of less time for development of *M. tuberculosis* modification of the macrophage. If vaccine-induced T cells were qualitatively different than those from chronic infection and present in higher quantities in the lung at the time of exposure, protection may be possible. Understanding why Th1 effector cells are ineffective during the early phases of infection and identification of markers of efficacy or of an optimal balance between effector and regulatory or exhaustion host responses may be critical for successful development of a TB vaccine.

CLINICAL FEATURES

The result of exposure to *M. tuberculosis* is no infection, transient infection,[63] or established infection. Established infection is so-called latent TB infection (LTBI). Individuals with LTBI have a positive TST or IGRA, but no clinical or radiographic evidence of active disease. TB disease occurs when manifestations of pulmonary or extrapulmonary TB become apparent, either clinically or on imaging studies.

The clinical presentation of pulmonary TB disease in childhood differs from that in adolescents and adults. The signs and symptoms of primary intrathoracic TB in children are often surprisingly mild, a result of the paucibacillary nature of the disease.[64] Nonproductive cough, mild dyspnea, and low-grade fever are the most common symptoms in infants. Chest roentgenograms may show hilar or mediastinal lymph node enlargement, a hallmark of childhood disease, and mild infiltrates. "Progressive primary disease" is characterized by lobular or lobar spread of TB and pulmonary dissemination is characterized by the appearance of miliary lesions. Complications of lymph node compression on the airway, such as segmental collapse, are relatively common, while parenchymal breakdown is uncommon.[65]

In contrast, adolescents and adults manifest more significant symptoms and signs because of the multibacillary nature of their disease.[66] The wide spectrum of clinical manifestations include chronic cough, low-grade fever, night sweats, fatigue, and weight loss. The disease occurs most commonly in the apical or posterior segment of the upper lobes, or the superior segment of the lower lobes. The typical pattern is airspace consolidation of a patchy or confluent nature, with cavitation occurring frequently. The development of fibrosis leads to volume loss in the involved lung. Older adults are more prone to having unusual radiographic manifestations of TB, including lower lung field disease.[67] At all ages, early pulmonary disease, identifiable by radiology, may be asymptomatic.

Extrapulmonary manifestations of disease occur in approximately 15% of immunocompetent adults and 25% of children.[68] Virtually any organ of the body can be involved. Superficial lymph node disease in the cervical or supraclavicular regions is the most common manifestation. Pleural TB accounts for almost 25% of the cases of extrapulmonary TB, but it is uncommon in children and rare in infants. Other sites of TB disease include the genitourinary system, the bones and joints, the peritoneum, and the pericardium.

Two forms of TB are life threatening: disseminated or miliary disease, and meningitis. The early clinical manifestations of miliary TB are protean, depending on the organs involved, including lungs, spleen, liver, bone marrow, meninges, or abdomen.[69] Central nervous system TB is fatal without effective treatment.[70] A meningeal exudate usually concentrates near the brainstem, while inflamed cortical or meningeal blood vessels lead to infarction of the cerebral cortex. Cranial nerve involvement is common, as is noncommunicating hydrocephalus. Death or profound handicap is a common outcome.

Adults with uncontrolled HIV infection who develop pulmonary TB often have a clinical and radiographic presentation that differs from that found in HIV-negative persons.[71] In advanced HIV infection, the radiographic presentation often includes hilar or mediastinal adenopathy, and diffuse or miliary pulmonary infiltrates, while cavitation is uncommon. Lower lung field involvement and endobronchial TB are much more common in patients with HIV infection. Disseminated or extrapulmonary TB occurs commonly. Patients with advanced HIV infection and TB who are started on both anti-TB drugs and antiretrovirals are prone to developing immune reconstitution inflammatory syndrome, which manifests as worsening of the original focus of infection or onset of new findings related to *M. tuberculosis* infection at other body sites.[72] The pathophysiology is dominated by a proinflammatory innate and adaptive immune response directed toward *M. tuberculosis* antigens.[73,74] The main treatment is corticosteroids to modulate the inflammation.

Diagnosis

Tuberculin Skin Test

A positive TST is the hallmark of latent infection with *M. tuberculosis* and remains positive for an individual's lifetime, even after chemotherapy.[75,76] The gold standard TST is the Mantoux test—the intradermal injection of purified protein derivative by use of a needle and syringe. The test should be read 48 to 72 hours after administration. Induration, not erythema, should be measured.

The appropriate cutoff size for a positive TST varies according to the clinical and epidemiological setting.[77,78] For adults and children at the highest risk for TB, a Mantoux induration of 5 mm is regarded as positive. For other groups at high risk for TB, induration of 10 mm is considered positive. In settings where TB is rare, the cutoff may be increased to 15 mm for individuals with no other risk factors for infection or disease.

Ten percent of adults and children with TB disease have a negative TST.[79,80] A variety of host-related factors such as young or old age, poor nutrition, immunosuppression by disease or drugs, viral infections, and overwhelming TB can lower TST reactivity. False-positive reactions may be the result of environmental mycobacterial exposure or BCG vaccination. The size of the skin test reaction after BCG vaccination varies with the strain and dose of the vaccine,[81,82] the route of administration,[83,84] the age of the person,[85–87] the nutritional status of the patient, the number of years since vaccination,[85,87,88] and the frequency of skin testing. There are conflicting findings about whether the TST reaction increases with repeated BCG vaccination or not.[89,90]

In a large number of studies of children who received BCG vaccine, the mean reaction to a TST ranged from 0 to 19 mm, although many experts believe that reactions larger than 10 to 15 mm that result from vaccination are unusual. Tuberculin reactivity wanes rapidly during the first few years after vaccination. Lifschitz found that approximately 50% of infants given BCG vaccine shortly after birth were tuberculin-negative at 6 months of age, and almost all children were tuberculin-negative at 1 year after vaccination.[85] Only 18% of Sri Lankan children vaccinated with BCG at birth had significant reactions at 1 year of age, and none was significant at 5 years of age.[91] A study from Canada investigated older children and adults who had received BCG vaccine by the scarification method on the lower back either in infancy or as older children.[92] Among children with a mean age of 11 years at skin testing, 4.9% vaccinated in infancy had a positive TST, compared with 12.5% of those vaccinated as older children. Among young adults with a mean age of 23 years at skin testing, 10.3% vaccinated in infancy had a positive TST compared with 25.5% of those vaccinated as older children. A similar study found that only 16% of U.S. naval recruits who had received BCG vaccine 8 to 15 years previously had a positive TST reaction at 10 mm or more.[93]

In summary, in BCG-vaccinated persons, the probability that a skin test reaction has resulted from infection by *M. tuberculosis* increases (1) with the size of the reaction, (2) when a patient had been in contact with a patient with infectious TB, (3) if the person is in a high-risk group for TB, (4) when the person's country of origin has a high prevalence of TB, and (5) when the interval between vaccination and skin testing is longer.[90]

Interferon-Gamma Release Assays

The newer IGRAs are also used to diagnose latent tuberculosis and contain antigens that are specific to *M. tuberculosis,* absent in BCG, and variably present in NTMs.[94] The QuantiFERON-TB Gold In-tube test (Qiagen, Germany) is based on a whole-blood enzyme-linked immunosorbent assay using three antigens: ESAT-6, CFP-10, and TB7.7. QuantiFERON-TB Gold Plus is the latest version of this test and includes additional ESAT-6 and CFP-10 epitopes that are targets of $CD8^+$ T cells. The test was designed to improve sensitivity and perform better in HIV-infected individuals with low CD4 T-cell counts. T-SPOT. TB (Oxford Immunotec, Oxford, UK) is also based on measurement of IFN-γ released by T cells stimulated with ESAT-6 and CFP-10, using an overnight enzyme-linked immunospot assay. These tests and other new tests may become important in clinical trials for new TB vaccines, addressing some of the methodologic problems encountered with previous BCG vaccine trials.

Microbiologic Diagnosis

The most rapid and widely available procedure to detect mycobacteria is microscopic examination of sputum or other body fluid with an acid-fast stain. Fluorochrome methods are more sensitive than carbolfuchsin techniques, but at least 10^4 acid-fast bacilli per milliliter of specimen are required for detection with either method. An acid-fast stain of sputum can identify 40% to 75% of adults with pulmonary TB.[95,96] Although environmental mycobacteria can be present in sputum and create a false-positive smear, the specificity of the acid-fast smear of sputum is high, especially when TB is endemic.[97] Most children with pulmonary TB do not spontaneously produce sputum and early morning gastric aspirates are used for diagnosis. As a consequence of the paucibacillary nature of childhood disease, sensitivity of acid-fast smears from these samples is low: usually less than 10% even in highly endemic areas.

Mycobacterial culture is commonly regarded as the gold standard for diagnosis. The best culture specimen is freshly expectorated sputum, from which *M. tuberculosis* can be isolated in approximately 80% of cases of pulmonary TB in adults.[98] Childhood gastric aspirate and induced sputum-derived cultures are positive in less than 50% of cases.[99]

Newer nucleic acid amplification techniques for direct detection of *M. tuberculosis* in sputum include Xpert MTB/RIF. In addition to rapid detection of presence of the pathogen, rifampin resistance may be evaluated simultaneously. A recent Cochrane review of 15 studies showed that Xpert had a pooled sensitivity and specificity of 88% and 98%, respectively, for replacement of smear microscopy.[100]

Newer Diagnostic Tests

In 2014, a consensus group convened by the WHO recommended the highest priority indications for TB diagnostic test development for impact.[101] First, a non–sputum-based, point-of-care test able to detect all forms of TB. Progress toward such a test, performed using blood or urine, is in early stages of development, and focuses on detection of specific host signatures or bacterial components like lipoarabinomannan. The recently marketed urine lipoarabinomannan detection test displays limited sensitivity, but may be useful for diagnosing TB in certain populations, such as HIV-infected persons.[102] Second, a simple, low-cost point-of-care triage test to be used by first-contact healthcare providers to rule out TB. Third, a point-of-care sputum-based test to be used as a replacement for smear microscopy. In some settings, such as South Africa, Xpert MTB/RIF is already used at a primary care level. Next-generation nucleic amplification tests hold the promise of being more compact and less expensive, and possibly more applicable to a primary care setting globally.[103] Finally, a rapid drug susceptibility test, which is likely to be incorporated into next-generation nuclear amplification tests[103] remains a priority.

Clinical Diagnosis

In both highly resourced and lesser-resourced environments, many cases of childhood TB are diagnosed on clinical grounds with the use of one of several scoring systems incorporating symptoms, signs, and, when available, radiographic findings.[104,105] Although helpful, these systems have low sensitivity and specificity.

TREATMENT AND INFECTION CONTROL

TB is treatable and preventable with antimicrobials. Guidelines for treatment are published by many expert groups, including the American Thoracic Society,[106,107] the American Academy of Pediatrics,[108] the Centers for Disease Control and Prevention,[109] and the WHO.[110] In general, TB disease should be treated with three or four drugs—isoniazid, rifampin, pyrazinamide, and ethambutol—for 2 months, followed by 4 months of isoniazid and rifampin.

Drug-resistant strains of *M. tuberculosis* are more difficult to treat. Strains are classified as extensively drug resistant when additional fluoroquinolone and injectable aminoglycoside resistance are present. Totally drug resistant strains of *M. tuberculosis* have also been described.[111] Treatment of MDR-TB is challenging because of lower efficacy, longer durations, and more adverse effects. With rising levels of drug resistance worldwide, the impact of an efficacious vaccine will be heightened.

The goals of infection control programs are to detect TB disease promptly, to isolate those who have or are suspected of having TB disease by using airborne precautions, and to treat people who have or who are suspected of having TB disease. Factors associated with infectiousness in adults include presence of a cough; lung cavities; acid-fast bacilli on sputum smear; disease of the lungs, airway, or larynx; and less than 2 weeks of adherent treatment.[112]

Bacille Calmette-Guérin Vaccine

BCG is a live attenuated strain of *M. bovis*. Two French scientists, Calmette, a physician, and Guérin, a veterinarian, selected a *M. bovis* strain isolated from a cow with tuberculous mastitis in 1908.[113] The isolate was cultured in a medium that contained glycerol, potato slices, and beef bile, and subcultured every 3 weeks for a total of 13 years or 239 cycles. Loss of virulence was shown first in animal models and phenotypic changes from rough, dry, and granular colonies to viscous, moist, and smooth ones were noted.

The vaccine strain was first used in 1921 in Paris, when it was given orally to infants.[114] In 1928, the League of Nations declared that oral BCG vaccine was safe. Unfortunately, from 1929 to 1930, 72 of 250 children vaccinated in Lübeck, Germany, died of TB, as the oral preparation was contaminated by virulent *M. tuberculosis*.[115] Despite this tragedy, BCG vaccination continued, with introduction of new methods of administration: intradermal in 1927, multiple puncture in 1939, and scarification in 1947.[116]

In 1948, the First International BCG Congress in Paris concluded that BCG was effective and safe, even though no controlled clinical trials or retrospective case-control studies of the intervention had been performed. After World War II, the WHO and the United Nations International Children's Emergency Fund (UNICEF) organized campaigns to promote vaccination with BCG in several countries. The seed-lot system for BCG was established in 1956,[113] and the WHO developed requirements for freeze-dried BCG vaccine in 1966.[117] Since 1974, BCG vaccination has been included in the WHO Expanded Programme on Immunization, which aims to strengthen the fight against infectious diseases among children in developing countries. Rates of BCG vaccination have increased dramatically; more than 4 billion persons have received the vaccine, and more than 100 million infants receive BCG annually at present.

Bacteriology of Bacille Calmette-Guérin Strains and Vaccine Constituents

In the decades since the first BCG created by Calmette and Guérin, multiple substrains have been generated using diverse culture methods that are best classified by genomic sequencing (Fig. 60.2).[118–122] A genealogy of BCG vaccine strains and a timeline for specific polymorphisms have been suggested.[118–121] BCG substrains differ in colony morphology, growth characteristics, biochemistry, immunogenicity, and virulence in animals.[123–134]

The variability among BCG strains is of concern for two reasons. First, extensive serial passage may have unintentionally resulted in overattenuation, compared to the original BCG strain.[135] Second, variability in substrains may be responsible, in part, for variability in BCG efficacy demonstrated in clinical trials (see below). The consequences of strain variation on human vaccine efficacy and adverse effects remain to be fully elucidated; multiple studies have now shown that different strains induce differential host responses in humans.[136–138] To prevent further accumulation of genotypic and phenotypic differences during vaccine production, the WHO and many national regulatory authorities have instituted standardized procedures for manufacture (see below).

Manufacturing, Quality Assurance, and Supply

BCG vaccine is produced from seed lots of lyophilized bacilli. A master seed lot is defined as a bacterial suspension of a single substrain originating from the bacillus of Calmette and Guérin that has been processed as a single lot and is of uniform composition.[139] The seed-lot system was adopted in the mid-1950s in an attempt to standardize production and vaccine characteristics. In the 1960s, the WHO recommended stabilization of the biologic characteristics of daughter strains by lyophilization and cryostorage of BCG.[140] Seed lots of the various BCG strains were originally maintained by the WHO and the Statens Serum Institut in Copenhagen.[117] Currently, BCG manufacture is the responsibility of individual suppliers, overseen by national regulatory authorities.

The classical method of manufacturing BCG involves inoculation into liquid medium for growth as a pellicle on the surface. Alternatively, organisms are dispersed through the liquid medium, which results in a slightly different colony morphology. Regardless, the WHO recommends, to avoid variation, that the total number of passages from master seed lot to final product should not exceed 12.[139,141] Early harvest of bacilli after 6 to 9 days of growth is essential for ultimate viability of the product. After filtering and pressing, the semidry mycobacterial mass is homogenized at controlled temperatures, diluted, and then freeze-dried. A stabilizer is added to the preparation.

Culture conditions can have profound effects on the final product.[123,142,143] For example, the Tice strain is grown in a medium containing glycerin, asparagine, citric acid, potassium phosphate, magnesium sulfate, and iron ammonium citrate. Lactose is added to the final preparation prior to freeze-drying.[144] In contrast, the Danish strain contains sodium glutamate, magnesium sulfate heptahydrate, dipotassium phosphate, citric acid monohydrate, L-asparagine monohydrate, ferric ammonium citrate, glycerol and water for

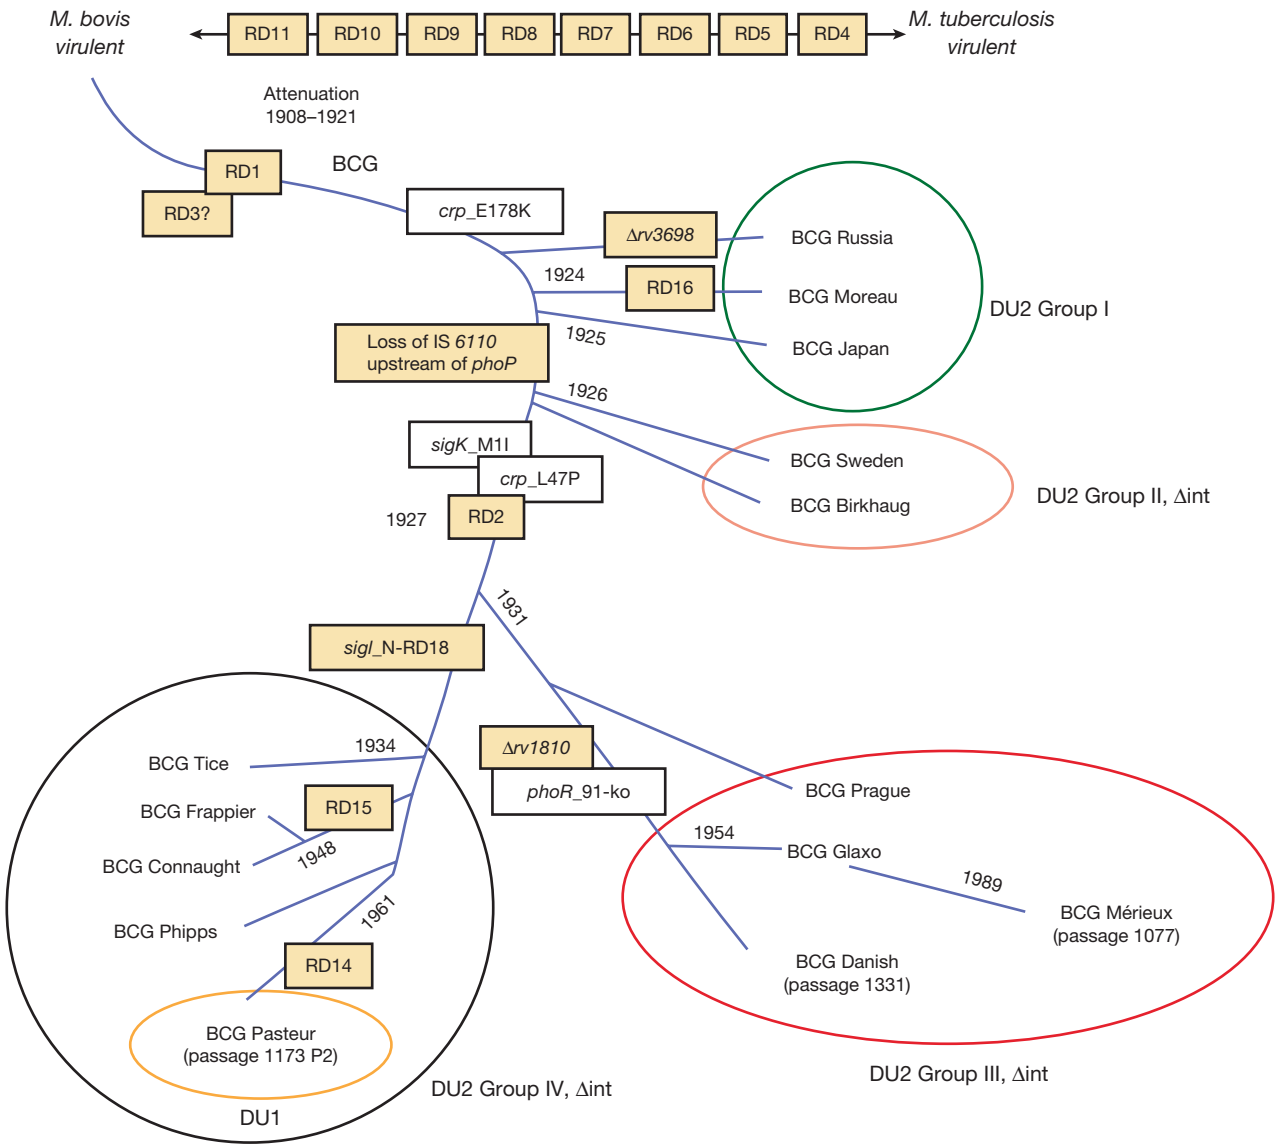

Figure 60.2. Classification of the bacille Calmette-Guérin (BCG) strains currently in clinical use. Of the 3954 protein-coding genes of BCG, 58 are present in two copies as a result of two independent tandem duplications, DU1 and DU2. Strains can be classified according to variation in DU1 and DU2. Genealogy is demonstrated by year in which deletions of groups of genes (RD [region of differentiation]) or individual genes, both shown in boxes, occurred. *(From Brosch R, Gordon SV, Garnier T, et al. Genome plasticity of BCG and impact on vaccine efficacy.* Proc Natl Acad Sci U S A. *2007;104[13]:5596–5601.)*

injection.[145] The Connaught strain contains monosodium glutamate, sodium chloride, disodium hydrogen phosphate, sodium dihydrogen phosphate, polysorbate 80, and water for injection.[146] It is conceivable that these differences may ultimately affect vaccine efficacy.

The most recent WHO recommendations to assure quality, safety, and efficacy of BCG were published in 2013.[147] WHO recommendations focus on the manufacture of lots that do not differ significantly from prior lots shown to be safe and effective in humans and do not state a preference of one vaccine over another.[147] WHO Reference Reagent substrains are available as comparators for validity and consistency monitoring in viability assays[147]; the Danish 1331, Tokyo 172-1, Russian BCG-I, and Moreau RDJ strains of BCG are available[148] (see "Products Available" below).

Viability is assessed either by determining the number of culturable particles using a national regulatory authority–approved method or by a bioluminescence or other biochemical method that has been validated, such as the adenosine triphosphate method.[147] As the lyophilization and reconstitution process results in cell death, the final product contains both live and dead bacilli. The final total bacterial mass of the vaccine appears to correlate with local reactogenicity, whereas the number of culturable organisms appears to correlate with tuberculin sensitivity.[117] The number of culturable bacilli from some vaccines may also correlate with the rate of complications in newborns (see "Safety" below).

Other routine quality-control procedures include a test of identity, a test for contamination, and tests for dermal reactivity and safety in guinea pigs. Thermal stability testing requirements are considered to be at the discretion of the national regulatory authority, and are generally based on determining the number of culturable particles before and after samples are maintained at appropriate temperatures for designated

periods, with the ratios of before-to-after values and the absolute value approved by the national regulatory authority.[147]

All freeze-dried BCG vaccines are sensitive to ultraviolet and fluorescent light and heat and should not be exposed to direct sunlight; BCG vaccines are supplied in dark brown glass vials or ampoules and are typically supplied in multidose containers.[150] After reconstitution of the multidose vial, the vaccine should be used as soon as possible, while the remaining vaccine should be stored at 2°C to 8°C for a total expiration time determined by individual stability studies: typically a few hours.[147] As a result, a substantial amount of BCG vaccine is wasted during routine use, contributing to periodic supply shortages.

United Nations agencies supply more than 120 million doses of BCG per year. UNICEF purchases vaccines through a WHO prequalification process, which determines eligibility of different vaccines for clinical use. Currently, there are four WHO prequalified producers and distributors of BCG vaccine: BB-NCIPD/Intervax, BCG Japan, Serum Institute of India (SII), and Statens Serum Institut (SSI) in Denmark.[151] However, a number of other manufacturers produce vaccine for local use.

Products Available. The various strains of BCG are generally known by the name of the country or laboratory in which they are kept. The following account for more than 90% of the vaccines in use worldwide: French (Pasteur) strain 1173 P2, Danish (SSI) strain 1331, Glaxo strain 1077, Tokyo strain 172-1, Russian strain BCG-I, and Moreau RDJ.[152] Other commonly used strains include the Montreal strain (Canada) and the Tice strain (United States). The Tice strain, originally derived from the Pasteur strain 1173 P2 and produced by Organon Teknika (now owned by Merck) is the only product approved for use in the United States.

Dosage and Route of Administration

Worldwide, BCG is most commonly administered by intradermal injection with a syringe and needle. The only alternate route used currently is percutaneous administration with a multipuncture device.[153–155] A Phase IV trial conducted in South Africa compared multipuncture (percutaneous) and intradermal administration of the Japanese BCG strain and demonstrated equivalence between the two routes, in terms of both efficacy to prevent pulmonary TB and adverse events.[156]

Intradermal injection can be technically difficult in newborns, but other methods of administration have not been as successful. Subcutaneous injection induces tuberculin sensitivity, but may result in abscesses and unsightly, retracted scars.[157] Other techniques, such as scarification, jet injection, and use of bifurcated needles, have yielded variable results.[157–159]

The recommended dose of BCG vaccine differs by vaccine strain and age of the recipient. Similarly, the number of colony-forming units per dose varies by vaccine strain.[117] Although many body sites can be used for vaccination, the most common site is the deltoid region of the arm, usually on the right.

A wide range in BCG dosing schedules exists globally.[160] The WHO recommends a single dose given in infancy.[161] The effect of delaying BCG vaccination beyond the immediate newborn period has been studied, with variable results in different settings (see "Immunogenicity" below). BCG can be given to low-birth-weight newborns, as these infants develop a specific immune response.[162] When vaccination of preterm infants at 34 to 35 weeks' gestation was compared with delaying the vaccination to 38 to 40 weeks' gestation, no difference in tuberculin reactivity, scar formation, or immune response could be shown.[163] Safety and immunogenicity has been shown following administration to infants as preterm as 31 weeks.[164] Mangtani and colleagues investigated the question of age of vaccine administration in their metaregression analysis of published BCG studies[165] and reported that BCG is most effective when given at younger ages. In addition, school-age children who received BCG were better protected if their prevaccination TST reaction was small, which suggests that vaccination prior to sensitization by NTM or even *M. tuberculosis* may be a more important determinant of success (see below).Despite the WHO recommendation to give a single dose to newborns, some countries continue to give the first dose of BCG in infancy followed by one or multiple vaccinations throughout childhood.[166] Although this is an area of active investigation, evidence to support revaccination of older children and adults does not exist currently (see below). In some settings, repeating BCG vaccination is based on lack of tuberculin sensitivity, the absence of a typical BCG scar, or an individual's risk of exposure.[167] Regardless, neither absence of a scar after BCG vaccination nor tuberculin sensitivity correlates with risk of TB disease after BCG vaccination.[168,169]

Immunogenicity

The qualitative or quantitative determinants of BCG-induced immunity required for protection against TB are not known. Furthermore, knowledge of natural host protection against *M. tuberculosis* infection and TB disease is incomplete (see above). It is known that a CD4 T-cell response is essential for protection, as illustrated by markedly increased risk of mycobacterial disease in the presence of genetic mutations of the IL-12/IFN-γ pathway,[170,171] and by increased TB disease risk in untreated, advanced HIV disease.[172] For this reason, TB vaccinology efforts have relied heavily on the paradigm that a CD4 T-cell response should be induced, with production of so-called type 1 cytokines, IFN-γ, IL-2. and tumor necrosis factor–α.

Multiple studies of human newborns vaccinated with BCG have shown potent induction of CD4 T cells that produce type 1 cytokines (Th1 response).[136,137,173–178] However, there is great variability in the magnitude and character of the Th1 immune response in infants. In a study of nearly 6000 infants, the magnitude and character of the T-cell response to BCG did not correlate with risk of TB disease in the first 2 years of life,[46] suggesting that a Th1 response may not be sufficient for protection against TB.

BCG-specific T cells are able to proliferate in vitro and may have cytotoxic potential.[176,179] CD8 T cells, which may contribute to protection against TB, are also induced by newborn BCG vaccination, although at much lower frequency and with lesser diverse cytokine production profiles, compared with CD4 T cells.[46,175,180] Induced CD8 T cells may be cytotoxic. The phenotype of CD4 T cells induced by vaccination of human newborns is a mixture of effector memory and central memory cells; that is, a mixture of shorter-lived, ready-for-action (effector) cells and longer-lived (memory) cells that require additional immune stimuli to become effector cells again.[176,177]

After newborn BCG vaccination, the immune response appears to peak between 6 and 10 weeks of age, after which there is a gradual decline in frequency of specific cells in peripheral blood.[176] The reduction in detectable peripheral blood cells may be a consequence of homing to specific organs.

The effect of HIV exposure and infection of the newborn on the BCG induced immune response has also been studied.[181–185] Overall, HIV exposure in infants who do not become infected appears to have little effect on the

BCG-induced immune response, measured over the first year of life. A dramatically different scenario occurs in infants who are HIV infected. In the HIV-infected group, when not on antiretroviral therapy, the magnitude of the peak specific response is much reduced, and virtually no specific immune response is detectable at 1 year of age.[181]

The host response to BCG vaccination of infants beyond the immediate newborn period has also been defined.[175,177,186] Various projects have assessed whether delaying vaccination to 6 weeks of age, or even later, would influence the BCG-induced immune response. The results have been conflicting—in some instances, a delay in vaccine administration was associated with enhanced immunogenicity, whereas in others there has been no enhancement.

The importance of the epidemiological setting in BCG-induced immunity has been evaluated systematically.[178,187–189] Malawian infants vaccinated with BCG demonstrate quantitative and qualitative characteristics of a Th1 response that are distinct from those of UK infants vaccinated with BCG. These results may also be the consequence of genetic or other differences between populations.

When considering prior mycobacterial exposure, infants born to mothers who are latently infected with *M. tuberculosis* appear to have a lower host response to BCG vaccination compared to infants born to mothers who are uninfected.[190] Similarly, environmental mycobacterial exposure prior to BCG vaccination in children and adults vaccinated beyond the immediate newborn period may result in lower host responses.[191] This may translate to lesser protection, as a negative TST at the time of vaccination correlates with BCG-induced protection against TB (see below). These studies suggest that preexisting mycobacterial infection may result in masking or blocking of host responses to BCG. The effect of non–mycobacterial infections, particularly helminth infections, on the BCG-induced response has been studied extensively.[192–194] These results are inconsistent—in some cases, lower host responses have been reported and in others there has been no effect. Again, these results may reflect study design and epidemiological and genetic diversity.

BCG vaccination of adults does induce an immune response that is similar in character to that of newborn vaccination, although the induced immune response may peak earlier in adults.[84,186] One study shows that BCG may safely be given to persons latently infected with *M. tuberculosis* with the baseline immune responses not impacting the ultimate vaccine response (Thomas J. Scriba, personal communication, 2016).

Data on animal host responses induced by BCG—and protection afforded by vaccination—should be interpreted with caution, as none of these completely replicate human disease. For example, TB in the mouse is a chronic disease, with the histological appearance in the lung differing from humans. In mice, the breakdown of granulomas is unusual, whereas this is common in adults with TB disease.[195] In the mouse, BCG induces a predominance of effector memory T cells, whereas in humans, both effector and central memory responses are induced. Nonhuman primate species, such as rhesus and cynomolgus macaques, may best model human TB where immune responses to BCG vaccination have been very similar to that described in humans.[196,197]

Conversion of the TST has been used widely to assess whether a person has responded to BCG vaccination; in the past, revaccination was often advised if no response was detectable. Unfortunately, neither the presence nor size of the postvaccination TST reaction reliably predicts protection afforded by BCG.[198,199] Results from the Medical Research Council's BCG trial in Great Britain demonstrate a high level of protection against TB and show that the degree of tuberculin sensitivity is independent of the degree of protection conferred by vaccination.[200] Other studies, such as the Chingleput trial in southern India, demonstrated poor protective efficacy while high levels of vaccine-induced tuberculin sensitivity were shown.[201,202]

Bacille Calmette-Guérin Efficacy and Effectiveness

Overall, BCG appears most protective against disseminated forms of childhood TB, such as miliary TB and TB meningitis, with an overall efficacy of approximately 80% (see below). Protective efficacy against active pulmonary disease has been variable, ranging from 0% to 80%; protection is greater early in childhood, in persons who are TST-negative prior to vaccination, and in persons who live further from the equator—the latter two variables may be related to environmental mycobacterial exposure (see below). BCG appears to have a modest effect in preventing *M. tuberculosis* infection: overall, approximately 20% efficacy (see below). Finally, BCG may protect against other mycobacterial disease: the vaccine is highly effective at preventing leprosy,[203] but has limited protective efficacy against Buruli ulcer.[204]

Selected Controlled Trials of Bacille Calmette-Guérin Efficacy

Fig. 60.3 and Table 60.1 summarize the efficacy of BCG as demonstrated in major case-control, cohort, and household-contact studies. Comparison of the trials is difficult because of differences in eligibility criteria, methods of disease surveillance, diagnostic/outcome criteria, vaccine strain and administration, trial setting and environmental factors. Comstock published a comprehensive comparison of the major BCG vaccine studies.[205] Extensive discussion comparing the controlled trials can also be found in other reviews and in previous editions of this textbook.[206–209]

The largest controlled clinical trials, each involving more than 10,000 participant years of follow up, are discussed here. Three trials demonstrated excellent protection against pulmonary and other forms of TB.[200,210,211] The first was conducted among Native Americans in the 1930s and involved school-age children. The estimated efficacy in preventing pulmonary TB in this trial was 74% (95% CI, 67–80%).[210] The second study was also conducted in the 1930s, in Chicago, among infants living in high-risk areas. The protective efficacy against pulmonary TB was 66% (95% CI, 40–81%).[211] A third trial was initiated in 1950 among British schoolchildren and showed 78% (95% CI, 69–84%) efficacy against pulmonary TB.[200] These three clinical trials had three characteristics in common. First, they were conducted in northern geographic areas with a low prevalence of environmental mycobacteria (see below). Second, infants or children were enrolled. Third, in subsequent critical evaluation of all controlled trials, the methodology and statistical precision of these three trials have been judged to be superior to those of the other major BCG trials—for example, the protective efficacy of each had narrow 95% CIs, which was not the case in the majority of other trials.[165,209,212]

Other controlled trials have demonstrated moderate to poor protective efficacy. The first was sponsored by the U.S. Public Health Service and conducted in Puerto Rico starting in 1949.[213] The efficacy in preventing TB disease in school-age children was 28%, with a wide 95% CI of 10% to 43%. A study conducted in southern India (Madanapalle) enrolled school-age children between 1950 and 1955.[214,215] After 15 years of follow-up, the protective effect had decreased to 19% (95% CI, −26% to 48%). A study conducted in Muscogee County,

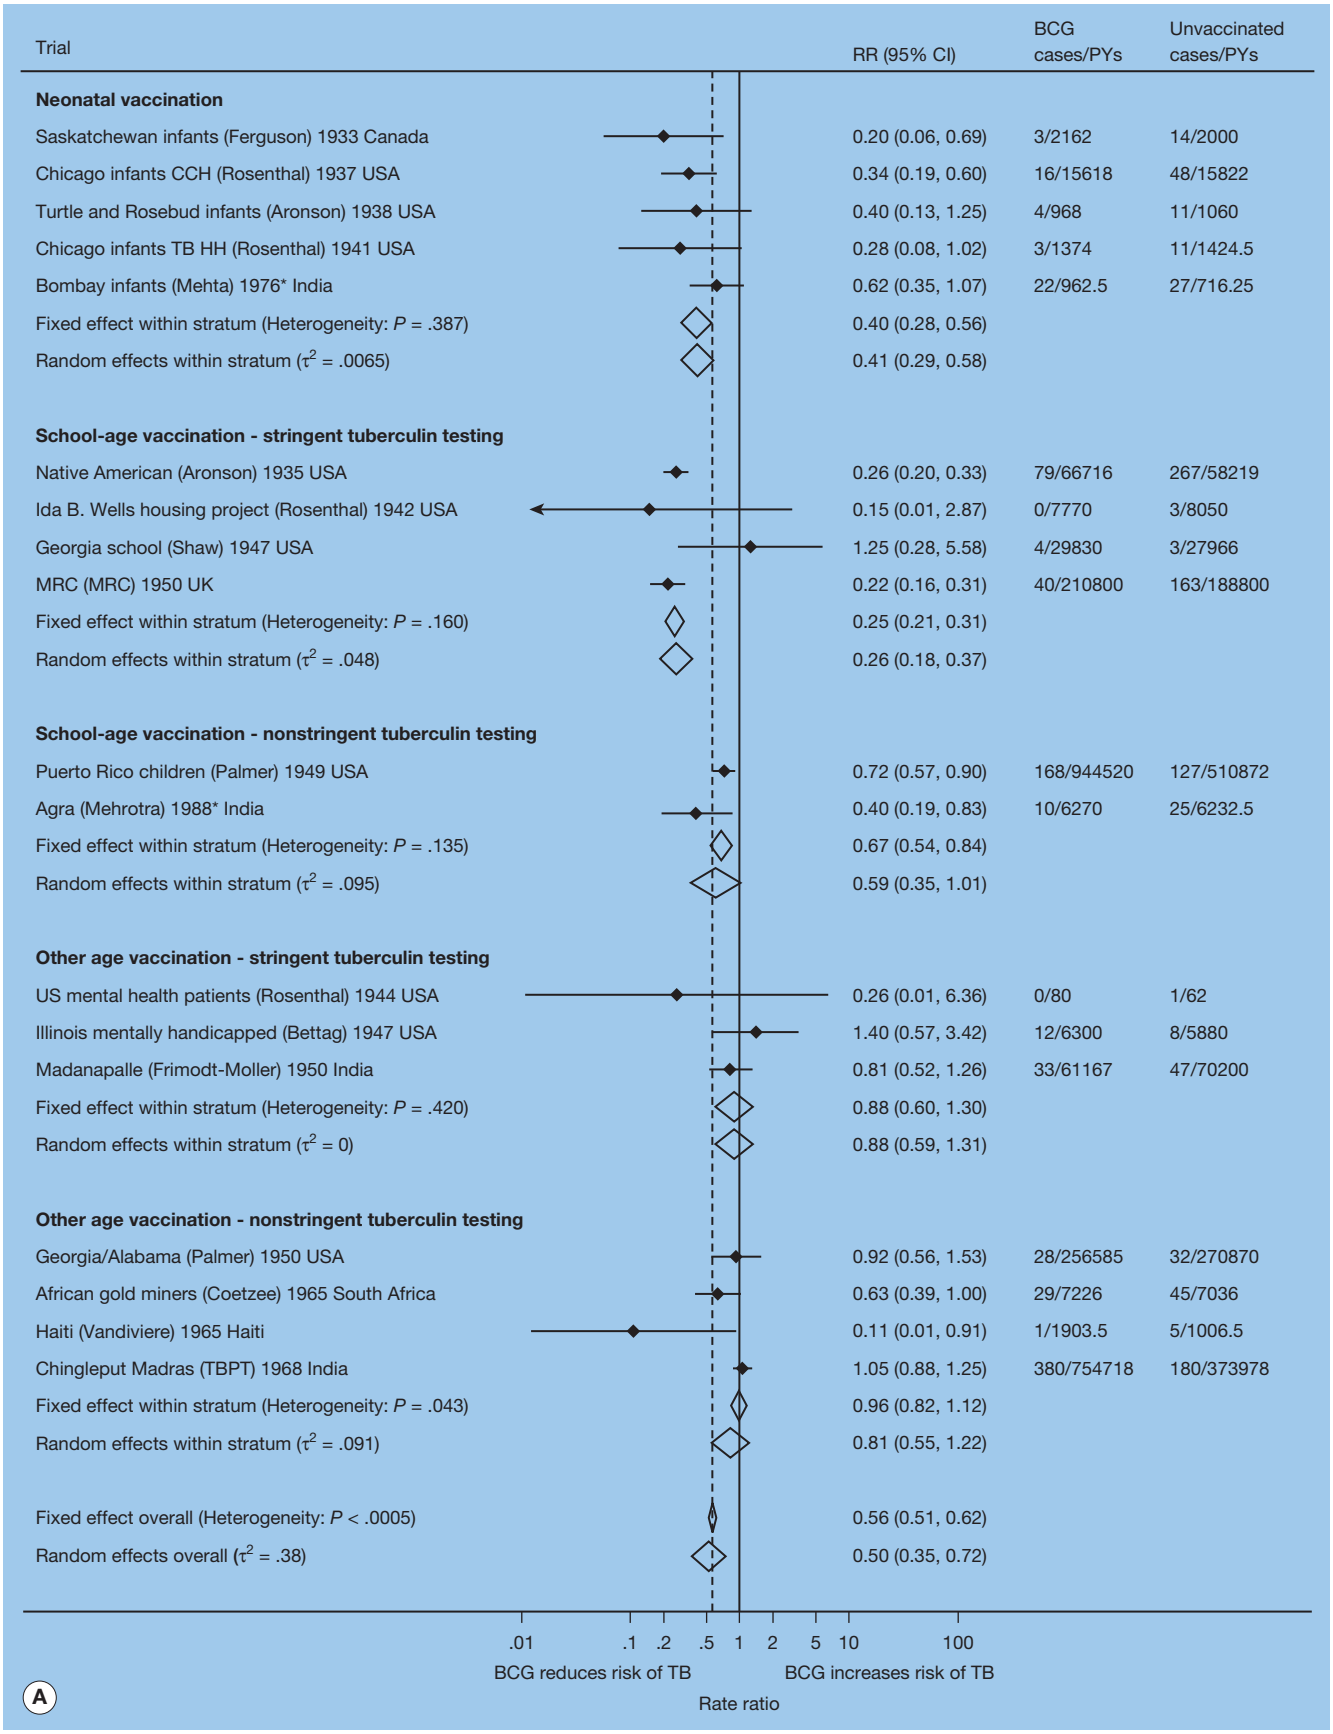

Figure 60.3. A, Rate ratios and 95% confidence intervals (CIs) for bacille Calmette-Guérin (BCG)'s efficacy in preventing pulmonary tuberculosis, stratified by age vaccinated and stringency of prevaccination tuberculin testing. Trials are ordered by year of study start (see Table 60.1 for details). The "other" age group includes studies in which older persons were vaccinated, as well as those in which BCG was given at any age. Both fixed effects and random effects metaanalyses were applied to determine summary results (for methods, see reference 165). *Date of study publication was used if study start date was not available.

Protection by BCG vaccine against tuberculosis: a systematic review of randomized controlled trials.* Clin Infect Dis*. 2014;58:470–480.)*

Georgia, beginning in 1947 had three cases of TB in the control group and five in the vaccinated group, resulting in a negative protective efficacy with wide CIs.[216,217] Similarly, no protective efficacy (efficacy, 8%; 95% CI, −53% to 44%) was shown in Georgia and Alabama in the 1950s.[218] All these studies have in common a high prevalence of environmental mycobacteria (see below), and multiple problems with methodology.[165,209,212]

The largest BCG field trial ever conducted commenced in 1968 in the Chingleput district of southern India, and involved 260,000 participants.[201,202] Persons of all ages except infants younger than 1 month of age, and regardless of skin test reaction, were randomized to receive one of two vaccines at one of two dosages, or to receive placebo. Follow-up continued for 10 years, with active study visits every 2.5 years. The study was confounded by bias; for example, follow-up varied among groups depending on size of the enrollment skin test reaction, age, and perception of risk. Furthermore, microbiological tests were completed on a fraction of the TB cases only; regardless, culture confirmation was the finally agreed outcome, because other outcome measures were not applied uniformly. Because of these and other shortcomings, cases among young children were probably missed. It is noteworthy that the study was conducted in a geographic area in which environmental mycobacteria are endemic. The first results were published in 1979, after 7.5 years of follow-up. Neither of the two vaccines studied, in full or reduced dosage, showed any evidence of protection against pulmonary TB, compared with that of placebo (efficacy, −5%; 95% CI, −25% to 12%).

Metaanalyses and Other Evidence of Bacille Calmette-Guérin Efficacy and Effectiveness

Colditz published the first metaanalysis of the efficacy of BCG in 1994.[219] Fourteen prospective trials and 12 case-control studies were included in the analysis. A random-effects model estimated a weighted average relative risk or odds ratio, from which protective efficacy was deducted. In prospective trials, the protective efficacy of BCG to prevent any form of TB was 51% (95% CI, 30–66%), and in case-control studies, 50% (95% CI, 36–61%). Seven trials reported on death as an end point: BCG had a protective efficacy of 71% (95% CI, 47–84%), while five studies reported meningitis and showed a protective effect of 64% (95% CI, 30–82%). BCG appeared more protective in children, especially when including only case-control studies where a positive culture or histology was used for diagnosis (83% protective; 95% CI, 38–93%).

Mangtani and associates published a very comprehensive assessment of 18 randomized trials reporting on BCG induced protection against TB, including six that reported meningitis as an outcome.[165] Both fixed-effect and random-effect models were applied in their systematic review and metaanalysis and metaregression. The overall protective efficacy of BCG against pulmonary TB was 50% (95% CI, 28–65%). Protection was highest in infants, at 69% (95% CI, 42–71%), compared with older ages. Protection against meningeal and miliary tuberculosis was 90% in infants (95% CI, 23–99%).

Roy focused on 14 studies, most with a retrospective case-control design, that addressed whether BCG could protect against *M. tuberculosis* infection in childhood, in a

TABLE 60.1 Characteristics of Trials of Bacille Calmette-Guérin Vaccination Against Pulmonary and Miliary or Meningeal Tuberculosis

Trial	Years, Start of Entry to End of Follow-Up	No. BCG Vaccinated/ No. Unvaccinated	Age at Vaccination and Tuberculin Testing Stringency, Where Applicable	Vaccine Strain
Saskatchewan Infants (Ferguson[228])[a]	1933–48	306/303	Neonatal	Frappier/Pasteur 450-S1, 468-S1
Native American (Aronson[265])[a]	1935–98	1551/1457	School age, stringent	Phipps/Pasteur 317 used at U.S. sites; Pasteur 575 used at Alaskan sites

systematic review and metaanalysis.[220] Infection was defined by a positive result using one of two types of IGRAs (enzyme-linked immunosorbent spot or QuantiFERON). The overall protective efficacy was 19% (95% CI, 8–69%). When the analysis was restricted to six studies with information on progression to active TB, BCG had a 27% effect in protection against infection (95% CI, 13–59%) and 71% against active disease (95% CI, 42–85%). Among those infected, protection against progression to disease was 58% (95% CI, 23–77%).

In the 1980s, the WHO initiated a global study using a standardized case-contact protocol to evaluate children who were household contacts of TB cases with infectious disease. The evaluation allowed an estimation of BCG efficacy; results were similar to those of the major controlled trials, with efficacy ranging from 0% to greater than 80%.[221–238] Studies that evaluated meningitis or miliary disease in children as outcomes demonstrated that BCG offers good protection.[153,198,238–243] Case-control and contact studies have the advantages of ease of conduct and lesser expense, but the potential for bias is increased.

Reasons for Variable Efficacy

The protection demonstrated in the major controlled BCG field trials ranged from 0% to 80%. In this section, variables that could have influenced the outcomes of these vaccine trials and of current vaccination practice are discussed.

Trial Methodology. It is a given that substantial variation will result from different trial designs, conducted in different time periods (between 1935 and 1975), in nine different geographic areas in three countries, by different investigators and various organizations. The role of methodologic and statistical variation among the eight major BCG trials has been evaluated critically.[205,212,244] Some authors argue that methodologic differences may have biased some of the trials and account for the variability in outcomes, whereas others believe that none

of the shortcomings could have appreciably influenced conclusions. Mangtani and associates evaluated bias in execution of studies systematically in a metaregression analysis.[165] The authors demonstrated that a lack of efficacy of BCG shown in many studies may have been the result of some sources of bias, such as diagnostic detection bias, although this finding was not consistent for all sources of bias.[165]

Vaccine Strain. At least six different vaccines were used in the trials. Thawed vaccine preparations were used in all studies except for the Chingleput trial, which used vaccine from reconstituted lyophilized vials. The differences in vaccine strains (see "Bacteriology of Bacille Calmette-Guérin Strains and Vaccine Constituents" above) are likely to have had an effect on outcome.

Environmental Mycobacteria, *Mycobacterium tuberculosis*, and Helminthic Exposure. Exposure to environmental mycobacteria may lead to tuberculin sensitization and immunity against *M. tuberculosis* and *M. bovis* BCG; environmental mycobacteria have many antigens in common with these organisms.[245] Environmental mycobacteria are endemic in tropical and subtropical regions of the world, including the southern areas of the United States, whereas human exposure to these organisms is less in Europe and northern parts of North America. Overall, BCG appears to be more protective in latitudes farther from the equator.[165] Three of the controlled trials were conducted in geographic areas where the prevalence of environmental mycobacteria was low, and these studies demonstrated the highest vaccine efficacy. In contrast, the five trials conducted in the southern United States and southern India, where the prevalence of environmental mycobacteria was high, demonstrated low vaccine efficacy.

Environmental mycobacteria may either block induction of immunity by BCG as immunity induced by the environmental mycobacteria may kill the live organism in the vaccine, or mask protection induced by BCG because protection may have been induced by the environmental organisms themselves.[246] For example, BCG-induced host responses, measured by a whole-blood IFN-γ assay or a purified protein derivative skin test, differ following BCG vaccination in the United Kingdom and Malawi; Malawi children have quantitatively greater baseline responses, whereas children from the United Kingdom demonstrate a greater increase in responses after vaccination.[189,247] This result suggests that sensitization by nontuberculous mycobacteria could inhibit immune responses to BCG vaccination.

An observer-blinded, cluster-randomized trial conducted in Brazil showed that efficacy of BCG vaccination at school-age was higher in Salvador, a coastal city where environmental mycobacterial exposure is thought to be low (efficacy, 34%; 95% CI, 7–53%), compared with Manaus, a city in the Amazon with presumed high environmental endemicity (efficacy, 8%; 95% CI, −39% to 40%).[248] In contrast, vaccine efficacy for neonatal vaccination was similar in Salvador (efficacy, 40%; 95% CI, 22–54%) and Manaus (efficacy, 36%; 95% CI, 11–53%). These findings concur with a blocking mechanism, as suggested by the Malawi/UK studies.

Although several studies suggest a possible effect of heterologous immunity from NTMs, there are major knowledge gaps in these studies. There is no qualified or reliable immunologic assay available to measure prior exposure or current infection with NTMs. Although intriguing, these previous studies were small and underpowered, focused on a limited number of immune responses—blood IGRAs or delayed-type hypersensitivity in skin—and employed whole-cell reagents rather than single proteins or peptide pools, while evaluating a limited number of NTMs in only a few regions of the world. With ongoing efforts to develop new vaccines for TB, understanding the role of NTM exposure and heterologous immune responses may be critical to success. Development of validated NTM-specific immunologic assays will be required to assess this important issue.

Evidence from animal and human studies indicates that sensitization to environmental mycobacteria provides protection against TB that is similar to that provided by BCG. In a study of 625,000 Navy recruits with serial skin testing using purified protein derivatives from *M. tuberculosis* and *Mycobacterium intracellulare*,[249] the incidence of active TB disease was lower in individuals with an *M. intracellulare* skin test result that was greater in magnitude than the *M. tuberculosis* skin test. As stated above, even *M. tuberculosis* infection appears to have a protective effect—a metaanalysis of the protective effect of latent infection against reinfection-mediated TB disease, incorporating studies from the preantibiotic era, showed a protective efficacy of approximately 80%.[39] The caveat from this observation is that many persons would have died from TB disease during the preantibiotic era, therefore skewing the results to show a positive effect on a population basis.

Other infections may also influence the BCG-induced response. For example, Ethiopian adults with latent *M. tuberculosis* and helminthic coinfection who are treated with albendazole prior to BCG vaccination demonstrated increased specific immune responses to the vaccine.[193] However, a large study in Uganda showed that treating maternal helminthic infection during pregnancy had little effect on the infant BCG-induced immune response[194] or on mycobacteria-specific immune responses in BCG-vaccinated 5-year-olds.[250] As mentioned before, the immune correlates of BCG-induced protection against TB disease are not known; consequently, results should be interpreted with caution. Interestingly, BCG vaccination may be associated with a lower helminthic infection rate.[251]

Host Genetic, Microbiotic, and Environmental Factors. The BCG trials were completed in populations that were genetically diverse. Human and animal evidence suggest that genetic factors may determine the host's response to BCG vaccines,[252–255] and therefore likely also protective efficacy. The role of genetic variation on susceptibility to mycobacterial disease and to infant immune responses to vaccination has been reviewed.[171,256,257]

The human microbiome has a significant influence of multiple health indicators; limited evidence suggests that infant microbiome constituents may also affect the BCG-induced immune response.[258]

Experimental research has demonstrated that nutritional deficiencies affect the magnitude and character of the immune response to BCG vaccination.[259–262] However, studies in humans remain controversial.[218,263]

Regional Differences in *Mycobacterium tuberculosis* Strains. There is marked heterogeneity among seven major families of *M. tuberculosis* that occur in different regions of the world.[10,264] This heterogeneity manifests in differential host responses to the pathogen, and epidemiological evidence suggests that BCG might have skewed the epidemic toward greater prominence of certain *M. tuberculosis* strains. It is therefore a reasonable hypothesis that variation among strains that occurred in different setting could have confounded results of clinical trials of BCG.

Duration of Protection and Revaccination

When Native American participants of the 1935 BCG trial were followed up for 60 years, an efficacy of 52% (95% CI,

27–69%) in protection against disease was found.[265] The results suggest that a long duration of protection from a single dose of BCG is possible. In contrast, a case-control study investigating efficacy of neonatal BCG vaccination over the first 20 years of life found 82% protection in children younger than 15 years of age, 67% protection in the 15- to 24-year-old age group, and 20% protection in persons 25 to 34 years of age, indicating better protection in younger age groups and waning immunity over time.[266] Furthermore, the kinetics of the host immune response to newborn BCG vaccination suggest that immunity is likely to be relatively short-lived.[176,181]

The practice of BCG revaccination continues in many places of the world (see above). The only large-scale efficacy trial of BCG revaccination was completed in Brazil, where school-age children received a second dose of BCG, following newborn BCG vaccination.[248] Interestingly, revaccination was poorly effective in preventing TB disease in the coastal region of Brazil, and not at all effective in the Amazon. In the coastal region, children without evidence of previous BCG vaccination showed greater protective efficacy than those who had received BCG before; the respective efficacies were 19% (95% CI, 7–53%) and 1% (95% CI, −27% to 33%). The results concur with those from a metaanalysis of BCG efficacy that suggests that prior exposure to environmental mycobacteria—presumedly high in the Amazon and low in the coastal region—and in the case of the Brazil study, prior exposure to BCG itself, results in lesser efficacy of BCG.[165]

Safety

BCG has been administered safely to billions of people throughout the world. Complications are rare, but rates of these vary depending on the skill and method of administration, the strain, dose, gender, age, and immune status of the recipient.[117,267,268] The Pasteur 1173 P2 and Danish 1331 strains induce more adverse reactions than the Glaxo 10777, Tokyo 172-1, or Moreau RDJ strains.[117] The concentration of live particles in BCG vaccines ranges from approximately 50,000 to 3 million per dose, depending on the strain; vaccines with relatively low numbers of live bacilli per dose are generally less reactogenic.[269] Women and older vaccinees are generally more likely to develop local reactions and abscesses, and vaccination at less than 6 months of age is better tolerated than after that age.[270]

Common Adverse Events in Nonimmunocompromised Persons

Local adverse reactions are common after BCG vaccination, but serious long-term complications from these are rare (Table 60.2). In summary, up to 95% of persons vaccinated with BCG develop a local reaction (Fig. 60.4). Erythema, induration, and tenderness are common. A papule that is often red, tender,

TABLE 60.2 Estimated Age-Specific Risks for Complications After Administration of Bacille Calmette-Guérin Vaccine

	Incidence per 1 Million Vaccinations	
Complication	**Age <1 y**	**Age 1–20 y**
Local subcutaneous abscess, regional lymphadenopathy	387	25
Musculoskeletal lesions	0.39–0.89	0.06
Multiple lymphadenitis, nonfatal disseminated lesions	0.31–0.39	0.36
Fatal disseminated lesions	0.19–1.56	0.06–0.72

From Lotte A, Wasz-Hockert O, Poisson N, et al. Second IUATLD study on complications induced by intradermal BCG vaccination. Bull Int Union Tuberc. *1988;63:47–59.*

Figure 60.4. Characteristic evolution of the injection sites after administration of intradermal bacille Calmette-Guérin. *(Courtesy Gregory D. Hussey.)*

and indurated may emerge 2 or more weeks after vaccination. Ulceration may follow, and if this occurs, healing takes 2 to 5 months, followed by scar formation. Ipsilateral lymphadenopathy may also occur and is usually less than 1.5 cm in greatest dimension and seen in the axilla.

A small U.S. study of healthy TST-negative adults vaccinated with BCG intradermally found that all patients developed a local reaction with erythema, induration, and tenderness at the vaccination site; 75% developed muscle soreness; and 70% had local ulceration with drainage.[271] Only 2% developed tender regional adenopathy. Overall, local ulceration and regional lymphadenitis occur in less than 1% of immunocompetent recipients who receive intradermal administration.[272] Certain BCG strains, such as the Tokyo and Moreau strains, are rarely associated with lymphadenitis, whereas this complication appears more often when the Pasteur strain is used.[272–274] Outbreaks of lymphadenitis have been reported following introduction of new BCG strains into vaccination programs[275,276]; altered administration technique may have contributed. The risk of suppurative lymphadenitis is greater among newborns than among older infants and children, especially when a full dose of vaccine is given.

A lasting cutaneous scar develops in most patients, although the likelihood is lower when vaccination is given in early infancy.[277]

The treatment of local adenitis as a complication of BCG vaccination is controversial and ranges from observation, to surgical drainage, to the administration of antimycobacterial drugs, to a combination of surgical management and medications.[278] Nonsuppurative lymph nodes usually improve spontaneously, although resolution may take several months. Several studies have shown that some children with lymphadenitis respond to a course of isoniazid of several weeks' or months' duration.[279–281] However, a metaanalysis of four randomized controlled trials revealed no significant difference in the frequency of suppuration between the treatment and control groups for the erythromycin and isoniazid treatments; the conclusion was that medical treatment does not reduce the frequency of suppuration.[282] Furthermore, a Cochrane evaluation concluded there was no evidence that antimicrobial therapy or aspiration was associated with an improved outcome.[283]

Persons with latent *M. tuberculosis* infection appear to have an accelerated adverse effect response to BCG vaccination, without any obvious difference in severity.[284] In a study of 82 South African adults, injection-site erythema (68%) and induration (86%) peaked 1 week after revaccination, whereas ulceration (76%) peaked at 2 weeks, and resolved by 3 months in all but three subjects. A residual scar was common (85%).

Rare Adverse Events

The risk of osteitis after BCG vaccination has varied from 0.01 to 300 per million doses.[267,285–288] In a controlled study of 132 former BCG osteitis patients, variant genotypes of the TLR2 and TLR6 genes were associated with a higher risk of BCG osteitis whereas TLR1 variant genotypes were associated with a decreased risk.[289]

Generalized BCG infection is extremely rare in immunocompetent patients.[290–294] Autopsy studies of children who died of unrelated causes show granulomas in various organs of vaccinated infants with apparently intact immune systems, suggesting that generalized nonfatal dissemination may occur in normal hosts.[292,295,296]

A report from Thailand described four immunocompetent neonates with fever and *M. tuberculosis* complex isolated from blood within 72 hours of BCG vaccination.[297] All infants recovered and remained healthy without treatment. One isolate was genotyped as *M. bovis* BCG, and all four infants were presumed to have had BCG bacteremia.

Treatment of extremely rare complications, including lupus vulgaris, erythema nodosum, iritis, osteomyelitis, and disseminated BCG disease, should include systemic anti-TB drugs; pyrazinamide should not be included because all BCG strains are resistant to this drug.[298]

Adverse Events in Immunocompromised Individuals

Fatal disseminated BCG disease has been reported at a rate of 0.19 to 1.56 cases per 1 million persons vaccinated.[272] Invariably, cases have occurred in patients with severe defects in cell-mediated immunity, such as those with HIV, severe combined immunodeficiency, and complete DiGeorge syndrome, but cases have also been associated with chronic granulomatous disease, malnutrition, cancer, and abnormalities of the IL-12–IFN-γ axis (genetic defects identified in IL-12p40, IL-12R, IFN-γR1,IFN-γR2, and STAT1).

Since the advent of the HIV era, it has become clear that BCG vaccination of untreated HIV-infected children places them at a dramatically increased risk of potentially severe and fatal adverse events; rates of disseminated BCG disease in this population have approached 1%.[299–301] These complications may also occur in BCG-vaccinated HIV-infected infants who are on antiretroviral therapy,[302] although early therapy reduces the risk dramatically.[303] BCG disease has also been described in a person who became infected with HIV as an adult and who had received BCG 30 years prior to becoming ill.[304]

All cases of BCG disease in HIV-infected children have followed vaccination in the neonatal period and there appears to be no clear association with particular BCG strains.[299–301] The median age of onset was 8 months (range, 3 to 35 months). Manifestations included local or regional lymphadenopathy in the majority of infants. Many cases of disseminated disease, often involving bone, nonregional lymph nodes, and multiple other organs, have been described. Disease was mostly associated with very low CD4 T-cell counts, and often occurred with other opportunistic infections. Outcome has been poor in the absence of antiretroviral therapy, even if antimycobacterial therapy is given: more than 80% of infants with disseminated disease and more than 50% of infants with local or regional disease will succumb to the disseminated infection. Antiretroviral therapy is associated with a vastly improved outcome.

HIV-exposed but uninfected infants may be at greater risk of other infectious diseases in the first year of life,[305] but no evidence of an increase of BCG-related adverse events have been reported in these infants. Variable results of immunogenicity of newborn BCG vaccination in this population has been reported[181,184]; regardless, delaying BCG vaccination to 8 weeks of age does not compromise ability of this vaccine to induce a robust immune response.[183]

Recommendations for Use

In the United States

The United States has never had a universal BCG vaccination program.[166] In the United States, TB control involves treatment of patients with disease, contact investigation, and prophylaxis for latent infection.[306,307] In this setting, BCG vaccination is considered only in special circumstances involving unavoidable continued exposure and failure to employ other methods of control. The Centers for Disease Control and Prevention's Advisory Council for the Elimination of Tuberculosis and

Advisory Committee on Immunization Practices have published guidelines for the use of BCG vaccination in young children and healthcare workers.[308] In the United States, BCG immunization should be considered for all persons with continuous exposure to MDR TB who cannot be removed from the exposure, but only if the person has a negative TST and is not infected with HIV; infants younger than 2 months of age with such exposure do not need a TST prior to vaccination. BCG should also be considered for children with continuous exposure to contagious drug-sensitive TB who cannot be removed from the exposure or treated with anti-TB therapy.

Vaccination with BCG should be considered for healthcare workers only in areas that have a high risk of transmission of MDR TB in which aggressive infection-control measures have been implemented and have failed.[308] Even in high-risk settings, BCG should not be the major method of control or protection, because the vaccine's efficacy is variable and does not protect unvaccinated patients or visitors, yet confounds TST interpretation, thereby also confounding surveillance and preventive treatment measures.

In the United States, it is recommended that local TB control authorities be contacted when BCG vaccination is considered.[309]

In Other Countries

Zwerling and associates published an atlas of global BCG vaccination policy and practices from 180 countries.[166,310] Like the United States, Canada, Italy, Belgium, and The Netherlands have never had universal BCG vaccination programs, and recommend use of the vaccine only in select cases. Ecuador, Australia, New Zealand, and Western European countries other than Belgium and The Netherlands had universal programs before, but now recommend vaccination for only select populations. The only European countries that practice universal BCG vaccination are Portugal and Ireland, and the vaccine is usually given to newborn babies.

The International Union against Tuberculosis and Lung Disease (IUATLD) has suggested criteria for countries to consider when shifting from routine universal BCG vaccination to selective vaccination of high-risk groups.[311] The IUATLD recommends that BCG be discontinued only if an efficient notification system is in place, and if either the average annual notification rate of smear-positive pulmonary TB is less than five per 100,000 population per year, or the average annual notification rate of TB meningitis in children younger than 5 years of age is less than one per 10 million population over the previous 5 years, or the average annual risk of TB infection is less than 0.1%.

It is known that BCG vaccine has some efficacy against leprosy[204] and that some countries, such as Brazil, Cuba, and Venezuela, recommend BCG vaccination for contacts of leprosy patients.[160] Widespread BCG vaccination may have contributed to the decline of leprosy in certain populations.[312,313] BCG vaccine also has a transient protective effect against *Mycobacterium ulcerans* disease, or Buruli ulcer, which manifests with skin lesions and osteomyelitis.[204] Finally, one of the most frequent indications for use of BCG in high-income countries today is for the treatment of bladder cancer by intravesicular administration, and here the vaccine has a nonspecific immunostimulant effect; it is worth noting that the supply and dose for this indication differs from that for prevention of TB.[314]

In the Setting of HIV Infection

HIV-infected persons are at increased risk of complications of BCG vaccination; this risk is mitigated by antiretroviral therapy, although not completely averted. The issues become prominent in the setting of infants born to HIV-infected mothers, where the majority of infants will be HIV-uninfected. However, the status will not be known immediately after birth, the time that BCG is given routinely in most countries. Additionally, in lesser-resourced environments, follow-up HIV testing and BCG vaccination of uninfected babies often cannot be guaranteed. Not vaccinating a significant portion of babies in countries where maternal HIV infection and TB disease is common, such as South Africa, could precipitate an epidemic of disseminated and pulmonary TB in infants.

The latest WHO recommendation and a follow-up position statement have addressed this dilemma.[315,316] BCG vaccination is now contraindicated in HIV-infected persons, including infants. The approach to HIV exposed infants depends on the existing public health structures. BCG administration should be delayed, if certain conditions are met, until HIV infection has been excluded in the baby. These conditions include a high uptake of maternal HIV testing coupled with effective prevention of mother-to-child HIV transmission strategies; early virological diagnosis of HIV infection coupled with early initiation of antiretroviral therapy; and coordination of prevention of mother-to-child HIV transmission, BCG vaccination, and TB control programs to minimize loss to follow up, implementation of alternative TB preventive strategies, and delivery of BCG vaccination following selective nonvaccination at birth. Although there have been significant advances in introduction of these programs globally, in many regions of the world, HIV-infected infants continue to receive BCG at birth.

Contraindications to Bacille Calmette-Guérin Vaccination

Contraindications vary among countries and often reflect different healthcare delivery resources available in the locale. In the United States, BCG vaccine is contraindicated for persons with impaired immunity, including patients with HIV infection, congenital immunodeficiency, leukemia, lymphoma, generalized malignant disease, and who are on suppressive corticosteroids, alkylating agents, antimetabolites, or radiation, as well as those who are pregnant.[308] Caution should also be used when administrating BCG to persons at high risk for HIV infection.

Nonspecific Effects of Bacille Calmette-Guérin

The major controlled trials that evaluated BCG-induced protection against TB in the United Kingdom and the United States in the first half of the 20th century showed an unanticipated effect: a reduction in nonaccidental deaths by 25% (95% CI, 6–41%).[317] Subsequently, observational studies, mainly conducted in West Africa, showed that BCG vaccination is associated with a 40% to 60% reduction in all-cause mortality, when compared with unvaccinated children.[318–326] The effects appear particularly prominent in the neonatal period, with a major effect on neonatal sepsis and respiratory infections.[327,328] In a randomized trial of immediate versus delayed BCG in 2343 infants in Guinea Bissau, there was no difference in the primary outcome of mortality at 6 months. Secondary analyses suggested possible mortality benefits of immediate BCG,[328] particularly in low-birth-weight infants. These results are controversial because the mortality trends were observed as early as 3 days after vaccination, there was no placebo injection, and there was a risk of allocation bias.[329] Some plausibility to the nonspecific effects of BCG has been provided by a finding that BCG induces epigenetic modifications of monocytes—the vaccine appears to "train" innate cells, which may result in protection against other pathogens.[330]

BCG may also enhance antibody responses and, in some cases, T-cell responses to other childhood vaccines, such as hepatitis B, tetanus toxoid, pertussis, and pneumococcal vaccines.[241,331–334] The mechanism of this beneficial effect is unclear.

Incomplete data suggest that BCG may also have nonspecific effects that extend to cancer and other chronic inflammatory disorders. BCG vaccination of newborns might reduce incidence of certain childhood cancers.[335] A cohort study of 542 malignant melanoma patients showed previous vaccination with BCG or vaccinia in childhood was associated with significantly longer life.[336] A large Danish case-cohort study found a beneficial effect of BCG vaccination on the risk of lymphomas.[337] Multiple observational studies have shown either a protective or no effect of newborn BCG vaccination on development of asthma. Subsequent metaanalyses show that an effect is unlikely, and if present, likely to be transient.[338,339] Furthermore, a systematic review and metaanalysis showed no association between childhood vaccination and emergence of inflammatory bowel disease,[340] although a Danish study suggested that BCG vaccination in infants younger than 4 months of age is associated with lower occurrence of the disease[341]; one of the hypothesized causes of inflammatory bowel disease is chronic mycobacterial infection.[342]

NEW TUBERCULOSIS VACCINES

Multiple modeling studies show that the global TB epidemic would be impacted significantly by interrupting transmission of *M. tuberculosis*. This may be achieved either by preventing infection or by preventing disease; preventing disease will have earlier and marginally greater impact in high-prevalence settings.[5,62,343] Although the ideal vaccine should have both effects, we do not currently know whether this is possible; regardless, TB vaccine development is shifting to add the goal of prevention of infection to that of prevention of disease.

The primary target populations should be adolescents and younger adults, and not infants; the first modern Phase IIb trial of a new TB vaccine was conducted in infants.[344] The bulk of global TB disease occurs in adolescents and younger adults.[1] These populations transmit *M. tuberculosis* and thus should be targeted for impact. In contrast, infants and children generally do not transmit the pathogen. Modeling shows that, compared with an infant vaccine, an adult vaccine would have considerably greater early impact on the epidemic and would be cost-effective, even with a relatively low efficacy and short protection duration.[6] Infants, HIV-infected persons, persons with comorbidities (e.g., diabetes mellitus), and the elderly should be included in the secondary testing of new candidates.

New Vaccines in Clinical Development

The last 15 years has seen a concerted effort toward developing novel TB vaccines that would be safe and more effective than BCG, while still being affordable and accessible to high-risk populations globally. Some of this research has been aimed at replacing BCG in infants with an improved vaccine, although it is now thought that this approach would have a limited impact on the global epidemic.[6] Rather, the focus has shifted to developing vaccines that would be delivered to adolescents and adults.

At the time of this writing, there are 16 TB vaccine candidates in clinical development globally (Fig. 60.5). The candidates include whole, live mycobacteria such as recombinant BCGs and recombinant *M. tuberculosis*, lysates of whole mycobacteria, subunit vaccines (adjuvanted recombinant proteins),

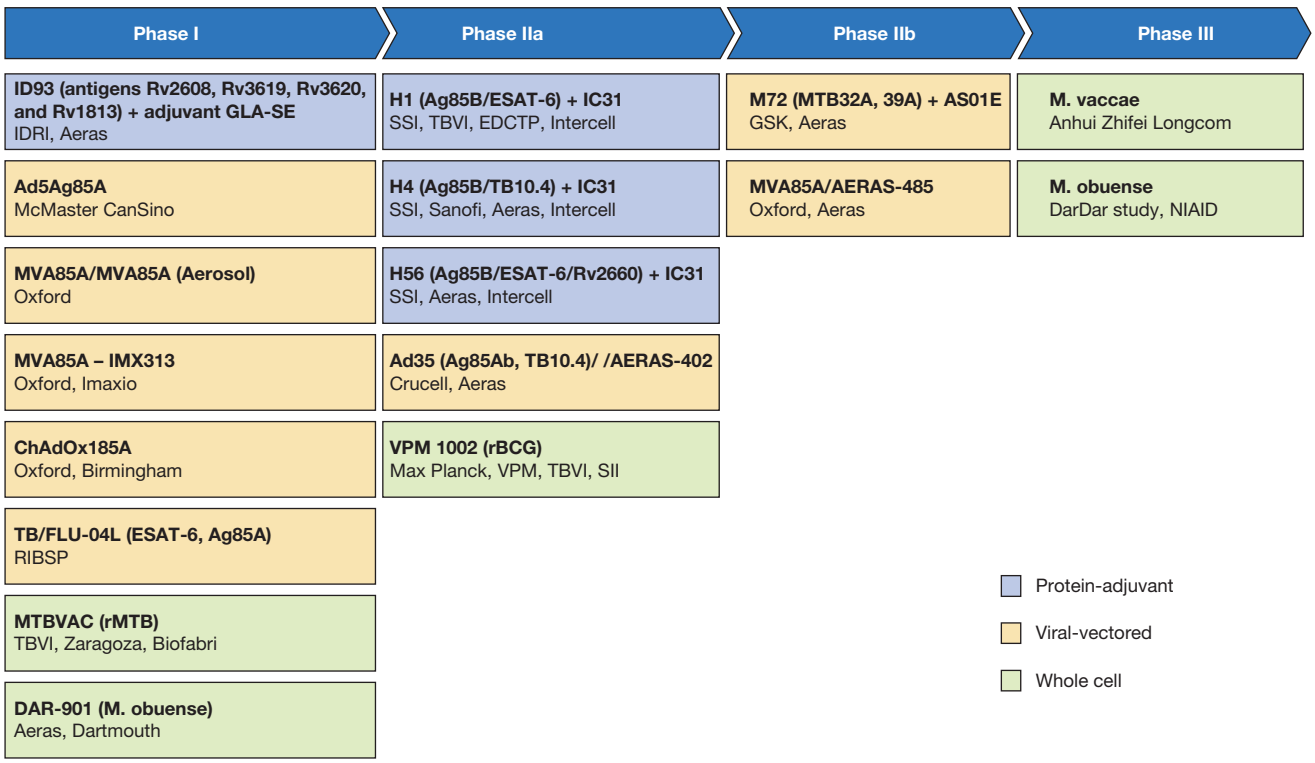

Figure 60.5. Tuberculosis vaccine candidates currently in clinical development. EDCTP, European and Developing Countries Clinical Trials Partnership; GSK, GlaxoSmithKline; IDRI, Infectious Disease Research Institute; NIAID, National Institute of Allergy and Infectious Diseases; RIBSP, Research Institute for Biological Safety Problems; SSI, Statens Seruminstitut; TBVI, Tuberculosis Vaccine Initiative.

and viral-vectored candidates.[345–348] Some efforts are also ongoing to evaluate combinations of these vaccine approaches. Two candidates have completed or are currently in Phase III testing, two candidates have completed or are currently in Phase II proof-of-concept trials, and multiple candidates are in earlier testing. Many more candidates are in preclinical product development.

Whole-Cell Vaccines

Mycobacteria other than *M. bovis* have been considered TB vaccine candidates for many years. A killed *M. tuberculosis* vaccine was studied in the 1930s and was found to have a protective efficacy of approximately 50% against disease in humans.[349] Until the modern era, only BCG and the vole bacillus (*M. microti*) have been considered seriously as candidates for vaccination. Whole mycobacterial vaccines, or vaccines derived from whole mycobacteria, are attractive since knowledge of specific antigens involved in a protective host response against TB remains limited.[350]

One whole-cell vaccine candidate, SRL172, has been tested in a Phase III trial. SRL172, thought at the time to be the environmental mycobacterium *Mycobacterium vaccae*, but more recently determined by 16S ribosomal RNA sequence to be *Mycobacterium obuense*, a close relative of *M. vaccae*, demonstrated limited efficacy against microbiologically confirmed TB in HIV-infected adults in Tanzania, when delivered as a series of five intradermal doses[351]: protection against microbiologically confirmed TB was 49% (95% CI, 4–61%). No protection was shown against disseminated TB or non–microbiologically confirmed TB. The vaccine was manufactured by a nonscalable process, but a liquid fermentation based manufacturing process was developed for this candidate. The new product, DAR901, is heat-inactivated and currently in first-in-human testing.

A heat-inactivated version of *M. vaccae*, already licensed as an immunotherapy in China (Vaccae), is currently in Phase III evaluation in China for prevention of TB in persons who are strongly TST positive, that is, with LTBI. Results are expected in 2017.

A live, attenuated *M. tuberculosis* candidate, known as MTBVAC, is currently in a Phase I trial in South Africa, after successful first-in-human testing in Europe. The candidate has two mutations—of phoP and fadD26—rendering it less virulent than BCG in immunocompromised animals.[352] Although initially developed as a replacement for BCG in infants, a shift in strategy now has this vaccine also targeted for use in adolescents and adults.

Multiple recombinant BCG candidates have emerged. The candidate in the most advanced stages of development is VPM1002, which is engineered to allow phagosomal acidification and lysosomal escape in the macrophages or dendritic cells that take up the organism, and as such potentially enhance induction of both CD4 and CD8 T-cell immunity.[353] The vaccine is currently in Phase II testing in India, on a track for BCG replacement. AERAS-422 was another recombinant BCG with a lysosomal escape mechanism, but its development was halted during its first-in-human trial because of a safety signal—two participants developed herpes zoster (Tom Evans, personal communication, 2016). rBCG30, a recombinant BCG that overexpresses antigen 85B (a 30-kDa antigen), completed a first-in-human study that demonstrated immunogenicity and an acceptable safety profile.[354] To date, the vaccine has not progressed further in development.

RUTI is a preparation of detoxified fragments of *M. tuberculosis* cells, delivered in liposomes, and being developed to prevent TB disease in persons with LTBI.[355–357] The vaccine is currently in Phase II testing.

Subunit Vaccines

The subunit vaccines currently in development contain a limited number of immunodominant *M. tuberculosis* antigens, typically as fusion proteins for ease of production, and formulated in Th1 cell-inducing adjuvants like AS01E,[358] GLA-SE,[359,360] CAF01,[361] or IC31.[362] Each of these candidates has demonstrated an acceptable safety profile, immunogenicity, and some degree of protection against *M. tuberculosis* challenge in animal models. The most advanced candidate in this category is M72/AS01E,[363–367] which is currently in a proof-of-concept Phase IIb trial, testing whether TB disease can be prevented in latently infected, HIV-negative adults in Africa. Another subunit vaccine, H4:IC31,[368] is currently in a proof-of-concept Phase II trial, testing whether *M. tuberculosis* infection can be prevented in adolescents without LTBI.

Virally Vectored Candidates

Viral vectors being developed as platforms for antigen delivery in TB vaccines include modified vaccinia Ankara (in the vaccine MVA85A),[344,369–375] influenza (TB/FLU-04L), and several human and chimpanzee adenoviruses (Ad5/Ag85[376] and Ad35/AERAS-402).[377–380] Most platforms contain attenuated, live, and replication-deficient viruses, and each of the clinical candidates express an antigen from the immunodominant *M. tuberculosis* antigen-85 complex, either as the sole antigen or in combination with one or more additional *M. tuberculosis* antigens.

MVA85A was evaluated recently in a Phase IIb trial in infants in South Africa, testing whether TB disease could be prevented if the vaccine is given as a boost at 4 months of age, following BCG vaccination at birth.[344] MVA85A induced a modest immune response in the infants and failed to show efficacy beyond that of BCG alone, leaving open the question of whether it was the nature or the magnitude of the induced immune response that was inadequate for protection. MVA has also been evaluated in a Phase II trial of HIV-infected persons, primarily assessing safety and immunogenicity, with disease prevention as an underpowered secondary end point. Although the safety profile was acceptable, and immunogenicity was shown, no protection was demonstrated. More recently, a combination approach of one or two doses of an adenovirus-vectored antigen-85A–expressing candidate followed by a single dose of MVA85A demonstrated robust $CD4^+$ and $CD8^+$ immune responses (Tom Evans, personal communication, 2016).

New Concepts in Vaccine Development

Targeting Different Immunological Compartments

The current portfolio of new TB vaccines in clinical trials relies on induction of a relatively narrow immune repertoire–classical major histocompatibility complex (MHC) class II–restricted Th1 CD4 cells, and in some cases, classical MHC class I–restricted CD8 T cells—so-called conventional T cells. (Whole mycobacterial candidates may be the exception.) This paradigm could be challenged, as one possible explanation of the MVA85A trial results is that CD4 T-cell immunity to 85A was insufficient to confer protection in newborns, compared with BCG alone (see above). However, it is not clear whether it was the quantity or the nature of the induced immune response that was inadequate. Furthermore, the immunodominant antigens/epitopes in current vaccines appear conserved across global TB strains, suggesting there may be benefit of the vaccine-induced T-cell responses for the TB pathogen.

In a paradigm shift, the field is moving toward developing vaccines that address immunological hypotheses other than that a conventional T-cell response is essential for protection.[381,382] The new approaches focus on eliciting a response in immunological compartments other than conventional T cells, or inducing responses to diverse classes of antigens. The immunity induced by new approaches could differ from that which occurs in the natural setting; many examples of vaccines that induce "unnatural immunity" already exist (e.g., natural infection with *Clostridium tetani* does not induce long-lived protection, whereas vaccination with tetanus toxoid does, and protein conjugation of various polysaccharide vaccines affords immune memory that does not occur when children younger than 2 years of age are immunized with the polysaccharide alone).

Induction of nonconventional immunity includes induction of antibodies, traditionally not thought to play a major role in protection against intracellular bacteria such as *M. tuberculosis*, but which may play a role in prevention of infection, rather than disease.[62] Other examples of induction of nonconventional immunity include exploitation of antigen presentation that is less polymorphic, involving molecules such as CD1, HLA-E, and MR1, or use of novel antigen classes, such as glycolipids or phosphoantigens. The cells targeted include CD1-restricted T cells, γδ T cells, and mucosal-associated invariant T cells.[381,382] Finally, preliminary results using an attenuated live replicating cytomegalovirus vector suggest that novel classes of T cells (e.g., HLA-E restricted CD8 T cells and MHCII restricted CD8 T cells) are elicited and that these may contribute to protection against TB, as has been suggested for HIV (Louis Picker, personal communication, 2016).

Antigen Selection

It is not known which antigens in the *M. tuberculosis* genome are responsible for host responses associated with protection. *M. tuberculosis* may hyperconserve immunodominant antigens, presumably to its own pathogenic advantage,[383,384] which has motivated the selection of nondominant antigens for a number of next-generation TB vaccine candidates. This is an area of active research.

Targeting the Lung in Vaccination

Preclinical data suggest that mucosal vaccination against TB elicits lung and systemic immunity that differs from that induced by parenteral vaccination, and in some cases, elicits enhanced protection. Furthermore, knowledge is emerging about so-called tissue-resident memory T (T_{RM}) cells,[385,386] which express receptors that allow homing to the lung, where they live for extended periods. (Classical central memory or long-lived T cells have receptors that allow preferential homing to lymph nodes.[387]) T_{RM} cells are thought to be particularly important for protection against pulmonary pathogens, and may be induced preferentially through mucosal vaccination approaches. New approaches in the field aim at defining the role of these cells in protection against TB. Overall, a strong rationale is proposed for developing aerosol vaccination approaches, which are currently being tested.[370,388]

61 Typhoid Fever Vaccines

Myron M. Levine

HISTORY OF THE DISEASE

Typhoid fever is an acute generalized infection of the mononuclear phagocyte system, intestinal lymphoid tissue, and gallbladder caused by *Salmonella enterica* serovar Typhi. A broad spectrum of clinical illness can ensue, with more severe forms being characterized by persisting high fever, abdominal discomfort, malaise, and headache. In the preantibiotic era, the disease ran its course over several weeks and was accompanied by a case-fatality rate of approximately 10% to 20%. Before the first quarter of the 19th century, typhoid fever was not recognized as a distinct clinical entity and was often confused with other prolonged febrile syndromes, particularly typhus fever of rickettsial origin. There is considerable debate over who first clearly differentiated typhus fever from typhoid (i.e., typhus-like) fever. Medical historians have argued over who should receive credit for this clinical clarification, and it has been variously bestowed on Huxham (1782),[1] Louis (1829),[2] Gerhard (1837),[3] and Schoenlein (1839).[4] Gerhard, in Philadelphia, argued that two similar, yet distinct, febrile illnesses existed that were clearly discernible from one another on the basis of pathologic findings; one (typhoid) manifested marked intestinal lesions. Schoenlein referred to two distinct forms of typhus: "exanthematicus" and "abdominalis." However, William Jenner is responsible for definitively dispelling controversy on the subject.[5,6] He provided precise clinical descriptions and observations of pathologic conditions from postmortem examinations that allowed a clear-cut differentiation between the two illnesses. Jenner argued that the pathologic lesions in Peyer patches and mesenteric lymph nodes were peculiar to typhoid and were never seen with typhus. In 1847, the term *enteric fever* was introduced in an attempt to replace "typhoid fever" and avoid confusion with "typhus."[7] Although this term is frequently used, it has by no means replaced the appellations typhoid fever and paratyphoid fever in common usage.

William Budd's book, *Typhoid Fever: Its Nature, Mode of Spreading and Prevention*, published in 1873,[8] was a milestone in epidemiology because it clearly described the contagious nature of the disease and incriminated transmission via fecally contaminated water sources years before the causative organism was identified. Eberth (1880)[9] visualized the causative bacilli in tissue sections from infected patients, and Gaffky (1884)[10] grew it in pure culture. Known in earlier years as *Bacillus typhosus, Eberthella typhosa, Salmonella typhi*, and *Salmonella typhosa*, it is currently referred to as *S. enterica* serovar Typhi (*Salmonella* Typhi).[11,12] *S. enterica* Paratyphi A and Paratyphi B (and uncommonly Paratyphi C) also cause enteric fever (paratyphoid fever), which is clinically indistinguishable from typhoid fever.

Inactivated (heat-killed, phenol-preserved) *S.* Typhi was used as a parenteral vaccine as far back as 1896 by Pfeiffer and Kolle[13] in Germany and by Wright in England.[14] Wright administered his vaccine (three doses 2 weeks apart) to two medical officers in the Indian Army, one of whom thereafter ingested wild typhoid bacilli without developing illness.

Wright then evaluated his vaccine in 2835 volunteers in the Indian Army.[15] Although local and generalized adverse reactions were common, his results were considered to be sufficiently encouraging for a decision to be made to vaccinate troops embarking for the Boer War in South Africa. Outcry over the frequency of adverse reactions led to a suspension of vaccination. However, on Wright's insistence, a board of inquiry was established to review data on the reactogenicity and efficacy of the vaccine. The committee concluded that the vaccine was efficacious and that its value in preventing typhoid fever exceeded the price paid in adverse reactions. By World War I, typhoid vaccination became virtually routine in the British Army.

WHY TYPHOID FEVER IS IMPORTANT

The transmission of typhoid fever is fostered where sanitation is primitive and water supplies are not treated, and where there exist chronic or short-term carriers of *S.* Typhi who serve as a reservoir of infection. In such situations, human fecal material can contaminate water supplies. In most endemic areas, the peak incidence of clinically recognizable, bacteriologically confirmed typhoid fever detected by passive surveillance is typically observed among school-age children. Typhoid constitutes the main enteric disease threat faced by children in developing countries after they have survived the gauntlet of diarrheal and dysenteric infections encountered during their first 5 years of life.[16]

Because the case-fatality rate in the preantibiotic era was 10% to 20%, typhoid fever was a much-feared disease. Following the discovery in 1948 that chloramphenicol (and subsequently certain other antibiotics) can successfully treat typhoid fever,[17] dropping the case-fatality rate to well below 1%, the interest in typhoid vaccines became a weathervane for the prevalence of antibiotic-resistant strains of *S.* Typhi. Interest in vaccines waned as long as effective and inexpensive oral antibiotics were available, only to resurge when resistant strains appeared and rendered treatment ineffectual. Beginning about 1990, strains of *S.* Typhi that exhibited plasmid-encoded resistance to all the oral antibiotics that were the mainstays of therapy in the 1970s and 1980s (chloramphenicol, trimethoprim-sulfamethoxazole, and amoxicillin) began to disseminate throughout Asia and northeast Africa.[16,18–22] This emergence of multiple-antibiotic–resistant typhoid during the last decade of the 20th century led to an increase in the incidence of severe cases, hospitalizations, and complications, and to an increase in typhoid mortality.[16,18–20,22]

CLINICAL DESCRIPTION OF TYPHOID FEVER

Typhoid fever exhibits a wide range of clinical severity. Classic full-blown cases begin with malaise, anorexia, myalgia, fever that increases in stepwise fashion to reach 39°C to 40°C, abdominal discomfort, and headaches.[23–25] A bronchitic cough is common in the early stage of illness. The fever often follows three stages. Initially, the temperature rises gradually, in stepwise fashion, by daily increments of 0.5°C to 1°C until, after 5 to 7 days, a sustained temperature of 39°C to 41°C is present. Without appropriate antimicrobial therapy, the fever remains at this level for approximately 10 to 14 days. With convalescence, the fever diminishes, also in stepwise fashion, over several days. During the period of sustained fever,

approximately 20% of white patients manifest an exanthem (so-called rose spots) consisting of subtle, salmon-colored macules, 2 to 4 mm in diameter, which blanch with pressure. Rose spots are seen most often on the chest, abdomen, and back; *S.* Typhi can be cultured from rose spots.[26] Constipation or loose stools may occur in older children and adults, whereas diarrhea is the more common bowel pattern alteration in young children with typhoid fever.

The peripheral leukocyte count in typhoid fever is often below 4500/mm^3, which helps in the differential diagnosis. Thrombocytopenia is also common, with platelets dropping to less than 80,000/mm^3. Liver dysfunction, as detected by mildly elevated serum transaminase values, is observed in most patients. Before the availability of fluoroquinolone antibiotics such as ciprofloxacin, approximately 10% of patients treated with earlier antimicrobials of choice, such as chloramphenicol, trimethoprim-sulfamethoxazole, or amoxicillin, manifested clinical relapses; notably, the clinical illness in relapse is much milder.

A particularly severe form of typhoid fever is occasionally encountered in which cerebral dysfunction—including obtundation, delirium, and coma—and shock are present.[27] In the 1970s and 1980s, this severe form of typhoid was encountered not infrequently on the Indonesian island of Java. Unless steroid therapy accompanies appropriate antimicrobial therapy in patients suffering from this severe form of the disease, the case-fatality rate can exceed 20%.[27]

Although infants may manifest severe clinical forms of typhoid fever, bacteremic *S.* Typhi infection in children younger than 2 years of age is often remarkably mild and is not recognized clinically as enteric fever but rather as a nondescript febrile syndrome.[28,29]

COMPLICATIONS OF TYPHOID FEVER

Complications may affect virtually any organ system. Two feared complications of typhoid fever, intestinal perforation and hemorrhage, are a consequence of the intestinal lesions that are prominent in the pathology of *S.* Typhi infection. These complications occur in approximately 0.5% to 1.0% of cases and are more common in persons who have been ill for several weeks without proper antibiotic therapy. Other uncommon complications of typhoid fever include typhoid hepatitis, empyema, osteomyelitis, and psychosis. More rarely, arthritis, meningitis, myocarditis, and empyema of the gallbladder can occur. Approximately 2% to 5% of patients with typhoid fever, depending on age and sex, become chronic gallbladder carriers of the organism.[30,31] More rarely, chronic renal or bladder carriers occur, the latter in patients harboring *Schistosoma haematobium* or *Schistosoma mansoni* bladder coinfection.

BACTERIOLOGY

Taxonomy in the genus *Salmonella* continues to evolve and can be confusing. Originally, speciation was based on association with distinct clinical syndromes. With the Kauffman-White serologic classification, each distinct O:H serotype was given species status, a situation that rather quickly became ponderous. In 1980, the Approved Lists described five species: *Salmonella enteritidis, S. typhi, Salmonella* Typhimurium, *Salmonella choleraesuis,* and *Salmonella arizonae*.[32] The most recent classification and speciation, based on DNA relatedness and molecular analysis, reduces the genus *Salmonella* to two species, *S. enterica* and *Salmonella bongori*. *S. enterica* is further subdivided into subspecies designated with Roman numerals.[11,12,33] Serotypes in *S. enterica* subspecies I are still almost always referred to by their previous genus and species designations. Thus, for example, to avoid confusion, *S. enterica* serovar Typhi continues to be referred to in most international journals of microbiology, infectious diseases, epidemiology, and vaccinology as *Salmonella* Typhi; use of a capital letter without italics indicates that Typhi designates a serovar, not a species. Following the most current taxonomy, *Salmonella* Typhi (abbreviated *S.* Typhi) is the terminology that will be used in this chapter.

Serologically, *S.* Typhi falls into group D *Salmonella* on the basis of its immunodominant lipopolysaccharide (LPS) O antigen 9.[34] *S.* Typhi is motile, and its Phase I peritrichous flagella bear flagellar (H) antigen d, which is also encountered in approximately 80 other bioserotypes of *Salmonella*.[34] Occasional isolates from Indonesia have flagella that bear other antigens (j and z66).[35,36] Strains freshly isolated from patients express on their surface a polysaccharide capsule, the Vi (for virulence) antigen.[34,37–40] Vi consists of a homopolymer of repeating unit (1 → 4) α-D-galacturonic acid that is 40% to 80% O-acetylated at the C3 position[41,42]; the presence of Vi prevents O antibody from binding to the O antigen.[38] There is evidence that each of the antigens O, Vi, and H, plays a protective role with certain typhoid vaccines.

At the level of the clinical microbiology laboratory, *S.* Typhi exhibits a remarkable degree of homogeneity, in comparison with the other species of *Salmonella*. *S.* Typhi rarely exhibits biochemical or serologic variability. One exception is found in Indonesia, where a few percent of isolates bear flagellar antigen j or z66 rather than d. Previously, only phage typing using Vi phages, pulsed-field gel electrophoresis, and ribotyping were helpful in differentiating strains from different geographic areas.[43–46] Currently, partial- and full-genome high-throughput sequencing have revolutionized the ability to differentiate *S.* Typhi strains from diverse sources.[47–52] *S.* Typhi does not ferment lactose; it produces hydrogen sulfide (H_2S), but does not produce gas. As a consequence, suspect colonies are evident on usual lactose-containing media such as *Salmonella-Shigella* agar or MacConkey agar as lactose-negative colonies. The biochemical pattern in triple-sugar iron agar is rather characteristic, manifested by an acid butt without gas, an alkaline slant, and obvious H_2S production. Fresh isolates typically agglutinate with Vi but not necessarily with group D antiserum. However, if the bacteria are boiled to remove the Vi capsule that overlies the LPS O antigen, a reaction with group D antiserum is readily seen. Fig. 61.1 is a diagrammatic representation of the relationships among the O (cell wall), Vi (capsular polysaccharide), and H (flagellar) antigens of *S.* Typhi.

The complete sequences of the approximately 4.8 million base-pair (bp) genomes of multiple-antibiotic–resistant *S.* Typhi strain CT18[47] and of antibiotic-sensitive strain Ty2[49] have been reported. Approximately 70% to 80% of the genome shares a backbone containing genes similar in sequence and order to those in *Escherichia coli* and other salmonellae. Intermittently along this backbone are clusters of *S. enterica*–specific and *S.* Typhi–specific genes (i.e., genes not found in *S.* Typhimurium or other *S. enterica* serovars) and more than 200 pseudogenes (including several that play a role in virulence in *S.* Typhimurium). In addition to the 218,150-bp plasmid encoding antibiotic resistance in CT18, another 106,516-bp plasmid was found that shows common derivation with the pFra virulence plasmid of *Yersinia pestis*.[47,48]

PATHOGENESIS

Pathogenesis of Acute Typhoid Fever

S. Typhi and *S.* Paratyphi A and *S.* Paratyphi B are highly invasive bacteria that pass through the intestinal mucosa of humans rapidly and efficiently to eventually reach the

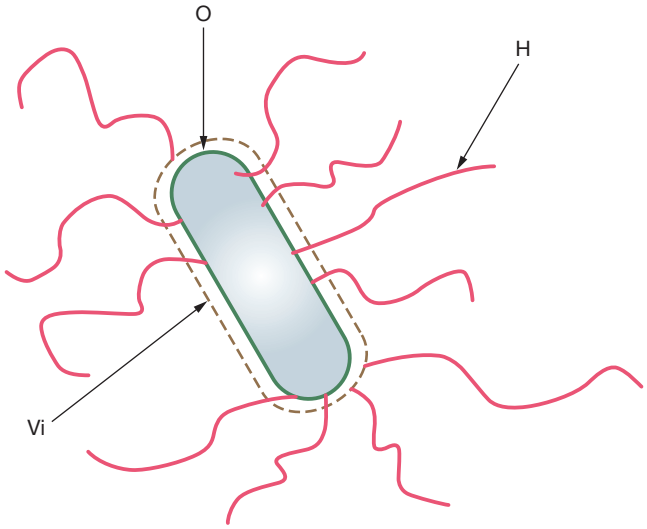

Figure 61.1. Demonstration of the locations of the O, Vi, and H antigens of *Salmonella* Typhi. The specific O antigen immunodominant epitope (epitope 9) that characterizes *S.* Typhi as falling in *Salmonella* group D consists of a tetrasaccharide repeat, wherein the dideoxyhexose sugar tyvelose is linked to a mannosyl-rhamnosyl-galactose backbone. Further internally, these O tetrasaccharide repeats are linked to core sugars, which are further linked to cell wall lipid A components. A capsular polysaccharide, the Vi antigen, overlies the O antigen. Peritrichous flagella emanating from the bacteria carry protein H antigen d in the case of *S.* Typhi (with a few exceptions from Indonesia that exhibit flagellar antigen z66).

reticuloendothelial system, where, after an 8- to 14-day incubation period, they precipitate a systemic illness.[53] *S.* Typhi is a highly host-adapted pathogen; humans comprise the only natural host and reservoir of this infection.

Comprehension of the steps involved in the pathogenesis of typhoid fever comes from four sources: (1) clinicopathologic observations in humans,[54,55] (2) volunteer studies,[56,56a–c] (3) studies of a chimpanzee model,[57,58] and (4) analogies drawn from *S.* Typhimurium and *Salmonella* Enteritidis infection in mice (the "mouse typhoid" model).[59,60] The following is a summary of the probable steps in the pathogenesis of *S.* Typhi infection in humans.

Susceptible human hosts ingest the causative organisms in contaminated food and water. The inoculum size and the type of vehicle in which it is ingested greatly influence the attack rate for typhoid fever and also affect the incubation period. Dosages of 10^9 and 10^8 pathogenic *S.* Typhi ingested by volunteers in 45 mL of skim milk induced clinical illness in 98% and 89% of persons, respectively; dosages of 10^5 organisms caused typhoid fever in 28% to 55% of volunteers, whereas none of 14 subjects who ingested 10^3 organisms without buffer developed clinical illness.[56]

A modern typhoid model was able to lower the inoculum of *S.* Typhi needed to cause clinical illness and bacteremia by administering the organisms with sodium bicarbonate to neutralize gastric acid.[61] Inocula of 10^3 or 10^4 typhoid bacilli evoked illness in 55% and 65% of volunteers, respectively.[61] When the ingested typhoid bacilli pass through the pylorus and reach the small intestine, they rapidly penetrate the mucosal epithelium by one of two mechanisms to arrive in the lamina propria. One mechanism of invasion involves typhoid bacilli being actively taken up by M cells,[62–64] the dome-like epithelial cells that cover Peyer's patches and other organized gut lymphoid tissue. From here they enter mononuclear and dendritic cells in the underlying lymphoid tissue. In a distinct second invasive mechanism, bacilli are believed to be internalized by enterocytes, wherein they enter membrane-bound vacuoles, which pass through the cell and ultimately release the organisms at the basal portion of the cell without destroying the enterocyte. Takeuchi provided a highly descriptive electron-photomicrographic documentation of the analogous passage of *S.* Typhimurium through intestinal mucosa.[65] A third paracellular mode of entry also has been proposed.[66]

On reaching the lamina propria in the nonimmune host, typhoid bacilli elicit an influx of macrophages that ingest the organisms but are generally unable to kill them. Some bacilli apparently remain in macrophages of the small intestinal lymphoid tissue. Other typhoid bacilli are drained into mesenteric lymph nodes, where further multiplication and ingestion by macrophages take place. Shortly after invasion of the intestinal mucosa, a primary bacteremia is believed to take place in which *S.* Typhi organisms are filtered from the circulation by fixed phagocytic cells of the mononuclear phagocyte system. It is believed that the main route by which typhoid bacilli reach the bloodstream in this early stage is by lymph that drains from mesenteric nodes to eventually reach the thoracic duct and then the general blood circulation. It is conceivable that ingestion of a massive inoculum followed by widespread invasion of the intestinal mucosa could result in rapid and direct invasion of the bloodstream. As a result of this primary bacteremia, the pathogen rapidly attains an intracellular haven throughout the organs of the reticuloendothelial system, where it resides during the incubation period (usually 8 to 14 days) until the onset of clinical typhoid fever.

Clinical illness is accompanied by a fairly sustained secondary bacteremia. In their report of experimental *S.* Typhi challenge studies in volunteers, Hornick and colleagues described one volunteer who began a 7-day course of oral chloramphenicol only 1 day after ingesting pathogenic *S.* Typhi, and who developed clinical typhoid fever 9 days after the antibiotic was discontinued.[56] This report provides evidence that the typhoid bacilli have attained their intracellular haven within 24 hours after ingestion.[56]

The Vi antigen is a virulence property.[37,40,67] Felix and Pitt, who originally described and named the antigen, showed that Vi antigen enhanced the pathogenicity of *S.* Typhi for mice.[37,67] Virtually all strains freshly isolated from patients possess this polysaccharide capsule. Both epidemiologic observations and studies in volunteers support the contention that *S.* Typhi strains that possess Vi are more virulent than strains lacking this polysaccharide.[56] Nevertheless, Vi-negative strains have caused typhoid fever when fed to volunteers.

A *S.* Typhi toxin has been described, but its role in pathogenesis is not yet defined.[68,68a]

Pathogenesis of the Chronic Typhoid Carrier State

During the primary bacteremia that follows ingestion of typhoid bacilli and seeds the mononuclear phagocyte system, organisms also reach the gallbladder, an organ for which *S.* Typhi has a remarkable predilection. After intravenous inoculation, *S.* Typhi rapidly appear in the gallbladder of rabbits.[69,70] *S.* Typhi can be readily cultured from bile or from bile-stained duodenal fluid in patients with acute typhoid fever.[71–74] In approximately 2% to 5% of patients, the gallbladder infection becomes chronic.[30,31] The proclivity to become a chronic carrier is greater in female patients and increases with age at the time of acute *S.* Typhi infection, thereby resembling the epidemiology of gallbladder disease. The infection tends to become chronic in persons who have a preexisting pathologic gallbladder condition at the time of acute *S.* Typhi infection.

DIAGNOSIS

Bacteriologic Diagnosis

Confirmation of the diagnosis of typhoid fever requires recovery of *S.* Typhi from a suitable clinical specimen. Because of practicality and relative ease of access, multiple blood cultures should be obtained from patients in whom the diagnosis is suspected clinically. The rate of recovery of *S.* Typhi in blood cultures depends on many factors, including the volume cultured, the ratio of the volume of blood to the volume of culture broth in which it is inoculated (ideally, the ratio should be at least 1:8), the inclusion of anticomplementary substances in the medium (such as sodium polyanetholsulfonate or bile), and whether the patient has already received antibiotics to which the *S.* Typhi is sensitive. With three 5-mL blood cultures, *S.* Typhi can be recovered from the blood in approximately 70% of suspected cases.

The gold standard of bacteriologic confirmation of typhoid fever is the bone marrow culture, which is positive in 85% to 96% of cases, even when the patient has received antibiotics.[26,75] In the 1980s, great interest was shown in the use of duodenal string devices to obtain bile-stained duodenal fluid for culture.[70–72,74] The combination of a duodenal string and two blood cultures provides a sensitivity of bacteriologic confirmation equal to that achieved with bone marrow cultures but without the invasiveness of the latter.[71] Stool cultures lead to recovery of the organism in only 45% to 65% of cases, with a somewhat higher yield in children.[72]

Serodiagnosis of Typhoid Fever

Serodiagnosis of typhoid fever has been attempted since the late 19th century, when Widal and Sicard (1896),[76] among others,[77,78] showed that the serum from patients with typhoid fever agglutinated typhoid bacilli. The Widal test, still practiced today in many areas, involves the search for agglutinins in the patient's serum and may be performed with antigen in tubes or on slides; the former is generally more accurate. By careful choice of antigen, both O and H antibodies can be selectively measured. By use of *S.* Typhi strain 0901, which lacks flagellar and Vi antigens, *S.* Typhi O antibody can be selectively measured. To detect antibodies against the appropriate H antigen (d), a strain such as *Salmonella* Virginia is selected that possesses the identical Phase I flagellar antigen (d) but shares no O somatic antigens with *S.* Typhi.[79] Most patients with typhoid fever have elevated levels of O and H antibody at the time of onset of clinical illness.[79,80] Anderson[81,82] and Anderson and Gunnell[83] emphasized the importance and usefulness of H titers in serodiagnosis of typhoid fever. However, others reported that the prevalence of H antibodies in adults living in endemic areas is too high for the test to be useful in that age group.[79] Nevertheless, it can be helpful in diagnosing children younger than 10 years of age in endemic areas and persons of any age from nonendemic areas.[79] A history of inoculation with parenteral killed whole-cell vaccines invalidates the Widal test. One report showed optimistic results for use of the slide test for O agglutinins of *S.* Typhi, even for adults in endemic areas.[84] Several relatively simple commercial serodiagnostic kits exist for detecting antibodies to *S.* Typhi O antigen and to a 50-kDa outer membrane protein antigen.[85–88]

Serologic tests to measure Vi antibody using highly purified Vi antigen are available.[89–91,91a] Although measuring the titer of serum Vi antibody is practical for the detection of chronic *S.* Typhi carriers, most of whom have highly elevated titers of Vi[91] antibody, it is of little help in diagnosing acute typhoid fever because only a minority of patients with acute infection manifest detectable Vi antibody.

Rapid Immunoassays

Many attempts have been made to develop tests that detect *S.* Typhi antigens or nucleic acid in blood, urine, or body fluids, thereby providing a rapid diagnostic test for typhoid fever.[92–104] With few exceptions, these tests have failed to warrant the enthusiasm of the initial reports. The immunoassays are based on the detection of the O, Vi, or other antigens of *S.* Typhi in blood or urine using coagglutination, enzyme-linked immunosorbent assay (ELISA), or countercurrent immunoelectrophoresis. The polymerase chain reaction methods attempt to amplify *S.* Typhi genes. These assays aim to be more sensitive, practical, economical, and rapid than bacteriologic culture, yet comparably specific. So far, no assay has adequately accomplished these objectives, and a satisfactory test that might replace bacteriologic culture remains a laudable but elusive goal.

TREATMENT WITH ANTIMICROBIALS

Treatment of Acute Typhoid Fever

The hallmark report of Woodward and colleagues[17] in the late 1940s first showed that the antibiotic chloramphenicol could drastically ameliorate the severity of clinical illness and drop the case-fatality rate to less than 1% (with early initiation of therapy). Several reviews summarize current treatment.[105–107] If it is known, or is likely, that strains are sensitive, oral ciprofloxacin is highly effective. In developing-country situations, where the cost of therapy is a critical factor, amoxicillin and trimethoprim-sulfamethoxazole remain useful oral drugs if prevalent strains are sensitive. In the face of resistance to ciprofloxacin and other oral fluoroquinolones, oral azithromycin and parenteral ceftriaxone are highly effective.

Treatment of the Chronic Carrier State

Before the appearance of fluoroquinolone antibiotics, to achieve a high cure rate in the treatment of chronic biliary carriers of *S.* Typhi, it was necessary to perform cholecystectomy followed by several weeks of intravenous ampicillin or oral amoxicillin plus probenecid. When ciprofloxacin and norfloxacin became available, it was found that 4 weeks of oral therapy without surgical removal of the gallbladder could successfully treat 90% of chronic carriers despite the presence of gallstones.[108,109] The fact that these oral bactericidal antibiotics are highly concentrated in bile led to these hallmark clinical results.

EPIDEMIOLOGY

Incidence and Prevalence Rates

In endemic areas, using passive surveillance that detects patients sufficiently ill to seek healthcare, a characteristic age-specific incidence of typhoid fever is typically seen with a very low incidence in infants younger than 1 year of age, a low or moderate incidence in preschool-age children 2 to 4 years of age, a peak incidence in school-age children (5 to 19 years), and a low incidence in adults older than 35 years. The apparent low incidence in infants relates in part to decreased exposure to vehicles of transmission, and the clinical consequence of *S.* Typhi infection in the infant host is often mild or atypical illness, even in the face of bacteremic infection.[28,29] Recent evidence based on systematic collection of blood cultures from febrile children (mainly detected during active household surveillance visits or when children seek care at ambulatory healthcare facilities) suggests that in some countries in

Asia, bacteremic *S.* Typhi infection in children 1 to 4 years of age may be much more common than previously appreciated.[110–115] Moreover, in some areas of South and Southeast Asia, high incidences of typhoid fever in preschool children have been recorded through passive surveillance.[116,117] It is assumed that in developing countries with primitive conditions of human waste disposal and widespread contamination of water supplies, water represents the most common vehicle of transmission, and that the number of organisms ingested is usually small. Thus, multiple subclinical and mild infections are believed to occur for each full-blown clinical case. In contrast, in more-developed countries with good sanitation, typhoid is transmitted when chronic carriers contaminate food vehicles through a breakdown in proper practices of personal and food hygiene. In these common-source foodborne outbreaks, the inocula ingested are presumably often relatively large, and high attack rates ensue; under these conditions, fewer subclinical cases occur.

It is difficult to quantify the magnitude of the typhoid fever problem worldwide because the clinical picture is confused with that of many other febrile infections (including paratyphoid), and the capacity for routine bacteriologic confirmation is absent in most areas of the less-developed world.[118–120] Nevertheless, incidence data are available from two sources. First, in the course of several vaccine field trials carried out from 1980 to 2011 in Latin America, Asia, and Africa, it was possible to confirm the incidence of typhoid fever that occurred in the unimmunized control subjects during several years of surveillance. In these trials, high annual typhoid fever incidence rates per 105 person-years of observation (PYO) were recorded, including 810/105 PYO in Indonesia,[121] 653/105 PYO in Nepal,[122] 470/105 PYO in South Africa,[123] 227/105 PYO in Chile,[124] 375/105 PYO in Vietnam,[125,126] 255/105 PYO in India,[127] and 210/105 PYO in Pakistan.[128] The method of surveillance in Chile, Indonesia, India, and Pakistan was passive and detected only those patients ill enough to seek attention at healthcare facilities. In contrast, the surveillance methods in the Nepal, South Africa, and Vietnam field trials included active case detection with household visits to look for febrile patients (in South Africa this was in addition to a passive surveillance system); subsequent follow-up (months 28 to 46) in the Vietnam trial involved passive surveillance.[126] Second, population-based studies to measure the incidence of bacteriologically confirmed typhoid fever, based on passive treatment facility–based surveillance, have been carried out in the last decade of the 20th and the first decade of the 21st century in Karachi, Pakistan[113,116]; Kolkata, India[116,129]; Mekong Delta, Vietnam[117]; North Jakarta, Indonesia[116]; and China.[116,130]

Seroepidemiologic studies that measure the prevalence of *S.* Typhi H antibody have been very useful in quantifying the prevalence of typhoid fever in different geographic areas.[79,118,131] However, this seroepidemiologic technique has not been widely applied.

The emergence in South Asia of paratyphoid fever caused by multiple-antibiotic–resistant *S.* Paratyphi A poses a challenge for both indigenous populations[132,133] and travelers[134] to this region from industrialized countries, because currently there are no licensed paratyphoid vaccines, and licensed oral Ty21a and parenteral Vi typhoid vaccines do not offer cross-protection.

RISK GROUPS

Three populations are at particularly high risk of developing typhoid fever and would benefit from immunoprophylaxis with a safe, effective, inexpensive, and practical vaccine. These include children in endemic areas,[28,79,110,112,113, 115–117,129,135–137] travelers and military personnel from industrialized countries who visit endemic areas in less-developed countries,[138–142] and clinical microbiology technicians.[143–145]

Seroepidemiologic studies in Peru and Chile in the 1970s (when typhoid was highly endemic in those countries) showed that by 15 to 19 years of age, 50% to 80% of teenagers had serologic evidence of past infection with *S.* Typhi.[79,118,131] In endemic areas, typhoid fever is a major cause of absenteeism from school and from employment. Direct expenditures for hospitalization and medication further raise the public health costs of this disease.[111,146] For areas in which it is unlikely that improved sanitation and treated water supplies will become a reality in the near future, a safe vaccine that confers long-term protection (e.g., Ty21a[147] or Vi conjugate[126]) would be particularly beneficial in relation to its cost, because an initial investment in immunization would provide many years of protection. Because typhoid fever exhibits its peak incidence in school-age children—a "captive" population in many countries—a school immunization program could target the high-risk population of schoolchildren.[148–151] For some urban slum and other populations in Asia where the incidence of typhoid fever may be known to be high in preschool children, the increasing use of a second measles-containing vaccine in the second year of life offers an opportunity to administer a two-dose regimen of Vi conjugate at approximately 9 and approximately 15 months of age, or to administer a single dose to toddlers (or older infants) if a single dose of the vaccine is highly immunogenic in those age groups.[152,153] Travelers from industrialized countries who visit less-developed countries in which typhoid fever is endemic are at particular risk of developing the disease.[138–142] Travelers are probably at special risk in endemic areas because they do not have the background immunity that much of the indigenous population has acquired as a consequence of multiple subclinical infections. For U.S. travelers, the Indian subcontinent (India, Pakistan, and Bangladesh), Mexico, Philippines, and Haiti are the areas of highest risk.[142] Since 1990, isolates from Asia and northeast Africa have shown increasing resistance to many clinically relevant antibiotics, including chloramphenicol, amoxicillin, and trimethoprim-sulfamethoxazole.[21,105,119,154] Partial resistance to ciprofloxacin and other fluoroquinolones is also prevalent in Southeast Asia and some other regions.[155–157]

Microbiology technicians in laboratories, particularly clinical laboratories, also constitute a high-risk group for the development of typhoid fever. The Centers for Disease Control and Prevention (CDC)[143] reported that 11.2% of the sporadic (i.e., not outbreak-associated) cases of typhoid fever in the United States in a 33-month period occurred in laboratory technicians. In the course of their work, these people process stool or blood cultures containing *S.* Typhi before it is recognized that the pathogen is present. The predilection for laboratory workers to develop typhoid fever suggests that, under these special conditions, the disease may be spread by aerosol or by direct contact. This observation is in contrast to the lack of contact spread of this infection under more natural conditions and may be related to the organism existing in pure culture in the laboratory.

MODES OF TRANSMISSION AND RESERVOIRS OF INFECTION

Humans are the sole reservoir of *S.* Typhi infection as well as the only natural host. The infection is transmitted when susceptible hosts ingest food or water that has been contaminated by fecal matter. In contrast, transmission from person to person by direct contact is exceedingly uncommon. As a consequence of these epidemiologic features, typhoid fever represents the quintessential infectious disease for which

transmission is related to levels of sanitation and quality of water supply. Typhoid fever can abound wherever sanitation and food hygiene are primitive. The highest incidence usually occurs where water supplies serving large populations are contaminated by fecal matter. This situation existed at the end of the 19th century in most large cities in the United States and Western Europe, where piped water supplies were available but the water was usually untreated.[158] The water sources (usually rivers) were also the repository for the discharged sewage of the cities. In this manner, the transmission of typhoid fever was amplified, causing the disease to be highly endemic in large cities throughout the United States and Europe. With the introduction of water treatment at the turn of the 20th century, including sand filtration and chlorination, the incidence of typhoid fever plummeted precipitously in the large cities of the United States despite the continued existence in those cities of many chronic carriers of *S.* Typhi.[158,159] Typhoid fever remains endemic in most of the less-developed areas of the world, where fecal contamination of water sources still occurs. This includes many countries in Africa, Asia, and Latin America.

Significance as a Public Health Problem

It has been estimated that each year, around 22 to 33 million cases and 216,000 to 500,000 deaths occur worldwide as a result of typhoid fever.[118–120,160] Data quantifying the incidence of bacteriologically confirmed typhoid fever are available from control (usually placebo recipient) groups participating in large-scale field trials of typhoid vaccines, or from populations in sites being prepared for field trials. It may be argued that such populations represent hot spots of typhoid and that the incidence rates from such areas cannot be readily extrapolated to other developing regions. Nevertheless, from sites being prepared for field trial evaluations of typhoid vaccines and from field trials carried out in the late 1970s through 2009 in South America (Chile), Africa (South Africa), and Asia (Nepal, Indonesia, India, Pakistan), annual incidence rates of 198 to 810 cases per 10^5 PYO were recorded (school-age children were the main age group under surveillance).[113,117,121–124,127–129]

PASSIVE IMMUNIZATION

Passive protection by means of antiserum or immunoglobulin is not used to prevent typhoid or paratyphoid fever.

ACTIVE IMMUNIZATION

History of Vaccine Development

For historical as well as practical purposes, the various typhoid vaccines that have been evaluated in clinical trials and the few that have been used as licensed vaccine products can be grouped into three categories:

- Vaccines no longer in use or no longer under investigation;
- Vaccines currently available in various countries as licensed products; and
- Future vaccines under active clinical evaluation.

The various past, present, and future typhoid vaccines can be considered to fall into five broad groups for review:

- Inactivated whole-cell parenteral vaccines;
- Subunit parenteral (which includes purified Vi polysaccharide) or aerosolized vaccines;
- Inactivated whole-cell oral vaccine;
- Attenuated *S.* Typhi strains used as live oral vaccines; and
- Parenteral polysaccharide-carrier protein conjugate vaccines.

Early Vaccine Approaches That Were Abandoned

For a more detailed review of the early vaccines, readers are referred to the chapters on typhoid vaccine in the first two editions of this book.[161,162] A few of the vaccines mentioned here were licensed products that at one time were in fairly widespread use. Others among the cited vaccines did not progress beyond early clinical trials or large-scale field trials because of unsatisfactory safety profiles, poor immunogenicity, disappointing efficacy relative to other typhoid vaccines, or difficulty in manufacture (e.g., loss of potency after lyophilization).

Alcohol-Inactivated Whole-Cell Parenteral Vaccine

The prototype alcohol-inactivated vaccine was prepared in the 1940s by Felix, who published experimental evidence contending that alcohol treatment of *S.* Typhi was superior in preserving the Vi antigen because it resulted in a vaccine that outperformed the heat-inactivated, phenol-preserved vaccine in the mouse protection assay.[163,164] For some years, this vaccine replaced the heat-inactivated, phenol-preserved vaccine in routine use by the British Armed Forces.

Formalin-Inactivated, Phenol-Preserved, Whole-Cell Parenteral Vaccine

This vaccine, which was evaluated for efficacy in a controlled field trial,[165] was prepared by inactivating *S.* Typhi with formalin and then preserving the vaccine in phenol.

Acetone-Inactivated and Dried Whole-Cell Parenteral Vaccine

This type of vaccine was prepared because of evidence showing that acetone inactivation preserves the Vi antigen (thereby increasing potency in active mouse protection assays) and improves the stability of the vaccine on long-term storage.[166–168] In preparing acetone-inactivated and dried vaccine, *S.* Typhi bacteria are precipitated and inactivated with acetone and then air dried or lyophilized.[167] The manufacturing process required to prepare acetone-inactivated, dried vaccine was much more demanding than for making heat-phenolized vaccine. Therefore, although there were some manufacturers of this vaccine until the 1990s (including Wyeth, which made a lyophilized formulation for use by the U.S. military), further production was discontinued.

Heat-Inactivated, Phenol-Preserved, Whole-Cell Parenteral Vaccine

Parenteral heat-inactivated, phenol-preserved, whole-cell vaccines to prevent typhoid fever were used since the end of the 19th century[14,15,169] and the experience with the early killed *S.* Typhi parenteral vaccines has been reviewed.[170] These vaccines, which were relatively easy to prepare and standardize, were the first typhoid vaccines to be widely used, particularly by the British and U.S. military in the first quarter of the 20th century. Use continued into the early 1990s of both the liquid and lyophilized formulations (and occasionally adsorbed to alum adjuvant). There are no current manufacturers of this vaccine. Readers are referred to previous editions of this book for technical information on this type of typhoid vaccine.

Oral-Inactivated, Whole-Cell Oral Vaccines

As early as the 1920s, Besredka[171,172] promulgated the use of killed *S*. Typhi or attenuated strains as oral vaccines to elicit "local immunity." In the 1960s and 1970s, several large-scale field trials[173–178] and experimental challenge studies in volunteers[179] were carried out to assess the efficacy of oral inactivated whole-cell vaccines, which at that time were widely sold and used in Europe. The oral killed vaccines evaluated in field trials or volunteer studies include acetone-inactivated vaccine and formalin-inactivated vaccine.

Parenteral Subunit (Including Early Attempts to Purify Vi Polysaccharide) or Aerosolized Subunit Vaccines

Many attempts were made to prepare extracts and sonicates of *S*. Typhi and to purify antigens for use as parenteral vaccines. The various subunit immunizing agents (which in the 1960s were referred to as chemical vaccines) evaluated for efficacy in controlled field trials (or in volunteer studies) included: freeze-and-thaw extract vaccines,[180] trypsinized extract vaccines,[181] purified LPS vaccines (hot water-phenol extraction method),[182] and purified Vi polysaccharide vaccine (prepared by a method that unwittingly denatured the polysaccharide).[183,184] One trypsinized extract chemical vaccine administered by aerosol was evaluated for efficacy in a controlled field trial.[173]

A parenteral freeze and thaw extract vaccine prepared by the method of Grasset[180] was assessed for efficacy in a controlled field trial in Poland.[185] Several trypsinized extract vaccines, prepared according to Topley and associates,[181] were subjected to field trials of efficacy in the Soviet Union and Poland.[165,185,186] Two parenteral purified LPS vaccines consisting of *S*. Typhi LPS O antigen prepared by the hot water–phenol extraction method[182] were evaluated in controlled field trials in Poland[185] and the Soviet Union.[165] In the early 1950s, Landy and coworkers[183,187] isolated Vi antigen from *Citrobacter freundii* (previous designations of this bacterium include *Paracolon ballerup*, *Bethesda ballerup*, and *Escherichia coli* 5396/38) and *S*. Typhi for use as a parenteral vaccine. Organisms grown on solid agar were inactivated with acetone, after which the dried, acetone-killed bacteria were submitted to multiple extractions with saline, ethanol, and acetic acid to separate Vi from protein, LPS, and nucleic acid. This early method of preparation of purified Vi antigen apparently denatured the polysaccharide, resulting in a complete loss of *O*-acetyl and a diminution of *N*-acetyl moieties.[40,188,189] Landy's denatured Vi vaccine was never evaluated for efficacy in field trials. However, in experimental challenge studies in volunteers, a single 25-μg parenteral dose conferred only modest (25% vaccine efficacy) insignificant protection.[56]

Attenuated Strains as Live Oral Vaccines

Attenuated *S*. Typhi strains evaluated in Phase I and Phase II clinical trials but abandoned from further development include: streptomycin-dependent strains[190–192]; Vi-positive variant of *galE* mutant Ty21a[193]; *galE,via* (Vi-negative) recombinant mutant strain EX642 derived from wild-type strain Ty2[194]; G 2260 hybrid strain (carrying DNA from *E. coli* K-12 and *Shigella flexneri*)[195]; Δ*aroA*, Δ*purA* auxotrophic strain 541Ty derived from wild-type strain CDC 10-80[196]; 543Ty, Vi-negative derivative of auxotrophic strain 541Ty[196]; Δ*aroC*, Δ*aroD* double-mutant recombinant strain CVD 906 (derived from wild-type strain ISP 1820, phage type 46)[197,198]; Δ*cya*, Δ*crp* mutant strain χ3927 (derived from wild-type strain Ty2)[199,200]; Δ*aroA*, Δ*phoP*/*phoQ* strain Ty445 (derived from wild-type strain CDC10–80)[201]; Δ*aroA*, Δ*aroD* strain PBCC211 (derived from wild-type strain CDC10–80)[202]; Δ*aroA*, Δ*aroD*, Δ*htrA* strain PBCC222 (Δ*htrA* derivative of PBCC211).[202]

Readers interested in details about these strains and their clinical evaluation are referred to earlier editions of this book.

Currently Licensed, Available Vaccines

Currently licensed, used, and commercially available typhoid vaccines include the following, which are described in Table 61.1:

- Purified Vi polysaccharide parenteral vaccine;
- Attenuated *galE*, *via* (Vi-negative) strain Ty21a, used as a live oral vaccine;
- Purified Vi polysaccharide conjugated to tetanus toxoid as a parenteral vaccine (two conjugates, so far, have been licensed in India, one is becoming widely used).[153,203–206,206a]

Results of the clinical trials and field trials that established the safety, immunogenicity, and efficacy of the available typhoid vaccines are described in other sections of this chapter.

Purified Vi Polysaccharide Vaccine

To purify Vi under nondenaturing conditions, Wong and colleagues[207] and Robbins and Robbins[40] treated *S*. Typhi with hexadecyltrimethylammonium bromide.[208] This extraction method results in nondenatured purified Vi that preserves the *O*- and *N*-acetyl moieties, as opposed to the methods used by Landy and coworkers that yielded denatured Vi. Fig. 61.2 shows the chemical structure of Vi polysaccharide.

TABLE 61.1 Currently Licensed Typhoid Vaccines

Type of Vaccine	Product Name	Producer	Site of Manufacture
Parenteral purified Vi polysaccharide	Typhim Vi	Sanofi Pasteur	France
	Typherix	GlaxoSmithKline	Belgium
	TypBar	Bharat Biotech	India
	Shantyph	Shanta Biotech	India
	Typho-Vi	BioMed	India
	Zerotyph inj	Boryung	South Korea
	Typhevac inj	Shanghai Institute of Biological Products	China
Live oral Ty21a	Vivotif	PaxVax Berna	Switzerland
	Zerotyph caps	Boryung	South Korea
Parenteral Vi conjugate	Typbar-TCV	Bharat Biotech International	India
	PedaTyph	Bio-Med	India

Attenuated *S.* Typhi Strain Ty21a as a Live Oral Vaccine

Ty21a was derived from wild-type strain Ty2 by treatment with the mutagenic agent nitrosoguanidine.[209] A mutant was selected that exhibited a complete absence of activity of the enzyme uridine diphosphate (UDP)-galactose-4-epimerase and a reduction of approximately 80% in the activity of two other Leloir enzymes, galactokinase and galactose-1-phosphate uridyl transferase. A further mutant was then selected that lacked the Vi antigen. This strain was designated Ty21a.[209]

For many years, it was thought that the *galE* and Vi mutations together accounted for the impressive safety of Ty21a.[210] It is now recognized that the *galE* and Vi mutations in Ty21a do not by themselves explain the attenuation of this strain.[194] Other mutations that also were induced by the nonspecific chemical mutagenesis contribute to the safety of this oral vaccine strain.[211] One such mutation may be in *rpoS* (*katF*), which encodes an RNA polymerase sigma factor; this mutation diminishes the ability of the bacteria to survive under stress, including nutrient deprivation.[212]

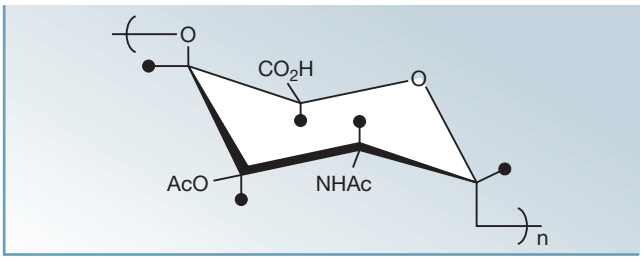

Figure 61.2. Chemical composition of Vi polysaccharide, which is a homopolymer of (1→4)-α-*D*-GalpANA, which is variably acetylated at carbon 3.

Purified Vi Polysaccharide Conjugate Vaccine

Two Vi polysaccharide conjugate vaccines, Typbar-TCV (Bharat Biotech) and PedaTyph (BioMed P), each consisting of Vi covalently linked to tetanus toxoid, have been licensed in India based on multisite clinical trial results that demonstrated safety and immunogenicity (serum anti-Vi antibodies) of each vaccine in infants and children[153,203,205,206]; Typbar-TCV was also tested in older children and adults up to age 45 years.[153]

Other conjugates that are in development but are not yet licensed are discussed later in this chapter (Table 61.2).

TABLE 61.2 Characteristics and Status of the Vi Conjugates Licensed by National Regulatory Agencies or in Clinical Development

Product	Developer (Manufacturer)	Source of Vi CPS	Carrier Protein	Conjugation Strategy	Amount of Conjugated Vi in Each Dose	Status of Licensure by National Regulatory Authority	WHO Prequalification
Typbar-TCV	Bharat Biotech International, Hyderabad, India	*S.* Typhi	Tetanus toxoid (TT)	TT is modified by attaching the homobifunctional linker adipic acid dihydrazide (ADH). Vi is then linked to TT-ADH using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) coupling chemistry	25 µg	Licensed by the Drug Controller General of India	Application in preparation
PedaTyph	BioMed	*S.* Typhi	Tetanus toxoid	Has not been described	5 µg	Licensed by the Drug Controller General of India	No
Vi-rEPA	NIH (Lanzhou Institute of Biological Products, Lanzhou, China)	*S.* Typhi	Recombinant exotoxin A of *Pseudomonas aeruginosa*	rEPA is modified by attaching the homobifunctional linker ADH. Vi is then linked to rEPA-ADH using EDC coupling chemistry	25 µg	In advanced clinical development	
Vi-CRM_{197}	Sclavo Behring Vaccines Institute of Global Health (BioE, Hyderabad, India)	*Citrobacter freundii*	CRM_{197}	CRM_{197} is modified by attaching the homobifunctional linker ADH. Vi is then linked to CRM_{197}-ADH using EDC coupling chemistry	5 µg		

CPS, capsular polysaccharide; WHO, World Health Organization.

VACCINE CONSTITUENTS

Purified Vi Polysaccharide Parenteral Vaccine

Purified Vi is available as a solution containing 25 µg of Vi polysaccharide in 0.5 mL of phenolic isotonic buffer. Each immunizing dose contains 25 µg of Vi polysaccharide, less than 1.25 mg of phenol in Typhim Vi and 1.1 mg in Typherix, and 0.5 mL (or as much as will suffice) of isotonic buffer (4.15 mg sodium chloride; 0.065 mg sodium dibasic phosphate, $2H_2O$; 0.023 mg sodium monobasic phosphate, $2H_2O$; and 0.5 mL [or as much as will suffice] of water for injection). The Vi vaccine manufactured by the Shanghai Institute of Biological Products contains 30 µg of Vi polysaccharide.

Ty21a Live Oral Vaccine

The enteric-coated capsule formulation of Ty21a consists of gelatin capsules coated with phthalate to render them resistant to acid. Each coated capsule contains 2 to 6×10^9 colony-forming units (CFU) of Ty21a, 5 to 50×10^9 nonviable Ty21a, 26 to 130 mg of sucrose, 1 to 5 mg of ascorbic acid, 1.4 to 7.0 mg of an amino acid mixture, 100 to 180 mg of lactose, and 3.6 to 4.4 mg of magnesium stearate (U.S. specifications). The sucrose, ascorbic acid, and the amino acid mixture are used as stabilizers for the lyophilization process. The lyophilized bacteria are mixed with lactose to achieve a defined potency of the lyophilate. Magnesium stearate is added to the lyophilized bacteria for a defined fluidity of the lyophilate.

The liquid suspension formulation of Ty21a consists of a vaccine sachet that contains 2 to 10×10^9 CFU of Ty21a, 5 to 60×10^9 nonviable Ty21a, 15 to 250 mg of sucrose, 0.6 to 10 mg of ascorbic acid, 0.8 to 15 mg of an amino acid mixture, 1.5 g of lactose, and 20 to 30 mg of aspartame. The accompanying sachet of buffer contains 2.4 to 2.9 g of sodium bicarbonate, 1.5 to 1.8 g of ascorbic acid, and 0.18 to 0.22 g of lactose. To prepare the liquid suspension, the contents of the two sachets are suspended in 100 mL of water.

Purified Vi Polysaccharide-Tetanus Toxoid Conjugate Parenteral Vaccine

One dose (0.5 mL) of Typbar-TCV contains 25 µg of Vi polysaccharide from *S.* Typhi linked to tetanus toxoid protein in isotonic saline.

One dose (0.5 mL) of the PedaTyph conjugate contains 5 µg of Vi polysaccharide from *S.* Typhi and 5 µg of tetanus toxoid protein in isotonic saline.

MANUFACTURE

Purified Vi Polysaccharide Parenteral Vaccine

Scale-up of production of Vi to an industrial manufacturing process was initially worked out by scientists from the laboratory of John B. Robbins at the National Institute of Child Health and Human Development and Sanofi Pasteur.[213] The Ty2 strain of *S.* Typhi is cultured in 1000-L fermenters, after which the bacteria are fixed with formaldehyde and Vi polysaccharide is extracted from supernates using cetrimonium bromide. The Vi is further purified, dried, dissolved in a buffer solution, and filter sterilized. After appropriate controls of this material, it is filled into single-dose syringes.

Ty21a Live Oral Vaccine

Galactose residues are an important component of the smooth LPS O antigen in wild-type *S.* Typhi. The enzyme encoded by *galE*, UDP-galactose-4-epimerase, isomerizes UDP-glucose to UDP-galactose, and vice versa (Fig. 61.3). UDP-galactose provides galactose residues that can be incorporated into the smooth LPS O antigen of *S.* Typhi. When grown in the absence of galactose, Ty21a does not express smooth O antigen, because it has no source of UDP-galactose; in this state it is not immunogenic.[214] In contrast, when *galE* mutant Ty21a is grown in the presence of exogenous galactose, the two other Leloir pathway enzymes (Fig. 61.3) allow this monosaccharide to be assimilated to UDP-galactose and used to synthesize smooth O antigen. However, because of the lack of epimerase, strain Ty21a (like other *galE* mutants)

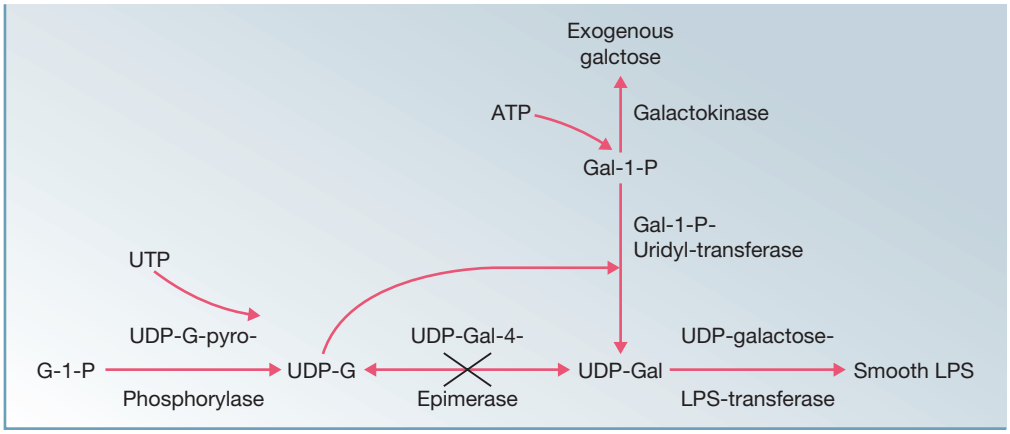

Figure 61.3. Scheme of incorporation of exogenous galactose by *galE* mutant Ty21a; attenuated *Salmonella* Typhi vaccine strain is shown. When grown in the absence of galactose, Ty21a does not produce smooth lipopolysaccharide (LPS) O antigen and is nonimmunogenic. Grown in the presence of exogenous galactose, this hexose is sequentially processed to become galactose-1-phosphate (Gal-1-P) and then uridine diphosphate-galactose (UDP-Gal). Because of the complete lack of UDP-Gal-4-epimerase in Ty21a, UDP-Gal cannot be converted to UDP-glucose (UDP-G), but it can be further incorporated into smooth LPS O antigen. However, the accumulation of UDP-Gal and Gal-1-P consequent to the block of UDP-Gal-4-epimerase activity results in bacteriolysis. *(Modified from Germanier R, Furer E. Immunity in experimental salmonellosis, II: basis for the avirulence and protective capacity of galE mutants of Salmonella* Typhimurium. Infect Immun. *1971;4:663–673.)*

accumulates galactose-1-phosphate and UDP-galactose when grown in the presence of exogenous galactose (Fig. 61.3). If the concentration of galactose reaches a certain level, accumulation of these intermediate products leads to bacterial death by lysis.[209] An appropriate concentration of galactose is included in the medium used in an early step of manufacture to ensure expression of smooth O antigen.

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

To manufacture Typbar-TCV, Bharat Biotech International uses Vi polysaccharide purified as is done for Typbar, their unconjugated Vi vaccine. The carrier protein, tetanus toxoid (TT), is modified by attaching the homobifunctional linker adipic acid dihydrazide (ADH). Vi is then linked to TT-ADH using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) coupling chemistry.

For PedaTyph no detailed description is available for the specific method of purification of the Vi polysaccharide component or of conjugation to the TT carrier protein. The manufacturer claims to have developed a "unique process of conjugation."

Producers of Currently Available Typhoid Vaccines

Purified Vi Polysaccharide Parenteral Vaccine

There are presently two licensed manufacturers of purified Vi among industrialized countries, Sanofi Pasteur Vaccines (Typhim Vi, available in the United States and many European and other countries) and GSK Biologics (Typherix, available in many European and other countries). In addition, several vaccine manufacturers in Asia (China, India, Vietnam),[151,215,216] Russia, and Cuba make Vi products for local and regional consumption.[217]

Ty21a Live Oral Vaccine

Ty21a is currently manufactured by two companies: PaxVax Berna, of Berne, Switzerland (Vivotif) and Boryung Pharmaceutical Co., Ltd., of Seoul, Korea (Zerotyph). Under license, Ty21a is also distributed by a number of other vaccine distributors.

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

Typbar-TCV is manufactured by Bharat Biotech International of Hyderabad, India.[153] PedaTyph vaccine is manufactured by Bio-Med Private Limited, located in Ghaziabad, India.[205,206]

Preparations Available, Including Combinations

Purified Vi Polysaccharide Parenteral Vaccine

Purified Vi is available as a solution containing 25 µg of Vi polysaccharide in 0.5 mL of phenolic isotonic buffer. Single-dose syringes are the usual formulation. By special order, 20-dose and 50-dose vials can be made available. The Vi vaccine formulation manufactured by the Shanghai Institute of Biological Products contains 30 µg of Vi polysaccharide.

Ty21a Live Oral Vaccine

There were three successive commercial formulations of Ty21a, each representing a notable improvement over the earlier version. The initial commercial formulation of Ty21a (which was available for only a very short time) consisted of gelatin-coated capsules containing either $NaHCO_3$ (0.4 to 0.5 g) or lyophilized vaccine (2 to 6×10^9 CFU/dose).[148,218–220] Vaccination with this initial formulation involved the ingestion of two gelatin capsules, each containing bicarbonate, followed by a third capsule containing vaccine; doses were ingested every other day for a total of three vaccine doses.

Field trials in Santiago, Chile, compared the efficacy of the gelatin capsule–$NaHCO_3$ formulation with a formulation consisting of lyophilized vaccine in enteric-coated capsules (2 to 6×10^9 CFU/capsule) that requires no pretreatment with buffer to neutralize gastric acid.[149,218] After results of controlled field trials demonstrated the unequivocal superiority of the enteric-coated capsule formulation over the gelatin-coated capsule formulation, the latter was withdrawn and replaced with the enteric-coated capsule formulation. Enteric-coated capsules should be ingested on a fasting stomach with a little water. The enteric-coated capsule formulation is the only one that is currently manufactured and available.

In 1997, the liquid suspension formulation of Ty21a was licensed in several countries with a three-dose immunization regimen that recommended that the doses be given every other day. Unfortunately, this useful formulation is no longer manufactured. In the late 1990s, when this formulation was available, it came as a double sachet, with one sachet containing 2 to 10×10^9 CFU of lyophilized vaccine and the other containing buffer. The contents of the two sachets were added to 100 mL of water with stirring, resulting in the vaccine suspension. Some authorities interested in controlling typhoid fever in endemic areas have urged that this formulation be manufactured once again for immunizing young children with Ty21a oral vaccine.[220a,281] At present, enteric-coated capsules, the formulation that is preferred by adult and older children because of its practicality, is the only formulation that is currently manufactured and available worldwide. This oral vaccine is also the only vaccine intended for self-administration.

Vi Combination Vaccines

Combination typhoid–hepatitis A vaccines (mainly for use by travelers) have been developed by GSK Biologics (Hepatyrix)[221–223] and Sanofi Pasteur MSD (Viatim).[223–226] Hepatyrix combines 25 µg of Vi and 1440 units of inactivated hepatitis A virus antigen adsorbed to 0.5 mg of alum adjuvant as a 1 mL liquid suspension in a prefilled syringe. Viatim comes formulated as a dual-chamber syringe in which one 0.5-mL chamber contains 25 µg of Vi polysaccharide and the other 0.5-mL chamber holds 160 antigen units of inactivated hepatitis A virus; a 25-gauge needle is attached to the dual-chamber syringe. As the plunger of the dual-chamber syringe is depressed, the vaccines from the two chambers mix and emerge as a combination.[223] Viatim uses the dual-chamber because the manufacturer's preliminary data suggested that a premixed combination diminished the response to the Vi component compared with antigen administered alone. Each of these combination vaccines stimulates seroconversion to the component vaccine antigens in a manner equivalent to monovalent Vi and hepatitis A vaccines.

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

One single-dose (0.5 mL) vial of Typbar-TCV Vi-TT conjugate vaccine contains 25 µg of purified Vi linked to TT, suspended in isotonic saline. Multidose (2.5 mL) vials contain five doses of Typbar-TCV in isotonic saline with 5 mg of 2-phenoxyethanol preservative. One vial of PedaTyph contains a single dose

(0.5 mL) of conjugate consisting of 5 μg of *S.* Typhi Vi polysaccharide conjugated to 5 μg of TT protein, in isotonic saline.

DOSAGE AND ROUTE

Purified Vi Polysaccharide Parenteral Vaccine

The modern nondenatured Vi vaccines are administered as a single subcutaneous or intramuscular injection generally containing 25 μg of purified polysaccharide.[122,123,213,227,228] Single doses that contain 30 μg and 50 μg of purified polysaccharide were also studied in Phase II, Phase III, and Phase IV clinical trials.[122,151,215,216,229]

Ty21a Live Oral Vaccine

Irrespective of the formulation or whether a three-dose or four-dose oral immunization schedule is followed, each dose (capsule or sachet of lyophilized vaccine) contains 2 to 6 × 10^9 CFU of Ty21a. With the enteric-coated capsule formulation, a four-dose oral immunization schedule is recommended in the United States and Canada, whereas in other countries a three-dose regimen is used. Ty21a vaccine is administered with an interval of 2 days between doses. Increasing the interval between doses of enteric-coated vaccine to 21 days does not enhance protection.[149,218] One of the field trials with Ty21a carried out in Santiago, Chile, showed that immunization with four doses within an 8-day period provides significantly greater protection than three doses.[150] Based on results of this field trial, the U.S. Food and Drug Administration (FDA) and the Canadian Drug Board licensed Ty21a as a four-dose immunization schedule, with a dose given every other day.

Two field trials, carried out in Chile[230] and Indonesia,[121] each directly compared the relative efficacies of three doses of Ty21a given in enteric-coated capsules versus vaccine administered as a liquid suspension (which is reconstituted by emptying a sachet containing lyophilized vaccine and a sachet containing buffer into 100 mL of water). The doses of vaccine were given every other day in the trial in Chile, whereas in Indonesia the doses were administered 1 week apart. In each of these trials, three doses of Ty21a in the liquid formulation provided better protection than the enteric-coated capsules. In the Chilean field trial, the difference in the level of efficacy conferred by the two formulations was highly significant.[230] In 1997, the liquid formulation of Ty21a was licensed by a number of countries with a three-dose immunization regimen that recommends an interval of 2 days between doses. However, because this formulation did not gain popularity among travelers, its manufacture was discontinued.

A practical question arises when a subject fails to complete the full course of immunization with three to four doses of Ty21a: Does one need simply to complete the number of doses, or must one complete the full schedule? A definitive answer is not available. However, as a rule of thumb, if less than 3 weeks have passed since the last dose, one may continue to complete the immunization with the missing doses. If more than 3 weeks have passed, the full regimen of this well-tolerated vaccine should be administered de novo.

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

A 0.5-mL dose of Typbar-TCV is administered intramuscularly to infants 6 months of age and older, toddlers, children, or adults. A single dose suffices for all age groups including infants age 6 months and older.[153] The manufacturer indicates that a booster may be administered after 3 years. However, the longevity of the serologic responses is not yet fully elucidated, so it is possible that a much longer interval may suffice before a recall booster is required. In subjects older than 2 years of age, PedaTyph Vi conjugate vaccine is administered intramuscularly in a two-dose schedule with 4 to 8 weeks between the doses. A booster is recommended every 10 years, although no data are available to support that recommendation. For children 3 to 23 months old, two doses of vaccine are recommended spaced 4 to 8 weeks apart followed by a booster at 24 to 30 months of age. The manufacturer also recommends a booster every 10 years thereafter in persons immunized at this young age.

VACCINE STABILITY

Purified Vi Polysaccharide Parenteral Vaccine

The Vi polysaccharide vaccine is highly stable and, in theory, should not require a cold chain even in tropical conditions, as it retains its physicochemical characteristics after 6 months' storage at 37°C and after 2 years at 22°C. Nevertheless, the manufacturers' labels recommend that the vaccine be stored in a refrigerator at 2°C to 8°C for up to 18 months, and they caution against freezing the products.

Ty21a Live Oral Vaccine

Long-term storage of Ty21a should be at 4°C. The shelf life of lyophilized Ty21a depends on residual moisture content and maintenance of a cold chain.[231,232] The potency requirements of Ty21a dictate that the viable counts in each dose (enteric-coated capsule or packet of lyophilized vaccine) exceed 2 × 10^9 CFU. Prolonged storage for 7 days at room temperature (20°C to 25°C) resulted in progressively lower viable counts over time. Nevertheless, after a 7-day test period, all 10 lots tested still met the minimum potency requirements.[233] Similarly, three separate lots of Ty21a maintained potency when stored at 37°C for 12 hours.[233]

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

Typbar-TCV conjugate is stored at 2°C to 8°C and has a 3-year shelf life at this temperature. If one or more doses are withdrawn from a multidose vial, the vial with remaining doses should be stored at 2°C to 8°C for further use but discarded after 6 hours.

The manufacturer of PedaTyph recommends that this vaccine be stored at 2°C to 8°C and that it must not be frozen. No stability data have been published.

IMMUNOGENICITY

Parenteral Inactivated Whole-Cell Vaccine

Although these vaccines, which conferred moderate protection, are no longer available, the immune responses that they elicited are described to provide background against which immune responses to newer vaccines can be compared.

Serum Antibody Response

Typically, in assessing the seroconversion after vaccination with a parenteral inactivated whole-cell typhoid vaccine, serum antibodies are measured to the O, H (d), and Vi antigens. O antibodies were formerly assayed by bacterial agglutination (Widal test),[234] but ELISA using purified LPS eventually replaced agglutination.[198,200,235–240] H antibody can be measured by agglutination using an appropriate whole-cell antigen

such as *S.* Virginia (which has the same d flagellar antigen as *S.* Typhi but lacks Vi and has distinct O antigens) or by ELISA using purified *S.* Typhi flagella.[235–238] Vi antibody can be measured by passive hemagglutination,[89,90] radioimmunoassay,[40,122,229,241] or ELISA.[91,123,153,242] It is important to use highly purified undenatured Vi antigen to avoid cross-reactions. For this reason, only since the 1980s has Vi serology become reliably specific.

Some evidence suggests that H antibodies may play a role in protection. In Yugoslavia, Poland, the Soviet Union, and Guyana, field trials of efficacy were carried out with several different well-characterized parenteral killed whole-cell vaccines, including alcohol-inactivated, heat-phenolized, and acetone-inactivated vaccines. Measurement of serologic responses to these vaccines in groups of vaccinees and in immunized laboratory animals allowed protective efficacy to be correlated with antibody response. Those killed whole-cell parenteral vaccines that were most protective in the field stimulated the highest levels of H antibody. A similar correlation between H titer and protection against typhoid fever was found in healthy young adult volunteers who in the 1960s and 1970s participated in experimental challenge studies to assess the efficacy of typhoid vaccines.[214,243,244] Control volunteers who had elevated H titers (presumably derived by natural infection or vaccination many years earlier during military service) were significantly protected against development of typhoid fever.

However, the most convincing evidence that H antibody is important comes from the field trial by Wahdan and colleagues[245] of an acetone-killed and dried vaccine prepared from a strain of *S.* Typhi that lacks H antigen. This vaccine, which did not elicit H antibodies, failed to confer significant protection.

O antibody that appears after inoculation with parenteral inactivated whole-cell typhoid vaccines is largely immunoglobulin (Ig) M, whereas the H antibody response is initially IgM and then becomes IgG.[246–251]

Mucosal Immune Response

Not surprisingly, the few studies that examined mucosal immunity after administration of parenteral inactivated whole-cell vaccine reported minimal secretory IgA (sIgA) antibody or gut-derived IgA antibody-secreting cell (ASC) responses.[246,252–254]

Cell-Mediated Immune Response

Some measurements of cell-mediated immune responses were reported after vaccination of humans with parenteral killed whole-cell vaccines.[255–258] The cell-mediated response after administration of these vaccines was not prominent.

Purified Vi Polysaccharide Parenteral Vaccine

Serum Antibody Response

Parenteral Vi polysaccharide vaccine elicits serum IgG Vi antibody responses in approximately 85% to 95% of adults and children older than 2 years of age. Table 61.3 shows the serum Vi and O antibody responses reported by Tacket and colleagues[229] after vaccination of young adults with one of two purified Vi antigen vaccines prepared from *S.* Typhi. The vaccines differed in their degree of purity: one Vi vaccine had 5% residual contamination with LPS, and the other was 99.8% pure. This difference was reflected in the serologic response. Although similar Vi antibody seroconversions occurred in approximately 90% of recipients of either preparation, those who received the more purified preparation had only a 26% seroconversion of O antibody, whereas 83% seroconverted to O antigen after inoculation with the less-purified vaccine.

The serologic responses of other groups of adults and children in nonendemic and endemic areas following immunization with a 25-μg dose of Vi polysaccharide vaccine and with antibodies measured by radioimmunoassay or ELISA are shown in Table 61.4.[122, 153,241,258,260,261] High rates of seroconversion (76% to 95%) were generally observed in adults in industrialized countries and children in developing countries, while a lower seroconversion rate (62.5%) was observed in Nepalese adults. Whereas at 1 month after immunization 87% of U.S. adults had serum anti-Vi titers of 1.0 μg/mL or greater, by 12 months only 57% and by 24 months only 46% still had this level of anti-Vi.[260]

High seroconversion rates measured by ELISA have been reported among preschool-age children 2 to 4 years of age (99%),[262] school-age children 4 to 14 years of age (99.5%),[227]

and adolescents 11 to 18 years of age (99%)[228] immunized with the Typherix vaccine. Agglutinating antibody responses were also seen in 96% of adults.[263] A report compared the ELISA serologic responses in Belgian adults after a dose of Typhim Vi or a dose of Typherix.[264] At 28 days after immunization, 94% of Typhim Vi and 95% of Typherix recipients had serum Vi antibodies. Measured again at 12 months after immunization, 74% and 67%, respectively, still had elevated Vi titers; the geometric mean titers (GMTs) of recipients of the two vaccines were very similar at 28 days and at 12 months after immunization.[264]

Purified Vi polysaccharide behaves like a T-lymphocyte–independent antigen. As with other T-cell–independent purified polysaccharide vaccines, Vi is not a good immunogen in infants. Many do not respond and among those who do, the responses are short lived. More importantly, in neither older children nor adults is the serum antibody response boosted by the administration of additional doses of Vi vaccine and, as with other purified polysaccharide vaccines, there is no evidence of immunologic memory.[241,265] Vi polysaccharide, like other purified polysaccharide vaccines, presumably stimulates short-lived B-cell responses by crosslinking the B-cell receptor.[266] This drives the B cells to differentiate to plasma cells that produce Vi antibody, and it results in a depletion of the pool of memory B cells without the generation of new memory B cells.[266] Thus, without the induction of immunologic memory, whatever serum antibody levels are reached after an initial parenteral inoculation with Vi cannot be boosted further by the administration of additional doses. Titers of serum Vi antibody after a dose of vaccine progressively fall over time.[241] In a large proportion of vaccinated subjects, antibody levels fall to putatively nonprotective levels after 2 years and drop even lower by 3 years.[260]

The depletion of memory B cells implies that the administration of subsequent doses of the T-independent polysaccharide vaccine may be accompanied by lower serologic responses than were observed after the initial vaccination (hyporesponsiveness). This phenomenon has been described with meningococcal polysaccharide[267,268] and pneumococcal polysaccharide[269,270] vaccines. There are only a few studies with limited data to be analyzed to address the question of whether hyporesponsiveness occurs with Vi vaccine and the data are conflicting.[226,241,264,271,272] Some data indicate that the response to a reimmunization with Vi 2 to 3 years after the initial immunization, when antibody titers have fallen, does not fully restore the titers to the peak level observed after the initial immunization.[226,264] By contrast, the study of Keitel and colleagues[241] showed that the titers after a reimmunization with Vi 27 months after the initial immunization did restore serum anti-Vi to the same peak titer recorded after the initial immunization with Vi more than 2 years earlier, and Roggelin and colleagues did not see evidence of a diminished responses in travelers who had previously received Vi vaccine.[271] A study with locally produced Vi vaccine was carried out in China to address the safety and immune responses of revaccination of school-age children 3 years after an initial Vi vaccination versus response to a primary immunization with Vi.[272] The GMT of serum Vi antibodies measured by passive hemagglutination was 1:40 in primary vaccinees and 1:29 in revaccinated children ($P = .24$); the rise in anti-Vi was 7.7-fold in primary vaccinees but was 3.1-fold in revaccinated children ($P < .001$).[272]

Relevant to the hyporesponsiveness question, there is only one report of a search for B memory (B_M) cells among peripheral blood mononuclear cells (PBMCs) in recipients of parenteral Vi vaccine. None of eight recipients of Vi had detectable IgG B_M for Vi but two vaccinees had low levels of Vi-specific IgA B_M cells.[273] Different levels of serum Vi antibody titers after administration of Vi polysaccharide vaccine have been proposed as constituting a threshold for protection at a given point in time, including 1.0 μg/mL[274] and 1.5 μg/mL.[275] The scarce published data indicate that most of the serum IgG antibody stimulated by Vi vaccine falls within the IgG_1 subtype.[153,276]

A randomized clinical trial in British adults compared responses to Vi and hepatitis A antigens after immunization with either Viatim (Sanofi Pasteur) or Hepatyrix (GSK Biologics) combination typhoid–hepatitis A vaccines. Viatim elicited stronger serologic responses to both typhoid and hepatitis A vaccine antigens but also caused significantly more, albeit mild, adverse reactions.

Mucosal Antibody Responses

There are no reports of mucosal sIgA anti-Vi antibody appearing in gut fluids or fecal extracts following parenteral vaccination with Vi polysaccharide. However, it has been hypothesized that in the small intestine of persons in developing countries serum IgG transudes onto the mucosal surface in quantities that may have protective biological consequences.[277] Because the small intestinal mucosa of children and adults residing in fecally contaminated environments in developing countries often exhibit evidence of environmental enteropathy,[278] such transudation of IgG may indeed be common.

Cell-Mediated Immune Responses

There are no reports of T-cell studies following immunization with T-independent Vi polysaccharide. However, there is one report of an attempt to detect IgG and IgA Vi-specific B_M cells in eight recipients of Vi. No Vi-specific IgG cells were detected but two of eight exhibited Vi-specific IgA B_M cells.

Ty21a Live Oral Vaccine

Serum Antibody Response

The serum antibody response has been extensively studied with Ty21a. Gilman and colleagues[214] noted that Ty21a vaccine grown in the presence of galactose (which leads to organisms bearing smooth LPS O antigen) was highly protective, whereas vaccine grown in the absence of galactose (resulting in rough organisms) was not. These investigators reported that recipients of vaccine grown in the presence of galactose experienced a significantly greater seroconversion of O antibody.

Using serum IgG O antibody measured by ELISA in Chilean 15- to 19-year-olds, Levine and associates[149] showed a correlation between seroconversion to various dosage schedules and formulations and protective efficacy in field trials (Table 61.5). With the currently licensed enteric-coated capsule formulation, there is a stepwise increase in the proportion of vaccinees who manifest significant rises in serum IgG O antibody depending on whether one, two, or three doses of vaccine are administered within 1 week. Although serum O antibody is not believed to be the operative mechanism of immunity elicited by attenuated strains, it clearly correlates with protection. Because measurement of serum IgG ELISA antibody to *S.* Typhi O antigen is a simple technique, it provides investigators with a practical tool for comparing immunization schedules and formulations and for evaluating new candidate live oral vaccines.

Two studies documented high rates of serum IgG O antibody seroconversion following immunization of children 2 to 6 years of age in Thailand with three liquid formulation doses of Ty21a (every-other-day schedule).[279,280] Investigators in Bangladesh also immunized children 2 to 5 years of age with three doses of a liquid formulation of Ty21a and recorded robust plasma IgA and IgG responses to a Ty21a membrane preparation.[281] Several large clinical trials examined the safety and immunogenicity of coadministering the first or the third dose of the liquid suspension formulation of Ty21a in a combination oral vaccine cocktail along with single-dose live oral cholera vaccine CVD 103-HgR.[282–284] These studies showed that there was no diminution in either the serum IgG *S.* Typhi O antibody response or the vibriocidal antibody response when these vaccines were coadministered as a combined oral vaccine cocktail compared with when they were administered alone.[282–284]

Large-scale field trial of Ty21a live oral typhoid vaccine in enteric-coated capsule formulation.* Lancet. *1987;1:1049–1052), Santiago, Chile.*

Mucosal Immune Responses

During the past decade, the intestinal mucosal immune response to Ty21a and several new live oral vaccines has been studied rather extensively. Most recipients of the usual three-dose oral regimen of Ty21a develop local antibody responses to O antigen.[246,253,254,285–294] Forrest[295] reported that the propensity to develop a significant rise in intestinal sIgA O antibody after immunization with Ty21a is inversely correlated with the preimmunization baseline level of intestinal antibody. Subjects who have elevated baseline titers of sIgA O antibody mount significantly lower-fold rises than do those vaccinees with absent or low titers. This inverse correlation between baseline titer and propensity to seroconvert has also been reported for the serum vibriocidal antibody response after immunization with live oral cholera vaccines[296,297] and with Ty21a expressing *Vibrio cholerae* 01 antigen.[298]

After oral administration of antigen, activated lymphocytes in the Peyer patches and other gut-associated lymphoid tissue migrate to local lymph nodes to mature. After maturation, they return to the lamina propria of the intestine, as well as to other organs of the mucosal immune system, such as the salivary glands, respiratory tract, genitourinary tract, and mammary glands. Kantele and coworkers[246,285–288,292,294] and Forrest[299] have shown that such gut-derived migrating cells can be detected in peripheral blood after oral immunization with Ty21a, and that the ability of these cells to secrete specific IgA antibody in the presence of specific antigen can be quantified by means of the enzyme-linked immunospot assay[300] or similar techniques.[299] These IgA-producing migrating cells are only detectable during a few days after immunization. The peak detection of gut-derived IgA ASCs in peripheral blood

after oral immunization with Ty21a occurs approximately 7 days after vaccination.[246,285–288,292]

Kantele[285] immunized adult Finnish volunteers with different formulations and immunization schedules of Ty21a, attempting to parallel the different regimens that were used in field trials of the efficacy of Ty21a in Chile and Indonesia. Kantele's results demonstrate that the gut-derived IgA ASC response closely correlates with the efficacy results recorded in field trials (Table 61.6). Thus three doses (taken every other day) of Ty21a are markedly more immunogenic than one dose, and Ty21a in a liquid suspension is more immunogenic than vaccine in enteric-coated capsules.

Forrest and associates[301] studied the mucosal immune response when three doses of Ty21a are administered per rectum on days 0, 2, and 5. Each dose of vaccine contained 2×10^{11} CFU, a 100-fold larger dose than is contained in the commercial Ty21a preparation. These vaccinees showed a significant increase in sIgA anti-*S.* Typhi O antibody in jejunal fluid, serum, and saliva and in gut-derived IgA ASCs.[301]

Wahid and colleagues[273] showed that oral immunization of North Americans with the U.S. four-dose regimen of Ty21a induced significant IgG and IgA B_M cell responses to flagella, which were detected among PBMCs. Notably, B_M cells specific for T-independent (LPS), as well as for T-dependent (flagella) *S.* Typhi antigens were documented after oral immunization with live oral Ty21a. B_M cells generally express high levels of CD27, and the phenotype of the IgG and IgA B_M cells responding to *S.* Typhi flagella was $CD19^+$ IgD^- $CD27^+$, concordant with other descriptions of B_M cells specific for bacterial proteins. The IgA B_M cells detected specifically responding to T-independent LPS also exhibited the classical $CD19^+$ IgD^- $CD27^+$ B_M phenotype.

Bhuiyan and colleagues[281] measured mucosal immune responses to Ty21a membrane antigen including IgA antibody in stool extracts and antibody in lymphocyte secretions following the ingestion by 2- to 5-year-old Bangladeshi children of three doses of a liquid formulation of Ty21a.

Cell-Mediated Immune Responses

Cell-mediated immune responses have been measured after vaccination with Ty21a.[254–256,302–311,311a] Oral Ty21a vaccine stimulates both $CD4^+$ T-helper cell and $CD8^+$ cytotoxic T-cell responses, both of which are believed to play roles in defense against *S.* Typhi. The cell-mediated immune responses that follow oral immunization of subjects with Ty21a include lymphoproliferative responses; secretion of T-helper type-1 cytokines (e.g., interferon-γ [IFN-γ]); secretion of tumor necrosis factor-α; appearance of classical class Ia–restricted $CD8^+$ cytotoxic T lymphocytes (CTLs),[305,312] and novel, nonclassical class Ib human leukocyte antigen-E–restricted $CD8^+$ CTLs[307,312] and antibody-dependent mononuclear cell killing of *S.* Typhi.[254–256,302] Newer live oral vaccines stimulate fairly potent cell-mediated immune responses.[312–317]

In their studies of the lymphocyte replication response to various *S.* Typhi antigens after oral immunization with Ty21a, Murphy and coworkers[303,304] observed that the most sensitive and specific antigen was heat-inactivated, phenol-preserved particulate *S.* Typhi. Sztein and coworkers[313,314,318,319] found purified flagella from *S.* Typhi to be an excellent stimulator of immune lymphocytes.

Tagliabue and coworkers[254–256,302] described a potent anti-*Salmonella* immune response after oral immunization with Ty21a that involves PBMCs and immune serum. Mixing PBMCs from a neutral donor with postimmunization sera from vaccinees results in marked inhibition of growth of *S.* Typhi. Neither mononuclear cells by themselves nor postvaccination serum alone had this effect. These investigators reported that the serum antibodies conferring specificity are of the IgA class and that intestinal sIgA could substitute for serum IgA.

Salerno-Goncalves and colleagues[305,307] observed that immunization with Ty21a induced specific CTLs that could lyse *S.* Typhi–infected cells and secrete IFN-γ, an important effector molecule against intracellular pathogens. Most Ty21a vaccinees exhibited consistently increased CD8-mediated lysis of target cells by postimmunization PBMCs compared with preimmunization levels. Using an IFN-γ enzyme-linked immunospot assay that they developed to quantify the frequency of IFN-γ spot-forming cells in PBMCs from Ty21a vaccinees, Salerno-Goncalves and coworkers[305] also detected significant increases in IFN-γ spot-forming cells after immunization compared with preimmunization levels. IFN-γ was secreted predominantly by $CD8^+$ T cells. A very strong correlation was recorded between the cytolytic activity of CTL lines and the frequency of IFN-γ spot-forming cell.[305]

Lundin and colleagues[320] corroborated that oral vaccination with three doses of Ty21a induces both $CD4^+$ and $CD8^+$ IFN-γ–producing cells and antigen-specific $CD4^+$ and $CD8^+$ memory T cells. Moreover, they studied the homing characteristics of T-cell responses and found that almost all the IFN-γ producing memory T cells express the gut-homing integrin β_7.

Based on their expression of homing molecules (CD62L, CCR7), CD45RO or CD45RA, two main populations of memory T cells are recognized: T central memory and T effector memory (T_{EM}).[321,322] Although T_{EM} populations appear ready for immediate effector action, T central memory cells are important in the generation of a new wave of effector T cells. Flow cytometric analysis has shown that T-cell clones derived from Ty21a vaccinees exhibit a T_{EM} phenotype—that is, CCR7(−), CD27(−), CD45RO(+), CD62L(−)—and coexpress gut-homing molecules (i.e., high levels of integrin $\alpha_4\beta_7$, intermediate levels of CCR9, and low levels of CD103).[307] The long-term T-cell responses to Ty21a are oligoclonal and involve multiple T-cell receptor Vbeta families. The *S.* Typhi–specific $CD8^+$ T cells bearing defined Vbeta specificities that appear after oral immunization with Ty21a are phenotypically and functionally consistent with T_{EM} cells with gut-homing potential.[307] Some of these key findings were confirmed by other investigators.[290,320] Two important recent observations

following immunization with Ty21a that help explain the longevity of protection are the appearance of $CD8^+$ T cells that produce interleukin (IL)-17A and the identification of multifunctional $CD8^+$ T_{memory} subsets that simultaneously produce combinations of IL-10, IL-17A, IL-2, IFN-γ, tumor necrosis factor-α, and macrophage inflammatory protein-1β.[310] These responses are likely to be important in resistance to *S.* Typhi by several mechanisms, including increased macrophage bactericidal activity, enhancement of antigen presentation, and lysis of *S.* Typhi–infected targets. Notably, no correlations were observed between cell-mediated immune and serum antibody responses in multiple studies.[313,314,323]

Purified Vi Polysaccharide–Protein Conjugate Parenteral Vaccines

There have been no reports monitoring B_M cells or T-cell responses in recipients of Vi conjugate vaccines.

Serum Antibody Response

Purified Vi Polysaccharide–Protein Conjugate Parenteral Vaccines. There remain impediments to the interpretation of serum anti-Vi antibody responses following immunization with Vi conjugate vaccines and in comparing the relative immunogenicity of one conjugate versus another. The following factors create the dilemma: (1) there does not exist a standardized ELISA method that all Vi conjugate vaccine developers, evaluators, and regulators agree should be the common accepted method for measuring antibodies; (2) only recently has a proposed human serum standard become available[324]; key stakeholders have not yet agreed upon a threshold titer that signifies protection at the time the specimen was collected or on a postimmunization titer that predicts long-term protection, with both being measured using an agreed upon ELISA method and with an accepted serum standard.[325] Because of this, while intrastudy interpretations of serological data from clinical trials with Vi conjugates are possible (e.g., titers achieved by the Vi-protein conjugate vaccine vs an unconjugated Vi polysaccharide vaccine within the same study[153,242,326]), comparisons of different conjugates cannot readily be made because so far two different conjugates have not been used in the same randomized study for direct comparison. These points need to be taken into consideration as one reviews the serological data from immunogenicity trials of several Vi conjugate vaccine, which trials are summarized in Table 61.7.

Typbar-TCV. Table 61.7 summarizes the immunogenicity of Typbar-TCV in stimulating serum Vi antibodies in individuals of different age groups.[153] In participants 2 years of age or older, unconjugated Vi served as the comparator. The Vi antibody response following a dose of Typbar-TCV was significantly stronger than following a dose of unconjugated Vi polysaccharide (Typbar) vaccine. There were also important differences in the quality of the antibody elicited. Typbar-TCV stimulated antibodies of higher avidity than the antibodies induced by unconjugated Vi vaccine.[153] The conjugate also primed the vaccinees to mount strong booster responses when a second dose of Vi conjugate was administered 720 days after the initial dose. The response to the booster included components of all IgG subclasses with significantly enhanced IgG_4 and IgG_3 compared to the antibodies elicited by a second dose of unconjugated Vi administered 720 days after an initial dose of unconjugated Vi vaccine.[153]

Vi-CRM_{197}. Table 61.7 shows the immune responses in adults, children, older infants, and younger infants with the Vi-CRM_{197} conjugate that is in clinical development by BioE (Hyderabad, India).[242,261,327] Shown are the results of clinical trials with early good manufacturing practices pilot lots undertaken by the developer, the Sclavo Behring Vaccines Institute of Global Health. Young infants (i.e., immunized within the first 6 months of life) mounted modest anti-Vi responses to this conjugate despite three spaced doses and it was not obvious that the subsequent two doses boosted antibody titers elicited by the first dose. All the Vi conjugates summarized in Tables 61.2 and 61.7 contain 25 μg of Vi polysaccharide as the saccharide component except for the PedaTyph and Vi-CRM_{197} conjugates that contain only 5 μg. This formulation was selected based on results of a Phase I trial in European adults that examined serum anti-Vi responses following administration of three concentrations of Vi-CRM_{197} containing 1.25 μg, 5.0 μg, or 12.5 μg of Vi antigen.

PedaTyph. At the time of its licensure by the Drug Controller General of India, there were no peer review publications that documented the clinical safety profile and immunogenicity of PedaTyph,[204] the first licensed (in India) Vi conjugate vaccine. Only limited serologic results were found on the manufacturer's website.[328] That a new vaccine can become licensed for use in infants on the basis of very limited safety and immunogenicity data, and without efficacy data, is a function of the differences in countries' criteria for licensure and use of the vaccine in that country.[203,204,327,329] In India, the initial paucity of published or otherwise public prelicensure data on the safety, immunogenicity, and efficacy of this vaccine generated active controversy.[203,204,329,330]

Subsequently, two postlicensure publications appeared that summarized the safety and immunogenicity results following immunization of Indian children younger than 5 years of age with PedaTyph.[205,206] Additional larger postlicensure trials intended to generate additional clinical data are underway with this Vi conjugate.

Vi-rEPA. Extensive serologic data demonstrate the serum Vi antibody responses to prelicensure lots of a still unlicensed Vi conjugate that uses recombinant exoprotein A of *Pseudomonas aeruginosa* as the carrier protein (see Table 61.7).[125,326,331,332] Table 61.7 summarizes the anti-Vi antibody responses in a subset of Vietnamese preschool-age children who participated in the efficacy trial of this vaccine. The GMT at 24 months after the two-dose regimen remained approximately 97-fold above baseline. Young infants given doses of Vi-rEPA at 2, 4, and 6 months of age and then boosted at 12 months of age exhibited prominent rises in anti-Vi at 13 months of age, 1 month after the booster.

Comparison With Natural Infection

The circulating, secretory, and cell-mediated immune responses are relatively strong after natural infection and include prominent serum and cell-mediated components.[56,79,333–339] Parenteral killed whole-cell vaccines elicit a serum response equal to that of natural infection but not a comparable cell-mediated response. With live oral vaccines, the opposite is true.

Murphy and associates[303,304] observed that the PBMCs from healthy adults living in typhoid-endemic areas who have no known history of acute typhoid fever often specifically proliferate when exposed to *S.* Typhi antigens. This corroborates results of antibody prevalence studies that indicate that considerable mild or subclinical infection occurs in such areas.

High titers of serum IgG antibodies directed at the capsular Vi polysaccharide antigen that covers *S.* Typhi are found in approximately 80% of chronic biliary carriers of *S.* Typhi[89,91] in endemic areas, but only rarely in healthy

persons[89,91,259]; 12% to 38% of persons with acute typhoid fever manifest elevated Vi titers.[89,91] Therefore, the measurement of Vi antibodies has been applied with success as a screening test to detect chronic carriers in nonendemic and endemic areas.[89–91,340–342] In endemic areas, a variable proportion of healthy subjects exhibit low titers of Vi antibody, and the prevalence increases with age.[122,343] The low titers of serum Vi antibody consequent to wild-type *S*. Typhi infection among persons living in endemic areas are mainly in the IgG_2 subclass.[343]

Using decomplemented human sera from cord bloods and persons of different age groups living in a typhoid hyperendemic area (Kathmandu, Nepal) versus in a nonendemic area (United Kingdom), Pulickal and coworkers[343] described a serum bactericidal assay that uses infant rabbit complement. Bactericidal antibodies were low in all UK age groups. Among the Nepali sera, GMTs of bactericidal antibody were high in cord blood, dropped drastically during infancy and childhood, and reached "adult" levels by the time the children were 9 to 15 years old. A correlation between bactericidal titers and anti-Vi in the Nepali sera was not observed.

EFFICACY AND EFFECTIVENESS OF TYPHOID VACCINES

Results of Controlled Field Trials

Parenteral Inactivated Whole-Cell Vaccines

Although the killed whole-cell vaccines are no longer available, a summary of their efficacy in controlled field trials provides helpful context when considering the performance of the main licensed vaccines that have been their successors (Vi polysaccharide and Ty21a). From the mid-1950s to the early 1970s, the World Health Organization (WHO) sponsored a series of well-designed, randomized, controlled field trials in countries with endemic typhoid to assess the absolute and relative efficacy of various typhoid vaccines and their duration of protection. In these studies, only culture-confirmed cases were used in calculating incidence rates and vaccine efficacy. In the first trial, in Yugoslavia, the efficacy of two doses of alcohol-killed vaccine was compared with that of heat-inactivated, phenol-preserved vaccine, with TT serving as the control vaccine.[344–346] Both vaccines gave significant protection, but the heat-inactivated, phenol-preserved vaccine proved to be superior to the alcohol-killed vaccine.

In the early 1950s, laboratory studies demonstrated that acetone-inactivated typhoid vaccine resulted in better preservation of the Vi antigen,[166] thus raising the question of whether such a vaccine might be superior to the heat-inactivated, phenol-preserved vaccine. The Walter Reed Army Institute of Research prepared for the WHO large reference lots of acetone-inactivated and heat-inactivated, phenol-preserved vaccines,[167,168] designated vaccines K and L, respectively, for large-scale field trials to be carried out in Yugoslavia,[347] Guyana,[348,349] Poland,[185,350] and the Soviet Union.[165] The K and L vaccines and the methods for their production also served as international standards to prepare future lots of vaccines of these types for subsequent field trials. For example, in addition to the K and L reference vaccines themselves, two additional K-type vaccines were tested in controlled field trials and provided critical information. These include a K-type vaccine used in a randomized, controlled field trial in Tonga to directly compare the efficacy of one versus two doses of vaccine[351]; a K-type vaccine made from a nonflagellated *S*. Typhi strain, which was field tested for efficacy in Alexandria, Egypt[352]; and a K-type vaccine evaluated in a single dose against an alum-adsorbed, heat-inactivated, phenol-preserved vaccine.[353,354]

The major conclusions that can be drawn from these field trials are the following:

- Both acetone-inactivated and heat-inactivated, phenol-preserved typhoid vaccines provided significant protection against typhoid fever after two subcutaneous doses, but the acetone-killed vaccine was somewhat better (79% to 88% protection for the K vaccine vs 51% to 66% for the L vaccine).[165,185,347,349]
- The efficacy of the reference K and L vaccines varied from one geographic site to another.
- When directly compared in a randomized trial (Tonga), two doses of an acetone-inactivated vaccine gave significantly better protection than a single dose.[351] Previously in nonrandomized comparisons, little difference had been noted between the efficacy conferred by one or two doses.[349]
- A K-type vaccine prepared from a nonflagellated *S*. Typhi strain failed to provide significant protection.[352]
- A single dose of a K-type vaccine, without adjuvant, provided protection comparable to that of a single dose of an alum-adsorbed, heat-inactivated, phenol-preserved vaccine.[353,354]

The K and L vaccines were also evaluated for efficacy in experimental challenge studies in North American volunteers.[56] Perhaps the most important insight to come from these studies was the observation that protection conferred by the vaccines was relative to the number of pathogenic *S*. Typhi administered in the experimental challenge. When the challenge inoculum was 10^5 pathogenic *S*. Typhi, the K and L vaccines provided approximately 70% protection. However, when the challenge inoculum contained 10^7 bacilli, there was virtually no protection demonstrable (0% to 14% vaccine efficacy). In nature, differences in inoculum size may be responsible for some of the differences of vaccine efficacy encountered among different field sites and over time.

Purified Vi Polysaccharide Parenteral Vaccine

Two pioneering randomized, controlled prelicensure field trials to assess the efficacy of the first nondenatured purified Vi vaccine were carried out in Nepal[122] and South Africa.[123] A single 25-μg dose conferred 72% protection against typhoid fever in Nepal during 17 months of follow-up, and 64% efficacy in South Africa over 21 months of surveillance. The Nepal trial included all ages from preschool to adults, whereas the South African trial was performed in schoolchildren (Table 61.8). A subsequent report from the South African trial showed that over 3 years of follow-up, vaccine efficacy was 55%.[274]

Subsequently, a Vi vaccine manufactured by the Shanghai Institute of Biological Products was evaluated in a randomized, placebo-controlled, double-blind trial in Guangxi, China.[215] In total, 65,287 subjects received a single 30-μg dose of Vi and 65,984 controls got a dose of saline; 92% of subjects were children 5 to 19 years of age at the time of vaccination.[215] During 19 months of follow-up, seven cases of blood culture–confirmed typhoid fever were detected among the vaccinees, versus 23 confirmed cases among the controls, demonstrating a vaccine efficacy of 69% (95% confidence interval [CI], 28% to 87%) (see Table 61.8).[215] Confirmatory data on the effectiveness of this vaccine from its use in relation to an outbreak of typhoid have been reported.[216]

Vi-negative strains of *S*. Typhi are rare in nature but such variants are capable of causing clinical typhoid fever.[56,355] Some have argued that because the Vi vaccine is unlikely to protect against such strains, the widespread use of Vi may select for such strains.[356–358] This hypothesis has biological plausibility because pathogenicity island 7 in the *S*. Typhi

chromosome, which contains the genes encoding the expression of Vi, is a relatively unstable region.[47] Heretofore, there has been no convincing evidence of the emergence of Vi-negative isolates of *S.* Typhi. However, arguably, there has not been sufficiently widespread and sustained use of Vi in an area of high endemicity to have created the selective pressure for emergence of Vi-negative strains that are known to exist in some populations.[355]

Ty21a Live Oral Vaccine

In early studies in adult volunteers, multiple doses of freshly harvested Ty21a organisms were found to be safe and to confer significant protection against experimental challenge.[214] Thereafter, a field trial of efficacy was carried out in Alexandria, Egypt, where approximately 16,000 schoolchildren 6 and 7 years of age were given three 10^9-organism doses of vaccine on Monday, Wednesday, and Friday of one week.[245,359] Lyophilized vaccine in glass vials was reconstituted with 30 mL of diluent and ingested by the children approximately 1 to 3 minutes after they chewed a tablet containing 1.0 g of $NaHCO_3$. Approximately 16,000 other children received placebo in this randomized, double-blind, controlled field trial. During 3 years of epidemiologic surveillance, only one culture-confirmed case of typhoid fever occurred among the vaccinees, as opposed to 22 cases among the controls (96% protection) (Table 61.9).

Although this preliminary field trial with Ty21a provided highly encouraging results, considerable further work needed to be done to ascertain whether Ty21a could be a practical public health tool. The liquid formulation used in Egypt was not readily amenable to mass production, so alternative formulations had to be prepared and evaluated. It was necessary to determine whether fewer (one or two) doses could protect, to assess the duration of protection, to investigate the effect of increased spacing between vaccine doses, and to ascertain whether infants and young children could be immunized safely and successfully. Many of these questions were answered in a series of five randomized, controlled field trials carried out in Santiago, Chile (four trials), and Indonesia (one trial) under the auspices of the WHO and the Pan American Health Organization.[124,147–150,218,230]

The four field trials in Chile involved approximately 532,000 children ages 6 to 19 years who were vaccinated in school-based programs, after which epidemiologic surveillance was maintained through the health centers of the National Health Service. Only culture-confirmed cases were used in the computation of incidence rates and vaccine efficacy.

In the field trial in the Western (Occidente) administrative area of Santiago,[218] the efficacy conferred by three doses of vaccine in enteric-coated capsules was compared with that provided by three doses of vaccine in the gelatin capsule–$NaHCO_3$ formulation. As seen in Table 61.10, over 3 years of surveillance the enteric-coated vaccine provided significantly superior protection. Over 7 years of follow-up, the regimen of three doses of Ty21a in enteric-coated capsules (every-other-day dosing) conferred 62% protection.[147]

Data from Ferreccio C, Levine MM, Rodriguez H, et al. Comparative efficacy of two, three, or four doses of Ty21a live oral typhoid vaccine in enteric-coated capsules: a field trial in an endemic area. J Infect Dis. *1989;159:766–769.*

A randomized, controlled, double-blind field trial in the Northern (Norte) area of Santiago showed that immunization with only one or two doses (given 1 week apart) of Ty21a in enteric-coated capsules resulted in a moderate level of protection that was short lived (Table 61.11).[124] Although two doses of vaccine conferred 60% protection during the first 2 years of surveillance, efficacy dropped to insignificant levels during the third year and virtually disappeared by the fourth year of surveillance.

A very large trial involving more than 200,000 schoolchildren was carried out in the Southern (Sur) and Central administrative areas of Santiago to compare directly the protective effects of two, three, or four doses of Ty21a vaccine in enteric-coated capsules and to assess the use of Ty21a as a public health tool.[150] No placebo group was included in this trial. The salient feature of this trial is the observation that ingestion of four doses of vaccine (administered on an every-other-day schedule) resulted in a significantly lower incidence of typhoid than three doses (Table 61.12). The results of this trial formed the basis for the recommended four-dose immunization schedule following licensure of Ty21a in the United States and Canada (a three-dose regimen is used elsewhere).

In the mid-1980s, the Swiss Serum and Vaccine Institute succeeded in preparing a liquid suspension formulation of Ty21a for large-scale field trials that was amenable to large-scale manufacture. The new formulation consisted of two packets, one containing a dose of lyophilized vaccine and the other containing buffer. Contents of the two packets were mixed in a cup containing 100 mL of water, and the suspension was then ingested by the vaccinee. Field trials were initiated in Santiago, Chile,[230] and in Plaju, Indonesia,[121] to directly compare this new liquid formulation of Ty21a (which somewhat resembles what was used in the Alexandria, Egypt, field trial) with the enteric-coated capsule formulation. Table 61.13

[a]Results of randomized, placebo-controlled field trials in Santiago, Chile, and Plaju, Indonesia.
Data from Levine M, Ferreccio C, Cryz S, et al. Comparison of enteric-coated capsules and liquid formulation of Ty21a typhoid vaccine in a randomized controlled field trial. Lancet. *1990;336:891–894; and Simanjuntak C, Paleologo F, Punjabi N, et al. Oral immunisation against typhoid fever in Indonesia with Ty21a vaccine.* Lancet. *1991;338:1055–1059.*

summarizes the results of these two trials. Vaccine administered as a liquid suspension was superior to vaccine in enteric-coated capsules. In the Santiago trial, the difference was highly significant. Ty21a given as a liquid suspension protected young children as well as older children.[230] In previous trials with enteric-coated vaccine, young children were not as well protected as older children.[218]

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

The two Vi conjugate vaccines that have been licensed (in India), Typbar-TCV and PedaTyph, were approved on the basis of clinical data supporting their safety, clinical tolerability, and immunogenicity. There have been no reports of these conjugates having been evaluated for efficacy in randomized, controlled, double-blind field trials. However, in 2016 there was a report of a quasirandomized, open-label trial of Ped-Typh that included 905 Kolkata children age 6 months to 12 years who received two doses of conjugate, 6 weeks apart, and were followed with active surveillance (weekly telephone calls plus monthly school visits) for 1 year, along with 860 unvaccinated control children.[206a] Overall, among the vaccinees, 61.8% were older than 5 years, 29.1% were age 3 to 5 years, and 9.1% were age 6 months to 2 years. The control children had a similar age distribution, as 61.8% were older than 5 years, 29.1% were age 3 to 5 years, and 12.7% were age 6 months to 2 years. Notably, no cases of blood culture–confirmed typhoid fever were recorded among the 905 vaccinees during the 1 year of surveillance versus 11 confirmed cases among the 860 unvaccinated control children, indicating a vaccine efficacy of 100% (95% CI, 97.7–100) ($P < .001$).

Correlates of Protection

Because of the complex nature of the pathogenesis of *S.* Typhi clinical infection, a protective role is probably played by secretory intestinal antibody (in preventing mucosal invasion), circulating antibody (against bacteremic organisms), and cell-mediated immunity (to eliminate intracellular bacilli). With parenteral vaccines, the circulating antibody response is substantial and presumably provides the predominant protective effect. In contrast, with live attenuated oral vaccines the circulating antibody response may be modest but the vigorous secretory intestinal IgA and cell-mediated immune responses evoked are believed to be responsible for the protection conferred by that type of vaccine.

Unfortunately, with *S.* Typhi the critical antigens responsible for protection are not agreed on, and data are somewhat contradictory. With parenteral whole-cell vaccines, elicitation of serum H (flagellar) antibodies in humans correlated with protection observed in field trials of efficacy and in volunteer challenge studies, whereas stimulation of O and Vi antibodies (measured in an era when highly purified, nondenatured Vi was not available for use as antigen) did not.[234,344,348,352] In contrast, with live oral vaccines the mucosal IgA and systemic cell-mediated immune responses appear in large part to be directed toward the O and H antigens, but not to the Vi antigen.[149,198,200,235–239,246,255,256,285–290,302,313,314,318–320,360–362] In fact, one attenuated strain (Ty21a) lacks Vi antigen[209] yet provides significant protection.[121,124,147,150,218,230,359]

Parenteral Inactivated Whole-Cell Vaccine

H antibodies appear to contribute to long-term protection. Killed whole-cell parenteral vaccines that were most protective in field trials elicited the highest levels of H antibody. Serum H antibody titers also correlated with protection against typhoid fever among young adult volunteers who participated in experimental challenge studies that assessed the efficacy of typhoid vaccines.[214,243,244] Control volunteers with elevated H titers (presumably derived by natural infection or vaccination many years earlier during military service) were significantly protected against development of typhoid fever compared with those who had no H antibody. The most convincing evidence that H antibody is important comes from the field trial by Wahdan and colleagues[245] of an acetone-killed and dried vaccine prepared from a strain of *S.* Typhi that lacks H antigen. This vaccine, which did not elicit H antibodies, failed to confer significant protection.

K-type whole-cell vaccine that stimulated higher levels of Vi (as well as H) antibody conferred better protection than L-type whole-cell vaccines that elicited lower titers of Vi (and H) antibodies.[40]

Purified Vi Polysaccharide Parenteral Vaccine

The protection conferred by parenteral Vi polysaccharide vaccine is clearly correlated with the ability to stimulate serum Vi antibodies.[122,123] The relatively short-lived nature (~2 years) of the antibody response[343] aligns with the length of protection conferred by unconjugated Vi polysaccharide.

Ty21a Live Oral Vaccine

Using serum IgG O antibody measured by ELISA in Chilean 15- to 19-year-olds, Levine and associates[149] showed a correlation between seroconversion to various dosage schedules and

formulations and protective efficacy in field trials (see Table 61.5). With the currently licensed enteric-coated capsule formulation, there is a stepwise increase in the proportion of vaccinees who manifest significant rises in serum IgG O antibody depending on whether one, two, or three doses of vaccine are administered within 1 week. Although serum O antibody is not believed to be the operative mechanism of immunity elicited by attenuated strains, it clearly correlates with protection. Because ELISA measurement of serum IgG antibody to *S.* Typhi O antigen is a simple technique, it provides investigators with a practical tool for comparing immunization schedules and formulations and for evaluating new candidate live oral vaccines.

Kantele and coworkers[246,285–288,292,294] showed that gut-derived migrating IgA O ASCs detected in the peripheral blood after oral immunization of adult Finnish volunteers with different formulations and immunization schedules of Ty21a closely correlated with the efficacy results recorded in field trials (see Table 61.6). Thus three doses (taken every other day) of Ty21a in enteric-coated capsules are markedly more immunogenic than one dose, and Ty21a in a liquid suspension is more immunogenic than vaccine in enteric-coated capsules.

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

Ample serological data document the immunogenicity of Typbar-TCV Vi conjugate vaccine, which is licensed in India. Although still unlicensed, extensive data demonstrate the serum Vi antibody responses to the extensively tested Vi-rEPA conjugate which has shown efficacy in a randomized controlled field trial.[125,326,331,332] Typbar-TCV has demonstrated robust immunogenicity following the administration of a single dose of vaccine in subjects age 6 months and above. No pre- or postlicensure trials have been undertaken to assess the level of protection conferred by Typbar-TCV. Limited published postlicensure data document the immunogenicity of PedaTyph and one small randomized, open-label trial comparing 905 children who received two doses of this Vi conjugate 6 weeks apart versus 860 unvaccinated children followed for 1 year found 100% efficacy. There were no confirmed cases among the 905 vaccinees versus 11 confirmed typhoid cases among the 860 similarly-aged controls.[206a]

Summary of Correlates of Protection

In summary, the correlate of protection of Vi-based parenteral vaccines (including unconjugated Vi polysaccharide and Vi conjugates) is serum IgG antibody measured by ELISA or by radioimmunoassay. However, there is not yet agreement on the titer that serves as a threshold indicating protection, nor is there yet a specific assay nor a standard reference serum that is accepted by all key stakeholders. Finally, there is ongoing research to try and identify a biological activity (e.g., bactericidal or opsophagocytic activity) of the antibodies that may provide a mechanistic correlate of protection.

For Ty21a live oral vaccine, mucosal IgA response to *S.* Typhi LPS, in particular IgA ASCs that make antibody to LPS, constitutes one correlate of protection. The rate of seroconversion of serum IgG antibodies directed against LPS also correlated with results of field trials of Ty21a. Formulations and regimens that elicited the strongest serum anti-O responses correlated with better efficacy in field trials. Finally, the elicitation of long-lived major histocompatibility complex I–restricted CD8 cytotoxic T-cell responses to targets infected with *S.* Typhi constitutes the most likely immune response that explains the long duration of protection stimulated by that live oral vaccine. However, a more formal quantitative correlation of cell-mediated immunity responses with efficacy has not been established. Regrettably, these modern cell-mediated immunity methods were not available when the large-scale efficacy trials of Ty21a were taking place.

Duration of Vaccine-Derived Immunity

Parenteral Inactivated Whole-Cell Vaccines

The longest periods of surveillance (7 years) for efficacy of the parenteral killed whole-cell vaccines were carried out in the Guyana and Tonga field trials. In Guyana, two doses of the acetone-killed K vaccine conferred a high level of protection (88%) for 7 years.[349] In contrast, in Tonga, two doses of a K-type vaccine provided moderate protection for a period of only 5 years, after which protection was no longer demonstrable.[351] Two doses of the heat-inactivated, phenol-preserved vaccine (L) tested in Guyana showed moderate (77%) protection during the first 3 years, but this level fell to 47% protection during the last 4 years of surveillance. In several other field trials in which the period of surveillance was only 2.5 years, the acetone-inactivated and the heat-inactivated, phenol-preserved vaccines conferred significant protection for at least 30 months.[165,185,347]

Purified Vi Polysaccharide Parenteral Vaccine

In the South African field trial, surveillance was maintained for 3 years. During this 3-year period, the efficacy of the Vi vaccine was 55% (see Table 61.8).[274] Similarly, in a field trial in Southern China, protective efficacy lasted only 2 years. Additional data showing that protection from Vi does not endure beyond 3 years came from an epidemiologic investigation of an outbreak of typhoid fever in French military personnel in Ivory Coast. The outbreak investigation revealed that soldiers immunized with Vi vaccine more than 3 years previously had a twofold higher risk of developing typhoid fever than soldiers immunized less than 3 years earlier.[363]

Ty21a Live Oral Vaccine

In the field trial in Alexandria, Egypt, three doses of a liquid formulation of vaccine conferred a high level of protection (96%) that persisted for 3 years, the point at which surveillance was discontinued.[359] Three doses of vaccine in enteric-coated capsules given at an interval of every-other-day conferred 67% protection over 3 years[218] and 62% protection over 7 years of follow-up in a field trial in Santiago, Chile[147]; fewer (one or two) doses of vaccine (given 1 week apart) in enteric-coated capsules, also in Santiago, conferred significant protection for 2 years but not longer.[124]

Three doses of Ty21a in a liquid formulation (administered at an every-other-day interval) provided 77% protection for 3 years[230] and 79% protection during a fourth and fifth year of follow-up (78% protection over the 5 years of follow-up) in a field trial in Santiago.[147]

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

The only data on the duration of efficacy of the Vi-TT conjugates licensed in India is the 1-year assessment of efficacy of Peda-Typh that showed no cases among 905 vaccinees during that short follow-up. Consequently, there are no data on the duration of efficacy conferred by these two licensed Vi conjugate vaccines. A field trial of efficacy of a prototype Vi-rEPA conjugate administered to preschool-age children in Vietnam

provided a point estimate of 89% efficacy over 46 months of follow-up (that included 27 months of active household visit surveillance and 19 months of passive health center-based surveillance).

Comparison of Vaccine-Derived Immunity With Natural Immunity

Several sources of data suggest that the immunity that follows clinical infection with pathogenic *S*. Typhi is relative and can be overcome. Marmion and colleagues[364] and others reported successive outbreaks of typhoid fever in soldiers who, in the space of a few months, experienced two separate bouts of typhoid fever. In the volunteer studies carried out by Hornick and colleagues[56] and DuPont and associates,[179] two relevant observations were reported. The first is that immunity to typhoid fever is relative and can be overcome if a large infecting dose is ingested. Second, the protective effect of a prior clinical typhoid infection was only 33%; that is, five of 22 volunteers (23%) who recovered from an induced *S*. Typhi infection developed typhoid fever when rechallenged with pathogenic organisms, as opposed to 11 of 34 (32%) control volunteers ($P > .05$).

Based on these observations, it can be argued that Vi polysaccharide vaccine, and Ty21a, as well as the no longer available parenteral killed whole-cell vaccines, stimulate rather credible immunity compared with natural immunity elicited by infection with wild-type *S*. Typhi. The same is likely to be true for Vi conjugate vaccines assuming that recently licensed Vi-TT conjugates confer similar levels and duration of protection as Vi-rEPA. Undoubtedly, in endemic areas most persons experience multiple subclinical *S*. Typhi infections, each serving to further boost the state of immunity; persons who develop overt disease represent a minority of all infected persons.

Postexposure Prophylaxis and Therapeutic Vaccination

Postexposure prophylaxis is not practiced with typhoid vaccines because the incubation after ingestion of a large inoculum may be less than 1 week, and the organisms rapidly gain their intracellular niche (within 24 hours). Thus, after exposure, there would be insufficient time after administration of the currently licensed vaccines to mount an effective immune response. There have been anecdotal reports of unsuccessful attempts to immunize chronic gallbladder carriers with the intent to interrupt chronic carriage.

Adverse Events

Parenteral Inactivated Whole-Cell Vaccines

Common. Although the parenteral killed whole-cell vaccines provided moderate to good protection, the high rates of systemic and local adverse reactions that were associated with their use made them unsatisfactory public health tools.[165,347,348,365–367]

Rare. Rarely, more significant reactions were attributed to vaccination with parenteral killed whole-cell typhoid vaccines. These included thrombocytopenic purpura,[368,369] acute renal disease,[370–374] dermatomyositis,[375] appendicitis,[376] erythema nodosum,[377] multiple sclerosis,[378] and a syndrome of high fever, severe malaise, and toxemia,[366,367] sometimes accompanied by coagulopathy, thrombocytopenia, hepatitis, and renal insufficiency.[379] Rarely, sudden death occurred after parenteral inoculation with inactivated whole-cell typhoid vaccine.[379] Among these rare severe adverse events, the syndrome of high fever and toxemia and the occurrence of sudden death have biologic plausibility based on abnormally potent responses of certain persons to *S*. Typhi endotoxin inoculated parenterally via whole-cell vaccine, leading to cytokine release and a cascade of events ultimately resulting in shock and perhaps death.

Purified Vi Polysaccharide Parenteral Vaccine

When Vi vaccine is highly purified, it is well tolerated.[213,227–229,241,272,380] As little as 5% impurity with LPS results in systemic adverse reactions in a proportion of recipients, emphasizing the importance of manufacturing highly purified Vi vaccine.[229] In controlled Phase II trials in U.S. adults, local reactions including pain and tenderness were the most common adverse events.[229,241] Passive surveillance carried out during field trials showed the Vi vaccine to be as well tolerated as the licensed (meningococcal and pneumococcal) polysaccharide vaccines that served as the control preparations in these trials.[122,123]

In one Belgian study, adults were randomly allocated to be inoculated with Typhim Vi or one of three lots of Typherix, and local and systemic reactogenicities were compared.[264] This was not a double-blind study. None of the recipients of either vaccine had high fever (≥39°C); 0% of Typhim Vi and 2% of Typherix recipients reported low-grade fever (<39°C). Local erythema, soreness, and swelling were reported significantly more often in the 100 recipients of Typhim Vi (21%, 33%, and 17%, respectively) than among the 300 subjects who received the lots of Typherix (3%, 8%, and 2%, respectively).

The results of postmarketing surveillance for Vi vaccine from the Vaccine Adverse Event Reporting System (VAERS) maintained by the CDC and the FDA were reported for the period 1994 (time of licensure) through June 2002.[381] A total of 321 adverse event reports were received in relation to administration of Vi vaccine, alone or in conjunction with other vaccines. The overall rate was 4.5 adverse events per 100,000 doses of Vi vaccine distributed, with a rate of serious adverse events of 0.34 per 100,000 doses distributed. Unexpected commonly reported symptoms included dizziness and pruritus.

Ty21a Live Oral Vaccine

Ty21a provides significant protection and appears to be quite safe.[121,149,245,279,280,382] Results of three double-blind, placebo-controlled studies that used active surveillance methods to assess the reactogenicity of Ty21a in adults and children are shown in Table 61.14. Surveillance methods to assess the reactogenicity of Ty21a in adults and children are shown in Table 61.14. The rates of adverse reactions in the vaccine recipients were not significantly higher than those for the placebo group for any symptom or sign. In large-scale field trials with Ty21a, involving approximately 550,000 schoolchildren in Chile and 32,000 schoolchildren in Egypt, and approximately 20,000 subjects ranging in age from 3 years to adulthood in Indonesia, passive surveillance failed to identify vaccine-related adverse reactions.[121,124,218,230,245,383]

The results of postmarketing surveillance for Ty21a vaccine from VAERS were reported from 1990 (immediately after licensure in December 1989) through June 2002.[381] A total of 345 reports of adverse event occurring in persons 18 to 65 years of age were received in relation to administration of Ty21a vaccine, alone or in conjunction with other vaccines. The overall rate was 9.7 adverse events per 100,000 doses of Ty21a vaccine distributed, with a rate of serious adverse events of 0.59 per 100,000 doses distributed. Unexpected commonly

TABLE 61.14 Randomized, Placebo-Controlled, Double-Blind Clinical Trials of Three Doses of Ty21a in Enteric-Coated Capsules or in Buffer Suspension to Assess Reactogenicity of the Vaccine in Adults, School-Age Children, and Preschool-Age Children

reported symptoms included fatigue and myalgias.[381] There is one report of two cases of reactive arthritis possibly associated with immunization with Ty21a[384]; interestingly, the affected persons were human leukocyte antigen B27–negative.

Purified Vi Polysaccharide–Tetanus Toxoid Conjugate Parenteral Vaccine

Most data establishing the safety of the Vi conjugate vaccines derive from prelicensure clinical trials,[153,205,206,242,326,331,332] except for one small postlicensure trial of one Indian conjugate. The collective experience with the two licensed Vi-TT conjugates and with the various other conjugates in clinical development reveal them to be similarly well tolerated as other conjugate vaccines in children and adults.

Indications

Populations for whom vaccine is indicated include the following:

- Travelers to less-developed areas where typhoid is known or believed to be endemic;
- Military personnel (who represent a special group of travelers);
- School-age children in areas in which typhoid is endemic, particularly where multiple antibiotic-resistant strains are prevalent;
- Preschool-age children where epidemiologic data indicate there is a notable disease burden (e.g., some urban slums in South Asia); and
- Microbiology technicians in clinical microbiology laboratories or in research laboratories in which *S.* Typhi is handled.

Table 61.15 summarizes the immunization schedules and dosages, for different age groups, for the oral Ty21a vaccine, the parenteral Vi vaccine, and one licensed Vi conjugate vaccine.[148,385]

Typhoid vaccine is not generally indicated after floods, earthquakes, or other natural disasters during which the water and sewage systems may suffer structural damage.[386,387] Resources should rather be directed toward repairing the contaminated water sources, which, it is hoped, could be achieved long before a mass vaccination could be completed and the protective effect of vaccine initiated. Nevertheless, there are situations in which typhoid vaccines may serve as a helpful adjunct to other control measures. For example, if a major upheaval occurs in a region of a country where typhoid is endemic, and where formidable economic or political obstacles are expected to impede timely improvements in water supply quality and sanitation infrastructure, selective vaccination of high-risk groups may be helpful.[388,389]

It was suggested that a period of increased risk for acquisition of typhoid fever occurred for approximately 10 days after the administration of the first dose of parenteral killed whole-cell vaccine; this was referred to as the negative phase after vaccination.[390–393] Such a phenomenon has not been described for Vi, Ty21a, or Vi conjugate vaccines.

Contraindications

There are no contraindications to immunization with parenteral Vi polysaccharide vaccine other than known hypersensitivity to any component of the vaccine. Because hyporesponsiveness has emerged as a concern after the repetitive administration of meningococcal[267,268] and pneumococcal[269,270] polysaccharide vaccines, this is a theoretical concern for reimmunizing persons who in recent years received multiple prior immunizations with Vi vaccine. There are no robust data to indicate that hyporesponsiveness frequently follows repetitive immunization with Vi, or that if it does occur it has any clinical consequences.[226,241,271,272] Thus, a history of having been immunized on multiple previous occasions with Vi, several years apart, is not a contraindication to administering another dose of the vaccine.

As a general rule, Ty21a should not be given to pregnant women, although adverse effects on the pregnant woman or fetus have not been reported. Similarly, caution should be taken before anyone with a known depression of cell-mediated immunity is given Ty21a. However, there would appear to be no risk for immunocompromised household contacts of Ty21a vaccinees, because excretion of Ty21a has never been detected in any subject given the available formulations that contain 2 to 6×10^9 CFU per dose.

TABLE 61.15 Immunization Schedules for Ty21a, Vi Polysaccharide, and Vi Conjugate Typhoid Vaccines

Vaccine	Formulation	Route	Age	No. of Doses	Interval Between Doses	Interval Until Next Booster
TY21A LIVE STRAIN						
Primary	Enteric-coated capsules	Oral	≥6 y	3 or 4[a]	2 days (~48 h)	5 y
	Reconstituted liquid suspension[b]	Oral	≥2 y	3	2 days (~48 h)	5 y
Booster	Enteric-coated capsules	Oral	≥6 y	3 or 4	2 days (~48 h)	5 y
	Reconstituted liquid suspension[b]	Oral	≥6 y	3	2 days (~48 h)	5 y
VI-CAPSULAR POLYSACCHARIDE						
Primary	Liquid	Intramuscular (0.5 mL)	≥2 y	1	–	3 y
Booster	Liquid	Intramuscular (0.5 mL)	≥2 y	1	–	3 y
VI CONJUGATE VACCINE[c]						
Primary	Liquid	Intramuscular (0.5 mL)	Adults and children > age 3 y	1	–	3 y[d]
Booster[d]	Liquid	Intramuscular (0.5 mL)	Adults and children > age 3 y	1	–	–
Primary	Liquid	Intramuscular (0.5 mL)	9–12 mo[e]	1	–	
Booster	Liquid	Intramuscular (0.5 mL)	24–36 mo	1	–	3 y

[a]Four doses in the United States and Canada; three doses in all other countries.
[b]The liquid suspension formulation is licensed in several countries but is not presently available commercially.
[c]The information given in the table is for the Bharat Biotech International Vi-TT conjugate (Typbar-TCV), as this is the only Vi conjugate vaccine that is currently both licensed (India) and has recommendations for its use from an immunization advisory committee (the Indian Academy of Pediatrics Advisory Committee on Vaccines and Immunization Practices).
[d]Only limited clinical and immunologic data are available to support the timing of the booster immunization schedule proposed by the manufacturer.
[e]Typbar-TCV has been licensed to be given as a single dose to infants as young as age 6 months. However, the Advisory Committee on Vaccines and Immunization Practices of the Indian Academy of Pediatrics currently recommends that Typbar-TCV be administered to infants at 9–12 months of age, either 1 month before or 1 month after the infants receive their first dose of measles-mumps-rubella (MMR) vaccine and that a second dose of the Vi conjugate vaccine be given between 24 and 35 months of age.[152] Should data become available showing that Typbar-TCV does not interfere with the magnitude of the immune responses to MMR vaccine, and vice versa, it is anticipated that in the future Typbar-TCV will be approved to be administered concomitantly with MMR1.

If immunocompromised persons, including those with HIV infection, must travel to endemic areas, Vi vaccine should be administered. A study of HIV-infected persons in Peru indicated that they were at greatly increased risk for developing typhoid fever,[394] whereas HIV positivity appeared to be protective against typhoid fever in Tanzania.[395]

Ty21a should not be administered to persons who are taking antibiotics. Certain antimalarials, particularly mefloquine, exhibit activity against Ty21a.[233,396,397] In clinical trials, coadministration of chloroquine, mefloquine, or chloroquine plus pyrimethamine-sulfadoxine did not significantly suppress the IgG O antibody response after immunization with Ty21a,[282,398] whereas coadministration of proguanil did.[282] On the basis of these data, it has been proposed that Ty21a should not be taken with proguanil. However, it has since been shown in a randomized, double-blind, placebo-controlled clinical trial that daily administration of Malarone (atovaquone plus proguanil) for 12 weeks did not diminish the serum IgG *S.* Typhi O antibody response in children (4 to 16 years of age) given three doses of the liquid formulation of Ty21a; notably, the first dose of Ty21a was coadministered with a dose of CVD 103-HgR live oral cholera vaccine.[399] Ty21a may be taken with chloroquine, but one should wait 8 to 24 hours after administration of mefloquine before initiating immunization with Ty21a.

PUBLIC HEALTH ASPECTS

Epidemiologic Results of Vaccination

Because of their reactogenicity, parenteral killed whole-cell vaccines were rarely used in a systematic fashion in public health programs in endemic areas. The one exception was Thailand, where in the 1980s school-based immunization programs used parenteral heat-inactivated, phenol-preserved vaccine to control endemic typhoid. A retrospective review suggested that the Thai control program was highly successful.[400]

The lack or rarity of frequent or severe adverse reactions associated with live oral vaccine Ty21a or with parenteral Vi polysaccharide vaccine renders them particularly suitable for public health use in school-based immunization programs. In a large effectiveness trial involving immunization of 216,692 schoolchildren in Santiago, Chile, with the enteric-coated capsule formulation of Ty21a, the vaccine was found to be quite practical for large-scale use in schools.[150] Similarly, in southern China, mass vaccination with parenteral Vi vaccine proved to be logistically feasible and practical in a targeted population of 118,000 persons, although it was concluded that great attention had to be paid to injection safety issues.[151] Large-scale feasibility projects of school-based immunization with Vi vaccine were also carried out in North Jakarta, Indonesia,[401] and in Hue, Vietnam.[402] These projects demonstrated the logistical feasibility, safety, and practicality of delivering Vi vaccine through school-based immunization programs.

A large-scale, cluster-randomized, postlicensure trial of the effectiveness of Vi vaccine was carried out in an urban slum in Kolkata, India.[127] Two new observations were generated during this trial. First, there was evidence of significant indirect protection whereby nonvaccinated subjects in the clusters that were allocated to receive Vi vaccine had significantly lower incidence rates of confirmed typhoid fever (16 cases among 12,206 contacts; 0.19 cases per 10^5 person-days of observation) than unvaccinated subjects in the hepatitis A vaccine clusters (31 cases among 12,877 subjects; 0.35 cases per 10^5

person-days of observation).[127] This translates to 45% indirect effectiveness (95% CI, 1% to 70%; $P = .04$). The second notable observation was that the point estimate of effectiveness of Vi vaccine in the Kolkata trial appeared to be higher among preschool-age children from 2 to 5 years of age (82% effectiveness; 95% CI, 58% to 92%) than among older children from 5 to 15 years of age (59% effectiveness; 95% CI, 18% to 79%) or subjects older than 15 years of age (48% vaccine effectiveness; 95% CI, 44% to 81%).[127] This was unusual in that with other typhoid vaccines, such as parenteral killed whole-cell and oral Ty21a, and with earlier trials of Vi vaccine, the level of protection was always lower in younger children than in older subjects.[218,349,403] Indeed, in contrast to the Kolkata results, another postlicensure effectiveness trial with a similar cluster-randomized design (with the same Vi vaccine [Typherix] as was used in Kolkata) that was carried out in subjects 2 to 16 years of age in poor urban squatter settlements in Karachi, Pakistan,[128] showed no evidence that Vi vaccine protected preschool-age children younger than 5 years of age, whereas it did confer significant protection to the older subjects. Nor was evidence of indirect protection observed in the Karachi effectiveness trial.[128] Differences in the level of immunization coverage between Kolkata and Karachi and inclusion of adults in the Kolkata trial could help explain the divergent results on indirect protection. There is no clear explanation for the unusually high level of protection of preschool-age children in the Kolkata trial and lack of protection of preschoolers in Karachi.

There is epidemiologic evidence that the large-scale field trials in Santiago, Chile, with Ty21a produced a herd immunity effect.[149] In children in the placebo group in the first field trial of Ty21a in Area Norte, Santiago, the incidence of typhoid fell progressively as each of three field trials was initiated in subsequent years in other administrative areas of the city.[149] The incidence rate in this group diminished by approximately 70% from the mean incidence in the 3 years before the field trials. These data suggest that systematic application of live oral typhoid vaccine, even with a formulation that provides only approximately 60% to 70% efficacy, can notably diminish the incidence of the disease in endemic areas.

Table 61.16 summarizes the salient features of the two typhoid vaccines that have been available in recent years, oral Ty21a and parenteral Vi polysaccharide, and for two Vi-TT conjugates licensed in India. One report of 905 children vaccinated with two doses of Peda-Typh and of 860 unvaccinated controls who were actively followed for 1 year provides the first efficacy data for that Indian Vi-TT conjugate.[206a] It is expected that planned postlicensure evaluations of Typbar-TCV and perhaps of other (future-licensed) Vi conjugates will generate additional more robust effectiveness data.

Disease Control Strategies

Because the peak incidence of clinically recognizable typhoid fever in most endemic areas (based on passive, health facility–based surveillance that detects cases severe enough to seek healthcare) occurs in school-age children 5 to 19 years of age, and because this is a captive population, in theory it should be possible to design control programs to incorporate school-based immunization with well-tolerated typhoid vaccines.[148,149] Field trials have clearly demonstrated that both Ty21a and Vi confer a moderate level of protection that endures for several years. Moreover, field experiences with both Ty21a and Vi support the logistical practicality of such an approach.[150,151,401,402] Ferreccio and colleagues[150] reported the practicality of school-based immunization in an effectiveness trial in 216,692 schoolchildren that compared two-dose, three-dose, and four-dose regimens (all doses given within 8 days) of Ty21a. Further encouragement for programmatic use of typhoid vaccines comes from the observation of Levine and coworkers[149] that a herd immunity effect was evident in geographically separate areas of Santiago after the large-scale use of typhoid vaccine in other areas. Similar positive experiences of logistical feasibility of school-based immunization have been demonstrated for Vi vaccine,[401,402] and evidence that Vi can confer indirect protection on unvaccinated contacts has also been reported.[127] There is also a report of a school-based immunization of 441 students in the face of an epidemic of typhoid in Guangxi, China, in which the vaccine showed 71% effectiveness (although with wide confidence limits).[216]

TABLE 61.16 Comparison of the Characteristics of Live Oral Vaccine Ty21a and Parenteral Vi Polysaccharide Vaccine

Characteristic	Ty21a		Vi	Vi Conjugate[a]
Formulation	**Enteric-Coated Capsules**	**Liquid Suspension[b]**	**Liquid**	**Liquid**
Type of vaccine	Live	Live	Subunit	Subunit
Route of administration	Oral	Oral	Parenteral	Parenteral
Immunization schedule	3 or 4 doses[c]	3 doses[c]	1 dose	1 or 2 doses
Cold chain required by manufacturer	Yes	Yes	Yes	Yes
Well tolerated	Yes	Yes	Yes	Yes
Range of efficacy	35–67%	55–96%	64–72%	89–100%
Duration of efficacy	62% for ≥7 y	78% for ≥5 y	55% for 3 y	89% for 46 mo
Herd immunity effect	Yes	Yes	Yes	?
Can interfere with use of serum Vi antibody as a screening test to detect chronic typhoid carriers	No	No	Yes	Yes

[a]The information given in this table on the route of administration, immunization schedule, and clinical tolerability are for the Bharat Biotech International Vi-TT conjugate (Typbar-TCV), as this is the only Vi conjugate vaccine that is currently both licensed (India) and has recommendations for its use from an immunization advisory committee (the Indian Academy of Pediatrics Advisory Committee on Vaccines and Immunization Practices).[152] Information on the level and duration of efficacy are based on prelicensure data from a field trial of Vi-rEPA,[125,126] and from a postlicensure efficacy evaluation of Peda-Typh limited to 1 year of follow-up.[206a]

[b]Lyophilized vaccine from a sachet is added to 100 mL of water, along with a buffer powder and stirred, resulting in a vaccine suspension.

[c]Given every other day (i.e., ~48 hours between doses).

Unfortunately, heretofore, with only a few exceptions, public health authorities in endemic areas have not enthusiastically embraced the use of Ty21a or Vi in school-based immunization programs. One reason that health authorities declined to institute school-based immunization with Ty21a or Vi is the concern that such a program would deflect scarce resources from the Expanded Programme on Immunization (EPI), which, in developing countries, focuses mainly on infants younger than 12 months of age. For this reason, as an alternative strategy, several national health authorities have expressed interest in the possible inclusion of a typhoid vaccine in the EPI for infants. Such a strategy would allow typhoid fever control to proceed without deflecting resources from the traditional infant-targeted EPI. Unfortunately, no data are currently available to demonstrate that, if either Ty21a or Vi were given to infants, the immunity elicited would endure and protect years later when the children reach the high-risk school-age years. The commercial liquid formulation of Ty21a was shown to be immunogenic in toddlers and preschool-age children 2 to 5 years of age,[279,280] but that formulation has not been tested in infants younger than 12 months of age and is not currently commercially available. Unconjugated Vi polysaccharide vaccine is not recommended for administration to infants.[213] If public health authorities in endemic areas desire typhoid vaccines that are immunogenic and protective in infants so that they can be added to the EPI, those vaccines are becoming available through the licensure of Vi conjugates (Typbar-TCV and PedaTyph, have already been licensed in India and the Indian Academy of Pediatrics has made specific recommendations on the pediatric target populations for Typbar-TCV). In future years the improved attenuated live oral vaccine strains that have been in clinical trials may also become available and they are expected to confer long-term protection as does Ty21a.

Cost–Benefit Information

Several studies have looked at cost–benefit, cost-effectiveness, and other health economic assessments of using typhoid immunization as a measure to control endemic disease.[111,146,404–407] The results of such analyses are very context-specific. The data of Ferreccio and colleagues[146] suggest that generically the two most important factors that drive the analysis in favor of cost-effectiveness are the magnitude of the disease burden (disease incidence) and the duration of protection conferred by the vaccine.

Eradication or Elimination

Whereas chronic carriers constitute the reservoir of *S*. Typhi, the maintenance of a high incidence of typhoid fever requires conditions that permit amplified transmission of *S*. Typhi to susceptible persons. Usually, this involves fecal contamination of water sources consumed by large numbers of persons. In the late 19th and early 20th centuries, it was demonstrated in Europe and the United States that treatment of municipal water supplies caused the incidence of typhoid fever to plummet, despite the continued existence in the population of large numbers of chronic carriers. Over one to two decades this led to near-elimination of typhoid fever from many areas.[158]

It is not known if programmatic use of Ty21a or Vi conjugate could accomplish the same near-elimination of typhoid fever as a public health problem, as have improvements of water and sanitation. Unconjugated Vi vaccine with its relatively short-term protection and Ty21a with its requirement for three spaced doses are not likely to be lynchpins of elimination campaigns. On the other hand, some Vi conjugates and a few attenuated strains that function as single-dose oral vaccines are much more amenable for this purpose. If these recently licensed and future vaccines are well tolerated, immunogenic in infants,[332] and confer a high level of long-lasting protection, they could serve as the basis of typhoid fever–control programs. Aggressive control programs that achieve a high level of coverage with such vaccines might nearly eliminate typhoid fever in certain populations as remaining chronic typhoid carriers would eventually die off and few new chronic carriers would replace them.

It is epidemiologically feasible that typhoid fever can someday be eradicated from the world. This would require a combination of treatment of water supplies and provision of sanitation to diminish transmission, systematic screening to detect chronic typhoid carriers and treatment of the carriers to diminish the reservoir of infection, and, finally, programmatic use of well-tolerated, highly effective typhoid vaccines that confer enduring protection. However, other pressing global priorities and the enormous costs involved so far keep typhoid eradication to the level of a theoretical concept. Even if typhoid fever were eliminated in large regions of the world where that disease is now endemic, the endemicity of paratyphoid A fever caused by *S*. Paratyphi A, which exhibits a clinically indistinguishable syndrome, would not be affected by Vi conjugate vaccines or live *S*. Typhi vaccines.

RECENTLY LICENSED AND FUTURE VACCINES

Vi Conjugates

Because purified Vi polysaccharide acts like a T-lymphocyte–independent antigen, the serum antibody response cannot be readily boosted by administration of additional doses of Vi vaccine.[241] In contrast, when Vi is conjugated to carrier proteins, such as tetanus or diphtheria toxoids, mutant diphtheria toxin CRM_{197}, cholera toxin, cholera toxin B subunit, or recombinant exotoxin A of *P. aeruginosa*, it behaves like a T-lymphocyte–dependent antigen.[42,265,408,409] In animal models, subsequent inoculations with Vi conjugate vaccine clearly boost the serum Vi antibody titer.[42,265,408,409] Clinical studies carried out in adults, school-age children, and preschool-age children in Vietnam compared the immunogenicity of two formulations of Vi–exoprotein A conjugate prepared using two different methods of conjugation. The conjugate prepared by treating the carrier protein with ADH and binding to Vi in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide elicited significantly higher titers of serum IgG Vi antibody than the other Vi conjugate (and also higher than Vi polysaccharide alone), yet was well tolerated. The superior conjugate showed a high rate of seroconversion in all ages after a single injection (containing 24 μg of Vi and 21.5 μg of exoprotein A) but a gradation in GMT that decreased progressively from adults to toddlers. The group of subjects given a second dose of this conjugate 6 weeks later exhibited a clear booster response in IgG Vi antibody titers.

Szu and colleagues[265,326] pursued a stepwise program to develop an optimal Vi conjugate vaccine that culminated in a candidate for clinical trials consisting of Vi polysaccharide conjugated to recombinant *P. aeruginosa* exotoxin A (Vi-rEPA). After demonstration of the safety and immunogenicity of this conjugate,[326] the efficacy conferred by a two-dose (6 weeks apart) immunization schedule of the vaccine was evaluated in a large-scale, randomized, controlled field trial in Vietnam in children 2 to 5 years of age.[125] The conjugate used in the Phase III field trial of efficacy in Vietnam contained 22.5 μg of Vi and 22 μg of exoprotein A per 0.5-mL dose of vaccine.[125]

In total, 5525 children received two doses of Vi conjugate and 5566 received placebo in a field trial in Vietnam that

TABLE 61.17 Cases of Typhoid Fever in Pediatric Recipients[a] of Parenteral Vi Conjugate Vaccine or Placebo in a Randomized, Double-Blind, Controlled Field Trial in Vietnam

	Vi-Recombinant Exoprotein A Conjugate	Placebo	Vaccine Efficacy (95% CI)	*P* Value
27 Months of Active Surveillance				
Two-dose recipients	5525	5566		
Typhoid fever cases[b]	4	47	91.5% (77.1–96.6%)	<.001
Cases/10^3 children	0.72	8.44		
All children (1 or 2 doses)	5991	6017		
Typhoid fever cases	5	56	91.1% (78.6–96.5%)	<.001
19 Months of Passive Surveillance

Cases/10^3 children	0.50	3.05		
Total 46 Months of Follow-up (27 Months of Active Plus 19 Months of Passive Surveillance)				
Typhoid fever cases[c]	8	73	89.0% (76.0–96.9%)	<.001
Cases/10^3 children	1.45	13.1		

[a]Children were 2, 3, 4, or 5 years of age at the time of vaccination and were followed for 27 months thereafter.
[b]Per protocol analysis.
[c]Intent-to-treat analysis.
CI, confidence interval.
Data from Lin FYC, Ho VA, Khiem HB, et al. The efficacy of a Salmonella *Typhi Vi conjugate vaccine in two-to five-year-old children.* N Engl J Med. *2001;344:1263–1269; and Mai NL, Phan VB, Vo AH, et al. Persistent efficacy of Vi conjugate vaccine against typhoid fever in young children.* N Engl J Med. *2003;349:1390–1391.*

evaluated the efficacy of Vi-rEPA conjugate. During 27 months of follow-up, active surveillance was carried out to detect cases of typhoid fever by visiting children weekly, eliciting a symptom history, and recording their axillary temperature. Subjects who had a temperature of 37.5°C or higher for at least 3 days were referred to a health center, where 5 mL of blood was drawn for bacteriologic culture. Typhoid fever was diagnosed in four of 5525 vaccinees and 47 of 5566 controls, demonstrating an efficacy of 91.5% (95% CI, 77.1% to 96.6%) (Table 61.17).[125] The level of efficacy did not vary by year of age among these 2- to 5-year-old children, nor did it appear to wane during the second year of surveillance.

After the code was broken, an additional 19 months of follow-up were instituted by means of passive surveillance. During these 19 months, three cases of confirmed typhoid fever were detected in vaccinees and 17 cases in placebo recipients who sought healthcare (82.4% efficacy; 95% CI, 22.3% to 99.1%). Over the full 46 months of follow-up (27 months using active and 19 months using passive surveillance methods), overall vaccine efficacy was 89.0% (95% CI, 76.0% to 96.9%) (see Table 61.17).[125,126] Subsequently, the prototype Vi-rEPA conjugate demonstrated satisfactory immunogenicity when young Vietnamese infants were immunized according to an EPI schedule (priming immunization with three doses at 2, 4, and 6 months of age followed by a reinforcing dose at age 12 months), and there was no significant interference with other EPI vaccines.[332]

Besides the two Vi conjugates licensed in India (Typbar-TCV and PedaTyph) and Vi-rEPA, Vi conjugate vaccines in clinical development include a Vi-CRM_{197} conjugate[327,410] manufactured by BioE (Hyderabad, India). Other Asian manufacturers are developing diphtheria toxoid–based conjugates that are slated for clinical trials in 2017 and 2018.

New Recombinant *Salmonella* Typhi Strains as Live Oral Vaccines

Various investigators have applied recombinant DNA technology to engineer new candidate vaccine strains of *S.* Typhi that will be as well tolerated as Ty21a but much more immunogenic, so that protective immunity can be elicited with a single dose. Toward that ambitious goal, candidate attenuated vaccine strains have been prepared by inactivating genes encoding various biochemical pathways,[194,196,197,411] global regulatory systems,[199,412] stress proteins,[413] other regulatory genes,[414,415] and putative virulence properties.[411]

Among these various strains, based on results of completed Phase I and Phase II clinical trials, three strains remain viable vaccine candidates and are in various stages of clinical development as live oral typhoid vaccines or as live vectors. The status of these vaccine strains is briefly summarized below.

***ΔaroC,ΔssaV* Strain M01ZH09.** The SsaV protein forms part of the *S. enterica* type III secretion system that plays a role in virulence, including affecting systemic invasiveness (in a mouse model) and replication in macrophages.[411] Hindle and coworkers[411] reported results of a small Phase I clinical trial with strain M01ZH09, a Δ*aroC,*Δ*ssaV* mutant of wild-type strain Ty2. In this small trial, the vaccine was well tolerated, minimally excreted, and moderately immunogenic.[411] A Phase II dose-ranging trial in U.S. adults compared the reactogenicity and immunogenicity of a single 5×10^7, 5×10^8, or 5×10^9 CFU dose of vaccine administered with bicarbonate buffer (16 subjects per vaccine dosage level, and a total of 12 placebo recipients).[362] Five recipients of the two higher dosage levels developed mild fevers. Immune responses were most prominent in recipients of the highest dosage level. Another Phase II trial showed that a single 5×10^9 CFU dose was immunogenic whether administered alone or after bicarbonate buffer (to neutralize gastric acid).[239] Single doses between 5×10^9 CFU and 1.7×10^{10} CFU were evaluated for clinical acceptability and immunogenicity in 187 healthy U.S. adults (150 vaccinees and 37 placebo recipients).[416] The vaccine was well tolerated and satisfactorily immunogenic. M01ZH09 was then evaluated in a randomized, placebo-controlled Phase II trial in Vietnamese children, 5 to 14 years of age, who ingested a 5×10^9 CFU dose of vaccine ($N = 101$) or placebo ($N = 50$).[417] The vaccine was well tolerated and

immunogenic; the magnitude of the serologic responses was modest.

Darton et al.[214] randomly allocated young Oxford adults to receive a single oral dose of M01ZH09 (n = 33) or a dose of placebo (n = 33) or (open label) three doses of Ty21a (n = 33). Twenty-eight days after vaccination the volunteers participated in an experimental challenge with wild-type *S.* Typhi. In a secondary analysis that involved comparing the number of cases in each randomized group that had fever (≥38°C) as a clinical endpoint plus blood culture confirmation, the efficacy of M01ZH09 was 52% (95% CI, −25 to 81%) and for Ty21a was 80% (95% CI, 16–95%). This analysis is relevant for two reasons. First, the definition of a case was similar to the early volunteer challenge studies of Ty21a at the University of Maryland in the early 1970s (with the identical Quailes challenge strain) that showed 87% vaccine efficacy for Ty21a.[214] Thus, this analysis provides a "bridge" between the somewhat different old Maryland and new Oxford challenge models. Second, the analysis that defines a case as having both clinical illness and a positive blood culture mimics the follow-up that would occur in a field trial of vaccine efficacy where blood cultures would only be obtained from enrolled subjects who have a febrile illness suggestive of typhoid fever. This analysis suggests that M01ZH09 is insufficiently protective when given as a single dose, even as it corroborates the efficacy of a three-dose regimen of Ty21a.

***ΔaroC,ΔaroD,ΔhtrA* Strain CVD 908-*htrA*.** Chatfield and coworkers[413] observed that inactivation of *htrA*, a gene encoding a stress protein that functions as a serine protease, attenuates wild-type *S.* Typhimurium for mice and protects orally immunized mice against challenge with a lethal dose of wild-type *S.* Typhimurium. Based on these observations, a deletion in *htrA* was introduced into Δ*aroC*,Δ*aroD S.* Typhi strain CVD 908 to yield the further derivative CVD 908-*htrA*. In Phase I clinical trials, single doses of CVD 908-*htrA* ranging from 5×10^7 to 5×10^9 CFU were as well tolerated as the CVD 908 parent,[237] although two of the 22 subjects developed loose stools[237]; mild diarrhea had not been observed in any recipients of CVD 908 during Phase I studies.[200,236] CVD 908-*htrA* stimulated significant rises in serum IgG O antibody, gut-derived IgA antibody ASCs, and cell-mediated immune responses in 90% to 100% of vaccinees. CVD 908-*htrA* was subsequently tested in a Phase II trial in which 79 subjects ingested either a 10^7 or a 10^8 CFU dose reconstituted from a lyophilate.[314,323] In this larger trial, the vaccine was again well tolerated and immunogenic.[314,323]

Strain CVD 909. A higher level of protection may be attainable if a live oral vaccine can stimulate Vi antibody (as Vi and Vi conjugate vaccines do), in addition to the other humoral and cellular responses elicited by live oral vaccines such as Ty21a.[149,252,255,285,299,307] Disappointingly, otherwise promising live oral vaccine strains CVD 908-*htrA*, Ty800, and M01ZH09, although they express Vi, have failed to consistently stimulate serum Vi antibodies or IgA Vi ASCs when administered as oral vaccines.[237,323,360] This is not surprising, because only 20% of patients with acute typhoid fever develop serum Vi antibodies.[89,91] On the other hand, chronic gallbladder carriers of *S.* Typhi typically manifest high titers of serum Vi antibody, demonstrating that infection with *S.* Typhi can stimulate serum Vi antibodies.[91] The fact that expression of Vi is highly regulated in relation to environmental signals such as osmolarity may explain these somewhat contradictory observations.[418] Two separate two-component systems are involved in this regulation.[414,418] Vi expression ensues when typhoid bacilli reside in certain extracellular environments such as blood and bile to protect them from complement-mediated, O antibody–dependent bacterial killing,[40,67,418,419] but it is apparently turned off when the bacteria gain their intracellular niche in macrophages. It was hypothesized that if Vi expression by a live oral vaccine can be rendered constitutive so that it is expressed continuously, this may allow the stimulation of serum IgG and mucosal IgA Vi antibodies in orally vaccinated subjects. The *viaB* locus of *S.* Typhi contains the genes required for synthesis, surface transport, and anchoring of Vi.[420,421] Wang and colleagues[422] replaced the promoter of *tviA*, the most upstream gene in the viaB locus of CVD 908-*htrA*, with a strong constitutive promoter to derive strain CVD 909, which expresses Vi constitutively. Phase I and Phase II clinical trials showed CVD 909 to be well tolerated.[273,423,424] Disappointingly, few subjects developed serum IgG Vi antibody after ingestion of CVD 909. In contrast, 75% of the recipients of a single dose containing 10^8 or 10^9 CFU did develop strong gut-derived IgA O antibody ASC responses, detected in PBMCs 1 week after oral vaccination and serum opsonophagocytic antibody.[423,425] Oral immunization with a single dose of CVD 909 has been shown to elicit powerful T-cell-mediated immune responses, including homing responses of T cells to the gut.[315,316] CVD 909 also stimulates strong IgA B_M cell responses.[273]

Attenuated Recombinant *Salmonella* Typhi Strains as Live Vector Vaccines

Attenuated *S.* Typhi strains can function as so-called live vectors to express critical genes of other organisms and deliver them to the host immune system.[426–428] The features of *Salmonella* strains that make them attractive as live vectors include the following: (1) the vaccines can be given via mucosal (oral or nasal) immunization; (2) *Salmonella* strains elicit a broad immune response that includes serum antibodies, mucosal sIgA antibodies, and different types of cell-mediated immune responses; and (3) considerable experience has been gained in recent years in genetically manipulating *Salmonella*. Only a few clinical trials with the new generation of attenuated *S.* Typhi carrying foreign antigens as live vectors have been published.[429–432] In animal models, *S.* Typhi can serve as a mucosal delivery system for DNA vaccines.[433–435]

***Salmonella* Paratyphi A Vaccines.** The emergence of multiple-antibiotic–resistant *S.* Paratyphi A as an increasingly important cause of endemic enteric fever in countries in South Asia[132,133] and among travelers[134] to endemic areas has stimulated efforts to develop vaccines to prevent paratyphoid A fever.

Salmonella *Paratyphi A Conjugate Vaccines.* Several companies and research institutes are developing Paratyphi A conjugate vaccines consisting of the O polysaccharide of *S.* Paratyphi A linked to a carrier protein such as CRM_{197} (GSK Vaccines Institute of Global Health and BioE), TT (Bharat Biotech International), diphtheria toxoid (International Vaccine Institute), and Paratyphi A flagellin (H:a) subunits (the Center for Vaccine Development [CVD] of the University of Maryland). These conjugates, which are in various preclinical stages, are slated for clinical trials in late 2017 and 2018.

Attenuated Recombinant* Salmonella *Paratyphi Strains as Live Vector Vaccines. Two attenuated *S.* Paratyphi strains that have been developed are Δ*phoPQ* mutant MGN 10028[436] and Δ*guaBA*,*clpX* mutant CVD 1902.[437] MGN 10028 has been shown to be immunogenic after oral immunization of rabbits, whereas CVD 1902 has been tested in a dosage-escalating Phase I clinical trial, where it was found to be well tolerated and immunogenic and is ready to enter Phase II trials.

62 Varicella Vaccines

Anne A. Gershon, Mona Marin, and Jane F. Seward

Varicella-zoster virus (VZV) causes two diseases, varicella (chickenpox) and herpes zoster (HZ, shingles). Infection with VZV (varicella) in temperate climates where vaccination is not used approaches 100% by the fourth decade of life. Whereas varicella may be mild in some people, epidemiologic studies indicate that there is significant morbidity and some mortality with primary infection in previously healthy persons. Takahashi developed the live attenuated varicella vaccine (Oka strain) in 1974,[1] and it was licensed in Japan in 1986. Varicella vaccine was licensed for routine use in childhood in the United States in 1995. Monovalent varicella vaccines are licensed and available throughout the world for the prevention of infection in healthy children, adolescents, and adults. A combination vaccine for the prevention of measles, mumps, rubella, and varicella was first licensed in the United States in 2005. Progress has been made in understanding the pathogenesis of HZ, and a large collaborative clinical trial has demonstrated the effectiveness of vaccination of the elderly for preventing HZ and its major complication, postherpetic neuralgia. Except for the varicella vaccine licensed in South Korea, all VZV vaccines available worldwide are based on the Oka strain; the live vaccine used to prevent HZ contains at least 14 times the amount of virus as the live attenuated varicella vaccine.[2] This chapter focuses on varicella vaccine; Chapter 63 discusses HZ vaccines.

HISTORICAL ASPECTS

Historically, varicella and smallpox were often confused; in 1767, Heberden clinically differentiated them. Numerous studies followed in which investigators induced varicella in volunteers by inoculation with vesicular fluid or exposure to patients with either varicella or HZ. They showed that varicella is an infectious disease (1875),[3] the two diseases are caused by the same agent,[4–6] and HZ is the result of reactivation of the virus acquired earlier in life.[7] The virus was first isolated in cell culture by Weller and Stoddard in 1952,[8] from vesicular fluid from varicella patients. Later studies indicated that the viruses isolated from subjects with varicella and HZ were morphologically and serologically identical, and the virus was named VZV.[9–11]

Molecular studies showed the restriction endonuclease patterns of viral genomes from a subject with varicella and subsequent HZ,[12] as well from vaccine recipients with subsequent HZ,[13,14] to be identical, proving that HZ is caused by reactivation of latent VZV.

CLINICAL DESCRIPTION

Varicella (Chickenpox)

VZV is transmitted by the airborne route.[15–17] Although it is less readily transmitted than measles, VZV is highly contagious, with secondary attack rates in susceptible household contacts of patients with varicella ranging from 61% to 100%.[18–21] VZV also can be transmitted to susceptible persons from patients with HZ, although studies suggest that the risk of viral transmission is considerably less from HZ than from varicella. In a household study, 16% of 71 susceptible children younger than 15 years exposed to HZ developed varicella, a risk approximately five times lower than that from varicella.[22] In a small daycare study, a 3-year-old with HZ transmitted varicella to approximately 30% of susceptible children.[23]

Immunocompetent Children and Adults

Patients with varicella typically have a generalized vesicular rash concentrated on the head and trunk, and fever. In the immunocompetent person, malaise and fever may occur 1 or 2 days before rash onset, but more commonly these symptoms occur concurrently with the appearance of the rash, a major differentiating feature from smallpox (Fig. 62.1).[24–26] The rash appears in crops; each crop usually progresses within less than 24 hours from macules to papules, vesicles, pustules, and, finally, crusts. New lesions occur in crops over the next few days, with various stages of healing. The lesions are pruritic and may scar.

The average number of skin vesicles ranges from 250 to 500 in otherwise healthy children.[20,27] The height of the fever usually parallels the extent of rash, and the subject is usually ill for 5 to 7 days. The rash has a central distribution, with a concentration of lesions on the trunk, scalp, and face. Second cases of varicella can occur in immunocompetent persons, but their incidence is unknown.[28–32] It is hypothesized that the avidity of VZV antibodies is lower in persons who develop second cases than in those who do not.[31] Another possibility is that VZV temporarily subverts the immune system by immune evasion.[33–35] Subclinical reinfection with VZV also occurs.[36–38]

Varicella in otherwise healthy children is usually not severe, but the disease has a wide variety of infrequent extracutaneous manifestations or complications.[39] These include pneumonia, encephalitis, cerebellar ataxia, arthritis, appendicitis, hepatitis, glomerulonephritis, pericarditis, and orchitis.[40–43] The most common complication in children is secondary bacterial infection.[40,42] Staphylococci or Group A β-hemolytic streptococci are the usual causative pathogens. Group A streptococcal infections may be unusually severe and even fatal after varicella.[44–47] The pathogenesis of severe group A streptococcal infections following varicella is probably multifactorial and could include breakdown of skin providing a portal of entry for streptococci, the type of streptococci, and possibly transient effects of the virus on white cell function.

Acute cerebellar ataxia may develop before rash onset or up to 10 days afterward, with truncal ataxia often the only neurologic sign. Cerebellar ataxia occurs in approximately 1 in 4000 varicella cases among children younger than 15 years old; the prognosis is usually good.[48] A more recent study from The Netherlands showed a risk of cerebellar ataxia after varicella, requiring hospitalization of 1 in 20,000 varicella cases in children younger than 5 years of age.[49] Varicella encephalitis is a more serious and less common complication in children (1 in 33,000 to 1 in 50,000 cases) than cerebellar ataxia and carries a more guarded prognosis.[48,50] Adults with varicella have significantly higher case morbidity and mortality with primary VZV infection than children.[42,51–54]

In adults, the height and duration of the febrile response are greater and rash is frequently more severe, with a greater

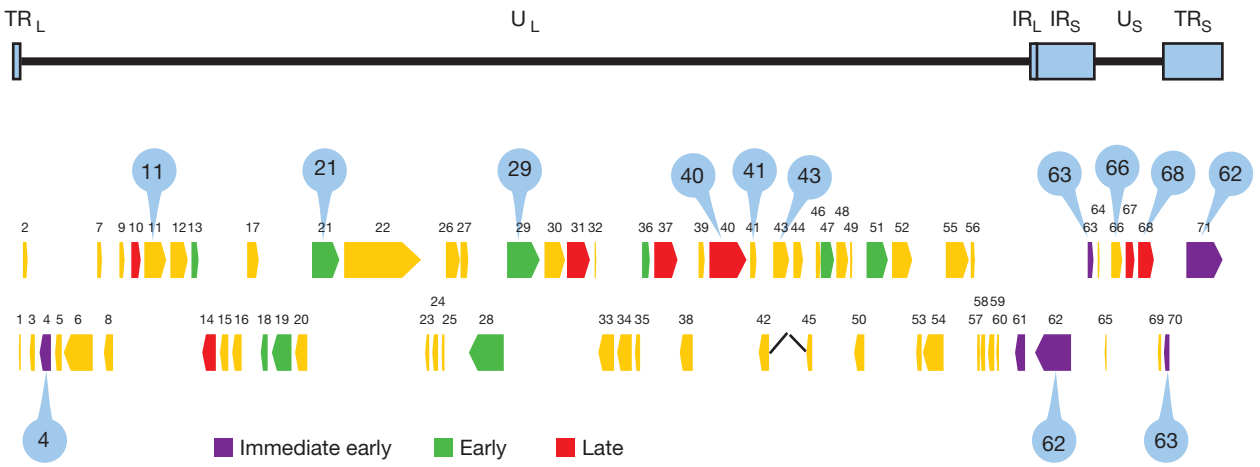

Figure 62.1. Varicella-zoster virus (VZV) transcripts detected in human trigeminal ganglia. The 125,000–base-pair VZV genome is composed of unique long (U_L) and unique short (U_S) segments each bound by respective inverted terminal repeats ($TR_{L/S}$) and internal repeats ($IR_{L/S}$). A total of 71 open reading frames have been annotated on the virus genome. Three open reading frames (ORFs)—62, 63, and 64—are located within the IR_S and are thus also present in the TR_S as ORFs 71, 70, and 69, respectively. Herpesvirus genes are classified as immediate-early, early, or late based on the time following infection of their transcription and their dependency on de novo protein or VZV DNA synthesis; however, for VZV this classification is based on homology to herpes simplex virus type 1. Multiple analyses of human trigeminal and dorsal root ganglia have identified transcripts mapping to VZV ORFs located throughout the virus genome *(blue balloons)*. *(Courtesy Randall Cohrs, PhD.)*

number of lesions and increased time for clearing.[55,56] Constitutional signs and symptoms and a prodrome are of greater intensity in adults.[25]

Pregnant Women and Newborns

Varicella may be more severe in pregnant women (especially in the last trimester) than in other adults.[57,58] Fetal morbidity is increased in pregnant women with varicella.[57,59] Varicella during pregnancy may damage the fetal central nervous system, resulting in permanent scarring of the skin, aplasia of extremities, chorioretinitis, microphthalmia, optic atrophy, cataract, Horner syndrome, blindness, mental retardation, fetal demise, and a high incidence of HZ and death in infancy. This constellation of problems in infants whose mothers had varicella in pregnancy is clinically diagnosed as the congenital varicella syndrome. There is a high correlation between the presence of limb abnormalities and serious central nervous system damage.[57] Various studies have indicated rates of the syndrome after maternal varicella in the range of 0.4% to 2.0%. Harger and colleagues noted that 0.4% of offspring of 347 women with laboratory-confirmed varicella in pregnancy had the congenital varicella syndrome.[60] A prospective case-control study of 106 pregnant women with varicella, including a metaanalysis combining the results of this study with those of other published prospective studies, estimated a 2% risk of varicella embryopathy if infection occurred during the first trimester of gestation.[61] Enders and associates prospectively studied 1373 women with varicella and 366 with HZ during pregnancy.[59] After maternal varicella, the risk of the fetal syndrome was 0.4% in weeks 1 through 12, and 2.0% in weeks 13 through 20. Although no cases occurred in pregnant women infected after 24 weeks of gestation in this study (346 pregnancies affected between 25 and 36 weeks were followed up), isolated cases with birth defects consistent with congenital varicella syndrome have been described after infections in the third trimester, with the latest occurring at 28 weeks of gestation.[62,63] These varying rates may not be significantly different; the syndrome is real but rare.

The study by Enders and associates is also the largest prospective study of consequences of HZ in pregnancy (366 women).[59] No cases of congenital varicella syndrome were reported. There are rare case reports of fetal abnormalities after maternal HZ,[64,65] but whether they represent the congenital varicella syndrome is unclear.[63] If it does occur, the congenital varicella syndrome acquired when a pregnant woman has HZ is exceedingly rare.[57] Infection at any time during fetal life may result in latent infection that is poorly controlled by the host and subsequently reactivates as HZ in infancy or early childhood.[57,59,66,67]

Maternal varicella that develops within 5 days before or 2 days after delivery is potentially very serious for the newborn infant.[57] Maternal antibodies to VZV may not have formed or crossed the placenta, and VZV may infect the baby before or after delivery. In addition, because of the immaturity of the infant's cellular immunity, it is at risk for severe varicella especially if there is no maternal antibody to VZV. The infected infant may develop hemorrhagic skin lesions and primary varicella pneumonia. Severe varicella can usually be avoided with prophylactic administration of passive immunization and acyclovir therapy.[57,68–71] Vaccination of women before pregnancy is the preferable strategy.[72]

Immunocompromised Persons

Varicella in immunodeficient patients can become very serious.[73] Those receiving chemotherapy or radiotherapy (or both) or high dosages of steroids for any reason (transplantation, severe asthma), and those with congenital deficits in cell-mediated immunity, are at greatest risk of developing severe varicella disease. The association between cancer therapy and severe varicella was noted in the early 1950s.[74] By 1975, 30% of children with leukemia who developed varicella manifested dissemination, with 7% mortality.[75] In the era of antiviral therapy, the prognosis improved with treatment administered early in the course of illness,[76] but deaths continued to occur. Severe varicella became especially common as greater numbers of children were treated successfully for malignant disease,[75] transplantation,[77] and asthma.[78,79] Although severe varicella occurred in children with HIV infection, the risk of severe varicella was not as great as for leukemic children.[80]

Herpes Zoster (Shingles)

During the primary infection with VZV, the virus reaches sensory ganglia by way of viremia and sensory nerves. Latency is then established in neurons of the dorsal roots and cranial nerves as well as in the myenteric neurons of the intestine.[81–86] Waning VZV cell-mediated immunity later in life or during immunosuppression enables reactivated VZV to cause HZ, usually a unilateral, painful vesicular rash. Compared with healthy persons, HZ in immunocompromised persons is more likely to be severe and disseminated. Additional information on HZ is found in Chapter 63.

VIROLOGY

VZV is an alpha herpesvirus.[73] Infection is confined to humans and some higher primates; there is one serotype. The virion has approximately 125,000 base pairs. The genome has been sequenced.[87] The linear genome is $(80 \pm 3) \times 10^6$ Da with internal inverted terminal sequences resulting in two predominant isomeric DNA molecules.[88–90] Virions are round or polygonal with a central double-stranded DNA core. The nucleocapsid is approximately 100 nm and formed of 162 hexagonal capsomeres organized into an icosahedron (20 sides).[87] The capsid is surrounded by a tegument and an envelope derived in part from cellular membranes. The diameter of the VZV particle is 180 to 200 nm in diameter. Seventy-four open reading frames (ORFs) encode at least 71 viral gene products (Fig. 62.1). VZV DNA is synthesized in a cascade of expression of immediate early (IE) or alpha regulatory genes, followed by expression of early (E) or beta genes that encode regulatory and structural proteins, followed by expression of late (L) or gamma genes that encode structural proteins. Interruption of the cascade, particularly at the IE stage, may result in failure to synthesize infectious virus.[91]

At least 30 polypeptides have been detected in VZV; at least nine are glycosylated.[91] The known glycoproteins (gps) are termed B, C, E, H, I, K, L, M, and N (Fig. 62.2), corresponding to those of herpes simplex virus (HSV). There is, however, no equivalent of the major gp of HSV, gD, in VZV.[87] Glycoproteins are expressed on the virion and on the surface of infected cells; they facilitate infection of other cells and are the target of neutralizing antibodies.[73] The major gp of VZV is gE, which is the most abundant gp and highly immunogenic. It is linked to gI and with gI is an Fc receptor on infected cells.[92] It also binds to mannose 6-phosphate receptors, along with other gps in the virus, which are critical to VZV infection. gE provides trafficking sequences that mediate assembly of viral proteins and envelopment in the *trans*-Golgi network.[93,94] gE and gI are thought to function as navigator gps, directing additional gps to the cell surface and *trans*-Golgi network, where final envelopment of virions takes place.[95–98] Mannose 6-phosphate receptors are receptors for VZV gps, and the interactions between these receptors, and VZV play critical roles in viral entry and egress from cells. gH plays a role in spread of VZV, and monoclonal antibodies to it prevent spread.[99,100] The insulin-degrading enzyme is also a receptor for VZV gE, and it is important for cell-to-cell spread and infectivity.[101–103]

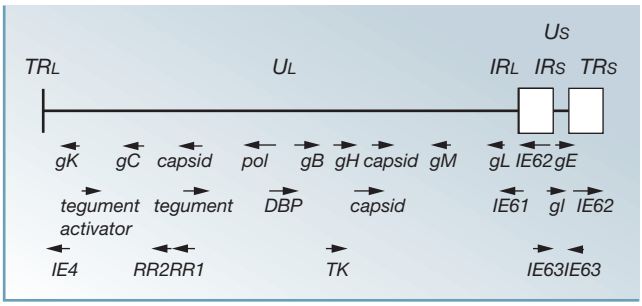

Figure 62.2. Structure of the varicella-zoster virus (VZV) genome. The linear double-stranded DNA consists of a long unique segment (U_L) of approximately 199 kbp, flanked by terminal and internal repeats (TR_L and IR_L), and a short unique sequence (U_S) of approximately 5.4 kbp, flanked by terminal and internal repeats of 6.8 kbp (TR_S and IR_S). The directions of transcription *(arrows)* of some of the important gene products are indicated below the map. *(From Gershon A, Silverstein S. Varicella-zoster virus. In: Richman D, Whitley R, Hayden F, eds.* Clinical Virology. *Washington, DC: ASM Press; 2009:451–473.)*

A new variant VZV virus with a mutated gE has been isolated from six persons in the United States, Canada, and Europe.[104–106] These viruses may be escape mutants; their biological significance remains to be defined. An immunocompetent 15-year-old boy with fatal hepatitis caused by a VZV with this mutation was described.[107] Because this is only one patient, and deaths from varicella occur without this mutation, the pathogenic potential of this mutated virus remains unknown. In addition to glycosylated proteins, some IE gene products of VZV are also immunogenic.[108] IE62 protein, which is encoded by VZV ORF62, is closely related to the regulatory polypeptide ICP4 of HSV 1. This protein was at one time thought to be purely nonstructural, as is ICP4 for HSV.[109] However, IE62 protein has been identified as a major component of the VZV tegument[110] and is highly immunogenic.[111] IE62 protein is the initial transactivating protein of VZV. Other regulatory proteins of VZV are encoded by ORFs 4, 10, 61, and 63.[112–116] It has been reported that during latency, six genes are expressed in sensory ganglia: IE genes (ORFs 4, 62, 63, and 66) and E genes (ORFs 21, 29); L genes are not expressed.[91,117–124] However, a study of specimens of human ganglia obtained at autopsy suggests that there may be some gene expression and that latency is incomplete.[125] False-positive results are proposed to be the result of cross-reacting antigens in patients with type A blood,[126] and neuromelanin may be mistaken for immunologic evidence of VZV proteins.[127] Studies of gastrointestinal neurons from asymptomatic persons undergoing surgery, however, are not subject to all these possibilities, and reveal that the same suite of six RNA transcripts mentioned above are found in human enteric ganglia.[86,128] Thus VZV gene expression during latency remains an unsettled issue.

Latent VZV occurs only in neurons.[129–133] Patients with impaired cell-mediated immunity have an increased incidence of HZ, consistent with the hypothesis that suppression of VZV reactivation is under immunologic control.[73] Rodent models of latent VZV infection may help clarify how latent infection with VZV is maintained.[121,134–136] There is an in vitro model of VZV latency in isolated myenteric sensory ganglia from guinea pigs that can be manipulated to reactivate in vitro,[81,117,137,138] as well as models that use the fetal human dorsal root ganglion.[85]

Growth of VZV in cell monolayer cultures is slow, with poor infectious yields and an absence of infectious virions in supernatant media. Viral spread occurs directly from an infected cell to another uninfected cell. In the infected person, VZV also spreads almost entirely from cell-to-cell, which is why cellular immunity is crucial in host defence. To obtain cell-free VZV in vitro, infectious virions must be released artificially by disruption of cells by methods such as sonication.[73] The cell-associated nature of the virus has tended to impede research on VZV and has played a role in slowing vaccine development.

Although there is only one VZV serotype, different genotypes have been identified.[139–154] Thus far, five major genotypes (clades 1 to 5) of wild-type VZV have been described, with an additional two putative clades (6 and 7) that remain to be

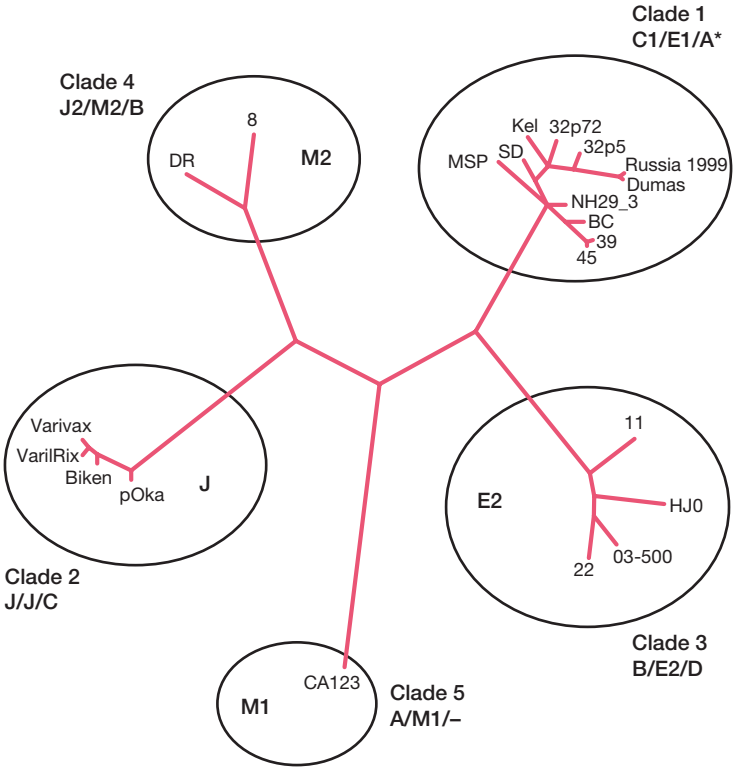

Figure 62.3. Phylogenetic tree showing five major varicella-zoster virus (VZV) clades. J, Japanese; E, European; M, mosaic. *(Modified from Loparev VN, Gonzalez A, Deleon-Carnes M, et al. Global identification of three major genotypes of varicella-zoster virus: longitudinal clustering and strategies for genotyping.* J Virol. *2004;78:8349–8358.)*

confirmed by whole-genome sequencing (Fig. 62.3).[145,147,150,153] The VZV clades show a distinctive geographic distribution,[141,146] although all clades circulate at low levels outside the regions where they predominate. For example, occasional clade 2 Asian strains have been identified in the United States and Australia,[147,154] and clade 5 African strains have been identified in the United Kingdom.[148] However, only the clade 1 and clade 3 strains most commonly isolated in temperate climates have been observed in most countries in Europe and in New Zealand.[144,147] This may reflect an ongoing shift in strain distribution and could be related to immigration and travel patterns. All seven clades have been observed in the United States, although clade 1 and clade 3 isolates predominate (approximately 80% clade 1 and clade 3). Clade 2 strains are the most prevalent genotypes in Japan and China[146,149]; the Oka vaccine is derived from a clade 2 strain bearing a genomic marker present in 10% of wild clade 2 strains (Pst 1 negative in Japan). Rare clade 2 wild-type strains bearing this marker have now been identified in the United States, Australia, and China.[142,147,154] Recent analyses of whole-genome sequences of VZV revealed the presence of small numbers of strain-specific markers that may prove useful for subgenotyping VZV clades[150,152]; phylogenetic analysis suggests that circulating genotypes arose through limited mutation and interstrain recombination.[151]

PATHOGENESIS AS IT RELATES TO PREVENTION

Varicella is a highly contagious disease.[155] Infectivity is postulated to occur by aerosol spread of virions from vesicular skin lesions,[156,157] and possibly to a lesser extent from respiratory secretions.[158] Airborne transmission has been described in hospital settings.[15,16] Studies of transmission of vaccine-type VZV in leukemic vaccinees have implicated skin lesions as the source of infectious virus.[157] In patients with varicella, virus isolation in cell culture from skin is easily accomplished, but it is extremely difficult to isolate VZV from respiratory secretions.[159] As a result of the loss of mannose 6-phosphate receptor in the superficial epidermis, high concentrations of cell-free VZV develop in skin vesicles; these virions may be aerosolized and transmit the virus to others from the skin.[156] Polymerase chain reaction (PCR) studies of respiratory secretions have yielded different results and have not clarified the issue of whether respiratory spread of VZV is significant.[160,161] In one study, VZV DNA was detected in the respiratory tract of 45 patients with varicella, in 28 patients (62%) on day 1, in 50% on day 6, and in 22% after day 6.[162] VZV DNA was detected in the saliva of 100% of 54 HZ patients.[163] Different rates of PCR positivity may reflect differences in primers and differences in respiratory secretion collection methods. Demonstration of VZV DNA by PCR does not necessarily indicate the presence of infectious virus. Prolonged presence of VZV DNA in secretions or dust has not been associated with transmission of this labile virus.

The pathogenesis of varicella was conceptualized by Grose in 1981,[164] based on the pathogenesis of mousepox, outlined by Fenner in 1948.[165] Host invasion of VZV is thought to occur in the conjunctivae or the mucosa of the upper respiratory tract (including tonsils). It was hypothesized that, in primary infection, VZV replicates locally in the lymph nodes for several days, causing a low-level primary viremia that delivers the virus to the viscera, where further multiplication occurs. A demonstrable secondary viremia of greater magnitude subsequently occurs. Culture of mononuclear cells and PCR testing of peripheral blood mononuclear cells from 5 days before to 2 days after appearance of rash in patients with natural varicella

yielded VZV.[162,166–171] Viremia has also been demonstrated in patients with HZ using either virus isolation or PCR.[172–175] The presence of VZV in $CD4^+$ and $CD8^+$ T lymphocytes also has been demonstrated by in situ hybridization during early varicella.[176] In a model of VZV infection in severe combined immunodeficient mice with human skin grafts (SCID-hu), VZV could also be detected in human T lymphocytes.[177]

Experiments with the SCID-hu mouse model, in which human skin was implanted into immunodeficient mice, suggested additional events in the pathogenesis of varicella.[178] VZV-infected human mononuclear cells injected into SCID-hu mice were found to infect the skin implant within 24 hours. Innate immune mechanisms were downregulated in infected keratinocytes, but not in neighboring ones. These observations suggested that the skin may be infected early after VZV enters a host, and that VZV circulates in memory $CD4^+$ T cells to establish focal infection of additional keratinocytes. The long incubation period of varicella is attributed to the time needed for VZV to overcome innate antiviral responses of cutaneous cells.[178] Exactly how this scenario relates to the Fenner model with infection of viscera is not yet clear.

IMMUNE RESPONSES TO VARICELLA-ZOSTER VIRUS

The precise roles of humoral immunity and cell-mediated immunity in protection against VZV infection are not entirely understood but are summarized as follows.[41,179]

Humoral Immunity

Serum Immunoglobulin M Antibody Response

After natural varicella and HZ, serum VZV immunoglobulin (Ig) M, if it occurs, may be detectable for days to weeks. As with many IgM tests, false-negative and false-positive reactions occur.[180] Fig. 62.4 shows the kinetics of humoral, nasopharyngeal, and cellular immunity in patients with clinical varicella from 10 days before rash onset to 20 days after onset.[181]

Serum Immunoglobulin G Antibody Response

After natural infection, VZV-specific IgG antibody, as measured by the fluorescent antibody to membrane antigen (FAMA) test and which correlates with neutralizing antibodies to VZV,[182] is detected in most patients within the first 4 days after the onset of rash.[180] Peak IgG levels are attained at 4 to 8 weeks, and levels usually remain high for up to 6 to 8 months, after which titers decline twofold to threefold. Positive VZV IgG FAMA titers have been detected decades after clinical varicella.[38,183–186]

Serum Immunoglobulin A Antibody Responses

Serum IgA antibody responses to natural infection are detectable early in the course of varicella.[181] Serum IgA antibody was detected in 44% of subjects up to 14 months after varicella.[181]

Nasopharyngeal Immunoglobulin A Antibody Responses

Nasopharyngeal VZV–specific IgA antibody responses are detectable at the onset of symptoms in patients with natural infections.[187] Maximal titers are attained at the third week of illness.[41]

Cell-Mediated Immunity

Cell-mediated immunity appears to be the response of major importance in control of VZV by the host. Structural and regulatory proteins of VZV are recognized during varicella by T lymphocytes, which induce protection from further VZV infection. Immunity is usually maintained for decades and is mediated by both $CD4^+$ and $CD8^+$ T lymphocytes. Memory T lymphocytes belong to the $CD45RO^+CCR7^-$ phenotype.[188] Memory responses may be maintained in part because of periodic exogenous reexposure to others with either varicella or HZ, as well as by possible endogenous reexposure to the virus during subclinical reactivation of VZV. T lymphocytes from varicella-immune persons produce cytokines of the T-helper cell type 1, such as interleukin-2 and interferon-γ, which potentiate clonal expansion of virus-specific T cells on

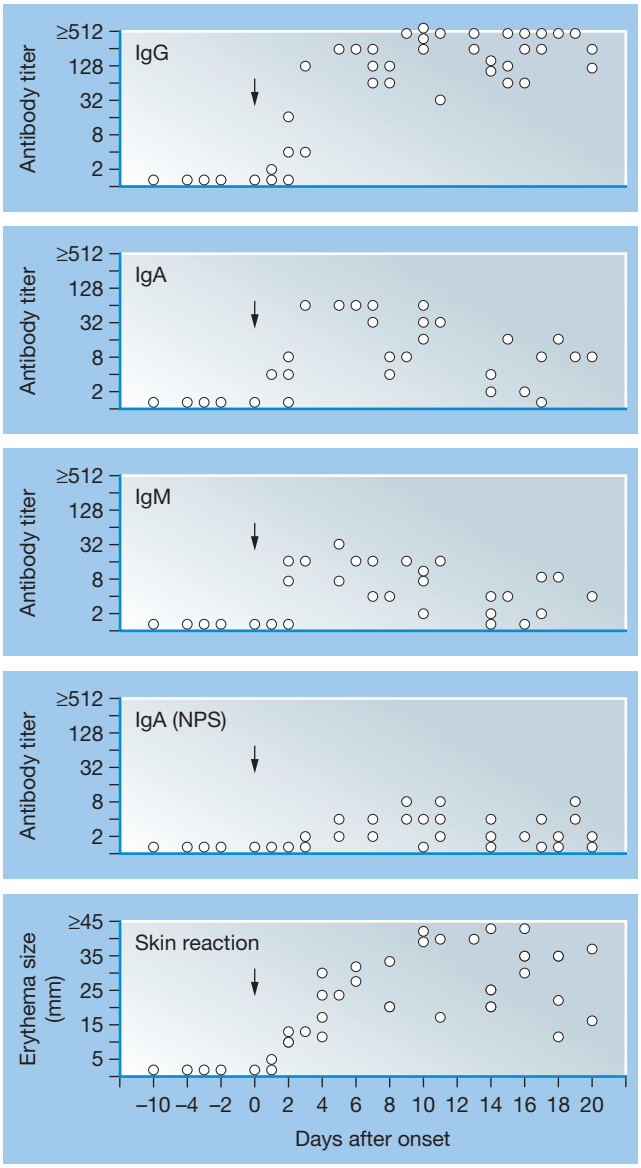

Figure 62.4. Kinetics of appearance of humoral (blood), nasopharyngeal (NPS, secretory), and cellular (skin reaction) immunity in patients with clinical varicella. Antibody titers were measured by fluorescent antibody to membrane antibody. Arrows at day 0 indicate the onset of varicella infection. *(From Baba K, Yabuuchi H, Takahashi M, et al. Seroepidemiologic behavior of varicella zoster virus infection in semiclosed community after introduction of VZV vaccine.* J Pediatr. *1984;105:712–716.)*

exposure to VZV antigens.[41] Natural killer cells, which are part of innate immunity, are another source of interferon-γ and play a role in host defense against VZV.[189,190] $CD4^+$ T lymphocytes provide help so that humoral responses to VZV antigens develop and are maintained after varicella.[191] gE-specific $CD4^+$ lymphocytes may play a role in long-term control of multiplication of VZV.[192] ORF4 protein is a target antigen for persistent VZV-specific $CD4^+$ T cells.[193]

Cell-mediated immune responses are promptly detected after natural infection; peak activity occurs within 1 to 2 weeks and then gradually decreases.[181,194–197] Cell-mediated immunity to VZV can be detected by stimulation of lymphocytes in vitro with VZV antigens,[198,199,200–203] and by lysis of histocompatible target cells by cytotoxic T cells stimulated with VZV antigens.[204–206] An enzyme-linked immunospot assay indicates synthesis of interferon-γ by T cells in response to antigenic stimulation by VZV that can be boosted by immunization.[207] Cellular immunity can also be assessed by an intradermal skin test composed of VZV antigens.[196,197,208] Using tetramer analysis, the importance of the CD4 response and cellular immunity to gE in recovery from varicella, a role for IE 63 in control of viral latency, and subclinical reactivation of VZV have been demonstrated.[191,192,209–211] Cell-mediated immune responses remain positive for many years; however, declining cell-mediated immunity occurs with advancing age, beginning at age 50.[202,212,213] The strongest cell-mediated immune responses to VZV appear to be in early adulthood.[214,215]

Clinical observations indicate that patients with isolated agammaglobulinemia have normal courses of varicella and become immune to the disease, whereas those with defects in cell-mediated immunity are at risk to develop disseminated and fatal VZV infections.[198] Cell-mediated immunity is probably crucial during VZV disease because spread in the body is by the intracellular route, rather than by release of cell-free virus as occurs in vesicular fluid. That cell-mediated immunity is required to maintain the balance between the host and latent VZV is also suggested by the correlation between diminished VZV cell-mediated immunity and an increased risk for HZ.[198,199] In contrast, elderly adults usually have high VZV antibody levels and are not particularly subject to second attacks of varicella. Thus, both antibodies and cellular immunity have roles in protection, suggesting that redundancy in the immune system provides the best protection against disease.

Subclinical Reactivation

Subclinical or clinical reactivation results in both antibody and cellular immune responses. Antibody responses to VZV in healthy subjects with past varicella are characterized by occasional high activity without symptoms, suggesting either exposure to VZV with exogenous boosting of immunity, or subclinical reactivation of VZV. Increases in cell-mediated immunity usually occur after HZ, even in immunocompromised patients.[216] Subclinical reactivation of VZV has been demonstrated by PCR in healthy and in immunocompromised persons.[163,217–220]

DIAGNOSIS

The diagnosis of VZV infection can usually be made clinically by the characteristic rash. In vaccinees who have breakthrough varicella, both clinical and laboratory diagnosis may be more difficult because of mild rashes indicative of partial immunity. For varicella, epidemiologic information, such as age of the patient, lack of history of the illness, and exposure to persons with varicella or HZ in the preceding 2 to 3 weeks, is useful for diagnosis. Unusual skin manifestations of varicella have been described in areas of chronic dermatitis or after sunburn.[221] HZ has a characteristic unilateral, painful, and sometimes pruritic, dermatomal rash. HZ may be confused with recurrent HSV infection.[222] HZ can also occur in the absence of a skin rash, which can make diagnosis extremely difficult.[223]

When it is deemed necessary to prove either varicella or HZ, laboratory diagnosis is best made by demonstration of viral antigens or DNA by PCR in vesicles or body fluids.[180] Virus isolation of VZV is expensive, insensitive, and time consuming, so it is little used today. Rapid diagnosis can also be accomplished by direct immunofluorescence. The direct immunofluorescence test is done by swabbing a suspicious skin lesion, making a smear on a glass slide, and staining with fluorescein-tagged monoclonal antibody to VZV gE.[180]

Vesicular fluid and swabs from maculopapular lesions, respiratory secretions, saliva or buccal secretions, cerebrospinal fluid (CSF), urine, and tissue specimens at autopsy may be tested for VZV by PCR.[180,224–230] It is possible to detect VZV DNA in saliva in patients with varicella and HZ, so in the absence of skin lesions, PCR testing of saliva can be diagnostic.[224,231] For patients with neurologic symptoms, PCR on CSF may reveal VZV infection.[154]

PCR is more sensitive than direct immunofluorescence for diagnosis.[224,230] Identification of VZV DNA by PCR, however, does not necessarily indicate infectivity of the virus.

Serologic methods are less useful than antigen detection methods for laboratory diagnosis of varicella and have limited value for diagnosis of HZ.[224] Varicella can be diagnosed by demonstration of IgM antibodies to VZV in serum, but a negative IgM test does not rule out the diagnosis.[224] Further studies of the kinetics of the IgM response are needed for accurate confirmation of varicella infections. Serologic tests are of limited value for the diagnosis of HZ, because heterologous rises in VZV antibody titer may occur when HSV reactivates in a person immune to varicella.[180] A transient IgM response may also follow HZ, as well as varicella.

Serologic tests to detect VZV IgG antibodies are used to assess immunity to varicella, most commonly in testing of healthcare workers, ideally before employment. Unfortunately, these tests often lack sensitivity and may yield false negative results, especially in vaccinated individuals. Alternatively, a documented history of at least two doses of live attenuated varicella vaccine or a history of varicella is indicative of immunity to varicella. The FAMA assay is considered the gold standard for determining VZV antibodies; this test, however, is rarely available. The major serologic assay in commercial use is the enzyme-linked immunosorbent assay (ELISA) for measurement of IgG antibodies to VZV. ELISA assays are fairly specific, but as many as 10% false-positive reactions in truly susceptible persons have been recorded.[232] Commercially available ELISA tests are also less sensitive than the FAMA test,[180,233] especially for assessing immunity after immunization. An ELISA that uses VZV gp as the antigen has been reported to be sensitive,[234] but it is not commercially available. Positive antibody titers detected by this method in young unvaccinated children, moreover indicate that the assay may be overly sensitive.[235] This assay has shown reproducibility when different batches of vaccine were used for immunization, and there was a linear concordance when neutralizing antibody levels and gp-ELISA titers were compared.[236] Specific gp-ELISA units, however, used as end points were not always consistent in published studies.

A latex agglutination assay based on the clumping of latex particles coated with VZV gps, in the presence of VZV antibody, has sensitivity similar to that of FAMA but is no longer commercially available.[184,185,237] A time-resolved fluorescence immunoassay for measuring antibodies to VZV is being evaluated in the United Kingdom for sensitivity and specificity.[238–240]

While the VZV skin test appears to be sensitive and specific for demonstrating immunity to varicella,[196,232,241] it is cumbersome to perform on children and is not currently available for clinical use. A serologic assay (termed "line assay") using five recombinant VZV antigens was described in which vaccinated children had weaker IgG responses to certain antigens (proteins 4, 14, and 49) than children who had experienced natural varicella. If extended and confirmed, this technique might provide a practical means to distinguish between varicella immunes and susceptibles as well as to identify individuals who had been vaccinated.[242]

A reliable, sensitive, rapid, available means of identifying people with immunity to varicella, particularly after immunization, continues to be very much needed. In summary, the most reliable indication of immunity to varicella today is medically diagnosed varicella or a written documentation of two doses of live attenuated varicella vaccine.

TREATMENT AND PROPHYLAXIS

Effective antiviral therapy for varicella and HZ first became available in the early 1970s. Antiviral therapy is helpful to speed recovery, but it does not terminate virus shedding or prevent latent infection. Vidarabine, the first successful antiviral drug, was supplanted by acyclovir, a DNA chain terminator and an inhibitor of DNA polymerase that is less toxic.[243–245] Intravenous acyclovir speeds healing of varicella and HZ in immunocompromised patients, and orally administered acyclovir, at high dosages, may be used to treat patients with HZ.[246,247] Orally administered acyclovir may be used to treat otherwise healthy children with varicella, but the antiviral effect on varicella is minimal, in part because of the poor absorption of the drug when given orally and the lower sensitivity of VZV to acyclovir, compared with that of HSV.

A double-blind placebo-controlled study in which 102 healthy children were given acyclovir (40 to 80 mg/kg) or placebo daily for 5 days, beginning within 24 hours of rash onset, revealed that the mean number of skin lesions was significantly reduced from over 500 to 336.[27] On average, there was 1 day less of fever. A multicenter collaborative study involving 815 similarly treated children given 80 mg/kg of acyclovir daily yielded similar results.[248] The benefit to secondary household cases (which are typically more severe than the first case in the household) was not different from that of primary cases. The modest benefit conferred by acyclovir therapy is not surprising in view of the typical self-limited nature of chickenpox. Studies in adolescents[249] and adults[250] have not indicated more striking antiviral effects, although acyclovir is recommended for these groups because they are at higher risk of developing severe varicella than healthy children. A study in otherwise healthy children with varicella indicated that 5 days of oral acyclovir is as effective as 7 days.[251]

The oral antiviral prodrug valacyclovir, which is well absorbed from the gastrointestinal tract and is rapidly converted to acyclovir in the body, results in blood levels of acyclovir that are significantly higher than those from oral acyclovir. Although valacyclovir has efficacy for treatment of HZ,[252] no treatment studies of varicella have been performed. One study, however, addresses dosage of valacyclovir for children.[253] Currently, it is acceptable to use valacyclovir to treat children older than age 2 years who have VZV.[254]

Famciclovir, which is also administered orally, is rapidly converted to penciclovir in the body; penciclovir has an action similar to that of acyclovir. At present, either valacyclovir or famciclovir is preferred treatment for HZ in nonimmunocompromised adolescents or adults. Famciclovir has not been studied for treatment of varicella.[255,256] The antiviral drug sorivudine[257] was not approved by the U.S. Food and Drug Administration (FDA) because of the lack of significant benefit over acyclovir and the potential for toxicity in patients being treated for cancer. This drug is available in countries other than the United States.

Postexposure prophylaxis with antiviral therapy for prevention of varicella has been tried and has met with some success in small studies. Acyclovir administered to 25 children after household exposure mostly prevented disease.[258] Immunity appears to persist for several years even with no evidence of clinical disease.[259] Unfortunately, however, less than 85% of patients may develop antibodies to VZV after this prophylaxis,[260] and adequate future protection cannot be ensured. Therefore, two doses of varicella vaccine should be administered subsequently, if possible, to children who did not develop varicella. Although dosages and timing have varied, administration of acyclovir at a dosage of 10 to 20 mg/kg four times a day between days 7 and 14 after exposure was most often used. Prophylaxis administered earlier than 1 week after exposure does not seem to provide as good protection.[261] There are no published studies in which immunization and antiviral therapy have been combined. Postexposure antiviral prophylaxis has not been studied in immunocompromised persons, for whom passive immunization with immunoglobulin is preferable. If passive immunization is not available, an alternative would be to treat immunocompromised patients who develop varicella with acyclovir at the very first sign of illness, but this approach may not be successful in all patients. For healthy nonpregnant persons, postexposure vaccination is preferred to preventive antiviral therapy (see "Passive Immunization" later).

EPIDEMIOLOGY

Varicella is a highly contagious disease that occurs worldwide and, in the absence of a vaccination program, affects nearly every person by mid adulthood. HZ cases represent a method for regular exposure and introduction of VZV into communities that otherwise may not be large enough to sustain VZV endemic transmission. The epidemiology of varicella in temperate climates is different from that in tropical climates; the differences may relate to properties of VZV, climate, population density, and the risk of exposure.[262–266] In temperate climates, most persons are infected by young adulthood, with the highest incidence of disease occurring among preschool-age children or children in early elementary school.[266–274]

Varicella shows a strong seasonal pattern in temperate and some tropical climates, with a peak incidence during winter and spring. Periodic large outbreaks may occur, with an interepidemic cycle of 2 to 5 years.[265,268–270,275–278] Outbreaks occur in settings where children congregate, such as childcare centers and schools, but have also been described in hospitals, facilities for institutionalized children and adults, refugee camps, and adult settings, including among healthcare workers, military personnel, and correctional facilities.[279–291]

Prior to the varicella vaccination program in the United States, the annual average varicella incidence measured from national household survey data was 15 to 16 cases per 1000 population.[265,267] Reported incidence from other countries has generally been lower than U.S. survey rates, most likely reflecting less-complete case ascertainment as a result of differences in study methods.[265,268–270,275–278] Apart from age, factors associated with differences in varicella incidence or seroprevalence include urban (as opposed to rural) residence, attendance in childcare facilities, attendance at and size of school, and presence of older siblings in the household, all of which are likely to increase the risk of exposure.[265,292–294] In countries where universal varicella vaccination programs are in place, not being vaccinated is a risk factor for varicella, and in the United

States, where high vaccine coverage has been achieved, one study highlighted that children of parents who refused varicella immunizations have nine times the risk of requiring a medical visit for varicella than did children whose parents accepted varicella vaccine for their children.[295]

VZV seroprevalence data reflect age-specific disease incidence. National data from the United States before use of varicella vaccine (1988 to 1994) demonstrated high population VZV seroprevalence: 86% for 6- to 11-year-olds, 93% for 12- to 19-year-olds, 95.5% for 20- to 29-year-olds, and 99% or greater for adults 30 years of age and older.[296] Similarly, more than 90% of adolescents (10 to 15 years of age) or young adults are VZV seropositive in many countries around the world where seroprevalence has been measured.[277,297–306] A comparative study of prevaccine VZV seroprevalence in 11 European countries using sera from 1995 to 2003 demonstrated that although the vast majority of children acquire VZV during childhood, the rate of transmission of VZV varied considerably between countries; VZV seroprevalence by 5 years of age was 97% in The Netherlands, approximately 70% in Spain and Germany, and 38% in Italy.[305] This study also highlighted that in some European countries, 10% or more of adolescents 10 to 14 years of age are susceptible to varicella (e.g., 18% in Italy); findings in Australia were similar.[307] Another survey of varicella occurrence among 70,226 school children in Greece showed that 21.4% of sixth grade children lacked a history of varicella and were probably susceptible as they entered adolescence.[308]

Differences in seroprevalence have been described by race, sex, country of origin, and number of siblings in the household.[296,298,309–313] Measuring VZV seroprevalence in countries that have implemented varicella vaccine programs presents new challenges because of the low sensitivity of commercially available VZV IgG tests to measure vaccine-induced immunity.[314] Using the gp-ELISA assay that has good sensitivity for detection of vaccine-induced immunity, the most recent serosurvey in the United States demonstrated that among children 6 to 11 years of age seroprevalence increased from 86% in the prevaccine era to 98% in 2009–10, attributed to the childhood vaccination program, while other age-group-specific estimates were similar to prevaccine estimates.[315]

Population-based epidemiology data are less complete for countries in tropical climates but VZV seroprevalence reflects a higher mean age of infection than in temperate climates,[266,316–321] with higher susceptibility among adults. In such countries, seroprevalence among adolescents or young adults has ranged from 10% to 20% in St. Lucia (an island community) to 80% to 100% in Taiwan and urban Calcutta, India, with rural-versus-urban and other differences described.[262–265,283,318,320,322–333] Similarly low VZV seroprevalence has been reported in isolated tribal adults in Eritrea (44%) and in rural Bengali adults 17 to 25 years of age (42%), compared with much higher VZV seroprevalences among similar-age nonisolated adults in Eritrea (91–96%) and among Bengali adults 17 to 25 years of age in Calcutta (96%).[264,334] Studies in adult subgroups who could be considered for screening and vaccination programs have demonstrated levels of seronegativity among healthcare workers ranging from 11% in Egypt, to 14% to 19% in Malaysia and Saudi Arabia, to 22% or higher in Thailand, to as high as 51% among first-year medical and engineering students in Sri Lanka.[290,335–337] Studies among women of childbearing age demonstrated that 27% lacked VZV antibodies in Iran and 56% in Sri Lanka, whereas 24% of Singapore military recruits were VZV seronegative.[338–340]

In island populations that may not have sufficient size to support continuous endemic transmission, seroprevalence can also vary with the timing of the last epidemic year in relation to the serologic study. For a number of countries the highest incidence was described in the driest, coolest months.[263,341] A study examining risk factors for susceptibility among newly arrived migrants in Canada found the highest varicella susceptibility among those originating from climates with the highest temperature and the most months of humidity per year (tropical rainforest).[342] Crowding in densely populated cities or in households may overcome VZV's diminished ability to spread in tropical climates. In several South American countries higher seropositivity rates in children and lower adult susceptibility were reported in Brazil, Argentina, Mexico, or Bolivia.[343–346]

Significance as Public Health Problems

Some countries have achieved control or elimination of other vaccine-preventable diseases using vaccines recommended for routine use in childhood vaccine programs.[347] Understanding the varicella and HZ health burden and costs as well as the costs and benefits of vaccination strategies is important when countries consider a varicella vaccination program. In the immediate prevaccine era in the United States, an average of 4 million varicella cases occurred each year, which resulted in an average of 11,000 to 13,500 hospitalizations (4.1 to 5.0 hospitalizations per 100,000 population) and 100 to 150 deaths annually (0.4 to 0.6 per million population).[52,53,267,348–350] Varicella also contributes significantly to the disease burden from invasive group A streptococcal infections in children.[44–46,351]

Risk factors for severe varicella include older and younger ages, cellular immune dysfunction caused by illness (e.g., acute leukemia) or medications, and intensity of exposure.[52,75,267,352] In developed countries where data on mortality have been reported, overall varicella mortality has ranged from 0.20 to 0.65 per million population in the United States, Australia, and the United Kingdom.[52,353–355] Population-based case-fatality data have been described only from developed countries with overall case-fatality rates of approximately 2.6 per 100,000 cases as described in the United States in the prevaccine era. The highest case-fatality rate (20 per 100,000 cases; 20 to 25 times higher than for preschool-age children) occurs among adults.[52,354,355] Second to mortality in developed countries, hospitalizations caused by varicella provide the next best estimate of severe disease burden. Various studies have described annual rates of varicella hospitalizations in the range of 4.0 to 4.5 per 100,000 population,[53,354] with some studies reporting lower or higher rates (2.6 to 9.9 per 100,000 population).[268,356] Reflecting the high incidence among children, the majority of varicella hospitalizations also occur among children; however, infants and adults are at significantly increased risk of severe disease and hospitalization compared with children 1 to 9 years of age.[48,53,267,354,357,358] Varicella also leads to a considerable number of school days missed for children as well as workdays missed for adult patients and for parents looking after sick children. These data are important for describing morbidity and for calculating the economic and societal costs of varicella, which is now vaccine preventable.

There are few data on the health burden of varicella in developing countries, in countries with high HIV seroprevalence, and in countries with tropical climates where a higher proportion of varicella cases may occur among adults. In these situations, varicella morbidity and mortality may be higher than described in developed countries. When comparing results across countries, however, differences in methods that may affect ascertainment of hospitalization, number of patients, and access to care must be considered. A large prospective household study in Guinea-Bissau in 2000–01 identified 1539 cases of varicella and found almost 80% of cases

occurred among children 1 to 9 years of age and only 4% of cases occurred among those older than 15 years of age.[352] However, 12% of cases occurred in infants and two patients died, so the case-fatality rate in this small series was 130 in 100,000 cases, approximately 50 times higher than in the United States.[52] Several studies in Sri Lanka have highlighted the high median age of varicella infection—14.5 years—and the associated morbidity.[340,359] One study of all patients admitted to the main infectious disease hospital in Sri Lanka from 2000 to 2001 demonstrated that 58% of the total 1690 hospitalizations resulted from varicella. Varicella was the most common disease treated at the infectious disease hospital and a significant cause of morbidity and mortality among adults.[359]

The estimated global annual varicella disease burden would include 140 million cases with approximately 6200 deaths.[360]

PASSIVE IMMUNIZATION

The first report indicating that varicella could be modified by human immunoglobulin (Ig) after exposure to VZV was in 1962.[20] It was demonstrated that varicella could be attenuated by giving Ig to varicella-susceptible children within 72 hours after household exposure. To try to improve passive immunization, globulin was prepared only from serum of patients recovering from HZ who had high VZV antibody titers. When given to healthy children who had been exposed to varicella, chickenpox was prevented.[361] This material, termed zoster immunoglobulin (ZIG) (ZIG), was then tested in a double-blind, controlled fashion in high-risk children with underlying leukemia, in whom it was found that that ZIG modified varicella.[362]

Subsequently, to increase the production of this product, which was in short supply, a high-potency globulin with titers equal to those in ZIG was prepared using plasma with high VZV antibody titers from persons who had not necessarily had HZ, increasing the potential donor pool.[363] Termed varicella-zoster immunoglobulin (VZIG), it was licensed and recommended for use in the United States in the early 1980s by the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC).[364] It was estimated that VZIG contained more than 10 times the amount of antibody to VZV as ordinary Ig. After licensure of varicella vaccine in the United States, however, use of VZIG declined dramatically, and its production was discontinued. It was supplanted by a Canadian product, VariZIG, available initially in the United States under an investigational new drug protocol and licensed in 2012. VariZIG can be obtained by calling the 24-hour telephone number of FFF Enterprises (800–843–7477) or ASD Healthcare (800–746–6273).[365]

Passive immunization is recommended for persons without evidence of varicella immunity who are at risk for severe disease and complications, and for whom varicella vaccine is contraindicated, including immunocompromised patients, neonates whose mothers develop varicella around the time of delivery (5 days before to 2 days after), hospitalized premature infants born at 28 weeks or more of gestation whose mothers do not have evidence of immunity, hospitalized premature infants born after fewer than 28 weeks of gestation or who weigh less than 1000 g at birth regardless of maternal immunity, and pregnant women.[365] If there is uncertainty about immunity to varicella in an immunocompromised person, many experts recommend that it is safest to administer passive immunization upon a close exposure to VZV. Results of serologic tests regarding immunity to VZV cannot be relied upon, especially in this situation. VariZIG prophylaxis should be administered as soon as possible after an exposure to VZV in high-risk patients but within 10 days of that exposure.[365]

Zoster immune plasma, rarely used today, has efficacy in preventing or modifying varicella in immunocompromised patients,[366,367] but treatment with zoster immune plasma of immunocompromised patients with disseminated HZ is not effective.[368] Although passive immunization is usually effective against varicella, on occasion, disease may be severe in passively immunized immunocompromised children.[76,362,368,369]

ACTIVE IMMUNIZATION: THE OKA VACCINE STRAIN

The Oka strain of VZV is the only vaccine strain now available other than a vaccine produced in Korea (SuduVax) in 1988, the molecular profile of which closely resembles that of the Oka strain.[370]

SuduVax contains the MAV/06 varicella strain that was isolated from a 33-month-old South Korean boy with chickenpox in 1989, in Seoul, South Korea.[371] Prior to clinical trials with Oka in the 1970s, the American KMcC strain underwent a few clinical trials; it proved inferior in attenuation compared with the Oka strain.[372–375]

To develop the Oka strain of varicella vaccine,[1,376] fluid was taken from the vesicles of an otherwise healthy 3-year-old boy (whose family name was Oka) who had typical chickenpox, caused by wild type (WT) VZV. His VZV was isolated in primary human embryo lung fibroblast cell cultures. The virus was serially propagated 11 times at 34°C in human fibroblast cell cultures, followed by 12 passages in guinea pig fibroblast cells to further attenuate the virus. Finally, there were two passages in WI-38 human diploid cells (HDCs) to prepare the master seed virus, followed by three passages in MRC-5 HDCs to prepare the working seed virus. Vaccine pools were usually made after two or three additional passages in MRC-5 cells.

For vaccine preparation, infected tissue cultures were washed with phosphate-buffered saline, and infected cells were harvested in the presence of ethylenediaminetetraacetic acid. The cell suspension in vaccine medium was then sonicated to obtain cell-free virus; a titer of 1500 to 5000 plaque-forming units (PFU) per milliliter of VZV was usually obtained. Initial safety testing of the vaccine included demonstration of lack of pathogenicity after parenteral and intracerebral inoculation of small animals and monkeys. The absence of C-type particles and latent viruses was confirmed morphologically and biochemically.

Vaccine Virus Attributes and Varicella-Zoster Virus Strain Identification

The Oka vaccine virus has various biological, biophysical, and molecular attributes that distinguish it from WT viruses.[13,377] The vaccine strain was cold-adapted to grow at 34°C, and it grows less well at 39°C than WT strains.[13] It also grows better in guinea pig cells and is more immunogenic for guinea pigs than WT VZV.[378–380] All varicella vaccines contain a mixture of Oka vaccine strain variants, even with some sequences resembling WT VZV, which might rarely impact virulence in recipients or laboratory identification of vaccine strains.[381–385]

The Oka strain (parental/wild and vaccine) and Dumas WT VZV have been sequenced (Fig. 62.5). Over the entire genome of 125,000 base pairs, 42 individual single nucleotide polymorphisms (SNPs) have been identified, only a third of which result in an amino acid substitution. Deep sequencing of the vaccine has identified additional putative polymorphisms, some of which have been confirmed.[385–387] Most of these differences are in ORF62 and its duplication, ORF71.[383,388,389] It is not known which, if any, of these mutations are responsible for attenuation of the vaccine strain.[381,390–394] Two independent laboratories have shown that four vaccine point

mutations are universally present in all strains isolated from documented vaccine adverse events, all of which are located in ORF62.[383,386,388,389] These findings provide a logical starting point for evaluating the contribution of individual, elevated-risk point mutations to VZV pathogenicity. Analysis of vaccine-associated SNPs among more than 100 documented cases of vaccine varicella and HZ revealed two loci in ORF62 at which selection of the WT allele has occurred. The data suggest that the WT allele at this locus in vaccine virus contributes to rash formation, although the mechanism for this remains unknown.[386]

Differences in the migration patterns of DNA fragments of the vaccine-type virus and WT strains were demonstrated after cleavage of purified DNA obtained from viruses propagated in cell cultures, using restriction endonucleases. In a comparison of DNA from the vaccine-type and WT viruses, different cleavage patterns were seen using HpaI, BamHI, BglI, and PstI enzymes.[376,395–397] In early U.S. studies using BglI, a novel restriction site in vaccine-type virus was demonstrated.[396] It was later found that approximately 20% of U.S. WT strains are also BglI-positive. With PstI, an additional cleavage site was demonstrated in WT virus circulating in the United States (PstI-positive) that is not found in vaccine-type virus.[395,398] Oka VZV is PstI-negative, and, with rare exceptions, circulating WT VZV in the United States is PstI-positive.[154] In Japan, however, approximately 10% of circulating WT VZVs are PstI-negative, as is the vOka strain and its parental strain pOka.

Historically, the first practical approach that did not require virus isolation to distinguish between vaccine-type and WT VZV used PCR-amplified DNA fragments followed by their digestion by specific restriction endonucleases.[398] This method is based on the differences (noted earlier) between WT VZV and the Oka strain. In one method, two primer pairs are used, one that generates a fragment flanking the BglI restriction site in vaccine-type virus (gene 54), and another that generates a fragment that is cleaved in all WT VZVs by PstI (gene 38).[398,399] All Oka strains lack a PstI restriction site and carry a BglI restriction site. Approximately 80% of WT VZVs in the United States lack a BglI restriction site, and until recently all had a PstI restriction site. Early studies of viruses obtained from New York, California, and Australia (113 specimens) did not identify circulating viruses with the DNA profile of the Oka strain; although a number of circulating Japanese genotype viruses (clade 2) were found, none lacked a PstI restriction site.[147] In 2001–02, 3% of strains from the West Coast of the United States tested by CDC laboratories ($N = 130$) were clade 2, but they were Pst1-positive.[143] A study of VZV isolates from West Coast cases of HZ meningitis/encephalitis, however, for the first time, identified three WT Oka-like clade 2 VZV strains lacking a Pst1 restriction site in the United States, indicating that vaccine-like WT strains have been introduced here.[154] In countries where the Japanese WT VZV is not circulating, a useful marker for the vaccine strain is the absence of a PstI restriction site; however, rare identifications in the United States,[54] Australia,[147] and China[142] of circulating Japanese WT strains that are Pst1-negative highlight the limitation of using the PstI marker alone as a vaccine strain marker. In Japan, PCR amplification of a portion of gene 14 and analysis of the PstI site was used to distinguish between vOka and other clinical isolates.[400] SmaI and NaeI restriction sites in ORF62, which clearly discriminate between the vOka strain and all WT strains,[390,401] have been used in rapid real-time PCR assays that are useful for identifying adverse events associated with varicella vaccine.[226,402]

Currently, it is recommended that for determining whether adverse events are attributed to vaccine type VZVs, markers in genes 38 (PstI), 54 (BglI), and 62 (especially at positions 106262, 108011) be used.[377] The marker at position 106262 in gene 62 results from the substitution of a C for T in the vaccine strain, resulting in a SmaI restriction site in vOka. In one instance, a marker at position 107252 was found in a WT VZV from an elderly patient with HZ, so this marker may not be useful for identifying vaccine-type VZV.[403] Nevertheless, it is now recommended that for identification of VZVs causing adverse events after vaccination that markers at the following positions be determined: 105705, 106262, 107252, and 108111

Figure 62.6. Summary of sequence analysis of the distinct nine clones isolated from Oka vaccine virus and the nine clones from Oka paternal virus. A, Structure of gene 62. Amino acid residues (aa) are numbered from 1 to 1310 moving from the N- to the C-terminus. Vertical lines indicate the positions of nucleotide differences between Oka vaccine and its parental viruses. **B,** Sequence analysis of clones from Oka vaccine and its parental virus. All nine clones of paternal virus had the same DNA sequence, whereas the vaccine virus was a mixture of at least eight different clones that had a variety of mutations at 15 positions. Nucleotide changes at eight positions caused amino acid conversions. *(From Gomi Y, Ozaki T, Nishimura N, et al. DNA sequence analysis of varicella-zoster virus gene 62 from subclinical infections in healthy children immunized with the Oka varicella vaccine.* Vaccine. *2008;26:5627–5632.)*

(Fig. 62.6).[385] Genotyping of ORFs 21, 22, and 50 has also been used to differentiate between U.S. WTs and Oka vaccine strains.[141,143,147]

It is now considered medically relevant to distinguish vaccine and wild strains of VZV in vaccinated patients with severe rash, neurologic events, or other suspected serious adverse events to determine if they are related to the Oka strain or not, and also to determine if HZ in a patient who was vaccinated in the past is caused by the Oka or the WT strain. The ability to distinguish between vaccine and WT VZV, as well as different genotypes, has led to the discovery that patients may (rarely) have acute or latent infection with more than one type of VZV.[404,405] Detailed methodologies for clinical microbiology laboratories have been published.[180]

Molecular Evidence of Attenuation

Remarkable mutations were identified in IE62 when the nucleotide sequences of the Oka vaccine and its parental VZV were compared.[381,391,392] As shown in Fig. 62.6, the vaccine virus gene 62 contains a mixture of different sequences that have variations at 15 nucleotide positions, whereas only one sequence is present for the Oka parental virus gene 62. There were no nucleotide changes in genes 4, 10, 61, or 63, all of whose products are known to transregulate VZV genes. Nucleotide changes in gene 62 of the Oka vaccine strain resulted in the creation of new restriction sites that were recognized by BssHII, SmaI, and NaeI, whereas that of the Oka parental virus and more than 200 other clinical isolates had none of these cleavage sites. Thus, the Oka vaccine virus can also be distinguished from the parental virus and other clinical isolates using a simplified restriction-enzyme fragment length polymorphism analysis using NaeI, SmaI, and BssHII.[392,406,407]

VZV gene 62 is present in large quantities in virion tegument,[110] and the yield of infectious virus generated by four overlapping cosmid clones is greatly improved when a gene 62–expressing plasmid is transfected.[408] Thus, the mutation in Oka gene 62 may influence the replication of the virus and play a role in the attenuation of VZV. Studies of the regulatory activities of gene 62 in a transient transfection assay indicate that this gene in the vaccine virus has weaker transactivation activity than that of the WT virus in activating IE gene promotors (such as gene 4), E gene promotors (such as gene 28 for DNA polymerase and gene 29 for the major DNA-binding protein), and L gene promoters (such as gene 68 for gE) (Fig. 62.7).[381] An ORF0 transitional stop codon mutation has recently been proposed as contributing to attenuation of Oka VZV.[382] Although there are clear molecular differences between WT VZV and the Oka strain, the exact molecular mechanisms of attenuation remain to be further identified.

Clinical Evidence of Attenuation

Clinical evidence of the attenuation of the Oka strain of VZV is as follows. First, the incidence of rash after subcutaneous injection and inhalational methods of delivering varicella vaccine is far lower than the incidence of rash and other symptoms of natural infection.[409] Second, when rare, inadvertent transmission of vaccine virus to a healthy susceptible contact occurs, the disease is invariably mild or subclinical.[157,229,410–414] The rate of transmissibility of the Oka strain in a household setting in leukemic vaccinees was four to five times lower than that of WT VZV,[157] and its transmissibility from healthy vaccinees is almost negligible. Clinical evidence of reversion of the Oka strain to virulence has not been observed. Additional evidence suggestive of attenuation is that, in contrast to natural

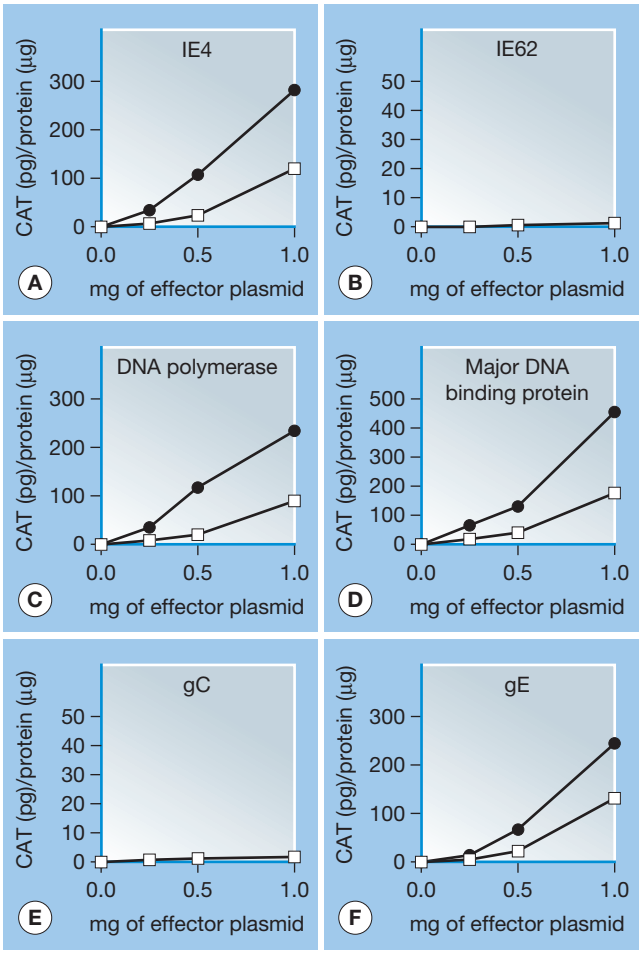

Figure 62.7. Comparison of transactivation activity by the Oka vaccine (squares) and its parental (circles) IE62 on varicella-zoster virus gene expression, including immediate early (IE) genes, E genes (DNA polymerase and DNA binding protein), and late genes (glycoproteins C and E). CV1 cells were cotransfected with 0.25 µg of a reporter plasmid and the same amounts of either pVac-IE62 or pPar-IE62. The CAT concentrations were standardized to each protein concentration. All experiments were repeated at least three times independently. *(From Gomi Y, Imagawa T, Takahashi M, et al. Comparison of DNA sequence and transactivation activity of open reading frame 62 of Oka varicella vaccine and its parental viruses.* Arch Virol Suppl. *2001;17:49–56.)*

infection, vOka uncommonly induces a viremia after immunization. Infectious viremia was not detected in 18 healthy or 10 immunocompromised vaccinees who had no clinical symptoms.[415] Viremia after vaccination was demonstrated using PCR, however, in five (3%) of 166 vaccinated Japanese children who were asymptomatic.[416] Viremia from vaccine virus was found in two leukemic children in remission for 5 and 6 months when they were immunized, one of whom died. They had vesicles and fever 32 and 20 days, respectively, after vaccination.[417,418] Thus, viremia may occur after vaccination but at a lower frequency than that seen with WT varicella. Viremia has also been documented after HZ and vaccination against HZ (reviewed in Levin[419]). Viremia can lead to latent VZV infection of neurons and explains why varicella vaccinees can develop HZ from vaccine-type virus although they never experienced a VZV rash.

Production and Constituents of Vaccine

For vaccine preparation, VZV-infected cells are harvested, suspended in the vaccine medium, and sonicated or otherwise ruptured to obtain cell-free virus. Clinical studies suggest that the ratio of viral antigen to infectious virus may be important in eliciting the immune response to vaccination.[420] Vaccine medium can vary according to the manufacturer; however, it generally contains sucrose and buffering salts. The vaccine is marketed in a lyophilized form to improve stability. Reconstitution is accomplished with sterile distilled water according to the manufacturer's directions. Manufacturers provide reconstitution fluid with the vaccine.

Oka varicella vaccine is produced in the United States (Varivax; ProQuad; Merck & Co.), Belgium (Varilrix; Priorix-tetra; GlaxoSmithKline), Japan (Okavax; Biken, distributed by Sanofi Pasteur), and China (four manufacturers: Shanghai Institute of Biologic Products, Changchun Keygen Biological Products Co., Changchun BCHT Biotechnology Co. [Baike], Changchun Changsheng Life Sciences Ltd.). SuduVax is produced in South Korea (Green Cross). The vaccines vary in passage number in HDCs, trace antibiotics added to ensure sterility, stabilizers, and other minor constituents. Inactive ingredients in Merck vaccines include: sucrose, hydrolyzed gelatin, NaCl, monosodium glutamate, sodium phosphate dibasic, potassium phosphate monobasic, KCl, urea, neomycin, and bovine serum. GlaxoSmithKline vaccines contain the following inactive substances: amino acids for injection, lactose, mannitol, neomycin sulfate, sorbitol, and water for injections.

Seed lots of Oka vaccine were prepared from virus passed 11 times in human embryo lung fibroblast cells, 12 times in guinea pig fibroblast cells, and five times in HDC. Manufacturers add from three to nine additional passages in HDC to prepare enough vaccine to meet marketing needs. Varicella vaccine is stored at refrigerator temperatures (2°C to 8°C) or at freezer temperature (less than −15°C), according to the manufacturer's instructions.

Vaccine Immunogenicity, Efficacy, and Safety

Takahashi initiated clinical trials with the Oka vaccine in Japan in 1974.[1] The vaccine was first given to 70 healthy children at dosages ranging from 100 to 2000 PFU. The vOka was immunogenic at dosages greater than 200 PFU, and no significant reactions were noted. Initial protective efficacy was demonstrated by vaccinating susceptible household contacts immediately after exposure.[421] When healthy children were vaccinated within 3 days of exposure, none of 18 developed varicella, whereas all the 19 unvaccinated contacts did. Additional early studies in Japan included vaccination of children with serious underlying diseases including malignancies where the potential severity of natural varicella was great. The Oka strain was licensed to several other pharmaceutical companies, each of which later conducted clinical trials in Europe, Asia, the United States, and Canada.[422,423] In the United States, there is ample evidence of the effectiveness and safety of vaccine, as it has been administered to healthy children since its licensure in 1995 (see reviews in references 424 to 426).

VARICELLA-ZOSTER VIRUS VACCINE IN HEALTHY CHILDREN

Dosage and Route of Administration

Currently licensed monovalent vaccines include Varivax (Merck), manufactured to guarantee greater than 1350 PFUs in a 0.5-mL dose at expiration and released across a dosage

range of 3000 to 17,000 PFU/dose; Varilrix (GlaxoSmithKline), 2000 PFU/dose; Okavax (Biken), not less than 1000 PFU/dose; four vaccines licensed in China with at least 2000 PFU/dose (0.5 mL) (manufacturers: Shanghai Institute of Biologic Products, Changchun Keygen Biological Products Co., Changchun BCHT Biotechnology Co. [Baike], Changchun Changsheng Life Sciences Ltd); and SuduVax (Green Cross, South Korea) with greater than 1350 PFUs/dose.

The Oka vaccine is administered subcutaneously. Although data on the intramuscular route are limited, it, too, appears to be safe and effective.[427] All manufactured varicella vaccines are lyophilized; both refrigerator-stable and frozen vaccine formulations are available. In 2006, a Merck process-upgrade varicella vaccine was developed for successful storage of varicella vaccine at refrigerator temperatures; it contains 50,000 PFU of VZV and was tested in 1366 children older than 13 years of age. Injection-site reactions were 10% more common than after Varivax, but not severe. Two doses were safely administered; immunogenicity was similar to that of Varivax.[428,429] In the United States, six formulations of Merck vaccines that contain vOka are licensed: monovalent, measles-mumps-rubella-varicella (MMRV), and HZ vaccines (both lyophilized) in refrigerator-stable and frozen formulations, but only the frozen formulations are available.

The MMRV vaccine (ProQuad, Merck), licensed for use in children 12 months to 12 years of age, contains the same measles, mumps, and rubella (MMR) components as those in MMRII, but it has a higher concentration of varicella vaccine virus (approximately 10,000 PFU at expiration) than does Varivax (1350 PFUs at expiration). This high dose of VZV in MMRV was required to achieve acceptable immune responses to the varicella component of the vaccine. The reason for the apparent interference with VZV immunity was not proven but assumed to be related to the measles virus component. A formulation of MMRV manufactured by GlaxoSmithKline (Priorix-Tetra) is also licensed for use in a number of countries. The titer of VZV is the same as that of Varilrix.[428,430] GlaxoSmithKline-manufactured varicella vaccines are lyophilized and stored at refrigerator temperatures.[431–433]

A number of dosage-range studies of vaccine administered subcutaneously were done before licensure of varicella vaccines. Children in Japan were given varying amounts of the vOka strain to determine the minimal effective dosage.[434–441] It is now clear, however, that the higher the vaccine dosage, the higher the resultant immune response.

Alternative methods of administration of varicella vaccine have been studied, such as inhalation. The vaccines were well tolerated and immunogenic but licensure for those methods of administration was not pursued.[442,443]

Immune Responses to Vaccination

Because prelicensure and postlicensure studies of safety and immunogenicity of varicella vaccine used varying dosages of the Oka strain and vaccines from several manufacturers, comparisons across studies are difficult. Additionally, different serologic tests have been used to assess immunogenicity, including neutralization, FAMA, gp-ELISA, and other immunofluorescent antibody tests. Finally, cutoff levels to define seroconversion with the gp-ELISA test have varied, with initial studies using greater than 0.6 gp-ELISA U/mL and newer studies using a higher cutoff level or serologic response rate of greater than 5 gp-ELISA U/mL.

After immunization with at least 500 PFU of the Oka strain, serum IgG antibody responses are easily detected within 1 month after vaccination, and antibody can then be detected for months to years thereafter. After immunization, however, individual and mean IgG antibody titers may be 10 to 30 times lower than those after natural infection, depending on the dosage of vaccine virus, the number of doses given, and the patient's age at immunization.[38,420,444,445] Early studies of duration of vaccine-induced immunity observed increasing titers of VZV antibodies with time. Presumably as a result of exposure to the WT virus and possibly subclinical reactivation of latent VZV[218,446] subclinical boosting of the immune response occurred, eventually resulting in IgG titers that were similar to those after natural infection.[447,448] An early study demonstrated asymptomatic increases in VZV antibody titers in vaccinated children, but it is unclear if this boosting was a consequence of exposure to WT VZV or subclinical reactivation of the vaccine virus or both.[449] Long-term studies are needed in countries with universal vaccine programs to assess duration of the immune response and protection from varicella in the absence of external boosting from varicella exposures. Internal boosting from silent reactivation of latent Oka VZV may also aid in boosting immunity.

Serum IgA antibody is detectable only occasionally and at low levels in vaccinees immunized by inhalation, and it is virtually undetectable in subjects immunized subcutaneously.[409] In contrast to the response after varicella, secretory IgA antibody responses to VZV have not been demonstrated after immunization, regardless of the route of administration or dosage of vaccine.[409] It is not known if IgA at mucosal sites offers protection against infection.

One study suggested that genetic factors play a role in humoral immune responses to varicella vaccine.[450] A study of 141 families with multiple children found a clustering of robust and less-vigorous humoral immune responses among siblings in certain families.

Immune Correlates of Protection Against Varicella

Immune correlates of protection against varicella have been studied but need further clarification and development. The partial efficacy of passive immunization shows that antibody is at least partly responsible for protection, but cell-mediated killing is also important, particularly for control of disease. It is probable that B- and T-cell functions induced by vaccination collaborate in protection. During prelicensure clinical trials conducted by Merck from 1982 to 1991 in the United States, a correlation between the dosage of vaccine administered and the antibody level measured by gp-ELISA was observed.[448] In 3303 children immunized in U.S. clinical trials during the late 1980s, VZV antibody titers were determined with the VZV gp-ELISA assay 6 weeks after immunization.[451] Their seroconversion rate was 96%, with a geometric mean titer (GMT) of 1 : 12 gp-ELISA U/mL. The cutoff point considered positive for seroconversion using the gp-ELISA test, however, was not given. In a subsequent analysis conducted by Merck in 2004, a cutoff of 5 gp-ELISA U/mL was used as a positive humoral immune response. After one dose of Varivax in 1104 vaccinees, the seroconversion rate was 87.3%, with a GMT of 12.8 gp-ELISA U/mL.[452] As part of this study, 1017 vaccinees received a second dose of varicella vaccine 3 months after the first. The seroconversion rate increased to 99.5% and the GMT to 141.5 gp-ELISA U/mL, indicating a marked booster response after the second dose.

A gp-ELISA titer of 5 U/mL or greater 6 weeks after vaccination is reported to be an approximate correlate of protection for individual vaccinees. Rates of breakthrough disease (defined as development of chickenpox resulting from WT VZV infection despite vaccination at least 6 weeks previously) were significantly lower among children with varicella antibody titers of greater than gp-ELISA 5 U/mL, compared with children with titers of less than gp-ELISA 5 U/mL.[235,453–455] After one dose of varicella vaccine, 85% to 89% of children

achieve this antibody level, and after two doses, more than 99% achieve this level. A second dose, either after 3 months or in 3 to 5 years, results in a marked boost in humoral and cellular immunity.[452,456–466] (See also Varivax and ProQuad package inserts.) The gp-ELISA assay, however, is not commercially available and, as has been mentioned, false-positive values may occur.

A positive FAMA titer or skin test after natural varicella, at the time of close exposure to VZV, is highly predictive of protection against disease.[196,232,241,467] A positive FAMA after vaccination, at the time of intimate exposure to the virus, also correlates strongly with protection.[232,467] In 2006, a seroprevalence study, using the FAMA assay, of toddlers vaccinated from 1998 to 2003 indicated a seroprevalence rate of 76% (FAMA >1:4) 6 to 16 weeks after one dose of Varivax.[467] A similar study in Korean infants who were vaccinated at 12 months of age and in whom VZV antibodies were measured by FAMA (cutoff: 1:4 or greater) a median of 6 months after vaccination showed a seroprevalence rate of 84%.[468] Consequently, it was postulated that many cases of varicella in vaccine recipients who received one dose might be the result of primary vaccine failure.

In prelicensure clinical trials, it was noted[451] that the seroconversion measured by gp-ELISA in 13- to 17-year-old adolescents was only 79%; moreover, their GMT was 1:6, half the level seen in healthy children in this study. These results led to the early recommendation in the United States of two doses of vaccine for persons 13 years of age and older. Since 2007, two doses of varicella vaccine have been recommended for all healthy children in the United States.

There are few published data on the use of commercially available VZV antibody tests to determine seroconversion rates in healthy children. Demonstrating the lower sensitivity of commercial assays compared with the gp-ELISA or FAMA assays, a study in Korea documented that only 45% of healthy children tested positive for VZV IgG antibodies by a commercial ELISA test (Dade Behring, Marburg, Germany) a median of 6 months after vaccination at 12 months of age, compared with 84% when FAMA was used.[468] One study suggests that a commercial ELISA test manufactured in Germany (Serion) may be useful and superior to the Dade Behring ELISA.[469]

The immunogenicity of Merck MMRV (ProQuad), licensed in the United States and a number of countries, is excellent for all four viral components. This combination vaccine was difficult to develop in the United States, because antibody titers to the varicella component were at first unacceptably low.[470–473] In prelicensure clinical trials, three dosages were tested in 1559 healthy children 12 to 23 months of age; they contained 3.48 $\log_{10}$ (approximately 3019), 3.97 $\log_{10}$ (approximately 9333), and 4.25 $\log_{10}$ (approximately 17,738) PFU of VZV. Because the safety and immunogenicity profiles were optimal in the children who received the higher dosage, a formulation close to this titer was chosen for licensure—not less than 3.99 $\log_{10}$.[457,458,462] Table 62.1 shows the antibody responses against all four virus components with the licensed MMRV formulation containing 3.99 $\log_{10}$ (approximately 10,000 PFU) of VZV.[474]

In another study of 2925 children in the United States and Canada, in which three consistency lots of ProQuad vaccine were tested, a response rate of greater than 5 gp-ELISA U/mL was reported in 93.5% after one dose.[460] Immunogenicity against VZV compared favorably with the values obtained in 1012 children who were given MMR and Varivax at separate sites.

In evaluating the MMRV vaccine produced by GlaxoSmithKline (Priorix-Tetra), antibody titers to VZV IgG were determined by indirect immunofluorescence (Virgo) in 371 children. The seroconversion rate after two doses 6 to 8 weeks apart was 100%.[430] Excellent responses to the MMR vaccine components also occurred.

Cell-Mediated Immune Responses

In vaccinated healthy children, the skin test became positive as early as 4 days after immunization in about half the children, 7 to 9 days before detection of neutralizing antibodies.[194] Similarly, in another study, lymphocyte transformation became positive approximately 1 week before neutralizing antibodies were detected.[475] The stimulation index against VZV antigen in 74 healthy U.S. children 6 weeks after immunization was 58.6 (±6.5) (Table 62.2).[459,476]

In a study conducted at Stanford University, 39 healthy children received one dose of varicella vaccine and a similar number received two doses given 3 months apart. The mean VZV stimulation index at 1 year after one dose was 9.3 (±1.3) and after two doses it was 22.2 (±6.42).[463] In a similar study, a second dose of varicella vaccine was given 4 to 6 years after the first dose to 419 healthy children. Before receipt of the second dose, the mean VZV stimulation index was 40.3 (±5), and 3 months later it was 61.4 (±6).[459]

Persistence of Varicella-Zoster Virus Antibodies and Cellular Immunity

Several studies indicate that humoral immunity persists for many years after immunization of healthy children with one

TABLE 62.1 Antibody Responses to One Dose or Two Doses of ProQuad in Clinical Trials

Antigen	Time	Subjects *(N)*	Response Rate[a] % (95% CI)	GMT Titer[b] (95% CI)
Measles	After 1 dose	943	97.8% (96.6%–98.6%)	2966.0 (2793.4–3149.2)
	After 2 doses	943	99.4% (98.6%–99.8%)	5919.3 (5486.2–6386.6)
Mumps	After 1 dose	920	98.7% (97.7%–99.3%)	106.7 (99.1–114.8)
	After 2 doses	920	99.9% (99.4%–100%)	253.1 (237.9–269.2)
Rubella	After 1 dose	937	97.7% (96.5%–98.5%)	91.1 (85.9–96.6)
	After 2 doses	937	98.3% (97.2%–99.0%)	158.8 (149.1–169.2)
Varicella-zoster virus	After 1 dose	864	86.6% (84.1%–88.8%)	11.6 (10.9–12.3)
	After 2 doses	864	99.4% (98.7%–99.8%)	477.5 (437–520.7)

[a]Seroconversion: ≤1.25 to ≥5 gp-ELISA U/mL.
[b]GMTs reported in mIU/mL for measles; Ab U/mL for mumps; IU/mL for rubella; and gp-ELISA U/mL for VZV.

vaccine dose, particularly when circulation of WT VZV continues. In Japan, a 5-year follow-up study of 26 healthy immunized children revealed that 100% had detectable neutralizing antibodies and 96% had positive FAMA titers.[447] None of these children developed breakthrough chickenpox, although many were exposed to VZV. In a subsequent study of 106 Japanese children, 14 of whom had been receiving steroid therapy when immunized up to 10 years previously, there were five cases of breakthrough chickenpox.[477] Four of the cases developed in year 1 after immunization. There were 147 recognized occasions when these children were exposed to VZV. Serum specimens were available from 38 children: FAMA antibody titers were 1 : 4 or greater in 37 (97%), with a GMT of 1 : 9. In 29 control children who had experienced natural varicella, FAMA titers were 1 : 4 or greater in 100%, with a GMT of 1 : 10. The VZV skin test was positive in 97% in each group. Because the average VZV antibody titer after immunization is lower than that after natural varicella, these results indicate that a boost in antibody titer had occurred in vaccinees, possibly as a result of subclinical reinfection after exposure to exogenous virus.

A 10-year follow-up as well as a subsequent 20-year follow-up after immunization in Japan showed that 25 of 25 young adults immunized as children remained seropositive.[477–479]

A follow-up of 87 U.S. vaccinees who were given approximately 17,000 PFU of vaccine revealed that 97% retained positive VZV immune responses (measured by gp-ELISA) 5 to 6 years after immunization.[480] In other U.S. studies, in which most of 127 vaccinees received dosages of vaccine of roughly 1000 to 3000 PFU, 95% remained seropositive for up to 6 years.[480] Persistence of antibodies for 2 years after vaccination was 94% in a study of 36 immunized toddlers.[481] Of more than 500 healthy additional children who were immunized in various studies in the United States, for whom there is a follow-up of as long as 6 years, greater than 95% remained seropositive by gp-ELISA.[453,482,483] Another group of 603 vaccinated children showed greater than 89% persistence of varicella antibodies 6 years after vaccination.[484] In a study of 53 vaccinated children whose FAMA antibody titers were measured for as long as 10 years after immunization, most remained VZV antibody positive.[485] Humoral immune responses against VZV, as measured by FAMA, appear to be more durable in healthy children than in immunized adults or leukemic children.[232,486]

A study of the persistence of antibodies after immunization with ProQuad in 3928 healthy children indicated that 1 year after vaccination, antibodies (measured for VZV by gp-ELISA) were detectable in 95% of children against all four viruses.[460] This study also measured antibody levels among study children 4 to 6 years old who had received Varivax 3 to 5 years earlier, before receiving MMRV as a second dose of the varicella vaccine component. Of these children, 88% had VZV gp-ELISA antibody levels of more than 5 U/mL before the second dose of varicella vaccine.[461]

A major question is whether vaccine-induced immunity to VZV will remain positive when exposures to VZV become unusual in the postvaccine era. It was possible to assess whether exposure and consequent boosting are required to maintain positive VZV antibody titers measured by FAMA after vaccination in a small group of handicapped institutionalized Japanese children with no exposures to VZV for 5 years after immunization.[487] The 16 vaccinated children, as well as seven children who had experienced natural varicella, maintained positive VZV antibody titers for 5 years. Skin test reactions also remained positive in 14 of 16 vaccinees. Six VZV-seronegative children remained seronegative during this 5-year period, indicating that no VZV was circulating in this isolated population. Thus, humoral and cellular immunity conferred by vaccine lasted at least 5 years, without boosting by natural infection. It is possible that subclinical reactivation of latent VZV may serve to stimulate immunity, making exogenous exposure to VZV alone less necessary to preserve immunologic memory.

Positive cell-mediated immunity, as measured by lymphocyte stimulation or skin testing, was shown to be durable for many years in a number of other studies in the United States and Japan, all of which, however, were done while there was continuing circulation of WT VZV.[477–480]

In a California study involving 11,356 children followed by active surveillance, the possibility of waning immunity after a single dose of varicella vaccine was explored. Breakthrough varicella, however, was not verified by laboratory testing; clinical illness was twice as likely to be moderate/severe (defined as manifesting over 50 skin lesions) in children who became ill more than 5 years after vaccination compared with those who developed breakthrough disease after a shorter interval. The annual breakthrough rate of disease was higher in children vaccinated 9 years earlier compared with those vaccinated 5 years previously.[488] Although this study suggests waning immunity, primary vaccine failure in 16% to 24% of children after one dose of vaccine also plays a significant role in the failure of a single dose of vaccine to provide complete protection against varicella.[467,489] The possibility of waning immunity after one dose of varicella was reexamined in a case-control study; it was found that development of breakthrough varicella was directly related to the interval of time after immunity. The study was

however retrospective and laboratory confirmation of varicella was not obtained.[490] Importantly, newer studies have not identified waning immunity after varicella vaccination in children who had had either one or two doses of varicella vaccine.[491,492] Additional studies regarding whether or not waning immunity follows varicella vaccine are indicated.

Measures of Protection

Prelicensure Efficacy

Before vaccine licensure in Japan, the United States, and Europe, a number of open-label (dosage-ranging) studies were conducted in Japan and elsewhere; two double-blind, placebo-controlled studies were conducted in the United States and Europe. The vaccine dosages used varied from less than 500 to 17,500 PFUs, limiting the ability to make comparisons across studies. In the original study conducted by Takahashi and colleagues, immunization was used to terminate a potential outbreak of nosocomial chickenpox.[1] All the immunized healthy children developed specific antibodies, and no further cases of varicella occurred. The vaccinated children were protected after four subsequent hospital exposures to varicella.[493] Although this was not a classic efficacy study, these data strongly suggested that live attenuated varicella vaccine would be effective in preventing disease.

Three double-blind, placebo-controlled efficacy studies have been done in healthy children. The first was conducted in the early 1980s using Merck's Oka vaccine in suburban Philadelphia.[494] In this study, 468 children were immunized with one dose of varicella vaccine containing approximately 17,000 PFU (the original report of 8700 PFU was erroneous), and 446 were given placebo. Over the following 9 months, there were 39 cases of varicella, all in the placebo recipients, with a calculated vaccine efficacy of 100%. Of 33 vaccine recipients exposed to varicella cases in their households, none developed varicella, so the vaccine was 100% efficacious after household exposure. During the second year of follow-up, one vaccinated child developed modified varicella consisting of 17 lesions after exposure to varicella, resulting in an efficacy of 98% overall and 92% after household exposures. During a 7-year follow-up, 95% of these vaccinees were estimated to have remained free of varicella.[482] These data cannot be compared with those of subsequent studies in the United States, however, because these children received the highest dosage of vaccine used in the United States as a monovalent vaccine.

A second double-blind, placebo-controlled study was performed in Finland, using vaccine produced by SmithKline Beecham (now GlaxoSmithKline). This study included 513 healthy children, ages 10 to 30 months, who were divided into three groups, given a high-dosage vaccine (10,000 or 15,850 PFU), a low-dosage vaccine (630 or 1260 PFU), or placebo. Eight children who were initially seropositive were excluded from analysis. Children were observed for 29 months on average. There were 65 serologically confirmed cases of varicella: five in the high-dosage group (3% attack rate; calculated vaccine efficacy: 88%), 19 in the low-dosage group (11.4% attack rate; calculated vaccine efficacy: 55%), and 41 (25.5% attack rate) in the placebo group. Breakthrough varicella in vaccinees was a minor illness with an average of less than 30 skin lesions.[495]

The third double-blind, placebo-controlled study was conducted in China using a live attenuated vOka strain vaccine (10,000 PFUs) manufactured by Changchun Keygen Biological Products Co.[496] The study was conducted among 5000 children 3 to 7 years of age with no history of varicella or varicella vaccine. Mumps vaccine was the placebo; the follow-up period was 12 months. Based on varicella incidence rates of 0.8 per thousand in the vaccine group (2/2476) and 8.7 per thousand in the control group (22/2534), vaccine efficacy was 90.8% (95% confidence interval [CI], 88.7–95%).

A 10-year follow-up of 2216 healthy children 1 to 12 years of age who were randomized to receive one or two doses of varicella vaccine (five different lots of vaccine ranging from 2900 to 9000 PFUs) (the licensed vaccine is 1350 PFUs at expiration) 3 months apart, yielded an estimated vaccine efficacy of varicella vaccine of 94.4% (one dose) versus 98.3% (two doses) ($P < .001$).[452] After household exposures, efficacy of one dose was 90.2%, versus 96.4% for two doses ($P = .112$).[452]

Postlicensure Vaccine Effectiveness for Prevention of Varicella

In the postlicensure period, monitoring vaccine performance is essential to assess effectiveness of the licensed vaccine product under conditions of community use. Considerable postlicensure experience has been gained from more than 20 years of use of varicella vaccine in the United States and from use in universal childhood vaccination programs in other countries. Vaccine effectiveness studies have used a variety of methods, including prospective and retrospective cohort, case cohort (screening method), case-control, and household secondary attack rate studies; they have been performed in schools, communities, clinical practices, and households. Case definitions for varicella and for moderate and severe disease vary between studies and may influence estimated vaccine effectiveness. Studies using a clinical case definition tend to underestimate vaccine effectiveness; those requiring laboratory confirmation may overestimate effectiveness.[497]

One Dose. A review of 17 postlicensure vaccine effectiveness evaluations in the United States in 2008 showed that one dose of varicella vaccine (Varivax) was 84.5% (median; range, 44–100%) effective in preventing varicella, and 100% effective (mean and median) in preventing severe varicella.[230,425,498–513] A systematic review that assessed the effectiveness of varicella vaccines identified 42 publications worldwide through the end of 2014.[230,425,498–514,515–538] This review reported that after one dose of monovalent vaccine there were 58 estimates of vaccine effectiveness for prevention of all varicella, 34 estimates for prevention of combined moderate and severe varicella (including two studies that provided estimates for moderate varicella alone), and 25 estimates for prevention of severe varicella.[514] The majority of the studies examined performance of varicella vaccine during outbreaks of varicella in schools and child-care centers; others were case-control, cohort, and household secondary-attack-rate studies. The metaanalysis of the reported estimates indicated that one dose of varicella vaccine was moderately effective at preventing all varicella (81%; 95% CI, 78–84%) and highly effective in preventing combined moderate to severe varicella (98%; 95% CI, 97–99%); effectiveness against severe disease was 100%.[514] Data are for effectiveness within the first decade after vaccination, with a median time since vaccination likely less than 10 years. Vaccine effectiveness estimates were similar whether the analysis was stratified by individual vaccines or study design (Table 62.3); pooled vaccine effectiveness estimates were 82% (95% CI, 79–85%) for Varivax, 77% (95% CI, 62–85%) for Varilrix, 86% (95% CI, 78–91%) for other vaccines (that included Okavax, Keygen, Shanghai, Baike, and Changsheng vaccines), and 81% (95% CI, 76–85%) for unspecified or more than one vaccine used. Most of the reported one-dose vaccine effectiveness estimates for prevention of all varicella were close to the pooled estimate. Two estimates, however, were below 50%, one each for Varivax (44%) and Varilrix (20%).

TABLE 62.3 One-Dose Varicella Vaccine Effectiveness Estimates by Type of Vaccine and Varicella Severity

Vaccine	Prevention of All Varicella			Prevention of Combined Moderate and Severe Varicella			Prevention of Severe Varicella		
	Estimates (N)	Pooled Estimate (95% CI)	Range of Reported Estimates	Estimates (N)	Pooled Estimate (95% CI)	Range of Reported Estimates	Estimates (N)	Median	Range
Varivax	26	82% (79–85%)	44–100%	18	98% (95–99%)	86–100%	10	100%	100%
Varilrix	10	77% (62–85%)	20–92%	6	98% (89–100%)	86[a]–100%	7	100%	100%
Other vaccines	5	86% (78–91%)	77–93%	1	100% (91–100%)	–	1	100%	–
Unspecified/ >1 vaccine used	17	81% (76–85%)	60–100%	9	99% (95–100%)	84–100%	7	100%	85[b]–100%

[a]86% is for prevention of moderate disease only.
[b]Severe disease defined as hospitalizations.
Moderate, 50–500 lesions, no complications; Severe: (a) >500 lesions or a complication requiring physician visit, or any complication (most studies); (b) any hospitalization regardless of the number of lesions (1 study); (c) >250, >200, and >150 lesions (3 studies, respectively); (d) disease severity scale used in clinical trials: number of lesions, fever, systemic signs, and subjective assessment of illness or other combination of clinical criteria (5 studies); (e) parental assessment of severity (2 studies).
Data from Marin M, Marti M, Kambhampati A, et al. Varicella vaccine effectiveness worldwide: a systematic review and meta-analysis. Pediatrics. *2016;137(3):e20153741.*

One possible explanation for low vaccine effectiveness estimates from some outbreak investigations is that outbreaks that come to public health attention are more likely to represent situations in which the vaccine failed and may therefore represent extreme estimates of vaccine effectiveness.[539] Only one study compared directly the effectiveness of one dose of Varivax and Varilrix and found lower effectiveness for Varilrix (56% vs 86%), but the overlapping CIs suggest that the values were not significantly different.[517] The same study provided the only estimate on VE for one dose of MMRV (55%), which was on the lower end of the range reported for monovalent vaccines but with wide CIs that overlapped those of the monovalent vaccines.

A long-term case-control effectiveness study has been carried out in private practices in the United States (Connecticut) since 1999.[230,511] Initial results showed that one dose of the vaccine was 85% (95% CI, 78–90%) effective in preventing PCR-confirmed varicella, and 97% effective in preventing severe varicella (95% CI, 93–99%). In vaccinated children, 86% had mild disease, compared with 48% of unvaccinated children ($P < .001$). A continuation of this study through 2004 indicated a drop in vaccine effectiveness from 97% in year 1 to 85% in year 2, with continued follow-up for as long as 8 years, during which time there was no further loss in vaccine effectiveness.[511] A follow-up analysis evaluating one- and two-dose vaccine effectiveness demonstrated that one-dose vaccine effectiveness through 8 years of follow-up was 86%.[518] Another U.S. study reported a significant decline in one-dose vaccine effectiveness, from 94% within 5 years after vaccination to 88% for 5 to 9 years and 82% for 10 years or longer after vaccination[519]; four other studies also reported a decline in vaccine effectiveness with time since vaccination, but the differences did not reach statistical significance.[422,520–522]

In summary, available data support similar performances of monovalent varicella vaccines in preventing varicella (see Table 62.3). The duration of protection after one dose is not fully understood or studied, especially in settings of low varicella incidence. Further studies could be beneficial, especially regarding effectiveness of MMRV vaccines, but instituting a second routine dose for children is a better way to increase effectiveness and improve herd immunity.

Risk Factors for Vaccine Failure. Several studies have identified potential risk factors for lower vaccine effectiveness (or vaccine failure), including asthma, eczema, early age at vaccination, time since vaccination, receipt of varicella vaccine within 28 days of MMR vaccine, and oral steroids around the time of acquisition of breakthrough disease.[499,502–506,510,540,541] Many other vaccine effectiveness studies that examined possible reasons for lower vaccine effectiveness did not find these or other factors, such as vaccine storage and handling problems, to be associated with vaccine failure. The relatively small number of cases in many studies limits the ability of researchers to conduct multivariate analyses and, thus, to examine the independent effect of each risk factor. Consistent with the findings described by Vazquez and associates of higher vaccine effectiveness during the first year after vaccination,[511] data from a large case-control study from China (1000 cases) also suggested lower vaccine effectiveness after the first year after vaccination; however, the differences did not reach statistical significance.[422] It was projected that a routine two-dose regimen of varicella vaccine for all vaccine recipients will decrease the incidence of breakthrough varicella.

Two Doses. Fewer studies assessed vaccine effectiveness after two doses of monovalent varicella vaccine in children because a routine two-dose regimen was a newer recommendation (e.g., in 2007 in the United States) and fewer other countries/regions adopted it. In the metaanalysis study, overall two doses of vaccine provided 10% or better protection than one dose.[514] The pooled two-dose vaccine effectiveness for prevention of all varicella, based on eight estimates reported through 2014, was 92% (95% CI, 88–95%)[515,516,518–521,532]; two of the estimates, both from outbreak investigations, were below 90%, which may have lowered the pooled estimate to the lower 90s.[515,516] A study published subsequently reported a vaccine effectiveness of 94%.[532a] The only vaccine effectiveness reported for two doses of MMRV/Priorix-Tetra was 91% (95% CI, 65–95%).[517]

The routine two-dose varicella vaccine recommendation for children in the United States since 2007 has provided opportunities to study the effectiveness of this policy. By individual studies, a follow-up of the aforementioned Connecticut case-control study through 2010 demonstrated that two doses of vaccine provided better protection than one dose; vaccine effectiveness for prevention of PCR-confirmed varicella was 98% after two doses, compared with 86% for one dose ($P < .001$). Of the 71 cases of laboratory-confirmed varicella in this

case-control study, none occurred in children who received two doses of vaccine.[518] A subsequent study confirmed the superiority of the two-dose regimen.[299] An earlier investigation of a varicella outbreak of 84 cases affecting a prekindergarten through elementary school complex of 880 children where greater than 97% of children had received at least one dose of varicella vaccine and 39% had received two doses, suggested that two doses did not improve protection compared with one dose (88.1% vs 83.4%, respectively).[515] Cases of putative varicella were subject to laboratory investigation, but in only two of 25 children who had received two doses was the diagnosis confirmed. The second estimate for two-dose vaccine effectiveness lower than 90% was also from an outbreak investigation; outbreaks in two schools were investigated and considering only students in classrooms with cases vaccine effectiveness was 84% in one school and 95% in the other.[516] In this study, laboratory testing could not confirm varicella as the etiology of the outbreak but clinical and epidemiologic data were suggestive. In a study during a varicella outbreak in an elementary school, the incremental benefit of the second dose during outbreak control efforts was 76% (95% CI, 44–90%) for students with classroom exposure. Students who received a second dose were classified as two-dose recipients 4 days after vaccination, thus assuming a rapid anamnestic immune response. The incremental effectiveness increased to 94% when a 10-day delay between the receipt of second dose and the date the immune status was assessed.[532] Although not calculated in the publication, using data provided in it (crude incidence rates for one dose, 4.9 cases per 1000 person-days; for two doses, 1.4 cases per 1000 person-days; and for unvaccinated children, 25.8 cases per 1000 person-days), one- and two-dose vaccine effectiveness estimates are 79% and 95%, respectively. A case-control study that enrolled 133 cases and 365 controls in all West Virginia public schools reported a two-dose vaccine effectiveness of 94%.[519] This study also examined two-dose vaccine effectiveness by time since vaccination and found no difference through 5 years since the second dose; there were too few subjects to confidently examine effectiveness for more than 5 years after the second dose. Another study conducted in the two varicella active surveillance sites during 2009–11 reported a two-dose vaccine effectiveness of 94% among children age 4 years and older (45 cases and 247 controls). In this study, about half of the cases were laboratory confirmed (26 cases); when only laboratory-confirmed cases were considered, two-dose vaccine effectiveness for prevention of all varicella was 96%.[532a] Outside the United States, one study each in Germany and Spain evaluated two-dose vaccine effectiveness both against PCR-confirmed cases and using a matched case-control study design; the reported estimates were 95% and 97%, higher than the one-dose estimates of 72% and 87%, respectively.[520,521]

Postexposure Effectiveness

In the 1970s and early 1980s, postexposure use of different formulations of varicella vaccine was extensively studied by Japanese researchers, who administered vaccine from 1 to more than 5 days after exposure, to children in hospital, community, and household settings (Fig. 62.8).[1,18,435,493,542–544] In two postexposure studies of healthy seronegative children comparing those vaccinated within 3 days of household exposure and those unvaccinated, vaccine effectiveness for prevention was 94.2% in one study and 100% in the other.[421,545] The vaccine was 100% effective in preventing moderate or severe disease if administered within 3 days of exposure.

A double-blind, placebo-controlled trial after exposure was conducted in the United States with an Oka/Merck vaccine (4350 PFU) given to healthy seronegative children 1 to 5 days after exposure in their households.[546] The vaccine was 90% effective in preventing disease if administered within 3 days of exposure, and 67% effective if administered within 5 days. It was 100% effective in preventing moderate or severe disease.

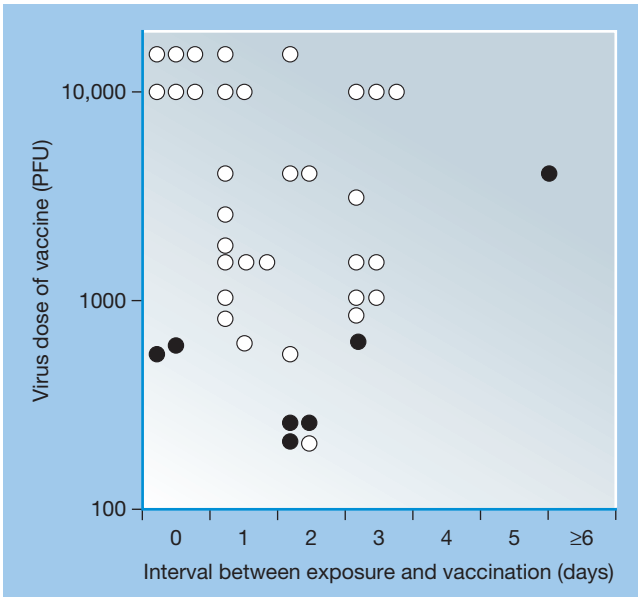

Figure 62.8. Postexposure immunization against varicella-zoster virus. The protective effect of inoculation with live varicella vaccine in household contacts with regard to the dose of virus and the time between exposure and vaccination. Solid circles, varicella; open circles, no varicella. *(Modified from Asano Y, Hirose S, Iwayama S, et al. Protective effect of immediate inoculation of a live varicella vaccine in household contacts in relation to the viral dose and interval between exposure and vaccination.* Biken J. *1982;25:43–45.)*

Studies conducted using licensed varicella vaccines after exposure have shown inconsistent results for prevention of disease of any severity but consistently high effectiveness for prevention of moderate and severe disease. A double-blind, placebo-controlled trial conducted in Israel among 30 families with 42 exposed children who were vaccinated within 3 days of exposure found that the vaccine was not effective in preventing disease (secondary attack rate of 42% of vaccinated children, compared with 45% of placebo recipients), but postexposure effectiveness was 86% in preventing moderate to severe disease.[547] The results of the three studies that used a comparison group were summarized in a 2014 Cochrane collaboration review.[548] These studies involved a combined total of 110 healthy children who were siblings of household contacts with varicella. The authors concluded that evidence suggests that varicella vaccine administered within 3 days to children following household contact with a case reduces infection rates and severity of cases.

Other uncontrolled observational studies have demonstrated high postexposure vaccine effectiveness in preventing either varicella or severe varicella disease when vaccination occurred within 3 to 5 days of exposure.[549–552] Postexposure use of varicella vaccine is currently recommended in the United States.[553]

Breakthrough Varicella

Breakthrough varicella is defined as varicella developing more than 42 days after immunization. Most published studies with long-term follow-up of healthy children vaccinated with one

dose report that despite high rates of seroconversion (measured by gp-ELISA), from 1% to 3% developed breakthrough chickenpox annually.[235,451,453,482,554] Studies of the rate of breakthrough varicella in vaccinated U.S. children for as long as 10 years after vaccination in prelicensure clinical trials indicated a rate of breakthrough varicella from 0% to 4% per year; lower rates of illness were associated with higher dosages of vaccine.[448] In a study in which 17,000 PFU was given, 95% of children remained varicella free 7 years after vaccination.[480,482] Protection after this dose of varicella vaccine was higher than that seen in other studies, in which lower dosages were administered. For example, in the study by Johnson and associates ($N = 280$; dosage: 950 to 3250 PFU), 17% developed varicella after 10 years[485]; in of the study by Clements and associates ($N = 465$; dosage: 950 to 3250 PFU), 19% had varicella after 5 years[453]; and in of the study by Takayama and colleagues ($N = 459$; dosage: 1000 PFU),[555] 34% had varicella after 7 years.

Breakthrough varicella in vaccinated children is typically a modified illness.[451] In U.S. clinical trials, where 12% of healthy children vaccinated with 1000 to 1625 PFU Oka (Merck) vaccine developed breakthrough disease after household exposure, these breakthrough infections were very mild, with one-tenth the number of expected skin lesions.[451] These observations are consistent with those of many other investigators.[374,447,453,481,485,499,554]

Most cases of breakthrough varicella manifest a skin rash of fewer than 50 lesions, unaccompanied by fever. Lesions may be vesicular but are more commonly atypical, with papules that do not progress to vesicles. In a prelicensure clinical survey, natural and breakthrough varicella were compared; children with varicella were examined by clinicians unaware of their vaccination status, using a standard examination. Breakthrough varicella was milder than primary infection. Vaccinated children were less likely to have fever (temperature >37.8°C, or >38.9°C; 12% and 3%, respectively) compared with 57% and 15% for unvaccinated children ($P < .001$ for both comparisons). Vaccinated children also had a lower median number of lesions (53 compared with 300 [$P < .001$]), a lower proportion had more than 500 lesions (1.7% compared with 17.4% [$P < .001$]), and they had a shorter duration of illness (6 days vs 7 days [$P < .001$]).[554] Considering household exposures only, breakthrough varicella cases had a higher number of lesions (median: 118) but still fewer than natural varicella (median: 326). Other than fever, associated constitutional symptoms were not different between the two groups—pruritus occurred in 89% with natural varicella and in 84% of the breakthrough cases.[554]

Postlicensure data on clinical presentation of breakthrough cases confirms that they are milder than cases in unvaccinated persons.[229,499,501,504,509,546,556,557]

In a 9-year summary of population-based varicella active surveillance data, clinical and epidemiologic characteristics of varicella were compared between 1671 one-dose vaccinated and 5609 unvaccinated cases among children 1 to 14 years old.[557] As seen in the prelicensure findings, vaccinated cases, compared with unvaccinated cases, had fewer lesions (75% vs 34% with fewer than 50 lesions), were less likely to have high and prolonged fever, or moderate or severe illness (38% vs 89%), or presence of a complication (5% vs 12%). Nevertheless, approximately 25% of vaccinated cases had more than 50 lesions, and some were associated with serious complications similar to those occurring in unvaccinated cases. Presumably, unmodified varicella disease and complications occur in persons who do not develop an adequate primary immune response from vaccination. Serious complications in vaccinated persons have included pneumonia, sepsis and secondary infection resulting in bacteremia, encephalitis, and aseptic meningitis, the last confirmed to be caused by WT varicella.[558,559,563a] Only rarely have varicella hospitalizations or deaths among persons who had received one dose of varicella vaccine been reported to the Vaccine Adverse Event Reporting System (VAERS), and when reported, have mostly been among patients who, at the time of vaccination, were unknowingly immunocompromised by a medical condition or medications (e.g., systemic steroids for asthma).[229,560–563] Six fatal cases of breakthrough varicella have been reported.[563a]

Several postlicensure studies examined the clinical presentation of breakthrough varicella in one- versus two-dose vaccinated children and did not identify a significant difference in rash severity even though two-dose recipients with varicella appear to present with fewer lesions than one-dose recipients, and no severe rash or complications involving disseminated VSV infection with other organ involvement in addition to skin had been reported to date in two-dose vaccine recipients.[491,519,563a,564] It is unclear if breakthrough varicella severity is truly similar among one- and two-dose recipients, or if only the more-severe spectrum of two-dose varicella is diagnosed.

The mild and atypical nature of breakthrough varicella makes clinical and laboratory diagnosis challenging.[179,224,557,565,566] Healthcare providers should seek history of exposure to varicella or HZ, and in countries that have instituted routine childhood vaccination programs, laboratory confirmation may be needed as disease declines to low levels. Experience with PCR confirmation of breakthrough disease was gained in a study of postlicensure vaccine effectiveness in clinical practice, although the aim of this study was not to evaluate the accuracy of PCR in breakthrough disease. In this study, the rate of confirmation in vaccinated cases was lower (46%) than in unvaccinated cases (90%), possibly as a result of increased PCR testing of children with minor rashes; atypical rashes are more likely to be examined for VZV in vaccinees than in children who have not been immunized.[567] In another study of 33 suspected varicella cases in vaccinated children, VZV was detected by PCR in 58% of cases overall and in 76% of those with adequate tissue specimens.[565] Nevertheless, PCR of skin rashes remains the best approach to diagnosis of breakthrough varicella.[224]

In contrast to the rarity of person-to-person transmission of the Oka strain, vaccinated persons with breakthrough varicella may transmit the WT virus to varicella-susceptible persons. The rate of spread of WT VZV from children with breakthrough disease to their *vaccinated* household contacts was reported to be 12%.[556] The contagiousness of WT VZV in healthy vaccinees was studied in a large household-contact postlicensure study where data were available on the vaccination status of both primary household cases and their unvaccinated and vaccinated sibling contacts. The transmission rate from vaccinated children with breakthrough infections to unvaccinated contacts was 37.1% (26 of 70), which was half the transmission rate from unvaccinated varicella cases to their unvaccinated siblings (71.5%; 1071 of 1499).[509] Vaccinated cases with fewer than 50 skin lesions were only one-third as contagious as unvaccinated cases. When vaccinees with breakthrough infections had more than 50 skin lesions, however, their transmission rate was similar to that seen in unvaccinated children with chickenpox.[509] Some varicella outbreaks in the United States have started with vaccinated cases, and outbreaks have been sustained in highly vaccinated school populations.[502,510,513,515] Administering two doses to all children may greatly decrease the number of outbreaks of varicella in schools and transmission of WT VZV in highly vaccinated populations.

Theoretically, reasons to decrease the rate of breakthrough varicella are to decrease transmission of VZV and to prevent the WT virus from establishing latent infection, which has the

potential to reactivate subsequently and cause HZ. Development of a VZV rash, either WT or caused by Oka, may be associated with subsequent development of HZ but is not required.[199,568] The rate of HZ after vaccination is lower in healthy children than after natural infection.[568–570,787] It is possible that development of HZ is also under genetic control.[571] During the period when only one dose of varicella vaccine was routine, approximately 50% of the reported cases of HZ after vaccination were caused by WT VZV, presumably resulting from asymptomatic as well as symptomatic reinfection by the WT virus.[561,562,570] This proportion will decrease as circulation of WT VZV continues to decrease during the varicella vaccination program. It is anticipated that in populations where two doses are routinely given, not only will the incidence of varicella fall, but so will the occurrence of HZ caused by WT VZV.

VARICELLA-ZOSTER VIRUS VACCINE IN ADOLESCENTS AND ADULTS

Safety and Immunogenicity

Varicella-susceptible adults benefit from vaccination.[54,572,573] Immunized adults have lower seroconversion rates than vaccinated healthy children. Early studies suggested that the vaccine was more immunogenic in adults than it is now recognized to be. In 1985, in Switzerland, 32 healthy seronegative adults, mainly medical personnel, were given an Oka strain vaccine manufactured by RIT, with a reported 90% seroconversion rate.[574] At a similar time, in the United Kingdom, 34 seronegative nurses were immunized with the same Oka strain (RIT), and 94% seroconverted as determined by several serologic tests, including ELISA and immunofluorescence.[575] In early U.S. studies,[546] 89% to 94% of 53 adults seroconverted after one dose of vaccine, as determined by FAMA.

In the National Institute of Allergy and Infectious Diseases (NIAID) collaborative study, from roughly 1980 to 1990, more than 350 healthy adults whose average age was 27 years were immunized in an open-label study.[38,486,576] Most were given two doses of vaccine 3 months apart; their FAMA seroconversion rate was 82% after one dose and 90% after two doses. This experience is also consistent with rates of gp-ELISA seroconversion in 79 vaccinated adolescents after one dose of vaccine.[451] In the NIAID study, the rate of mild vaccine-associated rash (average of nine skin lesions) was 10%, but there was no comparison group. Although it was possible to isolate vaccine-type VZV from skin lesions from a few vaccinees, there was no recognized spread to others.

Larger studies in adults using Varivax have indicated that adults require two doses of vaccine to achieve a seroconversion rate by gp-ELISA of greater than 90%.[577] As for children, there are scant data on seroconversions in healthy adults and those data are based only on commercially available tests. It would not be surprising, however, given the insensitivity of commercial tests, to find that many real seroconversions in vaccinated adults cannot be detected by standard ELISA assays. In one comparative study using latex agglutination, FAMA, and a commercial ELISA in 48 adults 1 to 3 years after immunization, positive VZV antibody levels were detected in 52%, 69%, and 36%, respectively.[184]

A study in Australia, in which two doses of GlaxoSmithKline varicella vaccine were administered to 100 susceptible healthcare workers 17 to 49 years of age, found that 95% of subjects had detectable antibodies using a commercial immunoassay 2 months after the first dose, and 100% of vaccinees had antibodies 6 weeks after the second dose.[578] Reports of complications in adults after vaccination are rare. A healthcare worker was reported to experience prolonged varicella viremia, streptococcal infection, and toxic shock after vaccination.[579]

Cytotoxic T lymphocytes directed against four proteins of VZV were observed in vaccinated adults in U.S. studies.[206] The cytotoxic T-cell response in 23 adult vaccinees was positive and similar to that observed in adults with past natural varicella. In other studies, the magnitude of the cell-mediated immune responses of adults to varicella vaccine were, however, lower than those observed in children.[463,486]

Duration of Immunity

Studies of U.S. adults vaccinated in the NIAID collaborative study indicated that 60% to 90% are seropositive by FAMA or latex agglutination antibody tests as long as 13 years after vaccination (Table 62.4).[486,572] In subsequent follow-up studies of a subset of these vaccinees (120 healthcare workers), 31% lost detectable FAMA antibodies after, on average, 8 years. Twelve (10%) developed varicella; all had mild infections despite loss of detectable VZV antibodies.[232] In another analysis of this study, 9% of almost 500 adult vaccinees developed chickenpox, with follow-up for some persons as long as 21 years. Most of these persons had received at least two doses of vaccine. Eighteen (21%) developed varicella after household exposure ($n = 85$). Neither the severity of breakthrough varicella nor the attack rate after household exposure appeared to increase with time (Fig. 62.9).[573]

A recent study found that 12% of 101 healthcare personnel with documentation of two doses of varicella vaccine were seronegative a median of 4 years after vaccination using a sensitive gp-ELISA test; seven seronegative healthcare workers received a third dose of varicella vaccine and all seroconverted; however, three of seven produced low avidity antibodies, suggesting that they may have mounted a primary immune response to the third dose.[580] Among 61 healthcare personnel with detectable vaccine-induced antibodies and specimens available for testing of antibody avidity, 14% had low avidity antibody, indicating that T-cell immunity may have been incompletely engaged by vaccination. Interpretation of antibody levels after two doses of vaccine is challenging and it is unclear whether absence of vaccine-induced antibodies represents lack of protection.

Follow-up of 100 healthcare workers who received two doses of GlaxoSmithKline varicella vaccine showed that three (4%) of 81 who had sera tested 12 months after the second dose (using an indirect immunofluorescent technique [Virgo]) had lost detectable antibody.[578]

TABLE 62.4 Follow-Up[a] of Healthy Adults After Varicella Vaccination

Follow-up Year	Patients *(N)*	Patients With Varicella *(N* [%])	Patients Seronegative After Vaccination (%)
1	343	8 (2)	34
2	234	8 (3)	33
3	174	2 (1)	40
4	115	5 (4)	10
5	68	4 (6)	30
6	45	2 (4)	10
7–13	40	2 (5)	18

[a]Long-term follow-up focused on breakthrough illness and antibody loss with time. During 13 years of follow-up, breakthrough varicella developed in 9%.

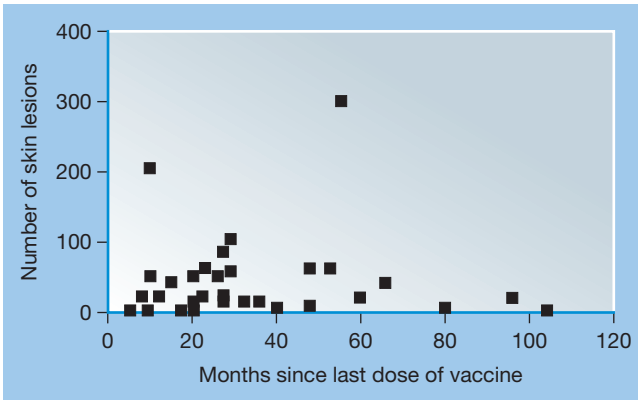

Figure 62.9. Number of skin lesions in 31 vaccinated adults with breakthrough varicella months to years later with respect to the time since the last dose of varicella vaccine was given. Note that the severity of illness did not increase with an increasing interval (in months) since immunization. The average number of skin lesions was 43. *(From Gershon A. Varicella-zoster virus: prospects for control.* Adv Pediatr Infect Dis. *1995;10:93–124.)*

Efficacy and Effectiveness

In the NIAID collaborative study, 57 adults were reported to have experienced household exposures to varicella, with 15 resultant breakthrough cases of chickenpox and an attack rate of 26%. An attack rate of 80% would have been expected had they been fully susceptible. This attack rate of 26% appeared to be higher than that seen in children who had been given similar lots and dosages of vaccine. Only adults who lost detectable VZV antibodies by FAMA or latex agglutination developed breakthrough varicella. However, only 50% of adults who had undetectable antibodies within the previous year developed clinical varicella after a household exposure. Most experienced a modified form of varicella.[38,576,581]

IMMUNOCOMPROMISED PATIENTS

Safety and Immunogenicity in Immunocompromised Children

In Japan in the mid-1970s, a group of 39 children with underlying diseases such as nephrosis, nephritis, asthma, and hepatitis, a third of whom were receiving steroids, were immunized. They were given a dosage of 1000 to 2000 PFU of the Oka vaccine manufactured by Biken. All developed VZV antibodies as determined by complement fixation.[1,376]

A major departure in immunization with live virus vaccines occurred when children with leukemia or other malignancies were vaccinated.[582] Before this, live vaccines were contraindicated in immunocompromised children. Given the high risk from natural varicella, however, 11 children with leukemia and six with solid tumors who were in remission were immunized in Japan. Their chemotherapy, 6-mercaptopurine and methotrexate, was withheld for 1 week before and 1 week after immunization.[582–586] In these studies, the seroconversion rate for antibodies against VZV, measured by complement fixation or immune adherence hemagglutination, approached 100%. Subsequently, a report of 326 leukemic children who were immunized in Japan was published, confirming and extending these data.[437] Most of these children seroconverted to VZV after immunization as determined by FAMA or immune adherence hemagglutination.

In the early 1970s, a chickenpox infection rate of 30% with 7% mortality was reported in U.S. children with leukemia.[75] Based on the successful studies on immunization of leukemic children in Japan, open-label clinical trials in children with acute lymphoblastic leukemia in remission were begun in the United States and Canada in 1979. It was these studies that brought varicella vaccine to the United States.

The largest clinical trial in leukemic children was conducted by the Varicella Vaccine Collaborative Study Group, which was organized to conduct these trials and was sponsored by NIAID.[199,201,411,486,581,587–590] At the time of immunization, children had to meet the following criteria: being in continuous remission from leukemia for at least 1 year, having no detectable antibodies to VZV by FAMA, having a positive response to mitogens in vitro, and having more than 700/mm^3 circulating lymphocytes. Over one decade, 64 children whose chemotherapy for leukemia had been completed and 511 children whose chemotherapy was suspended for 2 weeks (3 weeks for prednisone[591]) were immunized. Chemotherapy was mostly daily 6-mercaptopurine, weekly methotrexate, and monthly pulses of prednisone and vincristine, regimens that were more intense than those given to Japanese children in earlier studies. By the late 1980s in the United States, higher doses of methotrexate, prednisone, and cyclophosphamide were being administered. Although it was initially planned to administer one dose of vaccine, because of a failure of seroconversion as measured by FAMA after one dose in approximately 15% of the vaccinees with leukemia, and a loss of detectable VZV FAMA antibody after 1 year in approximately 5% of the vaccinees with leukemia, two doses of vaccine were finally recommended, given 3 months apart. In this study, a seroconversion to VZV occurred in 82% of leukemic children after one dose of vaccine and in 95% of leukemic children after two doses. In general, approximately 80% of vaccinees tested developed positive cell-mediated immune responses after one dose of vaccine and 90% after two doses, mirroring the experience with humoral immune responses.

Rash developed in 5% of leukemic children no longer receiving chemotherapy, and in approximately 50% of those still receiving maintenance chemotherapy, within 1 month after the first dose of vaccine.[486] Rashes were less common after the second dose, occurring in only 10% of children still receiving maintenance chemotherapy. The rash after vaccination in children with acute lymphoblastic leukemia is usually maculopapular and vesicular and can resemble a mild form of varicella. Approximately 40% of children receiving chemotherapy who developed rash were treated with high oral doses (900 mg/m^2 four times a day) of acyclovir (particularly those with more than 50 skin lesions or with rash that lasted more than 7 days). Children with more-severe rashes (usually those with more than 200 lesions) were treated with intravenous acyclovir at a standard dosage. Oka-strain VZV is sensitive to acyclovir, and acyclovir therapy did not appear to interfere with the development of the immune response.[486] There was no increase in the rate of relapse of leukemia in vaccinated leukemic children compared with children who had natural varicella.[587,592] In other, smaller studies, 84 leukemic children were immunized.[593,594] The seroconversion rates were similar to those observed in the collaborative study. Twenty-two children with solid tumors (Wilms tumor and rhabdomyosarcoma) also were immunized in the collaborative study (Gershon and colleagues, unpublished results, 1980–90). After two doses of vaccine, 77% seroconverted as determined by FAMA assay; 32% had minor vaccine-associated rashes.

In Japan, five cases of severe reactions to varicella vaccine, consisting of extensive skin rash and high fever, were reported.[437] These children were receiving high dosages of immunosuppressive medications that were not withheld before immunization. None suffered permanent sequelae; all recovered. In the United States, a few severe reactions to

vaccine were reported in leukemic children who received a vaccine lot that is no longer being used.[588,595] In postlicensure safety studies, several children with immunodeficiency diseases (discussed later) were diagnosed when they developed complications from Varivax.[229]

There are additional reports of immunization of small numbers of immunocompromised children. In a study of 23 French uremic children, vaccine was given before renal transplantation. It was well tolerated, with 87% seroconversion after one dose.[596] In Spain, 34 children, half on dialysis and half after transplantation, were immunized. Their ELISA seroconversion rate was 85% after one dose; 10% had a mild rash.[597] An additional 212 French children with renal failure were immunized before renal transplantation between 1980 and 1994. One year after immunization, 62% were VZV antibody positive by FAMA and ELISA.[598] There are additional reported safety and immunogenicity trials in children with renal failure[599] and after renal and liver transplantation.[600]

Several additional studies by the Pediatric AIDS Clinical Trials Group evaluated varicella vaccination in children with HIV infection. In a clinical trial involving 41 HIV-infected children whose $CD4^+$ T-lymphocyte levels were relatively normal (>25%) and who were at most mildly symptomatic (CDC stage N1 or A1) from HIV, 85% developed immune responses to VZV after two vaccine doses. Antibodies were detectable by FAMA in 60%, and a positive stimulation index developed in 83%. The rate of vaccine-associated rash was 5% and, unlike leukemic vaccinees, none required treatment with an antiviral drug to control rash from the vaccine.[601] In a Pediatric AIDS Clinical Trials Group study of 44 HIV-infected children with CD4 levels as low as 15%, vaccinated children also tolerated varicella vaccine well, with 80% developing an immune response after two doses.[602] Additional small studies in HIV-infected children have shown varicella vaccine to be immunogenic and safe.[603,604]

There is interest in boosting VZV immunity in HIV-infected persons who have had varicella, in hopes of protecting them from developing HZ by stimulating their cellular immune responses to VZV. Studies in children and adults with immunity to varicella are ongoing, using varying dosages of vaccine.[605,606] It appears that Zostavax is safe for HIV-infected adults with CD4 counts greater than 200/mm^3 (ACTG 5247).[607] Details can be found in Chapter 63.

Further studies in varicella-susceptible immunocompromised children are sparse. In Thailand, 29 children with chronic liver disease were safely immunized, with 100% seroconversion.[608] A clinical trial in which 11 children, ranging from 6 months to 8 years of age (median: 10 months of age), were given one dose of varicella vaccine approximately 3 months before liver transplantation was reported. Only three of 11 seroconverted, and after an exposure, passive immunization was still given.[609] A study in Switzerland that included children 6 months to 18 years of age (median: 7.8 years of age) who were at least 1 year after liver transplantation and on low immunosuppressive therapy reported that all 36 seronegative children reached antibody levels defined as protective and 97% remained seropositive a median of 1.7 years after vaccination. No breakthrough disease was reported a median of 4.1 years of follow-up.[610] In this study, two doses of GlaxoSmithKline varicella vaccine were administered but 22% of children required a third dose to sustain antibody levels defined as protective (≥50 IU/L). Varicella vaccine was administered to 21 Canadian children before solid-organ transplantation, with excellent persistence of antibody titers and no cases of breakthrough varicella.[611]

A study on safety and immunogenicity of Varivax after liver and intestinal transplantation included 16 varicella-susceptible children 13 to 76 months of age who were vaccinated 257 to 2045 days after transplantation. Five developed mild fever and non–injection-site rashes. Humoral and cellular immunity developed in 86% to 87%. No chickenpox occurred after five exposures to varicella.[612] There are additional reports on small numbers of children immunized after liver transplantation.[613,615,616] A small study of varicella vaccine in children with juvenile rheumatic arthritis receiving methotrexate and steroids showed no significant safety concerns and a 50% antibody response rate, measured by commercial ELISA, to one dose of varicella vaccine (IgG titers were detected in 72% of controls).[617] A small study in children with atopic dermatitis given GlaxoSmithKline varicella vaccine reported that the vaccine was well tolerated and immunogenic.[618] Another study in pediatric patients (12 months to 8 years of age) with asthma evaluated whether budesonide inhalation suspension reduces the immunogenicity of Merck varicella vaccine. There was no difference in the proportion of patients achieving a VZV antibody level, as measured by gp-ELISA, of 5 or greater gp U/mL (85%) (129/151) in the budesonide inhalation suspension group and 90% (83/92) in the nonsteroidal conventional therapy group (relative risk [RR] = 0.95; 95% CI, 0.86–1.04).[619] A small number of adults ($n = 45$) who had undergone stem cell transplantation were given Oka-RIT vaccine 4.5 and 6.5 months after transplantation. Many of these adults were seropositive before vaccination and immune responses to VZV in all patients were rather weak. There were no serious adverse events after vaccination, but during the follow up several patients developed a varicella-like illness (from Oka or WT VZV) and several developed clinical HZ. It was concluded that alternative strategies were necessary to prevent VZV infections in stem cell transplant patients.[620]

Duration of Immunity in Immunocompromised Patients

There has been a high degree of persistence of antibodies to VZV in vaccinated leukemics, although the rate of persistence is lower than that in healthy children. Over 11 years, 13% of vaccinees who originally seroconverted become seronegative by FAMA or latex agglutination.[486] Many were exposed to varicella but did not become ill. After a reseroconversion, titers in leukemic children usually remain detectable, and, in a number of patients who reseroconverted without symptoms, the Western blot antibody pattern was characteristic of an anamnestic response.[588,621] Furthermore, the attack rate of clinical varicella among leukemic vaccinees who had again become seronegative and who had household exposures was only 30%, not the 80% that would be expected in varicella-susceptible patients.[588] Neither the incidence nor the severity of breakthrough varicella in leukemic vaccinees increased with time, even as many of these vaccinees became young adults.[486] The meaning of loss of a detectable antibody titer years after immunization is difficult to interpret, but it may represent some waning of immunity. At present, however, no booster immunizations are recommended for these persons.

The only other study of immunocompromised patients for whom there is long-term follow-up involved antibody persistence in French children immunized before renal transplantation. After 10 years, 42% were seropositive by ELISA, a test that usually has low sensitivity.[598] It is possible that had a more sensitive test been used, the rate of antibody persistence would have been greater.

Prelicensure and Postlicensure Vaccine Performance in Immunocompromised Vaccinees

Significant information on efficacy in immunocompromised leukemic children in the United States and Canada was

gathered from the NIAID collaborative study. In this group, there were 123 household exposures to varicella over a decade, with 17 cases of breakthrough chickenpox, a rate of protection of 86%.[201,411,486,581] Varicella occurred in 39 vaccinated children, most of whom did not have household exposures to chickenpox; this was generally a modified illness, with an average of 96 skin lesions (range, 1 to 640). None of these leukemic children with breakthrough varicella required treatment with antiviral drugs.

The protective efficacy of vaccine was examined in 212 French children immunized prior to renal transplantation. They were compared with 49 similar children with no vaccination or chickenpox and 415 similar children who had previous varicella. The incidence of varicella was significantly lower in vaccinees (26 of 212 [12%]) than in those who were not vaccinated (22 of 49 [45%]). The disease was also less severe in the vaccinated children, with no deaths; there were three deaths from varicella in the unvaccinated group. Varicella occurred only in vaccinees who lost detectable VZV antibodies after vaccination; no cases of varicella were observed in those who remained antibody positive. Four (1%) of the 415 patients with a history of past varicella developed a second attack, which was similar to the attack rate in vaccinees.[598] The calculated vaccine efficacy in this study was 73%.

Attempts have been made to determine how effective live attenuated varicella vaccine is for HIV-infected children. One study of 356 HIV-infected children suggested that the vaccine was effective in preventing HZ, but it was not possible to distinguish between the protective effects of highly active antiretroviral therapy (HAART) on their immune systems in preventing zoster and those of the vaccine itself.[622] A subsequent collaborative study determined that the vaccine was 85% effective in protection against any varicella and 100% effective in preventing zoster, based on comparative disease incidence per 1000 person-years (PY) of observation, in 77 vaccinated HIV-infected children.[623] In this study, in which unvaccinated children served as controls, there was also no evidence that HAART alone was responsible for the high degree of prevention of VZV disease; the excellent degree of protection from both varicella and HZ was attributable to the vaccine itself.

There is no published information on the protective efficacy of varicella vaccine in children after liver transplantation or those with solid tumors.

VACCINE ADVERSE EVENTS

Prelicensure Studies

In two placebo-controlled studies, conducted by Merck[494] and GlaxoSmithKline,[495] the most common adverse events reported after varicella vaccination of healthy children were minor and included mild tenderness and redness at the injection site, fever (reported in one trial but not the other), and mild rash.[494,495] In the U.S. double-blind, placebo-controlled clinical trial,[494] the only complaints that occurred significantly more often in vaccinated children than in placebo recipients were pain (26.4% vs 17.5%) and redness (5% vs 2.5%) at the injection site ($P < .05$).[494] Nonspecific rash within 43 days of vaccination occurred among 2% of placebo and 4% of vaccine recipients, although the few generalized varicella-like rashes occurred in vaccine recipients. There was a similar rate of rash at the injection site, usually consisting of two to four lesions.

Among persons 13 years of age and older, a higher percentage of injection-site complaints was reported after both one and two doses of vaccine: 24.4% and 32.5%, respectively (Varivax package insert). Varicella-like rash at the injection site occurred in 3% of one-dose vaccine recipients and 1% of two-dose recipients. A nonlocalized rash occurred in 5.5% of vaccine recipients after the first injection and in 0.9% of vaccine recipients after the second, at a peak of 7 to 21 and 0 to 23 days postvaccination, respectively. There was no comparison group that received a placebo injection.

A study of the MMRV vaccine that is now licensed in the United States (ProQuad, Merck) was conducted among 480 healthy 12- to 23-month-old children. The children were randomized to receive either MMRV and placebo or MMRII and Varivax. The subjects who received MMRV and placebo received a second dose of MMRV 3 months later. Measles-like rash and fever (temperature higher than 38.9°C) during days 5 to 12 were more common after the first dose of MMRV (rash: 5.9%; fever: 27.7%) than after MMR and Varivax (rash: 1.9%; fever: 18.7%). Measles-like rashes in both groups averaged 6 days and were mild to moderate in intensity. Among the subjects with measles-like rashes, 30% had concurrent fever. The rate of varicella-like rashes after a single dose of MMRV (2.2%) was comparable with the rate in the group that received Varivax. The rate of adverse events was generally lower after the second MMRV dose than after the first.[458] Another study administering MMRV (ProQuad) for a second MMR or varicella vaccine dose at 4 to 6 years of age showed no differences between the children in systemic reactions, including fever, occurring within 43 days of vaccination.[461] Analysis of fever occurring 5 to 12 days after vaccination was not provided. Adverse reactions at the injection site, including pain/tenderness/soreness, erythema, and swelling were more common with MMRV vaccine than with MMR or Varivax, alone or in combination. However, there was no substantial increase in the number of injection-site reactions for MMRV. The reason for the increased rate of measles-like rashes after MMRV compared to MMR and monovalent varicella vaccine is not fully understood, but might suggest a more vigorous immune response in response to an increase in measles virus replication; the measles GMTs measured 6 weeks after vaccination were higher among children who received the first dose of MMRV vaccine than among children who received the first dose of MMR and varicella vaccine administered at the same visit, whereas the varicella GMTs were similar.[458] Statistical modeling indicated that the level of the measles antibody titer after receipt of MMRV vaccine was associated positively with the rate of fever and the rate of measles-like rashes.[474]

An MMRV vaccine (Priorix-Tetra) produced by GlaxoSmithKline is licensed in Canada, Australia, and some countries in Europe. The safety profile of this combination vaccine given as a first or second dose 6 to 8 weeks after the first dose was studied in children 12 to 18 months old; 371 were given MMRV and 123 were given MMR plus varicella vaccine.[430] After the first dose, a higher incidence of fever was observed within 15 days after MMRV vaccine compared with MMR plus varicella vaccine (67.7% vs 48.8%, $P < .05$). However, the incidence of grade 3 fever (temperature >39.5°C rectal, or >39.0°C axillary) did not differ between the two groups (11.6% vs 10.6%, $P = .87$). The incidence of local reactions, pain, and redness within 4 days of vaccination was higher in second-dose MMRV recipients than in children who received MMR plus varicella vaccine. This tendency was also present after dose one, although the differences were not significant.[430] Studies of safety and immunogenicity of the GlaxoSmithKline MMRV vaccine yielded similar findings.[624,625]

Postlicensure Studies

Monovalent Varicella Vaccine

In a clinical trial of two doses versus one dose conducted postlicensure among approximately 900 children ages 12 months to 12 years, the safety profile of the two-dose regimen

was comparable to that of the one-dose regimen. Incidence of injection-site complaints observed 3 or fewer days after vaccination was slightly higher after dose two (25%) than after dose one (21%) (P = .015). Incidence of systemic clinical complaints was lower after dose two; fever incidence from days 7 to 21 postvaccination was 7% after dose one and 4% after dose two (P = .009), and varicelliform rash incidence after dose one was 3%, compared with 1% after dose two (P = .008), with peak occurrence 8 to 21 days postvaccination.[456]

Postlicensure safety monitoring of Merck varicella vaccine in the United States, now reflecting more than 20 years' use and 150 million doses of vaccine distributed, has been reassuring. An early postlicensure study of almost 90,000 children and adults immunized in a northern California large health maintenance organization (vaccine safety datalink site) between 1995 and 1996 found that the vaccine was safe and free of rare complications. Clinical conditions were examined for elevated risk within 30 days of varicella vaccination. Cerebellar ataxia, reported to occur in one in 4000 persons after natural varicella, did not occur after varicella vaccination in this vaccinated cohort. There were no occurrences of encephalitis or bleeding disorders, although the study size was not sufficient to draw conclusions about prevention of these rarer complications of varicella potentially resulting from vaccination.[626]

Serious adverse events after varicella vaccination continue to be rare. Considering the approximately 48 million vaccine doses distributed in the United States from 1995 to 2005, there were 25,306 adverse events reported (52.7 per 100,000 doses distributed); 5% were classified as serious (2.6 per 100,000 doses distributed). The most common adverse events, accounting for 67% of all reports, have consistently been rash, fever, and injection-site reactions.[562] Similarly, postmarketing surveillance over the first 5 years of Varivax use in Europe (approximately 3.3 million doses distributed) found that most (88%) adverse events reported after vaccination were nonserious and the rate of reporting was 30 reports per 100,000 doses distributed.[627]

Serious adverse events that have been reported as temporally related to varicella vaccination include death, urticaria (including some cases of recurrent papular urticaria), ataxia (median: 16 days; range, 1 to 61 days), thrombocytopenia, pneumonia, anaphylaxis, encephalitis (median: 20 days; range, 4 to 365 days), erythema multiforme, stroke, and transverse myeltitis (see also the Varivax package insert).[229,561,628–631] Most of these events were not found to be caused by the vaccine virus (see later). In one study, no association between varicella vaccine and subsequent ischemic stroke was found[632]; stroke is a rare complication of natural varicella.[633] In Japan, a gelatin-free varicella vaccine with 1,300,000 doses distributed in 1999 and 2000 was associated with a marked reduction in reported anaphylactic reactions (no reports of serious reactions and five nonserious reactions) compared with 28 reports of serious anaphylactic reactions and 139 reports of nonserious reactions when gelatin-containing vaccine was in use, with 1,410,000 doses distributed from 1994 to 1999.[634]

For reported adverse events after vaccination that are plausibly biologically linked to the vaccine, laboratory testing of submitted specimens for VZV strain identification is critical. Early in the postlicensure period in the United States, a safety study linking reported serious adverse events with laboratory testing was undertaken by investigators at Merck and Columbia University using Merck's Worldwide Adverse Experience System.[229] This study is ongoing. Clinical data are reported, and coded laboratory specimens are tested in a blinded fashion, and the results are then analyzed together.[229,399] In particular, the study was probing for the following events: rashes of more than 50 lesions detected within 42 days after immunization; possible instances of secondary transmission of the Oka strain to others; varicella and HZ occurring after vaccination; and neurologic, dermatologic, and other possible complications of VZV infection after immunization. Analysis of data after approximately 48 million distributed doses of varicella vaccine in the United States showed that rashes caused by Oka strain occurred from 5 to 42 days after vaccination (median: 21 days) and ranged from one to 500 skin lesions (median: 51). In previously vaccinated persons, rashes caused by WT VZV occurred between 1 and 20 days after immunization (median: 8 days), with 10 to 1000 reported skin lesions (median: 100).[561] In the United States, strain identification to support vaccine safety evaluations is also available through the national VZV laboratory at the CDC, and in other countries (e.g., Canada, Australia, Germany) as well as regions (European) where similar programs for testing have been established.[627] HZ caused by vaccine strain VZV may occur in both healthy and in immunocompromised persons.[229,561,562,570] (For further details, see "Herpes Zoster in Vaccinated Persons" later.)

An Institute of Medicine systematic review of the epidemiologic, clinical, and biological evidence for adverse events associated with varicella vaccines through 2010 concluded that evidence supports causality in five adverse events: (1) disseminated vaccine strain virus without organ involvement (e.g., varicella-like rash extending to dermatomes beyond the initial injection); (2) disseminated vaccine strain virus with organ involvement (e.g., pneumonia, meningitis) in individuals with demonstrated immunodeficiencies; (3) vaccine strain reactivation (HZ) without organ involvement; (4) vaccine strain reactivation (HZ) with organ involvement; and (5) anaphylaxis.[635] These events are unusual or rare. A follow-up review of the evidence from the end of the Institute of Medicine report through 2012, identified evidence consistent with the Institute of Medicine report. Notable rare complications that have also been proven to be caused by VZV Oka strain include pneumonia, hepatitis, HZ meningitis, recurrent HZ, severe rash, secondary transmission, retinal necrosis,[636] vasculopathy of the central nervous system with immunodeficiency,[637] and, extremely rarely, death (see below). Treatment with an antiviral was often given, usually with recovery from VZV complications. Most of these patients were immunocompromised or had other serious medical conditions that were undiagnosed at the time of immunization, but others were basically healthy.[154,229,561,562,638] Two children with disseminated Oka disease were found to have an abnormality in invariant natural killer cells.[639,640] Two children and one adult with undiagnosed HIV infection who had very few $CD4^+$ lymphocytes developed disseminated varicella (as their presenting sign of HIV infection) from VZV Oka.[641–643] A vaccinee developed severe Oka varicella and was subsequently diagnosed with severe combined immunodeficiency.[644] Two children with neuroblastoma developed chronic HZ as a result of Oka VZV, which, with time and antiviral therapy, became drug resistant; they were then successfully treated with foscarnet.[645,646] Recurrent Oka HZ in a 2-year-old healthy boy was reported.[647] HZ and transmission of vaccine strain VZV are described in more detail in following sections.

Five fatal cases of Oka VZV infection have been described, all in immunocompromised patients. One was a child with leukemia from Germany who was vaccinated only 5 months after being in remission.[418] Another was a 15-month-old American child with undiagnosed symptoms of immunodeficiency who died after inadvertent vaccination against varicella.[648] Both of these children had pneumonia and characteristics of varicella. A third fatality was reported in an adult with a history of varicella in childhood, who was vaccinated against varicella following stem cell transplantation for lymphoma. He developed

persistent zoster involving skin and liver, despite treatment with valacyclovir. The VZV with which he was infected was found to be resistant to acyclovir.[649] A third death was reported in an elderly patient with chronic lymphocytic leukemia who had no longer been under immunosuppressive treatment for 6 months when he received the zoster vaccine.[649a] He developed disseminated VZV infection with multiorgan failure. A fourth death occurred in a child with a rare immunodeficiency (hypomorphic RAG2 deficiency) with late onset that was undiagnosed before vaccination. The child experienced autoimmune hemolytic anemia, hepatic and renal failure, and disseminated intravascular coagulation.[649b,649c] Additionally a child with DiGeorge syndrome and one diagnosed with severe combined immunodeficiency after vaccination died of pneumonia following MMRV and separate MMR and varicella immunizations, respectively, but it was unclear if the deaths were caused by varicella.[650,651]

Meningitis and encephalitis in association with HZ caused by VZV Oka strain has been confirmed by PCR in CSF in at least nine instances: one in a child with localized ophthalmic zoster on chemotherapy for cancer,[561,562] two in children with neuroblastoma who were receiving chemotherapy and developed disseminated HZ,[645,646] and six in otherwise healthy children, including one case of encephalitis.[154,405,559,627,652–654] All these patients recovered; most were treated with acyclovir. Other cases of HZ and meningitis in healthy vaccinated children with PCR-confirmed VZV in CSF have been reported.[559,561,562] These children all recovered, but without strain typing, it is not possible to assess vOka causality. Interestingly, WT VZV was identified as causal in an older woman given HZ vaccine who developed meningitis 1 day after immunization,[655] and in a few children who had been vaccinated.[154,562,656] These experiences illustrate the importance of typing of VZVs that are implicated as causing severe adverse events in vaccinated persons; not all are caused by the Oka strain, and those that are need to be identified as such, in the interest of assessing vaccine safety.

A pregnancy registry to track outcomes of inadvertent varicella vaccination 3 months before or during pregnancy was established in 1995 by Merck in collaboration with the CDC. A review of data reported after 10 years from the United States and Canada showed no features consistent with congenital varicella syndrome among the 531 live births of women prospectively enrolled in the registry, including among the 131 offspring of varicella-susceptible women (rate = 0; 95% CI, 0–6.7).[657] An updated report with 17 years of registry data (through 2012) continues to show no risk of congenital varicella syndrome among 788 live births of women prospectively enrolled in the registry including among the 160 offspring of seronegative women (rate = 0; 95% CI, 0–2.4).[658] Interestingly, the incidence of the congenital varicella syndrome significantly decreased in Australia after institution of their varicella immunization program.[659] No cases of the congenital varicella syndrome caused by Oka vaccine have been reported from any source. Because of a decrease in reporting and no data to indicate risk, the Merck/CDC varicella vaccine pregnancy registry was closed in 2013.[660]

There has been concern about the safety of various vaccines in children with defects in intermediary metabolism such as those with abnormal mitochondrial function. A retrospective study of varicella disease in 64 such children, however, revealed that 8% required hospitalization during clinical varicella. The conclusion of the study was that a clinical trial of varicella vaccine should be done in such children to determine whether vaccination is safer than the natural disease.[661]

Molecular studies of VZV DNA amplified from rashes in vaccinees with vesicular lesions have provided insight into possible virulence of the Oka strain, which is known to represent a mixture of VZVs with different SNPs.[662] Some studies have identified VZV in vesicles as clonal or monomorphic,[383,389] whereas others have found predominantly mixtures of the vaccine strain variants.[663] When mixtures are found, it is possible that more than one vesicle was sampled and incorporated into one specimen. Both research groups have primarily studied vesicular fluid that was not subjected to culture, making viral propagation in vitro an unlikely explanation for the described mixtures. One study suggested that there are specific VZV WT-like SNPs in the vaccine that are commonly associated with development of rash and thus may be associated with virulence.[386] Currently, there is considerable interest in whether recombinant VZVs (between WT and Oka) have emerged in the vaccine era.

Differing SNPs in vaccines prepared by Merck and GlaxoSmithKline have been identified. Merck's varicella vaccine is composed of 20% more WT SNPs than GlaxoSmithKline vaccines, which might relate to protection rates against varicella and occurrence of HZ after these vaccines.[393] There appear to be four core sets of SNPS that distinguish between wild and vaccine types of VZV.[385,393]

Combination Varicella (Measles-Mumps-Rubella-Varicella) Vaccines

Because of the higher rate of fever seen in prelicensure studies after the first dose of MMRV vaccine compared with MMR and varicella vaccines, postlicensure studies to evaluate the risk for febrile seizures were conducted by the vaccine manufacturer in the United States (Merck) and by the FDA and the CDC.[664,665] Compared with MMR and monovalent varicella vaccines, both studies demonstrated a twice-higher incidence of febrile seizures in vaccinated children (predominantly 12 to 23 months of age), 5 to 12 (RR, 2.0; 95% CI, 1.4–2.9%), or 7 to 10 (RR, 2.2; 95% CI, 1.0–4.7%) days after the first dose of MMRV, with one extra febrile seizure for every 2500 children vaccinated. No increased risk for febrile seizures was identified among children 4 to 6 years of age who received the second dose of MMRV compared with same-age children who received MMR and monovalent varicella vaccine at the same visit.[666] After consideration of the postlicensure data and other evidence, the ACIP adopted, in 2010, revised recommendations regarding the use of MMRV vaccine for the first dose and identified a personal or family (i.e., sibling or parent) history of seizure as a precaution for use of MMRV vaccine[667] (see "Routine Vaccination Schedule" later). Similar risk for febrile seizures after first dose Priorix-Tetra (GlaxoSmithKline MMRV) was identified in a study conducted in Germany.[668]

Transmission of Vaccine Virus

In leukemic vaccinees, the risk of transmission was directly proportional to the number of skin lesions in the vaccinee. Of 93 unimmunized and susceptible siblings exposed to a leukemic vaccinee with a vaccine-associated rash, 21 (23%) seroconverted. Of these contact children, five of 21 (24%) never developed a rash.[157] In comparison, the normal expected subclinical attack rate of WT varicella is approximately 5%.[20] In exposed infected siblings who developed rash, the median number of skin lesions was 12 (range, 1 to 200).[157] The greater the number of skin lesions in vaccinees, the greater the chance of transmission there was of the Oka strain. There was only one report of tertiary spread, further suggesting that the vaccine virus has limited ability for transmission.[157] No spread was found in 112 siblings exposed to a leukemic vaccinee who did not have a vaccine-associated rash.[157]

Transmission of the Oka strain was addressed in two clinical studies in healthy children using the Merck vaccine before

licensure.[439,669] In one, children in a household were randomized to receive either vaccine or placebo.[439] In that study, there was no transmission of clinical disease. However, three of the 439 initially seronegative placebo recipients exposed to vaccinees seroconverted to VZV without symptoms. No rash was reported in the vaccine recipients to whom they had been exposed. In view of the importance of rash in transmission, it seems that these results are more likely to be the result of serologic errors rather than actual transmission of VZV. In the second study, siblings of susceptible immunocompromised children (most with a diagnosis of leukemia) were vaccinated.[669] There was no evidence of clinical or serologic transmission of the Oka virus after vaccination in the approximately 30 families studied.

In contrast to data involving leukemic vaccinees in research studies,[201] in healthy vaccinees, transmission of Oka has been exceedingly rare, with only 11 documented occurrences from nine vaccinees (two vaccinees transmitted the virus to two other people each[412,414]), most commonly after household exposures. The exceptions are transmissions occurring in institutional and school settings. A 15-year-old institutionalized boy developed more than 500 lesions after vaccination and transmitted Oka strain to two other persons in his facility, including to an unvaccinated healthcare worker.[412] A 23-year-old kindergarten teacher with no history of varicella or varicella vaccination developed 50 to 100 vesicular lesions, confirmed as vOka, after exposure to a 5-year-old boy in her class 17 days after he developed HZ. He had received varicella vaccine (Varilrix) 13 months previously.[670] Thus, despite the distribution of more than 150 million doses of vaccine worldwide between 1995 and 2015, only these 11 cases of transmission have been reported. Although other cases of transmission have been suspected, they were not documented by laboratory testing, or perhaps they remain unreported in the literature. In contrast, the WT virus under similar circumstances, such as family contacts, is highly transmissible to susceptible persons from unvaccinated persons with a secondary attack rate as high as 87%,[20] and moderately transmissible from cases of natural varicella in vaccinees (secondary attack rate: approximately 37%).[509] In each instance of confirmed transmission of vaccine-type VZV, there was a rash caused by the Oka strain in the vaccinee. Among the secondary cases, seven were acquired from vaccinees with varicella-like rashes after vaccination, and four others were from children with HZ caused by the Oka strain.[229,410,412,414,627,670–673] The seven persons to whom transmission of Oka virus occurred directly from a healthy person soon after vaccination were a 4-month-old sibling, a healthy father, a pregnant mother, two healthy children of the vaccinee, an institutionalized adolescent, and a healthcare worker.[229,412,414,671] All these contact cases were mild. In addition, there was a report of neonatal varicella with vaccine-strain VZV diagnosed 22 days after maternal postpartum vaccination; the mother did not have a rash but the newborn was in the room when the mother was vaccinated and the most plausible mode of transmission was deemed aerosolization when the vaccine-filed syringe was cleared of air bubbles rather than transmission from the mother.[672]

The low transmission rate of the Oka strain is of importance because of the potential for spread of vaccine-type VZV from healthy vaccinees, such as healthcare workers, to other susceptibles. If a healthy vaccinee has no rash, the opportunity for viral spread of the virus may be close to nonexistent.

Herpes Zoster in Vaccinated Persons

During prelicensure clinical trials, a major question concerning the varicella vaccine was whether the vaccine virus could establish latency, potentially resulting in later development of HZ. It has now been demonstrated that the vaccine virus *can* become latent, and can later, reactivate to cause HZ in both healthy and immunocompromised persons.[649,674,675] In the postlicensure period, HZ after vaccination has been laboratory confirmed as both wild- and vaccine-strain VZV.[229,561,562,570] Some vaccine-strain HZ cases have required hospitalization and, as stated earlier, nine HZ cases had concurrent meningitis or encephalitis confirmed to be vaccine-strain VZV.[154,405,561,562,627,645,646,652–654] An analysis of data on HZ in vaccinated persons reported passively to the vaccine manufacturer found that HZ occurred a median of 362 days after vaccination; 30% to 40% of these cases were caused by WT VZV.[229,561,562] However, these data are not population based and are subject to reporting bias. In a cohort study of 172,163 vaccinated children from a U.S. health maintenance organization who were followed up for a median of 2.6 years, the incidence of HZ was 0.27 in 1000 PY. Most of the children were vaccinated between 12 and 18 months of age. The average age of children who contracted HZ was 4.1 years.[676] No comparative data are available on the risk of HZ after varicella acquired at this age. In a retrospective analysis of children in a large managed care practice, the incidence of laboratory-confirmed HZ was 0.48 per 1000 PY in vaccinated children and 2.30 per 1000 PY in unvaccinated children; the incidence of HZ in 118 vaccinated children was 79% lower than in unvaccinated children. Fifty percent of vaccinees had HZ caused by WT VZV.[570] Long-term follow-up of vaccinated, healthy children is required to provide detailed data of risks and severity of vaccine-strain HZ throughout the life span. It remains unclear whether the morbidity associated with Oka zoster is significantly less than that associated with the WT infection.[569,570] Only one case of HZ in a vaccinated adult (Varivax) resulting from the Oka strain has been recorded,[649] but the numbers of vaccinated adults is very small compared with numbers of children vaccinated. This case was fatal and occurred in an immunocompromised middle-aged man.[649] Finally, one case of proven Oka HZ in an immunocompetent 68-year-old woman who received Zostavax 9 months previously has been reported.[677] The effect of VZV vaccines on the occurrence of HZ is discussed in detail in Chapter 63.

INDICATIONS FOR VACCINATION

Single-antigen (monovalent) varicella vaccines are now widely available throughout the world, and MMRV vaccines are becoming more available. Varicella vaccines are licensed for use in healthy children 12 months of age and older, except for the GlaxoSmithKline varicella vaccine, which can be administered to children as young as 9 months in some countries. Okavax is licensed for use in certain groups of mildly immunocompromised persons (see package insert). In the United States, monovalent varicella vaccine (later Varivax) was initially available under a special protocol for use in children with acute lymphoblastic leukemia that was in remission; the protocol is no longer operative.[678] MMRV (ProQuad) is licensed in the United States for healthy children 1 to 12 years old (see package insert). Four domestic varicella vaccines are licensed and available in China.

Depending on the goals of a varicella vaccination program, indications for use of varicella vaccine vary from country to country. Possible vaccine strategies include universal vaccination of children after 9 or 12 months of age, preferably with catch-up vaccination of older children or adolescents to prevent development of a susceptible cohort that was neither vaccinated nor exposed to wild VZV. Other strategies include vaccination of adolescents and adults, including women of childbearing age, or targeted vaccination of high-risk groups, including children with HIV infection and candidates for

organ transplantation, healthcare workers, and family contacts of immunocompromised persons. Children being treated for leukemia or other malignancies or are otherwise immunocompromised should not be vaccinated; they are less likely to develop varicella than they used to be as a consequence of decreasing transmission of VZV in countries that use universal vaccination. If they are exposed to varicella or HZ, VariZIG is recommended for postexposure prophylaxis. Should varicella occur, however, immediate treatment with acyclovir should be given.

In 1995, the United States became the first country to recommend a national universal childhood vaccination program. Others that now implement universal childhood vaccination programs include Australia, Canada, Costa Rica, Germany, Greece, Israel, Japan, Qatar, Latvia, Luxembourg, Taiwan, Saudi Arabia, Turkey, South Korea, United Arab Emirates, Uruguay, and some areas of Italy and Spain. Targeted vaccination programs, most commonly for susceptible healthcare workers and immunocompromised persons for whom the vaccine is licensed, have been adopted in a number of countries in Europe.[679,680]

In countries with one-dose childhood vaccination programs, varicella vaccine is recommended for children 9 or 12 months through 12 years of age; two doses, 4 to 8 weeks apart, are recommended for persons aged 13 years or older. A routine two-dose vaccine policy for varicella-containing vaccines for children, similar to the policy recommendations for MMR vaccines, was recommended in 2007 in the United States by the ACIP and the American Academy of Pediatrics,[553,681] and in Germany in 2009.[682] Vaccine policy recommendations in the United States evolved between 1996 and 2007.[553] In 1995 and 1996, varicella vaccine was recommended for routine use in healthy children 12 to 18 months of age; for healthy, susceptible children 19 months through 12 years of age; and for persons in close contact with those at high risk for serious varicella.[683,684] Updated recommendations in 1999–2000 and in 2007 progressively expanded these recommendations to cover the entire susceptible population (Box 62.1).[553]

The following factors led to the change to a routine two-dose recommendation for children: instances of primary and possibly secondary vaccine failure, outbreaks of varicella in schools despite high rates of vaccination, costs for investigation and control of outbreaks, contagiousness of breakthrough varicella, boosting of both humoral and cell-mediated immunity after a second dose of vaccine, and the projected higher vaccine efficacy with two doses.[553,681] Catch-up programs for children who received only one dose were recommended. Without a second dose, it was predicted that there would be an accumulation of vaccinated adolescents who either had not seroconverted or had developed a completely protective antibody response after one dose and were therefore at risk of becoming varicella-susceptible young adults, potentially at high risk of developing severe varicella. Potentially, this would occur particularly when there was less opportunity for immune boosting because there was less circulation of WT VZV. Although it was not predicted that there would be complete protection against varicella after two routine doses of varicella vaccine, it was projected that numbers of breakthrough cases would fall significantly, with a subsequent decrease in transmission of the virus. Current U.S. recommendations are provided in detail in the next section.

BOX 62.1 Recommendations for Varicella Vaccine in the United States, 2007

Routine childhood schedule: two doses (at least 3 months apart)[a]

Preschool and school children:

- First dose at 12 to 15 months
- Second dose at 4 to 6 years,[a,b] or before the child enters school

Persons ≥13 years:

- Two doses (4 to 8 weeks apart)[a]

[a]Unless other evidence of immunity; see Box 62.2.
[b]Or at least 3 months after first dose.

Routine Vaccination Schedule

Children Younger Than 13 Years of Age

A routine two-dose varicella vaccine policy was recommended in the United States in 2007 (see Box 62.1).[553] All healthy children should receive two 0.5-mL doses of a varicella-containing vaccine administered subcutaneously. The recommended ages for administering the first (12 to 15 months) and the second (4 to 6 years) doses of MMR and varicella vaccines are harmonized; however, the second varicella vaccine dose may be administered at an earlier age if the interval between the first and second doses is at least 3 months. For the first dose vaccination at age 12 to 47 months, MMR vaccine and monovalent varicella vaccine or MMRV vaccine may be used. Because of the increased risk of febrile seizures following MMRV vaccine compared with MMR and monovalent varicella vaccines administered at the same visit (see "Vaccine Adverse Events" earlier), the CDC recommends that MMR vaccine and monovalent varicella vaccine be administered for the first dose in this age group, unless the parent or caregiver expresses a preference for MMRV vaccine. If the first dose is administered at age 48 months or older, and also for the second dose at any age, use of MMRV vaccine is preferred over separate injections of its equivalent component vaccines (i.e., MMR and varicella vaccines).[667]

Adults and Adolescents 13 Years of Age and Older

Because varicella infection is more severe among adolescents and adults, vaccination is important for them. MMRV vaccine is not licensed for use in this age group. Persons 13 years of age and older without evidence of immunity should receive two doses of monovalent varicella vaccine, 4 to 8 weeks apart. If an interval longer than 8 weeks elapses after the first dose, the second dose can be administered without restarting the schedule. Vaccinating adult groups at high risk of exposure/transmission or close contact with persons at high risk of severe varicella should be a priority. These groups include students and staff in schools, colleges, and other post–high school institutions, inmates and staff members of correctional institutions, and military personnel, international travelers, household contacts of immunocompromised persons, and healthcare workers. Because a fetus may be affected if a pregnant woman acquires varicella, women of childbearing age should be assessed for evidence of varicella immunity; if not pregnant, those without evidence of immunity may be immunized. If already pregnant, they should be vaccinated on completion or termination of the pregnancy, and they should receive the first dose of vaccine before discharge from the healthcare facility.

Healthcare Workers

Nosocomial transmission of VZV is a well-recognized medical and public health problem.[580,685–687] Because of their high risk of exposure to varicella or HZ and close contact with persons at high risk for serious complications, healthcare workers should be routinely vaccinated with two doses of varicella

vaccine unless they have other evidence of immunity. Birth in the United States before 1980 is not considered evidence of immunity in this group. In healthcare settings, serologic screening before vaccination of personnel with a negative or uncertain history of varicella is likely to be cost-effective because approximately 80% are likely to be immune. Some institutions may elect to perform serologic testing on all workers before vaccination because a small proportion of persons with a positive disease history may be susceptible.[688–692] Serologic testing after vaccination *is not recommended* unless a sensitive and specific test can be used. Available commercial assays are not sensitive enough to detect low levels of antibody after vaccination.[238–240,553]

Varicella vaccine is recommended in the United States for postexposure vaccination, for outbreak control, and for certain groups in whom there are adequate data on vaccine safety and immunogenicity or efficacy.[553] These include selected HIV-infected persons and certain groups of immunocompromised persons (see later).

Nursing Mothers

Varicella vaccine can be administered to nursing mothers. A small study of 12 seronegative women who received varicella vaccine after delivery and who breastfed their infants found no evidence of vaccine VZV excretion in breast milk.[693] VZV DNA was not detected by PCR in any of 217 breastmilk specimens. None of the infants were seropositive, and serum samples from six of the infants were all negative for VZV DNA by PCR.

Persons Infected With Human Immunodeficiency Virus

In small clinical trials, two doses of monovalent varicella vaccine were administered 3 months apart to HIV-infected children 1 to 8 years of age. The $CD4^+$ T-lymphocyte levels were higher than 25% (in 41 children) and 15% or higher (in 44 children), and more than 80% of the children had subsequent detectable immune responses (antibody and/or CMI) to VZV at 1 year after vaccination.[601,602] Because children infected with HIV are at greater risk than healthy children for morbidity from varicella and HZ, the ACIP recommended that, after weighing potential risks and benefits, monovalent varicella vaccine be considered for HIV-infected children with $CD4^+$ T-lymphocyte levels higher than 15%. Eligible children should receive two doses of monovalent varicella vaccine 3 months apart. Data on the use of varicella vaccine in HIV-infected adolescents and adults are lacking. Although the immunogenicity of vaccination might be lower and the safety profile different in older HIV-infected children, adolescents, and adults than in children 1 to 8 years of age, the risk for severe disease from wild VZV and the potential benefit of vaccination must be recognized. Expert opinion is that vaccination may be considered (two doses administered 3 months apart) for HIV-infected persons with $CD4^+$ T-lymphocyte levels higher than 200 cells/μL in these age groups. If vaccination of HIV-infected persons results in clinical disease, the use of acyclovir would be expected to modify the severity of disease. Monovalent varicella vaccine is highly effective in preventing both varicella and HZ in HIV-infected children.[623] *Because data are not available on safety, immunogenicity, or efficacy of MMRV vaccine in HIV-infected children, MMRV vaccine should not be substituted for the component vaccines when vaccinating these children.*

Evidence of Immunity

Box 62.2 lists the criteria used to evaluate evidence of immunity to varicella. Evidence of immunity includes documentation of age-appropriate vaccination; laboratory evidence of immunity or laboratory confirmation of disease; being born in the United States before 1980; a healthcare provider diagnosis of varicella or HZ; or verification of a history of varicella disease or of HZ. *Note: Birth in the United States before 1980 is not considered evidence of immunity for healthcare personnel, pregnant women, or immunocompromised persons.*

BOX 62.2 Evidence of Immunity

1. Documentation of age-appropriate vaccination:
   - Preschool-age children, 12 months or older: one dose
   - School-age children, adolescents, and adults: two doses[a,b]
2. Laboratory evidence of immunity[c] or laboratory confirmation of disease
3. Born in the United States before 1980[b,d]
4. A healthcare provider diagnosis of varicella or verification of history of varicella disease[c,e]
5. A healthcare provider diagnosis of herpes zoster or verification of history of herpes zoster

[a]Unless other evidence of immunity.
[b]For children who have received their first dose after 12 months of age and before age 13 years, and when the interval between the two doses was at least 28 days, the second dose is considered valid.
[c]Commercial assays can be used to assess disease-induced immunity, but they lack sensitivity to detect vaccine-induced immunity in all instances (may yield false-negative results).
[d]For healthcare workers, pregnant women, and immunocompromised persons, birth before 1980 should not be considered evidence of immunity.
[e]Verification can be done by any clinician (e.g., school or occupational clinic nurse, physician assistant, physician). For persons reporting or presenting with atypical or mild cases, assessment by a physician or designee is recommended, and either of the following should be sought: (1) an epidemiologic link to a typical varicella case, or (2) evidence of laboratory confirmation, if it was performed at the time of acute disease. When such documentation is lacking, persons should not be considered as having a valid history of disease, because other diseases may mimic mild atypical varicella.

Contraindications and Precautions

Information in package inserts should be reviewed carefully before administration of a varicella-containing vaccine. For contraindications and precautions to MMR components of MMRV vaccine, see Chapters 37, 40, and 53. Although no infants with congenital varicella syndrome secondary to vaccine-type virus have been reported,[657,658,660,694] vaccination in pregnancy is contraindicated.

PUBLIC HEALTH CONSIDERATIONS

Goals and Cost-Effectiveness of Vaccination

The goals of varicella vaccination programs vary. It may be prevention of varicella and its complications, prevention of severe disease and death, or disease prevention and control in selected target groups such as adolescents, adults, or healthcare workers. The goal of the U.S. vaccination program is a greater than 90% reduction in varicella disease. The United States adopted a strategy of universal childhood vaccination to achieve this goal.

The World Health Organization (WHO), in its 2014 position paper on varicella vaccines, recognized the strong scientific evidence that in immunocompetent individuals, varicella vaccine is safe and effective for preventing morbidity and

mortality from varicella.[695] The WHO recommended consideration of routine immunization of children against varicella in countries where varicella has an important public health impact. The WHO also recommended that in such countries, resources should be sufficient to support sustained vaccine coverage of 80% or greater, because when varicella vaccine coverage levels are less than 80%, there is a risk of shifting the infection to older ages in some settings, which may result in an increase in morbidity and mortality, despite a reduction in the total number of cases, because of the increased risk of severe disease in adults. The WHO recommended one dose if the goal of the vaccination program is to reduce severe morbidity and mortality from varicella, and two doses if the goal also includes reduction of the number of varicella cases and outbreaks. Healthcare workers constitute a special group who should receive two doses, particularly if they have contact with immunocompromised patients.

Several published studies on the significance of varicella as a public health problem were considered when varicella vaccine was added to the childhood immunization schedule in the United States.[40,696–698] An updated 2008 analysis examined the economic costs and benefits of a one- and two-dose vaccination program for children using estimates of varicella morbidity and mortality in the United States that accounted for the declines reported during the one-dose program, an assumption of neutrality regarding the potential effects of vaccination on HZ (similar to previous analyses), and direct and indirect costs at the time of the update. Compared with no vaccination program, a one-dose program was cost-saving from the healthcare payer and societal perspective, and a two-dose program was cost-saving from a societal perspective; the incremental cost of the second dose if a one-dose program was already in place was $109,000 per quality-adjusted life-year saved.[699] Several analyses in other countries have focused on costs of a two-dose varicella vaccination program during early childhood, adolescence, or both. These programs are cost-effective from the societal perspective, but not from the direct payer perspective.[700,701] Additional studies providing data on costs of varicella, as well as cost–benefit and cost-effectiveness studies providing economic evaluations of childhood vaccination programs and selective vaccination programs among adolescents, adults, women of childbearing age, military recruits, healthcare workers, seafarers, and pediatric liver and kidney transplant recipients, have since been published from many countries and in review articles.[280,614,686,687,690,702–721] Most studies did not include dynamic models that account for community protection effects and are likely to have underestimated the impact of varicella vaccination. There is general agreement that universal vaccination of children with one or two doses of varicella vaccine in the second year of life is beneficial from a societal perspective mainly because of savings from prevented lost workdays for the parents. From the healthcare payer perspective, most studies show that universal childhood vaccination programs will not provide savings at the current price of the vaccine. Exceptions are a study from Israel and the 2008 analysis from the United States that found that a national varicella vaccination program was cost saving or cost neutral (break-even), respectively, from the health service perspective.[699,707] No data on cost-effectiveness of routine childhood varicella vaccination are currently available from low- and middle-income countries.

Because of modeled predictions of an increase in HZ as a possible short- and medium-term effect of a varicella vaccination program, and the significant described health burden resulting from HZ, some economists have argued for including these costs in economic analyses, which in the short-to-medium term may make a varicella vaccination program much less cost-effective or even non–cost-effective. However, in the long term, as HZ incidence declines to levels lower than currently experienced, models predict the net health savings from varicella vaccination to increase substantially.[307,722]

A recent study modeling the combined effects of varicella (two doses in childhood) and HZ vaccination programs concluded that varicella vaccination will lead to a net increase in HZ for 40 years, and the effectiveness of this combined strategy is limited, as much of the increase in HZ is expected to occur in adults too young to be vaccinated against HZ in existing vaccine programs.[723] Varicella vaccination of susceptible adolescents would be expected to have a smaller potential effect on HZ epidemiology, although such a program would also be expected to have limited impact on varicella morbidity and mortality. These analyses, however, do not consider the potentially complex interactions that may be involved in maintenance of immunity to VZV after varicella or varicella vaccine. Both subclinical reactivation and external boosting may play important roles in maintaining VZV immunity, and it is plausible that a decline in external boosting may be compensated for by an increase in subclinical reactivation. This analysis in addition does not recognize that the age for HZ vaccination can be adjusted as epidemiologically necessary.

The costs and public health impact of varicella disease in hospital settings have been well documented with regard to such factors as work furloughs, serologic testing, patient isolation, administration of passive immunization, wages paid to replacement healthcare workers, and infection control expenses.[280,686,687,709,716] Most studies of vaccination programs aimed at preventing nosocomial VZV exposure and transmission to high-risk patients by vaccinating healthcare workers have found that these programs generate savings from an employer's perspective.[280,686,687,709,716,724,725,725a] Factors that affect the results the most are vaccine price and accuracy of screening of disease history as it relates to true susceptibility. In the United States, healthcare workers were designated as a priority group for vaccination at the start of the vaccination program because of their risk for close contact with persons at high risk for severe disease. Because nosocomial VZV problems are universal and the problem may be greater in populations where a higher proportion of adult healthcare workers are susceptible, protection of healthcare workers through vaccination should be strongly considered even in countries where a childhood vaccination program is not a high priority.[685]

Postvaccine Epidemiology

United States: One-Dose Varicella Program

In the United States, substantial reductions in varicella morbidity and mortality have occurred since implementation of the one-dose varicella vaccination program. By 2005, before implementation of the two-dose program, vaccine coverage among children 19 to 35 months of age was 88%.[553] Coverage reached 90% in 2007 and has stayed at or above that level since. Monitoring occurrence of infectious diseases in the United States is most commonly conducted using a nationally notifiable disease surveillance system. However, because varicella was not a nationally notifiable disease at the start of the vaccination program, active varicella surveillance was established in 1995 in three communities with a combined population of 1.2 million persons. Initial impact of the vaccination program was described in these communities; active surveillance continued through 2010 in two of them. Compared with 1995, vaccine coverage among children 19 to 35 months of age in the three communities had reached 74% to 84% by 2000, and reported varicella cases declined by 71%, 84%, and 79%.[509] Varicella-related hospitalizations had declined by approximately 80%.

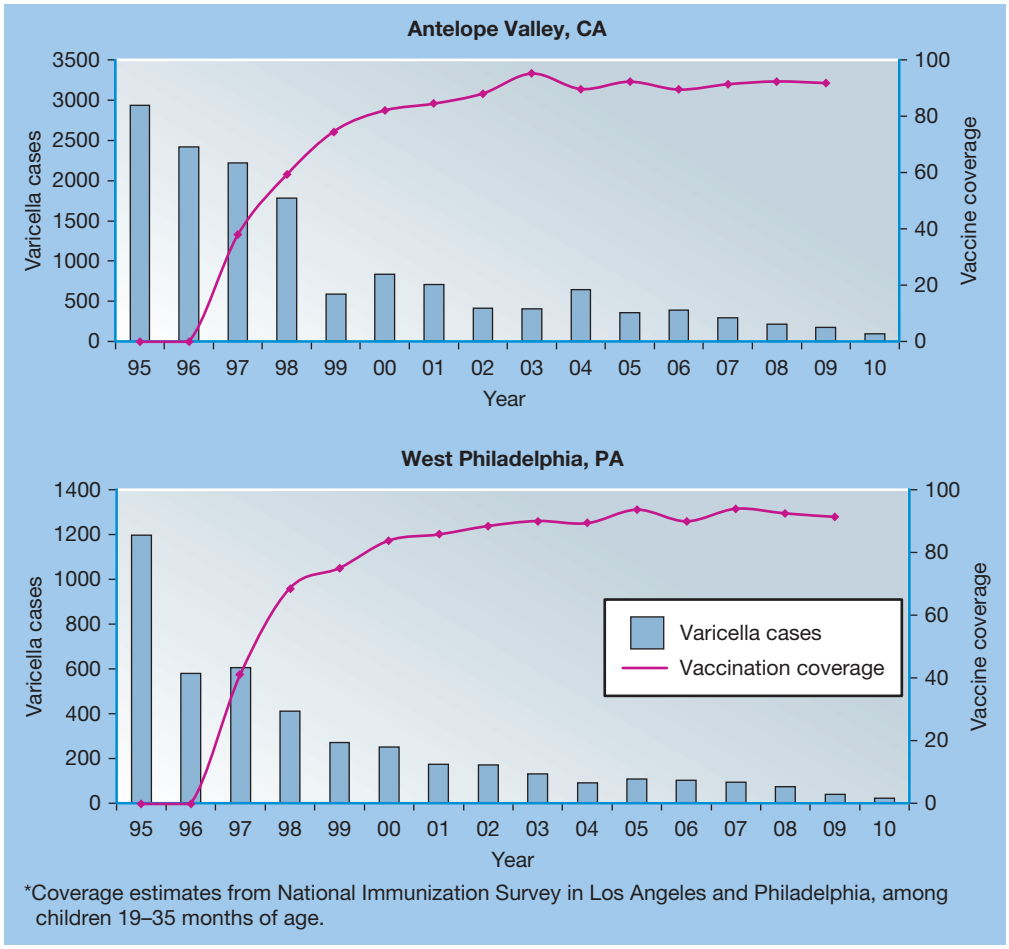

Figure 62.10. Reported varicella cases from 1995 to 2010 in two sentinel counties with vaccination coverage. *(From Guris D, Jumaan AO, Mascola L, et al. Changing varicella epidemiology in active surveillance sites: US, 1995–2005.* J Infect Dis. *2008;19[Suppl 2]:S71–S75; and Bialek SR, Perella D, Zhang J, et al. Impact of a routine two-dose varicella vaccination program on varicella epidemiology.* Pediatrics. *2013;132[5]:e1134–e1140.)*

By 2005, vaccine coverage had reached approximately 92% and 94% in two surveillance areas, Antelope Valley, California, and West Philadelphia, Pennsylvania, respectively, and varicella incidence had declined 90% in both sites, with declines in incidence in all age groups.[726] The greatest declines (>90%) occurred in children 1 to 9 years of age, but an approximately 80% decline in incidence also occurred in infants not eligible for vaccination (Fig. 62.10).[726] In the context of declines in varicella incidence in all age groups, the peak age of varicella infection increased from 3 to 6 years in 1995 to 9 to 11 years in 2005, and the proportion of persons who were vaccinated increased from less than 1% to 60% over the same time period.[726] From 1995 to 2005, the declines in incidence were mirrored by declines in the number, size, and duration of varicella outbreaks in childcare centers and schools.[727]

The effect of varicella vaccination on varicella incidence has also been noted from four states with consistent varicella reporting to the passive national notifiable disease surveillance system (Illinois, Michigan, Texas, and West Virginia), and from statewide survey or surveillance data in the states of Massachusetts and Connecticut.[424,728,730,731]

On the national level, significant declines in varicella-related deaths, hospitalizations, ambulatory visits, and health expenditures were noted initially within 5 to 6 years of program implementation (see Figs. 62.11 and 62.12).[349,350,732–735] Considering all ages and both underlying and contributing

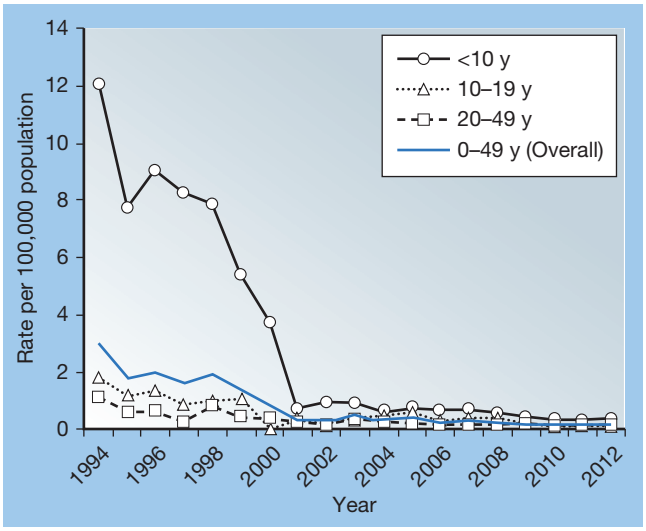

Figure 62.11. Reduction in varicella hospitalizations for different age groups after a vaccination program. *(From Leung J, Harpaz R. Impact of the maturing varicella vaccination program on varicella and related outcomes in the United States: 1994–2012.* J Pediatric Infect Dis Soc. *2016;5[4]:395–402.)*

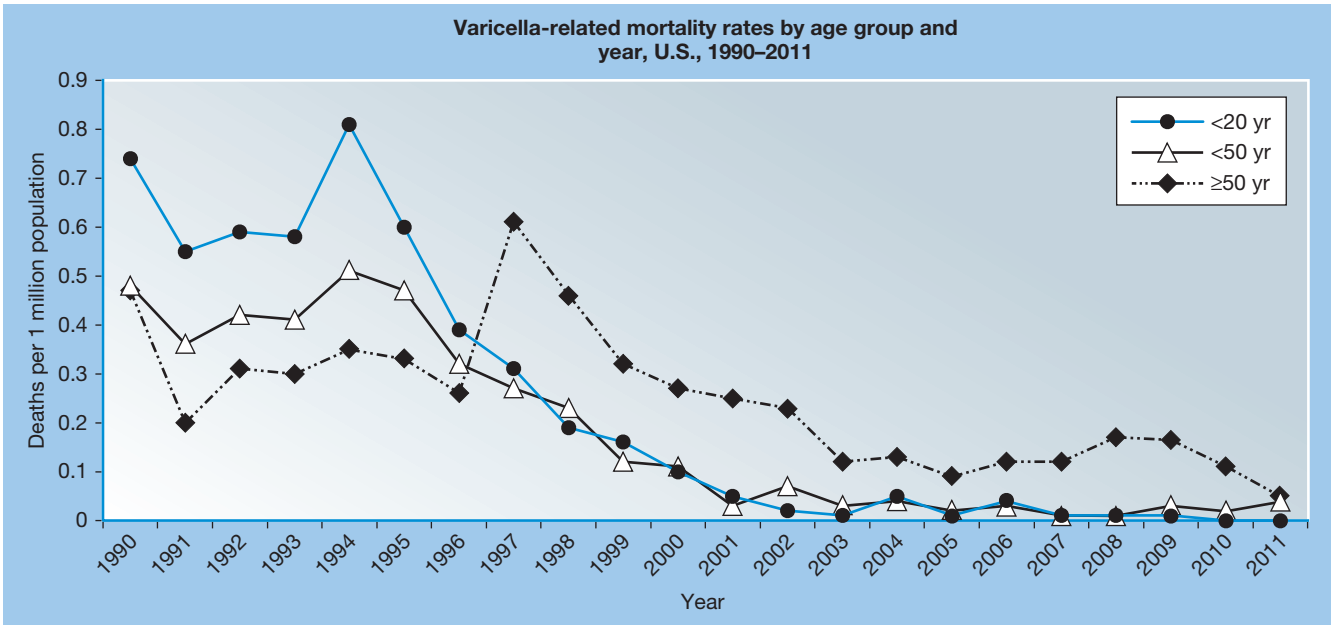

Figure 62.12. Annual age-specific mortality rates for varicella listed as the underlying cause, United States, 1990 to 2011. *(From Leung J, Bialek SR, Marin M. Trends in varicella mortality in the United States: data from vital statistics and national surveillance.* Hum Vaccin Immunother. *2015;11[3]:662–668.)*

causes of death, by 1999 to 2001, compared with the 5 years preceding the vaccination program (1990 to 1994), national varicella deaths declined from an average of 145 deaths a year to 66 deaths a year. Considering varicella as the underlying cause of death, over this time period only, mortality rates declined 92% in children 1 to 4 years old, and 74% to 89% in infants younger than 1 year and persons 5 to 49 years.[350] By 2005 to 2007, which still primarily reflected the impact of the one-dose vaccination program in children, the average age-adjusted mortality rate with varicella as an underlying cause of death declined 88% to 0.05 per million population from 0.41 per million in 1990 to 1994, and the age-specific mortality rates declined 97% among children and adolescents younger than 20 years of age, 90% among adults 20 to 49 years of age, and 67% among adults 50 years of age and older (Fig. 62.12).[732] During 2002 to 2007, there continued to be no racial differences in mortality rates, as achieved for the first time in 2001. Varicella hospitalizations declined significantly as well (Fig. 62.11). By 2002, compared with 1994 to 1995, hospitalizations for varicella declined by 88% and ambulatory visits by 59%, with more than 90% of the declines in children younger than 10 years of age and adolescents 10 to 19 years old. Direct medical expenditures for varicella hospitalizations and ambulatory visits decreased by 74%.[734]

Updated analyses showed continued declines in varicella hospitalizations in all age groups from 2000 to 2006, with an estimated 50,000 hospitalizations prevented during this time period, and a 98% reduction in varicella hospitalizations by 2004 among patients 0 to 4 years old.[735,736] Additional studies have documented the impact of the varicella vaccination program at local levels on hospitalizations, including reducing differences in varicella hospitalization rates between African American and white children emergency room visits, among Native American and Alaska Native populations, and, additionally, on invasive group A streptococcal infections.[564,737,740,742] In the latter study, no shift in the burden of varicella to older age groups was found in hospitalized patients.[742]

United States: Two-Dose Varicella Program

Despite these considerable successes in control of varicella disease and its severe complications in the United States, varicella outbreaks, albeit with milder cases and of shorter duration, have occurred in highly vaccinated school children, as mentioned previously. This, coupled with evidence that one dose of vaccine for children may not provide a sufficient immunologic "burst" to provide adequate and long-lasting immune memory, which may lead to cohorts of partially or fully susceptible vaccinated children aging into adolescence and adulthood,[743] resulted in adoption of a routine two-dose policy in the United States for children in 2007.

During the first 5 years after introduction of the two-dose program, the reported varicella incidence was the lowest since the start of the vaccine program compared with the fairly stable incidence from 2000 to 2006 with fewer outbreaks and milder disease.[564] In 2010, in the two varicella active surveillance sites, incidence declined 76% and 67% compared with 2006 and 98% in both sites since the vaccination program implementation in 1995.[564] Age-specific incidence rates were lower for all age groups in 2010 compared with 2006, and the decline was particularly pronounced among children 5 to 9 years of age (79% and 88% decline), the target age group for the two-dose vaccination program, with the next greatest declines in adolescents 10 to 14 years old (75% and 91% decline) and children 1 to 4 years of age (54% and 73% decline).[564]

By 2010, two-dose coverage among 4 to 6 year olds were 84% and 59% in the catchment area of the active surveillance sites. The median age of varicella infection increased from 6 to 8 years to 7 to 9 years among vaccinated patients and from 12 to 15 years to 16 to 20 years among unvaccinated patients, but the number of cases was significantly lower in each age group. An analysis of varicella outbreaks reported to the CDC from six states indicated that the routine two-dose program significantly reduced the number, size and

duration of outbreaks; the number of outbreaks declined 78%, from 147 in 2005 to 33 in 2012, and the median size from 12 to 7 cases.[744] Similar impact of the two-dose program was reported in Connecticut, a state with good varicella surveillance.[745] Analyses of passive national notifiable disease surveillance system data documented an 85% decline in varicella incidence from 2005–06 (the end of the one-dose varicella vaccination program) to 2013–14. In the four states with consistent reporting since before implementation of the vaccination program, incidence declined an average of 97% from 1993–95 to 2013–14 (range, 93–98%).[745a]

Additional significant declines in varicella-related hospitalizations and outpatient visits have been documented since the implementation of the two-dose varicella vaccination program.[746] Between 2006 and 2012, outpatient visits and hospitalizations declined 60% and 38%, respectively, for an overall decline of 84% and 93% compared with prevaccine years (1994–95).[746]

As far as mortality, while during 2008–11, the overall rate for varicella as the underlying cause of death remained unchanged from the end of the one-dose era, a decline in deaths in persons younger than age 20 years was seen, and there have been no deaths among 1 to 9 year olds in 2008–11 or among 10 to 19 year olds in 2010–11.[563]

Laboratory-confirmed varicella cases in two-dose vaccinated children have been confirmed, both in outbreak settings and in active surveillance sites, but are unusual.

Other Countries

As other countries have implemented one-dose childhood varicella vaccination programs, additional data on the impact of these programs have become available. In Germany, where a one-dose national vaccination program was implemented in 2004, a decrease in the incidence of varicella and its complications was observed using data from physician-based sentinel surveillance.[682,748] Reported varicella cases declined 55% from April 2005 to March 2009, with a 63% reduction among children 0 to 4 years of age. Comparing varicella seasons in 2005 and 2009, a 63% decline in cases and an 81% decline in varicella complications was apparent.[748] In a surveillance project in Munich and its surrounding districts, aside from reductions in incidence, a 43% decline in varicella hospitalizations in children younger than 17 years of age was reported during 2005 and 2009 with 78% decline among children younger than 5 years of age; coverage reached 53% in 2008–09.[747] Because of varicella cases occurring in vaccinated children and the experience of the United States, a two-dose schedule was formally recommended in Germany in July 2009.[682]

In Italy's Veneto region, varicella incidence rates decreased significantly 2.5 years after the universal vaccination program was introduced and greater than 70% vaccine coverage reached.[749]

In Canada, where the varicella vaccination program was recommended in 1999, declines of 81% to 88% in the number of hospitalized varicella cases were reported between 2000 and 2008, with effects of the vaccination program being noted beginning 1 to 2 years after the start of the program; indirect protection of persons outside the vaccinated cohorts was also documented.[750] Vaccination coverage was available for a few provinces and ranged from 74% to 91% in 2007–08.

The impact of a one-dose vaccination program on varicella and its complications has also been described from Taiwan, Uruguay, Sicily, and Australia.[738,741,751–755] Studies from Australia have indicated a significant decrease in both the congenital varicella syndrome (100%) and neonatal varicella (85%) as a result of the national vaccination program begun in 2005.[659]

In the Navarra region, Spain, where a two-dose routine childhood program was introduced from the beginning and high coverage was achieved early in the program, declines of 98.5% in incidence in children and 89% in hospitalizations were achieved within a period of only 5 years.[756]

A two-dose European study of GlaxoSmithKline MMRV vaccine that was randomized and controlled demonstrated an efficacy of 94.9% (97.5% CI, 92.4–96.6) against all varicella compared to 65.4% (97.5% CI, 57.2–72.1) efficacy after one dose.[757] In this study, the interval between the first and second dose of MMRV was 6 weeks. The follow-up lasted for 3 years.

Varicella Vaccine and Zoster

Because Oka VZV has the capacity to reactivate to cause HZ, understanding the effect of varicella vaccine on HZ epidemiology is important. This includes the risk of HZ after receiving the Oka strain in vaccinated persons, as well as the potential effect that the declining incidence of varicella disease from decreased viral transmission may have on HZ in the general population. Potential effects might either reduce or increase the risk of HZ. The risk of acquiring HZ is related to loss of cell-mediated immunity to VZV. Hope-Simpson first hypothesized that immunity to VZV may be maintained by periodic internal reactivation of VZV, and external boosting of immunity through exposures to varicella or HZ, or both.[446] The next section summarizes prelicensure and postlicensure studies of HZ in vaccinated immunocompromised and healthy persons, studies examining the effect of external and internal boosting of VZV immunity through varicella exposures on HZ incidence and risk, and HZ epidemiology in different populations in the prevaccine and postvaccine eras.

Varicella Vaccination and Risk (Incidence) of Zoster

Immunocompromised Persons. Prelicensure and postlicensure clinical studies have demonstrated a considerably lower risk of HZ in vaccinated immunocompromised children with leukemia, children undergoing renal transplantation, and HIV-infected children, compared with those with a history of natural varicella.

Because of the severity of HZ in immunocompromised populations, the effect of varicella vaccination on the risk of HZ was studied intensively in the prelicensure period. These persons were a pragmatic cohort to study because patients who have had natural chickenpox develop HZ at a much higher rate than healthy children, so it was possible to study the incidence of HZ in a relatively short time frame.[758] Vaccinated leukemic children were therefore followed closely for development of HZ and compared with leukemic children who had natural varicella. In Japan, one study found HZ in eight (15%) of 52 vaccinated leukemic children and in 11 (18%) of 63 leukemic children with a history of varicella.[759] In the United States, none of 34 vaccinated leukemic children, but 15 (21%) of 73 leukemic children with a history of varicella, developed HZ ($P = .017$), suggesting that HZ was less common after immunization than natural infection.[760] In the NIAID collaborative study, the rate of HZ was 2% in vaccinees and 15% in controls with a history of varicella. Members of a subset of these vaccinees were prospectively matched, according to chemotherapeutic protocol, with 96 leukemic children who had experienced natural varicella. A life-table analysis revealed that the incidence of HZ was about three times lower in vaccinees (8 per 1000 PY) than in the matched leukemic children who had experienced natural varicella (24.6 per 1000 PY; $P = .01$) (Fig. 62.13).[199,592] Thus, varicella vaccine was approximately 67% effective in this cohort in preventing HZ. Similar results were found in vaccinated children who

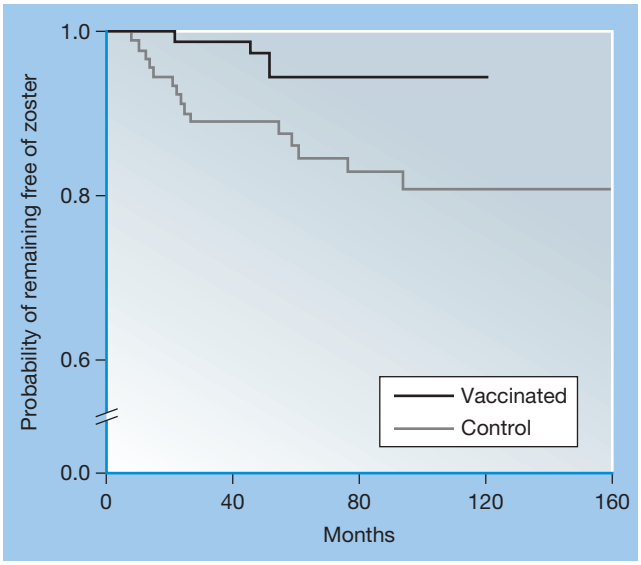

Figure 62.13. Zoster after vaccination in leukemic children after natural disease and immunization. Kaplan-Meier product-limit analysis of the probability of remaining free of zoster in 96 children with leukemia who received varicella vaccine and 96 children with leukemia who had naturally acquired chickenpox before or after the diagnosis of leukemia. *(From Hardy IB, Gershon A, Steinberg S, et al. The incidence of zoster after immunization with live attenuated varicella vaccine: a study in children with leukemia.* N Engl J Med. *1991;325:1545–1550.)*

underwent renal transplantation. In a study of French children undergoing renal transplantation, the rate of HZ over 10 years was 7% in vaccinees, 13% in those with varicella before transplantation, and 38% in those who developed varicella after grafting.[598]

In the postlicensure period, a study of HIV-infected children, after adjusting for receipt of HAART and excluding HZ occurring within 6 weeks of initiation of HAART (which could have resulted from immune reconstitution inflammatory syndrome), found varicella vaccine to be 100% effective (95% CI, 67–100%) in preventing HZ for a median of 4 years of follow-up after immunization.[623] Another study, from 1989 to 2006, reported a decline in HZ in HIV-positive children after the year 2000, coincidental with varicella vaccination and introduction of HAART therapy. The authors speculated that the decline probably represented the combined effect of immunization and HAART.[622]

Healthy Persons. Several prelicensure studies with long-term follow-up reported rates of HZ in healthy vaccinated children and adults. In one study, HZ was reported in six of 7000 vaccinated children 1 to 17 years of age, with 42,884 PY of follow-up, which represents 0.14 cases per 1000 PY of observation.[761] In the prevaccine era, the incidence of HZ in children 5 to 9 years of age was 0.3 cases per 1000 PY.[762] However, a number of these children would not have experienced varicella, so this comparison should be viewed with caution. The incidence rate among children of this age group would be higher if only children with a history of varicella were considered.

Data on HZ risk in healthy vaccinated adults are limited by small numbers.[763,764] In the NIAID collaborative study where healthy adults were vaccinated, two of 363 adults developed HZ with active follow-up of 1 to 27 years (mean: 5 years). Both of these adults had experienced breakthrough varicella, and in one instance HZ caused by the WT virus was documented; the other patient was not available for VZV genotyping.[764] The incidence of HZ in this group of adults was one per 1000 PY (95% CI, 0.12–3.62), which is low for middle-aged adults. Follow-up of these and additional adult vaccinees over additional time is critical to further evaluate possible effects of varicella vaccination on the incidence of HZ.[763] As has been mentioned, only one case of HZ caused by the Oka strain in an adult who was given Varivax has been recorded; this occurred in an immunocompromised patient and was fatal.[649]

The Postlicensure Period

Incidence and Trends of Herpes Zoster in Vaccinated Healthy Children. In the postlicensure period, it has become feasible to assess the risk of HZ in healthy vaccinated children, although there continue to be challenges because of the rarity of HZ in children and the availability of data on a comparable comparison group of children with a history of varicella. A cohort study of 172,163 vaccinated children from a health maintenance organization in Southern California who were followed up for a median duration of 2.6 years (25th percentile, 0.9 years; 75th percentile, 4.0 years) reported an incidence of HZ of 0.27 per 1000 PY. The average age of children who contracted HZ was 4.1 years.[676] No comparative data on HZ risk of similarly aged children with a history of varicella were then available.

Another study examining the risk of HZ in vaccinated healthy children compared with similarly aged children with a history of varicella was conducted in a population-based varicella and HZ active surveillance project site. From 2000 to 2006, starting 4 to 5 years after initiation of the varicella vaccine program in the United States and as varicella incidence was declining, HZ incidence declined 55% among children younger than 10 years. HZ incidence in vaccinated children during this time was 0.19 per 1000 PY; it was four to 12 times lower than among children with a history of varicella when two different methods were used to calculate the incidence of HZ.[569] These risks could translate into reductions of HZ incidence in vaccinated children on an order of magnitude of 77% to 92%. The clinical presentation of HZ also tended to be milder in vaccinated children than in children with varicella history, with less pain (45% vs 77%; $P < .001$), and when pain was reported, it was reported as less intense ($P = .03$). The vaccinated patients were also less likely to have vesicular lesions, and the rash was smaller, but these characteristics were not statistically significantly different by vaccination status. These data provide convincing evidence that the risk of HZ, at least in children for 5 to 10 years after vaccination, is lower in healthy vaccinated children than in those with a history of varicella.[569]

As has been mentioned, a third population-based study of 144,000 children and adolescents younger than 18 years of age, from 2005 to 2009, in a health maintenance organization in Portland, Oregon, investigated and laboratory-confirmed all suspected HZ cases in vaccinated and unvaccinated children. HZ incidence was 0.48 per 1000 PY in vaccinated children and 2.30 per 1000 PY in unvaccinated children, which translates into a 79% lower incidence in vaccinated than in unvaccinated children. Presumably, the rate in unvaccinated children is an underestimate, as the denominator for this group includes children who would not have been infected with VZV, as well as those with a varicella history.[570] Half of the HZ cases in the vaccinated children were WT VZV. In contrast, 96% of the HZ cases in unvaccinated children had a history of varicella. In contrast to the study mentioned above,[569] here there were no significant differences in clinical presentation by VZV strain.

A study in Israel reported a 36% lower incidence of HZ among vaccinated than among unvaccinated children in a population in which varicella vaccination in the pediatric population was estimated to be 28%.[765]

There are several possibilities, which are not mutually exclusive, about why HZ may be less common after vaccination than after natural infection. One is that the virus is attenuated and less able to reactivate than the WT virus. Another is that the vaccine strain may have less frequent access to sensory nerves to establish latency because there is a lower incidence of infection of the skin after vaccination than with the natural infection.[156] Finally, the latency burden of virus may be lower after vaccination than after natural infection. Not all vaccinees who develop zoster, however, have a history of previous skin rash; viremia (some of which may have been subclinical breakthrough infections after one dose of vaccine) undoubtedly also plays a role in establishment of latency. In cases of HZ in vaccinees in 2005–09 in the United States, up to half of cases in vaccinated children were caused by WT VZV, and these cases occurred in children with no history of clinical varicella.[561,562,570]

It was observed in Japan that HZ occurred more frequently in immunocompromised children who had a vaccine-associated rash (16% of 83) than in those with no rash after immunization (2% of 249).[568] This observation was confirmed and extended in the NIAID collaborative study.[199,592] Of 13 vaccinated leukemic children who developed HZ, 11 (85%) had a prior history of a VZV-related rash, either vaccine-associated (eight children) or breakthrough varicella (three children). The two children with no history of rash developed HZ at the injection site of the vaccine. In the 268 vaccinees who had any type of previous VZV-related rash, the chance of subsequent development of HZ was more than five times greater than in the 280 vaccinees who had no VZV-associated rash ($P \leq .02$). In the NIAID collaborative study, it was possible to type four of the viruses causing HZ. Two were caused by vaccine-type virus and two were caused by WT VZV.[486] It is now recognized, however, that there are two paths to latency of VZV, from the skin lesions by way of nerves to neurons and from viremia. In all probability WT HZ in vaccinees who have not experienced clinical varicella stems from VZV that reached neurons by asymptomatic viremia. As a result of better protection against breakthrough disease and decreased occurrence of viremia, the risk of HZ might be further reduced in children who have received two doses of varicella vaccine.

External Boosting of Immunity Through Exposures to Varicella and Risk of HZ. Several studies have either directly or indirectly examined the effect of exposure to varicella on the risk of HZ in both immunocompromised and healthy populations. Garnett and Grenfell examined weekly reported data in a time-series analysis and reported no association between the temporal occurrence of varicella and of HZ, although they reported some correlation with the annual data for some age groups.[317] Exposure to varicella disease does boost VZV-specific immunity; whether ongoing exposure throughout life is critical to maintenance of immunity to VZV through external boosting, especially as the population ages, is not certain, although some studies offer support to this hypothesis. A number of studies have examined the risk of HZ in occupational groups considered to have varied risk of exposure to children (as a surrogate of exposure to varicella). Two small studies reported that pediatricians had a lower incidence of HZ compared to the general population,[766] and to psychiatrists[767]; however, the studies had serious methodologic limitations. Terada and associates[766] based their findings on small numbers of cases, whereas the findings of Solomon and associates[767] were based on low response rates (31% of pediatricians) and found no differences between them and dermatologists and psychiatrists, groups considered to have different rates of exposure to varicella cases. There was no laboratory documentation of VZV infections in either study. A third epidemiologic study in Taiwan, using a nationwide insurance database, examined HZ incidence in healthcare workers compared with adults of similar age, in decade strata, and found a higher HZ incidence in the healthcare workers who might be expected to have a higher level of exposure to VZV.[768] In a case-control study in the United Kingdom, Thomas and associates studied the association of HZ risk and occupational exposure but also studied exposure to varicella specifically.[769] This study found a substantially lower risk of HZ among persons with more than five exposures to varicella in the past 10 years than among persons with no exposures (odds ratio, 0.29 [95% CI, 0.10–0.84]). In a subsequent analysis of the same data, Thomas reported that people who worked with young children (primary school teachers, nursery nurses, playgroup leaders, and other childcare providers) were significantly less likely to develop HZ after adjusting for age, sex, ethnicity, and a child living in the household (RR, 0.70; 95% CI, 0.58–0.85).[770] Several other studies found that living with or exposure to children (as a surrogate of varicella exposure) was associated with a lower HZ risk.[771,772] In the United States this potential effect disappeared over the first decade of the varicella vaccine program.[772] Studies in the United States, however, did not find any differences in HZ incidence comparing states with high and low varicella vaccine coverage. This grouping of states was considered to represent differing rates of varicella exposures in the population.[772] In addition, the results of the association between exposure to VZV and lower HZ risk were not duplicated in two other studies that were designed to examine these associations.[773,774] The first of these studies, a large case-control study in the United States, did not find any association with HZ and the number of varicella contacts; there was no trend, even at the highest exposure level (three or more contacts). Similarly, there was no association with exposure to persons with HZ or to children, or with workplace exposures.[773] In discussing potential explanations for the different findings between this and the Thomas study, Donahue and colleagues[773] noted that the proportion of cases and controls with various levels of varicella exposures were lower in the United States than in the United Kingdom, consistent with the vaccination program.

The second study examined data from a national random-digit dial telephone survey in the United States that obtained information on self-reported HZ, demographic characteristics, and exposure to children with chickenpox in the past decade. Previous exposure to chickenpox did not protect against HZ in this population. Seven percent of adults 65 years of age and older reported exposure to children with chickenpox in the past decade. The authors suggested that the potential contribution of exposure to chickenpox as a mechanism for maintaining cell-mediated immunity against HZ may be limited to a small percentage of the population.[774] This is consistent with the findings of Thomas and colleagues that only a small proportion of HZ cases reported the highest levels of exposure to varicella that were associated with decreased risk of HZ. On a total population basis, this may have limited impact on the overall risk of HZ. A number of studies, including a recent analysis by Leung and associates, have found a higher HZ incidence rate in women, including young women who are more likely than men to be primary caretakers.[769,772,775–777] As commented on by a number of investigators, this finding is not consistent with varicella exposures affecting the risk of HZ, at least on a population-based level. Recent research in Ontario, Canada, indicated that after introduction of a

publicly funded varicella vaccination program, there was no increase in the incidence of HZ in the general population although there was a decrease in incidence in children.[778] In the United States, a study that examined the influence of the varicella vaccination program on trends in HZ incidence in the population older than 65 years of age between 1992 and 2010 found that although HZ incidence has increased in elderly persons during this interval, introduction and widespread use of varicella vaccine did not seem to affect this increase—the increase in HZ incidence predates 1996 and the increase did not accelerate after implementation of varicella vaccination. Additionally, this study reported that state varicella vaccination coverage did not affect HZ incidence.[779] Finally, a study of secluded religious populations in Europe that had no contact with children indicated that their rate of HZ was similar to that of the general public over a 30-year period; the study concluded that boosting of immunity by contact with circulating VZV was not required for long-term protection against HZ.[780,781]

Mathematical modelers have used data from some of the aforementioned studies to predict the effect that a varicella vaccination program may have on HZ incidence. Using the assumption that exposure to varicella is an important mechanism for preventing reactivation of VZV, models predict that a short- to medium-term (more than 10 to 40 years in one study, and up to 70 years in another) increase in HZ cases may occur after implementation of varicella vaccination program, although, in the long term, a reduction in HZ cases is expected to occur, assuming that vaccine recipients have a lower risk of developing HZ than persons who acquire natural infection.[724] Considerable experience has now been gained with observing HZ epidemiology in countries implementing varicella vaccine programs, as well as in countries without a varicella vaccination program. The predictions of a short-term increase in HZ secondary to varicella vaccination to the levels predicted in the models have not been consistently observed, and it appears unlikely that increasing trends in HZ incidence can be attributable only to varicella vaccination. Studies in a number of countries (United States, United Kingdom, Canada, Spain, Japan) have documented increasing trends of HZ incidence in the absence of a vaccination program or increases that started years before use of varicella vaccine.[722,775,776,779,782–784]

In countries monitoring the effect of varicella vaccination on HZ, challenges include the following: (1) trends over time for HZ have not been described in detail, especially in the immediate prevaccine time period, so baseline data may not be available against which to interpret trends in HZ incidence; (2) studies have used different methodologies, making comparisons across studies difficult; (3) HZ is clinically diagnosed and rarely laboratory confirmed; (4) the age structures of populations under study may differ significantly, and calculating age-adjusted rates is essential to compare studies and to interpret trends over time within studies; and (5) few studies of the epidemiology of HZ have examined in detail other factors that may affect HZ, particularly immunocompromising medical conditions, medications, and certain other conditions (e.g., diabetes, stress).

A 2013 systematic multidisciplinary review of HZ risk reduction through exposure to varicella patients analyzed the peer-review publications on exogenous boosting studies: 13 observational studies on HZ incidence after widespread varicella vaccination; four longitudinal studies on VZV immunity after reexposure; nine epidemiological risk factors studies; seven mathematical modeling studies; and other studies. The authors concluded that exogenous boosting exists, although not for all persons nor in all situations, and that its magnitude is yet to be determined adequately in any field study.[785]

In addition to external boosting of VZV internal boosting occurs, by asymptomatic reactivation of the virus from latency. Asymptomatic reactivation of VZV has been described, initially by demonstration of increases in serum antibodies in the absence of symptoms,[786] and later by showing silent presence of VZV DNA in blood or saliva of immunocompromised and healthy individuals such as astronauts or stressed individuals.[217–220] The possibility of internal boosting does not seem to have been considered by computer modeling analyses.

Trends in Incidence of Herpes Zoster in the Population. The incidence of HZ is increasing in the United States and in other countries. The longest experience with monitoring the effect of the varicella vaccine program on HZ has been gained in the United States, where a childhood vaccine program has been in place for two decades. In the United States, HZ is not a nationally notifiable disease. Therefore, epidemiology of HZ has been studied using a variety of different methods and populations. Seven studies have reported on trends in HZ since vaccination in the overall population; some of these studies had baseline data available before the start of the varicella vaccination program for comparative purposes, and others did not. As previously described, two studies documented that trends in HZ in children younger than 10 years of age, and in children and adolescents younger than 18 years of age, are declining, consistent with a lower risk of HZ in vaccinated children.[569,570]

The first of these studies reported an increase in incidence of HZ in adolescents during 2000 and 2006.[569] A follow-up analysis that included 4 more years of data reported continued decreases in children younger than 10 years of age, while among older children and adolescents 10 to 19 years old the increase reported through 2006 did not continue further and lower rates were observed through 2010.[787] As the prevalence of WT VZV infection declines in these older children and an increasingly larger proportion in this cohort are children and adolescents who had received varicella vaccine and are at a lower risk for HZ, the earlier increases in HZ incidence in 10- to 19-year-olds would plausibly now be reversing. In the overall population, two other studies reported no change in age-adjusted rates of HZ over time periods spanning the first 7 to 8 years of the varicella vaccination program, as varicella incidence declined.[729,788] One of these studies found significant increases in HZ incidence rates among children 10 to 17 years of age that were attributable to increased use of oral steroids.[729]

Three additional studies showed increases of HZ in the overall population. The first study examined varicella and HZ trends in Massachusetts from 1999 to 2003, using data from a statewide phone survey, and noted that as varicella decreased by 66%, HZ increased significantly from an incidence of 2.77 to 5.25 per 1000 PY ($P \leq .001$).[730] The second study looked at HZ incidence among insured people in the United States from 1993 to 2006 from a MarketScan medical claims database and reported an overall incidence of HZ increasing from 1.9 per 1000 PY from 1994–95, to 3.4 per 1000 PY in the year 2000 (the period before significant vaccine impact), to 4.4 per 1000 PY in 2006. However, the incidence in the early years of the study was low compared with other population estimates. Increasing trends were observed in all age groups except children 0 to 17 years of age, where HZ rates stabilized after 1999, consistent with a decline in incidence in a subset of this population that had been vaccinated.[772]

A retrospective study of physician-diagnosed HZ among adults 22 years of age and older living in Olmstead County, Minnesota, showed continuous increases in age-adjusted HZ incidence over three time periods 1945–47, 1980–82, and

2005–07.[788a] Although methodologic differences complicate comparisons across studies, the rates described for 1945–47 in this study of adults only (0.76 per 1000 PY) were considerably lower than those described in most other studies of HZ incidence in the population (most commonly, 3 to 4 per 1000 PY) over the past 50 years, including from 1947 to 1962 in the United Kingdom, where Hope-Simpson described an incidence of HZ in his general practice of 3.4 per 1000 PY.[446] A study that examined HZ incidence among persons older than 65 years of age using Medicare claims data from 1992 through 2010 reported a 39% increase in age- and sex-standardized HZ incidence, from 10.0 per 1000 PY in 1992 to 13.9 per 1000 PY in 2010.[779] Also noteworthy is that the annual incidence of HZ in U.S. veterans almost doubled between 2000 and 2007, from 3.1 episodes per 1000 veterans to 5.2 episodes per 1000 veterans, but only in groups older than 40 years of age.[789]

Data are becoming available from other countries that assist in interpretation of HZ trends after vaccination. These countries are either not implementing vaccination programs or are in the early stages of implementing programs. In Australia, where a universal, publicly funded childhood varicella vaccination program was initiated in 2005, varicella decreased significantly between 1998–99 and 2008–09, with a significant rise in HZ.[790,791] The increase in HZ, however, was not necessarily attributed to vaccination programs. Three studies in Canada have documented increasing HZ trends either before or after initiation of a publicly funded vaccination program.[722,775,784] Brisson and colleagues[771,772] reported on trends in varicella and HZ in Canada and the United Kingdom between 1979 and 1997—over this time, the overall HZ consultation rates increased from 2.58 to 3.48 and from 3.15 to 3.82 per 1000 PY in Canada and the United Kingdom, respectively. Studies in Korea,[776] Madrid,[782] and Japan[783] examining HZ trends from 2003 to 2007, 1997 to 2004, and 1997 to 2006, respectively, have reported increasing HZ incidence, mainly reflecting increases among older adults.

In summary, although studies among vaccinated healthy children show declining rates of HZ, and some studies of population rates of HZ show stable incidence rates over time, the majority of studies examining overall population rates of HZ from around the world show evidence of increasing trends in HZ that are not explained by well-described risk factors for HZ, including age and immunocompromised conditions, nor to potential effects of the varicella vaccination program secondary to decline in varicella exposures. These increases preceded the use of varicella vaccine and have also been described in countries that are not implementing national varicella vaccine programs, as well as in countries with vaccination programs. Further studies are needed to understand factors that may explain these increases, including methodologic issues and improved ascertainment, changes in access to healthcare or health-seeking behaviors, and risk factors for HZ that have not been well described to date (e.g., chronic medical conditions like diabetes, stress, and possible immunocompromising effects of medications). The zoster vaccine, now licensed to prevent HZ (for persons 50 years of age and older) and postherpetic neuralgia (for persons 60 years of age and older), offers the opportunity to reduce the burden of illness caused by HZ in adults (see Chapter 63).

POTENTIAL FOR ELIMINATION OF ENDEMIC DISEASE TRANSMISSION AND ERADICATION

The varicella zoster virus is transmissible while the patient has varicella, and it is able to establish latency and cause HZ, which represents another potential source of introduction of VZV into communities. In addition, breakthrough varicella occurs in approximately 15% of exposed vaccinated children after they receive one dose of varicella vaccine. For these reasons, it is not likely that a universal, one-dose immunization program for varicella vaccine will eliminate circulation of the virus. Partial control was achieved in the United States with a one-dose vaccination program, and there is improved disease control with a routine two-dose program. Elimination of endemic disease transmission even with a two-dose policy may not completely eliminate varicella, and exposure to VZV from HZ patients will continue to occur. The widespread use of varicella vaccine, especially in a national vaccine program, however, has lowered virus transmission significantly and has improved the health of many children, adolescents, and adults, who no longer have to suffer with varicella and its serious complications and will experience less HZ. Complete eradication of diseases caused by VZV seems unlikely, but development of a highly effective subunit zoster vaccine that avoids latency may play a significant role in further decreasing transmission of VZV.[792]

Eventual availability of additional inactivated or subunit vaccines that avoid latency for prevention of varicella and HZ may offer additional possibilities for decreasing transmission of VZV in the future.

Acknowledgments

This chapter is dedicated to the memory of Prof. Dr. Michiaki Takahashi (1928–2013) who developed the live attenuated varicella vaccine.

We thank Judith Breuer and Scott Schmid for reviewing the section on molecular epidemiology and genotyping of VZV.

Work on this chapter was supported in part by grants R01-AI24021, AI41608, AI127187, and DK09394 from the National Institutes of Health.

References for this chapter are available at ExpertConsult.com.

63 Yellow Fever Vaccines

J. Erin Staples, Thomas P. Monath, Mark D. Gershman, and Alan D.T. Barrett

Yellow fever virus is the prototype member of the Flaviviridae (Latin *flavus*, "yellow," after the jaundice seen with the disease) family of viruses. The virus causes a viral hemorrhagic fever, a systemic illness characterized by high viremia, hepatic, renal, and myocardial injury; hemorrhage; and high lethality. A highly effective vaccine (17D), developed in 1936, is widely used to protect travelers to and residents of endemic regions of tropical South America and Africa. Although the vaccine provides long-lasting immunity, rare but serious side effects have emphasized the importance of determining the need for vaccination on a case-by-case basis and of continued exploration of new vaccines.

HISTORY OF DISEASE

The early history of yellow fever is uncertain owing to the inexactness of clinical and epidemiologic descriptions. Carter found the earliest record in a Mayan manuscript describing an epidemic with hematemesis (*xekik*, "black vomit") in Yucatan in 1648[1] and suggested that the virus and mosquito vector were introduced from West Africa during the slave trade 400 years ago.[2] The nosologic term "yellow fever" was first used in 1750 during an outbreak in Barbados.[3] Yellow fever became a major problem in the 18th century in colonial settlements in the Americas and West Africa.[4] It was introduced repeatedly into seaports in the United States and Europe via sailing vessels infested with *Aedes aegypti* mosquitoes that sustained transmission among the passengers and crew. In 1793, for example, yellow fever appeared in Philadelphia, the federal capital of the United States, killing 10% of the population.[5] Similar fates befell residents of other cities throughout the 18th and 19th centuries.[6,7] In one of the worst medical disasters in the early history of the United States, yellow fever caused more than 13,000 deaths in the lower Mississippi Valley in 1878.

Until the 20th century, yellow fever was widely believed to be an airborne miasma arising from filth, sewage, and rotting organic matter. Several physicians, most notably Carlos Finlay in Cuba, suggested that yellow fever was transmitted by mosquitoes.[8] Proof was not obtained until 1900, when Walter Reed and colleagues conducted experiments on human volunteers in Cuba and demonstrated that the agent was a filterable virus transmitted by *Ae. aegypti* mosquitoes.[9] This led to successes in preventing disease through mosquito abatement during the first 20 years of the 20th century. The last outbreak in the United States occurred in New Orleans in 1905, with 8399 cases and 908 deaths and the last human case of endemic yellow fever in the United States occurred in 1911 in Hawaii, prior to it becoming a state.[10]

In 1925, the Rockefeller Foundation's West African Yellow Fever Commission laboratory in Yaba (Lagos), Nigeria, set out to determine the etiology of yellow fever, using imported monkeys for isolation of the causative agent. On June 30, 1927, blood of a 28-year-old man called Asibi, a resident of the village of Kpeve, Ghana, was obtained 33 hours after the onset of mild yellow fever and was inoculated into a rhesus monkey at the field laboratory in Accra. The animal was moribund 4 days later and had hepatic lesions consistent with yellow fever. Blood from this monkey was inoculated intraperitoneally into a second animal, which was transported during the incubation period to Yaba, where it developed yellow fever the day after arrival. Stokes and associates established the Asibi strain by continuous direct passage in monkeys and indirect passage through *Ae. aegypti* mosquitoes.[11] Contemporary efforts at the Institut Pasteur in Dakar led to isolation of the French strain from a Syrian (François Mayali) with mild yellow fever.[12] Isolation of the Asibi and French strains in 1927 enabled the development of vaccines with research initiated immediately in England, the United States, West Africa, and Brazil. Many years later, comparison of the genomes of the Asibi and French viruses confirmed that despite differing passage histories, they were 99.8% identical at the sequence level, divergent at only 23 nucleotides and nine amino acids.[13]

Vaccine development was spurred, in part, by a growing number of laboratory infections. In the 5 years following isolation of yellow fever virus in 1927, 32 cases (five fatal) had occurred among laboratory workers.[14] In 1928, Edward Hindle of the Wellcome Research Laboratories in London described the first attempt to produce an inactivated vaccine.[15] This and other contemporary efforts on inactivated yellow fever vaccines were, however, unsuccessful. In 1931, Sawyer and associates at the Rockefeller Institute in New York first vaccinated humans with a live attenuated virus, the neuroadapted French strain, mixed with immune serum.[16]

In 1932, Sellards and Laigret tested the French strain passaged in mouse brain as a vaccine (French neurotropic vaccine) without immune serum in humans,[17] and in 1934, Mathis, Laigret, and Durieux described the first field trial of this vaccine.[18] Believing the mouse brain tissue virus to have safety concerns for use in humans, Theiler and Smith at the Rockefeller Foundation developed a live vaccine (17D) attenuated by serial passage of the Asibi strain in tissue cultures prepared from embryonated chicken eggs.[19–21] In 1936, the 17D vaccine was tested in a small number of human volunteers in New York,[22] and it entered field trials in Brazil the following year.[23] By 1939, more than 1 million Brazilians had received the 17D vaccine and more than 100,000 persons in French West Africa had received the French neurotropic vaccine.[24–26] During this era, important discoveries surrounding the epidemiology of yellow fever were made, first in South America and then in Africa, showing that yellow fever virus was transmitted between monkeys and forest mosquitoes. These findings suggested that eradication of yellow fever virus was unlikely and established a mandate for vaccinating human populations wherever there was a risk of exposure to the zoonotic cycle. During the 1940s, control of yellow fever at a population level was achieved in francophone Africa by a program of compulsory vaccination with the French neurotropic vaccine administered by scarification.[24] Immunization of laboratory workers, travelers, and military and expatriate residents in endemic areas removed the threat of acquiring the disease, and the disease faded from public view, having been transformed from a major human plague to a medical curiosity by the end of World War II.

DISEASE AND VACCINE IMPORTANCE

Despite the availability of a highly effective vaccine, full control of the disease has failed owing to incomplete implementation

of routine vaccination, the movement and migration of unvaccinated people into endemic areas, and the maintenance of the virus in an enzootic cycle.[27] Since the 1980s, there have been repeated resurgences of yellow fever, particularly in areas where the disease had not been reported for several decades.[28–32,32a,32b,32c] Yellow fever was the first disease for which the International Health Regulations required a certificate of vaccination for travelers entering a receptive (*Ae. aegypti*–infested) area from an endemic country.

In 2001, a previously unrecognized type of serious viscerotropic adverse event following 17D vaccine was first described. This reaction resembled wild-type yellow fever and has similar lethality, but it is, fortunately, rare. The awareness of this serious adverse event has led to the need for a more careful risk-to-benefit analysis for vaccine use in individual persons and populations and continued exploration into the vaccine attenuation and molecular determinants of both virulence as well as host factors involved in immune responses.

This chapter provides background information on the basic virology, virus transmission, clinical disease presentation, pathogenesis, immune response, and epidemiology of yellow fever before presenting detailed information on the development, immunogenicity, and reactogenicity of existing yellow fever virus vaccines. Finally, ongoing work to develop inactivated vaccines, to explore alternative delivery routes for dose sparing, and to use yellow fever virus vaccine in the development of chimeric vaccines is discussed.

BACKGROUND OF YELLOW FEVER VIRUS AND DISEASE

Virology

Yellow fever is the prototype member of the Flaviviridae (Latin *flavus,* "yellow") family, which includes approximately 60 positive-sense, enveloped, single-stranded RNA viruses, most of which are transmitted by mosquitoes or ticks.[33] This section focuses on the basic virology of yellow fever virus and the molecular basis for attenuation of yellow fever 17D vaccine. For reviews of flavivirus genome and protein structure, virus entry, and replication and assembly see Chambers and Monath,[34] Bollati and colleagues,[35] Kaufmann and Rossmann,[36] and Perera and Kuhn.[37]

Classification and Phylogenetic Relationships

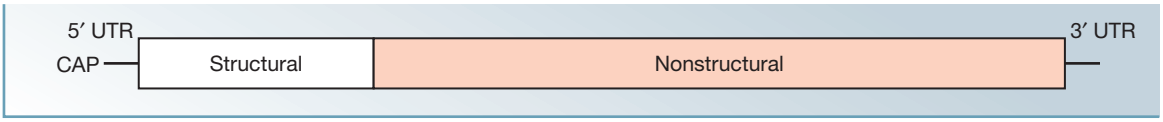
Members of the *Flavivirus* genus are distinguished serologically by the neutralization test and were originally classified into eight antigenic complexes.[38,39] In the current classification that synthesizes epidemiologic, antigenic, and genetic phylogeny, yellow fever virus is considered the type species in a complex of *Aedes*-borne flaviviruses that includes *Wesselsbron, Sepik, Edge Hill, Bouboui, Uganda S, Banzi, Jugra, Saboya,* and *Potiskum* viruses.[40–42]

Yellow fever viruses belong to a single serotype. The relatively high genetic stability of wild-type yellow fever viruses compared to many other RNA viruses is critical to the effectiveness of a single virus strain (17D) as a vaccine. Only seven distinct genotypes have been found by sequencing wild-type yellow fever virus strains of different geographic origin.[2,43–59] African virus strains belong to five distinct genotypes, which differ in nucleotide sequence by 0% to 26% and in amino acid sequence by 0% to 9%.[49,51,62a] The five African genotypes are West African type I (represented mainly by strains from eastern areas of the region, e.g., Nigeria) and genotype II (represented mainly by strains from the western West Africa, e.g., Senegal, Guinea Bissau); the East and Central Africa genotype (Central African Republic, Ethiopia, Sudan, Zaire, Uganda); the East Africa genotype (Uganda, Kenya); and the Angola genotype (1971 and 2015–16 outbreaks). The Central African, East African, and Angolan genotypes are notably different from the West African genotypes (7% amino acid differences),[54] consistent with their ecological separation, namely different mosquito vectors. Recent molecular clock studies showed the origins of yellow fever virus in Central Africa, with evolution from a common ancestral virus within approximately the last 1000 years.[60] The introduction of the virus from West Africa to the New World during the slave trade approximately 400 years ago was also confirmed.[2]

South American viruses fall into two phylogenetic groups with respect to certain structural (envelope [E]), nonstructural ([NS]; NS4A-NS4B), and 3′ noncoding region sequences.[53,61] In contrast to the situation in Africa, only two genotypes (I and II) are found in South America. Genotype I is widely dispersed in South America, including Brazil, Bolivia, Colombia, Ecuador, Panama, Venezuela, and Trinidad, whereas the (apparently older) genotype II circulates in the western part of the continent (Peru, Bolivia, portions of western Brazil) divergent by 0% to 4.6% at the amino acid sequence level.

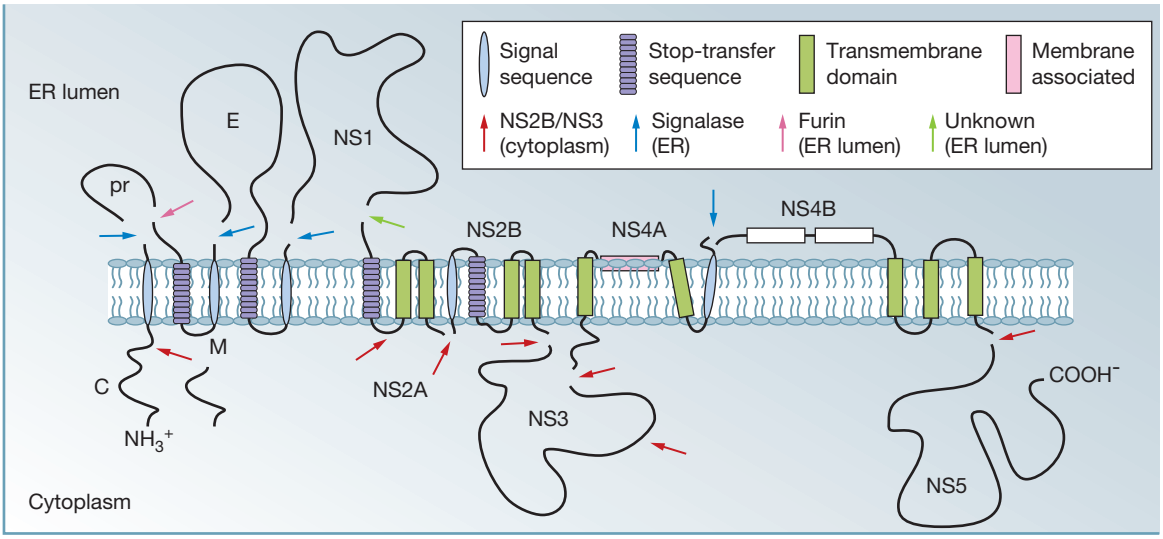
Biological differences between yellow fever strains are also considered in virus-specified factors. By cross absorption with polyclonal antisera, African and New World yellow fever viruses can be serologically distinguished.[62] Slight antigenic differences were discerned between East African and West African strains.[63] Wild-type strains vary with respect to reactivities with monoclonal antibodies[64] but have not been classified to geographic origin or genotype.[65]

Genome Structure and Gene Products



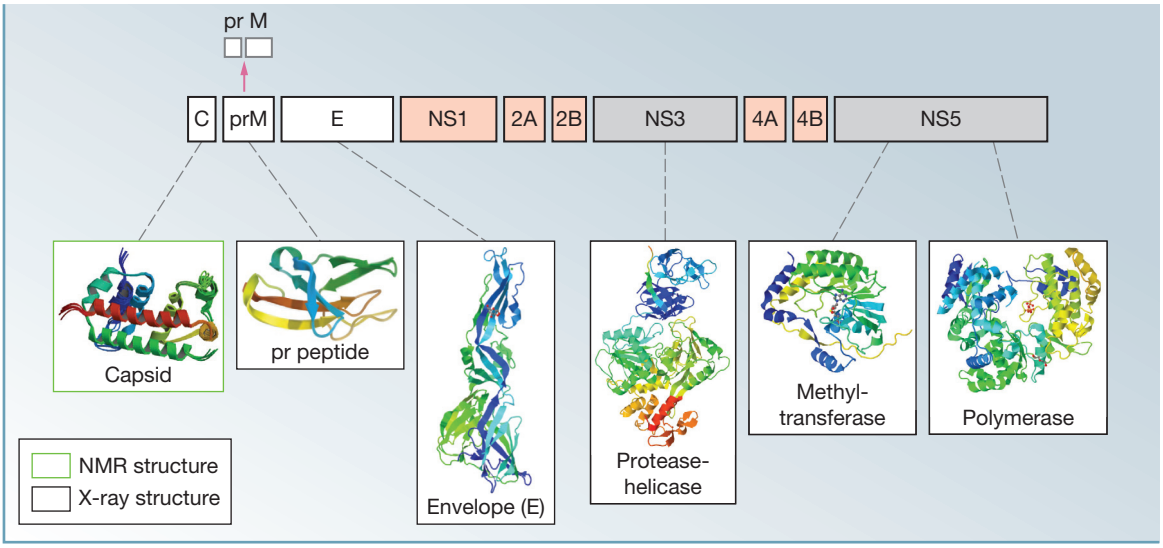
Flaviviruses are small (approximately 50 nm) spherical positive-sense, single-stranded RNA viruses with an envelope containing lipid and two envelope proteins and a single capsid protein. The genome of the prototype yellow fever virus strain 17D-204 contains 10,862 nucleotides, composed of a 5′-terminal type I cap structure, a short 5′ noncoding region, a single open reading frame of 10,233 nucleotides, and a 3′ noncoding region.[34,66] The 5′ and 3′ noncoding regions have conformational structure and interactive sequences important in cyclization of the viral genome during encapsidation and replication. The 3′ and 5′ noncoding regions function as promoters for negative and positive RNA strands, respectively, during replication, and mutations or deletions in the 3′ noncoding region affects replication and virulence.

The open reading frame encodes three structural proteins at the 5′ end (capsid [C], premembrane [prM], and E proteins), followed downstream by seven NS proteins. The proteins are encoded in the order C-prM/M-E-NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5 (Fig. 63.1).



Molecular Determinants of Virulence

The entire genomes have been sequenced of both the 17D and the French neurotropic vaccines and their wild-type progenitors, Asibi and the French viscerotropic virus.[13,67,68] This includes examples of the two substrains of 17D (17D-204 and 17DD) used by many of the producers.[13,69–73] Because a large number of mutations occurred during the more than 230 passages that separate vaccines from their parental strains and the lack of availability of the initial derivatives, it is impossible to define those responsible for attenuation, nor is it clear which determinants encode viscerotropism and neurotropism.



Sequence comparison of strains with different biological properties has reduced the number of possibilities and allowed some educated interpretations. Although some potentially

Structural proteomics of dengue virus.* Curr Opin Microbiol. *2010;11[4]:369–377.)*

important mutations have been identified, it is clear that virulence is multigenic, determined by contributions of both nonstructural and structural genes of the virus. It is also important to note that nearly all studies on the molecular determinants of virulence have employed wild-type mouse models, which reveal only one of the two biological properties of the virus (neurotropism). Mice deficient in the interferon-alpha/beta (IFN-α/β) receptor (A129) or the STAT1 signaling molecule (STAT129) were found to be highly susceptible to infection and disease, succumbing within 6 to 7 days. Importantly, these transgenic mice developed viscerotropic disease reminiscent of human yellow fever, instead of the encephalitic signs

typically observed in wild-type mice.[74] Asibi virus caused a lethal infection in these transgenic models, but infection with 17D-204 vaccine virus was subclinical, suggesting that this model might have applications for investigating the molecular basis of attenuation and virulence of yellow fever virus. Hamsters were shown to be susceptible to a lethal disease with hepatic dysfunction and necrosis resembling wild-type yellow fever after infection with virus strains adapted by serial passage in hamster liver.[75,76] This model also permits dissection of the molecular determinants associated with viscerotropism (at least for the hamster).

The first comparison of nucleotide and amino acid differences between 17D-204 (ATCC) and Asibi virus was made by Hahn and associates.[68] Of a total of 10,862 nucleotides, 67 changes (0.62%) were identified, resulting in mutations in 31 (0.91%) of 3411 amino acids. The changes were not randomly distributed across the genome; the highest rates of change were in genes encoding E, NS2A, and NS2B, and in the 3′ noncoding region. As additional sequences of 17D-204 and 17DD substrain vaccines became available, the number of amino acid differences between parental Asibi virus and attenuated 17D viruses, and shared by vaccines from different sources, was reduced from 31 to 20, and the number of nucleotide differences in the 3′ noncoding region was reduced from six to four (Table 63.1).[69,73,77] Although the possibilities have been reduced to a limited number of mutations, it has not been possible to determine precisely which are responsible for the reduced virulence of the vaccine strain.

The E protein contains structures involved in cell receptor interactions and virus entry into cells. Therefore, the eight amino acid differences between Asibi and vaccine strains are suspected to play a role in attenuation. The role of the E protein in neurovirulence is illustrated by a study in which heterologous yellow fever chimeras were constructed having a yellow fever 17D backbone and prM and E genes from flaviviruses with different neurovirulence profiles.[78]

The N-terminal 400 amino acids of the E protein form what is termed the *ectodomain*, and the C-terminal region contains a stem-anchor region that anchors the E protein in the virus envelope. The ectodomain contains three domains (I, II, and III) (Fig. 63.2).[79] Domains I and II are discontinuous in primary amino acid sequence, and domain III consists of a linear region of 100 amino acids, approximately residues 295 to 395. Mutations in three principal areas of E protein alter virulence properties of yellow fever and other flaviviruses. These include the tip of the fusion peptide in domain II, the molecular hinge between domains I and II, and the upper lateral surface of domain III, containing the putative receptor-ligand.[79,80] Among the eight amino acids in the E protein that distinguish Asibi and 17D viruses (see Table 63.1), four are nonconservative changes: E52 Gly→Arg, E200 Lys→Thr, E305 Ser→Phe, and E380 Thr→Arg. Wild-type yellow fever strains (Asibi, the French viscerotropic virus, and Peruvian strain 1899/81) share these amino acid residues, suggesting that one or more of the mutations at these sites in the 17D vaccine strain may contribute to attenuation.[13,68,81]

Amino acid residues E52, E173, and E200 are in the molecular hinge region and are also located in domain II at the top of the virion, where they are exposed to interactions with cell receptors and binding moieties. Mutations in the hinge region could alter the acid-dependent conformational change in E protein required for virus entry. Neuroadaptation of yellow fever 17D virus resulted in an increase in neurovirulence of the virus for mice and was associated with a reversion (Ile→Thr) at residue E173.[78,82] Furthermore, mutations in the hinge region at E176 and E177 of a yellow fever–Japanese encephalitis chimera were associated with attenuation.[83] Moreover, residue E173 is implicated in an epitope binding to wild-type specific monoclonal antibody (MAb 117).[84] Reversion of this amino acid to the wild-type Thr was implicated in the increased neurovirulence phenotype of a variant [17D(wt$^+$)] recovered from a 17D-204 vaccine.[85]

A chimeric virus composed of Japanese encephalitis prM-E genes in the yellow fever 17D backbone having a single amino acid change to the wild-type Japanese encephalitis amino acid at E279 in the molecular hinge caused an increase in neurovirulence for mice but reduced viscerotropism for monkeys.[86] This result suggested that neurovirulence and viscerotropism of yellow fever virus strains might not be linked at the molecular level. This may explain why the French neurotropic vaccine, which was developed by adapting the virus during over 128 passages in mouse brains, was highly neurovirulent for mice but had lost the ability to cause hepatitis in monkeys and humans. Similarly, dengue-2 virus adapted by sequential mouse brain passages was also attenuated for humans.[87,88] The adapted virus had a critical nonconservative (Glu→Lys) mutation at E126, also in the hinge region.[87,89]

Vaccine-specific mutations at positions E305 and E380 are located in domain III, and the mutation at position E299 is located at the interface of domains I and III. E305 and E380

TABLE 63.1 Amino Acid Differences Between Asibi Virus and Attenuated 17D Vaccines

Nucleotide	Gene	Amino Acid	Asibi	17D-204 and 17DD Vaccines
854	M	36	Leu	Phe
1127	E	52	Gly	Arg

10,800			G	A
10,847			A	C

Some authors[73,77] reported a mutation at E331 LYS in Asibi to ARG in 17D, but E331 is unique in Asibi compared to all other yellow fever genomes sequenced so it may be eliminated as relevant to the attenuation process.

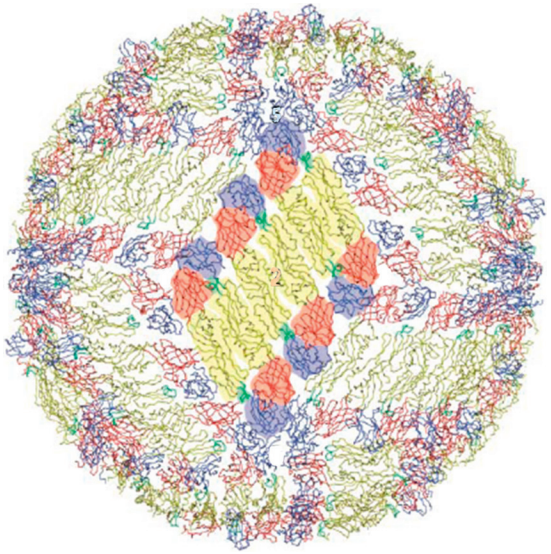

Figure 63.2. Crystal structure of the mature Flavivirus envelope. E protein monomers form head-to-tail dimers in a herringbone pattern. Each monomer consists of three domains dominated by b strands. Domains I, II, and III are colored red, yellow, and blue, respectively, and the fusion peptide is shown in green. The E protein dimers are organized as 30 rafts in a herringbone pattern. One of these rafts is highlighted in the figure. *(From Zhang Y, Corver J, Chipman PR, et al. Structures of immature flavivirus particles.* EMBO J. *2002;22: 2604–2613.)*

are located at the top surface of the virion in domain III. Because domain III contains ligands for cell-receptor interactions, these mutations could alter tropism of the vaccine virus. Yellow fever 17D strains that were neuroadapted and neurovirulent had reversions at E305, E325, and E380 (as well as the reversions to wild-type residues at E52 and 173 noted earlier).[78,82,90,91] Similarly, mutations in the region E308-E311 of tickborne encephalitis virus resulted in significant attenuation.[80] Moreover, the possible role of the E305 mutation was illustrated by sequence analysis of yellow fever 17D virus recovered from the brain of a child with a fatal yellow fever vaccine–associated neurotropic adverse event.[92,93] The 17D virus recovered had increased neurovirulence for mice and monkeys. The isolate differed from 17D vaccine at E303 Glu→Lys, located in domain III very near the 17D-204–substrain-specific E305 amino acid. However, two other mutations (at E155 and NS4B76) were also present in the brain isolate and could have played a role in reversion to virulence.

The mutation at amino acid E380 of 17D occurs in the moiety that is a putative integrin cell-receptor ligand; the sequence change in this motif is from Thr-Gly-Asp in Asibi to Arg-Gly-Asp (RGD) in 17D vaccine.[68] Although mutations in the RGD sequence predicted to alter integrin binding did not interfere with 17D virus replication,[94,95] studies with another flavivirus (Murray Valley encephalitis) also showed that RGD mutations attenuated neurovirulence for mice.[96,97] Multiplication of the Murray Valley encephalitis mutant viruses were also inhibited by heparin, suggesting that cell receptors other than integrin bind the viral ligands. The neuroinvasiveness of Japanese encephalitis and Murray Valley encephalitis viruses was attenuated by passage in adenocarcinoma cells, and the phenotypic changes were associated with mutations in the putative cell receptor-binding region of domain III (at E390 and E306, respectively).[98] The mutant viruses were inhibited by heparin and had enhanced affinity for glycoaminoglycan (GAG) receptors on nonneural cells, indicating that changes in charged amino acids with increased affinity for GAG receptors reduced viremia and neuroinvasion.

Collectively these studies suggest a role for similar mutations in domain III in the attenuation of yellow fever 17D, and this was demonstrated by two groups. The first investigated three amino acid substitutions (305 Phe→Val, 326 Lys→Glu, and 380 Arg→Thr) as critical determinants of mouse neuroinvasiveness in a severe combined immunodeficiency model. Virus containing vE326-Glu caused a rapid lethal encephalitis, but mutants with either E380-Thr or E305-Val did not independently affect neuroinvasiveness. Testing a panel of viruses with various amino acid substitutions at E326 revealed that attenuation of neuroinvasiveness required a positively charged residue (Lys or Arg) at this position. Molecular-modeling studies of protein domain III indicate that E326 and E380 contribute to charge clusters on the lateral surface of domain III that constitute putative heparin-binding sites.[91] The second group investigated E305, E325, and E380 and showed that these residues inhibit spread of 17D in extraneural tissues and attenuate virulence in types I/II IFN-deficient mice. One of these residues (E380-Arg) was a dominant GAG-binding determinant, which mediated more-rapid in vivo clearance of 17D from the bloodstream in comparison to 17D-derived variants with wild-type–like E protein.[95] However, these studies did not include wild-type strain Asibi for comparison.

The stem-anchor region of the E protein is involved in the reconfiguration of the E protein from dimeric to trimeric structure during low-pH–induced fusion and virus entry and also plays a role in localizing and retaining the envelope proteins in the ER during morphogenesis.[99–101] The Val→Ala mutation at amino acid E407 of Asibi virus occurs in the N-terminal stem-anchor region of the E protein. Mutations in this region can affect the structural integrity and three-dimensional structure of the prM-E heterodimer and are known to attenuate flaviviruses, including dengue, tickborne encephalitis group virus, Japanese encephalitis, and yellow fever–Japanese encephalitis chimeras.[83,87,102,103] In addition to the E protein, the M protein also contains a single amino acid substitution at residue 36 (L36F) and is found in a proapoptotic sequence described for dengue virus.[104]

The 17D vaccine is not fixed with respect to neurovirulence, so that sequential mouse-brain passage of the vaccine results in increasing mouse virulence.[105] The neuroadapted 17D virus reverted to the wild-type (Asibi) sequence at amino acid residues E52 and E173 and also accumulated mutations at the putative virulence determinant E305 (Ser→Val) and in nonstructural genes (NS1, NS2A, NS4A, NS4B, and NS5).[78,82] A chimeric virus with the original 17D backbone and the neuroadapted E sequence did not have increased neurovirulence compared to original 17D. In contrast, when all mutations in E and NS genes of the neuroadapted strain were introduced into the 17D infectious clone, neurovirulence was increased, illustrating that multiple genes were involved in virulence and implicating mutations in the NS proteins or the 3′ noncoding region of the virus. Studies with other flaviviruses also have shown that mutations in the NS coding region might reduce neurovirulence, probably by reducing the rate of replication.[73,106]

Eleven amino acid changes in the NS proteins of Asibi viruses occurred during the derivation of 17D vaccine (see Table 63.1): one in the NS1 protein; four in NS2A; one each in NS2B, NS3, NS4A, and NS4B; and two in NS5. Although the role of NS2A mutations are not known, this protein plays roles in viral RNA replication, and virion assembly and release.[107–109] The change in NS3 occurs at residue 485, in the region coding for the RNA helicase and triphosphatase enzymes for unwinding RNA during replication. The two mutations in the NS5 RNA dependent RNA polymerase potentially

influence replication efficiency and might contribute to attenuation of 17D. A plaque variant purified from a 17D vaccine had reduced mouse neurovirulence and differed at an amino acid residue in NS5 137 Pro→Ser.[110] This mutation is in a region encoding the methyltransferase activity of the NS5.

The 3′ noncoding region plays a critical role in replication, and changes in this sequence can contribute to attenuation. The 3′ noncoding proximal region is variable in length among yellow fever strains and contains one to three repeat sequence elements.[61] The 3′ terminal region contains a 90- to 120-nucleotide conserved region involved in folding of the stem-loop structure and serving as a promoter for minus strand synthesis during replication. Mutations in the stem-loop region can interfere with virus replication.[111,112] In the case of dengue-4 virus, the proximal region of the 3′ noncoding region does not appear to be critical to replication, but mutations or deletions in this region can nevertheless attenuate virulence.[113] It is clear that mutations in the 3′ noncoding region of 17D present in both the variable and the conserved proximal region might have contributed to attenuation of the vaccine virus. The change at nucleotide 10,367 might be an exception because one 17D vaccine contains a heterogeneous mixture including the wild-type sequence.[71]

Much less is known about the determinants of yellow fever virus viscerotropism, principally because of the difficulty of assessing this property in nonhuman primates. As noted earlier, the neurotropism and viscerotropism properties of yellow fever virus might reside in distinct regions, and thus one cannot conclude that attenuation of one feature correlates with attenuation of the other. However, the hinge region of E apparently contains residues implicated in both neurotropism and viscerotropism. A mutation at E279 in the hinge 4 region of a yellow fever–Japanese encephalitis chimeric virus reduced viscerotropism of the virus in nonhuman primates,[86] suggesting that mutations in the hinge region of the yellow fever genome during derivation of 17D virus could be responsible for attenuation of viscerotropism. The Met→Lys mutation at position E279 in the yellow fever–Japanese encephalitis chimera is within the beta-strand of the secondary structure, increases the net positive charge of the protein, and is predicted to result in a shortening of the beta-strand secondary structure.

Wang and colleagues compared the sequence of the French viscerotropic strain with that of the attenuated French neurotropic vaccine, which was derived by serial mouse brain adaptation.[13] French neurotropic vaccine is not viscerotropic for monkeys or humans, whereas it has enhanced neurovirulence for mice and monkeys. Comparison of the parental and vaccine strains revealed 35 (1%) amino acid changes, with the highest frequency of mutations in C, M, E, NS2A, and NS4B. The specific roles of these changes are unknown. Sequence comparison of French neurotropic vaccine with 17D vaccines showed only two shared differences from the parental strains and other wild-type yellow fever strains. These common differences, which evolved during the development of vaccine strains by adaptation to different hosts, were in the M protein (M36 Leu→Phe) and NS4B (95 Ile→Met). Thus, the molecular structures involved in viscerotropism remain uncertain.

Golden hamsters develop hepatitis resembling human yellow fever, and the model could potentially be used to identify molecular determinants of viscerotropism.[75] Unfortunately, to induce viscerotropic disease in the hamster, wild-type yellow fever virus must be adapted by serial liver–liver passage. Thus, Asibi virus became hamster-virulent between the sixth and seventh passage. The genome of the viscerotropic passage 7 virus contained seven amino acid mutations, of which five are in the E protein (positions E27 (Gln→His), E28 (Asp→Gly), E155 (Asp→Ala), E323 (Lys→Arg), and E331 (Lys→Arg)].[114] Two changes (E323 and E331) are in the part of domain III implicated as ligands for cell receptors, and thus they might be responsible for hepatotropism in hamsters. In addition, two amino acid mutations occurred in NS2A48 (Thr→Ala) and NS4B98 (Val→Ile). A mutation near the latter site in NS4B (at residue 95) is associated with attenuation of yellow fever 17D and French neurotropic vaccines. In addition the mutation at E155 in yellow fever 17D was associated with reversion to virulence (neurotropism) of yellow fever 17D.[92]

Further light was shed on the viscerotropism genes when McArthur and colleagues attempted to reproduce the serial passage experiment.[114,115] The second passage 7 virus was not lethal, although it still caused histopathologic changes in liver. The genome sequence of the first (lethal) and second (nonlethal) passage 7 viruses differed at two amino acids (E98 and E331). Thus, although these studies in hamsters do not identify individual amino acids involved in attenuation of 17D for humans, they do point to functional regions and specific determinants of the genome for further investigation. In contrast to the hamster, mice deficient in the IFN-α/β receptor (A129 mice) or the STAT1 signaling molecule (STAT129 mice) were susceptible to viscerotropic disease after infection with unadapted wild-type yellow fever virus and could serve as a useful model for future investigations of viral virulence determinants.[74] The 17D vaccine strain was attenuated in these mice and did not cause viscerotropic infection or injury.

Asibi and French viscerotropic viruses lost both neurotropism and viscerotropism after a few passages in HeLa (Henrietta Lacks) cells.[116,117] The HeLa cell–adapted virus contained 10 amino acid mutations, including five in the E protein, one in NS2A, and three in NS4B. The NS4B (95 Ile→Met) mutation is associated with attenuation of Asibi to 17D by passage in chick embryo tissue and of French viscerotropic virus to French neurotropic vaccine by passage in mouse brain; this mutation also appeared during HeLa cell adaptation, suggesting a role in attenuation of yellow fever vaccines. As pointed out earlier, a nearby mutation at NS4B98 was associated with viscerotropism for hamsters. HeLa-, chick embryo–, and mouse brain–adapted viruses share two phenotypic markers: loss of viscerotropism and loss of vector competence for *Ae. aegypti*. The role of NS4B95 is not known but NS4B plays a number of roles, including formation of the viral replication complex and inhibiting the host innate immune responses via blocking type I IFN signaling. The changes in the HeLa-passed virus E protein occur at E27 (Gln→His), E155 (Asp→Ala), E228 (Met→Lys), E331 (Lys→Arg), and E390 (His→Pro). Three mutations (at E27, E155, E331) were also associated with adaptation in the hamster, suggesting that they could be viscerotropism virulence factors.[114]

The interactions of yellow fever 17D virus with dendritic cells that are involved in early sites of replication after inoculation of the vaccine were studied by Palmer and colleagues. 17D virus replication in these cells was restricted, confined to the lysosomal compartment, and was rapidly processed with early expression of activation markers, suggesting a basis for attenuation and immunogenicity of the vaccine virus.[118] However, an earlier study found that 17D virus would replicate in both mature and immature dendritic cells.[119] Clearly, more work is needed in this area; however, it may be significant that that the two groups used 17D virus from different sources and so may differ in sequence. The ability to establish disseminated infection and cause viscerotropic disease in IFN-α/β-deficient (A129) mice correlated with infectivity for A129-derived, but not wild-type 129-derived, dendritic cells in vitro, indicating that these cells play an important gatekeeper role in pathogenesis.[74] As is pointed out later (see "Adverse Events"), yellow fever 17D vaccine is associated with rare neuro- and viscerotropic adverse events in patients with and without known

risk factors. The residual capacity to cause a disease in humans resembling wild-type yellow fever suggests that either attenuation of virulence is incomplete or there is a role for host genetic factors. Although many animals reveal the residual neurotropism of 17D virus, there is currently only one partially characterized mouse model of viscerotropic adverse events (IFN-receptor–deficient mice).[74] Such a model could be used to study the molecular basis of residual viscerotropism and to devise improved vaccines and treatment strategies.

In addition to attenuation of viscerotropism and neurotropism, a critical property of 17D vaccine is its inability to disseminate from the midgut to other tissues in the mosquito, and thus it is not transmissible from the mosquito to vertebrate hosts. Higgs and coworkers have used infectious clone technology to generate chimeras of Asibi and 17D viruses containing swapped residues in NS2A (four amino acids), NS4B (one amino acid), and the 3′ untranslated region (four nucleotides) to identify viral genes involved in dissemination in *Ae. aegypti*. Dissemination was found to be related to whether the chimera had an Asibi or 17D E protein domain III, but E domain III appeared not to be the only genetic factor controlling dissemination.[120,121]

While the precise molecular determinants of attenuation and virulence have not been elucidated, recent data have shed light on the molecular basis of attenuation of 17D vaccine. It is known that RNA viruses, including yellow fever virus, exist as a quasispecies, or a group of nucleotide sequences related by a similar mutation or mutations that compete within a viral population, because of the high error rate of the RNA-dependent RNA polymerase. Until recently, nucleotide sequences were obtained by "first-generation sequencing," such as Sanger sequencing (chain-termination method), where the nucleotide sequence of the dominant member of a population was obtained and the quasispecies was seen as a "consensus" sequence. However, "next-generation sequencing" (NGS) has enabled amplification of a single molecule to obtain nucleotide sequence of the quasispecies population. Comparison of a 17D-204 commercial lot with wild-type Asibi strain was undertaken by NGS and revealed that the wild-type virus population structure differs from that of the vaccine. Specifically, Asibi virus had the typical quasispecies structure of a RNA virus while in contrast the vaccine virus was relatively homogeneous suggesting that the lack of diversity in the 17D vaccine virus population may contribute to the attenuated phenotype.[122]

Molecular Identification of Antigenic Determinants in Yellow Fever Virus and Vaccine Strains and Their Relationship to Virulence

Monoclonal antibodies recognize structurally distinct regions in the E protein of yellow fever virus, including vaccine strain–specific epitopes and yellow fever virus–specific epitopes, as well as determinants cross reactive with specific heterologous flaviviruses and with broad flavivirus-group epitopes.[123–130] Antibodies against vaccine strain–specific, virus-specific, and flavivirus group–reactive epitopes neutralize virus, and many passively protect mice against intracerebral challenge. Interestingly, monoclonal antibodies generated following immunization with 17D virus neutralized wild-type (Asibi) virus but not 17D, and flavivirus group–reactive monoclonals generated after immunization with 17D, Asibi, or heterologous flaviviruses neutralized wild-type virus.[124,125,131] This multiplicity of neutralizing determinants helps explain the broad protective immunity afforded by 17D vaccine against wild virus strains and the partial cross-protection by heterologous flaviviruses against yellow fever.

Additional studies have defined epitopes that are substrain specific, differentiating 17D-204 vaccine from other yellow fever viruses and 17D-204 from 17DD vaccines and even distinguishing between vaccines of the same substrain from different manufacturers.[64,125] Plaque-size variants purified from 17D vaccine can also be distinguished in neutralization and hemagglutination inhibition tests.[64,123,132] Some monoclonals are specific for 17D and do not recognize wild-type virus.[126,133] The antigenic heterogeneity of 17D vaccine is due to the uncloned nature and different passage histories during manufacture and laboratory manipulation. At present, there is no recognized practical consequence, with respect to protective immunity, of the absence of some wild-type antigenic determinants in 17D vaccines.

Attenuation by passage of wild-type Asibi virus in HeLa cells was associated with acquisition of a vaccine-specific epitope recognized by MAb H5.[117] Gould and colleagues identified a plaque variant in 17D vaccine that reacted with a MAb specific for wild-type viruses and variants recovered from Asibi virus that reacted with a 17D-204 specific monoclonal, suggesting that 17D was derived by a process of selection of subpopulations during serial passage.[84]

Some neutralizing epitopes have been localized by sequencing escape mutants or wild-type antigenic variants recovered from 17D vaccine. An epitope at residue E173 is the only wild-type–specific antigenic determinant that has been localized[85]; this site is also a putative neurovirulence factor. A neutralization determinant in the E protein of both wild-type and 17D was identified at residues E71/72 in domain II of the E protein.[90,134] Ryman and colleagues found an additional neutralizing epitope at either E155 or 158 in domain I.[90] These data were confirmed using human MAb fragments that neutralized 17D and wild-type yellow fever viruses belonging to West African and to Central and East African genotypes.[135] This study suggested that amino acids E71 and E155 formed part of a single conformational epitope in the E protein dimer.

In a later analysis, Ryman and colleagues selected escape mutants from three 17D substrains with a monoclonal antibody (MAb 864) specific for 17D-204 virus that had a number of functional activities including neutralization, hemagglutination, and hemolytic and passive protection.[64,85,124] The escape mutants were characterized with respect to mouse neurovirulence and prM-E nucleotide sequence. One series of escape mutants had reduced neurovirulence for mice compared to the parental virus and had a Ser→Leu mutation at E325. E325 is the site of a Pro→Ser mutation that occurred in the derivation of 17D-204 from Asibi but is not present in the 17DD substrain and thus is not considered to be relevant to the attenuated vaccine phenotype.[68,69]

In contrast, another neutralization escape mutant was neurovirulent for mice and contained an amino acid mutation at E305 (Phe→Ser), which is a conserved substitution across all 17D strains (see Table 63.1). This mutation represents a reversion to the wild-type residue at E305. The E305 and E325 residues are spatially adjacent within domain III of the E glycoprotein and thus represent a conformational epitope recognized by the MAb 864 used to generate the different escape mutants.[85,136] The location of the epitope is consonant with the effector roles of antibody in blocking cell attachment and intracellular uncoating events. Clearly, this epitope also is critical to pathogenesis and neurovirulence. By Western blotting, the MAb 864 recognizes both the prM and E proteins,[84] suggesting that the E305-E325 epitope is involved in the prM-E interaction during virus assembly.[137]

Although an exhaustive search for neutralization and protective epitopes has not been made, it would appear that yellow fever viruses (like other flaviviruses) contain only

a few (but more than one) such determinants in the E protein, which are structurally diverse. These epitopes must be conserved across wild-type strains, consistent with the broad protective activity of yellow fever vaccine against wild virus strains.

Antigenic determinants involved in cell-mediated immunity have been localized in yellow fever 17D virus, dengue virus, and Murray Valley encephalitis viruses.[138–144] Yellow fever cytotoxic T-lymphocyte determinants are found in the E proteins and in multiple nonstructural proteins: NS1, NS2B, NS3, NS4B, and NS5.[145–147] These T-cell epitopes are highly conserved and probably contribute to the cross-protective activity of 17D vaccine against all geographic variants of wild-type yellow fever virus. In the case of yellow fever, cytotoxic T-cell epitopes were found on E, NS1, NS2B, and NS3, and these epitope sequences were conserved across multiple yellow fever strains.[145] T-cell responses tend to be cross-reactive.[143,144] Cytotoxic T-effector cells raised to Murray Valley encephalitis virus demonstrated significant cross-reactivity with target cells pulsed with yellow fever–derived NS3 peptides, despite the relative low sequence homology of the determinants.[148]

Modes of Transmission

The primary mode of transmission of yellow fever virus to humans is through the bite of an infected mosquito. Various mosquitoes are involved in the maintenance and transmission of yellow fever virus and the virus is maintained in an enzootic cycle by these mosquitoes and wild nonhuman primates. Other modes of transmissions, such as exposure to infected blood and aerosol, have occurred primarily among unvaccinated laboratory workers.

Transmission Cycles

The enzootic transmission cycle involves monkeys and diurnally active tree-hole–breeding mosquitoes (*Haemagogus* spp. in South America and *Aedes africanus* in Africa) (Fig. 63.3). Humans are sporadically exposed to infected mosquitoes when they encroach on this cycle during occupational or recreational activities ("jungle yellow fever"). This transmission cycle accounts for jungle yellow fever cases in South America and in the rainforest zone of Africa. In the moist savanna regions of Africa, tree-hole-breeding *Aedes* mosquitoes reach very high densities and are implicated in endemic and epidemic transmission, transferring virus from monkeys to humans and between humans. *Ae. aegypti*, a domestic mosquito that breeds in human-made containers and achieves highest densities in urban environments, can transmit yellow fever virus between humans ("urban yellow fever").

Many species of nonhuman primates are susceptible to yellow fever infection.[149] The majority of African species have viremic infections sufficient to infect mosquitoes without developing clinical illness, whereas some neotropical species (e.g., howler monkeys) develop fatal infections. Depletion of vertebrate hosts through natural immunization and death during epizootic waves is a factor in the cyclic appearance of yellow fever activity. In many areas, deforestation and hunting pressure have markedly reduced monkey populations, and human beings become the host in the yellow fever virus transmission cycle.[150,151] Although this point is still debated, there is little evidence that nonprimate vertebrates are involved in enzootic transmission.[150,152–154]

The pattern of yellow fever viral activity in South America is characterized by intermittent emergence around the edges of the Amazon region. These outbreaks are preceded by evidence for increased virus transmission between monkeys and

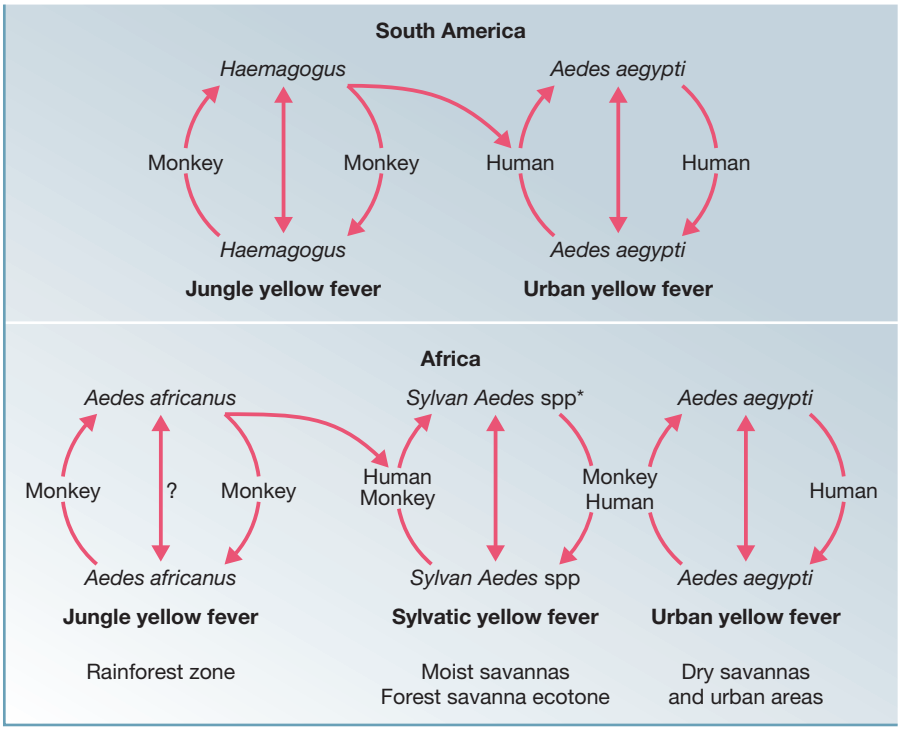

Figure 63.3. Transmission cycles of yellow fever virus in South America *(top)* and Africa *(bottom)*. In both continents, jungle yellow fever is transmitted through an enzootic cycle. Urban and sylvatic yellow fevers are transmitted in epidemic cycles. Transovarial transmission is indicated by vertical arrows showing virus transfer between mosquitoes, and this may be an important mechanism for virus survival over the long dry season. *Aedes* species found in West Africa include *Ae. furcifer*, *Ae. taylori*, *Ae. luteocephalus*, *Ae. africanus*, *Ae. opok*, *Ae. vittatus*, and *Ae. metallicus*. Species found in East Africa include *Ae. africanus* and *Ae. simpsoni* (complex).

Haemagogus spp. within the Amazon basin, which moves in a circular fashion within the forest or along gallery forests of river courses. A detailed analysis of the patterns of virus activity preceding and during epidemics in Brazil is provided by Mondet[155] and Vasconcelos and colleagues.[156]

The ecology of yellow fever virus differs in areas bordering the rainforest in Africa. A mosaic of savanna and forest in galleries along rivers characterizes this transitional vegetation zone. In this region and surrounding moist (Guinea) savanna, yellow fever virus transmission is effected by a wide variety of tree-hole–breeding mosquito vectors.[150,153,157–159] In West Africa, the principal vectors responsible for yellow fever virus transmission in the savanna zone include *Aedes furcifer, Aedes vittatus,* and *Aedes luteocephalus,* as well as *Ae. africanus*.[157] In East Africa, *Ae. africanus* and human-biting populations of the *Aedes simpsoni* species complex *(Ae. simpsoni, Aedes lilii, Aedes bromeliae)* play a similar role.[160–162] During the wet and early dry seasons, vector density reaches high levels. Vectors are active in plantation areas and in proximity to human dwellings and can enter houses.[158] Both humans and nonhuman primates may be involved as hosts in the transmission cycle, and the rate of virus transmission far exceeds that found in the rainforest zone. The savanna-forest ecotone and surrounding Guinea savanna has been described as the "zone of emergence" of yellow fever and represents the region principally affected by epidemics in Africa.[150,159]

An epidemiologically distinct transmission cycle involves *Ae. aegypti*, which breeds in containers used to store water or in artificial containers that collect rainwater around human habitations and predominantly feeds on humans. *Ae. aegypti* transmits yellow fever virus between humans, the sole viremic hosts in the cycle. The vector occurs in dry areas and heavily settled areas but is also widely dispersed in settlements in rural areas. Urban outbreaks have followed introduction by viremic persons from areas of jungle yellow fever activity.[163,164] In the Americas, urban yellow fever outbreaks were common prior to the successful eradication of the vector,[165–167] and outbreaks currently show signs of reoccurring owing to the repopulation of most urban areas with *Ae. aegypti*. The last documented urban outbreak in continental South America prior to efforts to control *Ae. aegypti* occurred in western Brazil in 1942. There was a long interval without urban yellow fever reports, and then *Ae. aegypti*–transmitted yellow fever was reported in Trinidad in 1954,[168] Santa Cruz, Bolivia in 1998,[169] and most recently, Asunción, Paraguay in 2008.[32]

Africa suffers many *Ae. aegypti*–borne epidemics, because the vector is prevalent in urban and rural areas. In dry areas (Sudan and Sahel savanna zones), where domiciliary *Ae. aegypti* might represent the only species capable of sustaining yellow fever virus transmission, outbreaks occur after introduction of the virus by viremic persons. *Ae. aegypti*–borne epidemics in the past 40 years include those in Senegal in 1965 and 2002; Angola in 1971, 2015–16; Ghana in 1969, 1977–80, and 1983; Côte d'Ivoire in 1982, 2001, and 2008; Nigeria between 1987 and 1991; and likely Democratic Republic of Congo (DRC) in 2016.[32a,170,171] Undoubtedly other outbreaks in Africa involved *Ae. aegypti*, but entomological investigations are infrequently performed or are too superficial to draw conclusions regarding the role of domestic vectors. In Africa, some feral populations of *Ae. aegypti* feed preferentially on mammals other than humans. *Aedes* spp. other than *Ae. aegypti* are responsible for interhuman yellow fever virus transmission, as noted earlier.

Maintenance of Yellow Fever Virus in Nature

The means of survival of yellow fever virus across the long dry season, when sylvatic mosquito vectors are virtually absent, remains incompletely understood. *Aedes* and *Haemagogus* eggs survive desiccation in tree holes and hatch with the return of rain. Experimental and field studies indicate that transovarial transmission is a means of virus survival across the dry season.[172–178] However, the filial infection rate of yellow fever virus by vertical transmission in mosquitoes is too low for this to maintain the virus indefinitely, and annual amplification in nonhuman primates is thus imperative. Low-level horizontal transmission by drought-resistant vectors and alternative horizontal and vertical transmission cycles involving ticks[179] have been suggested as ancillary mechanisms for survival across the dry season. Persistent infection of experimentally infected nonhuman primates has been documented,[180,181] but such infections are probably not accompanied by viremias sufficient to infect vectors.

Yellow Fever Virus in the Mosquito Vector

Infection of mosquitoes is initiated by ingestion of a blood meal containing a threshold concentration of virus (~3.5 $\log_{10}$/mL), resulting in infection of the midgut epithelium. The virus is released from the midgut into the hemolymph and spreads to other tissues, notably the reproductive tract and salivary glands. The time elapsed between ingestion of virus and secretion in saliva (the extrinsic incubation period) is temperature-dependent and has a median duration of 10 days at 25°C.[182] After the extrinsic incubation period, the vector is capable of transmitting virus when she refeeds on a susceptible host. Infection of reproductive tissues of the mosquito provides a mechanism for vertical transmission of yellow fever virus from the female mosquito to her progeny and from congenitally infected males to females during copulation.[172,177,178]

Transmission of Live Vaccine Viruses. The use of a live vaccine theoretically engenders a risk of secondary spread by mosquitoes, and passage of vaccine virus could result in a reversion to a more-virulent phenotype. This is unlikely for two reasons. First, viremia following 17D vaccination is very low and below the threshold of oral infection of the vector,[183,184] with a number of caveats including viremia may be higher in patients with viscerotropic adverse events, and viremia has not been measured in infants, who may sustain more-active infections than adults, or in immunosuppressed persons. Second, 17D virus is poorly infectious for mosquitoes. Whitman infected *Ae. aegypti* larvae with 17D virus after immersion in virus, but infected adult progeny were incapable of transmitting the virus.[185] Bhatt and colleagues reported that 17D vaccine virus inoculated by the intrathoracic route (thus bypassing the midgut barrier) replicated to a low level in *Ae. aegypti* and *Aedes albopictus*, but orally exposed mosquitoes contained no detectable virus after a 22-day extrinsic incubation period.[186] Jennings and colleagues showed that 45% of adult female *Ae. aegypti* that fed on a high concentration of 17D vaccine in an artificial blood meal developed midgut infections, but no virus was detected in head tissue.[92] In another study, only 1 of 32 *Ae. aegypti* orally exposed to 17D virus developed infection in head tissue, and none of the mosquitoes transmitted the virus.[187] Thus, yellow fever 17D virus has lost its ability to be transmitted by *Ae. aegypti*, possibly owing to inability of the virus to cross the midgut barrier.

At the molecular level, it has not been determined which mutations in 17D virus are responsible for restricted transmission by mosquitoes. However, it is of interest that Asibi virus passaged in HeLa cells lost mosquito competence and that this change may have been associated with a mutation at NS4B 95.[117,187] In support of a role for nonstructural genes in determining mosquito competence, studies of chimeric viruses in which the prM-E genes of Japanese encephalitis, West Nile,

and dengue were inserted into a 17D infectious clone showed retention of the 17D phenotype in mosquitoes.[186,188] The conclusion from these studies was that the inability to replicate efficiently in mosquitoes is determined by nonstructural genes of the virus and that the structural genes containing cell-receptor binding determinants were critical to dissemination.

An infectious clone of wild-type Asibi virus has been shown to infect and be transmitted by *Ae. aegypti*, allowing genetic modifications of the clone to define the molecular basis of virus infection in mosquitoes.[189] When the domain III of the envelope gene of 17D was inserted into the virulent wild-type (Asibi) infectious clone, the virus was markedly restricted for virus dissemination, indicating that the structural element of the vaccine strain containing putative cell attachment determinants was responsible for attenuation.[120] However, because the virus was still capable of escaping from the midgut barrier at a low rate, the study suggested that dissemination in the vector was also determined by the nonstructural genes.

Subsequent work substituting 17D nonstructural genes NS2A or NS4B into the Asibi backbone showed that the resulting viruses had substantially reduced ability to disseminate.[120] Moreover, when the Asibi prM-E structural genes were inserted into a 17D infectious clone, the resulting virus was attenuated for mosquitoes.[190] These studies showed that 17D virus, which contains multiple mutations in both structural and nonstructural genes, is attenuated for transmission by mosquitoes by virtue of multigenic properties.

Human Infection

Approximately 10^3 virions are inoculated during mosquito feeding.[191] Salivary virus is deposited mainly in the extravascular tissues of the skin of the host during probing, because saliva that is injected intravascularly is apparently reingested by the mosquito during blood feeding.[192] Virus replication is initiated in the epidermis and dermis at the site of inoculation, probably in Langerhans cells, and spreads through lymphatic channels to regional lymph nodes and then to other lymphoid organs and viscera via the bloodstream. In the immunized host, the small mosquito inoculum would encounter a vast excess of antibodies in extracellular transudate and lymph. This suggests that a low level of immunity is sufficient to protect the host against disease. It is not known whether immunity is sufficient to sterilize the mosquito inoculum. However, under conditions of artificial inoculation of 17D vaccine to previously vaccinated subjects or coadministration of vaccine viruses and immune serum, sufficient virus replication occurs for a booster or primary immune response, respectively.[16,183,193] It appears less likely that the amount of antigen inoculated (approximately 50,000 to 100,000 virions) would be capable of stimulating a booster response, with active replication.

The expression of neutralization epitopes (determined with monoclonal antibodies) can differ between yellow fever virus propagated in mosquito and in mammalian cells.[125] The evolutionary and functional relevance of this observation are uncertain, but it might represent a means whereby mosquitoes infected with yellow fever virus would avoid the effects of neutralizing antibodies ingested in a blood meal. In terms of flavivirus vaccine development, host specificity of neutralization determinants suggests that certain arthropod cells might not yield effective inactivated or subunit immunogens for vertebrates.

Other Modes of Human Infection

Laboratory infections with yellow fever virus were common in the prevaccine era and remain of concern today, particularly where unvaccinated clinical laboratory personnel encounter blood from patients during the early stage of illness. Some laboratory infections were probably acquired by the bite of mosquitoes experimentally infected in the laboratory or of wild mosquitoes infected after feeding on experimental animals; others were the result of direct contact with blood or aerosols of dried virus.[14,194–196] The stability of yellow fever virus is sufficient to permit transmission within short periods after generation of an infectious aerosol in the laboratory.[197] Under experimental conditions, a dose of only 10 mouse median lethal doses (MLD_{50}), equivalent to approximately 100 plaque-forming units (PFU), delivered by aerosol was sufficient to induce lethal infection in rhesus monkeys.[198] The absence of direct interhuman transmission indicates that virus is not shed in secreta or excreta at sufficiently high levels for transfer by contact or aerosols. There is no evidence that black vomit or urine is infectious. However, on numerous occasions, transmission has occurred between separately caged monkeys housed in a single room, possibly by aerosol spread.[199] Findlay and MacCallum[199] infected monkeys by a mucosal (intragastric) route and Bauer and Hudson[200] transmitted yellow fever virus to monkeys by rubbing virus on unbraided skin, a technique that might have exposed epidermal Langerhans cells to infection. Monkeys were efficiently infected with 17D vaccine applied to the skin by rubbing with a device that simply stripped the stratum corneum.[201] Some infections in laboratory workers may be explained by contact with viremic blood, but it remains unclear whether infection occurred via intact skin, via abrasions, or by contact with mucosal membranes.

There has been at least one case of perinatal transmission of wild-type yellow fever virus from a woman who developed her initial symptoms of yellow fever 3 days prior to giving birth.[202] The infant developed symptoms 3 days after birth and had yellow fever viral RNA in a blood sample obtained 5 days after illness onset. The infant unfortunately died of fulminant yellow fever on the twelfth day of life. In addition to perinatal transmission, the recent transmission of 17D vaccine to several infants via breastfeeding suggests that the natural virus may be spread the same way via either breast milk, in ingested blood, or possibly by inhalation.[203–205]

Yellow fever virus was extensively investigated in the U.S. Biological Weapons Program. Whereas the virus could infect by the aerosol route, it was considered too thermolabile for successful weaponization. Instead, extensive studies were undertaken on the use of *Ae. aegypti* as an entomologic weapon capable of delivering the virus.[206,207]

Clinical Description

The clinical spectrum of yellow fever is very broad, including subclinical infection, abortive infection with nonspecific flu-like illness, and potentially lethal hemorrhagic disease. This variability makes the clinical diagnosis of sporadic cases difficult and is responsible for the underestimation of morbidity and inflation of case-fatality rates when only cases of full-blown yellow fever are enumerated. As with many other infections, this variability in response is due to intrinsic and acquired host resistance factors and probably to differences in the pathogenicity of virus strains.

After an incubation period of 2 to 9 days (median, 4.3 days),[182] clinical disease begins abruptly with rigors and headache. The illness is often characterized by three stages.[14,208–210] The first stage, referred to as the period of infection, lasts 3 to 4 days and is marked by the virus being present in the blood.[14,211] Levels of the virus usually peak in the blood around days 2 to 3 of illness with titers of up to 5.6 $\log_{10}$ mouse intracerebral LD_{50}/mL, which may be equivalent to approximately 6.6 $\log_{10}$ PFU in cell culture.[211] This stage of illness is characterized by

fever, malaise, prostration, headache, photophobia, lumbosacral pain, pain in the lower extremities (particularly the knee joints), generalized myalgia, anorexia, nausea, vomiting, restlessness, irritability, and dizziness.[212] On physical examination the patient appears toxic, with hyperemia of the skin; congestion of the conjunctivae, gums, and face; epigastric tenderness; and tenderness and possible enlargement of the liver. The tongue is characteristically small and pointed and bright red at the tip and sides, with a white coating in the center. Early clinicians made much of this arcane sign, and it has stood the test of time. Initially, the pulse rate is high, but by the second day there is a bradycardia relative to fever (Faget sign). The average fever is 38.9°C to 39.4°C and lasts 3.3 days, but temperature can rise as high as 40.6°C. Young children can experience febrile convulsions. Laboratory abnormalities include leukopenia (1.5 to 2.5 $\times$ 10^9 cells/L) with a relative neutropenia. The leukopenia occurs precipitously, in concert with onset of illness.[14] Between 48 and 72 hours after onset, serum transaminase often are elevated and usually precede the appearance of jaundice.[213]

The period of infection may be followed by a distinct period of remission (also referred to as a period of calm), with abatement of fever and symptoms lasting up to 48 hours.[214] The remission is often not obvious or very brief. In cases of abortive infection, the patient simply recovers at this stage. Such cases typically remain anicteric, and the nonspecificity of the syndrome makes it impossible to diagnose yellow fever clinically except during an epidemic. A recent model that used data from previous outbreaks and serosurveys estimated that 55% of yellow fever virus infections are asymptomatic and 33% results in mild disease.[215]

The third stage of the disease, the period of intoxication, occurs on the third to sixth day after onset and is characterized by jaundice and the development of often life-threatening signs and symptoms. Approximately 12% of persons infected with yellow fever virus will enter the period of intoxication.[210,215,216] During this period, fever can reoccur, and there is relative bradycardia, nausea, vomiting, epigastric pain, jaundice, oliguria, and a hemorrhagic diathesis. Virus disappears from blood and antibodies appear. The subsequent course reflects dysfunction of multiple organ systems, including the liver, kidneys, and cardiovascular system. High levels of circulating proinflammatory cytokines are present, and the overall picture has the clinical characteristics of the systemic inflammatory response syndrome and multiple organ failure.

Serum aspartate aminotransferase and alanine aminotransferase peak early in the second week of illness and fall rapidly over a few days in patients who recover. Aspartate aminotransferase levels typically exceed alanine aminotransferase, probably owing to direct viral injury to myocardium and skeletal muscle. This distinguishes yellow fever from viral hepatitis, in which alanine aminotransferase levels typically exceed aspartate aminotransferase levels. Alkaline phosphatase levels are normal or only slightly elevated. Direct bilirubin levels are typically between 5 and 10 mg/dL.[217]

Kidney dysfunction is marked by an increase in albuminuria, reduction in urine output, and rising azotemia. Albumin levels in the urine typically range between 3 and 5 g/L but can reach 20 g/L. Serum creatinine levels are three to eight times normal. In some patients who survive the hepatitis phase, kidney failure predominates.[218] Death is preceded by virtually complete anuria. The hemorrhagic diathesis is manifested as coffee-grounds hematemesis, melena, hematuria, metrorrhagia, petechiae, ecchymoses, epistaxis, oozing of blood from the gums, and excessive bleeding at needle-puncture sites. Laboratory correlates include thrombocytopenia, prolonged clotting and prothrombin times, and reductions in clotting factors synthesized by the liver (factors II, V, VII, IX, and X). Some patients have clotting abnormalities that suggest disseminated intravascular coagulation (DIC), including diminished fibrinogen and factor VIII and the presence of fibrin split products.[219,220]

The clinical significance of myocardial injury remains poorly understood. The electrocardiogram can show sinus bradycardia without conduction defects, ST-T abnormalities, particularly elevated T waves, and extrasystoles,[14,221] presumably the result of virus replication and direct viral injury to the myocardium. Bradycardia can contribute to the physiologic decompensation associated with hypotension, reduced perfusion, and metabolic acidosis in severe cases. Acute cardiac enlargement can occur during the course of yellow fever infection.[14]

Central nervous system (CNS) signs include delirium, agitation, convulsions, stupor, and coma. In severe cases, the cerebrospinal fluid (CSF) is under increased pressure and might contain elevated protein but no cells. In one case, yellow fever virus was recovered from CSF after death.[222] In patients dying of yellow fever, CNS signs appear to result from cerebral edema or metabolic factors, based on the virtual absence of inflammatory changes in brain tissue. Pathologic changes include petechiae (perivascular hemorrhages) and edema.[223] True yellow fever viral encephalitis is exceedingly rare, with few extant clinical case reports of paralysis, optic neuritis, and cranial nerve palsy suggesting neurologic infection, but without substantiating virologic evidence to differentiate encephalitis from encephalopathy.[224,225]

The critical phase of the illness occurs between the fifth and 10th days, at which point the patient either dies or rapidly recovers.[214,217,226] A model incorporating data from several outbreaks estimated the case-fatality rate for severe yellow fever cases of 47%.[215] Characteristics noted to be potential risk factors for death include male gender, older age (>40 years), jaundice, leukocytosis, and higher levels of liver transaminases, bilirubin, and blood urea nitrogen.[209,211–213,217,226–228]

In one series of 103 hospitalized patients in Nigeria, the average stay in hospital for surviving patients was 14 days (range, 5 to 42 days) and the average duration of the acute illness was 17.8 days.[226] Although convalescence may be associated with weakness and fatigability lasting several weeks, healing of the liver and kidney is typically complete, without postnecrotic fibrosis. In some cases, jaundice and elevations in serum aminotransferases persist for months after onset.[213,217,229] It is uncertain whether patients with such atypical signs have had other underlying hematologic or hepatic diseases. In one study, the outcome of yellow fever in hepatitis B surface antigen–positive and –negative patients was similar.[230]

Complications of yellow fever include superimposed bacterial pneumonia, parotitis, and sepsis associated with recovery from renal tubular necrosis.[208,226] Late deaths during convalescence have been ascribed to myocarditis, arrhythmia, or heart failure, but documentation of these events is poor.[212]

Risk Factors for Developing Disease and Factors Impacting Disease Severity

Demographic and Occupational Risk Factors. The age, sex, and occupational distribution of yellow fever in South America and Africa differ. In South America, most disease is caused by the jungle transmission cycle where humans are infected by tree-top dwelling mosquitoes that previously fed on viremic monkeys.[153,165] Therefore, occupational activities, such as forest clearing, logging, and road construction, increase the risk of the disease.[165] Most of these activities are performed by young male adults.[231,232] The prevalence of immunity in male residents exceeds that in female residents by 2.5- to 7.5-fold.[233] The age and sex distribution of jungle yellow fever

cases differs from that observed in South America during *Ae. aegypti*–borne epidemics in the early 20th century.[233] In the urban transmission cycle, *Ae. aegypti* are breeding in and around houses and sustaining interhuman transmission of virus; thus a high prevalence of infection is often seen in children and women who are more likely to be in homes when the mosquitoes are active.

In Africa, the prevalence of natural immunity accumulates rapidly with age, so that children are at highest risk (Table 63.2).[163,209,212,234–251] A high attack rate in children (>70%) typically reflects an area where older persons are protected by previous yellow fever vaccination campaigns (e.g., Senegal, 1965; Burkina Faso and Ghana, 1983; Mali, 1987). However, in some epidemics affecting populations without prior vaccination, the attack rate has also been higher in children. In The Gambia, the disease incidence in persons 0 to 19 years old was significantly higher than in older adults ($P < .01$), possibly owing to naturally acquired yellow fever or heterologous flavivirus immunity in adults.[252] In Africa, a slight excess of cases among male residents has been observed during epidemics (Table 63.2). This pattern was seen regardless of the role of domiciliary *Ae. aegypti* or sylvatic vectors, and it is thus difficult to explain on the basis of differences in human behavior or exposure to mosquito bites. The higher percentage of male patients has been observed, not only among notified or hospitalized patients, but also in population-based surveys, indicating that it is not a result of reluctance of female patients to seek medical treatment. Serologic data have shown neither a consistently higher incidence of infection nor susceptibility to illness among male residents,[243,252] but limited sample size and sampling biases might preclude detection of small differences.

There are few data on the relationship between severity of illness and age. In the 1921 epidemic in Peru, the case-fatality rate was highest in infants and children 0 to 5 years old and in older adults (>50 years).[228] Other authors noted a higher case-fatality rate among the elderly,[209,211,227] but lethality in infants was not always assessed in these studies. Elderly persons have a higher risk than young adults of developing serious adverse reactions to yellow fever 17D vaccine,[253–255] and as discussed below in "Effects on Immune Response: Age," have enhanced viremia and delayed antibody responses after vaccination compared to younger persons.[256] Increased severity of illness in elderly persons is known to occur in other flaviviral infections, notably from Japanese encephalitis, St. Louis encephalitis, and West Nile viruses. In a mouse model, age-dependent defects in antibody response to West Nile virus were linked to delayed germinal center formation in lymph nodes draining the site of infection.[257]

Although data from some outbreaks and case series suggest that males are more likely than females to die of yellow fever,[227,258] this finding is not reported consistently in other studies. In fact, in the Kenyan outbreak from 1992–93, female patients were 10.9 times more likely to die than male patients.[236]

Race and Ethnicity. The older literature makes repeated reference to racial differences in the lethality of yellow fever, rates being lower in blacks than whites during outbreaks in West Africa, tropical America, and the United States.[209,259,260] It is uncertain whether the apparent increased resistance of blacks reflects acquired immunity or is a result of genetic factors. The question of racial differences in susceptibility to yellow fever will be resolved only by well-controlled epidemiologic and serologic studies in the setting of an outbreak affecting both races.

Genetic Factors. Resistance and susceptibility to flavivirus, including yellow fever virus, could be linked to genetic factors but, if so, they are likely to be multifactorial in humans.[261] In mice, flavivirus susceptibility has been mapped to a mutation in an allele in one of eight genes *(Oas1b)* encoding 2′5′ oligoadenylate synthetase (OAS), an enzyme important in type 1 IFN-mediated innate immunity.[262,263] A high degree of polymorphism in *Oas1* genes and mutations conferring susceptibility to flaviviruses might determine susceptibility to flaviviruses in humans[264]; in one fatal case of viscerotropic disease following 17D vaccine, a mutation in an *Oas1* allele was found that could have contributed to increased susceptibility.[265]

Genetic background also influences the immune response to flaviviruses in mice and to a limited degree in humans.[266,267] A case of viscerotropic disease following yellow fever 17D had wild-type OAS genes but polymorphisms in chemokine receptor 5 (CCR5) and its ligand RANTES (regulated upon activation, normal T-cell expressed and secreted).[266] The role of genetic factors in innate and adaptive immune responses to yellow fever infection has not been directly evaluated, and it is an area for future research with respect to both the natural disease and serious adverse events associated with 17D vaccine.

Virus-Specified Factors. Wild-type yellow fever virus strains in Africa and South America are classified into at least seven genotypes and there is microheterogeneity at the sequence level among strains within these groupings.[2,43,44,57] In animals, these wild-type yellow fever virus strains differ with respect to neurovirulence for mice or viscerotropism for monkeys.[268–270] Deubel and colleagues found that South American strains were neuroinvasive for 8-day-old mice,[65] whereas African viruses were not, and they suggested that the higher case-fatality rates in South America could be the result of strain differences in virulence. On the other hand, it was the impression of early workers that the South American viruses were less often lethal for rhesus monkeys.[271] Miller and colleagues showed that the mosquito responsible for epidemic transmission in Nigeria had a low vector capacity,[272] and they proposed that the vector served as a genetic bottleneck for selection of a virulent virus strain able to elicit high viremias in humans. No data exist on the potential virulence of the different wild-type yellow fever strains in humans. These data would be difficult to obtain because multiple strains within each genotype would have to be evaluated and because single mutations can affect the biological behavior of yellow fever virus.

Pathogenesis

Yellow fever virus has been found to be both viscerotropic, referring to the ability to cause viremia and to infect and damage liver, spleen, heart, and kidneys, and neurotropic, referring to the ability to infect the brain parenchyma and cause encephalitis. Wild-type yellow fever virus strains are predominantly viscerotropic in primates, including humans. With susceptible nonhuman primates, even if the virus is inoculated intracerebrally, death is from hepatitis rather than encephalitis. However, when a small amount of antibody is given to a monkey shortly before or at the same time as the virus is injected intracerebrally, the animal dies of encephalitis, presumably because the antibody is able to protect peripheral organs but not the brain.[225] This experiment reveals the essential duality of wild-type yellow fever virus (viscerotropism and neurotropism).

Antibody and (presumably) cellular responses occur coincident with the clinical crisis (period of intoxication), and both free virions and hemagglutinating, complement-fixing, or immune precipitating antigen, likely NS1, may be found in blood together with antibody at this time, suggesting that immune clearance of infected cells, associated with release of cytokines, might play a role in the pathogenesis of capillary

TABLE 63.2 Age and Sex Distribution of Yellow Fever Cases for Selected Epidemics in Africa, 1926–95[a]

Epidemic		Age Distribution					
Year	Country	Cases in Children (Age Range [y])	Total Cases	Children as Percentage of Total	Male/Female Ratio	Presumed Vectors (*Aedes* spp.)	Reference
1926–28	Ghana, Nigeria	32 (0–19)	122	26	2.3:1	*?Ae. aegypti*	Beeuwkes, 1936[209]
1940	Sudan (Nuba Mountains)	110 (0–19)	306	36	1.7:1	*Ae. aegypti, Ae. vittatus,* other sylvatic vectors	Kirk, 1941[212]
1965	Senegal (Diourbel)	86 (0–19)	89	97	—	*Ae. aegypti*	Brès et al, 1967[247]
1969	Nigeria (Jos Plateau area)	38 (0–19)	209	18	2.5:1	*Ae. luteocephalus*	Carey et al, 1972[238]
1969–1970	Ghana	99 (0–15)	164	60	—	*Ae. aegypti*	Addy et al, 1986[240]
1970	Nigeria (Okwoga District)	35 (0–19)	76	46	~ 1:1	*Ae. africanus*	Monath et al, 1973[239]
1977–1980	Ghana (Volta and Eastern Regions)	87 (0–15)	294	30	—	*Ae. aegypti*	Addy PA, Minami K, Agadzi VK, 1986[240]
1982	Côte d'Ivoire (Mbahiakro Subprefecture)	43 (0–15)	90	48	—	*Ae. aegypti*	Lhuillier et al, 1985[235]
1983	Burkina Faso (Manga and Fada N'Gourma regions)	40 (0–15)	45	89	~ 1:1	*Ae. furcifer*	Baudon et al, 1986[234] Roux et al, 1984[241]
1983	Ghana (Northern Region)	74 (0–15)	87	85	—	*Ae. aegypti*	World Health Organization, 1989[249]
1986	Nigeria (Oju LGA)	20 (0–19)	39	51	2:1	*Ae. africanus*	De Cock et al, 1988[244]
1987	Nigeria (Oyo State)	72 (0–19)	102	71	1.4:1	*Ae. aegypti*	Nasidi et al, 1989[163]
1987	Mali (Kati Cercle)	100 (0–15)	143	70	2.1:1	*Ae. furcifer, Ae. aegypti*	Kurz, 1988[248]
1990	Cameroon (Extreme North Province)	91 (0–9)	182	73	—	*Ae. aegypti*	Vicens et al, 1993[242]
1991	Nigeria	1209 (0–15)	2229	54	1.1:1	*Ae. aegypti*	WHO, 1993[245]
1992–1993	Kenya (Baringo and Elgeyo Marakwet Districts)	18 (0–19)	54	33	1.8:1	*Ae. africanus*	Sanders et al, 1998[236] WHO, 1993[246]
1993–1994	Ghana (Upper West Region)	47 (0–15)	69	68	2:1	Not known	WHO, 1994[250]
1994	Nigeria (Imo State)	37 (0–15)	116	32	1.3:1	*?Ae. africanus*	WHO, 1995[237]
1995	Senegal (Koungeheul District)	58 (0–19)	110	53	1.4:1	*Ae. aegypti; Ae. furcifer; Ae. metallicua,* and *Ae. luteocephalus*	Thonnon et al, 1998[251]

[a]Table includes data from outbreaks that have clearly documented the age and sex of yellow fever disease cases. For more recent outbreaks (e.g.., Uganda, Sudan, Ethiopia, Angola, and Democratic Republic of Congo), these data are not available.
WHO, World Health Organization.

leak and shock.[273,274] ter Meulen and colleagues found a pattern of elevated pro- and antiinflammatory cytokines (interleukin [IL]-6, tumor necrosis factor [TNF]-α, monocyte chemoattractant protein [MCP]-1, IL-1–receptor antagonist, IL-10), resembling bacterial sepsis in patients with fatal yellow fever, whereas patients with nonfatal yellow fever and without hemorrhagic diathesis only had antiinflammatory cytokine elevations.[275] Similar findings have been reported in cases of viscerotropic disease associated with 17D vaccine. Overall, these findings suggest that a cytokine storm, and in particular the vasoplegic response to the exuberant immune response, can contribute to lethality.

The cell types infected in vivo in viscerotropic infections are only partially defined. In the principal target organ, liver, Kupffer cells and hepatocytes are targets for replication. Human dendritic cells have been investigated in vitro following infection with 17D virus. A recent study that compared histopathologic features and immunohistochemical staining on tissues from persons who died following either wild-type yellow fever virus infection or viscerotropic disease secondary to 17DD vaccination found similar histopathology and immunohistochemical staining of hepatocytes and Kupffer cells for both conditions.[276] However, with viscerotropic disease cases, there was also staining of mesenchymal calls in the liver as well as other tissues, suggesting mesenchymal cell staining is unique and pathogenomic for viscerotropic disease caused by 17DD virus.

In rodents, yellow fever virus is principally neurotropic, and the only extraneural organ showing significant virus replication is the adrenal gland.[271] Mice develop encephalitis only after intracerebral, intraocular, or intranasal inoculation. The time to death is typically 7 to 10 days, depending on strain and brain passage history (neuroadaptation). Mice infected by the peripheral route develop encephalitis if the blood-brain barrier is not completely developed (as in suckling mice up to 5 to 7 days of age) or is compromised by sham intracerebral inoculation. In general, yellow fever virus is not neurotropic in humans. However, similar to what is seen with young mice, human infants are at increased risk of developing neurotropic disease following vaccination with yellow fever vaccine virus. Cases of encephalitis in young infants who acquired yellow fever 17D vaccine infection orally via breast milk from recently vaccinated lactating mothers emphasizes the susceptibility of very young infants to neurologic infection.[203–205] The pathway whereby virus invades the brain after parenteral inoculation is not established but is likely to be via the bloodstream, whereas in the case of exposure of infants through breastfeeding, the route is less clear. It could be via the olfactory apparatus or a mucosal route to the bloodstream. In experimental studies, monkeys were infected by virus inserted in the stomach via a catheter.[199] The basis for age-related susceptibility is uncertain. The blood–brain barrier is incomplete and matures during the first year of life. Zisman and colleagues suggested that development of resistance with age was related to maturation of macrophages involved in yellow fever virus clearance.[277]

The pathophysiology of yellow fever in rhesus monkeys and humans is characterized by liver dysfunction, kidney failure, coagulopathy, and shock[273,278,279]; monkeys develop a more-fulminating illness than humans, lasting only 3 to 4 days. Higher viral doses shorten the incubation period but do not alter the duration or outcome of illness,[280] implying that innate immune responses (e.g., IFN, cytokines, and natural killer [NK] cells) are downregulated and insufficient to clear even a minimal infection. Flaviviruses, including yellow fever virus, have multiple virus-specified mechanisms for evading innate immunity, including blocking of the IFN-induced JAK (Janus kinase)/STAT (signal transducer and activator of transcription) signaling pathway.[281] In the hamster model of viscerotropic yellow fever, proinflammatory cytokines (IFN-γ, IL-2, and TNF-α) were significantly reduced and the regulatory cytokine IL-10 significantly increased in the liver during the critical stage of virus replication, indicating a state of functional immune impairment.[282] The virus is rapidly internalized and cells are activated and serve to present antigens even though replication may be restricted.[118] Human vascular endothelial cells are susceptible to infection in vitro, with release of RANTES and IL-6, suggesting that endothelial infection and the resulting inflammatory response could mediate vascular leak in vivo.[283]

The course of infection following subcutaneous inoculation of wild-type yellow fever virus in the monkey model has not been investigated, but in the initial stage of infection it is likely to follow the same course as described for the 17D vaccine strain, which multiplies in skin at the site of inoculation and spreads to draining lymph nodes, then central lymph nodes, and subsequently to visceral organs.[284] After intraperitoneal inoculation of rhesus monkeys with wild-type virus, Kupffer cells in the liver are infected first (24 hours after inoculation). Virus is then detectable on day 2 in serum and kidney and on day 3 in bone marrow, spleen, and lymph nodes.[273] Early injury to Kupffer cells is also noted after subcutaneous infection of monkeys.[279,285] Infection and degeneration of hepatocytes is a relatively late event, occurring in the last 24 to 48 hours before death in the monkey and in the last phase of infection in humans. In fatal human cases, a median of 75% (range, 5% to 100%) of hepatocytes undergo coagulative necrosis.[286]

Infection with yellow fever virus induces pathologic changes in several organs, including liver, kidney, heart, and lymphoid tissues. The outcomes are a result of direct viral cytopathic effect, the necrosis and apoptosis of hepatocyte cells in the midzone, accompanied by minimal inflammatory response as well as low-flow hypoxia and cytokine overproduction. Quaresma and colleagues[287] review these events. Yellow fever virus infections typically affected the midzone of the liver lobule, with sparing of cells bordering the central vein and portal tracts. The reason for this peculiar distribution of hepatic injury is unknown. Midzonal necrosis has been described in low-flow hypoxia, owing to adenosine triphosphate depletion and oxidative stress of marginally oxygenated cells at the border between anoxic and normoxic cells,[288] and a similar mechanism might contribute to injury in yellow fever infection. However, yellow fever virus antigen and RNA have been observed principally in hepatocytes in the midzone,[289,290] suggesting a predilection of these cells to virus replication.

Injury to hepatocytes is characterized by eosinophilic degeneration with condensed nuclear chromatin (Councilman bodies), indicating apoptosis, rather than by ballooning and rarefaction necrosis seen in virus hepatitis and Labrea hepatitis.[291] Apoptosis has been confirmed in liver tissue of fatal human cases of dengue hemorrhagic fever, in dengue and yellow fever–induced cell death of human hepatocyte cells in culture, and in an immunocytochemical study of liver samples from fatal human cases of yellow fever showing staining for Fas ligand on cells in the hepatic midzone.[292–295] The apoptotic mode of cell death, rather than ballooning necrosis, might explain the minimal inflammation, principally characterized as $CD4^+$ T cells,[296] in hepatic tissue affected by yellow fever. Quaresma and colleagues showed that the midzonal cellular response associated with apoptosis included macrophages, NK cells, and $CD4^+$, $CD8^+$, $CD68^+$ Kupffer, and $CD20^+$ cells.[289,292,297] The portal tracts also showed evidence of immune activation. Although the local inflammatory responses were modest, they reflect the sequential involvement of innate and adaptive immune activation mechanisms related to yellow fever virus infection of the hepatic target tissue. Other hepatic

changes associated with yellow fever virus infection of the liver include microvesicular fat and ceroid or lipofuscin deposits and intranuclear (Torres) bodies. Because little inflammation occurs, the reticulin framework is preserved and complete healing occurs without residual fibrosis.

Kidney pathology is also characterized by eosinophilic degeneration and fatty change of renal tubular epithelium without inflammation. These changes might represent late-stage injury following shock. In monkeys, oliguria with maintenance of tubular function indicated prerenal failure associated with hypotension and the hepatorenal syndrome; acute tubular necrosis was a terminal event.[279] Yellow fever virus antigen was found in renal tubular cells of fatal human cases, suggesting that direct viral injury is responsible.[298] Glomerular lesions (Schiff-positive changes in basement membrane and degeneration of cells lining the Bowman capsule), and yellow fever antigen in glomerulae 2 to 3 days after infection have been observed in monkeys, implying that direct viral injury accounts for albuminuria observed in advance of kidney failure (Monath TP, unpublished observation, 1980).[299] The reports of finding yellow fever 17D virus (genomes) in the urine of 44% of vaccinated subjects, with samples taken as late as 25 days after vaccination, suggests that the kidney is a site of replication in humans, because viremia is generally cleared by the second week after vaccination.[300] However, in monkeys, 17D genomes were not detected in kidney tissue after 17D vaccination, but lymph tissues remained positive after clearance of virus from blood by antibody.[284] Thus, it is possible that shedding of genomes in urine reflects renal clearance of virus from other organs. Other flaviviruses, including dengue and members of the Japanese encephalitis complex, have also been found in urine.

Direct virus injury to myocardial fibers, which show cloudy swelling and fatty changes and viral antigen, can contribute to shock.[298,301,302] DIC and decreased synthesis of vitamin K–dependent coagulation factors by the liver contribute to the bleeding diathesis.[278] Platelet dysfunction, demonstrated by collagen and adenosine diphosphate–stimulated aggregation, has been reported in the monkey model (Fisher-Hoch S, et al., unpublished observations, 1985). Patients dying of yellow fever show cerebral edema at autopsy, probably the result of microvascular dysfunction.

Lymphocytic elements in the germinal centers of spleen, lymph nodes, tonsils, and Peyer patches are depleted, and large mononuclear or histiocytic cells accumulate in the splenic follicles.[279,286] Necrosis of germinal centers is more striking in monkeys than in humans. It is unknown to what extent the lymphoid injury is the direct result of virus replication.

Immune Response to Natural Infection

Most of our knowledge about the innate and adaptive immune response to yellow fever virus infection is derived from studies of patients receiving the live 17D vaccine (see "Immune Responses to Vaccination" later). However, what is known about the kinetics of the antibody response following wild-type infection is reviewed here.

The humoral response to wild-type yellow fever virus is characterized by the appearance of immunoglobulin (Ig) M antibodies, typically detected either with an enzyme-linked immunosorbent assay (ELISA) or indirect immunofluorescence assay (IFA), during the first week of illness.[234,303,304] IgM levels peak during the second week after onset, and decline rapidly over 30 to 60 days. IgM antibodies have been found to persist for prolonged periods after 17D vaccination, and they might also persist following wild-type yellow fever, but this has not been thoroughly evaluated. The magnitude of the IgM response in cases of primary yellow fever infection is significantly greater than in patients with prior flavivirus exposure, in whom the ratio of IgM to IgG is low. Antibodies with biological activity (goose erythrocyte hemagglutination-inhibition and neutralization) appear rapidly, typically by the fifth day of illness.[17,305,306] However, hemagglutination-inhibiting (HI) and neutralizing antibody responses are not linked in all cases, reflecting different HI and neutralizing antigenic determinants on the viral envelope.[307] HI antibodies recognize antigen preparations of the virus and prevent the antigens from causing agglutination of erythrocytes, a common feature of many viruses. HI antibodies peak between 30 and 60 days after infection, and a significant decline in titer occurs during the succeeding 6 months. Neutralizing antibodies are able to neutralize live virus and prevent the virus from either infecting young mice or susceptible cell cultures. These antibodies persist for many years, if not lifelong, after natural yellow fever virus infection, and they provide complete protection against disease on reexposure to the virus. Neutralizing antibodies have been documented as long as 78 years after illness.[308,309] No documented case of a second clinical yellow fever infection has been reported.

Complement-fixing (CF) antibodies appear during the second week after onset, rise during the convalescent period, and decline between 4 and 12 months after onset. IgM and neutralizing antibody responses following 17D vaccine are generally similar (see "Immune Responses to Vaccination" later), except that CF antibodies are absent in flavivirus-naïve subjects. Antibody responses following primary yellow fever are specific for yellow fever antigen. With affinity maturation, specificity declines, and cross reactions with related flaviviruses appear during the second week after onset.[305] Patients with prior heterologous flavivirus immunity develop broadly cross-reactive antibody responses. The specificity of the immune response differs with the test used: the hemagglutination-inhibition test is the least specific, CF is intermediate, and neutralization is the most specific. The IgM antibody-capture ELISA is specific in cases of primary infection, but cross reactions develop over time and in cases with prior flavivirus experience. Because of the lower sensitivity of the IFA, IgM antibodies are specific in patients with secondary infections.[304]

Protein and Epitope Specificity and Functionality of Antibody Responses to Yellow Fever

The E protein of yellow fever viruses (and other flaviviruses) contains antigenic determinants responsible for neutralization and cytotoxic T-cell responses, and thus it plays the principal role in protective immunity.[130] This was demonstrated by active immunization of mice with recombinant vaccinia virus expressing the E protein[310] and by passive immunization of mice with anti-E monoclonal antibodies.[311,312] These studies demonstrate the role of neutralizing antibodies as a mediator of protective immunity against yellow fever.

Yellow fever–neutralizing epitopes are conformational (composed of discontinuous peptide sequences) or contiguous.[85,90,136] Yellow fever virus contains multiple neutralizing determinants, some of which are conserved across strains.[90,134,135] Three type-specific neutralization epitopes mapped at the genomic level by sequencing escape mutants are found at E-71/72 in domain II (recognized by yellow fever type-specific MAb 2E10), E155 in domain I (recognized by yellow fever type-specific MAb B39), and E305/325 in domain III (recognized by yellow fever substrain-specific MAb 864). Other epitopes show cross-reactive neutralizing activity, and some of these are strongly neutralizing (e.g., an epitope in the fusion loop of the E protein that blocks virus internalization).[313] (See Vaughan and colleagues for an inventory of

epitopes.[314]) The composite polyclonal immune response is therefore capable of protecting against multiple strains of virus that might differ at one or several, but not all, epitopes. This antigenic structure probably underlies the efficacy of vaccination with a single yellow fever strain (17D) against wild-type strains of yellow fever virus.

Neutralization is a multihit phenomenon, and the number of antibody molecules required to neutralize the virus depends on accessibility of the epitope (in general, epitopes on the external surface of domain III are strong neutralizers, and epitopes on domains I and II are less potent) and affinity of the antibody. The most potent neutralizing antibodies have the lowest occupancy requirements for neutralization.[315] The importance of accessibility of epitopes on the complex array of 180 E protein molecules on the intact virion surface has been demonstrated in a number of elegant studies with dengue and West Nile viruses.[315,316] In a study of the fine-specificity of the antibody response to yellow fever 17D, a high proportion of neutralizing activity was associated with antibodies directed to complex quaternary epitopes on the virion surface. Interestingly, domain III-specific antibodies (presumed to have the highest neutralizing activity) as well as broadly flavivirus cross-reactive antibodies were absent or present at very low titers.[317] Similar importance of quaternary epitopes in dengue virus neutralization has been emphasized.

Neutralization occurs both as an extracellular event (in which antibody bound to virus interferes with virion attachment to cell receptors) and intracellularly.[315] Intracellular neutralization is mediated by antibodies inhibiting acid-dependent fusion of virions to the endosomal membrane, thus preventing release of viral RNA into the cytoplasm.[313,315,318] The importance of the Fc domain of neutralizing antibody was demonstrated by comparing the in vitro and in vivo activities of $F(ab')_2$ fragments of monoclonal antibodies.[319] $F(ab')_2$ fragments neutralized strongly in vitro but did not protect against yellow fever virus infection, whereas the full IgG molecule was protective. Presumably, the mediator of protection is complement or Fc-mediated antibody-dependent cell-mediated cytotoxicity, but alteration in reactivity of the hypervariable domain with antigenic determinants could also be involved. The prM proteins of many flaviviruses have been shown to contain epitopes with weak neutralizing activity, but to date such epitopes have not been characterized for yellow fever virus.

The humoral immune responses to nonstructural yellow fever proteins have not been extensively studied in human infections, but their role has been partially explored experimentally. Antibody responses to natural infections with dengue, Japanese encephalitis, and West Nile virus nonstructural proteins NS1, NS3, and NS5 have been described.[320] These antibodies distinguish infection immunity from immunity to inactivated vaccines.[321] Antibody responses to natural infections analyzed by Western blot show that anti-NS1 antibodies are type-specific and thus have value in diagnosing infection with cross-reactive flaviviruses.[322] The NS1 protein is present in the cytoplasm and on the surface of infected cells, is secreted from infected cells, and contains determinants that elicit CF antibodies. MAb analysis of NS1 revealed the presence of both type-specific and cross-reactive epitopes, which are principally conformation-dependent.[323]

Mice and monkeys actively immunized with native or recombinant NS1 were protected against lethal yellow fever in the absence of neutralizing antibody,[324–326] the principal correlate of protection being complement-mediated cytolytic antibodies. Passive transfer of MAbs against NS1 having high complement fixation activity, but not antibodies with low or no complement fixation activity, afforded protection.[327] These studies suggested that antibodies recognizing cell membrane–bound NS1 might promote viral clearance by sensitizing infected cells to C1q-mediated cytolysis. An intact Fc portion of the immunoglobulin molecule is required for protection by anti-NS1, and antibody isotype-dependent differences in protective activities have been demonstrated.[319,327,328]

Natural infection with yellow fever virus is associated with the presence of soluble CF antigen (NS1) in blood during the acute phase of infection[273] and is followed by strong CF antibody responses (presumably directed against NS1). Detection of NS1 antigen early in the course of illness has emerged as an important diagnostic test for dengue, and it is likely that such a test would have value in yellow fever (in particular, for primary infections). Because CF antibody responses occur late after infection, and vaccination with 17D virus does not induce a CF antibody response,[329,330] it is uncertain to what extent complement-dependent anti-NS1 antibodies play a role in vivo in recovery or protection. Further studies in humans are needed to define the kinetics of the anti-NS1 response after natural infection.

Cross Protection

Previous infection with some flaviviruses might ameliorate the clinical severity of yellow fever though the evidence is conflicting. Observational studies going back to 1815 suggested that flavivirus immunity (e.g., to dengue) was the basis for resistance to yellow fever in long-term residents of endemic areas,[331–333] and it was later proposed as a barrier to introduction of yellow fever into Asia.[334–336] Early experiments indicated that passive transfer of dengue antibodies did not protect monkeys against challenge with yellow fever virus.[332] In contrast, monkeys *actively* immunized with dengue were relatively resistant to challenge with yellow fever virus, suggesting that cellular immunity played a role in cross protection.[337] Monkeys actively immunized with two African flaviviruses (Zika and Wesselsbron), but not with West Nile or Banzi viruses, resisted challenge with yellow fever virus.[338] In The Gambia (1978–79), the infection-to-illness (jaundice) ratio was higher in humans with prior flavivirus exposure.[252] However, in Nigeria (Oju Region, 1986), jaundice rates were not significantly different for patients with primary yellow fever virus infection (14/84 [17%]) and superinfections (13/53 [25%]) (odds ratio, 0.62; 95% confidence interval [CI], 0.24–1.56) (De Cock KM and Monath TP, unpublished data, 1987). The discrepancy could reflect differences in the specific heterologous flaviviruses responsible for prior immunity.

In retrospective studies, sera from dengue-immune subjects who had not been vaccinated against yellow fever neutralized yellow fever virus[339,340] (this finding needs to be confirmed in prospective analyses of seronegative patients who sustain dengue infections). A retrospective analysis of an outbreak of yellow fever among military recruits in Ecuador demonstrated that prior immunity to dengue type 2 significantly reduced the clinical severity of yellow fever and protected against death from the infection.[341]

Confirmation of the protective activity of dengue immunity is a matter of considerable importance because dengue occurs in the yellow fever–endemic regions in the Americas and Africa. In a limited retrospective analysis, yellow fever immunization did not provide cross protection of humans against West Nile fever.[342] The hypothetical suggestion has been made that prior yellow fever immunization could enhance dengue infections, leading to an increased incidence of dengue hemorrhagic fever and shock syndrome,[343] but there is no evidence to substantiate this suggestion. Similarly, prior dengue immunity could theoretically diminish the response to live attenuated yellow fever vaccine. This is discussed later

in "Heterologous Flavivirus Immunity" in the section "Results of Vaccination."

Antibody-Dependent Enhancement

Immune enhancement is believed to play a role in the pathogenesis of dengue hemorrhagic fever in patients with nonneutralizing antibodies from a previous dengue infection who are infected with a new dengue serotype. Although antibody-dependent enhancement of flavivirus replication in monocyte/macrophages has been demonstrated in vitro for a number of flaviviruses, including yellow fever,[344–347] the evidence for in vivo enhancement mediated by yellow fever antibodies is mixed. In one study, human volunteers previously immunized with yellow fever 17D had increased immune responses to live dengue-2 vaccine, possibly owing to antibody-mediated enhancement of dengue virus replication[348,349] or to rapid expansion of group-reactive memory T- and B-cell clones. An intriguing observation in a study of a live chimeric yellow fever and Japanese encephalitis vaccine in yellow fever–immune and –nonimmune subjects was a tendency toward higher viremias in the immune subjects, suggesting the possibility of immune enhancement.[193] However, the effect was slight, and the sample size was small. The chimeric virus system provides an ideal setting to test the immune enhancement hypothesis in humans.

Diagnosis

The preliminary diagnosis of yellow fever is based on the patient's clinical features, yellow fever vaccination status, and history of residence or recent travel to a yellow fever–endemic zone. Mild yellow fever cannot be distinguished clinically from a range of other infections and is unlikely to be recognized as yellow fever. Cases of yellow fever with jaundice must be differentiated from viral hepatitis, malaria, leptospirosis, louseborne relapsing fever (*Borrelia recurrentis*), Congo-Crimean hemorrhagic fever, Rift Valley fever, typhoid, Q fever, and typhus, as well as surgical drug-induced, and toxic causes of jaundice.[350] It also needs to be differentiated from other viral hemorrhagic fevers, which usually manifest without jaundice, include dengue hemorrhagic fever, Lassa fever, Marburg and Ebola virus diseases, and Bolivian, Argentinean, and Venezuelan hemorrhagic fevers.[351]

Specific laboratory diagnosis is made by detection of virus, viral RNA, or viral antigen in blood or by serology. Virus is readily isolated from blood during the first 4 days after onset, but isolations as late as 12 days or longer are recorded.[352] Of 90 cases confirmed during a yellow fever outbreak in Côte d'Ivoire in 1982, 27 (30%) were diagnosed by virus isolation from blood; all but three virus-positive patients were in the preicteric stage.[235] The virus can also be recovered from postmortem liver tissue.

Virus isolation was traditionally accomplished by intracerebral inoculation of suckling mice or intrathoracic inoculation of *Toxorhynchites* mosquitoes. Suckling mice develop encephalitis 7 to 14 days after inoculation, depending on the infectious dose; a virus-specific diagnosis may be made by immunofluorescence on impression slides of brain tissue or by serologic methods. Viral antigen is detected by immunofluorescence in head-squash preparations of inoculated mosquitoes after an incubation period of 10 to 12 days. Currently, cell culture is most often used to isolate the virus and is more sensitive than previous techniques.[353] *Aedes pseudoscutellaris* (AP61) cells are more sensitive than other in vitro methods for primary isolation of yellow fever virus[353,354] and show cytopathic effects within 5 to 7 days after inoculation and viral antigen detectable by immunofluorescence in advance of cytopathic effects (e.g., day 3 after inoculation). *Ae. albopictus* (C6/36) cells, *Toxorhynchites amboinensis* cells, and mammalian cells (e.g., Vero, SW13) may be used, particularly if combined with reverse-transcription polymerase chain reaction (RT-PCR) or detection of viral antigen.[355]

RT-PCR is now more commonly used than virus isolation to diagnose yellow fever disease in the acute period owing to its rapid turnaround time and the increased sensitivity it provides over viral isolation.[356] Sera that were negative by virus isolation can contain viral RNA detectable by RT-PCR.[357] A seminested polymerase chain reaction (PCR) analysis used to detect viremia in serum following 17D vaccination serum samples was sensitive enough to detect 1.15 PFU/mL.[358] Although RT-PCR testing has traditionally been available only in more advanced laboratories, recent work to develop more field-ready RT-PCR, more specifically isothermal protocol based on helicase-dependent amplification technology (RT-tHDA), has shown some promise to use this technology in more resource limited settings.[359] RT-PCR has been used to detect wild-type yellow fever viral genome and 17D viral genome in serum and human tissues (liver, spleen)[360–363] and a variety of tissues from nonhuman primates infected with 17D virus.[284] RT-PCR and sequencing is the preferred method for distinguishing wild-type yellow fever from a case of vaccine-associated viscerotropic disease. Using different primer sets along the length of the virus, RT-PCR can be used to sequence the infecting virus and thus help determine the origin of the virus and differentiate between natural infection and possible vaccine virus in the case of serious adverse events that occur in endemic areas. Although RT-PCR has been used to characterize the viremia seen following vaccination, only a limited number of yellow fever cases have been evaluated with RT-PCR. A recent quality assessment of laboratories performing RT-PCR testing for yellow fever viral RNA did suggest problems with sensitivity for wild-type infection with 38% (12/32) of laboratories not detecting wild-type yellow fever virus strains.[364] There was also problem with specificity as 78% (25/32) of laboratories had false-positive RT-PCR result for yellow fever. These data suggest noticeable variability between laboratories performing RT-PCR testing and emphasizes the need for confirmatory testing at reference laboratories.

Rapid, early diagnosis is also possible by measurement of yellow fever viral antigen in serum by immunoassay.[353,365] The sensitivity of the assay for detection of virus in serum is significantly lower than with RT-PCR, approximately 3 $\log_{10}$ PFU/0.1 mL. Under field conditions, antigen-detection ELISA had a sensitivity of 69% and specificity of 100% compared to virus isolation in AP61 cell culture.

Ideally, diagnostic samples should be kept cold or kept frozen on dry ice or liquid nitrogen to maintain stability of infectious virus and RNA. However, a suitable alternative may be to dry the sample on filter paper discs, a procedure commonly used for antibody samples. When maintained at room temperature, yellow fever virus infectivity and RNA was still detectable by culture and RT-PCR after 90 days.[366] Samples for RT-PCR and ELISA do not need to be handled in a way that preserves infectivity; specimens may also be intentionally inactivated as a safety precaution where the diagnosis of dangerous pathogens (e.g., other viral hemorrhagic fevers) is considered.

Identification of yellow fever virus has been accomplished by a highly sensitive microarray amplification and hybridization method as well as NGS.[367,368] Using microarrays with multiple probes or NGS could be useful for differential diagnosis, particularly when the etiology is unclear or their might be several pathogens cocirculating in an area at one time.

Examination of liver reveals the typical pathoanatomic features of yellow fever, including midzone necrosis.[369,370] *Liver*

biopsy should never be performed during the illness, because fatal hemorrhage can ensue. Histopathologic diagnosis may be difficult in patients who die after the second week of illness. Electron microscopy can reveal typical flavivirus particles in intracellular vacuoles.[371] Definitive postmortem diagnosis may be made by immunocytochemical staining for yellow fever viral antigen in liver, heart, or kidney,[290,298,372–374] even in specimens stored for years at ambient temperature. The distribution of virus in the liver is midzonal, suggesting that hepatocytes bordering the central veins and portal tracts undergo less-active virus replication. Viral genome may also be detected in formalin-fixed embedded tissues by hybridization.[290] RT-PCR can be used on RNA extracted from fixed tissues[375] to obtain yellow fever virus sequences from fatal cases as well as historical materials for epidemiologic and evolutionary studies; however, the quality of the formalin-fixation is critical.

Although older methods for serologic diagnosis (hemagglutination-inhibition and complement fixation) are useful, they have been replaced by the IgM-capture ELISA and newer IFAs.[376,377] The presence of IgM antibodies in a single sample provides a presumptive diagnosis, and confirmation is made using a plaque-reduction neutralization test to document a rise in virus-specific titers between paired acute and convalescent samples or a fall in titer between early and late convalescent samples. In general, the sensitivity of yellow fever IgM assays that are currently used is high for wild-type infection (though the sensitivity is lower for IgM formed following vaccination).[364] The specificity of the IgM ELISA is also high in primary infections and in many cases of secondary infection.[303] However, cross reactions complicate the diagnosis of yellow fever by all serologic methods, particularly in Africa, where multiple flaviviruses cocirculate. In a study conducted in Colombia, roughly 40% of both persons infected with wild-type yellow fever virus and those who received 17D vaccine were found to be dengue IgM–positive.[339] Furthermore, the phenomenon of "original antigenic sin" complicates flavivirus serologic investigations. Patients who have had prior heterologous infection and who develop yellow fever can have higher responses to the original virus, and those who have had prior yellow fever virus infection or vaccination and who are subsequently infected with another flavivirus can have higher responses to yellow fever.[342,378]

Detection of NS1 antigen in serum during the acute phase of illness is an important new method that has been successfully applied to the diagnosis of primary infections with dengue viruses.[379] However, antibodies to individual nonstructural proteins have not been investigated for the diagnosis of yellow fever but it should be evaluated with a high priority because it can be used as a bedside test-strip method.

An important diagnostic issue, in situations where yellow fever 17D vaccine is used in areas endemic for yellow fever, is the differentiation of yellow fever vaccine–associated viscerotropic disease (YEL-AVD) from wild-type yellow fever, because these conditions cannot be distinguished clinically. A case in point is the identification of a case of YEL-AVD during a retrospective study of genomic sequences of (supposedly) wild-type yellow fever strains.[380] The differential diagnosis can be made only by genomic sequencing of virus isolate or RT-PCR amplicon, or by MAb analysis of an isolate.[163]

Treatment

Although multiple drugs have been evaluated or used empirically to treat yellow fever disease, to date, none has demonstrated specific benefit.[381,382] Management is supportive and based on symptoms and the organ systems involved.

Supportive Care

In 1984, an expert panel recommended measures to improve the care and management of patients with yellow fever.[210] The recommendations included maintenance of nutrition and prevention of hypoglycemia; nasogastric suction to prevent gastric distention and aspiration; treatment of hypotension by fluid replacement and, if necessary, vasoactive drugs; administration of oxygen; correction of metabolic acidosis; treatment of bleeding with fresh-frozen plasma; dialysis if indicated by renal failure; and treatment of secondary infections with antibiotics. Use of heparin to reverse DIC is reserved for patients with documented consumption of clotting factors and activation of fibrinolytic mechanisms.

The final stage of yellow fever disease has features resembling a cytokine storm or septic shock.[279] Stress-dose corticosteroids (200 to 300 mg/day) have been shown to have therapeutic benefit in patients with septic shock, at least for those with adrenal insufficiency,[383] and appear to have also benefited patients with YEL-AVD.[384] Corticosteroids are indicated for treatment of selected patients with acute disseminated encephalomyelitis (ADEM) associated with yellow fever vaccine. There are no experimental or clinical data on other treatment approaches, such as monoclonal antibodies against cytokines or hemofiltration, for late-stage yellow fever disease. Finally, orthotropic liver transplantation theoretically might be considered as a clinical intervention in fulminant hepatitis caused by yellow fever virus as apoptotic cell death is central to the pathogenesis of yellow fever. However, the feasibility of transplantation should be explored first with a monkey model and even if successful, would have limited utility for the majority of yellow fever cases which often occur in locations where transplantation is not available.

Therapeutic Considerations

Treatment by administration of immune serum or by cross-circulation from an immune donor animal after clinical onset of yellow fever has minimal therapeutic effect.[381] One patient with YEL-AVD was treated with intravenous immunoglobulin (IVIg) during the acute illness and failed to survive suggesting no benefit of the treatment.[265] Furthermore, treatment with a mouse monoclonal neutralizing antibody that was given as a last resort to a yellow fever patient in late-stage hepatorenal failure did not provide any beneficial effect.[385] However, a human/mouse chimeric IgG monoclonal (but not IgM) was shown to protect IFN knockout mice when given before or up to 48 hours after lethal challenge with 17D virus.[386] Based on these available data, it is unlikely that antibody would be useful except in the setting of postexposure prophylaxis when given before onset of clinical disease or as treatment given during the earliest stages of illness or potentially to an immunocompromised individual.[386,387]

There are several reports in the literature on treatment of flavivirus infections of humans (dengue, Japanese encephalitis, and St. Louis encephalitis viruses) with IFN-α claiming improvement or reduced mortality, although the studies were small and not controlled.[388–390] IFNs have been investigated for the prevention and treatment of yellow fever in monkeys. Animals receiving 3 mg/kg of the IFN inducer polyinosinic:polycytidylic acid intravenously 8 hours before or 8 hours after viral challenge had low-level viremia and were significantly protected (71–75% survival) compared to untreated controls (0% survival), but those treated 24 hours after challenge were not protected.[391] IFN-γ administered to monkeys 24 hours in advance of challenge and at daily intervals for 4 days reduced yellow fever viremia and significantly delayed hepatic dysfunction and death.[392] IFN-γ knockout

C57BL/6J mice demonstrated deficient yellow fever viral clearance and reduced numbers of inflammatory cells after intracerebral inoculation when compared to normal C57BL/6J mice also undergoing intracerebral inoculation.[393] The requirement to administer IFNs very shortly before infection or during the incubation period likely suggests that it might not be a viable treatment option for wild-type yellow fever. In a hamster model of yellow fever, an adenovirus vector expressing IFN-α was found to be protective when administered intranasally 7 days before or up to 2 days after a lethal challenge.[394] This outcome appears to be similar to what can be achieved with exogenous IFN treatment.

Molecular targets for rational design and development of antiviral drugs against flaviviruses include both virus-specified functions (e.g., NS5 polymerase and methyltransferase)[395] and host cell enzymes.[396] This field is expanding owing to the interest in developing drugs against dengue and hepatitis C virus; a comprehensive review is not within the scope of this chapter. A partial list of compounds with antiviral activity against yellow fever in vitro, and in some cases in vivo, includes nucleosides and plant-derived alkaloids[397–403] that target inosine monophosphate dehydrogenase (ribavirin, EICAR [5-ethynyl-1-β-D-ribofuranosylimidazole-4-carboxamide], tiazofurin, selenazofurin, and mycophenolic acid), an adenosine inhibitor,[403] orotidine 5′-monophosphate decarboxylase (pyrazofurin and 6-azauridine), pyrazine carboxamine derivatives,[402] cytidine triphosphate synthetase (carbodine and cyclopentenyl cytosine), 2′-C-methylcytidine,[397] dihydrofolate reductase (methotrexate), and sulfated polymers (suramin, pentosan polysulfate, dextran sulfate, and PAVAS [sulfated copolymers of acrylic acid with vinyl alcohol]) that interfere with viral affinity for heparin sulfate on the cell surface.[400,404]

Ribavirin is active against yellow fever virus in vitro, and the mechanism of action appears to be inhibition of cellular inosine monophosphate dehydrogenase and the resulting depletion of intracellular guanosine triphosphate pools[405] but at concentrations that are too high (9–10 mg/mL) for safe and effective treatment in vivo. Monkeys treated with ribavirin were not significantly protected against a yellow fever virus challenge,[406] but dose and formulation might not have been optimized. In a hamster model of viscerotropic yellow fever, ribavirin dramatically reduced liver injury when administered as long as 5 days after infection (the time of peak liver injury in untreated controls).[407] The treatment effect may be explained by the high dose of ribavirin used in that study (80 mg/kg loading dose, followed by 40 mg/kg daily through day 7), which was nearly three times higher than that used in the treatment of human patients with hemorrhagic fevers (e.g., Lassa fever and Hantaan virus infection). If treatment is given earlier (e.g., initiated before or up to 2 days after challenge), a lower dose (50 mg/kg per day) was effective.[408] There are no clinical data to support safety of high doses of intravenous ribavirin that might be expected to ameliorate infection with yellow fever virus. Synergistic effects of ribavirin and related compounds, such as tiazofurin and selenazole, have been demonstrated in vitro but not investigated in vivo.

Interfering RNA targeting the E or NS1 genes has shown activity in yellow fever virus infections in vitro and in mice.[409] Protection was demonstrated in mice treated 12 hours before intracerebral virus challenge with short hairpin RNA-encoding plasmids, which were also injected intracerebrally; various controls showed that the effect was not a result of IFN induction. Formulation and delivery of RNA interference remains a challenge for development of interfering RNA. Other approaches to RNA therapeutics (e.g., RNA aptamers) have not been investigated in yellow fever.

EPIDEMIOLOGY

A detailed comprehension of the geography, seasonality, and incidence of yellow fever virus is critical to the proper use of yellow fever vaccine for both endemic and traveler populations. For more detail on risk factors for disease, see "Risk Factors for Developing Disease and Factors Impacting Disease Severity" under "Clinical Description" above.

Distribution of Yellow Fever Virus

Geographic Distribution

Yellow fever virus occurs in tropical South America and sub-Saharan Africa, where it is maintained in an enzootic transmission cycle involving tree-hole–breeding mosquitoes and nonhuman primates (see "Transmission Cycles" above for more details). The first map of endemic regions based on yellow fever serology surveys conducted in the 1930s[410,411] was prepared by the International Quarantine Commission and published by the United Nations Relief and Rehabilitation Administration (UNRRA) in 1946. This map has been modified from time to time based on new information and in 2008 there was a concerted effort by the World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) to homogenize yellow fever risk maps.[31,412–414] The current risk maps incorporated all available data to establish risk categories of endemic, transitional, low, and no risk (Fig. 63.4). However, much of the data used to determine areas of risk are out of date and in some areas based on scanty serologic data. Updated data, particularly in Africa, are needed to improve knowledge on yellow fever risk areas.

Seasonal Distribution and Climatic Factors Impacting Viral Activity

In South America, the incidence of yellow fever is highest during months of high rainfall, humidity, and temperature (January to May; peak incidence, February and March), corresponding to the activity of *Haemagogus* mosquitoes, which breed in tree holes and are thus dependent on rainwater. Human exposure during agricultural activities is also increased at this time of the year. In the savanna zone of West Africa, cases appear during the mid-rainy season (August) and peak during the early dry season (October), corresponding to the period of maximum longevity of sylvatic mosquito vectors.[415] The domiciliary vector *Ae. aegypti* breeds in receptacles used by humans for water storage and is thus less dependent on rainfall. Where this mosquito is involved in virus transmission, yellow fever can occur in the dry season in rural areas and in heavily settled urban areas. Thus, season is only a partially reliable guide to determining the risk of exposure and to making decisions on the need for immunization of travelers.

Fluctuations in rainfall profoundly affect the abundance of mosquito vectors and the potential for yellow fever epidemics.[150,158–160,416–418] The yellow fever outbreak in The Gambia in 1978 occurred after a period of two successive years of excess rainfall.[416] Similarly, excessive rainfall and prolongation of the rainy season reflected by vegetational indices in satellite images preceded the emergence of a sylvatic yellow fever epidemic in Nigeria in 1986.[418] In Brazil, excessive rainfall and abnormally high temperatures (a consequence of an El Niño event) occurred during December 1999 and the first quarter of 2000, coinciding with the emergence of a large jungle yellow fever outbreak.[419]

Temperature influences the transmission rates of several arboviruses.[420] The extrinsic incubation period of yellow fever

virus in the mosquito vector is very sensitive to temperature, and an increase of a few degrees can shorten the extrinsic incubation period by days, resulting in a significantly increased rate of transmission.[182,421] Even brief exposure to high temperatures (e.g., in a sunlit forest clearing) can have this effect. Warm temperature also increases biting and reproductive rates of *Ae. aegypti*.[422] Thus, long-term environmental change (global warming) might increase transmission rates of yellow fever virus.[423]

Incidence and Disease Occurrence

Endemic and Epidemic Areas

The last global disease estimate for the number of yellow fever cases and deaths was published by the WHO in the early 1990s. The WHO estimated that there were roughly 200,000 cases and 30,000 deaths occurring annually from yellow fever.[424] Since then, updated estimates of the disease burden in Africa have been published with an estimated 130,000 cases and 78,000 deaths occurring from yellow fever in 2013.[425] Overall, the 2013 estimates of disease were less than those from the 1990s, but the estimates of deaths were increased. The reduction in disease cases was attributed to the recent mass vaccination campaigns that have occurred predominantly in West Africa; the increase in deaths was likely the result of more precise estimates of disease occurrence and severity.[27,215,425,426] In the Americas, similar improvements in vaccination coverage have also occurred in recent years,[427] further suggesting that the global disease burden is less than previously estimated.

The disease burden estimates are substantially higher than the actual number of yellow fever disease cases and deaths reported from endemic regions on an annual basis. From 1995 through 2014, there has been a median of 273 yellow fever disease cases (range, 21 to 2794) and a median of 88 deaths (range, 12 to 287) reported annually (Table 63.3).[30,426,428–434] This notable difference between the estimated and reported disease burden is thought to be partly because of occurrence of the disease in remote areas, late recognition of outbreaks, and lack of diagnostic facilities. Where specific investigations have been undertaken, the ratio of actual cases to official notifications varies between 1 and 311 to 1 (Table 63.4).[163,214,236–240,244,247,249,252,435]

In Africa, there are 33 countries that are considered to have endemic transmission of yellow fever.[27] However, risk of

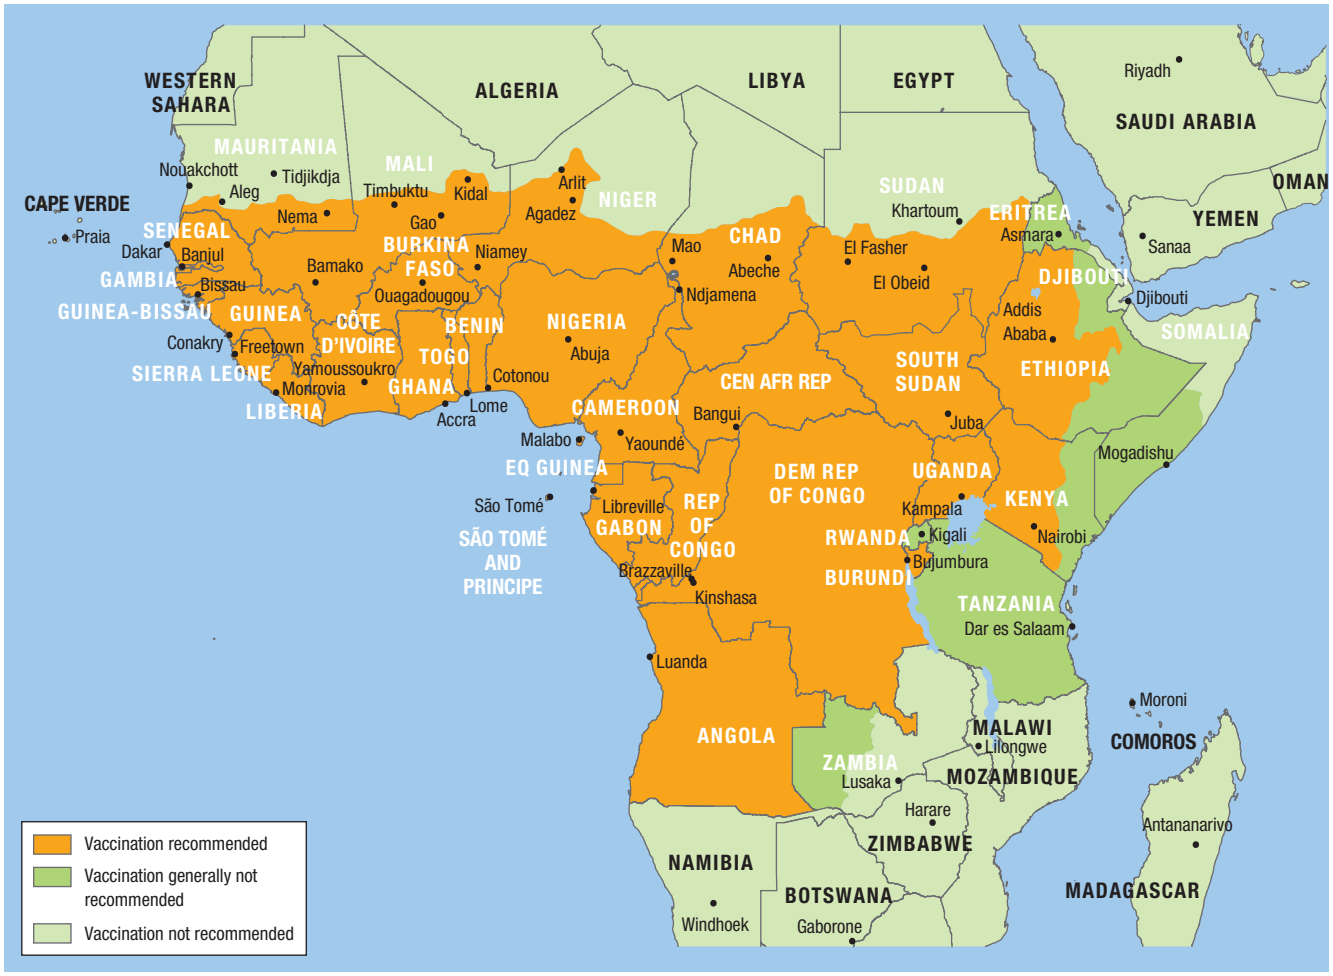

Figure 63.4. Regions of Africa and South America with yellow fever virus activity. Orange denotes areas considered to be endemic for yellow fever. Endemic areas have reported human disease regularly. The darker green denotes transitional areas; these areas have not reported human disease cases but have found antibodies against yellow fever virus and have the right vectors and nonhuman primate species to sustain virus transmission. Areas in light green are areas where there is no yellow fever virus transmission; some of these areas might be at risk for urban transmission as they have the right vectors to transmit the virus readily between humans. *(Modified from Centers for Disease Control and Prevention.* CDC Health Information for International Travel 2016. *New York: Oxford University Press; 2016.)*

Figure 63.4, cont'd

yellow fever disease varies among countries,[51,160] and often within a country, as many countries are not holoendemic.[412] The highest risk for disease occurs in West Africa where disease cases are reported on an annual basis (see Table 63.3).[436] Central and East African countries have a lower disease risk, often with no disease cases reported for several decades.[32a,51,160] For instance in Ethiopia, the first recognized outbreak of disease occurred in the early 1960s and no disease activity was reported again until 2013.[30] Another example is Angola, which experienced one of the largest disease outbreaks in recent history in 2015–16. Prior to this they last reported cases in 1988.[33] The differential risk of yellow fever, falling as one moves west to east and south in Africa, is thought to be potentially related to differences in the strains circulating in the region, in the frequency in which humans come into contact with sylvatic cycles, in population immunity, and in seasonal variations.[51,160]

From 1995 to 2014, there were 7714 cases reported from Africa countries. However, on an annual basis the number of cases reported varied between seven and 2677 cases (median, 165), suggesting inconsistency of reporting (Fig. 63.5 and see Table 63.3). During the years 1995 to 2014, there were 1062

[a]List includes outbreaks where an epidemiologic investigation was performed to estimate the actual number compared to the number of cases that were officially notified.

deaths reported from African countries, for a case-fatality ratio of 14%. The case-fatality rate in Africa is likely underestimated by official reports, because data are unavailable on the number of deaths. In addition, patients with severe yellow fever are often removed from hospitals by relatives, so that the outcome of disease is not recorded. The annual incidence varies by country and region, reflecting periodic expansions of yellow fever viral activity, but accuracy of reporting limits interpretation.

Major epidemics in Africa are a consequence of interhuman transmission by domestic *Ae. aegypti* and sylvatic *Aedes* spp. vectors present in high-density, high human populations, and low immunization coverage. During outbreaks of disease in Africa, it has been estimated through serosurveys that roughly 20% to 40% of a population will become infected with yellow fever.[163,214,237,241,242,244,247,252,437] In comparison, the burden of endemic yellow fever virus infection has been less-well characterized. In Nigeria (1970–71), a laboratory diagnosis of yellow fever was made in two of 205 patients (1%) hospitalized with jaundice in areas without epidemic activity.[438] Using data from serologic surveys in Nigeria and an estimated 7:1 infection-to-illness ratio, the annual incidence of overt infection with jaundice was estimated to be between 1.1 and 2.4 per 1000 population, and yellow fever deaths were estimated to be between 0.2 and 0.5 per 1000 population.[439] This estimate of endemic disease is likely lower as one moves eastward in Africa. Based on a serologic survey conducted in Central African Republic during 2009, the rate of disease with jaundice was 0.9 per 1000 population and death was 0.2 per 1000 population.[243] While indicating that endemic yellow fever may be a silent cause of significant morbidity, the incidence levels are 25- to 50-fold lower than those occurring during epidemics, and, thus, are below the threshold of detection by existing passive surveillance systems. It is likely that endemic yellow fever activity varies considerably from year to year and that it causes thousands of unrecorded deaths annually in West Africa. This provides a strong rationale for preventive immunization.

There are 13 countries in South and Central America that are considered endemic for yellow fever disease. Although only sporadic cases and small outbreaks are reported in these regions, nearly all major urban areas in the American tropics have been reinfested with *A. aegypti* and many persons living in these regions have not been vaccinated.[32b] Improvements in roads, increased settlement within the Amazon region, and more ready movements between these areas have led to more unvaccinated people moving in and out of endemic zones.

Between 1995 and 2014, 2432 cases (median, 95 cases; range, 14–542 cases/year) and 1164 deaths (case fatality ratio of 48%) were reported from South American countries (see Table 63.3 and Fig. 63.5). The annual incidence varies by country owing to fluctuating wandering epizootic activity that depends on herd immunity levels in monkey populations. The lower case numbers and incidence of yellow fever in South America than in Africa is a consequence of transmission by enzootic vectors (principally from monkey to human), low densities of vectors, susceptible monkeys and human hosts, and relatively high vaccination coverage. The higher case-fatality rate in South America probably reflects hospitalization of severe cases and surveillance based on death reports and the postmortem examination of livers rather than the South American virus strains being more virulent than those in Africa.[65]

Increased virus transmission, particularly in the endemic areas of South America, occurs with a periodicity of 7 to 10 years, in part because immunologically susceptible monkey populations are replenished at a slow rate after epizootics. Larger expansions of the disease into areas on the edge of the endemic region, such as Argentina, Paraguay, Trinidad, and coastal Brazil occur less frequently often at intervals of more than 30 to 40 years and was last seen from late 2016 to early 2017.[32,32b]

In South America, disease cases are reported routinely from Bolivia, Brazil, Colombia, and Peru. In comparison, Guyana, Panama, Suriname, and Trinidad have not reported cases for several decades. The last report of yellow fever laboratory-confirmed cases from French Guyana was in 1998, from Venezuela in 2005, and from Ecuador in 2011. Argentina and Paraguay last reported cases in 2008, which was the first disease activity reported since the 1960s and 1970s, respectively.[440]

For additional reviews on the epidemiology of yellow fever epidemiology see references 28, 170, 441, and 442.

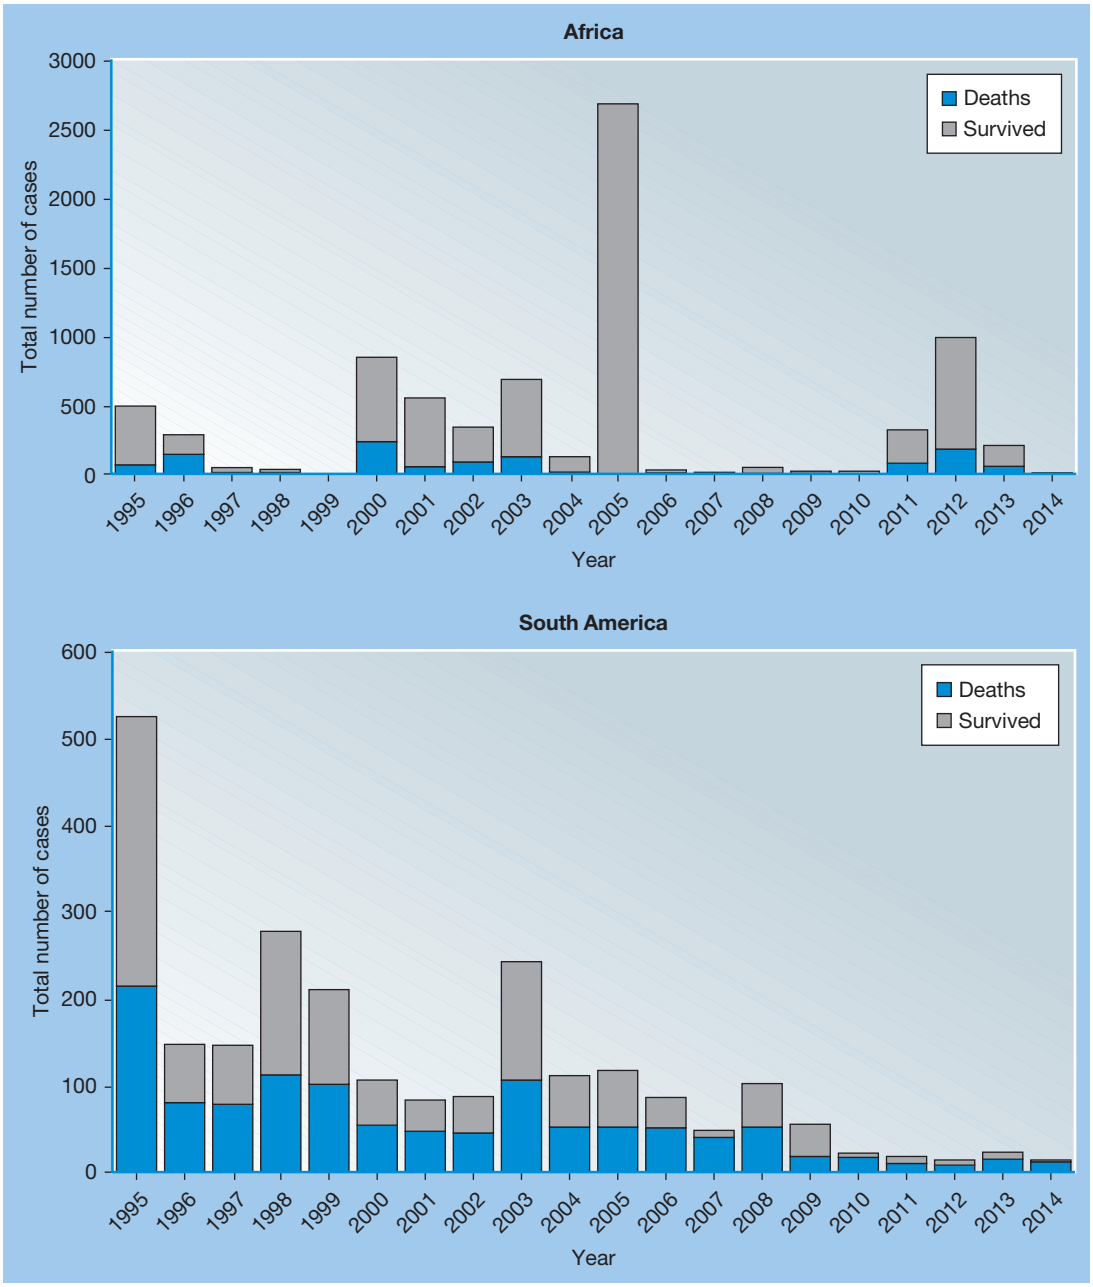

Figure 63.5. Annual number of yellow fever cases by outcome in Africa and South America reported to the World Health Organization, 1995–2014. Note the difference in scale. Overall, more cases were reported in Africa, but the proportion of cases who died following the diagnosis of yellow fever is much higher in South America.

Yellow Fever in Expatriate Residents, Travelers, and Military Personnel

In the prevaccine era, yellow fever virus was a major threat to expatriates living in and travelers to tropical America and Africa, including U.S. military personnel stationed overseas.[443] Fourteen cases occurred in Navy personnel in Honduras and Nicaragua in 1919,[444] and a suspected case was reported in Brazil in 1929.[445] A single case, acquired in Fernando Po in 1938, was reported among 2300 seamen of the Polish merchant fleet serving in the tropics.[446] In the United States, the last imported case in the prevaccine era occurred in a Mexican immigrant who died in Texas in 1924.

After yellow fever vaccination came into general use, yellow fever disease cases became increasingly uncommon. During World War II, a few cases among Europeans were reported during[212] and after[447] the 1941 outbreak in the Sudan and among British forces in West Africa in 1942.[448] In 1952, a fatal case of yellow fever occurred in a previously vaccinated European working in Uganda.[449] In 1979, two fatal cases occurred in unvaccinated French tourists who visited an area of Senegal bordering The Gambia.[450–452] These infections were acquired 1 year after a major outbreak in a region where the resident population had a high background of vaccine immunity. The French tourists returned to France during the early phase of illness and died in hospital in Paris. In 1979, a nonfatal case also occurred in a European resident of Dakar who visited the Gambian border,[450] and in 1981, an unvaccinated Lebanese resident in Senegal died of yellow fever after visiting a camp near The Gambia.[453] In 1985, a nonfatal case of yellow fever

occurred in The Netherlands in a female traveler to The Gambia, Senegal, and Guinea-Bissau.[454] In 1988, a vaccinated Spanish woman acquired yellow fever during travels through Mali, Burkina Faso, Niger, and Mauritania,[455] 1 year after a widespread increase in yellow fever activity in West Africa.

From 1996 to 2015, there have been six cases in unvaccinated tourists from the United States and Europe to South America and West Africa (Table 63.5). In all cases, the affected patients died after returning to their country of residence. Two fatal cases occurred in an unvaccinated American[369] and a Swiss[456] tourists who had visited jungle areas near Manaus, Brazil, in 1996, and returned home during the early phase of illness or during the incubation period, respectively. These cases occurred during a period of increased yellow fever viral activity in the Amazon basin. In August 1999, a 40-year-old unvaccinated man became ill in Germany after a visit to Côte d'Ivoire and died 4 days later in hospital.[362,457] In September 1999, a 48-year-old unvaccinated male U.S. citizen became ill on a trip to southern Venezuela; he returned to California on the fifth day of illness and died in hospital on the 11th day after onset.[457] In November 2001, a 47-year-old female unvaccinated Belgian tourist acquired yellow fever in The Gambia, returned home while ill, and died in hospital.[362,385,458,459] In March 2002, an unvaccinated U.S. citizen acquired yellow fever while on a fishing trip on the Rio Negro (Amazonas, Brazil) and died in a Texas hospital.[370,460]

During 2016–17, an unprecedented number of disease cases have been reported among travelers or persons from a nonendemic area who were working in an area undergoing an outbreak. At least 16 cases have been reported among residents from countries not contiguous with the outbreak areas in both African and South America (E. Staples, unpublished data).[463a,463b]

Risk of Acquiring Yellow Fever During Travel. The risk of a traveler acquiring yellow fever is determined by vaccination status, geographic location, season, duration of travel, activities that lead to exposure to mosquito bite, and the intensity of yellow fever virus transmission occurring at the time of travel. Exposure in an area undergoing an outbreak, even for a short period, may be associated with a high risk of infection. Although nearly all recent episodes of yellow fever among unvaccinated travelers have occurred in conjunction with increases in yellow fever activity, information about increased risk was often not readily available at the time. Increased yellow fever viral activity in a region often spans 2 or more years and affects contiguous areas in an expanding fashion, but such extensions in time and place may be invisible to passive surveillance systems. Moreover, in areas where vaccination is widely practiced, yellow fever virus can circulate silently between monkeys and mosquitoes, with few human cases in the indigenous population. A Belgian traveler who acquired yellow fever after spending 1 week in The Gambia in 2001 is a case in point.[385] There was no evidence of yellow fever virus transmission at the time, and there was a high prevalence of vaccine immunity in the local population. Season is also an important risk factor for yellow fever with most cases in travelers occurring during the period of virus amplification (late rainy season to early dry season).

During interepidemic periods in Africa, the incidence of overt disease is below the threshold of detection by existing surveillance. Such interepidemic conditions can last years or even decades in specific countries or regions. Epidemiologic silence can provide a sense of false security and lead to travel without the benefit of vaccination. Surveys in endemic areas of rural West Africa during silent periods indicate that the annual incidence of yellow fever illness approximates 1.1 to 2.4 per 1000 population and yellow fever death 0.2 to 0.5 per 1000 population, below detection by existing surveillance.[31] In unvaccinated travelers to these areas, the risk of yellow fever illness may be estimated at one per 1000 population per month and death at one per 5000 (1 : 2000 risk of illness and 1 : 10,000 risk of death from yellow fever for a typical 2-week journey),[461] but risk varies considerably with season and location (e.g., West Africa having a higher risk than East or Central Africa). These estimates, which are based on risk to local residents, might overestimate the risk to travelers who take precautions against mosquito bites and have less outdoor exposure than the indigenous population.

In South America, the incidence of disease is lower than in Africa. The risk of illness and death for the traveler is probably 10 times lower than in rural West Africa—approximately one per 20,000 population for illness and approximately one per 100,000 population for death per 2-week journey—but the risk varies greatly with specific location and season.[461] As in Africa, zoonotic virus transmission is often epidemiologically silent. The low reported incidence of yellow fever has diminished concern among travelers. In Brazil, for example, where the majority of the population lives in coastal regions outside the endemic zone, unimmunized recreational or vocational

travelers to the interior are the usual victims of yellow fever. Four of the six cases among travelers from the United States and Europe between 1996 and 2002 were exposed in South America (see Table 63.5).

Current yellow fever virus activity is found on the WHO website (http://www.who.int/csr/don/archive/disease/yellow_fever/en/) and is published in the WHO *Weekly Epidemiological Record*, and by the CDC's Division of Global Migration and Quarantine. Annual or biannual summaries of morbidity and epidemiologic trends are also published in the *Weekly Epidemiological Record*. Although these materials have significant limitations owing to underreporting, they provide a picture of current hot spots of yellow fever virus activity. The user should keep in mind that endemic (and even epidemic) yellow fever occurs in areas that are silent with respect to official reports.

Many nonendemic countries with *Ae. aegypti* require a valid yellow fever International Certificate of Vaccination or Prophylaxis (ICVP) for entry from a yellow fever–endemic region. A current listing of receptive countries that require a valid certificate is provided in the most recent WHO *International Travel and Health* (green book) and the CDC's *Health Information for International Travel* (yellow book).[413,414]

Risk of Spread to Nonendemic Areas

Areas at highest risk for the introduction and secondary spread are areas with *Ae. aegypti* and tend to be in the Americas and include coastal regions and interior towns infested by this vector in Argentina, Brazil, Peru, Bolivia, Ecuador, Venezuela, Colombia, the Guianas, Central America, the West Indies, Mexico, and the southern United States. All these areas have been affected by yellow fever in the past and have had recent circulation of dengue and Zika viruses, related flaviviruses with a similar urban transmission cycle. Within individual countries currently affected by yellow fever, the disease may be acquired by unvaccinated residents who travel from an uninfected area to a region of endemic activity.[462] This is a recurring theme in South America, where unvaccinated migrant workers move from a coastal area or the Andean highlands into the Amazon region. In Brazil during the first half of 2000, 11 (14%) of 77 reported yellow fever cases were in tourists from coastal areas to the endemic part of the country.[419,463] In Africa, similar episodes undoubtedly are common, but tend only to be recognized when larger cluster of disease cases are detected by the surveillance system or viral activity is recognized first in sylvatic areas before being introduced into an urban area with *Ae. aegypti*.[418,464]

The risk that urban yellow fever will reemerge continues to exist owing to the expansion of urban centers, increased air travel, and the continued spread of *Ae. aegypti*.[170,418,465,466] These factors have also likely led to the rising global incidence of other *Ae. aegypti*–transmitted viruses, such as dengue, chikungunya, and Zika.[465,467,468] *Ae. aegypti*–infested regions of southern Europe, the Middle East, Asia, Australia, and Oceania are also at risk for introduction of yellow fever virus. The virus has never been recorded in India or other parts of Asia. The possible reasons for its absence include both demographic and biological factors.[336] The most likely mode of introduction of yellow fever from endemic areas to Asia is by air travel of viremic humans, and all receptive areas can be reached by air from an endemic region within less than the incubation period of yellow fever.[465] However, yellow fever occurs in remote areas and affects persons engaged in subsistence farming, who are infrequent international travelers. Even if the disease occurs in more urban areas, like it did in Luanda, Angola, in 2016, there will need to be some degree of unchecked expansion of the virus (e.g., no vaccination coverage in the population) to increase the risk of introducing the virus to a nonendemic area in Asia, and the virus will need to be introduced during a time when *Ae. aegypti* are active.[469] Biological factors that could limit the risk of introduction include cross-protection from dengue or Japanese encephalitis viruses, as the majority of persons residing in Asia are immune to dengue or frequently are immunized against Japanese encephalitis. A third hypothesis is that *Ae. aegypti* strains in Asia could have low vector competence for yellow fever virus.[470,471] It is likely that all of these mechanisms combine to reduce the likelihood of introduction and spread of yellow fever virus in Asia.

Spread of yellow fever virus outside its traditional boundaries and reemergence of the urban disease in Africa or the Americas would greatly increase the demand for yellow fever vaccine, as was seen in 2016 when demand outstripped supply during the response in Angola. During periods of increased epizootic transmission, a high risk of introduction of yellow fever into large unvaccinated coastal populations juxtaposed to endemic areas has been postulated.[472] Ecological changes resulting from deforestation are also changing the landscape of sylvatic yellow fever.[473] Destruction of habitats of nonhuman primates and certain vectors might reduce transmission in some areas, but in general such effects are counterbalanced by increased human encroachment into enzootic areas and opportunities for interhuman transmission of the virus.[469]

PASSIVE IMMUNIZATION AND PASSIVE-ACTIVE IMMUNIZATION

Antiserum to yellow fever virus produced in horses, monkeys, or chimpanzees protects rhesus monkeys against lethal yellow fever when given 1 to 3 days after challenge.[381,474,475]

As noted under "Treatment" above, IFN-α when given to monkeys shortly before and shortly after their exposure to wild-type yellow fever virus, resulted in lower viremias and increased survival compared to untreated controls.[391] The requirement to administer IFNs very shortly before infection or during the incubation period likely precludes their clinical use in prophylaxis of wild-type yellow fever. However, in a patient with known exposure (e.g., in the case of an unimmunized laboratory worker with accidental infection), early postexposure prophylaxis with IFN-α, or preferably with immune plasma, would be indicated. As noted previously, a defective adenovirus type 5 vector carrying the gene for the consensus sequence of IFN-α protected hamsters in the 2-day postchallenge period.[394] It is possible to envisage use of such a strategy in a population affected by a yellow fever outbreak during the time period before an effective vaccination campaign could be mounted.

Before vaccines were developed, passive immunization was widely used for preexposure prophylaxis. The concept was established in the 19th century,[476] and convalescent serum was first used in the early 20th century.[477] Experimental validation occurred after isolation of yellow fever virus. In 1928, Stokes and colleagues reported that pretreatment with a small volume of convalescent serum protected monkeys against lethal challenge.[11] Because of an increasing number of laboratory infections, standard practice was to administer convalescent serum to at-risk laboratory workers and to inject large amounts after accidental exposures. The potency of passive antibody and the schedule of immunization were not carefully controlled, and laboratory-acquired disease occurred in persons who had been previously immunized[478]; such cases were the result of inadequate dosage of antibody and the long interval between transfer of serum and exposure.[280] In monkey studies, transfer of immune serum prior to challenge was protective, immunization 24 hours after experimental challenge protected 55% of the animals, and transfer at 48 or 72 hours protected only

15% to 20%.[479] Administration of antibody after clinical onset was ineffective.

Because of the difficulty in obtaining sufficient amounts of potent human serum, hyperimmune antibodies were prepared in nonhuman primates, horses, and goats.[480,481] Antibodies raised in monkeys and horses were shown to protect susceptible rhesus macaques. Heterologous antisera had limited usefulness for repeated administration to humans but were applied together with partially attenuated virus to achieve active immunization. Passive-active immunization using an excess of human or animal serum mixed with partially attenuated virus (French neurotropic strain) elicited active immunity without untoward effects, and this became standard practice.[17,18] However, it was a cumbersome method, requiring that the amount of immune serum be sufficient to protect against disease but not completely neutralize the virus and prevent active infection.[482] Heterologous serum was problematic, because allergic reactions occurred in 85% of recipients of goat serum, and late reactions similar to abortive yellow fever infection were noted in some cases, possibly the result of rapid clearance of the heterologous serum, allowing replication of the underattenuated vaccines used in these studies (e.g., the 17E strain). Monkey serum was safer (with respect to hypersensitivity reactions), but frequent failure to seroconvert was attributed to vaccine neutralization by the antiserum. Passive-active immunization was discontinued in 1936 with the advent of vaccines that could be administered safely without serum.[22]

Recent Application of Passive Immunization

Commercial lots of serum Ig contain high titers of neutralizing antibodies to yellow fever (Monath TP, unpublished observations, 2004),[483,484] presumably because 5% to 10% of plasma donors have been immunized during military service in the United States. There are no published reports of off-label use of IVIg for passive immunoprophylaxis of persons with contraindications to active vaccination. A patient with chronic lymphocytic leukemia, in whom active vaccination was contraindicated, was planning a short trip to the Amazon region and was passively immunized with commercial IVIg having a $\log_{10}$ neutralization index (LNI) of 3.0, to achieve a high initial passive titer and a protective level of antibody throughout several weeks of travel (McMullen R, et al, unpublished data, 2000). The level of antibody considered to be protective was an LNI of 0.7 based on studies in nonhuman primates.[485] In a second case report, a kidney transplant recipient on maintenance immunosuppression was given three doses of IVIg from days 20 to 22 post vaccination in response to an elevation in his liver enzymes.[484] The patient did not develop any serious adverse events and was found to develop a neutralizing antibody and T-cell response following vaccination, albeit lower than normal controls. Although these approaches might have merit for certain patients who cannot avoid travel to a high-risk area, they are expensive, require monitoring of antibody levels in IVIg and the patient, and are not supported by clinical data on efficacy.

The development of humanized mouse MAbs that target epitopes present in both wild-type and vaccine yellow fever viruses holds some promise as a potential passive immunization strategy. These antibodies provide several potential advantages such as being easily produced, being more capable of quantitating the amount delivered, and being relatively safe compared IVIg, which is a blood product. Studies of a humanized MAb (2C9-cIgG) that targets the E protein domain II epitope in both immunocompromised mice and immunocompetent hamsters conferred increased survival in the animals when challenged.[386,387] Human/mouse chimeric IgG and IgM monoclonals were derived from this antibody and the IgG construct (but not IgM) was shown to protect IFN knockout mice when given before or up to 48 hours after lethal challenge with 17D virus.[386] However, more work is needed to determine if these antibodies will provide adequate protection if given to humans who cannot safely receive vaccine.

Maternal Antibody

Transplacental transfer of yellow fever virus–specific neutralizing antibodies has been documented in monkeys[486] and humans,[167] and antibody has also been found in breast milk of immune mothers.[487] Because yellow fever 17D vaccine is not administered to infants younger than 6 months of age for safety reasons, maternal immunity typically does not pose an obstacle to effective immunization but should, in endemic areas, offer infants some initial protection against wild-type disease.

ACTIVE IMMUNIZATION

Inactivated Vaccines

After isolation of the virus in 1927, attempts to develop an inactivated vaccine were made at the Wellcome Bureau of Scientific Research in London,[16,488] at the Oswaldo Cruz Institute in Brazil,[489] and at the Pasteur Institute, Paris.[474] The vaccines were prepared by phenol or formaldehyde treatment of infected monkey liver and/or spleen. Hindle inoculated rhesus monkeys with a single dose of inactivated liver tissue emulsion containing more than 10,000 monkey lethal doses per gram and found that 80% of the immunized monkeys were protected against challenge.[15] However, his and others' studies were not controlled for residual live virus, nor were serologic studies performed. Subsequent studies in monkeys yielded erratic results,[490,491] and human trials in Brazil involving 25,000 persons were inconclusive.[474] Burke and Davis[478] reported yellow fever in a person who had previously received inactivated liver-tissue vaccine.

As virologic techniques improved, antigens were tested that were more suitable for vaccine production than infected monkey viscera. Gordon and Hughes[492] prepared vaccines from heat- or UV-inactivated virus tissue cultures (viscerotropic virus) or from mouse brain (neurotropic virus) containing known amounts of virus. Preparations containing residual live virus caused illness in monkeys, and survivors were immune to challenge. However, monkeys given various doses of fully inactivated vaccines did not develop antibodies and were not protected. It appeared that the preparations lacked sufficient antigenic potency or the methods that inactivated virus also destroyed its antigenic properties. However, all studies employed a single dose of vaccine, a procedure that would not be expected to be very effective in the case of an inactivated vaccine. Sellards inoculated mice with multiple sequential doses of phenol-inactivated mouse brain and demonstrated protection against challenge, and rabbits immunized sequentially with inactivated virus developed neutralizing antibodies.[493] However, prime-boost vaccination strategies were not used in monkeys or humans.

Methodological problems in antigen production, virus inactivation and potency assays, ignorance about immunologic principles, and the lack of adjuvants were obstacles to the early development of inactivated vaccines. Given the growth characteristics of yellow fever virus, with titers of 10^7 to 10^8 achievable in cell culture and the success of inactivated vaccines against other flaviviruses (Japanese encephalitis, tick-borne encephalitis), there is no doubt that a satisfactory

product could be developed today. The failure of the early efforts to produce inactivated vaccines led, in part, to development of live vaccines.

With the recognition of serious adverse events following the 17D vaccine, there is renewed interest in inactivated whole virus and recombinant subunit vaccines.[494] Three companies (Xcellerex, Bio-Manguinhos, and Najit Pharma) have reported development of whole-virus inactivated vaccines prepared from the 17D or 17DD strains propagated in Vero cells, purified, and inactivated by different methods.[495–498] Analysis of the inactivated vaccine identified mutations in E protein and NS4B protein that suggested viral adaptation to Vero cells.[499] At least two vaccines inactivated with β-propiolactone and adjuvanted with aluminum hydroxide have been developed.[496,498] Both of these vaccines induced neutralizing antibodies in rodents and protected them against lethal challenge. In addition, the vaccine developed by Xcellerex was also found to protect hamsters against lethal challenge and induce neutralizing antibodies in monkeys and humans.[496,500] In a Phase I clinical trial, two doses of 4.8 μg (a dose similar to that in a commercial vaccine against Japanese encephalitis) spaced 21 days apart induced neutralizing antibodies within 10 days of the second vaccination in all subjects.[500] Neutralizing antibody titers were similar to those induced by commercial vaccines against Japanese encephalitis and tickborne encephalitis.

Live Vaccines

French Neurotropic Vaccine (Discontinued)

In 1930, Theiler showed that mice were susceptible to intracerebral inoculation of yellow fever virus.[501] Following the lead of Pasteur, who had attenuated rabies virus by passage in rabbit brains, Theiler made a series of mouse brain passages of the French strain and showed that the adapted virus lost its viscerotropism for monkeys and protected them against challenge. However, in subsequent studies the neuroadapted virus caused fever and viremia in a high proportion of monkeys, and it caused lethal encephalitis after intracerebral or intranasal inoculation and, in some animals, after subcutaneous inoculation.[16,225,271,493,502] The virus was considered too dangerous without the coadministration of immune serum. Consequently, the first human volunteers were given immune human serum and neuroadapted virus (see "Passive Immunization and Passive-Active Immunization" earlier).[16] This regimen resulted in the development of active immunity.

In 1932, Sellards and Laigret reported the first immunizations with the French strain in the absence of immune serum.[17,503] Systemic adverse reactions were attributed to underattenuation. To address this problem, the mouse brain virus was attenuated by aging at room temperature. Subjects received three inoculations at intervals of 20 days with virus that had been aged for decreasing lengths of time.[504] Preliminary studies indicated that the vaccine regimen was well tolerated and that 90% of inoculated subjects seroconverted after the second dose. By 1934, 3196 persons in French West Africa had received immunizations with this regimen, and 70% of those studied developed antibodies after the first dose.[18] One-third of the recipients experienced a febrile reaction after the first dose, and there were two serious adverse events (myelitis, meningitis). In 1935, Nicolle and Laigret[505] simplified the method to a single inoculation of mouse-brain virus aged for 24 hours and treated with olive oil or egg yolk to retard diffusion from the inoculation site. By 1939, more than 20,000 persons in West Africa had received either the single- or three-dose schedule. Concerns about reactogenicity decreased with increased vaccine use, despite occasional reports of postvaccine encephalitis.[25,506] Careful follow-up studies were not routinely conducted, and the threat of natural infection superseded concerns about vaccine safety.

In 1939, Peltier and colleagues[507] simplified yellow fever immunization by conversion from subcutaneous inoculation to the scarification technique used to deliver smallpox vaccine. In 1939, nearly 100,000 persons were given French neurotropic vaccine and smallpox vaccines simultaneously, without recognized adverse events. Of 1387 subjects followed, 96% developed neutralizing antibodies 1 month after immunization. By 1941, French neurotropic vaccine administered by scarification had been given to 1.9 million people in francophone Africa, and immunization was then made compulsory. By 1947, 14 million persons had been immunized.[24] In 1946, the UNRRA Standing Technical Committee on Health approved the French neurotropic vaccine, and the WHO granted similar approval in 1948.

French neurotropic vaccine was prepared at the Pasteur Institute in Dakar by the intracerebral inoculation of 2.5- to 3-month-old mice with approximately 20,000 LD_{50} (median lethal dose) of the French virus.[508] A seed lot system was not used, although passage level was restricted. Mice showing illness were killed and the brains were aseptically removed and lyophilized. After sterility testing, brains were pooled, ground to powdered form, and again tested for sterility. The vaccine powder was filled into ampoules containing one-tenth of a mouse brain (0.4 g), equivalent to 100 doses, and tested for sterility and potency. After reconstitution in 2 mL of diluent, the recommended minimum potency was 5000 mouse LD_{50}/dose. The vaccine was quite stable and was stored at 4°C but shipped at ambient temperature. After reconstitution in a solution of gum arabic, a drop of the solution was placed on the skin, and scarification was performed with a vaccinostyle or similar instrument typically used to perform smallpox vaccinations.

By 1953, 56 million doses had been delivered in francophone Africa (twice the population of the region).[26] As a result the incidence of yellow fever declined in francophone countries (Fig. 63.6), but not in neighboring Nigeria and Ghana, where immunization was not practiced. Seroconversion rates were shown to exceed 95%,[509] and population surveys in French West Africa showed that the prevalence of immunity rose from approximately 20% before vaccination to 86% in 1952 to 1953.[510]

The safety of French neurotropic vaccine was not carefully evaluated during the ramp-up to achieve full coverage. It was known that French neurotropic vaccine caused viremia in two-thirds of subjects, that 10% to 15% experienced a mild reaction with fever, headache, and backache on days 4 to 6, and that rare cases of meningoencephalitis occurred 10 to 15 days after vaccination.[25,511,512] The incidence of encephalitis was initially estimated at between one per 3000 and one per 10,000,[512] but its importance was minimized because full recovery was the rule and because no serious reactions were noted during campaigns in French West Africa involving more than 40 million persons.[24,513] However, contemporary reports described outbreaks of encephalitis and deaths following yellow fever immunization in French Equatorial Africa.[514]

English and American workers considered French neurotropic vaccine too dangerous for routine use, but when epidemics struck in Nigeria (1951–52) and Central America (1950–52), the danger of yellow fever exceeded those of vaccine-associated risks. In Nigeria, use of French neurotropic vaccine was followed by an outbreak of encephalitis principally in children, with an incidence of 3% to 4% and a case fatality of 40%.[515,516] Autopsies showed lesions of encephalitis consistent with direct viral injury, and yellow fever virus was isolated from brain tissue, confirming that French neurotropic vaccine, and not an adventitious agent, was responsible. In

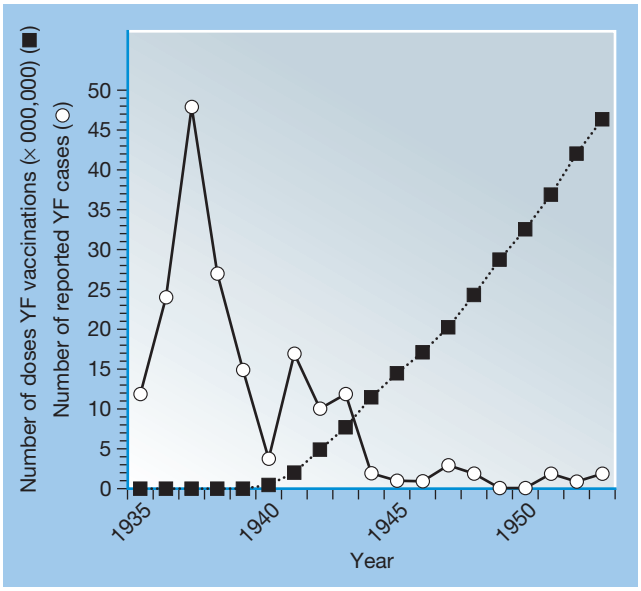

Figure 63.6. Cumulative number of doses of French neurotropic vaccine administered and incidence of yellow fever, French West Africa, 1935–53. Compulsory vaccination of the indigenous population resulted in virtual disappearance of the disease. Neighboring Anglophone countries, which did not practice immunization, continued to have epidemic yellow fever (YF). *(From Monath TP. Yellow fever vaccines: the success of empiricism, pitfalls of application, and transition to molecular vaccinology. In: Plotkin S, Fantini M, eds.* Vaccinia, Vaccination, and Vaccinology: Jenner, Pasteur and their Successors. *Paris, France: Elsevier; 1996:157–182. Data from Durieux C. Mass yellow fever vaccination in French Africa south of the Sahara. Costa Rica and Honduras, 10 definite and five possible cases of postvaccination encephalitis occurred in children.[517]

The increased recognition of severe reactions in children led to a change in the policy for use of French neurotropic vaccine. In 1959 to 1960, vaccination was restricted to persons older than 10 years of age.[518] The distribution of vaccine decreased from approximately 8 million doses to 4 million doses per year. Within 5 years of cessation of routine immunization of children, epidemic yellow fever reappeared in Senegal for the first time in 28 years.[247] The 1965 epidemic at Diourbel was the largest on record in West Africa, affecting up to 20,000 persons. Because of the high incidence of yellow fever in children and limited supplies of the safer 17D vaccine, the age limit for use of French neurotropic vaccine was reduced to the original 2 years. Among 498,887 persons vaccinated with French neurotropic vaccine, there were 231 cases of postvaccination encephalitis.[519] The majority of cases occurred in children 2 to 11 years of age, in whom the incidence of encephalitis was approximately 1.4 per 1000 and the case-fatality rate was 9%.[519,520] Collomb and colleagues have described the clinical syndromes associated with acute encephalitis and the neuropsychiatric residua.[521]

The high numbers of disease cases and vaccine adverse events in young children in West Africa confirmed the need to provide a high rate of coverage of the childhood population in Africa and the need to use a safer method of immunization. In 1966, the Pasteur Institute, with the assistance of the WHO, expanded production of 17D vaccine at Dakar, and by 1970 an official policy was established for use of 17D in persons younger than 5 years of age.[522] Small amounts of French neurotropic vaccine were used in regions with poor accessibility, where use of the more thermolabile 17D vaccine was problematic, but in 1982 production of the neurotropic vaccine was discontinued.

The potential contamination of the French neurotropic vaccine with murine viruses (e.g., lymphocytic choriomeningitis) has not been fully evaluated. The isolation of yellow fever virus from brain tissue of fatal cases[515] and absence of murine viruses in French neurotropic vaccine lots[523] supports the hypothesis that the vaccine and not an adventitious agent was responsible for encephalitis. In addition to its inherent neurotropism, French neurotropic vaccine appears to be genetically less stable than yellow fever 17D virus based on mutations and phenotypic changes occurring during laboratory passage.[524] It is possible that some adverse reactions to the vaccine reflected reversion of the virus during manufacture or during replication of the vaccine in human hosts.

Yellow Fever 17D Vaccine

The 17D vaccine is the only product currently approved for immunization against yellow fever. Several recombinant or subunit vaccines using 17D virus have been and are being explored (see "Future Yellow Fever Vaccines and Yellow Fever–Vectored Vaccines" later).

Development and Early Clinical Testing. The original development of this vaccine, described by Lloyd and colleagues[525] and Theiler and Smith,[19] was achieved by empirical methods of sequential passage of the prototype Asibi virus in a substrate that was restrictive for growth. This process enhanced the selection of variants with altered biological properties, without neuroadaptation by mouse brain passage as in the case of French neurotropic vaccine. The first successful in vitro passages of Asibi virus were achieved in cultures of minced mouse embryo tissues. After 18 subcultures, the virus was passed to cultures of minced whole-chick embryo. After 58 passages, the virus, now designated subculture series 17D, was propagated by subcultures in minced chick embryo cultures from which the brain and spinal cord had been removed. The final passage prior to human inoculation was in embryonated eggs.

A reduction in monkey neurovirulence and loss of viscerotropism occurred between the 89th and 114th passages, and a reduction in mouse neurovirulence occurred between the 114th and 176th passages. Monkeys inoculated by peripheral routes did not develop encephalitis; those inoculated intracerebrally developed histopathologic changes, but only 5% to 10% succumbed to encephalitis. The animals developed antibodies and resisted challenge with Asibi virus. Preclinical safety and efficacy were deemed sufficient to permit human studies. The initial trials using virus at the 227th and 229th passage levels were conducted in 1936, first in yellow fever immune and then in nonimmune volunteers.[21,22] The trials showed acceptable tolerability and development of neutralizing antibodies. In early 1937, 17D vaccine was taken to Brazil, where it was used in trials of increasing size, leading to the establishment of local manufacturing capacity and the initiation of a mass vaccination campaign in 1938.[22,23,526] Between 1938 and 1941, more than 2 million persons were immunized in Brazil.

Seed Lot System. During the initial phase of yellow fever vaccine production at the Rockefeller Foundation in New York and in Brazil between 1937 and 1941, a number of different substrains were used, representing independent parallel subculture lineages originating at about the 200th passage of the

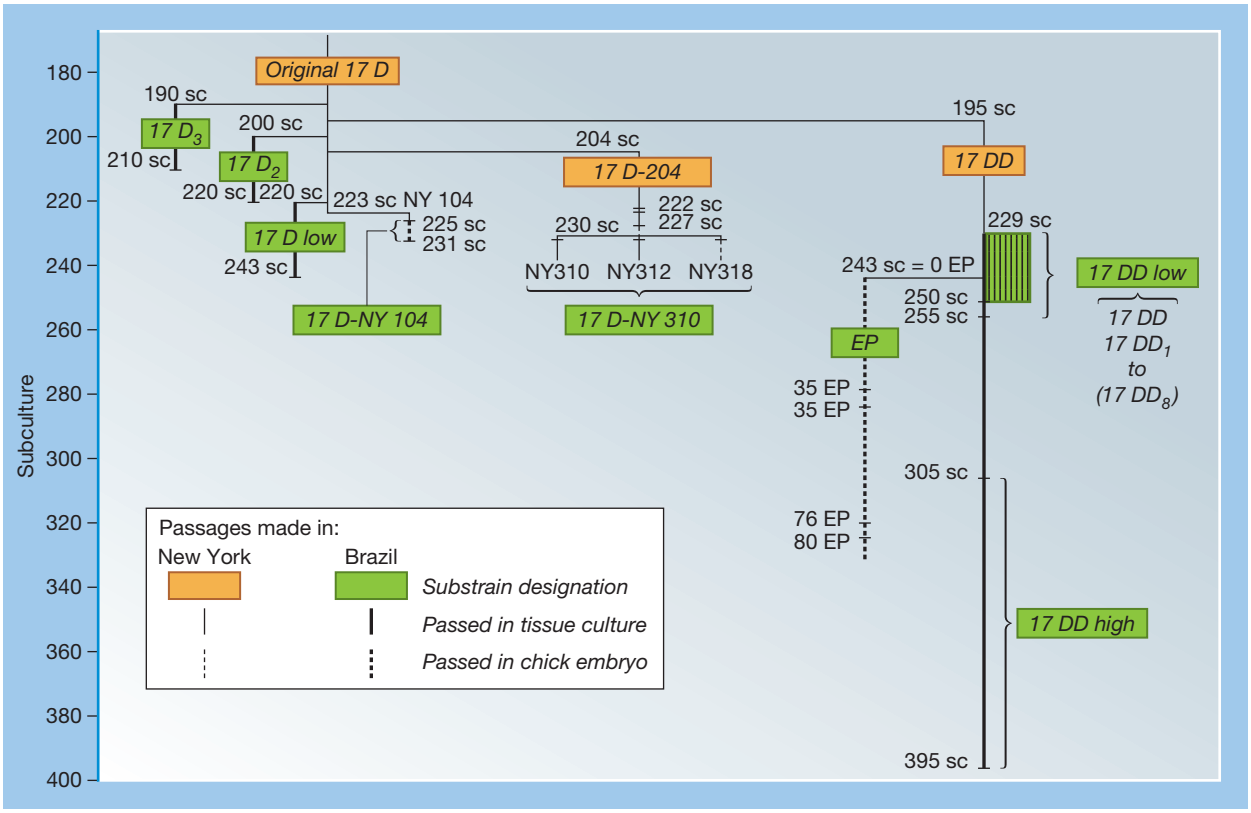

Figure 63.7. Derivation of early vaccine lots from the original 17D virus before the seed lot system was introduced (see text). *(From Fox JP, Penna HA. Behavior of 17D yellow fever virus in rhesus monkeys. original 17D line (Fig. 63.7). Two main lineages (17D-204 and 17DD) are used for vaccine production (see "Substrains" later).

Between 1938 and 1941, field trials and experimental studies revealed the importance of controlling passage level and virus substrain. Substrains 17DD high (305th to 395th passage levels) and $17D_2$ (passage 220) were found to be overattenuated, with poor seroconversion rates in humans and low levels of viremia and poor immunogenicity in monkeys,[269,527] indicating that loss of immunogenicity could occur in as few as 20 passages in minced chicken embryo tissue cultures. More important, some substrains were associated with the appearance of encephalitis. In 1941, following an outbreak of postvaccination encephalitis in Brazil, a survey of 55,073 persons who received different lots of the same substrain (NY17D-104) revealed the occurrence of 273 (0.5%) severe systemic reactions, including 199 (0.36%) with CNS signs and one fatal case of encephalitis.[528]

A controlled study was performed, in which more than 19,000 subjects received different vaccine lots, including EP, $17D_3$, 17D-NY 310, and 17D-NY 104 (see Fig. 63.7), that had been associated with the highest incidence of severe reactions or a control vaccine prepared from uninfected chick embryos. Children 5 to 14 years old sustained the highest incidence of encephalitis, with onset of CNS signs 9 to 12 days after immunization. The highest incidence of encephalitis (13/1000) was observed in recipients of the 17D-NY 104 vaccine. This substrain was shown also to produce the highest incidence of encephalitis in monkey neurovirulence tests. Other substrains (17D-NY 310 and $17D_3$) that were associated with encephalitis in humans, but at a lower incidence than 17D-NY 104, caused early-onset and prolonged fever in monkeys. Unfortunately, these substrains and vaccine lots have not been retained and are not available for sequencing studies.

Recognizing that continued serial passage could lead to unwanted alterations in the biological properties of 17D vaccine, the Rio de Janeiro laboratory instituted a "seed-lot" system in 1941, in which primary seed and secondary seed lots were prepared, and the latter used to prepare multiple vaccine batches. The primary and secondary seeds were extensively characterized, and all vaccine lots were restricted to a single passage from the secondary seed. This system was used from 1942 onwards by many manufacturers, and was formally established as a biological standard by UNRRA in 1945.[529] However, appropriate seed lots were not distributed to all manufacturers, and preparation of vaccines by serial passage and without adequate neurovirulence testing continued in some countries in the 1950s. Several cases of encephalitis were reported following use of such vaccines at the Pasteur Institute during that time.[530] In 1957, publication of the WHO Requirements for Yellow Fever Vaccine further standardized the seed lot and manufacturing procedures; this guidance has been retained with subsequent updates.[531]

Production

Vaccine Producers. Currently there are at least six manufacturers of yellow fever 17D vaccine (Table 63.6); Central Research Institute in Kasauli, India, stopped production in 2011, but plans to resume production in the future. Four manufacturers in Brazil, France, Russia, and Senegal are WHO prequalified to supply vaccine for the Expanded Programme on Immunization (EPI) and mass vaccination campaigns

TABLE 63.6 Manufacturers of Yellow Fever 17D Vaccine

Country	Manufacturer	Trade Name	Prequalified by the WHO	Comment
Brazil	Bio-Manguinhos, Rio de Janeiro	—	Yes	Only 17DD vaccine in use; national use, exported
China	China National Biotech Group, Beijing	—	No	National use
France	Sanofi Pasteur, Marcy l'Etoile	Stamaril	Yes	National use, exported
Russia	Chumakov Institute, Moscow	—	Yes	National use, exported
Senegal	Institut Pasteur, Dakar	—	Yes	National use, exported
United States	Sanofi Pasteur, Swiftwater, PA	YF-Vax	No	National use, limited export market

WHO, World Health Organization.

during routine and emergency operations. Prior to 2002, roughly 5 million doses of vaccine were produced by prequalified manufacturers (namely Sanofi Pasteur) and distributed by United Nations Children's Fund (UNICEF). Since 2002, there has been a concerted effort to increase the coverage of vaccine through large preventive campaigns being conducted in West Africa, as well as increasing demand through the EPI and establishment of a vaccine stockpile. In 2013, 31 million doses of vaccine were produced for use in 30 Global Alliance for Vaccines and Immunization (GAVI)-eligible countries.[532] However, it is projected that 62 million doses were needed per year for 2014–17 to supply the EPI, mass vaccination campaigns, and emergency response stockpiles for these countries. In addition, the Pan American Health Organization (PAHO) estimated that countries in its region will need at least 20 million doses of vaccine yearly. Vaccine supplies have been limited by a number of issues such as availability of pathogen-free eggs, manufacturing equipment, and maintenance of good manufacturing practices by some of the manufacturers of prequalified vaccine.[532] Vaccine demand is anticipated to continue to outstrip vaccine supply for the immediate future.

Sanofi Pasteur exports vaccine for the travel market while the other manufacturers offer vaccine to limited populations (see Table 63.6). The number of manufacturers has decreased since the 1990s, and facilities in the United Kingdom, The Netherlands, Germany, Colombia, Australia, Nigeria, and South Africa are no longer active. Berna Biotech acquired the 17D vaccine from Germany (Robert Koch Institute) and following acquisition of Berna by Crucell, Crucell brought the vaccine (BERNA-YF or Flavimun) through Phase III trials and preregistration in Switzerland; however, following Crucell was acquired by Johnson & Johnson in 2011, and the program was discontinued in 2014. Interestingly, this vaccine, derived from a seed stock prepared for the WHO (YF17D-213/77), was demonstrably less neurovirulent than two licensed 17D-204–derived viruses.[533]

Substrains. All yellow fever vaccines are live attenuated vaccines derived from the 17D strain and are produced in embryonated eggs. The WHO has established standards of safety and potency (see "Method of Manufacture" later). The biological performance of all 17D vaccines is presumed to be similar or identical with respect to seroconversion rate, quality of the immune response, durability of immunity, safety, and tolerability. Vaccines in current production differ, however, with respect to 17D substrain, passage level, formulation with stabilizers, thermostability, salt and other excipients, and the diluent used for reconstitution. 17D vaccines are not biologically cloned and are heterogeneous mixtures of multiple virion subpopulations (genetic swarms).[122] Unsurprisingly, differences have been found in plaque size[534,535] and in the nucleotide sequences of these vaccines in current use.[70–73,77]

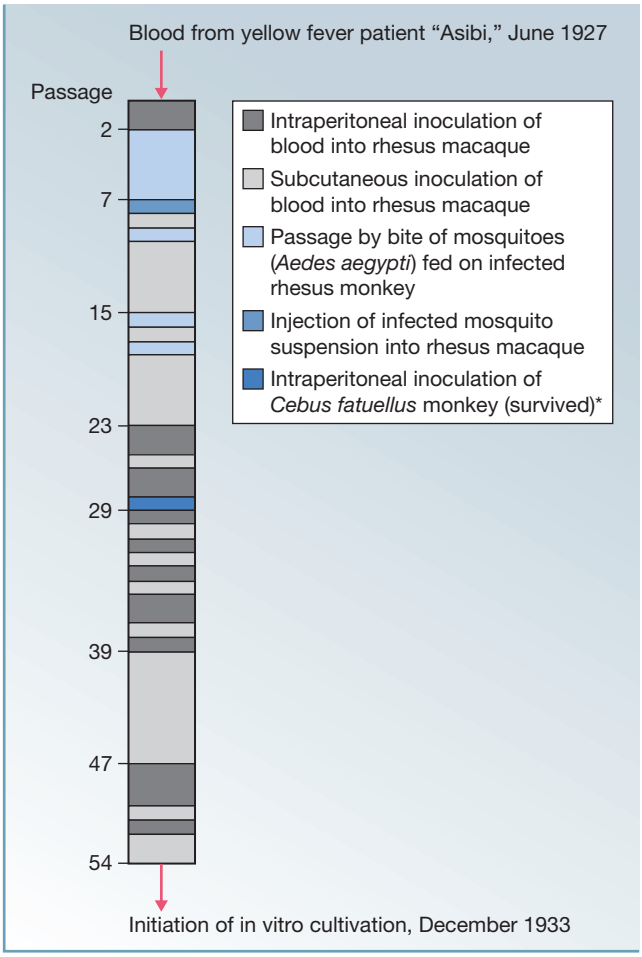

Figure 63.8. Passage history of Asibi virus from original isolation to the initiation of in vitro culture for development of the 17D vaccine. *This inoculation is not counted by the authors but represents a passage in the history of Asibi virus before cultivation in vitro.

There is no evidence to suggest that such variations affect safety or efficacy.

Before the attenuation process was initiated, Asibi virus was passaged sequentially 54 times in monkeys, either by direct injection of blood from the previous animal or with an intervening passage in *Ae. aegypti* mosquitoes (Fig. 63.8). Throughout this passage history the virus maintained its virulence for rhesus monkeys. Figs. 63.7 to 63.9 show the virus passage

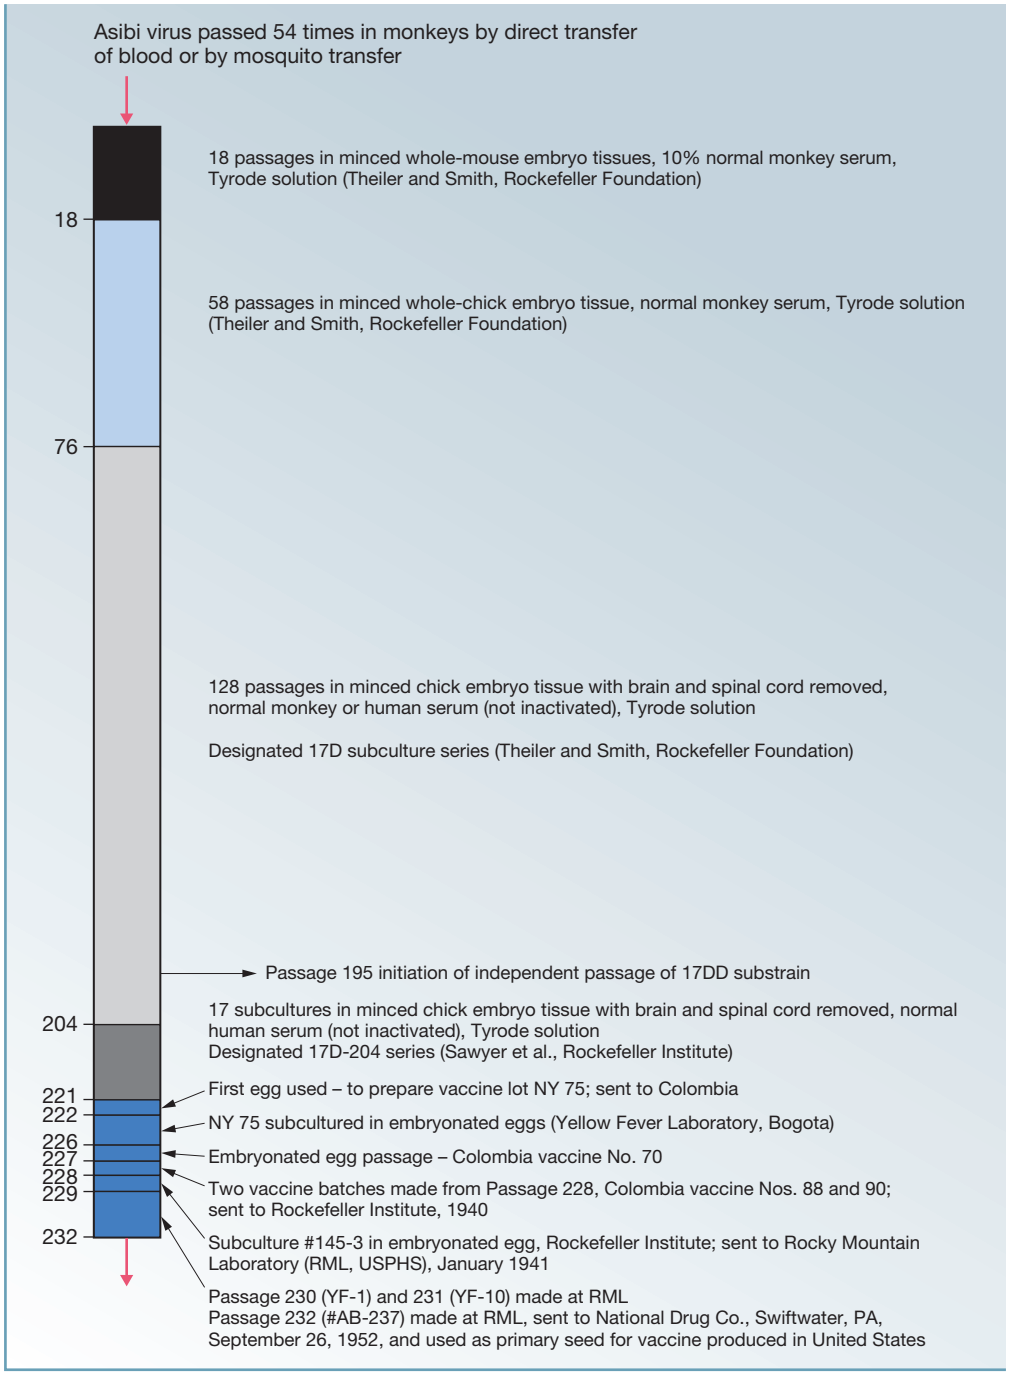

Figure 63.9. Passage history of the seed virus used to prepare yellow fever vaccines. USPHS, U.S. Public Health Service. *(Modified from Brès P, Koch M.* Production and testing of the WHO yellow fever primary seed lot 213–77 and reference batch 168–73.WHO Expert Committee on Biological Standardization, 36th Report. *Geneva, Switzerland: World Health Organization; 1987.)*

history during the original development of 17D vaccines. In vitro cultivation began in December 1933 with the passage of the virulent Asibi strain in mouse embryo tissue culture and subsequently in chick embryo tissue culture to produce attenuated 17D vaccines (Fig. 63.9).[525] Two 17D substrains—17DD and 17D-204—currently used for vaccine manufacture represent independent subcultures performed at the Rockefeller Foundation in New York (see Fig. 63.7). The 17DD and 17D-204 substrains were derived from passage levels 195 and 204, respectively, of the original 17D virus (see Figs. 63.7 and 63.9). 17DD virus was sent to Brazil at passage level 229, whereupon it was passed 14 times in minced chicken embryo tissue cultures and then, beginning at passage 243, in whole embryonated eggs (the EP lineage in Fig. 63.7). Primary and secondary seeds were prepared in Brazil at passages 284 and 285, respectively, and the current vaccine is at passage 286. One of two 17DD primary seeds was transferred to the Pasteur Institute in Dakar, Senegal, and was used for a time to prepare new seed stocks for vaccine manufacture; manufacture was subsequently switched to 17D.

The 17D-204 substrain (and a derivative, 17D-213/77) has been used by all other manufacturers. At passage level 222, the virus was propagated in embryonated eggs to prepare vaccine lot NY 75 (see Fig. 63.9). This vaccine was transferred to the Yellow Fever Laboratory in Bogota, Colombia, where additional egg passages were performed. Colombia No. 88 was returned to the Rockefeller Institute in 1940, whereupon a small number of passages in eggs were made at the Rockefeller Foundation or the Rocky Mountain Laboratory (National Institutes of Health) prior to the manufacture of primary seed stocks in France, the United States, Australia, The Netherlands, Germany, Colombia, South Africa, England, and India (Fig. 63.10). Deep sequencing of the parental Asibi strain and 17D-204 (YF-Vax) found both viruses to contain quasispecies though Asibi actually contained more than the vaccine virus.[122] Furthermore, the analysis indicated that none of the attenuating mutations in 17D-204 were present in Asibi virus quasispecies suggesting that the mutations in the vaccine were discrete and not due to selection of genomes in the wild-type population.

The Pasteur Institute in Dakar switched from 17DD to 17D-204 virus for preparation of secondary seed free from avian leukosis virus. In 1977, the Robert Koch Institute (Berlin) prepared for the WHO a primary seed free from avian leukosis virus, and it maintains this as a reference stock (designated 17D-213/77)[536] available to new manufacturers and as a source for emergency production. The Robert Koch vaccine was acquired by Berna Vaccines and produced in Switzerland. Crucell subsequently acquired Berna Vaccines and developed this vaccine (Flavimun) through late clinical stages but has yet to market the vaccine.[537] Russia is the only other manufacturing site using the 17D-213/77 virus for production. Current 17D-204 vaccines are produced at passage levels between 233 and 239. The 17DD vaccine is at higher passage, and the manufacturer in Brazil (Bio-Manguinhos) has on at least two occasions made new working virus seeds by making an additional passage in eggs rather than from the master virus seed, which was depleted. These additional passages were extensively characterized by sequencing and monkey neurovirulence testing.

The 17DD and 17D-204 substrains are distinguishable by MAb analysis, indicating variations in antigenic determinants on the E protein.[131,132,135,538] Antigenic differences have also been identified between vaccines produced from the 17D-204 substrain by different manufacturers.[132] Examination of yellow fever vaccines manufactured in 11 countries by T_1 oligonucleotide fingerprinting revealed a very high degree of genetic similarity, and sequencing showed all the mutations that distinguish Asibi parental strain from 17D are maintained.[536,539,540] The primary seed and vaccine produced in South Africa differed at one and two oligonucleotides, respectively. This difference was confirmed at the sequence level by Xie,[110] who found two changes in the 3′ noncoding region. A comparison of the nucleotide and amino acid sequences of the 17DD substrain vaccine produced in Brazil, the WHO reference vaccine (17D-213), and 17D-204 strains manufactured in the United States, France, and the United Kingdom, revealed that 17DD vaccine had accumulated fewer nucleotide and amino acid changes per passage during the process of development and attenuation than 17D-204 vaccine viruses.[71,72,539]

Depending on the specific substrain, 17DD and 17D vaccines differ in up to 17 amino acid residues in the coding region.[69,72,539] At 12 other amino acid residues, variability is observed between vaccines belonging to the 17D-204 substrain (including the WHO 17D-213/77 virus); six of these amino acid changes are unique to the China 17D-Tiantan substrain suggesting this is the most divergent.[72] These differences among vaccines do not appear to be related to attenuation, because all vaccine strains are attenuated and one or more vaccine strains has an identical residue at each position to that found in parental (virulent) Asibi virus (refer to Table 63.1 for shared differences of all vaccine strains and Asibi virus that might play a role in attenuation).

The neurovirulence phenotypes of 17DD and 17D-204 substrains have been examined in mice and monkeys.[268,534,541–543] Vaccines were compared with respect to average survival time and mortality after intranasal inoculation of young adult mice. 17DD substrain vaccines were neuroinvasive after intranasal inoculation, whereas those derived from 17D-204 were not. In monkeys subjected to the WHO standard intracerebral neurovirulence test, higher clinical and histopathologic lesion scores were found in the brains of animals inoculated with 17DD than in those inoculated with 17D-204 vaccines.[541,544] A newer study found further differences in the neurovirulence of 17D-204 and 17D-213, with 17D-213 vaccine having lower neurovirulence in monkeys and mice than 17D-204.[534] The difference in neurovirulence between the two substrain 17D vaccines was attributed to mutations in E envelope coding region and NS4B coding region. However, both 17DD and 17D vaccines passed WHO standards and were well within the limits of acceptable safety in the monkey test. Overall, the data suggest that 17DD vaccine may be somewhat more neurovirulent than 17D-204 substrain vaccines, as determined in animal models. In humans, however, this difference has not been appreciated as the rates of serious neurologic adverse events reported through passive surveillance have found slightly lower rates in Brazil (0.37 neurologic disease cases per 100,000 doses) where 17DD is used, compared to rates in the United States (0.8 per 100,000 doses) where 17D-204 is used.[255,259a,545] However, rates varied annually, particularly in Brazil, suggesting that the adverse event rates potentially were similar between the two vaccines. Given these data and the long history of use of both 17DD and 17D vaccines in many millions of persons, there is no reason to suspect that these vaccine substrains differ with respect to safety for humans.

The safety and immunogenicity of the 17DD and 17D-204 lineage (17D-213/77) vaccines have been compared in a clinical trial and had virtually identical safety profiles, seroconversion rates, geometric mean titers, and distribution of antibody titers.[546–548]

Method of Manufacture. Biological standards for yellow fever vaccines have been established by the WHO,[531] and all vaccines approved for international use must comply with these basic standards and be produced according to good manufacturing practices. National control authorities, such as the United States Food and Drug Administration (FDA), govern marketing approval, and thus biological standards differ somewhat from country to country. Manufacturers currently use seeds free from avian leukosis virus, but testing for other viral adventitious agents varies.

Primary (master) and secondary (manufacturer's working) virus seeds are tested for bacteria, fungi, mycoplasma, and adventitious viruses and are subjected to a standard safety and immunogenicity test in rhesus or cynomolgus monkeys.[531] A minimum of 10 monkeys are inoculated intracerebrally with 0.25 mL of virus containing 5000 to 50,000 MLD_{50}, the equivalent in international units to 3.7 to 4.7 $\log_{10}$ IU (see the discussion of potency measurements later in this section). Animals are monitored for clinical signs, viremia, antibody responses, and semiquantitative neuropathologic lesions at 30 days and are subjected to statistical analysis (Table 63.7).[531,549,550] For comparison, a reference control is inoculated into 10 other animals. Some authorities have advised using a reference vaccine with high neuropathologic scores that failed the safety test, such as 17D Lot 6766,[541,549] but generally, when making a new virus seed, manufacturers are advised to use an internal

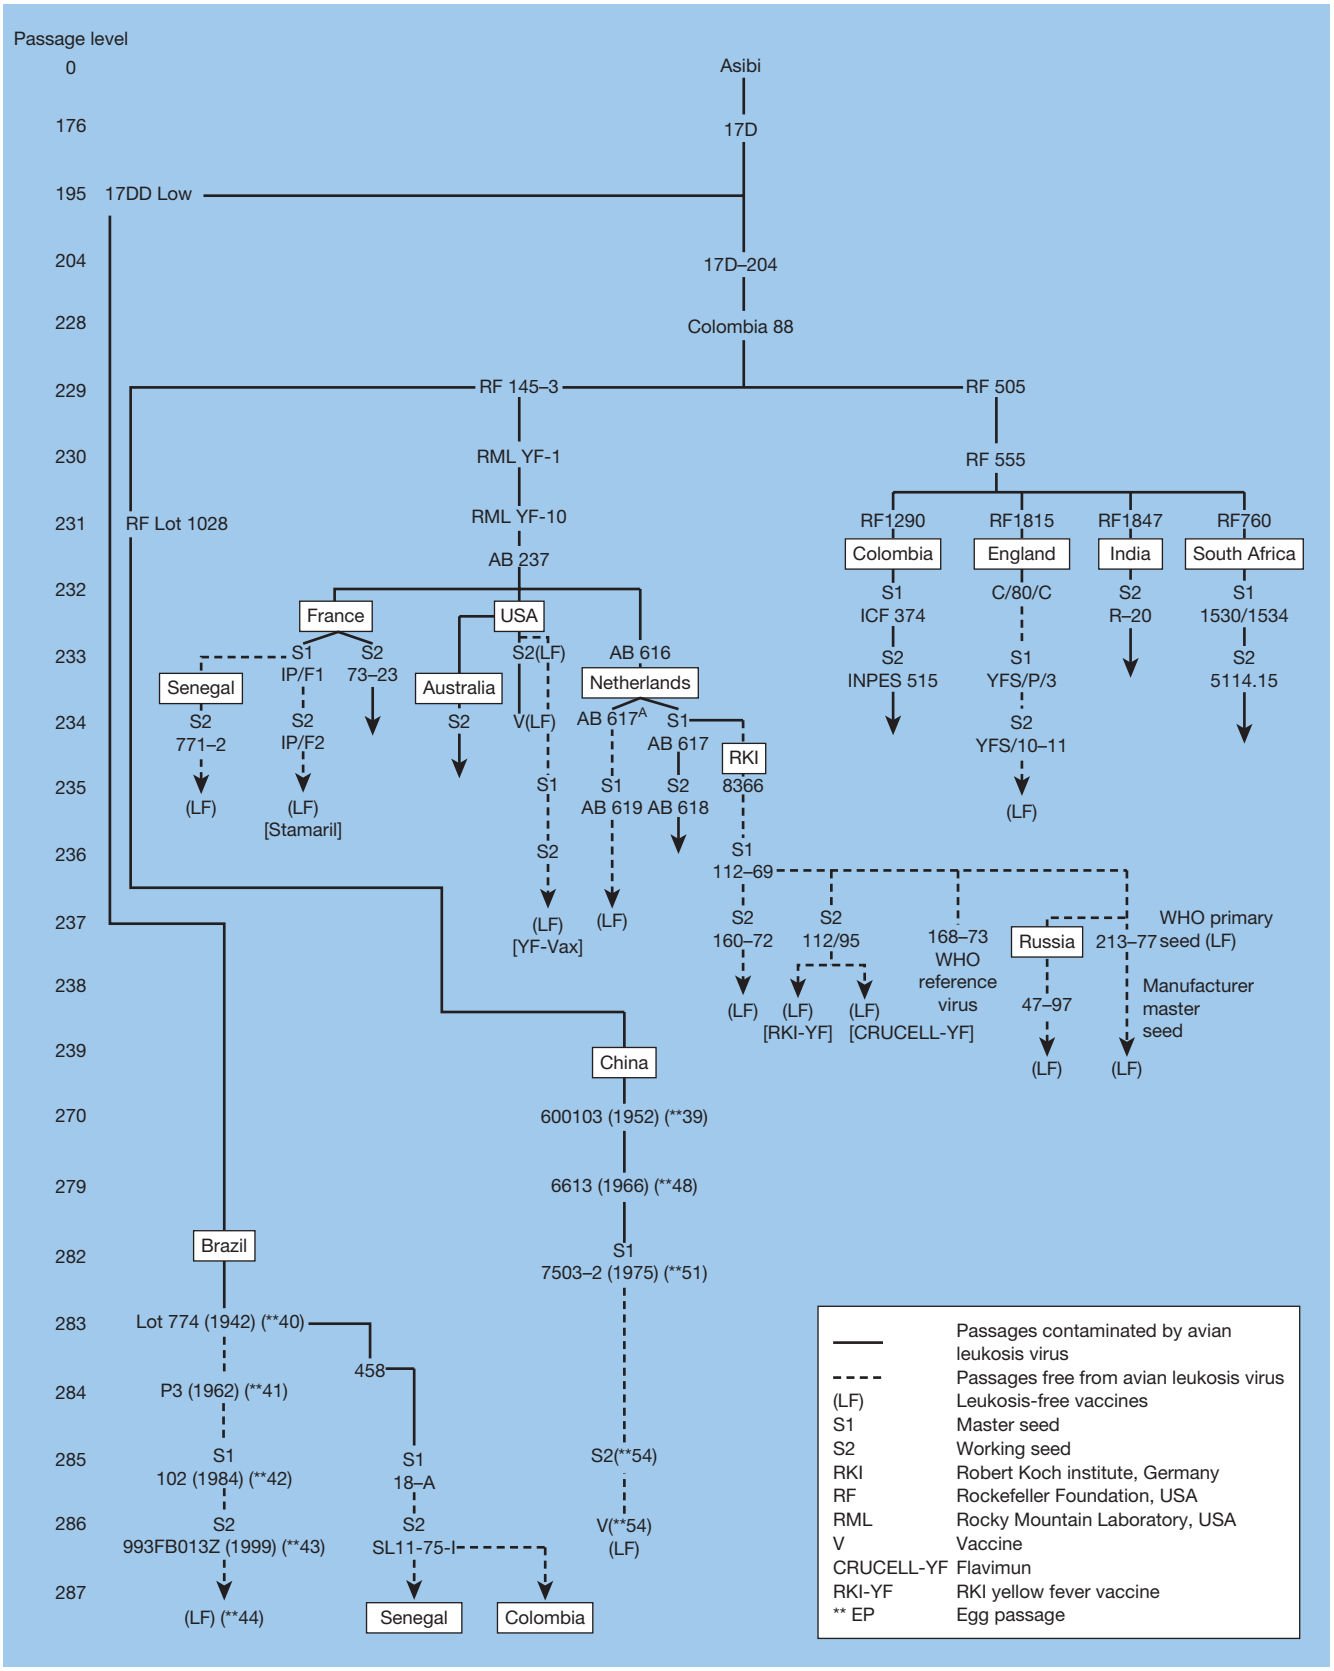

Figure 63.10. History and genealogy of 17D vaccines and reference viruses. *(From World Health Organization.* Recommendations to Assure the Quality, Safety, and Efficacy of Live-Attenuated Yellow Fever Viruses, WHO Document TRS 872, Annex 2. *Geneva, Switzerland: World Health Organization; 2010.)*

TABLE 63.7 Biological Standards for Monkey Safety Tests[a] on 17D Vaccine Seeds

Criterion	Test	Result
Viscerotropism	Viremia level on days 2, 4, and 6	Viremia <500 IU/0.03 mL in all samples, and not greater than 100 IU in more than one sample
Immunogenicity	Neutralizing antibody	>90% seroconversion on day 30
Neurotropism	Clinical observation daily for 30 days	Frequency of encephalitis and semiquantitative clinical score less than reference seed
	Histologic evaluation (day 30)	Mean lesion scores shall not be significantly greater than reference seed[b]

[a]Ten nonimmune rhesus or cynomolgus monkeys are inoculated in the frontal lobe with 5000–50,000 MLD_{50} and monitored for 30 days.

[b]Histologic grading performed on five levels of brain and six of cervical and lumbar spinal cord, using semiquantitative grading score of inflammation and neuronal degeneration. Areas of brain studied include target areas (areas that show more-severe lesions irrespective of degree of neurovirulence of virus tested), spared areas, and discriminator areas that distinguish between vaccines of low and high neurovirulence. Mean group scores for target and discriminator areas combined and for discriminator areas alone are calculated. The mean score for the test monkeys should not be significantly greater (at 5% significance level) than overall mean score for monkeys injected with reference virus.

MLD_{50}, mouse median lethal doses.

World Health Organization. Recommendations to Assure the Quality, Safety and Efficacy of Live Attenuated Yellow Fever Vaccines. *TRS 872, Annex 2. WHO Tech Rep. Ser. Geneva, Switzerland: WHO; 2010.*

reference control (e.g., a current working virus seed) that passed the test previously.[531,534,543]

The neurovirulence test has been extensively deployed for new chimeric vaccines that use 17D as a vector.[542] The sensitivity of this test is quite high, and single mutations in the virus were represented by changes in neuropathologic scores.[86] The value of the test to distinguish a 17D vaccine (seed) that has increased viscerotropism (by measuring viremia) has not been demonstrated and is uncertain.

In a study of rhesus monkeys inoculated by either the intracerebral or subcutaneous route with 17DD vaccine, viremia was measured daily by plaque assay and RT-PCR.[551] The proportion of animals developing viremia following intracerebral inoculation was higher than after subcutaneous inoculation, raising the question whether the neurovirulence test (intracerebral) is an appropriate way to measure viscerotropism. However, considering the combined groups (intracerebral and subcutaneous inoculation), the duration of viremia was only 2 to 6 days, and mean titers by plaque assay were 1.62 (standard deviation [SD], 0.76) $\log_{10}$ PFU/mL.

The genomes of many seed viruses used for production have been sequenced, and this will probably be a future requirement.[552] Minor differences and heterogeneities at individual amino acids occur across vaccines and passage levels used by different manufacturers (see "Substrains" earlier).

Vaccine is produced by aseptic inoculation of working virus seed into viable embryonated eggs.[553,554] Uninoculated control eggs (80 eggs per batch) are included and tested. All current manufacturers, as required, use eggs from closed, special pathogen-free flocks.[531] The dose of seed virus inoculated into 7- to 9-day-old embryonated eggs is 2000 to 5000 MLD_{50} or the equivalent in international units, in 0.1 mL (see the discussion of potency measurements later in this section). After incubation for 3 to 4 days, the peak titer of virus,[555] infected embryos are aseptically harvested. Embryos must be less than 12 days of age at the time of harvest. A single harvest is the pool of embryos inoculated together in a single production run.

Methods for recovery of virus from infected embryos vary, but all include addition of sterile water for injection (typically 1 to 2 mL/embryo), homogenization to pulp, and clarification by centrifugation to yield supernatant fluid harvest. Individual harvests containing homogenate from a single pool of embryos are held frozen pending sterility tests.

The vaccine must be prepared aseptically, because terminal sterile filtration cannot be performed owing to high loss of virus. Sterility tests are performed at one or more steps prior to pooling single harvests into the final bulk, which may contain one or a pool of single harvests. The amount of final bulk prepared is determined principally by the volume capacity of the lyophilizer. The final bulk is diluted and blended with stabilizers (e.g., hydrolyzed porcine gelatin and sorbitol, but stabilizers vary by manufacturer) based on potency (infectivity titer) to produce the drug product, filled into glass vials, and lyophilized. Sterile filtration is not performed because the consistency of the product renders filtration difficult and results in significant loss of titer. The manufacturing process is thus performed aseptically under Class 100 (Class A) conditions.

The target infectivity titer is adjusted for losses expected across lyophilization and losses expected between release and end of shelf life. Consequently, the release titer must exceed the compendial minimum (3 $\log_{10}$ IU). Data from current manufacturers indicate potencies range from 3.5 to 6.0 $\log_{10}$ IU/0.5 mL dose.[552] The excess at release is determined to provide for minimum potency at the end of shelf life (2 or 3 years, depending on the manufacturer). The yield per embryo is typically in the range of 100 to 300 doses.

The original WHO biological standard is tied to mouse MLD_{50} (determined by intracerebral inoculation of mice 4 to 6 weeks of age) or the equivalent in a plaque assay. Because of the variability of the mouse and plaque assays and difficulty in establishing the PFU-to-MLD_{50} ratio, and to assist manufacturers in the control of yellow fever vaccines, the National Institute for Biological Standards and Control (NIBSC, United Kingdom) conducted a study with the aim of establishing an international standard.[556] The study confirmed that the ratio of PFU to MLD_{50} was approximately 10:1. An international standard (NIBSC code No. 99/616) preparation of 17D vaccine was established and was approved by the WHO for use by manufacturers and national control laboratories.[552,556] The new standard for minimum potency is established at 3 $\log_{10}$ IU, which is approximately equivalent to 3 $\log_{10}$ MLD_{50} and 4 $\log_{10}$ PFU.[552]

There has never been an upper limit established for potency, and some vaccine batches have titers up to 6 $\log_{10}$ IU. The current view is that manufacturers should establish their own internal upper limit using trend analysis of multiple batches, and the upper limit should be approved by the national control authority. Interestingly, there are no clinical data comparing 17D vaccines at high versus standard dose but one dose-ranging study using a lower-than-normal standard dose of 17DD vaccine found that there were similar seroconversion rates and viremia levels seen with 10-fold lower doses than standard.[557,558] In animals it is possible to show prozone effects, with lower immunogenicity at high doses (see "Vaccine Substrain or Dose").

The final vaccine bulk is tested for absence of adventitious agents. Standards vary across national control authorities but include tests for bacteria (including *Mycobacterium avium*), fungi, and mycoplasma. Because yellow fever 17D vaccines were developed before the application of modern tests for adventitious viruses, the standards for testing may be less stringent than for new vaccines in some countries. Control (uninfected) eggs are routinely incubated along with eggs used for vaccine manufacture and are tested for viability, sterility, and hemagglutinating viruses. The in vitro virus test in cell cultures and the in vivo virus test in mice, guinea pigs, and eggs are required by some control authorities.

These tests, which require subculture or blind passage, are complicated by the requirement to neutralize the test article (yellow fever 17D virus) in order to observe cultures or in vivo hosts for inapparent viruses. Neutralization requires a potent antiserum that has been raised in a pathogen-free host against yellow fever virus antigen produced in a host other than eggs. The neutralization procedure may be difficult, particularly when high-titer preparations must be tested in sensitive indicator cells or in suckling mice. Protein content before addition of stabilizers may not exceed 0.25 mg/dose.

After filling, the final product is tested for identity by neutralization test, potency, thermostability, sterility, general safety in mice and guinea pigs, residual moisture, residual ovalbumin, and endotoxin. Some countries require that a monkey safety test be performed on each vaccine lot. As specified by the WHO standards,[531] potency must be at least 3 $\log_{10}$ IU/mL. The dose in the final container exceeds the minimum specification by 50-fold to account for potential losses during storage and losses during thermostability testing (see "Vaccine Thermostability" later).

Sanofi Pasteur has conducted extensive analyses of 17D vaccine batches produced over 12 years.[559] The vaccine was genetically stable and homogeneous with respect to plaque size, mouse LD_{50} and average survival time, and virus load measured by quantitative PCR.[560] An important aspect of this and related analyses was the definition of the ratio between genome equivalents and infectious units, which is approximately 1000 : 1,[559,561] which is similar to findings for other flaviviruses. Because the vaccine contains an excess of likely defective particles, this could explain prozone effects seen in animals at high doses. It is also uncertain whether the actual content of infectious virus could exceed that measured in mice or cell culture, and whether the defective virus in the vaccine modulates infectivity in vivo.

Constituents. There are no antibiotics or preservatives in yellow fever vaccines. Because of the risk of bacterial contamination and the thermal instability of the virus after reconstitution, single-dose and (especially) multidose vials must be used within a short time, as specified in the package label: typically 1 hour, or up to 8 hours if maintained on ice. Salt, buffer, and stabilizer excipients vary by manufacturer. The stabilized vaccine manufactured in France by Sanofi Pasteur (Stamaril) contains no animal-derived excipients and is reconstituted in 0.4% saline. Each dose contains 16.0 mg lactose, 8.0 mg sorbitol, 833 µg L-histidine hydrochloride, 362 µg L-alanine, 1.6 mg sodium chloride, 54 µg potassium chloride, 598 µg sodium phosphate-dibasic dodecahydrate, 63 µg potassium phosphate-monobasic, 39 µg calcium chloride, and 29 µg magnesium sulfate. In contrast, the same manufacturer's product made in the United States (YF-Vax) is stabilized with sorbitol and hydrolyzed porcine gelatin and is reconstituted with 0.9% saline. The amount of hydrolyzed porcine gelatin per dose in these stabilized vaccines is approximately 10 mg. Osmolality of 17D vaccines is slightly above normal serum levels.

Adventitious Viruses. In 1966, yellow fever 17D vaccine was discovered to be contaminated with avian leukosis virus.[562] All vaccines produced at that time contained the agent, owing to the high prevalence of infection of chicken embryos. New seeds free of avian leukosis virus were developed in the 1970s, and all manufacturers now employ leukosis-free seeds as stipulated by WHO standards.[531] Although the presence of leukosis virus in yellow fever vaccine is certainly undesirable because of the possibility of insertion of leukosis virus oncogenes, there is no evidence to implicate the virus in human disease. The question was addressed by a retrospective survey of World War II veterans for cancer deaths.[563] The incidence of all cancers, lymphoma, and leukemia was not significantly different (and in fact was lower) in persons vaccinated 5 to 22 years previously with 17D vaccine than in those not vaccinated. All manufacturers are required to use eggs from specific pathogen-free flocks.

Vaccines manufactured in eggs, including yellow fever 17D, test positive by the product-enhanced reverse-transcriptase assay, reflecting the presence of defective particles containing endogenous avian leukosis or retrovirus sequences. No evidence has been found for infectious or inducible replication of competent retroviruses or for infection with avian leukosis or endogenous avian retrovirus in humans.[564–567] However, one study found viral nucleic acid of avian leukosis virus that was attributed to endogenous retroviruses in the chicken germline.[564] Tests for retroviral contamination by amplification in avian cell culture and quantitative PCR may be required for future regulatory approval of yellow fever vaccines made in eggs.

During the original formulation and early use of 17D vaccines, pooled human serum was used as a stabilizer. Vaccines were thereby contaminated with hepatitis B virus, resulting in outbreaks of jaundice.[568–570] Human serum was eliminated from yellow fever vaccines by 1942. Current vaccines carry no inherent risk of contamination with human hepatitis viruses.

Preparations Available, Including Combinations. All yellow fever vaccines approved for distribution are live attenuated 17DD or 17D-204 substrain viruses, prepared in embryonated chicken eggs, and formulated as lyophilized powder. Vaccines vary with respect to stabilizer additives and salt content. Some contain sodium chloride and buffer salts and are reconstituted with sterile water, and others are reconstituted with saline solution.

Vaccines differ with respect to expiration date, but all require storage at the point of use at 2°C to 8°C and should be used within 1 hour after reconstitution. However, for use in mass immunization campaigns and the EPI, reconstituted vaccine may be used during an 8-hour workday if it is maintained on ice. Vaccines are supplied in single-dose and multidose containers with up to 20 doses.[574a]

Vaccines produced in France (Stamaril, Sanofi Pasteur); Brazil (Bio-Manguinhos), Russia (Chumakov Institute), and Senegal (Pasteur Institute) are exported for international use or supplied to the EPI through the UNICEF and PAHO bid markets (i.e., prequalified). The vaccines produced elsewhere are used almost exclusively in-country for travelers and military personnel.

Although certain combination vaccines have been clinically tested (including yellow fever–measles and yellow fever–typhoid), no products are currently commercialized.

Genetic Stability

Vaccine Thermostability. In 1987, the WHO published an addendum to the biological standards, with a guideline (not a formal requirement) that vaccines meet a stability standard.[571] The specification included two criteria: the lyophilized

vaccine held at 37°C for 14 days must maintain minimum potency (>1000 MLD_{50} per 0.5 mL dose) and show a mean loss of titer of less than 1 $\log_{10}$ LD_{50}. Of the vaccines produced by the 12 approved manufacturers at that time, only five met the stability specifications.[572] Current WHO requirements for yellow fever vaccine make the stability standard a requirement and the specification has been reconsidered and determined to be appropriate[531]; vaccines produced worldwide meet the specification.[552]

Without stabilizers, lyophilized yellow fever vaccine loses 1.5 to 2.5 $\log_{10}$/dose during 14 days at 37°C. Stabilized vaccines lose only 0.3 to 0.5 $\log_{10}$ per dose during this interval. In one study, a stabilized lyophilized vaccine produced in Senegal met WHO standards after storage at 2°C to 8°C for more than 3 years.[573,574] Storage at −20°C was superior to storage at 2°C to 8°C. Stabilized yellow fever vaccine has a similar or better stability profile than other thermolabile vaccines used in the EPI (including polio, measles, and pertussis vaccines). Thus, although the lyophilized vaccine requires proper storage and handling under cold-chain conditions in the field, yellow fever vaccine is not the weak link in the EPI system.

Stabilizers differ by manufacturer. The vaccine producers in the United States use sorbitol and gelatin. The YF-Vax product label provides stability data at 35°C to 37°C and 45°C to 47°C.[575] The half-life of the lyophilized vaccine at these temperatures is 14 and 4.5 days, respectively, determined by Vero cell plaque assay. The vaccine made in France is stabilized with sugars, amino acids, and divalent cations (see "Constituents" earlier). A disadvantage of yellow fever vaccine, particularly for multidose containers, is its instability after reconstitution. According to the product label, the vaccine must be held on ice after reconstitution and is discarded after 1 hour, although, for practical use in the field, the WHO recommends that a longer interval (6 hours) may be used if the vaccine is maintained on ice.[531]

During Replication in the Host. 17D vaccines are not plaque-purified and contain heterogeneous subpopulations with differing mouse neurovirulence.[85,110,534,535] One variant recovered from 17D vaccine by plaque purification had a wild-type epitope and amino acid change at position E-173.[84,85] The relative proportion of plaque size variants in 17D vaccines changes with passage.[534,535] Consensus sequencing and later deep sequencing of 17D vaccines revealed nucleotide heterogeneities within structural and nonstructural genes and the 3′ noncoding region, and studies on a 17DD secondary seed and vaccine lots derived from it revealed four nucleotide heterogeneities within structural and nonstructural genes, indicating the quasispecies nature of the vaccine.[71,122,543]

Given the safety record of 17D vaccines since stabilization of passage level, genotypic and phenotypic heterogeneity does not appear to pose a safety problem. No individual plaque variant of 17D virus has shown a mouse neurovirulence phenotype that exceeds the vaccine itself, and thus changes in the relative proportion of variants on replication in humans might not alter virulence. Xie and colleagues[576] sequenced 17D virus strains isolated from the sera of six subjects given the 17D-204 vaccine produced in the United States. No mutations were found in the structural genes, and no more than two nucleotide changes were found in NS5 regions. Similarly, virus strains recovered from sera of monkeys 12 days after intracerebral inoculation of 17D-204 vaccine contained no mutations or a single silent mutation in NS5. These results indicate a high degree of genetic stability of 17D virus during in vivo replication. Mutations tend to accumulate at a significantly lower rate than expected for an RNA virus.[577] In addition, studies employing a truly clonal yellow fever 17D virus as a vector for foreign genes have been very successful, indicating that the quasispecies nature of 17D vaccine is not critical to safety and efficacy and that it should be possible to develop a molecular (or biological) clone of 17D as a vaccine.

Rare mutational events in 17D vaccine during replication in the host have been shown to alter pathogenicity. The first of two published fatal cases of encephalitis occurred in 1965 in a 3-year-old child who received 17D-204 vaccine.[97] Jennings and colleagues[92] defined the characteristics of the virus from brain tissue and commercial 17D vaccines at similar laboratory passage level. Compared to commercial vaccine, the brain isolate had higher neurovirulence for mice, caused severe encephalitis in a cynomolgus monkey, and reacted with a wild-type–specific MAb. The brain isolate differed from 17D-204 at two residues in the E gene (E-155 and E-303) and one in NS4B. There is a potential role for these mutations in neurovirulence, particularly the change at position E-303. A single mutation occurring during in vitro passage in the heterologous E protein of a chimeric yellow fever vaccine increased the neurovirulence of the virus.[86]

The occurrence of serious adverse events, particularly viscerotropic adverse events, raises the question of whether such events are caused by mutations that change virulence or tropism of the virus or selection of virulent variants in vivo. The data obtained so far—consensus sequencing of multiple virus isolates from organs of patients—indicate that host susceptibility rather than a change in the virus is responsible for such events.

Biodistribution. In a study in cynomolgus macaques, the sites of virus replication of 17D vaccine were determined in vivo, and the relationship between neutralizing antibody response and viral clearance was described.[284] 17D vaccine virus was detected in sera of seven (47%) of 15 monkeys between 2 and 5 days after vaccination, with a mean peak titer (±SD) of 67.3 (±94.8) PFU/mL, and a mean number of viremic days of 1.4 (±1.6). Neutralizing antibodies appeared by day 7 in 12 of 15 (80%) monkeys and by day 14 in 100%. Viral RNA was detected on day 3 in the skin (inoculation site), lymph nodes, and bone marrow and on day 7 in the skin, lymph nodes, spleen, thymus, adrenal gland, liver, and bone marrow. By day 14, viral RNA was present only in lymphoid tissues, and by day 46, viral clearance was complete (no data were collected in between days 15 and 45). Virus loads were generally low, in the range of 50 to 500 PFU equivalents (Eq/g).

The observation that human vaccinees shed 17D virus (genomes detected by RT-PCR) in urine after clearance of virus from blood[300] was noted earlier in "Pathogenesis." This observation does not necessarily mean that 17D virus infects the kidney or collecting system, because virus produced elsewhere could be shed in the urine (no 17D virus was found in kidney of vaccinated monkeys).[284] The finding of genomes in urine in humans raises the possibility of persistent infection and a possible explanation for highly durable immunity and persisting IgM antibodies. There are no known clinical consequences; the patients of some concern might be those who sustained neurotropic adverse events, but neurologic abnormalities appearing late (years) after the acute event have not been described.

Dose and Route of Administration. Yellow fever 17D vaccine is given by the subcutaneous route in a volume of 0.5 mL, generally in the upper arm. Use of the subcutaneous route of inoculation in humans followed the exhaustive preclinical evaluations of 17D virus in nonhuman primates at the Rockefeller Institute in the 1930s, in which this route of inoculation was employed, and the subcutaneous route is nearly universally used in practice. The Summary of Product Characteristics approved by the European Union Committee for Medicinal Products for Human Use for the 17D vaccine

manufactured in France (Stamaril) specifies that the vaccine may be given by either the subcutaneous or intramuscular route. However, there are no clinical data comparing the two routes of immunization with 17D virus, and there is only one extant published report of intramuscular inoculation.[483]

The minimum dosage requirement is 3 $\log_{10}$ IU/dose. Because commercial vaccines contain an excess of virus to provide for losses during storage, the delivered dose is higher than the minimum standard. Most vaccines contain around 3.7 to 4.7 $\log_{10}$ IU/dose on release, but some have potencies as high as 6 $\log_{10}$ IU/dose.[552]

As discussed in detail under "Vaccine Substrain and Dose," there are safety and efficacy concerns related to dosage, both at the low and high ends of the dosage range. To stretch vaccine supplies, there is renewed interest in dosage-sparing approaches. The WHO recently released a white paper (information paper) that was endorsed by the Strategic Advisory Group of Experts (SAGE) for the use of fractional doses of the vaccine for outbreak responses.[574a] Clinical studies have shown some promising results with 10-fold reduction in vaccine dose producing similar viremia levels and seroconversion rates to a standard (full) dose.[557,558]

Attempts to immunize monkeys with 17D vaccine by the oral route or by the intestinal route using acid-stable capsules were not successful,[199] but application of virus by intranasal spray resulted in uniform seroconversion.[579] Intranasal immunization has not been attempted in humans. The residual neurotropism of 17D virus raises safety concerns because of the possible exposure of olfactory neurons in the nasal cavity and potential for direct access to the brain via the ethmoid route. The finding of neurotropic disease in three breastfed infants whose mothers were vaccinated[203–205] does suggest that either intranasal or gastric inoculation might result in effective inoculation with seroconversion but could also result in neurologic adverse events.

Skin Immunization. In 1950, a decision was made in Nigeria to prepare 17D vaccine for immunization by scarification, which would simplify and reduce the cost of delivery and would permit use of formulations with less-stringent requirements for sterility.[580] Beginning in 1951, trials were initiated using 17D vaccine alone, 17D combined with smallpox vaccine, or 17D and smallpox vaccine given together but at different sites.[580–584] The vaccine was prepared in eggs or by passage of the egg vaccine in mouse brain. Clinical trials revealed lack of seroconversion in up to 15% of those vaccinated with 17D alone and in 35% of those receiving combined yellow fever and smallpox immunization.[585] Revaccination with 17D at an interval of 14 days increased the seroconversion rate.[586]

Studies in West Africa and Malaya suggested that the cause of these vaccine failures might have been cross-protective heterologous flavivirus immunity.[587–589] A head-to-head comparison of 17D and French neurotropic vaccine delivered by scarification showed a higher seroconversion rate in subjects given the French vaccine.[580] The apparent lower seroconversion rate of 17D applied by scarification was probably not because of vaccine titer differences,[586] but rather a result of the inherently higher capacity of French neurotropic vaccine to replicate at the dose delivered by this method. A newer study that delivered 17D vaccine either subcutaneously or transcutaneously to persons with and without atopic dermatitis found that persons who received 17D vaccine transcutaneously had lower rates of seroconversion (82%) 30 days postvaccination than did those receiving the vaccine subcutaneously (91%) (P = .059).[590] When seroconversion rates for normal controls were compared, the difference was significant at 100% (21/21) for subcutaneous and 74% (14/19) for transcutaneous delivery (P = .02). Seroconversion rates for patients with atopic dermatitis were similar between subcutaneous (93%) and transcutaneous (90%) delivery but were lower overall; in this group an inverse correlation between the immune response and IgE levels were observed. The authors thought that the lower seroconversion rates with transcutaneous delivery were partly from inadequate viral penetration and infection of the skin. Previously, scarification was not adopted for routine delivery of 17D vaccine in anglophone Africa owing to similar uncertainties about efficacy, as well as lack of an efficient cold-chain, absence of a public health policy for yellow fever vaccine production and immunization after independence from colonial rule, and the development of improved methods for subcutaneous vaccine delivery (the jet injector).

The early workers who used the epidermal route of immunization (scarification) had no specific knowledge of the role of Langerhans cells as the initial target cell in human infection with flaviviruses. Needleless immunization of the skin, or the use of microneedles that deliver live vaccine to the epidermis in a more controlled fashion than the original scarification methods, offer considerable promise as an improved vaccination method for 17D and other live flavivirus vaccines.[591] Monkeys were efficiently immunized with a chimeric yellow fever 17D and Japanese encephalitis vaccine delivered by rubbing the skin with vaccine and a device that strips the stratum corneum.[201]

A clinical trial of 17D vaccine was conducted in 155 naïve and 20 previously vaccinated subjects randomized 1:1 to receive intradermal injection of 0.1 mL (one-fifth of a standard dose) or subcutaneous injection of a full dose.[592] One hundred percent of subjects developed neutralizing antibodies, and no differences in titer were observed between intradermal and subcutaneous delivery. The intradermal group had increased erythema and swelling at the site of inoculation, consistent with other vaccines given by this route. The intradermal route is attractive as a means of needleless delivery and dose sparing.

Cost of Manufacture and Vaccine Price. The cost of manufacture of yellow fever vaccine is modest, but it is highly dependent upon local conditions (personnel wages, overhead, etc.). Price and sales margins vary by market segment. In 2013, the cost of yellow fever vaccine for UNICEF, which procures the vaccine for use in Africa, and for prices on PAHO bid orders for vaccine supplied to South American countries in five- and 10-dose containers, varied between US$0.67 and US$1.40 per dose.[532] In contrast, the price charged to the patient in travel clinics in the United States is US$150 to US$350 per dose.[461,593]

RESULTS OF VACCINATION

Immune Responses to Vaccination

Innate Immune Responses to Vaccination

Innate immune responses to yellow fever vaccine serve two important functions: they provide relatively immediate protective expression of antiviral molecules that stimulates and modulates the adaptive immune response, including a mixed T-helper (Th)1/Th2 $CD4^+$ response and rapid activation of $CD8^+$ cytotoxic T cells.[594,595] The immunologic basis for susceptibility to serious (viscerotropic) adverse events following 17D vaccine is suspected to lie in deficits or dysfunctions in the innate immune response. It is generally believed that the strong activation of innate immunity is central to why yellow fever vaccine is such a strong immunogen and generates such long-lived immunity by virtue of early development of Th2 memory $CD4^+$ cells and persistent B-cell populations.

Within the first few days after vaccination, a robust innate immune response is generated, peaking on day 7 and

diminishing thereafter, that includes NK cell activation, Toll-like receptor (TLR) activation, non–TLR-dependent sensor activation, proinflammatory cytokines, IFNs, and various IFN-stimulated gene products with antiviral activity appearing during the early phase of virus replication, prior to the advent of virus-specific cytotoxic T cells and Ig.[596,597] In peripheral blood, increases in percentages of $CD86^+$ myeloid dendritic cells, plasmacytoid dendritic cells, monocytes and $CD14^+$ $CD16^+$ inflammatory monocytes are observed.[595]

In vaccinated humans, a pattern of early activation of NK cells and monocytes has been observed, including upregulated expression of TLR3 and TLR9 and activation-related markers CD69, CD38 and CD16, increased expression of major histocompatibility complex (MHC) class II antigens, and increased levels of circulating IFN-γ.[598] CD38 is known to trigger cytotoxic activity of NK cells, and CD16 is involved in antibody-dependent cell-mediated cytotoxicity. TLR signaling also controls the life span of dendritic cells by modulating apoptotic and antiapoptotic molecules, an effect that can dramatically affect immune responses. Following vaccination, 10 of 15 subjects developed circulating IFN-α.[599] IFN appeared and peaked 24 hours after viremia, in concert with the appearance of HI antibodies, and levels declined rapidly thereafter.[599] These results are consistent with a subsequent study showing that 2′,5′-OAS activity in peripheral blood mononuclear cells increased by day 4 and peaked on day 7 after 17D immunization.[600]

The role of IFN in clearance of 17D and inhibition of the immune response to coadministered vaccines has not been clarified. It is likely that common side effects of 17D vaccine (headache, myalgia, asthenia) and the mild leukopenia associated with vaccination are related to release of IFN-α and other cytokines.[596,601] Increases in serum β_2-microglobulin, neopterin,[358] and TNF-α have been found also during the first week after 17D vaccination, but not after revaccination. The increase in β_2-microglobulin reflects activation of T lymphocytes bearing MHC class I antigens, and neopterin is released by monocyte/macrophages in response to IFN-γ released by activated T lymphocytes. Two cytokines found to be consistently elevated after 17D vaccination were IFN-γ–induced protein 10 (IP-10) and IL-1α.[594] This finding is similar to results obtained with dengue, West Nile virus, and tickborne encephalitis.

Silva and colleagues[602] phenotyped proinflammatory and regulatory cytokines expressed on peripheral blood cells of patients following yellow fever vaccination. During the first week, innate immune cells increased including TNF^+ neutrophils and monocytes and $IFN\text{-}\gamma^+$ NK cells. Later (days 15 to 30), regulatory cytokine expression, such as $IL\text{-}10^+$ monocytes, was increased. Their studies showed that a proinflammatory cytokine pattern occurred early, followed later by appearance of a mixed proinflammatory–regulatory cytokine pattern.

Systems biology approaches have now been applied to the elucidation of genes activated and downregulated in healthy human subjects following 17D vaccination.[594–596,603–605] In several studies, as many as 125 different genes were upregulated after 17D vaccination. Genes that involved recognition of foreign (viral) RNA included membrane-associated sensors, activated TLR2, TLR7, TLR8, and TLR9 (TLR3 is likely activated also), non–TLR-dependent cytoplasmic sensors, retinoic acid–inducible gene I *(RIG-I)*, and melanoma differentiation–associated gene 5 *(MDA5)*. For example, TLR7 sensors transduce a signal, via the adaptor MyD88 (myeloid differentiation 88), to upregulate expression of inflammatory cytokines such as IL-6, IL-12, and TNF (via mitogen-activated protein kinase and nuclear factor κB activation) and type I IFNs (via IFN regulatory factor 7 activation). These pathways involve multiple intermediate molecules, such as TRIM (tripartite motif) and TNFR-associated factor (TRAF), and ubiquitination steps, and the transcriptional profiling demonstrated the activation of these gene pathways. TLR2 pathways are associated with cytokines promoting a Th2 phenotype, and TLR7, TLR8, and TLR9 are associated with Th1 pathways. The pattern of TLR activation is consistent with the finding of a mixed Th1/Th2 $CD4^+$ cell response to 17D vaccine.

With the resulting production of IFN-α and IFN-β, there was broad activation of multiple IFN-induced genes involved in antiviral responses including STAT1; OAS 1, OAS 2, OAS 3, and IFN-stimulating gene (ISG) 20, which degrade viral RNA double-stranded RNA-activated protein kinase (PKR); MX1, MX2, and EIF2AK2, which inhibit viral replication; and ISG15 involved in ISGylation and ubiquitination.[594,595,600,603] Other major pathways and transcriptional elements that were upregulated include integrated stress response genes, complement system genes, and monocyte/macrophage and NK cell–associated genes. Activation of the complement system included C1Qa, C1Qb, C3AR1, and SERPING1. The complement system has been shown in studies of West Nile virus to be critical to survival and T- and B-cell responses.[606] NK cell–associated genes are upregulated, and these cells show increased expression of TLR3 and TLR9 and various markers, including CD69, CD38, and CD16.[598]

Activation of inflammasome includes upregulation of caspase-1, caspase-5, and IL-1β production. Activation of the inflammasome may in turn depend on TLR triggers, IFN regulatory factor 3, and activation of nuclear factor κB. IL-1β may serve as an adjuvant to T- and B-cell responses. An important transcriptional element upregulates ETS2, which transduces multiple genes involved in activating NK cells, antigen-presenting cells, and T and B cells. TNF receptor superfamily (TNFRSF) genes are activated, including TNFRSF17, a receptor for B-cell activating factor (BAFF, also known as TNFSF13B) that is known to regulate B-cell responses.

Investigation of the genes activated following vaccination with 17D have provided a more-detailed view of the interplay of innate and adaptive responses and have elucidated specific gene signatures correlating with T- and B-cell responses.[594,595,603] A gene signature, including EIF2AK4 and C1qB, accurately correlated with $CD8^+$ T cell responses, whereas B-cell growth factor TNFRS17 predicted the neutralizing antibody response with up to 100% accuracy.[594] Activation of genes associated with B-cell activation tended to occur late (days 10 to 14), in concert with the appearance of neutralizing antibodies. *FOXO3A* and *E2F1* gene activation is also notable in these studies[595] because these genes are mediators of apoptosis, which is an early event in 17D infected cells, compared to wild-type yellow fever, and may be an important factor in the attenuation phenotype of 17D.[607]

The bridge between the innate and adaptive response depends on upregulation of MHC and costimulatory molecules (e.g., CD40, CD80, and CD86) on dendritic cells, recruitment of and antigen presentation to $CD4^+$ and $CD8^+$ T cells, control of dendritic cell life span, and IL-6–induced suppression of regulatory T cells. Owing to the activation of multiple TLRs, a mixed Th1/Th2 cytokine and T-helper response is evoked.[603,608] The very robust innate response to 17D virus probably underlies the rapid, strong, and durable adaptive responses. It is also likely that patients who have an unfavorable outcome to disease and vaccination have defects in innate and adaptive immune responses that result in virus outracing immunity during the early stage of infection or develop immunopathologic responses during the later stages, such as cytokine storm, through a dysregulated immune response characterized by an overexuberant proinflammatory cytokine response.[275]

Adaptive Immune Responses to Vaccination

The key protective elements of immunity to yellow fever are T cells and neutralizing antibodies. Yellow fever vaccine induces cytotoxic $CD4^+$ and $CD8^+$ cells that destroy cells infected with the vaccine virus (or wild-type virus, if exposed) and a mixed Th1/Th2 $CD4^+$ helper response for antibody production during the second week. Neutralizing antibodies elicited by the vaccine in advance of exposure to the bite of an infected mosquito are the key mediators of immunity and prevent virus replication and spread. Patients with defective innate or adaptive immunity can develop severe infections caused by 17D vaccine; fortunately these events are very rare.

Humoral Immune Responses to Vaccination. Although the immune response to 17D vaccine is broad and involves all arms of the immune system, humoral immunity mediated by viral-specific antibodies is the primary protective element of immunity. Using knockout mouse models, $CD4^+$ T cells, B cells, and antibodies were all found to be required to provide the mice full protection against a subsequent challenge.[609] The principal role of humoral antibodies in protection was also shown by transferring serum from immune hamsters and monkeys before or shortly after challenge with virulent yellow fever.[280,479,610]

Test Methods Affecting Interpretation of Antibody Responses. The neutralization test is the gold standard for measuring immunity following vaccination. Unfortunately, it is not widely available and is difficult and time consuming.

Various methods have been used to measure neutralizing antibodies, and these methods vary with respect to sensitivity (Table 63.8). Tests in mice were used through the 1950s and in some laboratories thereafter, but these tests were subject to considerable variability (reviewed by Smithburn[611]). The intraperitoneal neutralization test in newborn or 18- to 21-day-old mice was shown to be more sensitive for detecting neutralizing antibodies than the intracerebral test, owing to the higher and more rapid lethality of virus for mice inoculated by the latter route.[612,613]

Tissue culture neutralization tests have replaced tests in mice. These tests avoid the need for animals, are considerably more convenient and less costly, provide results in a shorter time (5 to 7 days vs 21 days in mice), and are more reliable and quantitative.[612,614,615] A standardized plaque-reduction test has been described,[612,616] but these reports are quite old.

A variety of continuous cell lines, including monkey kidney cells (MA-104, LLC-MK2, and Vero), hamster kidney (BHK-21), porcine kidney (PS), and primary chick or duck embryo cells, may be used for plaque assays. A comparative study showed that the intraperitoneal neutralization test performed in newborn mice was a somewhat more sensitive assay for neutralizing antibodies than the constant serum-varying virus plaque-reduction test in MA-104 cells.[612] The cell culture test was, however, more sensitive than the intracerebral suckling or adult mouse tests. Similarly, Poland and colleagues[614] showed that a constant virus-serum dilution plaque-reduction test in Vero cells was more sensitive than the intracerebral adult mouse neutralization test.

Differences in test sensitivity account for the variable geometric mean antibody responses noted in clinical trials (Table 63.9).[329,358,361,537,547,548,592,601,617–647] However, they do not appear to influence seroconversion rates, when seroconversion is measured relatively early (e.g., 1 month or several months) after vaccination. The determination of low antibody levels, for example many years after vaccination, may be problematic if an insensitive test is used. In a study of persons vaccinated 30 to 35 years earlier, Poland and colleagues[614] found that the intracerebral adult mouse neutralization test had a 52% false-negative rate compared to plaque reduction, with the false-negative sera having low antibody titers.

A standardized assay was not used across clinical trials (see Table 63.9). The serum-dilution plaque-neutralization test has been used in recent years as the method of choice in many clinical studies of yellow fever vaccines, including randomized trials.[496,547] The percentage of plaque reduction used to define the titer end point has varied between 50% and 90% (50% has been the most commonly used end point for vaccine

TABLE 63.8 Methods Used to Measure Yellow Fever Antibody Responses in Animals and Humans

Host	Description	End Point	Comment
Monkey (rhesus)	Simultaneous SC or IP inoculation of test serum and virus	Death	Used in early studies before development of mouse model
Mouse (adult)	IC inoculation of preincubated mixture of serum with constant virus dose (100 LD_{50})	Survival ratio or survival time; quantitative test (log_{10} neutralization index) measures difference in virus titer between test and control sera	In screening test, survival time end point was more sensitive
Mouse (adult)	IC inoculation of starch followed by IP inoculation of serum–virus mixture	Survival ratio	Extensively employed in early serologic surveys
Mouse (18–21 days old)	IP inoculation of serum–virus mixture	Survival ratio	More sensitive (higher serum antibody titers) than adult mouse tests
Mouse (newborn)	SC, IP, or IC inoculation of serum–virus mixtures	Survival ratio	
Cell culture	Constant serum-varying virus dilution	Log_{10} neutralization index determined by plaque reduction or cytopathic effect	Measures quantity of virus neutralized by undiluted or low dilution of serum
Cell culture	Constant virus-varying serum dilution	Highest serum dilution reducing a defined proportion of plaques	Sensitivity varies with end point selected (50%, 70%, 90% plaque reduction)

IC, intracerebral; IP, intraperitoneal; LD_{50}, median lethal dose for 50% of test subjects; SC, subcutaneous.

studies but 90% is preferred for diagnostic evaluation). Some investigators have expressed the titer end point as a reciprocal dilution of the highest serum dilution reducing plaques by the specified percentage; others have attempted to standardize the test with an international reference serum and expressed the titer in IU/mL.[547] Hence the sensitivity (reflected by geometric mean antibody titer) has varied considerably, presumably owing to the methodological differences in virus strains and cell lines used, as well as the use of accessory factor (complement), agar overlay composition, and plaque-detection staining methods.[556] These variables make it impossible to compare immunogenicity in terms of antibody titers across different clinical trials.

The constant serum–varying virus neutralization test has been considered by some to be a preferable method for determining the antibody response to yellow fever vaccine.[193,601] This method has been compared to the mouse neutralization test[612] and was formally validated prior to a Phase III trial.[601] More importantly, the test serves as a surrogate for protection, because the cutoff for a positive antibody test (LNI of 0.7) has been established by studies in monkeys in which animals were challenged with lethal wild-type virus.[485] Moreover, the level of neutralization (quantity of virus neutralized) in undiluted or minimally diluted serum may be biologically more meaningful than a serum dilution end point titer. In contrast, the level of seroprotection in the serum dilution–constant virus neutralization test has not yet been agreed on by any regulatory agency. The LNI test may, however, be slightly less sensitive than the serum dilution–constant virus plaque-reduction method and appears to be influenced by antibody affinity, which can change over time. For measurement of the immune response in an individual, the difference in titer between prevaccination and postvaccination sera expressed as the LNI represents the neutralizing capacity of the serum.

The test is performed by mixing a volume of normal or test serum (undiluted or at a very low dilution) with an equal volume of a series of 10-fold dilutions of virus over a range that includes the virus titer end point (e.g., 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}). After incubation for a suitable period (e.g., 1 hour at 37°C) the serum–virus mixtures are titrated in cell culture by plaque assay. The titer of virus (expressed as $\log_{10}$ PFU/mL) of the test series is subtracted from the titer in the control series to determine the LNI. For example, if the virus titer with normal serum is 5 $\log_{10}$ PFU/mL and with the test serum it is 2 $\log_{10}$ PFU/mL, the LNI is 3.0, reflecting neutralization of 3 logs of virus. If a prevaccination serum is not available, the LNI is calculated using a normal serum control. Because complement increases the sensitivity of the yellow fever neutralization test, and because complement levels may be unstable in stored sera, it is preferable to heat-inactivate test samples; some laboratories add complement (or a standard source of fresh-frozen serum) to the virus-serum mixture.

The IFA, ELISA, hemagglutination-inhibition, and complement-fixation methods have been used to measure responses to yellow fever vaccine.[376,536,612,632,648,649] When compared to the plaque-reduction neutralization test, a commercial indirect fluorescent antibody assay (Euroimmun AG, Lübeck, Germany) showed greater than 95% specificity and sensitivity for detecting IgG antibodies following primary yellow fever vaccination, and it appears to be suitable for rapid determination of serologic response.[376] There was a high (98%) correlation in categorical response but no correlation between indirect fluorescent antibody and neutralizing antibody titer.[364] Where critical decisions on protective immunity are required, however, confirmation by neutralization test may be warranted until sufficient data on sensitivity of indirect fluorescent antibody tests accumulate. The hemagglutination-inhibition test is less sensitive than neutralization and is complicated by low specificity in persons with prior flavivirus exposure.[650] The choice of yellow fever antigen might affect results; use of 17D viral antigen provided a more sensitive assay for detecting vaccine-induced immunity than antigens prepared from the French neurotropic virus or a wild-type (JSS) strain.[649]

Persons without prior flavivirus exposure generally do not develop CF antibodies after administration of 17D vaccine.[329,330] Consequently, it was thought that the complement-fixation test distinguishes recent infection with wild-type virus from vaccine-induced immunity. However, in one study, subjects with prior heterologous flavivirus immunity developed broadly cross-reactive CF antibodies to yellow fever following 17D vaccination.[329] The complement-fixation test might correlate with protein-specific antibodies to NS1. When measured by ELISA or Western blot, anti-NS1 antibodies are absent after primary 17D vaccination, but they can be found in vaccinated persons who have preexisting flavivirus immunity. IgG ELISA is insensitive and unsatisfactory for detecting seroconversion to 17D vaccine.[364,600,651]

IgM antibody responses measured by IFA and ELISA are further discussed in "Antibody Subclass Response" later.

Neutralizing Antibody Response in Clinical Trials. The neutralizing antibody response to 17D vaccine has been evaluated in numerous studies since the vaccine was developed in the late 1930s. Theiler and Smith[21] and Smith and colleagues[22] demonstrated appearance of neutralizing antibodies within 1 to 2 weeks after immunization. In a field study in Brazil (1937–38), 94% of 882 vaccinees seroconverted after vaccination.[22] Subsequent clinical trials have confirmed the high immunogenicity of yellow fever 17D vaccine, with development of neutralizing antibodies exceeding 90% in nearly all studies (see Table 63.9). Since 2000, there have been at least five large randomized immunogenicity trials in adults or children, the purpose of which was to compare vaccines for registration by local national control authorities[537,548,601,619] or to compare lots made from new secondary seeds and 17D and 17DD substrain vaccines.[547] Response rates have been similar for vaccines produced from the 17DD and 17D-204 (or 17D-213) substrains, for vaccines formulated with or without stabilizers, and for vaccines with and without avian leukosis virus.

Neutralizing antibody levels following 17D vaccine show a degree of individual variability (Fig. 63.11).[317,601] However, when a validated LNI assay was applied in a randomized clinical trial setting, the 95% confidence limits were quite narrow: Among seronegative subjects treated with YF-Vax (N = 291), geometric mean LNI was 2.20, 95% CI was 2.12, 2.28; for ARILVAX-treated subjects (N = 283), geometric mean LNI was 2.08 and 95% CI was 1.97, 2.13.[601] These data are similar to those reported in other trials using the plaque-reduction neutralization method.[547]

Kinetics of the Antibody Immune Response. Studies in rhesus monkeys established that neutralizing antibodies were detectable in serum on day 6 or 7 following inoculation of 17D virus, at which time the animals were completely refractory to challenge. Significant protection was present 1 to 2 days before the appearance of detectable neutralizing antibodies,[611,613] suggesting that very low levels of antibody were protective. Occasional animals survived challenge at even earlier times after 17D immunization, suggesting that IFN or other antiviral mechanisms may also play a role in protection.

Human immunization with 17D virus is also followed by the rapid appearance of neutralizing antibodies, detection of antibodies being dependent upon the sensitivity of the neutralization assay. Early studies using the mouse protection test failed to detect antibodies 7 days after vaccination, but the

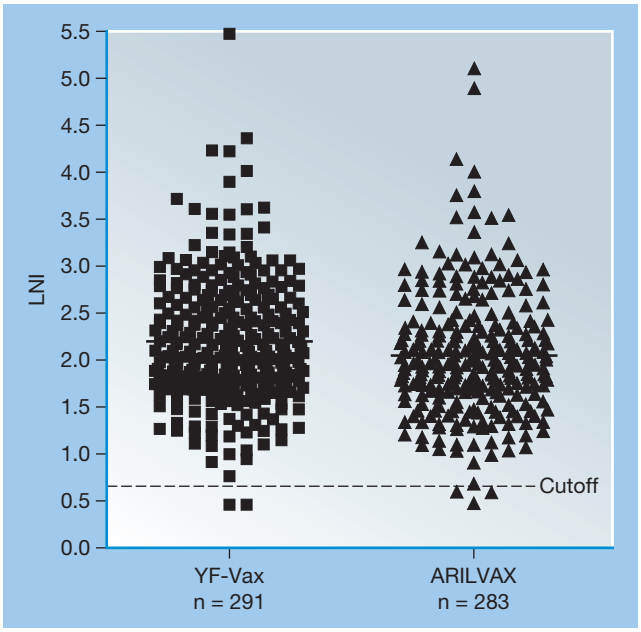

Figure 63.11. Variability of the neutralizing antibody responses in seronegative healthy adults in a Phase III clinical trial of YF-Vax and ARILVAX. LNI, $\log_{10}$ neutralization index. *(From Acambis Inc. Clinical study report, Protocol H-070-005, 1999; see Monath TP, Nichols R, Archambault WT, et al. Comparative safety and immunogenicity of two yellow fever 17D vaccines [ARILVAX and YF-VAX] in a phase III multicenter, double-blind clinical trial.* Am J Trop Med Hyg. *2002;66[5]:533–541.)*

majority of subjects had seroconverted by day 14.[21,22] Smithburn and Mahaffy[613] found neutralizing antibodies in 10% of a small group of subjects on day 7 and in 90% on day 10 after immunization. Wisseman and colleagues[633] found no evidence of immunity on day 6, but all subjects had seroconverted by day 14 after vaccination. In a newer study, Lang and colleagues[622] found that 86% to 88% of adult subjects seroconverted by day 14, and 99% to 100% had seroconverted by day 28 after vaccination. Similarly, Reinhardt and colleagues[358] showed that all subjects seroconverted between days 6 and 13 and that mean antibody titers increased slightly from 1:71 on day 13 to 1:88 on day 26 after vaccination. Monath and colleagues[193] found that 80% of subjects seroconverted by day 11 and 100% by day 31, with a marked increase in antibody level measured by LNI from 1.26 to 3.98. Silva and colleagues[602] found that 30% of subjects developed neutralizing antibodies by day 7 and 100% by day 15 after vaccination. Based on human and monkey studies, Courtois[652] concluded that "man seems unable to form antibodies so early as the rhesus but by the 10th day his serum has a very high degree of protective activity. Judging from the studies carried out in monkeys, it seems probable that a protective mechanism begins to operate in man by the 8th or 9th day." This conclusion was incorporated into the International Health Regulations,[653] which stipulate that the vaccination certificate for yellow fever is valid 10 days after administration of 17D vaccine.

Studies employing more-sensitive neutralization tests have demonstrated antibodies at earlier times following administration of 17D vaccine. Monath[654] found the earliest evidence for neutralizing antibodies by plaque-reduction assay on day 4 in one of four volunteers, and all subjects had seroconverted by day 8. Time to appearance of antibodies was not shortened by use of a kinetic neutralization test. Bonnevie-Nielsen and colleagues[600] found no antibodies by plaque-reduction neutralization test on day 4 after vaccination; 25% were immune on day 7 and 88% on day 12. Thus, it appears that immunity to yellow fever can occur in a minority subset of vaccinees during the first week after immunization. Neutralizing antibody levels continue to increase during the first month after immunization, with peak titers found at 3 to 4 weeks.[633,654] In one study of 238 subjects in Brazil, who were tested at various time points up to 17 months after vaccination, neutralizing antibody titers began to decline at around 13 months.[623]

Antibody Subclass Response. IgM antibodies appear rapidly after 17D vaccination, but as discussed later they can persist for long periods of time and therefore do not indicate recent immunization. The ELISA and indirect fluorescent antibody methods are more-practical approaches for measuring IgM antibodies than fractionating serum for neutralization testing.

The primary immune response is characterized by the appearance of neutralizing antibodies of the IgM class between days 4 and 7, several days before detection of IgG antibodies.[654] Titers of IgM neutralizing antibodies were 16- to 256-fold higher than IgG antibodies during the first 4 to 6 weeks after immunization. During a field study in Nigeria, 141 (37%) of 385 persons vaccinated with 17D seroconverted by IgM antibody-capture ELISA.[163] However, prior flavivirus exposure in this population was high, and this might have reduced IgM responses. In clinical studies in Europe, IgM antibodies measured by capture ELISA appeared in 83% of volunteers within 2 weeks after primary immunization.[358,601] De Melo and colleagues[623] studied 238 subjects in Brazil who received 17DD vaccine, of whom 82% had had prior dengue infections. Prior dengue immunity did not significantly reduce the IgM antibody response to yellow fever vaccine. In this study, 71% of the subjects developed IgM antibodies as determined by ELISA.

Nogueira and colleagues[655] found persistence of IgM antibodies for at least 2 months after vaccination with 17DD vaccine and de Melo and colleagues[623] found 43% of subjects remained IgM positive when tested between 100 and 349 days after vaccination. More recently, Gibney and colleagues[656] found that 73% of persons vaccinated 3 to 4 years previously were IgM-positive. In contrast, IgM antibodies were not detected in another cohort of subjects tested 2 years after primary immunization.[601] (See "Duration of Immunity" later for more discussion on reasons for persistence.)

The memory B-cell response after yellow fever revaccination was not associated with an IgM response in one study where the interval between primary and revaccination was relatively short (2 years),[601] whereas in another study four of five subjects revaccinated with an interval longer than 10 years developed anti–yellow fever IgM.[358] Two individuals who had received yellow fever vaccine 23 and 45 years previously and then received yellow fever vaccine through transfused blood products developed IgM antibodies against yellow fever virus.[657] IgM responses measured by indirect fluorescent antibody test were less common in subjects who had preexisting heterologous flavivirus immunity, but all responded with IgG antibodies.[376]

The IgM antibody capture ELISA was evaluated in 21 Cuban subjects who received 17D vaccine.[377] The test was similar in sensitivity to the plaque-reduction neutralization. Of 17 naïve subjects, 16 (94%) seroconverted by IgM ELISA. The test was highly specific and showed no cross reactions with dengue antigen. However, 11% of dengue immune sera cross-reacted by IgM ELISA using yellow fever antigen. Similar results were reported in subjects with and without preexisting Japanese encephalitis antibody who received 17D vaccine.[658] On day 10 after 17D vaccination, yellow fever virus–specific neutralizing antibodies were detected in six of 19 subjects and IgM

antibodies were detected in seven of 19 subjects. On day 14, all subjects had IgM and neutralizing antibody responses. From these limited studies, it appears that the IgM capture ELISA may be similar in sensitivity to the neutralization test in detecting serologic response to 17D vaccine when sera are obtained early after vaccination.

The indirect fluorescent antibody test was compared with plaque reduction in 17D primary vaccinees.[376] An overall correlation of 99% with neutralization was observed in primary vaccinees. Sensitivity and specificity of both the IgG and IgM responses were greater than 94%.

Despite the early work showing functional (neutralization) activity of IgM, the role of IgM antibody in protection or recovery from infection has not been clearly shown. In one study of 2C9 MAb with the same antigen recombining site but different isotypes (IgG or IgM), only the IgG molecule protected AG129 mice from peripheral yellow fever virus challenge.[386] This observation suggests that the ability of 2C9 IgG to protect was owing to the Fc portion of the IgG molecule. On the other hand, protection against another flavivirus (West Nile virus) in the mouse model was found to be highly dependent on the early IgM response.[659]

Serologic Specificity. The primary neutralizing antibody response to 17D vaccine is highly specific, characterized by no or very-low-titer antibodies to other flaviviruses.[342,633] In addition, neutralization titers in persons receiving 17D vaccine are higher against the homologous (vaccine virus) than against wild strains but antigenic conservation of neutralization epitopes is sufficient to ensure vaccine efficacy. Neutralizing antibodies in the IgG and IgM fractions of serum display similar specificity in primary vaccinees, whereas IgG (but not IgM) from a person who had been vaccinated three times and was tested 18 months after the last immunization showed some flavivirus cross-reactivity.[654] IgM responses determined by indirect fluorescent antibody assay or ELISA tend to be yellow fever–specific even in subjects with preexisting heterologous flavivirus experience, although fewer such subjects develop IgM responses than in primary vaccination.[376] In contrast, one report described a high rate of IgM seroconversion to dengue in yellow fever vaccinees, although prior dengue exposure could not be excluded in all subjects.[339] The HI antibody response to primary immunization is also yellow fever specific.[650] In contrast, persons with heterologous immunity respond to 17D vaccination with the development of a broadened response and appearance of both homologous (yellow fever) and heterologous N, HI, IgG ELISA, and IFA and CF antibodies.[329,633,654] Similarly, persons with prior 17D immunity respond to natural infection with heterologous flaviviruses with the development of a broadened flavivirus group response.[342,660] Yellow fever–immune subjects given a monotypic ChimeriVax dengue-2 vaccine developed high titers of heterotypic neutralizing antibodies to dengue types 1, 3, and 4.[661]

The phenomenon of "original antigenic sin" has been noted in persons previously vaccinated with 17D virus and subsequently infected with another flavivirus. In such cases, an anamnestic response leads to a rapid rise in yellow fever antibodies, whereas the response to the heterologous antigen is delayed. This phenomenon was observed in yellow fever–immune volunteers who were vaccinated with experimental dengue-2 vaccines.[348,662] Original antigenic sin might lead to diagnostic confusion in patients with clinical syndromes resembling naturally acquired yellow fever.[378]

Antibody-Dependent Enhancement. Clinical experience indicates that there is no evidence that yellow fever vaccination increases the risk of severe dengue disease. This is a question of immense importance, because dengue viruses are encroaching on yellow fever endemic areas in South America, where routine 17D vaccination is performed. Serologic studies should be performed in individual cases of dengue hemorrhagic fever to define the role of prior yellow fever immunity. In the case of Japanese encephalitis, preexisting immunity did not increase viremia following yellow fever 17D vaccination.[183]

Cellular Immune Response to Vaccination. Cytotoxic T lymphocytes mediate killing of flavivirus-infected cells and are an important effector mechanism of viral clearance during primary infections. T-cell responses following 17D vaccination are both broad (representing a diverse oligoclonal repertoire of cells) and long lasting (many years).[145,146,604,663,664] Beginning during the first week after vaccination, effector $CD8^+$ cytotoxic T cells with antiviral activity and $CD4^+$ cells with a mixed Th1/Th2 pattern appear very rapidly.[594,595,665,666] At 2 to 4 weeks after vaccination, effector cell populations peak before contracting into a memory $CD45RA^+$ T-cell population.[667]

The first study of antigen-specific T-cell responses was by Co and colleagues,[145] who studied the T-cell responses in four human subjects vaccinated with 17D. All four subjects responded by lymphoproliferation, cytotoxic T-cell, and IFN-γ ELISPOT (enzyme-linked immunospot) assays. Antigen-specific responses by IFN-γ on an ELISPOT assay were observed at the earliest time point studied (14 days) and were detectable at 19 months after vaccination. $CD8^+$ T-cell lines were established, the majority of which were HLA-B35 restricted. $CD8^+$ T-cell epitopes were recognized in viral proteins E, NS1, NS2B, and NS3. T-cell frequencies specific for these epitopes were in the range of 10^{-4}. Subsequently, Co and colleagues studied the dynamics of $CD8^+$ T-cell responses to defined HLA-B35–restricted 17D epitopes in human subjects. Positive cells were detected as early at 7 days and peaked 2 weeks after vaccination, with approximately 1% of peptide-specific cells at that time point.[663]

Miller and colleagues[665] and Akondy and colleagues[146] studied $CD8^+$ T-cell responses following inoculation of 17D vaccine in healthy adults. Two weeks after vaccination, there was a maximum expansion of a pool of effector $CD8^+$ T cells (Fig. 63.12). These cells were characterized by expression of

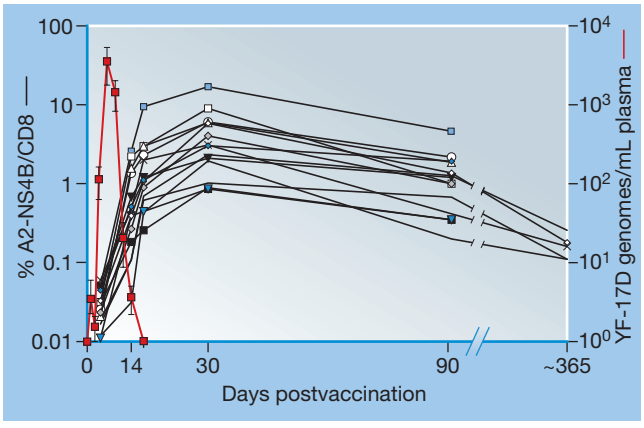

Figure 63.12. Kinetics of the yellow fever 17D–specific $CD8^+$ T-cell response by major histocompatibility complex (MHC) class I tetramer staining in human subjects. The red line indicates the level of 17D RNA in blood (mean ± standard deviation). The black lines are responses of individual subjects, showing the percentage of positive cells against an immunodominant epitope on NS4B. *(From Akondy RS, Monson ND, Miller JD, et al. The yellow fever virus vaccine induces a broad and polyfunctional human memory CD8+ T cell response.* J Immunol. *2009;183:7919–7930.)*

T-cell activation markers, CD38, CD127, CCR7, and HLA-DR. In addition, at the peak of the response on day 15, up to 15% of $CD8^+$ T cells were specifically activated; they also expressed Ki-67, perforin, and granzyme B. Interestingly, these cells downregulated expression of antiapoptotic Bcl-2 molecules, suggesting that the responding T cells proliferate, acquire cytolytic potential, and have increased susceptibility to apoptosis. At 2 to 4 weeks after vaccination, virus-specific effector populations contracted 90%, downregulated expression of the activation markers, and gradually differentiated into long-lived memory cells that reexpressed CD127, Bcl-2, and CD45RA. These differentiated $CCR7^-$ $CD45RA^+$ memory $CD8^+$ cells were polyfunctional; produced multiple cytokines, including IFN-γ, TNF-α, IL-2, and macrophage inflammatory protein (MIP)-1β; demonstrated robust proliferation upon restimulation; and are likely important in long-term protection against exposure to yellow fever virus.[146] Additional experiments monitoring the activation status of cytomegalovirus, Epstein-Barr, and influenza-specific $CD8^+$ T cells in subjects inoculated with 17D vaccine showed that bystander activation does not contribute to the peak of the anti-17D $CD8^+$ T-cell response and indicated that the observed T-cell responses were primarily 17D specific. A separate study was able to show a positive correlation between the initial viral load in persons receiving 17D vaccine and the magnitude of the $CD8^+$ T-cell response.[668] However, above a certain viral level the magnitude of the $CD8^+$ T-cell response is saturated or plateaus. These results in combination with that of dose-sparing studies suggest that sufficient levels of viral antigen need to be given with certain viral vaccines, like yellow fever vaccine, to ensure a complete immunologic response.[557,558,668]

In other studies, lymphocyte subsets were defined in 17D first-time vaccinees and revaccinees.[618] The results confirmed the observations just described, in that activated $CD8^+$ cells expressing CD38 proliferated after primary and revaccination. In addition $CD3^+$ and $CD4^+$ cell subsets increased in both groups; the increase in $CD4^+$ and $CD8^+$ memory cells was greater in revaccinated subjects. In persons with prior flavivirus experience, memory T-helper and B cells reactive to specific and cross-reactive antigenic determinants contribute to the rapid anamnestic antibody response.

Using different knockout mice with various deficiencies in T and B cells, Bassi and colleagues found that $CD8^+$ cells were in fact not needed to develop protective immune response following vaccination when the mice were challenged intracerebrally with 17D virus.[609] However, $CD8^+$ cells facilitated virus clearance and were necessary in B-cell deficient mice to ensure their survival when challenged. Furthermore, $CD8^+$ cells also appeared to facilitate viral clearance in mice that were vaccinated and then challenged 28 days later; without $CD8^+$ cells, virus was found to persist in the brains of the inoculated animals. These results suggest that $CD8^+$ cells help control viral proliferation and might be necessary for complete viral clearance.

A detailed analysis of cell surface markers in peripheral blood of subjects following yellow fever 17D vaccination showed a complex sequential activation and regulation of B and T cells.[604] The authors speculated that this finely tuned activation of innate and adaptive immune responses determined the outcome of infection (recovery-immunity vs runaway infection and vaccine-related adverse events). The most striking changes occurred between days 7 and 15, the period in which the adaptive immune response occurs. Changes in B cells reflected both activation and modulation, upregulation of IL-1OR, $CD69^+$, CD32 (FcγR), and decreased $CD23^+$ expression. $CD4^+$ T-cell activation occurred early and $CD8^+$ activation occurred later. Again, both T-cell activation markers and simultaneous increases in regulatory T cells were found. This study provides a basis for future analyses of B- and T-cell dysregulation in patients with viscerotropic adverse events.

Effects on Immune Response

Age. Some reports suggested that young children did not respond as well as older persons to 17D vaccine or that they lost immunity more rapidly,[669,670] but this was not confirmed in other studies.[648,671] Newer studies have also had conflicting results.

In a study of seronegative Ghanaian infants 6 and 9 months of age immunized with 17D vaccine manufactured by the Institut Pasteur in Senegal, seroconversion rates 3 months after vaccination were 99% and 98%, with a mean 50% plaque-reduction neutralization titers of 159 and 130, respectively.[620] In comparison, two pediatric studies performed in South America showed lower seroconversions rates for children.[548,619] One trial had lower neutralizing antibody responses in children to YF-Vax and ARILVAX (90.6% and 94.9% seroconversion and geometric mean LNIs of 1.26 and 1.32, respectively)[619] compared to a study of the same vaccines in adults (99.3% and 98.6% seroconversion and geometric mean LNIs of 2.21 and 2.06, respectively) (see Table 63.9).[601] The two trials used the same serologic assay and testing laboratory, but they were conducted in different populations (in children in Peru and in adults in the United States). Although antibodies to dengue were present at baseline in approximately 15% of the pediatric subjects, there was no effect of this covariate on seroconversion or on geometric mean antibody titers.[619] In a large double-blind clinical study performed in Brazil that compared 17DD and 17D-213/77 vaccines in children found seroconversion rates of 89% (95%CI, 85% to 91%) and 87% (95%CI, 83% to 90%), respectively.[548] These seroconversion rates are lower than the 99% seroconversion seen in a previous trial of similar design in adults.[547] Given these data, the WHO has called for additional study on this topic.[672] However, when a review of all pediatric data was recently conducted, Staples and colleagues[673] found an estimated seroconversion rate, when study size differences and variability between studies were accounted for using a random effects model, of 93% (95% CI, 88% to 96%) among 4675 children at 1 to 2 months of age following their primary yellow fever vaccination. Furthermore, when the random effects model was used to compare seroconversion rates between children younger than 9 months of age and those 9 months of age or older, there was no difference. For children younger than 9 months of age, data from four studies provided an estimated seroconversion rate of 95% (95% CI, 91% to 98%). In children 9 months of age or older, data from 11 studies provided an estimated seroconversion rate of 92% (95% CI, 86% to 96%).

In a large clinical trial, there was no difference between young adult and elderly (60 years of age and older) subjects in the rate of seroconversion to 17D vaccines.[674] Seroconversion rates were 97% to 100% in all ages, and the rare primary vaccine failures were observed only in the younger age groups. Geometric mean LNIs were similar across age groups (Fig. 63.13). In a smaller trial comparing persons 18 to 30 years of age to those 65 years of age and older, similar geometric mean titers were found at 28 days after vaccination.[256] However, at 10 days postvaccination, the older adults had lower seroconversion rates (50% vs 77%) and significantly lower geometric mean titers when compared to young adults. Furthermore, the study also found older adults to have higher viremia levels detectable for longer periods. These results in combination with others suggest that T-cell immune response might be delayed but the magnitude of the B-cell response, in terms of antibody production, appears to be intact.

Sex. There does not appear to be a strong gender bias. In one large trial, the magnitude of the neutralizing antibody response was statistically significantly higher in male than in female subjects,[601] although the seroconversion rates did not differ and the difference in geometric mean LNI was not biologically relevant (<0.3 $\log_{10}$) (Table 63.10). In a study in Brazil, the seroconversion rate in male subjects (but not the antibody titer) was higher than in female subjects.[547] Similarly, Niedrig and colleagues also reported higher neutralizing and IgM antibody titers in male vaccinees.[376] Naturally acquired yellow fever disease is more common in men and could to some degree, though not completely, be attributed to epidemiologic factors. Postvaccinal encephalitis caused by French neurotropic vaccine was also higher in male than in female patients, suggesting that male patients undergo a more active infection. However, it has been noted that men have greater serologic responses to some nonreplicating vaccines (e.g., pneumococcal and meningococcal polysaccharide),[675] so that the gender difference seen with yellow fever might represent an immunologic mechanism unrelated to replication of the virus.

Race. European Americans were noted to have higher mean neutralizing antibody response than African Americans in two studies (see Table 63.10).[601,621] The response was also statistically higher in European Americans than in Latin Americans and Africans.[601,676] Anecdotal evidence suggests that the lethality of wild-type yellow fever appears to be higher in whites than blacks. The trial data showing higher antibody responses in whites might reflect a higher level of susceptibility (e.g., lack of previous flavivirus immunity), virus replication, and antigen expression in this racial group.

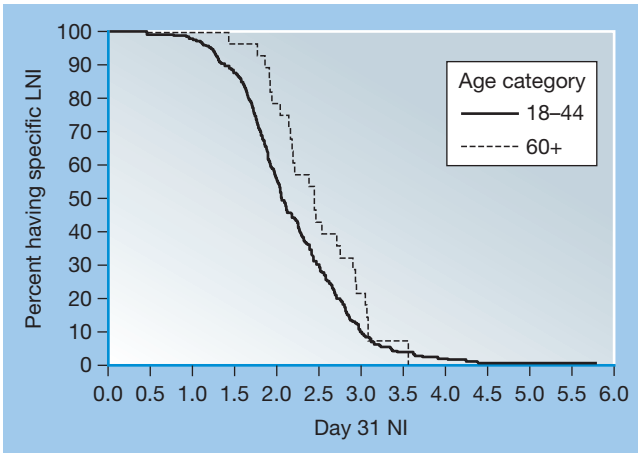

Figure 63.13. Reverse cumulative distribution of neutralizing antibody titers ($\log_{10}$ neutralization index [LNI]) for persons 18 to 44 years of age and 60 years of age and older. *(From Monath TP, Cetron MS, McCarthy K, et al. Yellow fever 17D vaccine safety and immunogenicity in the elderly.* Hum Vaccin. *2005;1:207–214.)*

Genetic Restriction. No studies have been reported on genetic restriction of immune responses to yellow fever vaccine. This is an area deserving study, because studies in mice indicate that haplotype influences replication of flaviviruses[261,262] and the immune response to live viruses.[267,677]

Vaccine Substrain or Dose. All yellow fever 17D vaccines contain a minimum of 3 $\log_{10}$ IU/dose.[531] Vaccine potency of manufactured lots exceeds this minimal limit by approximately five- to 50-fold to account for losses upon storage. The infectivity assay underestimates the number of genome equivalents (measured by RT-PCR) by approximately 1000-fold,[559] and the difference can be composed of both noninfectious (defective) and infectious virions that were not detected by the assay used.

Although there have been several studies documenting similar neutralizing antibody responses and titers following vaccination with different substrains of yellow fever vaccine, few studies have explored the innate and cellular immune responses to different substrains. In one comparative study, both 17DD and 17D-213/77 elicited a balanced cytokine profile in children 9 to 12 months of age.[678] However, there were subtle differences in the cytokine profiles between the substrains with 17DD eliciting a slight predominance of neutrophil-derived TNF-α and neutrophils and monocyte-producing IL-12, whereas 17D-213/77 had more of a predominance of IL-12$^+$CD8$^+$ T cells and IL-10 production. Whether these differences are substantial enough to impact longer-term immunity is unclear.

A dose–response relationship was observed in rhesus monkeys inoculated intramuscularly with 17D vaccine.[485,679] The dose at which 90% of the animals developed a rise in LNI greater than 0.7 was approximately 1000 MLD_{50} (approximately 4 $\log_{10}$ PFU) and the 90% protective dose against lethal challenge was approximately 200 MLD_{50} (approximately 400 PFU). The 50% immunizing dose was approximately 2 MLD_{50} (approximately 20 PFU). The relationship between PFU and MLD_{50} is approximately 10 : 1.[263]

Dose–response in humans was first determined by Fox and colleagues[680] in 1943. The minimal dose resulting in seroconversion was between 14 and 140 MLD_{50} (presumed equivalent doses in IU and estimated to represent 140 and 1400 PFU,

Data from Monath TP, Nichols R, Archambault WT, et al. Comparative safety and immunogenicity of two yellow fever 17D vaccines (ARILVAX and YELLOW FEVER-VAX) in a Phase III multicenter, double-blind clinical trial. Am J Trop Med Hyg. *2002;66(5):533–541.*

respectively). At a dose of 14 MLD_{50}, 70% of the volunteers seroconverted. Large scale-field trials of various vaccine lots, some of which were of suboptimal potency, indicated that administration of doses in the range of 10 to 50 MLD_{50} immunized more than 85% of vaccinees.

More recent dose–response studies (Table 63.11) indicate that doses of 100 to 300 PFU result in the development of neutralizing antibodies in approximately 90% of yellow fever naïve persons vaccinated.[557,558,638,681,682] In addition, an unpublished study of ARILVAX (17D-204 vaccine previously manufactured in the United Kingdom) found that 13 of 15 (93%) subjects given 200 PFU seroconverted and that all subjects seroconverted at a dose of 2000 PFU or more. Roukens and colleagues[592] gave 17D vaccine by the intradermal route at one-fifth dose and found no differences in antibody response compared to the standard dose given subcutaneously, but the trial design did not elucidate whether this was the result of a more effective route of inoculation or simply because (as expected from the foregoing) 17D vaccine efficacy drops off only at very low doses.

These data are promising that the potential amount of antigen in a dose of the vaccine could be lowered and thus have a dramatic effect on vaccine supply. Due to the large outbreaks in 2016 in Angola and later DRC, WHO reviewed available data and with the approval of SAGE endorsed the use of fractional doses in response to an emergency situation where extension of the outbreak is imminent and in which current vaccine supply is insufficient.[575] In fact, one-fifth doses of 17DD vaccine were used in Kinshasha, DRC, to preempt the spread of disease. Fractional doses were delivered to all persons aged 2 years and older; children younger than 2 years and pregnant women were given a full dose of the vaccine.[574a]

To reset the potency specifications for release of vaccine at a lower dose would require amending both national licenses and WHO requirements, with data on long-term stability, statistical noninferiority end points in clinical studies, effects of heterologous flavivirus immunity, and follow-up studies on duration of immunity.

Interestingly, an inverse relationship between vaccine dose and antibody titer has been consistently observed.[269,634,638,681] Smith and colleagues[681] found significantly higher antibody responses in subjects given doses of 5 to 50 MLD_{50} than in those given doses of 500 to 5000 MLD_{50}. In monkeys, inoculation of large doses of 17D virus resulted in earlier appearance of viremia, but viremia was inconsistent, lower in magnitude, and briefer in duration than after inoculation of diluted virus.[479] Limited replication of the virus after the inoculation of very large doses might explain the lower magnitude of the immune response. This dose prozone effect is also clearly evident in mice (Fig. 63.14) and may be explained by the presence of IFN (produced in the infected egg), defective interfering particles, noninfectious antigen competing for cell receptors, or induction of a strong innate immune response by virus inoculated at the high dose range. Similar effects have been also noted with chimeric viruses using yellow fever as a vector for the envelope genes of heterologous flaviviruses.[193,284]

Panthier[530] suggested that a low dose of 17D vaccine might cause a delay in antibody response and an increased risk of neurologic accidents (encephalitis). This hypothesis was based on a single case of encephalitis in a 4-week-old infant after pricking the skin with a needle dipped in 17D vaccine and on the work of Fox and Penna[269] in monkeys. Low-dose vaccine administration attributable to loss of vaccine potency was suggested as a factor in encephalitis caused by French neurotropic vaccine in some epidemics.[682] It is now known, however, that vaccination of infants younger than 4 months of age carries a higher risk of encephalitis owing to age susceptibility, not vaccine dose. Moreover, application of low doses of 17D

[a]Seroconversion is defined by development of neutralizing antibodies in subjects who were seronegative at baseline or fourfold increase in titers.
[b]The LD_{50}-to-PFU ratio varies for different vaccines, based on differences between the sensitivity of the assays employed or (possibly) mouse virulence of the vaccines. The Wellcome vaccine had an MLD_{50}-to-PFU ratio of 0.17,[634] whereas the Bio-Manguinhos vaccine had an MLD_{50}-to-PFU ratio of 2.9.[638]
[c]Range of doses for volunteers receiving different vaccine lots tested in the study.

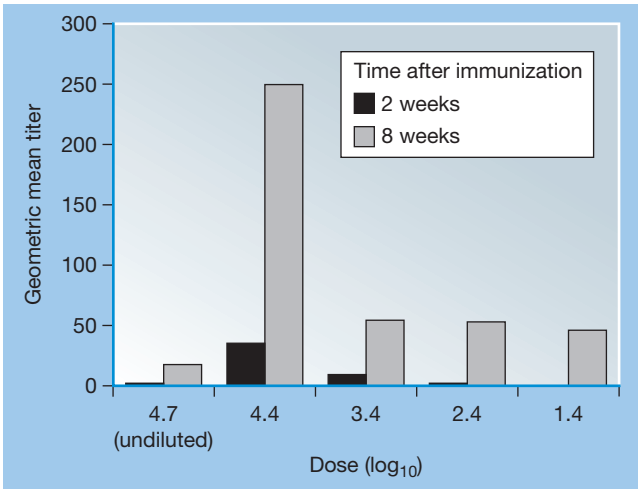

Figure 63.14. Neutralizing antibody response to yellow fever 17D vaccine in mice. Geometric mean titer, groups of five Swiss Webster mice inoculated subcutaneously with 0.1 mL of graded doses of commercial yellow fever 17D vaccine and tested 2 and 8 weeks after immunization. Antibody titers are geometric mean 50% plaque-reduction end points. A prozone was observed, with lower responses in mice given the highest virus dose. *(Courtesy F. Guirakhoo and TP Monath, unpublished data, 1997.)*

vaccine by scarification was not associated with adverse reactions and a large cluster of postvaccinal encephalitis have also occurred when the French neurotropic vaccine was used at a standard dose.[68,519,580]

Heterologous Flavivirus Immunity

Immunization in Persons With Heterologous Immunity. Using neutralization tests, yellow fever is distinct from other flaviviruses,[38] but it shares antigenic determinants detected by binding assays, hemagglutination inhibition, and complement-fixation.[305] Owing to these cross-reactive determinants, the immune response to 17D vaccine is qualitatively different in naïve persons and in those with prior heterologous immunity.

Interference With 17D Vaccine Caused by Heterologous Immunity. The evidence for interference with 17D vaccine in humans is conflicting, and discrepancies across studies may be because of the number of prior flavivirus infections, the breadth of the heterotypic response, or the identity of the viruses responsible for prior infection. Prior infection with members of the Japanese encephalitis complex does not appear to alter the immune response to 17D vaccine. Pond and colleagues[650] observed that natural immunity to St. Louis encephalitis virus had no effect on seroconversion rates to 17D vaccine. Persons with monotypic neutralizing antibodies to Japanese encephalitis virus or with broad flavivirus cross reactions had neutralizing antibody responses to 17D equivalent to those of immunologic-naïve subjects.[633] Moreover, viremic responses to 17D were not significantly different in persons with and without prior Japanese encephalitis immunity, indicating that replication of 17D virus was not reduced.[183] The results of these studies and those of Pond and colleagues[650] are consistent because St. Louis and Japanese encephalitis viruses are close antigenic relatives.

Pond and colleagues[650] also observed that persons with natural immunity to dengue had lower seroconversion rates to 17D vaccine than nonimmune subjects, an observation that appears to be consistent with the experimental data in dengue-immune monkeys challenged with wild-type yellow fever virus[337] and with epidemiologic evidence suggesting cross protection in human populations.[334–336] However, in a large clinical study of dengue-immune versus nonimmune children, there was no statistical influence of preexisting dengue neutralizing antibodies on seroconversion rates and geometric mean neutralizing antibody titers following 17D immunization.[619] In a study of primary vaccinees in Brazil, de Melo and colleagues[623] found that subjects with prior dengue immunity had lower geometric mean neutralizing antibody titers (geometric mean titers 860) than those without dengue immunity (geometric mean titers 1120), although the difference was not statistically significant.

Yellow fever antibodies acquired by natural infection with heterologous flaviviruses significantly blunted the magnitude of the neutralizing antibody response to 17D vaccine.[329,681] Interference was particularly evident when 17D vaccine was given by scarification, possibly owing to the lower dose of 17D administered by this route. Low response rates to 17D vaccine administered by scarification were associated with preexisting heterologous flavivirus immunity in multiple studies in Africa.[586,588,589] In contrast, volunteers who had previously received a live attenuated dengue vaccine and were subsequently given 17D vaccine had similar immune responses to yellow fever as dengue nonimmune controls, suggesting no interference with yellow fever vaccine replication.[348] It is possible that the lack of interference was related to the attenuated properties of the dengue infection. In a study conducted in Nigeria, Omilabu and colleagues[684] found no restriction of neutralizing antibody responses to 17D vaccine in persons with various patterns of preexisting flavivirus immunity. In general, however, immune activation at the time of vaccination will likely impede the response, as was shown when the immunologic response was compared between vaccine recipients in Uganda and recipients in Switzerland.[676] Uganda had a lower proportion of individuals with detectable viremia and lower levels of viremia; individuals also developed lower neutralizing antibody titers when compared to vaccinated persons in Switzerland. The authors found that at baseline, persons in Uganda had higher levels of $CD8^+$ T cells and B cells, as well as proinflammatory monocytes, and this negatively correlated with subsequent antibody titers. These findings suggest that immune activation prior to vaccination decreased the response to the vaccine and could explain some of the findings seen related to dengue immunity.

A number of new vaccine candidates have been developed using 17D virus as a vector for foreign genes, including chimeric viruses in which the prM-E genes of 17D virus have been exchanged for the corresponding genes of a heterologous flavivirus.[685–687] Because the chimeras contain nonstructural genes that could induce antivector immunity, studies were performed to investigate interactions between 17D and the chimeric vaccines. In one published study, there was a suggestion (not statistically significant) that prior immunization with a chimeric yellow fever–Japanese encephalitis vaccine (ChimeriVax-JE) reduced the seroconversion rate and geometric mean neutralizing antibody titer to 17D vaccine given 30 days later.[617] However, in a larger clinical trial, there was no interference with respect to the response to 17D vaccine in subjects who had been given ChimeriVax-JE vaccine 30 days previously.[688] The interactions between dengue and yellow fever appear to differ (see the next section). There is no clear evidence that prior flavivirus immunity enhances replication of yellow fever 17D virus or the immune response to 17D virus (see "Antibody-Dependent Enhancement" earlier).

Heterologous Immunization in Persons Immune to Yellow Fever 17D. Several live attenuated flavivirus vaccines have been evaluated in persons with prior immunity to 17D vaccine, including empirically derived dengue type 2 vaccines.[349,662] In yellow fever–immune persons, the response to dengue vaccine was independent of dose and was of greater magnitude and

duration than in nonimmune persons. The results suggested that cross-reactive nonneutralizing antibodies might have enhanced dengue virus replication in vivo. Similarly, a clinical study of a chimeric vaccine in which 17D vectored the prM-E genes of dengue type 2 virus showed significantly higher, durable neutralizing antibody responses to dengue in yellow fever–immune subjects. In addition, a notable broadening of the response occurred across all four dengue serotypes, indicating that the initial 17D vaccine had primed for an anamnestic response to cross-reactive shared epitopes.[661,689] This was also true when a tetravalent mixture of chimeric 17D viruses with envelope genes of dengue types 1 to 4 was given to yellow fever immune and nonimmune subjects.[690,691] There were also slightly higher geometric mean titers seen when the chimeric tetravalent dengue vaccine was given within 3 years of their yellow fever vaccination rather than 3 or more years after.[692] Finally, tetravalent dengue vaccination induced a slight increase in the geometric mean titers of yellow fever in children previously vaccinated against yellow fever.[692]

Data on interactions between yellow fever 17D and chimeric vaccines are inconsistent. In two published studies, prior yellow fever vaccination did not influence the immune response to ChimeriVax-JE vaccine.[193,617] However, in a third study, yellow fever 17D vaccine administered 30 days prior to ChimeriVax-JE vaccine did not affect seroconversion to the Japanese encephalitis virus, but it blunted the neutralizing antibody titer.[688] The data suggested that when a more-immunogenic vaccine (17D) preceded a more-attenuated live vaccine (ChimeriVax-JE), cross-reactive antibody and/or T-cell responses to the yellow fever backbone could blunt the infection and neutralizing antibody response to the second vaccine.

Interestingly, in studies in which viremia was evaluated in yellow fever immune and nonimmune subjects who received ChimeriVax–dengue-2[661] and ChimeriVax-JE vaccines,[193] a higher proportion of yellow fever–immune subjects developed viremia, and viremia levels were slightly higher than in nonimmune subjects, suggesting in vivo immune enhancement. However, the differences in viremia were subtle and were not statistically significant. In a study of tetravalent dengue vaccine, the early viremia profiles were quite similar in the yellow fever–immune and –naïve groups,[689] suggesting that, in this case, prior yellow fever immunity modulated the antibody response (through immunologic memory) rather than abrogating the infection. Now that dengue vaccines are undergoing clinical evaluation, it is very important to determine whether prior dengue vaccination diminishes the viremia following 17D vaccination, which might be expected based on epidemiologic and experimental studies suggesting unidirectional cross-protection between dengue and yellow fever.[337,341]

Prior 17D immunization modulates the response to inactivated flavivirus vaccines through memory responses of IgG-producing B cells and restimulation of memory T cells. In yellow fever–immune subjects receiving inactivated tickborne encephalitis vaccine, anti–tickborne encephalitis antibodies appeared earlier and in higher titers than in nonimmune subjects.[693] The anamnestic response was also characterized by the appearance of cross-reactive heterologous antibodies.

Simultaneous and Combined Vaccination. Yellow fever vaccine has been given simultaneously at different sites or as a mixture, combined with a variety of other vaccines with at least 18 unique antigens contained in 11 inactivated and 10 live-attenuated vaccines (Table 63.12).* These studies are relevant to the use of 17D vaccine in routine childhood immunization programs and to the immunization of travelers but there are limitations to many of the studies including: (a) studies were conducted several decades ago, using different vaccine preparation than currently available; (b) low numbers of subjects; (c) exclusion of targeted populations (e.g., children or adults); and (d) exclusion of special populations (e.g., those with altered immune system).

Based on the available data for inactivated vaccines, there are no safety concerns with the coadministration of yellow fever vaccine and inactivated vaccines. Immunogenicity for most vaccines appears not to be compromised when yellow fever vaccine is coadministered with inactivated vaccines.

For the coadministration of yellow fever vaccine with other live-attenuated vaccines, there are no safety concerns with coadministration with most vaccines. However, data from two studies on the coadministration of yellow fever vaccine and a dengue chimeric vaccine based on the yellow fever vaccine backbone found increased rates of both systemic and local adverse events.[661,691] Although there was no increase in serious adverse events noted, there was limited power to detect serious events. Immunogenicity for most vaccines is also not compromised when yellow fever vaccine is coadministered with other live-attenuated vaccines. Possible interference with yellow fever immune responses were noted when live vaccinia or measles vaccine[626] or inactivated hepatitis B vaccine[637] were concurrently administered with 17D, but these results were not confirmed in other trials for these specific antigens. However, a trial of the concurrent administration of yellow fever vaccine and the combined measles, mumps, and rubella vaccine to children 12 to 23 months of age found a significant decrease in the seroconversion rates and geometric mean titers obtained against yellow fever, mumps, and rubella when the vaccines were coadministered versus administered 28 days apart; no decreases were noted in the immune response to measles.[548] A second study in children receiving polio, yellow fever, and measles and rubella vaccines in Africa found similar rates of seroconversion when the vaccines were administered alone versus together, although the GMTs for yellow fever were significantly reduced when the vaccine was given at the same time as measles and rubella compared to alone.[720a] Immunologic interference was also noted in persons who received yellow fever vaccine 1 year before the chimeric tetravalent dengue vaccine based on the yellow fever vaccine backbone.[690] The study found an initial delay in the antibody response to dengue-1 among yellow fever vaccine-primed persons. In a separate study, the immunologic response to the chimeric dengue vaccine was not different between two groups of children who had either received yellow fever vaccine 2 to 5 years or 6 to 11 years previously.[692]

An interesting observation, not relevant to current vaccination practices, was the mutual interference resulting from simultaneous or sequential administration of 17D and inactivated parenteral whole-cell cholera (vi) vaccines.[696,698] The interference induced by 17D vaccine with vibriocidal responses was not confirmed in another study[697] and might not be real. The basis for interference is obscure, because the interval between cholera and yellow fever immunization was as long as 4 weeks. Trials of combined yellow fever and live oral cholera vaccine (alone or with Ty21a live typhoid vaccine) showed no one-way interference with anticholera immunity or yellow fever antibody responses.[701,707]

Lipopolysaccharide is known to have adjuvant activity, and coadministration of the typhoid vi vaccine appeared to enhance antibody titers to yellow fever, especially when the typhoid vaccine was concurrently administered with yellow fever.[642] In other studies, however, no enhancement was observed when typhoid vi and meningococcus conjugate vaccines were coadministered with 17D.[645,647] An enhanced neutralizing antibody response to yellow fever was observed in a

[e]More adverse events reported in one study when meningococcal vaccine was administered with yellow fever and typhoid vaccines when compared to meningococcal vaccine alone.

study of combined 17D-measles vaccine, perhaps owing to cytokine induction by the unrelated virus.[639] Interactions with an experimental Japanese encephalitis vaccine (ChimeriVax-JE) using 17D as a live vector are discussed in "Interference with 17D Vaccine Caused by Heterologous Immunity" earlier.

There are no published studies on the coadministration of yellow fever vaccine and anthrax, *Haemophilus influenzae* b, human papillomavirus, live-attenuated influenza, inactivated Japanese encephalitis, pneumococcal, rabies, rotavirus, tickborne encephalitis, and varicella zoster vaccines. One individual received zoster vaccine 21 days prior to receiving yellow fever vaccine[712] and there were no safety concerns; they developed protective immunity against yellow fever virus.

Coadministration of Immune Serum Globulin and Yellow Fever Vaccine. Seroconversion rates and neutralizing antibody titers were not affected by the intramuscular administration of 5 mL of commercial pooled immune serum globulin containing high titers of yellow fever–neutralizing antibodies 0 to 7 days before or at intervals after yellow fever 17D immunization[483]; this was a finding of practical importance before the advent of vaccines against hepatitis A. The results are not unexpected given the success of passive–active immunization and the observation that revaccination of persons with neutralizing antibodies often results in a booster response.[621,713] In 2007, available units of IVIg manufactured from plasma donations sourced in the United States contained yellow fever–neutralizing antibodies ranging in titer from 80 to 320.[484]

Administration of immunoglobulin for hepatitis A prophylaxis concurrently with 17D vaccine for travel, practiced until the mid-1990s before hepatitis A vaccines were available, has been proposed to explain the absence of cases of YEL-AVD. A clinical study performed in 2006 to investigate the effect of immune serum globulin on viremia and immune responses following 17D vaccine, as a possible means of managing subjects who have contraindications to 17D vaccine or who have risk factors for adverse events such as advanced age, did not show any significant alteration in immune response to the vaccine when coadministered with immune serum globulin.[361]

EVIDENCE THAT YELLOW FEVER VACCINE PROTECTS AGAINST DISEASE

Although a large body of preclinical data in nonhuman primates has demonstrated the protective activity of yellow fever 17D vaccination against lethal challenge,[485,611] there have been no controlled clinical trials performed showing the effectiveness of 17D vaccine in humans. Several observational studies, however, attest to the effectiveness of the vaccine in humans.

Laboratory infections with yellow fever were commonplace before routine immunization, but disappeared thereafter. Observations over 50 years showed that jungle yellow fever in Brazil and other South American countries occurred only in persons who had not been immunized with 17D and that immunization during outbreaks resulted in rapid disappearance of cases.[167] Yellow fever in francophone Africa virtually disappeared after the institution in 1941 of mandatory immunization with French neurotropic vaccine (see Fig. 63.6).[714] A high rate of coverage of the population was followed by a marked reduction in the incidence of yellow fever, despite continued human exposure to the enzootic cycle. Yellow fever epidemics were reported during the 1940s and 1950s from neighboring anglophone countries, particularly Nigeria, in which routine vaccination was not practiced.

An assessment of the effectiveness of 17D vaccine was made during an epidemic in Nigeria in 1986 (De Cock KM and Monath TP, unpublished observation, 1986). By determining vaccine coverage and the number of serologically confirmed yellow fever cases among vaccinated and unvaccinated subjects, vaccine efficacy was estimated to be 85%. The assessment was complicated by the simultaneous occurrence of natural infection and immunization in the population, with the potential for natural infection prior to onset of vaccine immunity, and by the reliance on historical data about disease and vaccination.

Because yellow fever vaccination is the standard of care, placebo-controlled efficacy trials cannot be performed today. New yellow fever vaccines will be licensed based on noninferiority of immunologic surrogates. Further studies on the effectiveness of yellow fever vaccines, which could be done using case-control methodology, are nevertheless warranted, particularly in populations affected by HIV or malnutrition, where vaccine efficacy may be impaired.[715]

DURATION OF IMMUNITY

Neutralizing antibody titers peak approximately 30 days after vaccination and wane thereafter. Persons with a detectable neutralizing antibody titer (LNI = 0.7; plaque-reduction titer using a 50% cutoff = 10) are believed to be protected against clinical infection with wild-type virus, although some studies in animal models suggest a higher level of antibody (e.g., titer = 40) may be required for protection.[485,617,679,716] The level of neutralizing antibodies determines the degree of protection, as observed in the case of persons who are revaccinated with 17D virus and in whom a high antibody level might result in sterilizing immunity, whereas lower levels allow sufficient replication for a boost in immunity (Fig. 63.15). As might be expected, the level of neutralizing antibody after primary or revaccination with 17D determined the level of antibodies present over time.[621]

Immunity following 17D vaccination is remarkably durable, and it has been concluded by many advisory committees that vaccination confers lifelong immunity.[672,673] In the last two years both SAGE and the Advisory Committee on Immunization Practices (ACIP) have revisited the data on long-term

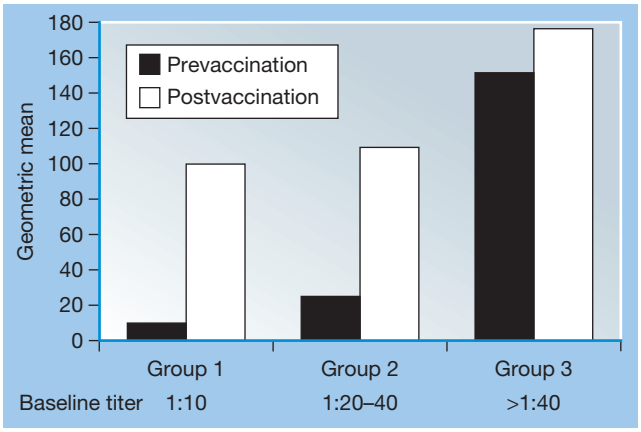

Figure 63.15. Relationship between preexisting neutralizing antibody level and the response (increase in antibody titer) to revaccination with yellow fever 17D. The higher the baseline titer, the lower the increase after revaccination. *(Data from Hepburn MJ, Kortepeter MG, Pittman PR, et al. Neutralizing antibody response to booster vaccination with the 17D yellow fever vaccine.* Vaccine. *2006;24[15]: 2843–2849.)*

immunity following yellow fever vaccination. In a comprehensive review, Gotuzzo and associates found that 75% to 100% of vaccinated persons had protective levels of antibodies more than 10 years postvaccination.[717] In addition, they also found very few vaccine failures (n = 10) reported following yellow fever vaccination. When a similar review was later conducted by the yellow fever vaccine work group of ACIP, one additional study was identified yielding immunogenicity data on 1137 persons vaccinated 10 or more years previously (Table 63.13).[340,358,614,623,649,651,660,718–723] Using a random effects model to account for the number of individuals enrolled in the different studies, the estimated seropositivity rate for persons vaccinated 10 or more years previously was 92% (95% CI, 85–96%).[673] Of the 164 persons vaccinated 20 or more years previously, the estimated seropositivity rate was 80% (95% CI, 74–86%). The ACIP working group, also identified an additional 13 vaccine failures for a total of 24 vaccine failures in more than 540 million doses delivered.[448,449,455,724–726] Of the 24 vaccine failures, five occurred within 10 days of vaccination and likely never seroconverted before developing disease; 16 occurred in individuals who were vaccinated in the last 10 years; and only three occurred in persons who were vaccinated more than 10 years previously, namely at 11, 20, and 27 years postvaccination.[673,726] Given these data, SAGE and ACIP no longer recommend booster doses for most healthy individuals.

Following the recommendation that booster doses of yellow fever vaccine are no longer needed, the World Health Assembly reviewed and approved a proposal to remove the booster dose requirement from International Health Regulations.[727] This change became effective in June 2016. The previous recommendation for requiring proof of vaccination every 10 years was established based on published studies from the 1960s showing that neutralizing antibodies were present in 92% to 97% of persons 16 to 19 years after vaccination.[649,660]

Despite the WHO recommendation to remove booster doses for yellow fever vaccine, certain regulatory authorities have not accepted this recommendation. Based on studies of neutralizing antibody titers and subsets of memory T and B cells at various times postvaccination,[720,728] Brazilian authorities have recommended one booster dose 10 years after primary vaccination in adults and one booster dose at 5 years of age in children who received their initial dose at 9 months of age. Data from a cohort of 651 adults in Brazil found that 93% (95% CI, 88–96%) of vaccine recipients were seropositive at 30 days postvaccination compared to 85% (95% CI, 80–90%) at 12 or more years postvaccination.[720] Interestingly, lower rates of seropositivity (76%; 95% CI, 68–83%) were seen in persons who were 5 to 9 years postvaccination. The authors noted the difference in their results compared to other studies and suggested these differences might be the result of variation in the immune response to specific vaccine strains (i.e., 17DD vs 17D-204) or to preexisting immunity or immune stimulation that might exist in endemic areas compared to nonendemic areas as was seen in a separate study comparing the immune response to yellow fever vaccination

among Swiss and African cohorts.[676] The Brazilian Collaborative Group for Studies on Yellow Fever Vaccines implemented a more comprehensive, prospective longitudinal study to further explore the duration of immunity following yellow fever vaccination in Brazil.

Although booster doses of yellow fever vaccine are no longer being recommended for most travelers, certain groups, such as pregnant women, hematopoietic stem cell recipients, and HIV-infected persons, might need additional doses of yellow fever vaccine either because of a lack of initial seroconversion or of more rapidly declining antibody titers caused by an underlying condition (see "Primary Vaccine Failure" later for more information on these groups).[673,729] Although initial seroconversion data on children suggest their immune responses to yellow fever vaccine are similar to that of adults,[673] additional work assessing antibody duration should be performed to ensure that persons who receive the vaccine as children will not develop disease decades later as a consequence of declining antibody titers over time.[672]

The basis of durable yellow fever immunity is a matter of speculation. Persistent infection of human cells in culture by yellow fever 17D virus has been described.[730] A human macrophage cell line and human peripheral blood mononuclear cells became persistently infected, with continued production of infectious virus without the appearance of cytopathic effects, in a fluctuating pattern suggesting a role for defective interfering particles.[344] Yellow fever virus was recovered from the brains of rhesus monkeys up to 159 days[181] and from sera 30 days after intracerebral inoculation.[180] A variant virus recovered from a 17D vaccine pool caused persistent infection of mouse brain without overt disease.[84] Although the brain may be a privileged site with respect to immune clearance and is not infected in the course of the vast majority of persons who receive 17D vaccine, these observations, as well as the prolonged synthesis of IgM antibodies in persons immunized with 17D virus,[654,656] suggest that chronic persistent infection or storage of antigen in vivo, possibly in follicular dendritic cells, might explain the durability of the human immune response. In one study of 44 travelers, yellow fever vaccine viral RNA was detected in the urine of two subjects at 21 days and 6 months postvaccination.[731] However, yellow fever vaccine virus RNA was not detected in urine of the remaining 42 persons tested from 0 to 11 months postvaccination. Another hypothesis for the persistence of IgM antibodies following vaccination is incomplete class switching either caused by alterations in the vaccine virus because of the attenuation process or potential interference of the vaccine virus in the regulation or recognition of molecules needed for class switching.[656]

Yellow fever 17D elicits a robust innate immune response in mice and humans, activating TLRs 2, 7, 8, and 9.[608] This drives a strong adaptive immune response, which apparently is associated with a long-lived population of plasma cells secreting antibody. Whether or not restimulation is required (as suggested earlier) or whether the long-lived antibody production occurs simply as a result of the early strong innate response is unclear.

REVACCINATION

Yellow fever vaccination establishes a large pool of memory B and T cells that respond to subsequent exposure to wild-type virus or revaccination. 17D vaccine induces prolonged and continuous antibody production by long-lived plasma cells as a first line of defense, and memory B cells respond with a boost in antibody production on reexposure to the antigen. In addition, a pool of highly functional $CD45RA^+$ memory $CD8^+$ T cells is established after 17D vaccination, in which cells respond rapidly after restimulation, proliferate, and produce multiple effector cytokines and cytotoxic enzymes.[146,665]

According to recent changes to International Health Regulations,[732] the yellow fever immunization certificate for international travel is valid for the lifetime of the vaccinee. Most countries have adopted this change, which is noted under the yellow fever vaccine requirements on both the WHO and CDC's travelers' health websites.[742a] However, not all countries with yellow fever vaccination requirements have adopted this change. In practice, at travel clinics, the vast majority of people receiving 17D vaccine are primary vaccinees. In one study of 3207 travelers who received yellow fever vaccine at a travel clinic visit in the United States, only 149 (5%) had reportedly received a previous dose of yellow fever vaccine 10 or more years previously.[733] These data are similar to unpublished data from three clinics in France (2003–05) indicating that 6% (6211 of 102,112) of persons to whom 17D vaccine was given were revaccinees (Goujon C and Godineau J-P, personal communication, 2006). In contrast, in countries such as Brazil that have conducted repeated mass immunization campaigns in the endemic areas, (multiple) revaccination has been commonplace.

In some studies, prior immunity inhibited the response to revaccination, an expected finding for a live vaccine. A booster response to revaccination was found to be more likely in persons with a low neutralizing antibody titer.[621,734] In others, revaccination or vaccination of persons with naturally acquired immunity was followed by a booster response in the majority of subjects, indicating that sufficient virus replication had occurred or that the antigenic mass of neutralized virus in the vaccine dose was sufficient to elicit a memory response.

Smith and colleagues[681] revaccinated eight subjects who had received 17D vaccine at least once (and up to five times) between 1 and 14 years previously and who had LNIs of 2.1 to 3.6. Only one subject developed a significant rise in neutralizing antibodies. Wisseman and Sweet[713] revaccinated 11 adults 14 months after primary immunization. None had detectable viremia after revaccination, but all responded with a rise in neutralizing antibodies, and seven (64%) had greater than fourfold increases in titer. The geometric mean titers rose from 121 to 576 after revaccination, but in most subjects the response was lower than the response to primary immunization. The dose of virus administered by Wisseman and Sweet was 10- to 30-fold higher than that administered by Smith and colleagues[681]; this plus the lower number of prior immunizations might explain the difference between the studies. Fox and Cabral[670] also concluded that a higher dose of 17D was required to boost immunity in persons with preexisting immunity. In another study, two subjects who were revaccinated 3 to 18 months after their last immunization had a rise in hemagglutination-inhibition but not neutralizing antibody titers.[654] Reinhardt and colleagues[358] noted modest increases in neutralizing antibodies in five of five subjects revaccinated after an interval of more than 10 years, whereas Monath and colleagues[193] found that only three of six subjects revaccinated after a short interval (9 months) developed increases in neutralizing antibodies.

Hepburn and colleagues[621] compared the responses of healthy adult subjects according to the level of neutralizing antibodies present before revaccination. The intervals between previous vaccination and revaccination were not established in this study. As expected, the level of preexisting neutralizing antibodies had a profound effect on the magnitude of the neutralizing antibody response to revaccination (see Fig. 63.15). Subjects with baseline antibody titers of 10 had a 10.1-fold rise (95% CI, 9.26–10.95) in antibody titer versus 2.46 (95% CI, 3.63–5.01) in subjects who had a baseline titer of 20 to 40 (geometric mean, 25.6). Subjects with high baseline

titers (>40; geometric mean, 152) had little or no response to revaccination (sterile immunity). However, the loss of neutralizing antibodies after revaccination was more rapid in subjects with low antibody titers before revaccination. Subjects with low pre-revaccination titers (1:10) dropped to low titers (<1:40) faster (median, 768 days) than those with titers of 20 to 40 (3340 days) or greater than 40 (7709 days).

CORRELATES OF PROTECTION

In the majority of vaccinees, antibody titers are lower and their appearance is delayed compared to natural infection with yellow fever virus,[14,22,308] reflecting less virus replication and antigen expression of the attenuated strain. The minimal protective level of neutralizing antibodies induced by 17D vaccine has been estimated by dose–response studies in rhesus monkeys that were challenged after immunization with virulent yellow fever.[485,539,679] An LNI, measured by plaque reduction, of greater than 0.7 of that measured before challenge (20 weeks after immunization) was strongly associated with protection (Table 63.14). Of 11 vaccinated monkeys that succumbed to challenge, 10 had a prechallenge LNI lower than 0.5 and one had an LNI of 0.9. Clinical trials of 17D vaccine have shown geometric mean LNI values greater than 2.2 measured within a relatively brief interval (usually 1 month) after vaccination (see Table 63.9). Antibody titers measured by serum-dilution plaque-reduction tests have been more variable. WHO currently considers a titer of 10 or greater in the serum-dilution plaque-reduction test with a 50% cutoff as protective for nonhuman primates in new seed lot production guidelines for manufacturers.[531]

Other experimental evidence supports the concept that minimal immunity is required for protection. Neutralizing antibodies appear in the sera of rhesus monkeys on days 6 to 7 after inoculation of 17D virus. However, some monkeys survive challenge performed after a shorter interval (1, 3, or 5 days) after vaccination, despite the absence of detectable antibodies.[20,613] Early protection may be mediated by a low-level specific antibody response (see "Kinetics of the Antibody Immune Response" earlier) or by innate immune responses.

For pivotal trials of a yellow fever 17D vaccine between 1999 and 2001, the FDA recognized neutralizing antibodies as a surrogate for protective immunity against yellow fever virus and accepted the LNI 0.7 as the minimum level for protection based on published animal studies[485,601,619] and data showing that passive immunization with antibodies is sufficient for protection (see "Passive Immunization and Passive-Active Immunization" earlier). Because there was an accepted immune surrogate, it was possible to use the seroconversion rate (using the LNI 0.7 cutoff) as the primary end point in pivotal trials.

Passive immunization is an established method for defining the level of antibody required to protect against virus challenge. Hamsters were injected with graded doses of homologous yellow fever immune serum or control serum and challenged 24 hours after transfer. Before challenge, hamsters were bled for measurement of passively acquired neutralizing antibody (i.e., plaque-reduction neutralization test with 50% cutoff [$PRNT_{50}$]). After challenge, hamsters were followed for illness, death, and weight change. Full protection was observed in animals with $PRNT_{50}$ titers 40 or greater, and partial protection was observed in animals with passive titers of 10 to 20.[716] These are somewhat higher titers than established as the immune correlate for encephalitis viruses (e.g., Japanese encephalitis), where a titer of 10 is considered protective in both mice and humans.[735] It is possible that higher neutralizing antibody titers are required to protect against viscerotropic infections than are required to protect the brain against neuroinvasion.

TABLE 63.14 Neutralizing Antibody Response to Yellow Fever 17D Vaccine Correlates With Protection Against Challenge With 5.0 Log_{10} LD_{50} of Virulent Asibi Virus

Log Neutralization Index (Plaque Reduction)	Protected	
	Yes	No
>0.7	51/54 (94%)	1/11 (9%)
<0.7	3/54 (6%)	10/11 (91%)

PRIMARY VACCINE FAILURE

A small minority of healthy persons inoculated with 17D vaccine do not develop detectable neutralizing antibodies (see Table 63.9). Although there are few reports on this question, it appears that failure to mount a response on primary immunization does not represent an absolute refractoriness, because revaccination may be followed by development of neutralizing antibodies.[600]

Development of clinical yellow fever in persons with a history of 17D vaccination has been reported rarely, with approximately 24 cases reported among at least 540 million persons vaccinated (see "Kinetics of the Antibody Immune Response" earlier for more details).[448,449,455,672,673,724–726]

Malnutrition and Vitamin Deficiency

Protein-calorie malnutrition has been associated with failure to respond immunologically to 17D vaccine. In a study of eight children (mean age, 2 years) with kwashiorkor, only one seroconverted after 17D vaccination, compared to five of six control children.[736] Further studies are required to assess the relevance of this finding to use of 17D vaccine in the EPI in Africa, particularly where covariates, such as HIV infection, can diminish immunoresponsiveness. Although there were no obvious adverse effects of immunization in the small series of kwashiorkor patients, the safety of yellow fever immunization in infants with malnutrition has not been fully assessed. Gandra and Scrimshaw[737] showed that 17D vaccine administered to children 4 to 11 years old recovering from malnutrition resulted in a significant catabolic effect lasting up to 12 days, in the absence of fever or other signs of increased metabolic rate. This suggests that 17D vaccine could result in a net loss of body nitrogen and aggravate the clinical effects of protein malnutrition. Further studies in fasted adults showed that metabolic changes and mobilization of protein associated with yellow fever immunization were related to dietary factors; a catabolic effect was not observed in subjects consuming a high-protein diet.[738,739]

Vitamin A deficiency is associated with impaired T-helper function, antibody responses, and susceptibility to infectious diseases. Adults with low and high vitamin A levels were vaccinated against yellow fever in a controlled double-blind trial. T-cell responses measured by proliferation, some cytokines, and neutralizing antibodies tended to be lower in the subjects with low vitamin A.[740]

Pregnancy

In a field study conducted in Nigeria, the IgM ELISA and neutralizing antibody responses to 17D vaccine were statistically

significantly impaired in pregnant women compared to nonpregnant girls and women of childbearing age, male students, and the general population.[625] The majority (88%) of the subjects were immunized in the third trimester of pregnancy. Only 39% of the pregnant women developed neutralizing antibodies, compared to 82% to 94% of the other groups. The difference was attributed to the immunosuppression associated with pregnancy, emphasizing the need to reimmunize at-risk women who have been inadvertently vaccinated during pregnancy.

In contrast, a study in Brazil of 433 women inadvertently immunized with the 17DD vaccine during pregnancy showed a 98% seroconversion rate by neutralization test.[741] The majority of the subjects were in the early stage of pregnancy (mean gestational age at immunization, 5.7 weeks; SD, 4.9 weeks). The difference between this study and that of Nasidi and colleagues might be explained based on gestational age, nutritional factors, or preexisting heterologous flavivirus immunity (not defined). It is unlikely that difference in the vaccine substrain played a role.

Hematopoietic Stem Cell Transplant Recipients

Data are limited on safety and immunogenicity for yellow fever vaccine in hematopoietic stem cell transplant recipients. However, data suggest most recipients become seronegative to live viral vaccine antigens after transplantation.[742] Infectious Diseases Society of America guidelines recommend readministering live viral vaccines, such as measles, mumps, and rubella vaccine and varicella vaccine, to posttransplantation patients if the recipient is seronegative and is no longer immunosuppressed.[743]

HIV Infection

There is limited evidence to suggest that asymptomatic HIV infection reduces immune responses to yellow fever vaccine.[715,744] HIV infection reduces immunologic responsiveness to a number of nonreplicating and live childhood vaccines. In the case of inactivated flaviviral vaccines, HIV infection reduced the seroconversion rate or resulted in lower geometric titers to Japanese encephalitis vaccine[745,746] and reduced seroconversion rates to tickborne encephalitis vaccine when compared to uninfected controls.[747] Some case reports indicate that vaccination of HIV-infected subjects who are not immunosuppressed ($CD4^+$ T lymphocytes >500/mm^3) was followed by seroconversion.[748] Tattevin and colleagues[749] vaccinated 12 subjects with $CD4^+$ counts as low as 240/mm^3 without adverse effects; all developed yellow fever–neutralizing antibodies, and there were no significant changes in $CD4^+$ cell counts or viral loads. On the other hand, 17D vaccine was administered to 33 adult travelers with HIV infection and $CD4^+$ cell counts greater than 200 per mm[750]; only 70% responded by 1 month after vaccination, and one person seroreverted between 1 and 3 months after vaccination. A separate study found 93% (13/14) of HIV-infected persons with no baseline immunity seroconverted following vaccination, but the time needed to achieve seroconversion was prolonged.[751]

A retrospective cohort study found that significantly fewer HIV-infected persons had yellow fever–neutralizing antibodies at 1 year after vaccination compared with vaccinated uninfected persons (83% and 97%, respectively; $P = .01$).[715] Among HIV-infected infants in one developing nation, only 17% developed neutralizing antibodies within 10 months of yellow fever vaccine compared with 74% of HIV-uninfected controls matched for age and nutritional status.[752] In addition to a suboptimal immune response in primary vaccine recipients, a small study also found that there was a booster effect following repeat vaccination in only three of nine HIV-infected persons.[751]

Antiretroviral therapy with resulting improvements in $CD4^+$ counts is associated with an improved response to vaccines. If feasible, patients starting on antiretroviral therapy should be deferred for 17D vaccination until $CD4^+$ counts exceed 350 to 400 per mm^3 for several months and HIV RNA levels become undetectable.

The results of these various studies indicate that HIV infection can impair the immune response to 17D vaccine. Because both HIV and 17D viruses exhibit tropism for human lymphoid cells,[753] it is possible that HIV infection interferes with replication of 17D vaccine. This is supported by data that found HIV viral load was more likely to determine immune response to the vaccine than the CD4 count was.[744,754] In vitro studies and clinical trials comparing 17D viremia in HIV-infected and -uninfected subjects would help address how HIV infection affects the immune response to the vaccine.

Yellow Fever Vaccine, Antimalarial Drugs, and Tuberculin Skin Tests

Chloroquine is known to inhibit the immune response to inactivated rabies vaccine and live oral cholera vaccine, and it interferes with flavivirus replication in vitro. In humans, there was no inhibitory effect of chloroquine at doses used for malaria prophylaxis on the response to yellow fever 17D.[755]

Despite an earlier study to the contrary, yellow fever vaccine does not appear to depress tuberculin skin test sensitivity[756] and is unlikely to adversely affect the course of active tuberculosis. However, there are no field studies of this question.

Other Host-Specific Effects

Evaluation of neutralizing antibody responses in a large clinical trial revealed some heretofore unknown and subtle host effects on the immune response (see Table 63.10).[601] The mean LNI was higher in smokers than in nonsmokers. There are few studies on the interaction of smoking and the immune system, but most report a suppressive effect, for example after hepatitis B vaccine.[757] In the case of 17D vaccine, it was postulated that the adaptive immune response might be enhanced by the suppression of innate immune responses (e.g., NK cell function) attributable to smoking.

ADVERSE EVENTS

17D vaccines are widely acknowledged as one of the safest vaccines in use. More than 540 million persons have been immunized, and the vaccine has a long record of tolerability and safety.[672,682,758,759] However, the vaccine has been under close scrutiny as clinical, histopathologic, and virologic evidence linked 17D vaccine in 2001 to a previously unrecognized serious adverse events, namely viscerotropic disease.

Viremia Following 17D Vaccination

Whereas wild-type yellow fever virus causes high levels of viremia in monkeys and humans, 17D vaccine induces minimal virus titers in circulating blood. A control test for the reduced viscerotropism of 17D vaccines is the measurement of viremia in monkeys on days 2, 4, and 6 following intracerebral inoculation, which must not exceed 500 IU per 0.03 mL on any day and must not exceed 100 IU per 0.03 mL on more than one day.[531]

Viremia following 17D vaccination has been measured in adult humans. Smith and colleagues[22] found virus in serum of 13 (46%) of 28 subjects given 3.0 to 4.0 $\log_{10}$ MLD_{50} of

17D vaccine. The earliest onset of viremia occurred on day 4 and the latest on day 10. Of the 13 viremic subjects, four were viremic for 1 day, five for 2 days, and four for 3 days. The quantity of virus in blood was extremely small in all cases (<2 MLD_{50}/0.03 mL). Sweet and Kitaoka[183] measured viremias in subjects with and without prevaccination neutralizing antibodies to Japanese encephalitis virus. The 17D vaccine (National Drug Co., Philadelphia, PA) contained about 6.4 log_{10} suckling mouse intracerebral LD_{50}/dose (equivalent to approximately 5.3 to 5.8 log_{10} MLD_{50},[679] and thus substantially higher than the dose used by Smith and colleagues).[22] Viremia was measured by intracerebral inoculation of infant mice with undiluted serum. Of 25 subjects without preexisting flavivirus immunity, 15 (60%) had detectable viremia on 1 or more days during the 6-day sampling period (days 3 to 8 after vaccination). The highest incidence of viremia (48%) was on day 5, and the mean duration was 1.9 days. Titers were very low, because none of the sera caused 100% mortality in infant mice. There was no difference in the incidence or duration of viremia in subjects with preexisting immunity to Japanese encephalitis virus.[679]

In a study of 15 young adults, Wheelock and Sibley[599] determined 17D viremia by a more-sensitive method: inoculation of 0.1 mL of plasma into tube cultures of BHK-21 cells. Fourteen subjects (93.3%) had detectable viremia. The average time to onset of viremia was 4.4 days (range, 3 to 6 days), and the mean duration was 2.5 days (range, 1 to 5 days). Viremic days were sequential and continuous in most cases, but one subject had detectable viremia on days 4, 8, and 9. A rough estimation of the level of viremia was possible based on the detection in cell cultures inoculated with varying volumes of plasma. Virus titers were exceedingly low; in only three of 14 subjects was virus detected in cultures inoculated with 0.001 mL of plasma.

Actis and Sa Fleitas[760] studied 12 adults who received an unspecified dose of 17DD-EP vaccine produced in Brazil. The duration and level of viremia, detected by intracerebral inoculation of weanling mice, was similar to those in previous studies, but a somewhat higher proportion of subjects were viremic than in other studies using mice for detection of viremia. In two clinical trials of a chimeric yellow fever–Japanese encephalitis vaccine, yellow fever 17D (YF-Vax) was used as a control for safety in healthy adults 18 to 59 years of age and viremia was measured by plaque assay in Vero cells.[193,617] Nearly all subjects were viremic on one or more days. Approximately 30% to 60% of the subjects were viremic between days 4 and 6 after vaccination, with lower percentages at earlier and later time points (Fig. 63.16). The mean duration of viremia was approximately 2 days. Viremia levels were low (mean peak titers <20 PFU) and in no case exceeded 2 log_{10} PFU/mL. Six previously vaccinated subjects experienced no viremia after revaccination.

Similarly, Reinhardt and colleagues[358] inoculated 12 naïve and five previously vaccinated healthy adults 18 to 50 years of age with the yellow fever 17D vaccine manufactured by the Robert Koch Institute. Viremia levels were measured by plaque assay in PS cells and by RT-PCR. The pattern and level of viremia were similar to those described earlier. There was no correlation between the level of viremia and the height of the neutralizing antibody response. The highest incidence of viremia by plaque assay was on days 5 (42%) and 6 (33%), the duration of viremia was 1 to 3 days, and the peak titer was 97 PFU/mL, with most values less than 20 PFU/mL. All 12 naïve subjects, including five who had no viremia by plaque assay, tested positive by RT-PCR, and sera contained detectable viral RNA at least 1 day longer than by infectivity assay. None of the revaccinated subjects tested positive by RT-PCR or plaque assay.

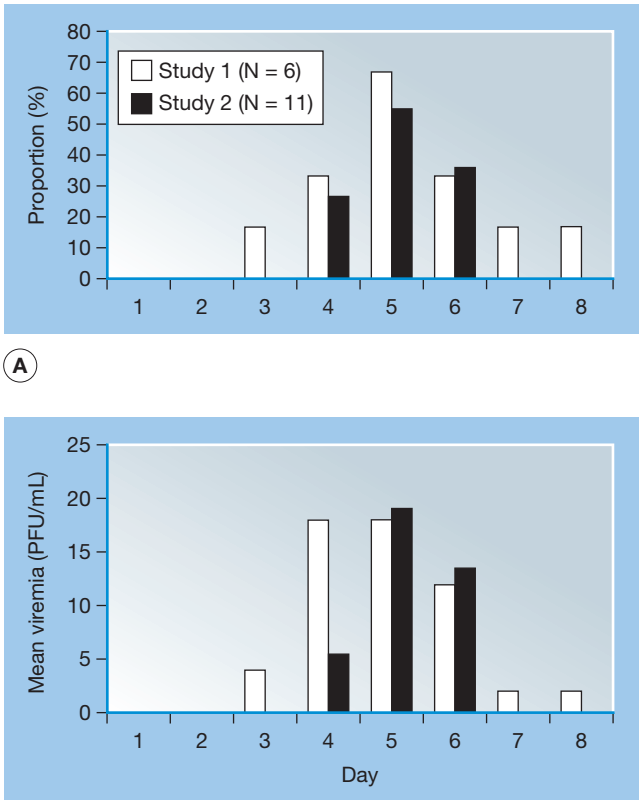

Figure 63.16. A, Percentages of healthy adults in two studies with viremia detectable by plaque assay following inoculation of yellow fever 17D vaccine (YF-Vax). **B,** Mean viremia levels in the same studies. Viremia occurred principally between days 4 and 6 and did not exceed 2 log_{10} PFU/mL in any subject. PFU, plaque-forming units. *(Data from Monath TP, McCarthy K, Bedford P, et al. Clinical proof of principle for ChimeriVax: recombinant live, attenuated vaccines against flavivirus infections.* Vaccine*. 2002;20[7–8]:1004–1018; and an unpublished study, 2004.)*

In two newer studies using the same cohort of 80 flavivirus-naïve adult subjects, infectivity assays found 54 (68%) were positive and all had detectable viral genomes by TaqMan real-time PCR.[361,668] Viral genomes were detected as early as 2 days after vaccination and were no longer detected in most recipients 11 days after vaccination. For all individuals, the peak viremia occurred between 5 and 7 days postvaccination, which is similar to previous studies that have used less-sensitive techniques.

Surprisingly, in a study of eight seronegative healthy adults who were 18 to 55 years old, had no history of prior yellow fever immunization, and who received the 17DD Brazilian vaccine, no viremia could be detected by plaque assay or RT-PCR on days 2, 4, and 7 after inoculation.[618] There are no previous data to suggest that the 17DD strain would be less viremogenic than the 17D-204 used in all the studies of viremia cited earlier, and the viremia profile in monkeys is similar.[551] In fact, a newer study using quantitative RT-PCR following 17DD vaccination documented viremia in up to 15% of vaccine recipients with peak viremia occurring 5 days postvaccination.[557] In a much larger study of 1087 adults in Brazil, viremia was detected in 2.2% and 3.7% of subjects who received 17D-DD and 17D vaccines, respectively, suggesting no difference between vaccines.[547] However, the publication

did not provide exact denominators or covariates (baseline immunity), and the overall incidence of viremia is lower than expected from previous studies.

The objectives of dose sparing and needleless immunization have spurred renewed interest in epidermal and intradermal immunization, as well as administration of lower amounts of vaccine virus. Monkeys given a chimeric yellow fever–Japanese encephalitis vaccine developed higher viremias after epidermal than subcutaneous inoculation.[201] However, a clinical trial of intradermal 17D at one-fifth dose versus subcutaneous inoculation at full dose did not show a difference in the proportion viremic or titers estimated by RT-PCR.[592] In a study exploring the viremia and immune response to different doses of 17DD vaccine, a 10-fold lower dose than what is currently used was able to solicit equivalent viremia levels and kinetics as full dose vaccine.[557,558] Doses 50- to 1000-fold lower than reference were also able to induce low levels of detectable viremia but the kinetics were different and doses containing 200-fold lower than reference amounts of 17DD virus produced lower rates of seroconversions.

Taken together, these studies confirm that very low levels of virus are present in circulating blood for a brief period following 17D vaccination. Viremia occurs during the latter half of the first week after vaccination, and thus the incubation period and duration of viremia are not dissimilar to natural infection with yellow fever virus. Cessation of viremia corresponds to the time of appearance of neutralizing antibodies 8 to 9 days after immunization (see "Kinetics of the Antibody Immune Response" earlier). Titers of virus in blood are far below the infection threshold for mosquito vectors. The low viremia following 17D vaccine might also explain the apparent low risk of transmission of the virus to the fetus in women who have been immunized during pregnancy (see "Pregnancy and Adverse Events" later) and the low incidence of neuroinvasion and yellow fever vaccine–associated neurologic disease (YEL-AND), formerly called postvaccinal encephalitis. Detection of viremia is influenced by test methodology. PCR is more sensitive than infectivity assays[358,559] and might detect viral RNA in the absence of infectivity; for example, after the appearance of antibody.

There are no data on viremia levels in infants or children given 17D vaccine. The higher risk of YEL-AND in young infants suggests the possibility that viremia levels may be higher or more prolonged; alternatively, susceptibility could reflect immaturity of the blood-brain barrier. There are limited data on the viremia levels seen for older adults. One study found that travelers 60 years of age and older were more likely to have detectable viremia with higher levels that were present for longer when compared to younger adults.[256] This finding, in addition to the delayed antibody response in older adults compared to younger adults, has been hypothesized as a reason more serious adverse events have been identified among older vaccine recipients. No data are available on the height and duration of viremia in persons who are immunosuppressed.

Viremia is an accepted marker of viscerotropism of wild-type yellow fever virus and is the basis for the 17D vaccine safety test in monkeys that specifies limits on the level of viremia for release of virus seeds. To differentiate the normal, low-level transient viremia observed in the course of normal vaccination from the viremia that may be anticipated in a viscerotropic vaccine accident, prolonged or abnormally high viremia has been incorporated into the yellow fever vaccine algorithm that is provided with the Brighton case definition for viscerotropic disease.[761] In one subject with YEL-AVD, in whom the pattern of viremia was adequately measured, viremia was prolonged and reached a level approximately 100-fold higher than seen following normal vaccination.[266]

Historical Problems

There have been two notable adverse events in the history of 17D vaccine that have led to changes in manufacturing and delivery of the vaccine. The first (described in "Seed Lot System" under "Yellow Fever 17D Vaccine" earlier) was the occurrence of YEL-AND associated with uncontrolled passage of 17D substrains during the early years of vaccine manufacture.[269,528,682] The problem was resolved when stabilization of passage level during vaccine manufacture was instituted in 1941. The second event was the development of acute hepatitis in persons who received 17D vaccine, which was recognized as early as 1937 by Findlay and MacCallum.[762] Cases were reported in Brazil during the vaccination campaigns between 1938 and 1940 and, after careful study, were attributed to an adventitious agent in the vaccine rather than to viscerotropism of 17D virus.[763] In 1942, a massive outbreak of hepatitis appeared in United States military personnel immunized with 17D vaccine, resulting in approximately 28,000 cases and 62 deaths.[570] These reactions were the result of using pooled human serum (contaminated with hepatitis B virus) as a vaccine stabilizer.[568] This practice was discontinued in Brazil in 1940 and in the United States in 1943,[764] and the problem resolved.

Common Adverse Events and Clinical Studies

Historical Events and Studies

Fever, headache, and backache, described as mild, were noted since the earliest studies of 17D vaccine.[21] During large-scale field studies in Brazil in 1937 to 1938, Soper and colleagues noted mild systemic reactions in 5% to 8% of vaccinees.[527] Among 2457 persons in Brazil from whom "reasonably accurate" clinical follow-up was obtained by Smith and colleagues, 15% complained of headache for 1 to 2 days, 10% developed pains in the body (usually accompanied by headache), 1.4% missed time from work (usually only 1 day), and 0.2% spent 1 or more days in bed.[22] These reactions, which were generally considered mild, occurred on the fifth sixth, or seventh day after immunization. Local reactions at the site of inoculation were not observed, and no systemic allergic reactions were noted.

Recent Clinical Studies

Reactogenicity of 17D vaccine was monitored in twenty-four clinical studies conducted between 1953 and 2014, including one placebo-controlled study (Table 63.15).* Self-limited and mild local reactions (erythema and pain at the inoculation site) and systemic reactions (headache, headache and fever, and fever without symptoms) occurred in a minority of subjects 3 to 7 days after immunization. Reactogenicity in children typically less than 1 year of age is no greater (or perhaps less) than in adults; this conclusion was also made during the early studies in Brazil in 1937 to 1938.[22]

When subjects were under daily surveillance using a diary card to record local and systemic adverse events, a higher incidence of adverse events was detected (Tables 63.16 and 63.17).[624,634]

In one study, 1440 subjects were monitored; half of subjects received YF-Vax (U.S.-produced vaccine) and half received ARILVAX (UK-produced vaccine).[601] Safety was assessed through a diary card and by clinic visits, recording all signs

[e]This was a study of combined or sequential vaccination; only subjects receiving 17D alone are included in the table.
GI, gastrointestinal.

and symptoms. There were no serious adverse events attributable to either vaccine. Significantly more subjects in the YF-Vax group (72%) experienced one or more nonserious vaccine-related adverse events than in the ARILVAX group (65%, $P = .008$) (see Table 63.17). The difference was because of a higher rate of local reactions of mild to moderate severity caused by YF-Vax.

The most common systemic side effects were headache, asthenia, myalgia, malaise, fever, and chills. These systemic adverse events are presumably caused by activation of T lymphocytes and the release of cytokines, including IFNs and TNF-α during the viremic period.[358] These were generally mild or moderate, but 7% to 8% of all treatment-emergent events were severe and were reported to interfere with normal activities. Rash was noted in approximately 3% of the subjects and urticaria in 0.3%. There were no cases of anaphylaxis, serum sickness, or other severe allergic reactions. The incidence of nonserious adverse events was lower in elderly persons than in younger subjects, and the difference was statistically significant for headache, malaise, injection site edema, and pain. Lower reactogenicity of 17D vaccine in elderly versus young adult travelers was also noted in a report by Philipps and colleagues.[769] Injection-site reactions occurred between days 1 and 5. Systemic adverse events also occurred at highest incidence during days 1 to 5, but they continued between days 6 and 11. The mean white blood cell count decreased slightly between baseline and day 11, with a mild neutropenia. No subjects developed clinically significant thrombocytopenia ($<0.5 \times 10^5/\mu L$).

Elevations in aspartate aminotransferase were seen in 3.5% to 3.9% of subjects; 3.9% to 4.6% of subjects had an increase in alanine aminotransferase from normal to abnormal range between baseline and day 11. In most cases, levels were minimally elevated and levels returned to normal or had decreased by day 31. Subjects with elevated serum enzymes had no associated syndrome or constellation of other clinical laboratory abnormalities. There was no relationship between elevated serum enzymes and use of concomitant medications.

In a second randomized, double-blind Phase III 17D vaccine study, a total of 1107 healthy children 9 months to 10 years of age in Peru were recruited (see Table 63.17).[619] Safety was assessed through a diary card and by clinic visits, recording all signs and symptoms. No treatment-related serious adverse events were reported. A similar proportion of subjects in each group reported at least one adverse event: 441 of 738 (59.8%) for ARILVAX versus 211 of 369 (59.9%) for YF-Vax. Most (591; 96.7%) of the adverse events were mild and resolved without treatment. These trials were comparative studies of two vaccines, intended to show noninferiority against a comparator vaccine. Without a placebo group, it is difficult to ascribe systemic adverse events and minor laboratory abnormalities to the vaccines under study.

One double-blind trial included a placebo control.[546] This study, conducted in Brazil, enrolled 1087 subjects 15 to 68 years of age; 272 received a 17D-213 yellow fever vaccine, 543 received two lots of the 17DD vaccine, and 272 received placebo (see Table 63.17). The study participants recorded on a diary card all signs and symptoms for a 10-day period. There were no severe or immediate adverse events, and four hospitalizations within 30 days of vaccination were for reasons unrelated to vaccination.[546] Compared to placebo, there was slightly more local reactions reported among vaccinees compared to the placebo group (5% vs 2.6%; $P = .23$) and more systemic adverse events reported among vaccinees compared to placebo group (20% vs 14%, $P = .11$). The proportion of vaccinees seeking medical care or missing work related to their

[a]Adverse events considered remotely, possibly, probably, or definitely related to clinical trial materials.
[b]Based on Fisher's exact test; *P* value is provided for each adverse event wherever the percentage for either treatment group is not less than 5%.
[c]Defined as myalgia plus headache or fever.
AE, adverse event.
Data from Belmusto-Worn VE, Sanchez JL, McCarthy K, et al. Randomized, double-blind, phase III, pivotal field trial of the comparative immunogenicity, safety, and tolerability of two yellow fever 17D vaccines (ARILVAX and Yellow Fever-VAX) in healthy infants and children in Peru. Am J Trop Med Hyg. *2005;72(2):189–197; Camacho LA, de Aguiar SG, Freire S, et al. Reactogenicity of yellow fever vaccines in a randomized, placebo-controlled trial.* Rev Saude Publica. *2005;39(3):413–420; and Monath TP, Nichols R, Archambault WT, et al. Comparative safety and immunogenicity of two yellow fever 17D vaccines (ARILVAX and Yellow Fever-VAX) in a phase III multicenter, double-blind clinical trial.* Am J Trop Med Hyg. *2002;66(5):533–541.*

systemic signs and symptoms were again slightly higher than placebo (7.9% vs 5.1%, $P = .26$).

Fever, myalgia, and headache were the most common symptoms, and the incidence of flu-like symptoms (myalgia and/or headache with fever) was more prominent in vaccinees when compared to placebo controls (6.5% vs 2.6%, $P = .06$). In contrast, nausea, vomiting, and gastrointestinal events occurred as often in vaccinees as in placebo controls (4.2% vs 3.7%, $P = .93$). It may be concluded that 50% of local events and 34% of systemic events among subjects inoculated with 17D-213/17DD yellow fever vaccine could have been explained by the vaccine virus. Among subjects who were seropositive before vaccination the difference between vaccinees pooled together and the placebo group was almost nil for the rate of systemic and local adverse events. Viremia was detected in 3% to 6% of vaccinees up to 10 days after vaccination, and variations in liver enzyme levels after vaccination were similar in placebo and vaccine recipients.

The safety of the 17D vaccine was also studied during the 2001 vaccination campaign against yellow fever in Abidjan, Côte d'Ivoire.[770] Active surveillance system for adverse events following immunization (AEFI) during a 4-week period was established. More than 2.6 million doses were administered and 87 adverse events were reported, including one male subject with a fatal outcome. He developed a severe abscess, resulting in myositis, and died from complications of diabetes, which had been previously unrecognized. Of those with AEFI, hospitalization was required for 13 (15%) patients, 54 (62%) were treated in ambulatory settings, and 20 (23%) recovered without further intervention. No sequelae were observed among the 86 survivors. The male-to-female ratio was 1 : 1. The mean age of the persons reporting an adverse event was 25 years (median, 23 years; range, 1 to 61 years). No case of YEL-AVD was reported.

Serious Adverse Events

Immediate-Onset Adverse Events

Hypersensitivity reactions to egg proteins in yellow fever vaccine have been extremely uncommon. No severe reactions were observed during initial use of the vaccine in more than 2 million persons. Guinea pig sensitization tests with 17D vaccine showed that anaphylactic reactions were reduced when the test vaccine was prepared from embryos less than 13 days old.[771] For this reason, the age of embryos at time of harvest for production of 17D vaccine is 12 days or less.[531,554] Yellow fever vaccine contains multiple proteins derived from egg white and yolk.[772] The WHO requirements for 17D vaccine specify that each dose contain a level of residual ovalbumin acceptable to the national regulatory agency.[531] One major commercial 17D vaccine specifies an upper limit of ovalbumin of 5 µg per 0.5 mL dose. In one study, 17D vaccine produced in the United States contained 7.8 µg ovalbumin per 0.5 mL dose.[773]

The first report of allergic phenomena associated with use of 17D vaccine was in 1942, during large-scale immunization of military personnel. Sulzberger and Asher described three patients with a serum sickness syndrome (urticaria or erythema multiforme-like rash accompanied by malaise, fever, arthralgia, pruritus, nausea, and vomiting) with onset between 3 and 7 days after receipt of different lots of 17D vaccine.[774] In 1943, Swartz described a patient who had a strong history of egg and other food allergies and who developed anaphylaxis 5 minutes after receiving simultaneous injections of 17D and cholera vaccines.[775] Skin testing revealed marked reactions to egg white and chicken meat and a moderate reaction to 17D (but not cholera) vaccine. Sprague and Barnard reported a case of severe anaphylaxis occurring within 15 minutes after 17D vaccine in a man with known egg allergy.[776]

The consensus based on observations during the first 20 years of use of 17D vaccine was that allergic reactions were extremely rare, occurring at an incidence of less than 1 per million, with reactions occurring principally in persons with known egg sensitivity. Reactions are typically mild and thus might be underreported.

Kouwenaar found the incidence of allergic reactions to yellow fever vaccine to be higher than expected, particularly in persons with a history of various allergies.[765] He vaccinated 242 persons having allergic histories with 0.1 mL of 17D vaccine by the intradermal route; if no reaction occurred within 45 minutes, the subjects received the remaining 0.4 mL subcutaneously. Nine (3.7%) of the subjects experienced allergic reactions; these were characterized clinically as exacerbations of

known but dormant allergy (eczema, asthma, rhinitis) in four patients, urticaria occurring less than 3 days after vaccination (two patients), and "serum sickness–like disease" urticaria or rash occurring 6 to 14 days after vaccination (three patients). Of the nine subjects reacting to yellow fever vaccination, two had a known history of egg allergy and the others had various other food allergies, asthma, or hay fever. In a control group of 465 persons without a history of allergy, only three patients (0.6%) had a late reaction to yellow fever vaccine: facial erythema in two and urticaria in one. In an additional group of 185 nonallergic persons who were reimmunized with 17D vaccine, one (0.5%) experienced generalized urticaria. The skin test has a very low positive predictive value for the development of allergic response to yellow fever vaccine and there are insufficient data on the more important question of the negative predictive value of the skin test.

More recent and definitive data on the incidence of allergic reactions are few, principally because a prior history of intolerance or allergy to eggs, egg products, chicken proteins, or egg-based vaccines or gelatin stabilizer in vaccines is considered a contraindication to the use of 17D vaccine, and few immunizations are given to such persons. Guidelines for use of yellow fever and other egg-based vaccines recommend that egg-sensitive patients undergo scratch, prick, or needle puncture testing with 1 : 10 diluted vaccine and a negative and positive (histamine) control. If the test is negative, an intradermal test is performed with 0.02 mL of 1 : 100 vaccine.[575,777] Application of this skin test procedure in clinical practice was described by Mosimann and colleagues.[778] In the case of a positive intradermal test (a wheal 5 mm or larger), and an established need for yellow fever vaccine, the patient may undergo a desensitization procedure consisting of increasing subcutaneous doses at 15- to 20-minute intervals under the supervision of an experienced physician in the management of allergic complications. In a newer study of six persons with reported egg allergies, the skin prick test was used to determine the level of reactivity.[779] Persons with skin prick tests of less than 3 mm were administered 1 : 10 dilution intradermal and then the rest of the vaccine subcutaneously and those with a positive skin prick test had a seven-step desensitization protocol. All six patients were successfully vaccinated with one skin-prick-positive patient developing generalized urticaria.

In one study, 30,000 Navy and Marine Corps personnel were screened for a history of egg sensitivity and 42 allergic patients underwent scratch and intradermal testing with crude egg white and a variety of egg-based vaccines including yellow fever 17D; most patients also underwent oral egg challenge.[780] The study demonstrated that a history of egg allergy was not a strong contraindication to administration of egg-based vaccines, because only 16% of the egg-sensitive subjects experienced any reaction, and these were mild in all cases. Skin tests were positive in 31% of the egg-sensitive subjects. Vaccination was performed in 39 subjects (excluding three subjects with strongly positive intradermal tests) using the egg-based vaccines. Intradermal skin testing with vaccine had reasonably high negative predictive value (0.80) but a lower positive predictive value (0.57) for an allergic reaction. However, the strength of positivity of the intradermal test appeared to correlate with severity of symptoms after vaccination.

Sensitization to egg-white protein by prior immunization with rabies vaccine produced in chick embryo cell culture was reported to cause a positive intradermal or scratch skin test to yellow fever vaccine.[781] No systemic allergic reactions have been noted in such cases. Similarly, prior yellow fever vaccination was reported to sensitize against a rabies vaccine manufactured in duck embryo cells.[782] There are no current precautions regarding sequential immunization with vaccines produced in chick tissue or cells, but few studies of egg- or chick cell–based vaccine interactions have been performed. Influenza vaccine, which is manufactured in eggs but contains little residual egg protein, can generally be safely given to egg-allergic persons.[783] As noted later, gelatin (used as a vaccine stabilizer) must be considered in the evaluation of cross-sensitization to vaccines.

A case report of a woman who had no history of egg allergy and suffered an anaphylactic reaction following yellow fever vaccine is of interest.[784] The patient had a history of intolerance to foods containing raw, but not cooked, eggs and had positive skin tests to raw egg antigen and 17D vaccine prepared from egg tissues without exposure to heat. Because few foods contain raw eggs and these are mixed with other ingredients, persons sensitized to raw eggs might not give an allergic history when queried before vaccination.

Since 1990, the CDC and FDA have enhanced procedures for reporting AEFI through the Vaccine Adverse Events Reporting System (VAERS).[785] Data collected between 1990 and 1997 revealed 40 cases of nonfatal hypersensitivity-type reactions (urticaria, angioedema, bronchospasm, anaphylaxis) temporally associated with yellow fever vaccine.[786] The incidence of anaphylactic reactions cannot be established with accuracy. However, based on the number of vaccine doses distributed in the United States during the interval under study (5.2 million) and the assumption that all reported events are caused by 17D vaccine, the incidence of anaphylactic reactions was estimated to be 0.8 per 100,000 doses. A second analysis identified 28 cases of anaphylaxis following 17D vaccination reported to VAERS between 2000 and 2006. Based on the number of vaccine doses distributed in the United States during this study period (1.5 million), the incidence of anaphylactic reactions was estimated to be 1.8 per 100,000 doses.[255] In the most recent analysis, 30 anaphylactic reactions were reported to VAERS from 2007–13 for an incidence of 1.3 per 100,000 doses.[259a] Although egg protein has been implicated in hypersensitivity reactions to yellow fever vaccine, other components might also play a role; for example, hydrolyzed porcine gelatin incorporated as a stabilizer by some manufacturers. Gelatin has been implicated in allergic reactions to measles, varicella, and Japanese encephalitis vaccines.[787,788]

After large-scale vaccination campaigns in which 17D vaccine was administered to 38 million people in eight west African countries during 2007 to 2010, 11 hypersensitivity reactions were identified, one of which was fatal.[789] The incidence of hypersensitivity reactions was calculated to be 0.03 per 100,000 doses. A published review of 17 years of worldwide use of the 17D-204 vaccine Stamaril, involving 276 million doses distributed, estimated a reporting rate of anaphylaxis of 0.01 per 100,000 doses.[790] In yellow fever nonendemic countries (Europe, Australia, and New Zealand), where 16.2 million doses were distributed during the same period, there were 33 reports meeting any level of the Brighton Collaboration anaphylaxis case definition, yielding a reporting rate of 0.2 per 100,000 doses. It is unclear why these reporting rates are lower than those published from United States, but it might be partly because of low sensitivity of vaccine adverse event surveillance systems in endemic countries, where the vast majority of doses of 17D vaccine are administered.

Rare Adverse Events Temporally Related to 17D Vaccine

There are a number of individual case reports of adverse events possibly associated with yellow fever vaccination.[791–806] Although some are credible, such as the occurrence of ketoacidosis in an insulin-dependent diabetic patient 4 days after vaccination,[791] others, such as chronic lymphocytic leukemia[792] and malaria recrudescence,[804] likely represent chance

associations in time. The absence of similar observations over the long history of use of yellow fever vaccine supports this view.

A case of severe gastroparesis was reported in temporal association with 17D vaccine in a patient in the United States. Gastroparesis has been described as a rare adverse event following other vaccines.[807] A case of multiple evanescent white dot syndrome, an inflammatory chorioretinal disorder, was reported in a 50-year-old woman who developed rapidly progressive left eye visual loss starting 10 days after 17D and hepatitis A vaccination.[793] Her visual symptoms and funduscopic examination normalized spontaneously within 6 weeks. A 33-year-old man presented 3 weeks after receiving hepatitis A, yellow fever, and typhoid vaccinations with sudden onset of intermittent floaters and flashing lights in his right eye.[806] He was diagnosed with acute multifocal choroiditis that resolved after 8 weeks. A case of Kawasaki disease occurring in a 12-year-old boy with symptom onset 20 days after 17D vaccination was reported.[794] A case of autoimmune hepatitis was reported in a 31-year-old woman who received 17D and hepatitis A vaccines.[795] Her symptoms, including itching, started 11 days following vaccination. She later developed jaundice, significant elevation of liver function tests, and histopathologic findings from liver biopsy consistent with autoimmune hepatitis. Another case report described an immunocompetent 64-year-old woman who developed localized herpes zoster 3 days after yellow fever vaccination.[797] Similar associations have been made with live (smallpox and varicella) and inactivated (hepatitis A, influenza, rabies, and Japanese encephalitis) vaccines. Mention is made in the literature of a favorable effect of yellow fever vaccine on reducing the incidence of recurrent herpes labialis in 11 patients,[801] but this observation was not confirmed in a subsequent clinical trial.[808]

A case report described a patient who developed confusion and difficulty walking 1 week after yellow fever vaccination and in whom YEL-AND was suspected; however, her symptoms did not resolve. She was discovered to have an auditory neuroma and hydrocephalus; her physicians concluded that YEL-AND was responsible for the acute decompensation of her underlying disease.[809] Two case reports of dermatologic symptoms following 17D vaccination include a male with an uncommon presentation of pityriasis rosea[810] and a woman who developed a localized bullous fixed drug eruption.[811] One report describes the isolation of yellow fever vaccine virus in cell culture from a respiratory swab taken from a female college student with an influenza-like illness.[812]

Reactions Resulting From Improper Handling and Use of Yellow Fever Vaccine

Because yellow fever vaccine contains no preservative, improper handling of multiple-dose vials can lead to bacterial contamination, sometimes with serious consequences. Repeated use of the same needle and syringe, rubbing dirt or other materials into the inoculation site, and other practices can also contribute to infection. Four known outbreaks of serious illness have been associated with contamination of yellow fever vaccine vials or inoculation equipment in Africa (Table 63.18). The clinical picture in all four episodes was similar, with marked swelling and pain of the vaccinated arm beginning hours after immunization and progressing in the most severe cases to cardiovascular shock and death within hours to several days.[813–815] Some, but not all, cases had signs of necrotizing myositis (gangrene). In all episodes, known or potential problems with use of multidose vaccine containers contaminated after reconstitution, improperly sterilized jet injector equipment, or reuse of syringes and needles were involved. Although no etiologic agent was implicated, *Clostridia* and group A or anaerobic *Streptococcus* were suspected.

There have been at least three reports in the literature of an inadvertent administration of an overdose of the vaccine.[816–818] In one report, 14 adults were unintentionally given 25 times the recommended dose of the vaccine during an outbreak control immunization campaign in Minas Gerais (Brazil).[816] No adverse events were observed. Another case was reported in which 12.5 times the recommended disease of the vaccine was given[817]; again, no adverse events were observed. In the last report, 49 people were inadvertently administered 10 times the normal dose of yellow fever vaccine during a reactive campaign in Brazil.[818] All were followed for 45 days and only one, a 6-year-old girl, required emergency care 2 days after vaccination for fever, abdominal pain, and vomiting. She was found to have mild elevated bilirubin and the authors concluded she might have had mild viscerotropic disease.

Pregnancy and Adverse Events

Because spontaneous abortion, stillbirth, and congenital malformation have not been observed in the aftermath of yellow fever epidemics, there was little concern about the use of a live attenuated vaccine derived from a wild-type virus. In one report of (wild-type) yellow fever death of a pregnant woman,

TABLE 63.18 Episodes Involving Multiple Serious Adverse Events Characterized by Cellulitis or Necrotizing Myositis Associated With Probable Bacterial Contamination of 17D Vaccine After Reconstitution or Infection of Inoculation Site

			Deaths				
Year	Location	No. Cases	No.	%	Incidence[a]	Circumstances	Reference
1974	Côte d'Ivoire	39	8	20.5	5.3/100,000 immunizations	Cases occurred at 9 designated vaccinating centers; 5-dose vials pooled to prepare 50–100 doses for jet injection	World Health Organization, 1986[815]
1982	Ghana	6	2	33.3		Cases occurred at a single center; possible contaminated 50-dose vial or syringe	World Health Organization, 1986[815]
1984	Benin	31	11	35.5	4/10,000	Cases associated with one vaccinating team, six vaccinating sessions using multidose vials, jet injectors	World Health Organization, 1985[814]
1987	Nigeria	25	5	20		Illegal clinics, unauthorized inoculators, reuse of syringes, multidose vials	Oyelami et al, 1994[813]

[a]Estimated, because number of persons vaccinated with vaccine vial(s) implicated in the contamination is unknown.

there was no evidence that the fetus had developed hepatitis.[819] In another report, two women 2 and 5 months pregnant died of yellow fever; in neither case did the fetal livers show necrosis.[820] However, in a case in Brazil, a newborn infant acquired a fatal case of wild-type yellow fever 3 days after birth.[202] The mother had a mild case of yellow fever beginning 3 days before delivery. Transmission could have occurred via the placenta shortly before birth, during childbirth, or possibly via breast milk after birth.

Initially, the use of yellow fever vaccine in pregnancy was not constrained, and many women were vaccinated without any reported adverse effects. In Paris, Stefanopoulo and Duvolon immunized more than 200 pregnant women between 1936 and 1946,[821] and in Brazil, Smith and colleagues vaccinated "a considerable number of women in all stages of pregnancy with no untoward effects."[22]

A few studies have addressed the risk of congenital infection in pregnant women who were inadvertently immunized with 17D vaccine during emergency vaccination campaigns. Nasidi and colleagues studied 101 women who were immunized in Nigeria in 1986.[625] Four women (4%) were immunized in the first trimester, eight (8%) in the second trimester, and 89 (88%) in the third trimester. There were no adverse effects on fetuses or neonates attributable to vaccination among 40 infants who were carefully followed up. No evidence for transplacental infection was obtained in 40 babies whose cord blood was tested for IgM antibodies. However, the women immunized during pregnancy had a significantly lower seroconversion rate (39%) compared to control groups immunized during the campaign (see "Pregnancy" under "Primary Vaccine Failure" earlier for more details).

A second study was conducted following a vaccination campaign in Trinidad in 1989.[822] Approximately 400,000 persons were immunized and 100 to 200 were estimated to have inadvertently received 17D vaccine during pregnancy. Forty-one cord bloods were obtained from babies born to mothers who had received 17D vaccine during the first trimester. One infant (normal, full term) had IgM antibody in cord blood, suggesting that congenital infection with 17D virus might have occurred.

In a separate case-control study of 17D vaccination during early pregnancy, the relative risk of spontaneous abortion was estimated to be 2.3, but statistical power was low.[823]

In one additional study, pregnant women who were inadvertently immunized against yellow fever during a mass vaccination campaign conducted in Brazil in 2000 were followed to evaluate the possible effects of the 17D vaccine on conception and pregnancy and to assess congenital infection resulting from immunization, if any.[741] A total of 480 pregnant women were identified, having received the vaccine at a mean gestational age of 5.7 weeks (95% CI, 5.2–6.2). After a minimum 6-week interval, a total of 20% of women reported mild adverse events, such as headache, fever, or myalgia. At birth, no yellow fever IgM antibodies were detected in the infants and no placental or umbilical cord blood was PCR positive. The incidence of malformations (2%, or 7/304 babies), miscarriages (3%, or 11/441 pregnancies), stillbirths (0.7%), and premature delivery (8%) was similar to that found in the general population. Of 304 babies born to pregnant women vaccinated during the campaign, no increase in the rates of serious defects were detected when compared to a reference population of approximately 10,000 births before the vaccination campaign.[824] The only dysmorphism that was statistically more frequent in infants born to yellow fever vaccinees was nevus but the authors suggested that the finding could have resulted from assessment bias. One infant experienced a transient bilateral hypoacousia, three infants had an abnormal funduscopic examination, and four infants with neurologic abnormalities were IgG negative at 1 year of age. An accurate evaluation of a risk of miscarriage could not be performed owing to a delayed presentation of women following vaccination.

A manufacturer's review of 17 years of pharmacovigilance data for Stamaril, which is distributed worldwide, excluding North America, identified reports of 195 cases of inadvertent vaccination during pregnancy, with all but one being from Europe.[790] Spontaneous abortion was reported in 24 cases (12%), which was not higher than the background rate of 10% to 15% reported for the general population in Europe. There were 14 reports of congenital abnormalities or psychomotor retardation, with no consistent pattern. The observed reporting rate for congenital abnormalities was felt to be consistent with the known incidence of major congenital anomalies in Europe.

Rate of Occurrence

A serious adverse event is defined as any adverse experience that occurs after administration of a vaccine, including 17D vaccine, and results in death, life-threatening illness, congenital anomaly, inpatient hospitalization, prolongation of existing hospitalization, or persistent or significant disability. In some countries, significant medical events are also reported as serious adverse events.

From late 1930s to 2014, the total number of yellow fever immunizations administered worldwide approximates 540 million; the majority of which have been performed in developing countries. Surveillance for adverse events has been passive and insensitive to the discovery of rare events.

Khromava and associates used VAERS data to estimate the incidence of all serious adverse events in the civilian population in the United States, where approximately 300,000 doses are distributed annually.[253] The VAERS database contains reports of adverse events and does not assign causality, other than temporal association. The overall incidence of serious adverse events following yellow fever vaccination between 1990 and 2002 was 1.6 per 100,000 doses. Rates in the (younger) military population were about one half that in the civilian sector and were not different from those associated with typhoid vaccine. Lindsey and associates performed an analysis of VAERS data to estimate the incidence of serious adverse events in the United States civilian population for the years 2000–13, during which an average of 268,000 doses were distributed annually.[255,259a] The overall incidence for that time period was 4.2 per 100,000 doses. Cottin and associates used pharmacovigilance data from 16.2 million doses of Stamaril distributed to Europe, Australia, and New Zealand during 1993 to 2010 to estimate the incidence of serious adverse events to be 5.1 per 100,000 doses.[790] Bruegelmans and colleagues estimated the incidence of serious adverse events to be 0.43 per 100,000 doses in preventive vaccination campaigns in eight West African countries during 2007 to 2010, in which approximately 38 million doses of yellow fever vaccine were administered.[789] Biscayart and associates estimated an incidence of 1.8 serious adverse events per 100,000 doses administered in various provinces of Argentina in 2008 after a yellow fever outbreak in the northeastern province of Misiones resulted in approximately 2 million doses being administered.[825] However, it is not clear that the classification of adverse events as "serious" was the same in each of these recent studies as in the prior published studies using VAERS data from the United States.

Age is an important determinant of severity of adverse events to 17D vaccines. Several publications reported on the age and the occurrence of serious adverse events following the administration of 17D vaccines. Three publications

reported on age-specific incidence of serious adverse events with similar age stratification.[674,826,827] In U.S. and Australian residents, persons older than 65 years of age had a nine to 16 times higher risk of developing a serious adverse event following administration of 17D vaccines than did adults 25 to 44 years of age, which suggests that immune senescence might play a role (Table 63.19). When applying a decennial age stratification for the civilian population, the relative risk of developing serious adverse events for persons 60 years of age and older was six to 10 times higher compared to younger adults in one study[253] and 1.5 to 4.1 times higher in two other studies.[255,259a] Table 63.20 summarizes the findings for U.S. civilian and U.S. military observations. None of these retrospective studies adequately determined causal relationships between vaccine and adverse events, and elderly persons may be more likely to develop coincident illnesses than younger persons.

A similar conclusion with respect to age-related risk was reached after analysis of postmarketing surveillance data for ARILVAX in the United Kingdom.[674] This report also compared the neutralizing antibody responses in elderly and young adults. No differences were found, suggesting that if immune senescence plays a role, it might reflect an age-dependent impairment of cellular immunity.

A mathematical model was developed to evaluate the risk of developing a serious adverse event.[828] The authors used the U.S. data[253] and reached a conclusion that contraindicated yellow fever vaccination in patients 60 years of age and older, taking into account that the risk of serious adverse events (including deaths) is higher for that age group. A number of issues in this analysis, which applied U.S. data to the situation in a yellow fever–endemic country, were raised by Martins and associates.[545] There is a higher fatal outcome of wild-type yellow fever infection in older adults, a risk of a reintroduction of yellow fever by travelers into new countries, and lower risk of serious adverse events from vaccine in revaccinated or naturally immune people in endemic countries. In an analysis of the manufacturer's pharmacovigilance database for Stamaril, involving a 17-year time period during which 16.2 million doses were distributed to yellow fever nonendemic countries, Cottin and associates concluded that there was no evidence for a higher risk of serious adverse events after vaccination for travelers older than 60 years of age compared to that for younger travelers.[790] This age analysis was limited by the absence of age distribution data of vaccine recipients. However, to obtain a crude estimate of the age distribution of Stamaril recipients in yellow fever nonendemic countries, the authors used a computerized primary care database from the United Kingdom containing data for patients who received Stamaril.

TABLE 63.19 Retrospective Analysis of the Incidence of Serious Adverse Events in Persons Receiving Yellow Fever Vaccine in the United States and Australia

Age (y)	Doses	Serious Adverse Events[a]	Reporting Rate per 100,000	Relative Reporting Rate (95% CI)
UNITED STATES, 1990–98

Data from a retrospective survey reported in Lindsey NP, Schroeder BA, Miller ER, et al. Adverse event reports following yellow fever vaccination. Vaccine. *2008;26:6077–6082.*

Yellow Fever Vaccine–Associated Neurologic Disease

Two types of YEL-AND have been recognized following yellow fever vaccination. In the first type, yellow fever vaccine virus invades the CNS to cause encephalitis or meningitis; this is often referred to as *neurotropic disease*. In the second, yellow fever vaccine virus elicits an autoimmune reaction in which antibodies or T cells produced in response to the vaccine causes either central or peripheral demyelination that can result in a number of clinical syndromes such as ADEM or Guillain-Barré syndrome.

History of Neurovirulence of Vaccine

The 17D vaccine strains retain a degree of neurovirulence as demonstrated by intracerebral inoculation of mice and monkeys[542] and by the occurrence of rare cases of neurologic accidents in humans. A bimodal age-related risk of these accidents has been illustrated, with young infants and the elderly being at highest risk.

Historically, the typical syndrome associated with 17D vaccine has been encephalitis, characterized by onset of signs and symptoms 2 to 24 days after immunization. These include fever and variable neurologic signs including meningismus, convulsions, obtundation, and paresis. The CSF contains 100 to 500 cells (mixed polymorphonuclear and lymphocytic) and increased protein concentration. The clinical course has typically been brief and recovery generally complete. However, two fatal cases have been reported, including a 3-year-old girl who died of encephalitis following vaccination with a strain of yellow fever vaccine virus that had mutated to be more neurovirulent, and a 53-year-old man who had asymptomatic HIV with a CD4+ count of 108 cells/mm^3 and died from meningoencephalitis following yellow fever vaccination.[587,829] There has also been another complication described, including a 29-year-old man who had residual mild ataxia 11 months after onset.[830] The overall case-fatality rate of neurologic adverse events is very low and appears to be less than 1% based on the limited number of deaths reported among persons with neurologic disease following yellow fever vaccination.

In neurotropic cases, with a clinical picture of acute viral meningoencephalitis or meningitis, the mechanism is thought to be neuroinvasion and direct viral injury by 17D virus. Virus was recovered from brain tissue of a patient with a fatal case of encephalitis,[92] and 17D virus genome has been detected by PCR in the CSF from other neurotropic cases (Centers for Disease Control and Prevention, unpublished data, 2015).[203] In addition, in a number of cases, CSF has been tested for IgM and found positive.[545,831] However, as pointed out below, a substantial number of subjects have other manifestations of an autoimmune nature, such as ADEM and Guillain-Barré syndrome; it is uncertain whether low-grade viral infection of the brain might occur in these cases or is necessary for this type of pathogenesis to occur.

After standardized manufacturing procedures were instituted in the early 1940s, no cases of encephalitis temporally associated with 17D vaccine were reported for approximately 10 years.[682,821] From 1945 to 1988, a total of 17 yellow fever–associated encephalitis cases were reported worldwide, with only one reported fatal outcome.[587,682,832–842] In 1952–53, five cases occurred among 1800 children vaccinated at earlier than 1 year of age at the Pasteur Institute in Paris for an incidence of 2.8 cases per 1000 vaccinated (Table 63.21).[682] The incidence was even higher at four per 1000 vaccinated among the infants younger than 6 months of age. These cases constitute the first evidence that 17D vaccine manufactured according to biological standards and with restricted passage may be encephalitogenic in very young infants. Fifteen cases occurred during the 1950s, when there was no age restriction on use of the vaccine in infants. Of the 15 cases, 13 (87%) occurred in infants younger than 4 months of age, and all were younger than 7 months of age. Recommendations for restriction of use of 17D vaccine to infants older than 6 months of age were followed by a reduction in incidence of encephalitis.[843] Between 1960 and 1988, only two cases were reported, one of which occurred in a 1-month-old infant in France, at the time the age limitation was not universally practiced (see Table 63.21).[832] The only fatal case reported during this period was reported in 1965 and was a 3-year-old girl who died of encephalitis.[587] The virus was found to have a mutation in the yellow fever virus isolated.[92]

There are no reports of encephalitis in infants vaccinated for international travel since the recommendation for restricted use of the vaccine in children younger than 6 months of age has been universally adopted. Current recommendations for the minimum age for vaccination differ, typically from 9 months to 12 months of age, and depend on the recommendations of national health authorities based on risk of exposure to natural infection with yellow fever. During ongoing or threatened epidemics, it may be advisable to immunize infants from the age of 6 months, but in no case should the vaccine be administered to infants younger than 6 months.

The basis for increased risk of encephalitis in young infants is unknown, but it parallels the increased susceptibility of neonatal mice to neuroinvasion and neurovirulence of yellow fever and other flaviviruses. Possibilities include immaturity of the blood-brain barrier, prolonged or higher viremia, and immaturity of the immune system and delayed clearance of the infection. There are no data on 17D viremia levels or on the kinetics of the immune response in infants or children.

The incidence of encephalitis following 17D vaccine has been more common in male than in female patients. A slight excess of male patients (56%) was noted also in the cases of encephalitis following use of the French neurotropic vaccine.[519]

Case Definitions

In 2002, the Yellow Fever Vaccine Safety working group was organized by the CDC to review case reports of encephalitis in the VAERS database. As a result, the Yellow Fever Vaccine Safety working group refined and broadened the identification of the syndrome from encephalitis to YEL-AND to encompass all the neurologic syndromes reported as adverse events following 17D vaccines. The working group developed case

TABLE 63.21 Incidence of Yellow Fever Vaccine–Associated Neurologic Disease in Infants Vaccinated With 17D Vaccines in France

Location	Years	Age	No. Vaccinations	No. Encephalitis Cases	Incidence per 1000	Case Fatality (%)	Reference
Paris	1952–53	<6 mo	1000	4	4	0	Stuart, 1956[682]
		7–12 mo	800	1	1.25	0

definitions for cases with a neurotropic involvement (encephalitis), with an autoimmune involvement in the CNS (yellow fever vaccine–associated autoimmune disease in the CNS [YEL-AAD-CNS]) or with an autoimmune involvement in the peripheral nervous system (YEL-AAD-PNS).[729,831]

In addition to the case definitions, the Yellow Fever Vaccine Safety working group devised causality determinations for 17D vaccine.[729,831] For neurotropic disease, causality was principally based on testing CSF for virus, viral RNA, or IgM antibodies. There was no specific testing available for the autoimmune-mediated events of ADEM and Guillain-Barré syndrome, although their clinical diagnosis was made using appropriate studies such as neuroimaging, electroencephalography, electromyelography, nerve conduction studies, and tests for myelin antibody. Because no yellow fever vaccine-specific confirmatory laboratory tests exist for ADEM and Guillain-Barré syndrome, their causality determinations only specify "suspect" and "probable" levels of certainty. If there was no evidence of another diagnosis, a case was further classified depending on whether 17D vaccine was the only vaccine administered.[831]

The distinction between neurotropic disease (meningoencephalitis) and ADEM is not always clear, either clinically or through diagnostic testing. For neurotropic cases, the detection of the 17D virus in CSF by either culture or nucleic acid amplification is diagnostic. The detection of yellow fever virus IgM and neutralizing antibodies in the CSF also supports the diagnosis. Because IgM antibodies do not normally cross the blood-brain barrier, their production in the CSF is considered indicative of local CNS infection. There have been a number of ADEM cases following yellow fever vaccination in which IgM was detected in CSF, but neutralizing antibody tests were not routinely perform to determine if antibodies were in fact specific for yellow fever virus.[831,844] The pathogenesis of ADEM could result in the production of cross-reacting nonspecific autoantibodies, or it might involve low-level viral neuroinvasion insufficient to cause overt disease before viral clearance but sufficient to stimulate yellow fever virus-specific IgM antibody production and to trigger an autoimmune process. Detection of yellow fever virus neutralizing antibodies in CSF might differentiate specific IgM antibodies associated with neuroinvasion from nonspecific cross-reactive antibodies produced as a result of the autoimmune pathogenesis of ADEM.

Since 2007, the Brighton Collaboration, whose goal is to improve the comparability of vaccine safety data through the development of standardized cases definitions,[845] has published a series of case definitions for neurologic adverse events that have been reported postvaccination, including aseptic meningitis,[846] Guillain-Barré syndrome,[847] encephalitis, myelitis, and ADEM.[848] Having more standardized case definitions that can be used in variety of settings, regardless of resources, should help improve the capture and comparability of YEL-AND cases moving forward.

Summary of Cases Reported Between 1992 and 2014

Between 1992 and 2014, more than 200 YEL-AND cases have been reported worldwide. These predominantly included cases of meningoencephalitis, ADEM, and Guillain-Barré syndrome,[253,255,259a,545,790,825,829,831,844,849–854] but they also included cases of unusual neurologic syndromes such as ataxia, Bell palsy, transverse myelitis, longitudinal myelitis, bulbar palsy, mononeuritis, optic neuritis, and CNS vasculitis with stroke.[259a,796,799,800,803,805,855,856] Not all these unusual cases had a clear relationship between the event and vaccination, particularly as several of these events also occur as independent events in the population.

Although the neurotropic manifestation of YEL-AND has classically been regarded to be encephalitis or meningoencephalitis, aseptic meningitis also appears to be part of this disease spectrum. Several more recent published reports discuss patients with aseptic meningitis,[851,853] including 35 cases identified following a mass 17D vaccination campaign in the Brazilian state of Rio Grande do Sul in 2009. In practice, the clinical distinction between aseptic meningitis and encephalitis is not always clear.

Comparing more recent YEL-AND cases with earlier cases reported prior to 1992, there has been a notable increase in the number of cases reported and a change in the epidemiology of cases. Since 1992, YEL-AND cases have been predominantly adults, whereas the earlier timeframe largely involved cases among infants (see "History" above). Some of these differences are likely explained by establishment of a minimal age for vaccination, increased sensitivity of case detection, and a probable increase in vaccine use in elderly travelers.

Detailed descriptive statistics for all cases reported worldwide since 1992 are not possible because data are incomplete and reporting details are variable. However, data for all YEL-AND cases reported to United States VAERS (the inception of VAERS in the United States was 1990) from 1992 through 2013 are sufficiently complete to describe basic demographic features and explore differences between the syndromes (Table 63.22). Among these 52 cases, the distribution of YEL-AND syndromes is 23 neurotropic (44%), 10 ADEM (19%), and 20 Guillain-Barré (38%). One case was classified as encephalitis/ADEM owing to overlapping clinical and laboratory features. The median age of all cases is 45 years, with a range of 16 to 78 years; 83% (43/52) were male. The median onset of symptoms is 13 days (range, 2 to 56)

TABLE 63.22 Descriptive Statistics, U.S. Cases of Neurologic Disease Following Yellow Fever Vaccination, 1992–2013[a]

Category	No. of Cases	Male	Female	Mean Age (y)	Median Age (y [Range])	Mean Onset (Days)	Median Onset (Days [Range])
Encephalitis	16	14[b]	2	52.3	65 (16–78)	13.2	11.5 (2–34)
Meningitis	7	6	1	39	34 (19–67)	19.3	13 (10–56)
ADEM	10	9[b]	1	29.9	21.5 (17–61)	13.2	10.5 (2–44)
GBS	20	15	5	47	48 (17–76)	13.5	13.5 (2–29)
Total	52[b]	43[b]	9	44	45 (16–78)	14.3	12.5 (2–56)

[a]All yellow fever vaccine-associated neurologic disease (YEL-AND) cases meet either the CDC Yellow Fever Vaccine Safety Working Group YEL-AND case definition or the Brighton Collaboration case definitions for encephalitis, aseptic meningitis, ADEM, or GBS.
[b]One case in a male patient was classified as encephalitis/ADEM. This case was only counted once in the total count of cases, but was included in the category calculations for both encephalitis and ADEM.
ADEM, acute disseminated encephalomyelitis; GBS, Guillain-Barré Syndrome.

following vaccination. Among the four neurologic syndromes, males made up the majority of cases, but the median age ranged between the syndromes with persons with ADEM and meningitis having lower median ages than encephalitis. The differences in the age between syndromes, particularly for encephalitis compared to meningitis, is similar to what has been reported with West Nile virus disease cases.[857]

Although the higher proportion of YEL-AND cases among males might be partly because of differences in vaccination rates between sexes, the finding in VAERS cases is similar to the higher rate of YEL-AND reported among male infants before 1989 and an excess of encephalitis cases being identified among males who had received the French neurotropic vaccine.[519] The reason for the apparent predilection for YEL-AND among males who receive yellow fever vaccine is not known.

Risk of Occurrence

The incidence of YEL-AND in very young infants may be estimated at 0.5 to 4.0 per 1000 doses based on two reports that provided denominator data (see Table 63.21). In contrast, the risk of developing encephalitis in persons older than 9 months of age (the current minimum age recommended for routine immunization in the United States[729]) is much lower. Three studies of VAERS data have estimated the overall incidence of YEL-AND in the civilian U.S. population between 1990 and 2013 to be 0.4 to 0.8 per 100,000 doses (Table 63.23).[253,255,259a] This incidence is identical to that estimated from postmarketing surveillance data in the United Kingdom.[849] However, rates reported from other locations have varied substantially from 0.016 cases per 100,000 doses in several African countries[789] to a high of 9.9 cases per 100,000 doses in France (see Table 63.23).[850]

Reporting rates of YEL-AND often vary between nonendemic and endemic areas and based on the level of surveillance (see Table 63.23). In 2013, Cottin and associates[790] identified 24 cases of YEL-AND being reported following the administration of 276 million doses of Stamaril (17D vaccine manufactured in France) for an overall reporting rate of 0.008 per 100,000 doses distributed worldwide. In comparison, the rate among travelers from nonendemic areas (e.g., Europe, Australia, and New Zealand) was higher at 0.15 cases per 100,000 doses. Data from the Brazil's National System for Surveillance of Adverse Events Following Immunization for 2007–12 found an overall reporting rate of 0.2 YEL-AND cases per 100,000 doses, but it was as high as 1.1 per 100,000 doses in Rio Grande do Sul in 2009.[545] The discrepancy between YEL-AND reporting rates for Brazil as a whole versus Rio Grande do Sul state was attributed to the intensity of surveillance for AEFI that varies throughout this large country. Interestingly, the rates of YEL-AND among primary vaccine recipients in Brazil are not dissimilar to those reported from other countries that looked primarily at a traveler population (e.g., VAERS data).

As noted earlier, the incidence of YEL-AND is age dependent, particularly in travelers. In persons older than 60 years of age, the incidence of YEL-AND was estimated at 1.4 to 2.2 per 100,000 doses.[253,255,259a] The relative risk of YEL-AND in persons older than age 60 years is 2.4 to 3.5 times higher than in young adults. Roukens and associates found that following primary 17D vaccination, compared to younger subjects, elderly (60 to 81 years old) travelers had a delayed antibody response and higher PCR viremia levels.[256] If viremia is related to neuroinvasion, this might provide an explanation for increased risk of YEL-AND in the elderly. Further studies to confirm this theory are needed. In endemic areas of Brazil, the rates of YEL-AND were found in be highest in 5- to 9-year-olds

[a]YEL-AND includes meningitis, encephalitis, meningoencephalitis, ADEM, GBS, and other less-common neurologic syndromes.
[b]This study calculated a worldwide reporting rate for YEL-AND of 0.008/100,00 doses, based on 276 million doses of vaccine distributed globally. However, since all 24 cases of YEL-AND were reported from nonendemic countries, the low worldwide reporting rate likely reflects significant underreporting from endemic countries.
[c]Data reported are only for U.S. civilian cases.
[d]This published study includes an overlap period from years 2000 through 2002 with the Khromava 2005 study. The number of unique YEL-AND cases reported during 2003 through 2006 is six.
[e]This published study includes an overlap period from years 2007 through 2008 with the Martins 2014 study. The number of unique YEL-AND cases reported during 2000 through 2006 is 79.
[f]Data are reported for the entire country of Brazil.
ADEM, acute disseminated encephalomyelitis; GBS, Guillain-Barré syndrome; YEL-AND, yellow fever vaccine–associated neurologic disease.

even when looking specifically at first-time vaccine recipients.[545] It is unclear why the age-based risk groups are different based on the population but it could be hypothesized that it is related to base-line rates of exposures to flaviviruses, such as yellow fever and dengue viruses.

Yellow Fever Vaccine–Associated Viscerotropic Disease

YEL-AVD is a fulminant 17D virus infection of liver and visceral organs clinically and, to some degree, pathophysiologically resembling naturally acquired yellow fever. Fortunately, YEL-AVD is rare, but it can be lethal, with more than 60% of recognized cases dying.[729] The severity of YEL-AVD mandates a careful analysis of risk versus benefit of vaccination[494] and underlies the efforts to revise geographic risk of exposure to yellow fever during travel (see Fig. 63.4).

History

YEL-AVD was first recognized in 2001 when several cases of multiorgan system failure were described following 17D vaccination.[374,858–860] The original seven reported cases were associated with vaccines manufactured in Brazil (17DD substrain), France, and the United States (17D-204 substrain). The signs and symptoms of the syndrome resembled wild-type yellow fever virus infections and disease and included a rapid onset of high fever, malaise, and myalgia within 2 to 5 days of vaccination, followed by jaundice, oliguria, cardiovascular instability, and hemorrhage. Six of the seven cases died. Large amounts of yellow fever viral antigen were found in liver, heart, and other affected organs.

Shortly after the initial published reports of YEL-AVD in 2001, three additional brief reports describing milder nonfatal cases of visceral dysfunction following 17D vaccination were published.[861–863] Since 2001, additional cases of YEL-AVD have been published, both fatal and nonfatal.[265,266,360,849,854,864–874] A number of unpublished cases have also been reported by vaccine manufacturers, including 18 cases from Brazil,[851] most of which were fatal (Bio-Manguinhos, unpublished work, 2011).

In addition to the prospective identification of YEL-AVD cases, both confirmed and suspect cases of YEL-AVD have been identified retrospectively, dating back to at least the 1970s, if not before.[44,380,515,864] A retrospective analysis of 79 yellow fever samples in Brazil identified a patient who died in 1975 with "yellow fever" but whose partial genomic sequence provided evidence of the presence of a 17DD vaccine virus.[44,380] In 2010, a review of historical case reports in the United States described a 75-year-old man who became ill 6 days after receiving 17D-204 vaccine in 1973.[864] The man developed sepsis-like syndrome with multiorgan failure and died 11 days after vaccination. Histopathologic examination of the liver from this patient was not considered to be entirely characteristic for yellow fever, but the case met current criteria for viscerotropic disease and might have been confirmed if clinical suspicion for YEL-AVD existed at the time and there was more conclusive testing available. Even dating back to the 1950s, there was a description of potential YEL-AVD cases by Macnamara.[515] He reported a "number of cases of sickness which commenced several days after vaccination and exhibited jaundice, vomiting and albuminuria were seen by the doctor at a hospital serving an area in which a vaccination campaign was conducted. An epidemic of yellow fever, however, had been in progress so that naturally occurring yellow fever cannot be excluded, although it was felt by the doctor in charge that vaccination might well be the cause."

Case Definitions

The first case definition for YEL-AVD was developed by the Yellow Fever Vaccine Safety working group in 2002.[729] A suspect case was defined as a person with clinical symptoms and signs suggestive of organ failure following yellow fever vaccination. Probable and definitive cases were suspect cases with either abnormal histopathology or specific testing performed to document the abnormal presence and concentration of yellow fever vaccine virus or specific antigens in blood or tissues.[729] The case definition and causality classifications were also adopted by other yellow fever vaccine safety working groups in South America and Europe.[360,790]

In 2008, the Brighton Collaboration assembled a working group to devise a new case definition of viscerotropic disease as an adverse event following immunization. This case definition, with an unlinked yellow fever vaccine causality assessment, was published in 2012.[761]

Summary of Reported Cases

As of February 2017, at least 100 cases of viscerotropic disease have been reported worldwide following the administration of 17D vaccines from various manufacturers. As might be expected, with one exception, YEL-AVD has been observed only in persons with first-time vaccination and presumably without preexisting yellow fever immunity. The solitary reported case of YEL-AVD after a booster dose was never confirmed with yellow fever virus–specific testing. It was reported with minimal clinical detail in an aggregate report of YEL-AVD cases retrieved from a vaccine manufacturer's pharmacovigilance database.[790] From the little information provided, it is likely that this case would not meet either of the existing case definitions.

Detailed descriptive statistics for all reported cases worldwide are not possible because data are incomplete and reporting details and case classifications are variable, often case reports. However, data for all 24 YEL-AVD cases reported in the United States are sufficiently complete to describe basic demographic features and clinical outcomes of cases (Table 63.24). The median age of patients is 66 years (range, 21–79) and 71% (17/24) are male. The median time to symptom onset is 4 days (range, 1–18 days). Overall, 46% (11/24) of patients died with a median time to death from vaccination of 11 days (range, 8–30). There are a few notable demographic and clinical differences between males and females reported to with YEL-AVD. The median age for women is substantially lower at 31 years when compared to men who had a median age of 70 years but the age ranges are similar. Furthermore, the case-fatality rate is 71% in women but only 35% in men (Table 63.24). Although the numbers are small and might reflect a surveillance detection artifact, overall, the disease appears to be more severe in young girls and women.[875,876] This gender difference remains unexplained.

Review of Signs and Symptoms

Symptoms of YEL-AVD typically start 3 to 4 days after vaccination (range, 1–18 days) (Centers for Disease Control and Prevention, unpublished data, 2015)[729] and commonly include fever, myalgias, malaise, headache, and gastrointestinal symptoms (e.g., anorexia and diarrhea).[877] Laboratory abnormalities include elevations of liver transaminases, total bilirubin and creatinine in serum, decreased platelet counts in blood, and elevated proinflammatory cytokines. Less commonly reported abnormalities include elevated creatine phosphokinase, indicating rhabdomyolysis, and prolonged clotting times and/or elevated fibrin degradation products, which, when severe enough, indicate DIC.

TABLE 63.24 Descriptive Statistics, U.S. Cases of Viscerotropic Disease Following Yellow Fever Vaccination, 1973–2014[a,b]

		Age (y)			Onset (Days Postvaccination)			Death (Days Postvaccination)

[a]Viscerotropic disease cases in the United States obtained from reports to VAERS or publication in medical literature.
[b]All viscerotropic disease cases meet either the CDC Yellow Fever Vaccine Safety Working Group YEL-AVD case definition or the Brighton Collaboration viscerotropic disease case definition.

TABLE 63.25 Reporting Rates for Yellow Fever Vaccine–Associated Viscerotropic Disease

Location	Reporting Period	Number of Cases	Number of Doses	Reporting Rate per 100,000 Doses	Reference
NONENDEMIC					
U.K.	1991–2003	4	3,046,007	0.13	Kitchener, 2004[849]
Europe, Australia, New Zealand	1993–2011	12	16,200,000	0.07	Cottin et al, 2013[a,790]
U.S.	1990–2002	7	2,230,760	0.3	Khromava et al, 2005[b,253]
U.S.	2000–06	6[c]	1,534,170	0.4	Lindsey et al, 2008[b,255]
U.S.	2007–13	6[b]	2,224,790	0.3	Linsey et al, 2016
ENDEMIC					
Peru	2007	5	63,174	7.9	Whittembury et al, 2009[360]
Brazil	1999–2009	20	107,649,393	0.019	Martins et al, 2010[851]
West African Countries	2007–10	5	38,009,411	0.013	Breugelmans et al, 2013[789]
Argentina	2008–09	12	1,943,000	0.6	Biscayart et al, 2014[825]

[a]This study calculated a worldwide reporting rate for YEL-AVD of 0.004/100,000 doses, based on 276 million doses of vaccine distributed globally. However, 11 of 12 cases of YEL-AVD were reported from nonendemic countries, and for one case the country of origin was unknown. This suggests that the low worldwide reporting rate reflects significant underreporting from endemic countries.
[b]Data reported are only for U.S. civilian cases.
[c]This published study includes an overlap from years 2000 through 2002 with the Khromava 2005 study. However, all six YEL-AVD cases were reported during the nonoverlapping period of 2003 through 2006.
YEL-AVD, yellow fever vaccine–associated viscerotropic disease.

Several patients with more mild disease thought to be YEL-AVD have been reported.[360,790] However, the majority of reported cases have had more severe disease with evidence of shock characterized by hypotension, organ hypoperfusion, and respiratory failure. These patients often require intravenous vasopressor medication, mechanical ventilation, and hemodialysis. An apparent difference between life-threatening wild-type yellow fever and YEL-AVD is the absence of severe hemorrhage (black vomit) in the latter. In several persons surviving long enough for an assessment of their immune response, antibody titers to yellow fever virus were unusually high compared to the typical response to 17D vaccination (≥1 : 10,240).[360,374] For details of individual case clinical features and laboratory abnormalities, see Martin M and associates,[374] Vasconcelos PF and associates,[858] Whittembury A and associates,[360] and Monath TP and associates.[878]

Reporting Rate

Worldwide, there have been a number of studies estimating reporting rates for YEL-AVD from endemic and nonendemic countries, including some after large national vaccination campaigns involving the administration of millions of doses of 17D vaccine (Table 63.25). The reporting rates vary from a low of 0.013 cases per 100,000 doses in several African countries[789] to a high of 7.9 cases per 100,000 doses in Peru.[360] The lowest rate is likely represents significant underreporting from the involved African countries; the high rate reported in Peru is an unexplained unique occurrence, and is discussed in more detail below.

Similar to YEL-AND, reporting rates for YEL-AVD tend to vary between nonendemic and endemic areas (see Table 63.25).[254] From VAERS data, the rate of YEL-AVD in United States civilians is estimated to be 0.25 to 0.4 per 100,000 doses distributed.[253,255,259a] This is similar to the rate reported from postmarketing surveillance data in the United Kingdom.[849] However, the rate of YEL-AVD following Stamaril in nonendemic areas (e.g., Europe, Australia, and New Zealand) was lower at 0.07 per 100,000 doses.[790] In comparison, the rates in endemic areas range from 0.004 to 0.6 per 100,000 doses[789,790,825,851] The highest rate of 0.6 per 100,000 doses was reported in Argentina[825] (other rates in endemic areas are <0.02 per 100,000 doses) and was similar to the rate reported in nonendemic countries. One potential explanation for this is that the national data in Argentina includes a fair number of travelers receiving the vaccine beyond those receiving the vaccine in the small endemic region in the north of the country (Misiones Province). Finally, reporting rates of YEL-AVD also vary by age with older age groups found to have increased rates (See "Advanced Age" under "Risk Factors for Yellow Fever

Vaccine–Associated Viscerotropic Disease" below for more details).[254]

Pathogenesis

The biodistribution of 17D virus in normal nonhuman primates[284] indicates that 17D virus replication is generally limited to lymphoid tissues. In contrast, the individual patients who have developed YEL-AVD have a different biodistribution of 17D virus that involves widespread replication in visceral organs.[276,360,858,859,868] Indeed, the pathogenesis of YEL-AVD closely resembles that of wild-type yellow fever. The disease is characterized by replication of 17D virus in liver, kidney, heart, and other vital organs, and by pathoanatomic changes similar to those observed in wild-type disease, including apoptotic Councilman bodies in the liver. Major hemorrhage appears to be less prominent in YEL-AVD than in wild-type disease. As in the wild-type disease, the terminal events with circulatory shock and multiorgan failure resemble systemic inflammatory response syndrome.

The immune responses in a few cases of YEL-AVD have been described. These studies have shown a cytokine activation profile similar to that seen in wild-type yellow fever, with elevations of both proinflammatory (IL-6, IL-8, IL-17, MCP-1, growth-related oncogene [GRO], and RANTES) and regulatory cytokines (IL-4, IL-5, IL-10), increased incidence of NK cells, cells expressing cytokines, and massive activation of T and B cells.[867,879] These exaggerated cytokine changes and immune responses, reflecting an overwhelming infection, are likely to play a pathologic role. The innate responses in such patients might be defective.[266,865,880] The role of the adaptive response in the pathogenesis of YEL-AVD (and wild-type yellow fever) is speculative, but it has been suggested that a vigorous cytotoxic T-cell and antibody response in the presence of widespread tissue antigen might have pathologic consequences.[381]

Risk Factors for Yellow Fever Vaccine–Associated Viscerotropic Disease

Advanced Age. Advanced age was initially associated with the occurrence of YEL-AVD cases in the United States.[826] Subsequent analyses showed that serious adverse events, in general, were more common in the elderly. An analysis of VAERS reports between 1990 and 2002 yielded an incidence of YEL-AVD in the civilian population ages 60 to 69 years and 70 years and older in the United States that was 4.4 and 13.4 times higher, respectively, than in young adults.[253] During this period, the overall incidence of YEL-AVD in persons older than age 60 years was 1.8 per 100,000 doses compared to 0.1 per 100,000 doses in persons younger than age 60 years, based on an experience of 2.2 million doses of 17D vaccine administered to civilians. In an analysis of VAERS reports from between 2000 and 2006, based on an experience of 1.5 million doses administered to civilians, the overall incidence of YEL-AVD was 0.4 per 100,000 doses. For persons 60 to 69 years of age and for persons 70 years of age and older, the incidence was estimated to be 1 per 100,000 doses and 2.3 per 100,000 doses, respectively.[255] An analysis of the reporting rate ratios for several studies found the ratios to be two to 37 times higher for persons 60 years of age or older (or 65 years of age or older in some studies) compared to young age cohorts.[254] However, whereas the reporting rate of YEL-AVD is higher in the elderly, severity (as reflected by the case-fatality rate) appears to be greater in young persons and possibly in young females.[875,876] The reason for the increased severity of YEL-AVD in younger persons is not known but could be related to a more robust immune response associated with systemic inflammatory response syndrome and cytokine storm similar to what is seen with dengue hemorrhagic fever.

Until recently, the majority of cases of YEL-AVD reported from Brazil occurred in children and young-to-middle-aged adults.[851] It was previously thought that a potential predilection for severe reactions in the elderly might not be apparent in Brazil, because many older persons were previously vaccinated and therefore immune to YEL-AVD. Three cases of YEL-AVD were reported in primary vaccine recipients older than age 60 years following the mass vaccination campaigns in the southern states of Rio Grande do Sul and São Paulo in 2008–09, and conducted in response to a large epizootic expansion (Bio-Manguinhos, unpublished work, 2011). This population was largely unvaccinated, because these areas had not experienced outbreaks in many years.[881] This experience suggests that in Brazil, advanced age might be a risk factor for YEL-AVD in primary vaccinees, just as in the United States. Indeed, calculations using age-stratified data for YEL-AVD cases and 17DD doses administered between 1999 and 2009 yield a crude estimate of 0.017 cases per 100,000 doses for persons younger than age 60 years versus 0.047 cases per 100,000 doses for persons 60 years of age and older.[851]

Thymic Disease. A history of thymus disease has been also identified as a risk factor for YEL-AVD.[869] Four (17%) of the initial 23 17D vaccine recipients with YEL-AVD worldwide had a history of diseases involving the thymus, all of which are extremely rare, suggesting that compromised thymic function may be another independent risk factor for developing YEL-AVD. One fatal case in the United States occurred in a 67-year-old woman who had a history of thymectomy for a malignant thymoma approximately 2 years before vaccination. A second case in the United States occurred in a 70-year-old man who had a history of hyperthyroidism, myasthenia gravis, and thymectomy for thymoma 20 years before vaccination. This patient survived. A third case was reported from Switzerland and occurred in a 50-year-old man who had a history of thymectomy for thymoma 8 years prior to vaccination. This patient also survived. The last case was reported from Colombia and was a 44-year-old man who developed fulminant hepatic failure and died following 17DD yellow fever vaccine. This patient had a thymectomy for benign thymoma 2 years before vaccination.

Following the initial description of the four cases, a history of thymic disease was added to the package insert and vaccine policy statements as a contraindication to vaccination. Since then only one case of YEL-AVD has been identified in a patient with a thymoma. The patient's thymoma was occult at the time of vaccination and was only discovered after she presented with symptoms of YEL-AVD.[873] Autopsy performed after her death confirmed the diagnosis of a thymoma and YEL-AVD.

Genetic Factors. Genetic factors determining susceptibility to 17D (and perhaps flaviviruses in general) are suspected to play a role in cases of YEL-AVD. Two familial clusters, each involving two cases, have been reported in Brazil. The first cluster was recognized after a 19-year-old woman died from a fatal case of YEL-AVD (confirmed by 17D RNA amplification from multiple organs) in 2001.[870] Upon interviewing the family, they reported that the woman's sister, who had received yellow fever vaccine in 1999 when she was 12 years old, had a very similar reaction after vaccination, with jaundice, hypotension, bleeding, thrombocytopenia, and renal dysfunction. No yellow fever virus-specific testing had been done on clinical specimens from the younger sister so the case was classified retrospectively as suspect. The second cluster occurred in 2009 when two brothers ages 30 and 34 years, both with Addison

disease treated with physiologic corticosteroid replacement therapy, died from illnesses clinically compatible with YEL-AVD after receiving 17DD vaccine.[851] An autopsy was not performed on either brother; however, immunohistochemistry was positive for yellow fever antigen in liver tissue (from postmortem liver biopsy) from one brother and 17D RNA was amplified from serum drawn 9 days after vaccination from the other brother (Bio-Manguinhos, unpublished work, 2011).

Flavivirus susceptibility in mice has been mapped to a mutation in an allele in one of eight genes *(Oas1b)* encoding 2′,5′-OAS, an enzyme important in type 1 IFN-mediated innate immunity.[262,264] Belsher and associates determined the OAS genotype in a 22-year-old woman with fatal YEL-AVD and found polymorphisms in *Oas1* and *Oas2* genes that could have impaired enzymatic functions important in innate immune responses to infection.[265] There were no abnormalities in CCR5 or RANTES genes, TLR3 (a susceptibility factor in West Nile), or DC-SIGN (dendritic cell–specific intercellular adhesion molecule-3-grabbing nonintegrin), a major Flavivirus receptor.

Pulendran and associates studied a 64-year-old patient with a severe but nonfatal case of YEL-AVD.[266] In this case, no mutations were found in OAS genes, TLR3, or DC-SIGN, but the patient had markedly elevated levels of RANTES and $CD14^{+}$ $CD16^{bright}$ monocytes in blood, which expressed CCR5 receptors for RANTES and could have reflected some impairment in trafficking of these cells. This patient was found to be heterozygous for the CCR5-Δ32 mutation (which is known to determine resistance to HIV) and to have a polymorphism in the promoter region of RANTES gene that regulates gene activity. The significance of the CCR5 and RANTES gene polymorphisms is not clear, but they could impair important effector mechanisms in innate immunity. Because of the CCR5-Δ32 mutation in this case and the role of CCR5 deficiency in susceptibility to West Nile virus,[882] it has been suggested that caution be exercised in yellow fever vaccination of HIV-infected subjects treated with CCR5 inhibitors, such as maraviroc.[883] Host genetics have been studied in a few other cases of YEL-AVD without finding a consistent defect.[360]

Because the viscerotropic response to 17D is likely related to host genetics, it is advisable to ask travelers whether severe reactions to 17D vaccine have occurred in a family member and to avoid vaccinating someone with a family history of a serious adverse event.

Other Considerations

Vaccine Virus. Almost all reported cases of YEL-AVD have occurred in persons given different lots of the vaccine. However, there has been one known cluster of five cases of YEL-AVD associated with the same lot of yellow fever vaccine.[360] This occurred in 2007 after a vaccination campaign in a nonendemic area of Peru. Four patients died of confirmed YEL-AVD. The overall incidence of YEL-AVD in this campaign was 7.9 per 100,000 doses, and the lot-specific incidence was 11.7 per 100,000 doses of the implicated lot. A thorough investigation detected no abnormalities of the implicated vaccine lot and no common risk factors among the five patients. The incidence of YEL-AVD associated with this campaign in Peru was substantially higher than previous risk estimates from other countries and remains unexplained, and no other clusters of YEL-AVD have been reported.

The genetic stability of the 17D-204 yellow fever vaccine strain, used in Stamaril, was studied by genetic sequence analysis of virus obtained from 12 bulk lots manufactured between 1990 and 2002, with identical sequences being confirmed.[559] In addition, comprehensive analyses of viral plaque size distributions, an additional marker for genetic stability, also was consistent with homogeneity of the viral population in those bulk lots. The total virus load, as measured by quantitative RT-PCR, was equally homogeneous and hence confirmed the consistency in the manufacturing process. Data obtained in animal models with yellow fever virus from these bulk lots were also consistent.

Analyses of the vaccine lots and seed viruses associated with cases revealed no evidence for mutations in the vaccine that could explain the adverse events. More important, analyses of 17D and 17DD viruses recovered from patients' tissues did not reveal mutations compared to the vaccine strains, indicating that even with in vivo amplification and selection as a filter to select for variants associated with pathogenicity, no evidence for a change in the virus was obtained.[360,374,858,868] Additionally, vaccine viral isolates from patients with YEL-AVD do not reproduce a similar syndrome when inoculated into healthy primates and golden hamsters.[380,868,884] Overall, these data suggest that mutations to the vaccine during manufacturing are unlikely to occur and be a risk factor for YEL-AVD. Although deep sequencing methods were not available at the time the isolates from patients were examined, the consensus sequence defined the majority virus population recovered from vital organs and should be reflective of the virus population causing the pathological process.

Autoimmune Disease. Twelve patients who developed YEL-AVD had a history of autoimmune disease. These include three patients with systemic lupus erythematosus, one with cutaneous lupus, two with Addison disease, one with Crohn disease in remission, one with a history of polymyalgia rheumatica and hypothyroidism, one with ulcerative colitis, two with myasthenia gravis, and one with pernicious anemia (Centers for Disease Control and Prevention, unpublished data, 2015).[360,374,851,864,867,869] Complete details are not available regarding medications these patients were taking, which might have included immunosuppressive medications. Six of the patients with underlying autoimmune disease were older than 60 years, and two of these six had a history of thymectomy for a thymoma; both factors are considered to be independently associated with increased risk of YEL-AVD.

More information is needed regarding the number of patients with underlying autoimmune disease who have been safely vaccinated to better address the potential risk of YEL-AVD in persons with autoimmune disease. Nevertheless, it is concerning that 12 (approximately 12%) of approximately 100 reported patients with YEL-AVD had a history of autoimmune disease, whereas the prevalence of autoimmune disease in the United States is 3%.[885] This suggests that autoimmune diseases, possibly in conjunction with other risk factors, including immunosuppressive medication, could increase the risk of YEL-AVD. Definitive risk assessment data are lacking to guide decision making about yellow fever vaccination in these patients. However, healthcare providers should consider the possibility of diminished immune function resulting from the autoimmune disease state itself and/or the treating medication in deciding whether or not to administer yellow fever vaccine to these patients.

Surveillance. The recognition of viscerotropic adverse events is especially difficult in endemic areas, where the syndrome could be confused with wild-type yellow fever.[380] During summer 2001 in Minas Gerais (Brazil), health authorities initiated a mass immunization campaign to control an outbreak involving 81 suspected cases and 32 confirmed cases, including 17 fatal outcomes (for a 53% case-fatality rate).Two cases of a fatal yellow fever disease in a 39-year-old man and a 69-year-old man who received the 17D vaccine 2 and 14 days, respectively, before the onset of signs and symptoms were of

special interest as suspect YEL-AVD. The molecular characterization of the virus isolated from fresh tissue and serum, however, revealed wild-type yellow fever virus.[886] Therefore, it is important to carefully analyze virus isolates by molecular techniques from case reports of yellow fever disease temporally associated with the administration of yellow fever vaccine in endemic areas.

Immunoglobulin Administration. The relatively recent recognition of YEL-AVD in developed countries may be attributable to improved surveillance for vaccine-associated adverse events. Other explanations have been suggested, in particular the possibility that immunoglobulin administered for hepatitis A prophylaxis in the era before marketing approval of hepatitis A vaccines (1995) might have provided protection against viscerotropic disease. However, this theory was not substantiated by a randomized, double-blind, controlled trial.[361] In the trial, 40 subjects were given both 17D vaccine and intramuscular human immunoglobulin and 40 subjects were given 17D vaccine and saline injection placebo. The coadministration of immunoglobulin with 17D vaccine did not reduce the incidence of vaccine-induced viremia nor were yellow fever antibody or T-cell responses to the vaccine altered. However, there were some limitations of the study design[887] and the results were unexpected given the documented role of passive antibody in protection against yellow fever.

Recommendations for Evaluation of Suspect Yellow Fever Vaccine–Associated Viscerotropic Disease Cases

Patients with an undiagnosed febrile illness occurring within 10 days after vaccination should be investigated and those with elevated liver enzyme levels and reduced platelet counts should be hospitalized for observation. To provide much-needed data on causality, serial samples for quantitative viremia, antibody, and cytokine studies should be undertaken and buffy coat cells or peripheral blood mononuclear cells frozen appropriately for future immunologic and genetic studies. If autopsy is performed on fatal cases, samples of multiple organs should be preserved for histopathology and immunocytochemistry and frozen (on dry ice or liquid nitrogen) for virologic studies. In the United States, such cases should be promptly reported to the VAERS (800–822–7967) and consultation sought with the Division of Vector-Borne Diseases at the CDC in Fort Collins, CO (970–221–6400) for diagnostic testing support. In other countries, such cases should be promptly reported to the country-specific health authorities and advice sought about obtaining diagnostic testing.

Impact of Serious Adverse Events

Impact on Travel Vaccination

The risk of acquiring yellow fever virus infection during travel to an endemic and epidemic area may exceed the risk of YEL-AVD for the vast majority of persons and travel destinations.[461] However, the epidemiologic risk of transmission is variable in time and place even in endemic areas. Hence, physicians should be aware of this serious complication of 17D vaccines and that it occurs at higher incidence in primary vaccination of elderly persons. Physicians should also stay up-to-date on yellow fever endemic and epidemic areas.[412] Information on occurrence of human cases may not be an adequate guide, as monkey-to-monkey transmission can occur in remote and sparsely inhabited areas, and vaccination rates can be high in endemic areas. Special attention is also drawn to the fact that in at least one case the intended travel destination was not within the yellow fever endemic zone, and therefore vaccination was not necessary.[374] This is likely also true (though not published) in two other cases, and a fourth was immunized in the military for deployment (a practice that did not generally take into account whether the actual destination was in a yellow fever–endemic area).[888]

Impact in the Endemic Areas

YEL-AVD and YEL-AND are recognized as significant factors to be considered in the implementation of yellow fever vaccination strategies in South America, in particular when mass vaccination is conducted in areas where routine vaccinations have not heretofore been performed. Only five young children (10 months to 5 years of age) have been reported with cases of YEL-AVD (all in Brazil), although millions of doses of yellow fever vaccine are given annually in the EPI in endemic countries of South America, generally at 9 to 12 months of age. Thus, vaccine safety does not appear to be a major concern for use of 17D vaccines in this age group, where it is most cost effective as a means of long-term protection of the population against epidemic and endemic disease.

On the other hand, when mass immunizations have been given in areas of periodic epizootic expansions outside the traditional endemic area, such as occurred in 1998 to 2000 and 2007 to 2008 in eastern and southern Brazil or during the campaign in Ica Province, Peru, in 2007, involving very large numbers of vaccinations in nonimmune adults, cases of YEL-AVD have appeared.[360,858,881,889] The authorities have argued that without vaccinations, many lives would have been lost to wild-type yellow fever, and that the penalty to pay for prevention was a relatively smaller number of lives lost to vaccine accidents. However, in Ica where there were five YEL-AVD cases, vaccination was undertaken in an area where yellow fever virus is not found and probably should not have been given, demonstrating the need to carefully evaluate risk factors when considering vaccination.

In Africa, routine immunization of infants at 9 months of age is established in many endemic countries, and catch-up campaigns are being implemented as part of the Yellow Fever Initiative described later in the discussion under "Public Health Considerations." To date, 11 potential YEL-AND or YEL-AVD cases have been documented with the enhanced surveillance efforts that were performed these mass campaigns.[789] However, this is in the context of over 38 million doses of the vaccine being delivered and offering protection to persons living in areas at high risk of yellow fever virus infection.

INDICATIONS, CONTRAINDICATIONS, AND PRECAUTIONS FOR VACCINATION

Indications

All inhabitants of countries or areas within countries endemic for yellow fever should be routinely immunized, preferably at 9 months of age. Fig. 63.4 shows the areas endemic for yellow fever. Within these countries, priorities for immunization may be established related to risk of exposure to yellow fever virus. For example, residents in rural areas and areas of historical yellow fever epidemic activity are at higher risk than residents in large cities or areas in which yellow fever has not occurred in many years. Persons migrating from nonendemic to endemic areas are at high risk and should be immunized. Because such movements are difficult to control, and the potential exists for spread of yellow fever virus from rural to

urban areas, a policy of universal immunization in many countries within the endemic zone is favored.

However, in many countries a distinction is drawn between endemic and nonendemic regions within national borders. For example, in many countries in South America, the coastal zone is traditionally outside the endemic region. Many of these areas contain very large human populations and major urbanizations, and these regions have been excluded from routine yellow fever immunization. New safety concerns for use of 17D vaccine have reinforced the policy to exclude these coastal zones. Mass vaccination of adults in a nonendemic region of Peru (Ica Province) was associated with a high incidence of YEL-AVD in 2007.[360] Adverse events also led to the cessation of a mass vaccination program in the nonendemic region of coastal Brazil in 2000.

During epidemics of yellow fever, mass immunization should be instituted at the earliest possible stage of the outbreak. Priorities for immunizing population subsets according to geography or age group are determined by local information on the progress of the outbreak and on the history of prior vaccination coverage.

Immigrants, travelers, and military personnel and dependents require immunization at least 10 days before arrival in endemic areas as even a short stay in an area of virus transmission is dangerous.[461,732] Because native inhabitants may be immune and the virus can circulate in a silent zoonotic cycle, the absence of recent notification of yellow fever in an area is not an indication that it is safe to enter without vaccination. On the other hand, the notification of human cases within the past 1 to 2 years is an indication of high risk. Short-stay travelers to large cities within endemic areas, such as the coastal metropolises of West Africa (e.g., Accra, Lagos, Dakar, Abidjan) are at lower risk in the absence of a reported outbreak. However, cases of urban yellow fever were reported within the city of Abidjan (Côte d'Ivoire) in 2001 and again in 2008.[428,890] Similarly, urban areas located within endemic regions, such as Iquitos, Peru, represent areas of risk. Clearly, visitors to urban regions reporting yellow fever or juxtaposed to areas of ongoing virus activity require vaccination. Coastal areas of East Africa and most of South America are outside the area of yellow fever transmission; however, there was expansion of yellow fever activity in coastal states in Brazil in late 2008 through early 2009 and again in late 2016 through early 2017. Current information of yellow fever endemic and epidemic activity may be obtained on the WHO website[891] and the CDC's traveler's health website.[892]

Some countries in the endemic zones and some countries outside the endemic zones but infested with *Ae. aegypti* and receptive to the introduction of yellow fever virus require a valid certificate of immunization for travelers from endemic countries. A full listing is given in the WHO document International Travel and Health[414,893] and in CDC's Health Information for International Travel.[413,894] Some countries require a valid certificate even if the traveler has been in transit through an endemic country and even if the disembarking traveler is in transit. Controls at airports and borders are highly variable, but travelers respecting the regulations avoid unnecessary delays. Persons with a contraindication to immunization (see the next section) should have their medical provider fill out the Medical Contraindication to Vaccination section of the ICVP and also obtain a letter from the provider stating why immunization could not be performed.

Contraindications and Precautions

Contraindications and precautions to the administration of yellow fever 17D vaccine specified by the ACIP[729] are shown in Box 63.1 and described in this section. The medical practitioner administering yellow fever vaccine has the responsibility to assess the risks associated with 17D vaccine, the risk of exposure to natural infection with yellow fever virus, and the statutory and practical requirements for a certificate of immunization. This should take into account the details of the patient's medical history, the itinerary of travel, and existing regulations. In two surveys of subjects seeking travel health advice, 2% to 6% had one or more potential precautions or contraindications for yellow fever vaccination.[733,895]

BOX 63.1 Contraindications to and Precautions for Yellow Fever Vaccine Administration Based on the Recommendations of the Advisory Committee on Immunization Practices[a,729]

CONTRAINDICATIONS

- Allergy to vaccine components[b]
- Age <6 months
- Symptomatic HIV infection or $CD4^+$ T-lymphocytes <200/mm^3 (or <15% of total in children <6 years)
- Thymus disorder associated with abnormal immune function; history of thymectomy
- Primary immunodeficiencies
- Malignant neoplasms
- Transplantation
- Immunosuppressive and immunomodulatory therapies

PRECAUTIONS

- Age 6–8 months
- Age ≥60 years
- Asymptomatic HIV infection and $CD4^+$ T-lymphocytes 200 to 499/mm^3 (or 15–24% of total in children <6 years)
- Pregnancy
- Breastfeeding

[a]Recommendations are made for travelers and laboratory workers in the United States and might differ from vaccine recommendations in other countries and in areas with endemic yellow fever disease.
[b]Includes egg allergy (oral intolerance to eggs).

Young Age

Infants are at higher risk for YEL-AND, and this risk is inversely proportional to age. The vaccine should never be administered to infants younger than 6 months.[672,729] Routine immunization may be performed at 9 months of age. Age 6 to 8 months is a precaution for yellow fever vaccination.[729] Such infants should be immunized only if there is a significant risk of natural infection, such as residence in or travel to a rural area in the yellow fever endemic zone or in the context of an ongoing epidemic. If possible, travel should be delayed until the infant is 9 months of age. Where the risk of exposure to yellow fever virus is very low (e.g., in large urban areas in endemic countries, especially in the context of brief visits by tourists), it is advisable to delay immunization until 12 months of age.

Advanced Age

Age 60 years or older is considered a precaution for yellow fever vaccination for primary vaccine recipients[729] owing to higher reporting rates of severe and serious adverse events, including YEL-AND and YEL-AVD in this population (see "Adverse Events" earlier).[253–255,259a,826,827,849] The relative risk of a serious adverse event increases with advancing age beyond 60 years, and the precaution for vaccination should be

considered in that light. The risk for YEL-AND and YEL-AVD also are increased in this age group, at 1.8 and 1.4 cases per 100,000 doses, respectively, compared with 0.8 and 0.4 cases per 100,000 doses, respectively, for all yellow fever vaccine recipients.[255] YEL-AND and YEL-AVD have occurred exclusively in the setting of primary vaccination, and there is far less risk to persons 60 years of age or older who are revaccinated, unless they have some underlying acquired immunosuppressive disorder. The reason for the higher risk of adverse events is not completely elucidated but one study did find that older adults have a delayed immunologic response to yellow fever vaccination and develop higher levels of viremia post vaccination than younger adults.[256]

Pregnancy

For a discussion of the risks of congenital infection, see "Pregnancy" under "Adverse Events" earlier.

The hypothetical risk of transplacental infection and the recognition that young infants (and, thus, potentially, the unborn fetus) were susceptible to neuroinvasion by 17D virus led to the general recommendation that the vaccine not be administered during pregnancy unless it is clearly required based on a high risk of natural infection.[672,729] Both the ACIP and the WHO recommend that a risk-to-benefit assessment be performed for all pregnant women for whom yellow fever vaccine is being considered. Inadvertent immunization of women (generally in the early stages of pregnancy) is definitely not an indication for therapeutic abortion. Women should be cautioned that there is a hypothetical risk, but they should be reassured that no harm to the fetus has ever been demonstrated. Fear of potential adverse effects might have led to an increase in therapeutic abortions during a vaccination campaign in Trinidad in 1977 to 1978.[896] If possible, women should wait until 4 weeks after vaccination before conceiving.[729]

Pregnant women who have received the vaccine should be reassured that there is no risk to them and very low risk to the fetus. These women should be followed to parturition, and if fetal abnormality is noted, an infant blood sample should be obtained for IgM test to determine whether congenital infection had occurred. Data on whether the immune response to yellow fever vaccination during pregnancy is impaired are conflicting (Goujon C and Godineau J-P, personal communication, 2006) and might be related to the timing of the vaccination during pregnancy.[625,741]

Breastfeeding

Very limited safety data are available on the use of 17D vaccine in breastfeeding women and their infants. Although a very large number of lactating women have been successfully immunized during emergency vaccination campaigns without a significant number of adverse events being reported, cases of serious adverse events occurring in breastfed infants whose mothers were vaccinated raises concern over the use of the vaccine in lactating women.[729,897] Two probable and one confirmed case of YEL-AND have been reported in infants whose mothers were vaccinated with yellow fever vaccine.[203–205] The infants were breastfed exclusively, were younger than 1 month at the time of the exposure, and had not received the vaccine themselves. The interval between vaccination and onset of symptoms in breastfeeding infants was 3 to 4 weeks. Yellow fever vaccine virus was recovered from the CSF of the confirmed case patient, and yellow fever–specific IgM antibodies were detected in the CSF of the probable case patients. Testing was not performed on the breast milk in any case to confirm the presence of vaccine virus.

West Nile virus RNA has been found in human breast milk[898] and some tickborne flaviviruses (tickborne encephalitis, Powassan encephalitis) are secreted in milk of domesticated livestock, which can be a source of oral infection of humans. Given these findings, the ACIP states that breastfeeding is a precaution to yellow fever vaccination.[729] The WHO recommends that a risk-to-benefit assessment be conducted for lactating women for whom yellow fever vaccination is being considered, but also states that lactating women should be advised that the benefits of breastfeeding far outweigh alternatives.[672] Further research is needed to document the risk for potential vaccine exposure through breastfeeding.

Altered Immune State

Data on the safety and efficacy of yellow fever vaccination in persons with altered immune function remain limited. However, yellow fever vaccine is contraindicated in patients who are immunosuppressed as a result of primary or acquired immune deficiency or medication because of the theoretical and occasionally documented risk of serious adverse events. Specifically, yellow fever vaccine is contraindicated in persons with primary immune deficiency disorders, malignant neoplasms, transplantation, or treatment with radiation or immunosuppressive drugs including high-dose corticosteroids, alkylating agents, antimetabolites, TNF-α inhibitors, and IL-1 blockers, and MAbs targeting immune cells (e.g., rituximab).[729] In addition, yellow fever vaccine is contraindicated in persons with symptomatic HIV infection or $CD4^+$ counts less than 200/mm^3 or less than 15% of total lymphocytes for children younger than age 6 years.[729] The theoretical concern about use of CCR5-receptor blocking agents was noted in the section on HIV, earlier. Low-dose corticosteroid treatment (20 mg prednisone or equivalent per day), short-term corticosteroids (course of <2 weeks), and topical, inhaled, or intraarticular or bursal injections of corticosteroids do not pose a contraindication to yellow fever vaccination.[729] If feasible, immunosuppressive medication should be stopped until immune function is restored or improved before yellow fever vaccination.

Four (17%) of the initial 23 reported YEL-AVD cases were noted to occur in persons who had had thymectomies performed for thymomas,[869] and in 2003, "thymus disorder" was added to the 17D vaccine package insert as a contraindication. Since this recommendations was made, there has been only one fatal case of YEL-AVD reported in a person with an occult thymoma that was only detected after vaccination and when she developed symptoms to YEL-AVD.[873] To date, no evidence has been identified of immune dysfunction or increased risk for yellow fever vaccine-associated serious adverse events in persons who have undergone incidental surgical removal of their thymus or have had indirect radiation therapy in the distant past.

Although there has been a recent increase in the number of persons who are HIV-infected and have been vaccinated against yellow fever, data on the safety and immunogenicity of the vaccine are limited to approximately 800 HIV-infected persons with less than 25 of these individuals having $CD4^+$ counts of less than 200 per mm^3 when they were vaccinated.[715,744,748–752,899–901] As noted above, the vaccine is contraindicated for persons with symptoms HIV or $CD4^+$ counts of less than 200 per mm^3. This recommendation is made partly because of the report of a healthy adult who had low $CD4^+$ cell counts as a result of HIV infection and who developed fatal YEL-AND following 17D vaccination.[829] The ACIP also considers asymptomatic HIV infection and $CD4^+$ T-lymphocytes counts of 200 to 499/mm^3 (or 15% to 24%

of total in children younger than age 6 years) to be a precaution for vaccination. This is partly because of the theoretical safety concerns but also because of the lower rates of seroconversion and more rapid antibody decay seen among persons infected with HIV who are vaccinated when compared to healthy persons (see "HIV Infection" under "Primary Vaccine Failure" earlier).[715,744] For HIV-infected persons who experience immune reconstitution in response to antiretroviral therapy, their current CD4 count and symptoms of HIV infection (if stable over a 3-month period) rather than a CD4 count nadir and a history of prior opportunistic infections/symptomatic HIV should be used to categorize their HIV status.[413] Finally, if an asymptomatic HIV-infected person has no evidence of immune suppression based on $CD4^+$ counts ($\geq$500 cells/mm^3), yellow fever vaccine can be administered, if recommended on the basis of their destination-specific yellow fever risk.

Policy decisions regarding use of 17D vaccine in endemic areas, including emergency vaccination to control outbreaks or in routine immunization programs, must also take into account benefits and potential risks related to the prevalence of HIV in the population and the sensitivity of surveillance for adverse events.[902] Where emergency and preventive vaccination has been deployed in areas of Africa with a relatively high prevalence of HIV infection and follow-up was conducted, no safety concerns have been noted.[770,901,902] Current policy supports use of live vaccines, including yellow fever 17D for children, regardless of possible HIV exposure, as a means of ensuring immunization coverage and controlling epidemic yellow fever.[903]

There is increasing evidence from case reports that autoimmune diseases constitute a risk factor for YEL-AVD (see "Autoimmune Disease" under "Other Considerations" for YEL-AVD above). In 2010, 11 (17%) of 65 YEL-AVD cases had a history of autoimmune disease, such as systemic lupus erythematosus, or diseases with the potential for autoimmune etiology. There may have been other confounding risk factors also (e.g., advanced age, thymectomy, medications). However, the association with autoimmune diseases emphasizes the need for caution in patients with any immune dysregulation and further analysis of the risk and pathogenesis of adverse events.

An individual risk-to-benefit assessment must be performed for every patient who has a history of immunosuppression and who is traveling to an endemic area. If travel is unavoidable and contraindications to vaccination exist, the physician should provide a medical waiver and should counsel the patient about measures to avoid mosquito exposure. For select travelers, passive immunization could be considered (see "Passive Immunization and Passive-Active Immunization" above for more information) but this practice is complex and expensive and likely is not a viable option for most immunosuppressed individuals.

Blood, Bone Marrow, and Organ Donation

Transfusion-related transmission of yellow fever vaccine virus has been documented among persons receiving blood products that were collected from recently vaccinated persons.[657] Blood donation centers should screen blood donors to determine if they received a yellow fever vaccine within the past 2 weeks and defer these donors. However, practices vary among blood collection centers, and questions about vaccination history might not routinely be asked. Vaccine recipients should be advised to delay blood donations until 30 days after vaccination.

No formal recommendations have been made on the suitability of persons who have received 17D vaccine at a remote point in time as organ or bone marrow donors. This issue has been raised because of the possibility that 17D virus causes a latent, persistent infection (reviewed in "Duration of Immunity" under "Results of Vaccination" earlier) that is contained and irrelevant in the immune host but that might cause systemic infection in an immunosuppressed transplant recipient. The risk to recipients is purely hypothetical. Unless the vaccine changed its tropism and virulence during latency, the risk to the recipient, even if infected, appears to be small. In a single report, bone marrow from a donor twin immunized 1 month previously with yellow fever 17D was grafted to an identical twin.[904] The recipient failed to develop yellow fever antibodies, indicating that no yellow fever B cell clone had been transferred or that immunosuppressive therapy might have masked an immune response by the recipient to transferred virus. There were no untoward events attributable to the potential transfer of 17D virus.

There are no data on whether yellow fever vaccine induces transient false-positive serologic tests for HIV, syphilis, or other bloodborne viruses, as has been reported for influenza and smallpox vaccines.[905]

Allergy to Vaccine Constituents

Documented allergy to a vaccine component, including eggs (cooked or raw), egg products, chicken meat, or gelatin or a severe allergic reaction to previous administration of the vaccine (or other vaccines prepared in eggs, such as influenza) constitute a contraindication to vaccine administration. The product label for YF-Vax also notes that the vaccine stopper contains latex rubber, which might cause allergic reactions.[575] Generally, persons who are able to eat eggs and egg products without allergic reactions can receive the vaccine. Egg allergy is more common in children than adults. If there is doubt about egg allergy, a test may be performed to determine egg-white IgE (by skin prick or serum test) or allergy to the yellow fever vaccine itself using a scratch or prick test with 1 : 10-diluted vaccine followed (if positive wheal and flare) by an intradermal test with 0.02 mL of 1 : 100-diluted vaccine, using appropriate controls. The methods are described in the YF-Vax package insert.[575] Desensitization may be considered in the event of demonstrated allergy if vaccination is required for travel and has been shown to be effective in a limited number of persons with egg allergies.[779] This should ideally be performed by an allergist.

It should be noted that the small dose of vaccine given in the allergy skin test may be sufficient for effective immunization. Roukens and associates[906] used an intradermal test dose of 0.1 mL (undiluted vaccine) in seven egg-allergic subjects and found that all seroconverted. However, the procedure (using much smaller doses than in the U.S. product [YF-Vax] label) was not followed in this case. Nevertheless, before performing desensitization in a known allergic patient who has received an intradermal test dose of vaccine, it is useful (if feasible) to wait 14 days and perform a neutralization test. If the patient is found to have neutralizing antibodies, the patient may be considered to have been satisfactorily vaccinated.

Waiver of Yellow Fever Vaccination

If a contraindication to yellow fever vaccination exists or a precaution exists for which the physician judges that the risk of adverse events outweighs the risk of exposure to wild-type virus, a waiver may be provided. The Medical Contraindications to Vaccination form is part of the ICVP and should be signed and validated with the stamp of a designated yellow fever vaccinating center.[413,732]

Patients Who Receive Yellow Fever Vaccine but Have Contraindications and Are at Risk for Adverse Events

For immunosuppressed patients who are inadvertently vaccinated, combinations of IVIg (derived from U.S. plasma donations only), IFN-α, or IFN-ribavirin[408] (all of which are commercially available) may be considered. Treatment should be initiated as early as possible, and certainly within 48 to 72 hours after vaccination. Although there are no clinical data to provide a guide, it appears preferable to use IFN-α rather than a pegylated IFN, because the pharmacokinetics of IFN-α are short (peak blood levels of 3 to 12 hours) and pegylated IFN has delayed action (15 to 44 hours); IFN-α treatment may be repeated daily for several days during the period of active vaccine virus replication.

Because these treatments are not labeled for this indication, and only preclinical data are available, no dosing regimens are provided here. Physicians who encounter such cases should seek advice from an infectious diseases specialist. Interference with the vaccine's efficacy could potentially result from treatment, and the patient's neutralizing antibody level should be confirmed 14 days or more after vaccination and before travel to an endemic area.

PUBLIC HEALTH CONSIDERATIONS

Recommended Use and Epidemiologic Results of Vaccination

South America

It is estimated that approximately 25% of the total population in the endemic countries of South America inhabit the yellow fever endemic zone, meaning that the majority of the population lives in more densely populated areas along the east and west coasts of the South American continent (see Fig. 63.4). Yellow fever immunization has been implemented for decades in all countries with endemic yellow fever in South America, but vaccination coverage and strategies vary by country. Vaccination policy has changed, encouraged by PAHO, toward implementing yellow fever vaccination in the EPI and away from intermittent mass campaigns. Currently, 10 of the 13 countries considered to be endemic for yellow fever vaccinate all children from 9 to 12 months of age against yellow fever as part of the EPI. Only Argentina, Brazil, and Suriname limit their coverage to children residing in at-risk areas. However, vaccination coverage rates have varied and are lower than wanted to protect the at-risk population and protect against outbreaks of the disease. From 2010 to 2014, the vaccination coverage for yellow fever in the region was approximately 75% but varied from 51% to 99% depending on the country. One reason cited for the lower vaccination rates was limited availability of the vaccine.[440]

Enhanced efforts to cover the population have occurred during periods of increased viral activity or geographic expansion. An example of geographic expansion is the period 1999 to 2000, when a large epizootic epidemic swept Brazil, causing 192 human cases and threatening densely populated areas on the fringe of the endemic zone. During that interval more than 35 million doses of vaccine were administered in mass campaigns, and consideration was given to introducing routine immunization in coastal areas outside the endemic zone. Following other major epizootic waves between 2007 and 2009 and starting in late 2016, which involved states in southern and coastal Brazil, additional mass campaigns were instituted. Between 1999 and 2009, the interval covering these major expansions of yellow fever in Brazil, 104 million doses were used.[907]

A continuing debate for policymakers is the need for vaccination of the large population in the nonendemic coastal region of Brazil at risk for urban yellow fever.[908] The risk of serious adverse events, particularly YEL-AVD, has been judged to outweigh the benefits,[828] although it is acknowledged that the introduction into the EPI would exclude higher-risk elderly persons and gradually provide an immune barrier to urban yellow fever. The dramatic clinical presentation of yellow fever and improved surveillance for infectious diseases are important factors in making healthcare policy decisions of this sort, because an urban outbreak of yellow fever would come to light quickly and could be contained rapidly.

The result of vaccination policies in South America is difficult to assess by historical comparisons with the prevaccine era, because confounding events coincided with the introduction of wide-scale immunization, including the introduction of active surveillance (using viscerotomy, initiated in 1930) and the expansion of human settlements in endemic areas. Nevertheless, in countries like Brazil, which instituted a program of immunization, the incidence of jungle yellow fever has declined as vaccination coverage increased.[909]

Africa

The increased incidence of epidemic yellow fever in Africa, beginning in the mid-1980s[28,170,910] and the recognition that the disease predominantly affects children,[28,163] led to a reassessment of vaccination policy for Africa. In 1988, the joint UNICEF and WHO Technical Group on Immunization for the African Region and the EPI Global Advisory Group recommended that countries endemic for yellow fever incorporate 17D vaccine into the routine EPI schedule, either at 6 months of age or at 9 months of age, together with measles vaccine.[911,912] In 1990, this recommendation was reemphasized, with the additional suggestion that catch-up immunization of older children is needed in countries at high risk. Surveys conducted between 1987 and 1990 indicated coverage of approximately 80% of infants by 1 year of age in The Gambia, Côte d'Ivoire, and Senegal, but rates of only approximately 40% in Burkina Faso, Chad, Mauritania, and the Central African Republic.

By 1991, 14 countries (Angola, Burkina Faso, Cameroon, Central African Republic, Chad, Côte d'Ivoire, Gambia, Ghana, Mali, Mauritania, Niger, Nigeria, Senegal, and Togo) at risk for yellow fever had officially incorporated 17D vaccine in the EPI, but uptake of the vaccine was poor in most countries, principally because of lack of donor funding for purchase of vaccine. In 1992 (13 countries reporting), the overall coverage was 19%; in 1993 (12 countries reporting) coverage was 14%; in 1993 (11 countries reporting), coverage was 29%.[913] By 1995, rates were less than 50% in all countries, except The Gambia, the Central African Republic, and Burkina Faso. The Gambia, which suffered a major outbreak in 1978 to 1979[252] and responded with mass immunization of children and adults, followed by sustained high rates of coverage of infants in the EPI, is one of the few African countries that has maintained a high level of vaccine coverage against yellow fever.

Another technical consensus meeting was held at the WHO in 1998, at which time 17 of the 34 countries endemic for yellow fever had incorporated vaccine into the EPI, although coverage remained low. Vaccination coverage has gradually improved over the last few years, in part because donor agencies, including the Bill & Melinda Gates Foundation and the Global Alliance for Vaccines and Immunization (GAVI), have provided funds for yellow fever vaccine purchases. Of interest was the forecast for vaccine doses required under assumptions of increased coverage rates. In 1997, only 4 million doses of vaccine were supplied by UNICEF to African countries, whereas 24 million doses were required to achieve 80% coverage of

children living in high- and moderate-risk areas in the 34 affected countries, and 240 million doses were required to undertake preventive mass campaigns. Demands for vaccine in response to outbreaks could severely stretch the capacity of manufacturers. These scenarios should be compared to the annual production capacity of approximately 30 million doses from manufacturers serving the African market. Shortages of vaccine for control of epidemics have been experienced, for example, during an outbreak in Guinea in 2000 and 2001,[911,914] leading to a recommendation for a strategic stockpile of vaccine to be held by UNICEF.

The Guinea case study led to an initiative whereby GAVI encouraged and supported inclusion of yellow fever vaccine in the EPI, encouraged catch-up campaigns, and provided a 6-million dose emergency stockpile of vaccine for rapid distribution in emergencies. In 2007, $58 million was pledged by GAVI to perform catch-up yellow fever immunization campaigns with the target of reaching 48 million people in West Africa.[915] By 2010, the number of African countries practicing routine infant immunization had risen to 24 compared with 15 in 1999.

In 2006, the WHO launched the Yellow Fever Initiative.[27,916] The purpose of the initiative is to ensure inclusion of yellow fever vaccine in the EPI at age 9 months and older, implement preventive mass immunization campaigns for older persons in high-risk areas, and ensure adequate supplies of the vaccine. The initiative has been very successful, providing more than 95 million persons protection against yellow fever disease in Africa and increasing the production capacity of the vaccine from 30 million doses in 2000 to more than 75 million doses in 2009.[426,916] From 2007 to 2014, preventive campaigns have been conducted in 13 countries, including 11 high-risk countries in West Africa as well as the Central African Republic and Sudan. Because of larger-than-anticipated vaccine needs in Nigeria, Nigeria has been partially vaccinated and all at-risk persons are expected to be vaccinated (assuming sufficient vaccine supplies) by 2017.[426] Reported vaccine coverage rates are greater than 80% for these preventive campaigns and no outbreaks have been reported in areas that have been vaccinated.

To guide the deployment of vaccine in catch-up campaigns in Africa, the WHO prepared a model to identify high-risk areas.[436] The risk assessment model employed indicators of exposure to yellow fever virus and susceptibility of the population and was used to prioritize areas to vaccine within West African countries. Following the use of this model, the WHO has led efforts with other partners to better estimate additional areas at risk in other countries in Africa.[149] The second risk assessment approach divides countries into zones in which the ecology is considered to be similar for the circulation of yellow fever virus. Areas are then randomly selected in each zone and teams travel to these locations to conduct human serosurveys and surveillance for mosquito vectors.[243] The rates of yellow fever virus–specific antibodies among humans and the number and types of vectors in ecologic zones are then used to recommend whether preventive vaccination or introduction of routine yellow fever vaccination is required.[426] These substantial efforts to better define risk areas and improve vaccination coverage have greatly reduced the risk of disease among those most at risk and have helped to decrease the potential of subsequent large outbreaks like those that were seen in the 1980s in Nigeria. However, until all risk assessments and campaigns are completed and high vaccination coverage sustained, there will continue to be a risk of outbreaks of disease in the region, as was seen in Angola and DRC in 2016. Finally, although these measures will help lower disease risk, these approaches will not guarantee that unvaccinated persons will not be infected if they live or travel to an endemic area.

Distribution of Yellow Fever Vaccine to At-Risk Travelers

Tourism and travel continue to increase at a rapid rate. The International Tourism Association estimates that 3.2 million persons traveled from the United States to South America and Africa in 2014.[917] Yellow fever is one of the most important vaccines for travel, because it is a lethal disease and because a certificate of vaccination is required for entry to some countries. Yellow fever is the one of the only vaccines for which such a certificate is required under the International Health Regulations. The International Health Regulations also specify that yellow fever vaccine be administered only by approved vaccinating centers. This restriction provides assurances that the vaccine will be properly stored and delivered using aseptic technique within the specified time after reconstitution. A vaccination certificate, specifying the date of immunization and the vaccine lot number and signed by personnel at the vaccinating center and validated with a uniform stamp, constitutes proof of valid immunization for the purposes of international travel.

In the United States, the CDC has the statutory authority to approve centers. This authority is delegated, in turn, to state health departments.[918] There are currently just over 6700 certified yellow fever vaccination centers in the United States, concentrated principally in large metropolitan areas and in gateway cities and represented by organized travel clinics.[919] Difficulty in accessing a yellow fever vaccinating center can contribute to undervaccination.[369,920]

A study of travelers to yellow fever–endemic African destinations from Johannesburg International Airport found that 76% had proof of yellow fever vaccination.[921] Among U.S. travelers attending a travel health clinic in Boston, 90% to 93% of the travelers going to a yellow fever endemic or partially endemic country were vaccinated prior to traveling.[733] However, these findings need to be tempered by the fact that many travelers never seek pretravel consultation. A study also performed in Boston at Logan Internal Airport found that only 46% of travelers to low- or low-middle-income countries sought pretravel advice.[922] Fear of adverse events can also contribute to declining vaccine uptake. The unfortunate result may be reports of fatal yellow fever among travelers.

Yellow fever vaccine should be administered 10 days or more before entering a country with endemic yellow fever. One survey of Israeli travelers showed that 11% of travelers to South America and 33% of travelers to Africa received their vaccinations fewer than 10 days before departure.[923] In practice, because travelers generally disembark some time before entering a rural area where exposure could occur, delayed immunization is of little consequence. However, delayed vaccination could represent a risk under certain circumstances; for example, in persons moving from uninfected to infected areas within a country or from an infected to a receptive zone.

Unnecessary use of yellow fever vaccine is also a significant problem. At least one case of fatal iatrogenic YEL-AVD occurred in a traveler bound from Australia for the Hajj to Saudi Arabia,[924] a country in which there was no risk of natural exposure and whose regulations did not require a certificate of yellow fever vaccination for travelers from a nonendemic area.[924] In another case, a Spanish traveler received 17D vaccine for travel to Mauritius, where yellow fever does not occur. Finally, a U.S. traveler recent died of YEL-AVD after he was given yellow fever vaccine for travel to Pakistan (Centers for Disease Control and Prevention, unpublished data, 2015). These unfortunate cases emphasize the importance of determining the need for vaccination on a case-by-case basis.

Cost-to-Benefit Analysis of Immunization

In an analysis of the benefit of immunization versus risk of yellow fever, Brès[758] concluded that a "fire-fighting" approach (emergency mass immunization in the face of outbreaks) was less costly than preventive immunization. Monath and Nasidi,[439] using a model in which routine yellow fever vaccination was hypothetically introduced into the EPI in Nigeria, explored this question. They concluded that 15 to 18 years would be required to achieve an effective immune barrier to epidemic spread, at which time routine immunization was seven- to eightfold more efficient than emergency control in the number of cases and deaths prevented. The cost of routine immunization was estimated at US$763 per case and US$3817 per death prevented during epidemics, with lower costs if prevention of endemic disease was taken into account. These cost-to-effectiveness ratios compared favorably to those for other infections preventable by EPI vaccines in Africa.[925] A more recent cost-to-benefit analysis performed when the WHO position paper on yellow fever vaccination was updated, found that the cost per dose of yellow fever vaccine is similar for various strategies.[926] Cost was estimated to be approximately US$0.67 per dose for each strategy (e.g., EPI, preventive and reactive vaccination campaigns) but the breakdown of cost (e.g., cold chain, vaccine price) varied based on strategy. These data suggest that vaccine utilization strategies should be driven by factors other than cost (e.g., vaccine availability).

Eradication or Elimination? Level of Herd Immunity Required

It was established as early as the 1930s that eradication by means of human vaccination is not feasible, because yellow fever virus circulates independently of humans in nonhuman primates and mosquitoes.[927] To eliminate the disease through vaccination nearly 100% coverage would be necessary to prevent cases of jungle yellow fever acquired by exposure to enzootic vectors. Prevention of epidemics involving interhuman transmission by *Ae. aegypti* or sylvatic vectors in Africa or South America would also require a high prevalence of immunity. This was shown in the case of the severe epidemic in Senegal in 1965, where the prevalence of immunity before the epidemic in children younger than 10 years (the age group affected during the outbreak) was estimated to have been 57%.[247]

Brès concluded that herd immunity must exceed 90% to preclude epidemic yellow fever.[758] Mathematical models have been applied to the calculation of the proportion of human hosts susceptible to infection required to sustain an epidemic (reproductive rate of infection >1), but they require an understanding of the biting rate, probability of feeding on a human host, and transmission efficiency of the vector.[272,421,928] The effect of herd immunity on yellow fever transmission under different assumptions of vectorial capacity was explored by Monath and Nasidi.[439] The prevalence of immunity in the human population required to preclude an epidemic was estimated to be between 60% and 90%. In a separate analysis, Massad and associates[928] reached a very similar conclusion, estimating that 58% to 88% yellow fever vaccination coverage rates would be required to prevent urban yellow fever in Sao Paulo State, Brazil. A more recent model estimated that 67% vaccination coverage in an area would result in 1 to 12 local cases in an area and no spread of activity to new areas only 7% of the time using a moderate transmissibility scenario with an R_0 of 4.1.[469]

FUTURE YELLOW FEVER VACCINES AND YELLOW FEVER–VECTORED VACCINES

At the Oswaldo Cruz Foundation in Rio de Janeiro, research has been sponsored by the WHO aimed at developing a novel method for manufacturing 17D vaccine. The approach used a full-length complementary DNA (cDNA) clone of 17D-204 virus. The cDNA was reverse transcribed to full-length positive strand RNA and transfected into primary chick-embryo cells. The progeny virus was investigated as a vaccine candidate but was found to have a marginally acceptable neurovirulence profile.[541] Unlike current yellow fever vaccines, which are heterogeneous mixtures of virion subpopulations, the new vaccine is genetically homogeneous. More recently, a group inserted full length 17D cDNA after a cytomegalovirus promoter and showed that they were able to get seroconversion and neutralizing antibodies formed in mice.[929] It is likely that with additional work, cDNA-based vaccines could be derived that would be safe and effective. The benefits of this approach are genetic homogeneity, reduced likelihood of selection of a subpopulation during replication in vitro or in vivo, manufacture of seed virus from bacterial plasmids (reducing the risk of adventitious viruses), production of vaccine in a cell culture system, and potentially longer-term immunity than might be achieved with an inactivated vaccine. However, it must be recognizes that DNA vaccines in general have been weakly immunogenic, unless delivered by electroporation, a method that would not be well suited to routine infant immunization.

An important aspect of the infectious clone work is that it set a precedent for novel chimeric vaccines in which heterologous flavivirus prM-E genes (e.g., of Japanese encephalitis virus, West Nile, or dengue) have been inserted into the yellow fever 17D virus infectious clone.[193,284,617,685–687,930–933] The Japanese encephalitis vaccine produced by this method (Imojev, Sanofi Pasteur) is licensed for use in some countries and the dengue vaccine is in licensing registration. Characterization of chimeric viruses has shown that the nonstructural genes of yellow fever 17D confer a highly attenuated phenotype on the vaccine candidates, including the restricted ability to replicate in mosquito vectors, while retaining the ability of the vaccines to efficiently immunize mice, monkeys, and humans. 17D virus has also been investigated as a vector for unrelated antigens (review in Bonaldo and associates 2014[934]) including the glycoprotein of Lassa virus,[935,936] a malaria cytotoxic T-lymphocyte epitope,[937] simian immunodeficiency virus and HIV *gag* sequences,[938–940] amastigote surface protein-2 of *Trypanosoma cruzi*,[941,942] influenza A viral epitopes,[943] and a tumor antigen.[944] The foreign gene carrying capacity is limited by the small size of the 17D genome. The foreign genes were inserted at viral protease cleavage sites, such as between NS2B and NS3, or between E and NS1,[945] leaving the E gene intact, so that antivector immunity would not be a problem in previously vaccinated subjects or for boosting immune responses. Foreign epitopes have also been inserted in the E protein fg loop,[946] but the carrying capacity of such constructs is a limitation.

Workers at Bio-Manguinhos in Brazil have produced a new seed stock and vaccines in primary chick embryo cell culture, rather than embryonated eggs. A cell-based method would have substantial advantages for manufacture and control. Good yields (>6 $\log_{10}$ PFU/mL) were obtained, and the virus obtained showed no changes in consensus sequence or immunogenicity; however, higher scores were obtained in the monkey neurovirulence test, and the vaccine was not pursued.[947] Yields are very robust (7 to 8 $\log_{10}$ PFU/mL), and effective dose requirements are low. The emerging data with chimeric yellow fever vaccines indicates that a similar approach could be used to manufacture yellow fever vaccines.

Several groups are engaged in developing nonreplicating vaccines, including whole-virion chemically inactivated vaccines produced in Vero cells[495,496,498,500] and a recombinant subunit vaccine produced in plants. The advantage of these vaccines is that they will not cause serious adverse events related to viral replication and can likely be given to persons with a contraindication to receiving 17D vaccine. Safety and immunogenicity have been demonstrated for one inactivated vaccine in a Phase I trial.[500] Fraunhofer USA used a tobacco plant expression system to produce yellow fever E protein. Fraunhofer entered into an agreement with iBio Corporation for commercial applications of the technology. Recently iBio entered into a licensing agreement with Bio-Manguinhos to further develop the subunit vaccine.[948] A disadvantage for use in endemic areas is the need to boost immunity at intervals, whereas the live vaccine induces long-lasting protection.

Combination vaccines are not being pursued actively by industry. Potential combinations of value might include yellow fever and measles vaccines for the EPI and the combinations of 17D vaccine with inactivated vaccines (e.g., hepatitis A, typhoid), as a means of simplifying immunization regimens for travelers. Again, it is likely that the development of chimeric yellow fever–vectored vaccines will lead to combination vaccines against yellow fever and dengue and against dengue and Japanese encephalitis; the combination of these vaccines with measles or meningococcal vaccines would be of interest for use in the EPI.

64 Zika Virus

Stanley A. Plotkin and Barney S. Graham

Although development of vaccines against the Zika virus is still in early stages, the rapidity and extent of research efforts to create a vaccine justify a brief chapter on the subject. The virus is native to Africa and was first isolated from sentinel monkeys placed in the Zika Forest in Uganda in the 1940s as part of surveillance efforts for mosquito-borne viruses at what is now the Ugandan Virology Research Institute. The virus eventually spread to other parts of Africa, Southeast Asia, and, most notably, Micronesia, in particular the island of Yap, where it caused widespread disease, including, in retrospect, the manifestations described below.[1] No animal reservoir is known. Genetic mutations in the virus have been documented as Zika virus spread from Africa to other parts of the world, but a direct association between new RNA sequences and pathogenesis or transmission has not been demonstrated.[2,3]

The world began paying attention to Zika after the virus was transferred from Micronesia to Brazil sometime in 2013 or 2014, possibly through the agency of infected people participating in athletic events in northern Brazil.[1] The vectors of the virus are *Aedes aegyptii* and *Aedes albopictus* mosquitoes, which are ubiquitous. From Brazil, Zika virus has spread to Columbia, Central America, Mexico, the Caribbean islands, and Florida.[4] The fact that Zika virus can persist in blood, semen, urine, and perhaps also in female genital secretions for extended periods has allowed transmission through sexual exposure and the potential for infection from blood transfusions.[5,6]

The Zika virus is a typical flavivirus, with a positive strand RNA genome coding for the envelope (E), premembrane (prM), and capsid structural antigens as well as nonstructural proteins (Fig. 64.1). Infection by Zika elicits antibody responses, particularly to the E, prM, and the nonstructural NS1 protein. Both $CD4^+$ and $CD8^+$ T cells are elicited by infection, and although passive administration of antibodies is protective, cellular responses may also participate in controlling replication.[7] Antibodies directed against domain III of the E protein are known to be particularly important for protection against other flaviviruses.[7,8] The impact of preceding dengue virus infection on Zika and vice versa is the subject of active investigation, particularly with respect to antibody-dependent enhancement.[9,10] It has been shown that to date Zika virus consists of only one serotype and that neutralization of one ZIKV strain will predict neutralization of all others.[3]

Although 20% of people infected with Zika have fever and related symptoms, and Guillain-Barré syndrome occurs in approximately 1 in 4000 infections,[11–13] the effect on fetuses carried by women infected in pregnancy has called particular attention to the virus. Zika can invade and destroy neurological stem cells in the fetus, resulting in microcephaly and other adverse effects on the fetal brain.[14–17] The risk of abnormal development of the brain is highest after infections in the first trimester of pregnancy, but infections even later in pregnancy can apparently lead to fetal damage (Box 64.1). The full spectrum of the congenital Zika syndrome is currently unknown, but microcephaly occurs in a minimum of 0.88% of infants born to infected mothers and may be as high as 13% after first trimester infections.[14] Testicular damage has also been demonstrated in rodents.[18]

VACCINE DEVELOPMENT

Development of vaccines against other flaviviruses suggests that a vaccine against Zika is feasible. The objective of vaccination is the induction of neutralizing antibodies against the virus primarily directed against epitopes on the E protein. Aside from inactivated virus vaccines, most candidate vaccines contain the E protein together with the prM or M proteins for conformational purposes. Live, attenuated vaccines have the advantage of also stimulating $CD8^+$ T-cell responses that prevent replication but also carry more risk of persistence or shedding and unintentional infections.

Table 64.1 lists some of the Zika vaccine approaches now in preclinical and clinical development, although other approaches not currently known to us are probably also being studied.[3,7,19–21] The strategies being pursued are those classic

TABLE 64.1 Zika Vaccines in Development (Incomplete List)

Vaccine Type	Antigen	Developer
DNA plasmids	M-E	Beth Israel
DNA plasmids	prM-E	NIAID, Inovio
mRNA	prM-E	Moderna, University of Pennsylvania
Inactivated virus	All	Walter Reed, Sanofi Pasteur, Takeda, Emergent Biosolutions, Valneva
Chimeric dengue	prM-E	NIAID
Chimeric yellow fever	prM-E	Sanofi Pasteur
Self-amplifying RNA	prM-E	GlaxoSmithKline
Live attenuated	All	UTMB by mutation, Codagenix by codon-deoptimization
VSV vector	prM-E+/–C	Harvard
Adenovirus vector	M-E	Beth Israel (possibly J&J)
Measles vector	prM-E	Institut Pasteur (with Themis)

for vaccine development against flaviviruses and other viruses, including live-attenuated strains, chemically inactivated whole virus, DNA plasmids, or mRNA coding for critical proteins; self-amplifying viral RNA; subviral particles or viruslike particles; and chimeric Zika–yellow fever or dengue replicating viruses, subunit proteins, and peptides. Critically important to success is that passive antibody is protective in animal models and that neutralization titers correlate with protection.[3,19–21] Thus, the correlate of protection is likely to be conformation-dependent E protein–specific antibody. The envelope protein also contains a fusion loop region that induces neutralizing antibodies that cross-react with other flaviviruses.[22,23] In preclinical studies, vaccines based on DNA plasmids, mRNA, adenovirus vectors, or inactivated virus have been protective against Zika virus challenge in rodent and monkey models. Clinical data will be available by the time this book is published.

Evidence for efficacy in animals as well as immunogenicity in humans is promising, and a Zika vaccine usable in emergencies could be available within a few years. However, licensing authorities will require considerable safety testing relative to concerns about Guillain-Barré syndrome or fetal abnormalities after vaccination. Although Zika vaccines will probably have commercial interest, the formation of the global fund for development of vaccines against emerging diseases, called Coalition for Epidemic Preparedness and Innovations (CEPI), will aid in achieving the goal of protection against Zika. This international fund has been created to accelerate vaccine development against epidemic infection even if a large commercial market is not anticipated.

The use of a Zika vaccine will depend on its future epidemiology, but unless the virus extinguishes itself because of high immunity in the population, residents in endemic countries as well as travelers to those countries would be candidates for vaccination. Because the most devastating effects of Zika virus occur as a result of infection during pregnancy, vaccinating women of child-bearing age will have a high priority.

65 Zoster Vaccines

Myron J. Levin

Herpes zoster (HZ), also called shingles, is a dermatomal-vesicular disease. (A dermatome is the area of skin innervated by one sensory nerve, and thus has bilateral symmetry and does not cross the midline.) Fig. 65.1 depicts the right C4-C5 cervical nerve dermatome. The cutaneous component of HZ is usually preceded by prodromal pain in the affected dermatome, followed 1 to 3 days later by the appearance of vesicular skin lesions that are accompanied by pain that often persists after the skin lesions heal.[1]

In 1892, Bokay made the seminal observation that hinted at the cause of HZ. He reported five instances in which varicella occurred in children exposed to adults with HZ, leading him to query: "I would like to bring up the question of whether or not the unknown infectious material of chickenpox could under certain circumstances manifest itself, instead of as a generalized eruption, as a zoster eruption."[2] In the ensuing half century, clinical and histologic evidence lent support to this prescient suggestion.[3–6]

In the 1950s, viruses isolated from varicella or HZ were recognized to have similar properties in tissue culture. Convalescent serum samples from varicella or HZ fixed complement using antigen from vesicle fluid from either varicella or HZ cases, and immunofluorescence techniques, demonstrated that a new antibody appeared in blood 3 days after varicella infection that equally stained cells infected with virus isolated from either varicella or HZ.[7] Antibody appearing after varicella was subsequently shown to neutralize viral isolates from either varicella or HZ. Weller and coworkers concluded that the same virus caused both diseases and named it "varicella-zoster virus" (VZV).[8]

The etiologic relationship between these two diseases was elegantly proved when two isolates were obtained from an immunocompromised child. The first isolate was obtained when the child developed varicella, and the second isolate was obtained several years later when HZ developed. DNA extracted from the two isolates were identical by restriction endonuclease mapping using multiple enzymes that focused on known variable regions of the VZV genome.[9]

PATHOGENESIS

Localization of Latent Varicella-Zoster Virus in Sensory Ganglia

The VZV and herpes simplex viruses are α-herpesviruses that cause human infections. The molecular virology of VZV, a member of the Herpesviridae family, is described in Chapter 62. An essential and unique feature of α-herpesviruses is their ability to become latent in neurons in sensory ganglia during their initial (primary) infection. The primary infection with VZV is manifest clinically as varicella (chickenpox), which is endemic worldwide. Varicella usually occurs in childhood in temperate climates, generally as winter–spring epidemics.[10,11] In countries with widespread immunization against varicella, this pattern is disappearing. In tropical climates, the prevalence of varicella remains high in late adolescence or young adulthood. Because varicella vaccine was not introduced into the United States until 1995, more than 97% of adults have had varicella.[12]

VZV is transmitted by an airborne route as droplet spread from the pharynx or from aerosols from skin lesions of an index case of varicella or HZ (see Chapter 62). It is postulated that the initial replication of VZV occurs in epithelial cells lining the nasopharynx and subsequently spreads to adjacent lymphoid tissue, thereby infecting memory $CD4^+$ T cells, such as those that are abundant in tonsillar lymphoid tissue.[13–15] Dendritic cells have a central role in this process.[16] Activated $CD4^+$ T cells expressing cutaneous homing markers are preferentially infected and are then able to deliver VZV to cutaneous epithelia within a few days of infection.[14,15,17] Infection of cells at the dermal–epidermal junction leads to the most visible consequence of VZV viremia, which is the characteristic vesicular lesion.[18] The incubation period prior to varicella symptoms after exposure may be explained by the time required for dissemination of VZV by circulating T cells, initial cell-to-cell transmission in tissues, innate immune responses that delay VZV replication, and the development of specific immune pathogenesis that results in skin lesions.[15]

The significance of the varicella lesions for the pathogenesis of HZ is that the termini of sensory axons are located at the dermal–epidermal junction at the base of vesicles. It is hypothesized that from this locus, VZV enters and ascends by retrograde axonal transport to become latent in the soma of neurons in sensory ganglia. This mechanism is suggested by the clinical observation that the dermatomes most frequently affected with HZ are those that have the highest density of skin lesions during varicella and vesicular fluid has very high titers of cell-free VZV.[1,10,13] Moreover, early studies with the varicella vaccine indicated that vaccine recipients were much more likely to develop subsequent HZ with the vaccine strain virus if they had a vaccine-related rash in the post-vaccine period.[19] In addition, vaccine-related HZ occurring in recipients of the varicella vaccine most often appears in the dermatome where the vaccine is administered.[20] However, this is not always the case, suggesting that viremia occurs after varicella vaccine administration. As viremia is characteristic of varicella, this could provide an alternative or additional mechanism for VZV to gain access to sensory ganglia.[13,15,17] The presence of VZV in autonomic ganglia and enteric neurons also indicates that the viremia of varicella can seed these ganglia.[21,22]

Nature of Latent Varicella-Zoster Virus DNA

Cranial and dorsal root sensory ganglia, autonomic ganglia, and enteric neurons contain VZV DNA detectable by polymerase chain reaction (PCR). This is true of more than 90% of adult trigeminal ganglia and 70% of thoracic ganglia, reflecting the prevaccine epidemiology of varicella; other cranial nerve and autonomic ganglia contain latent VZV DNA.[21–26]

Approximately 2% to 5% of neurons in sensory ganglia contain latent VZV DNA, which is absent in nonneuronal satellite cells.[27,28] The VZV DNA in neurons is latent in the sense that infectious virus cannot be isolated from ganglia. The latent VZV DNA is present in the nuclei of neurons in a circular form different from that present in intact virions.[24,29]

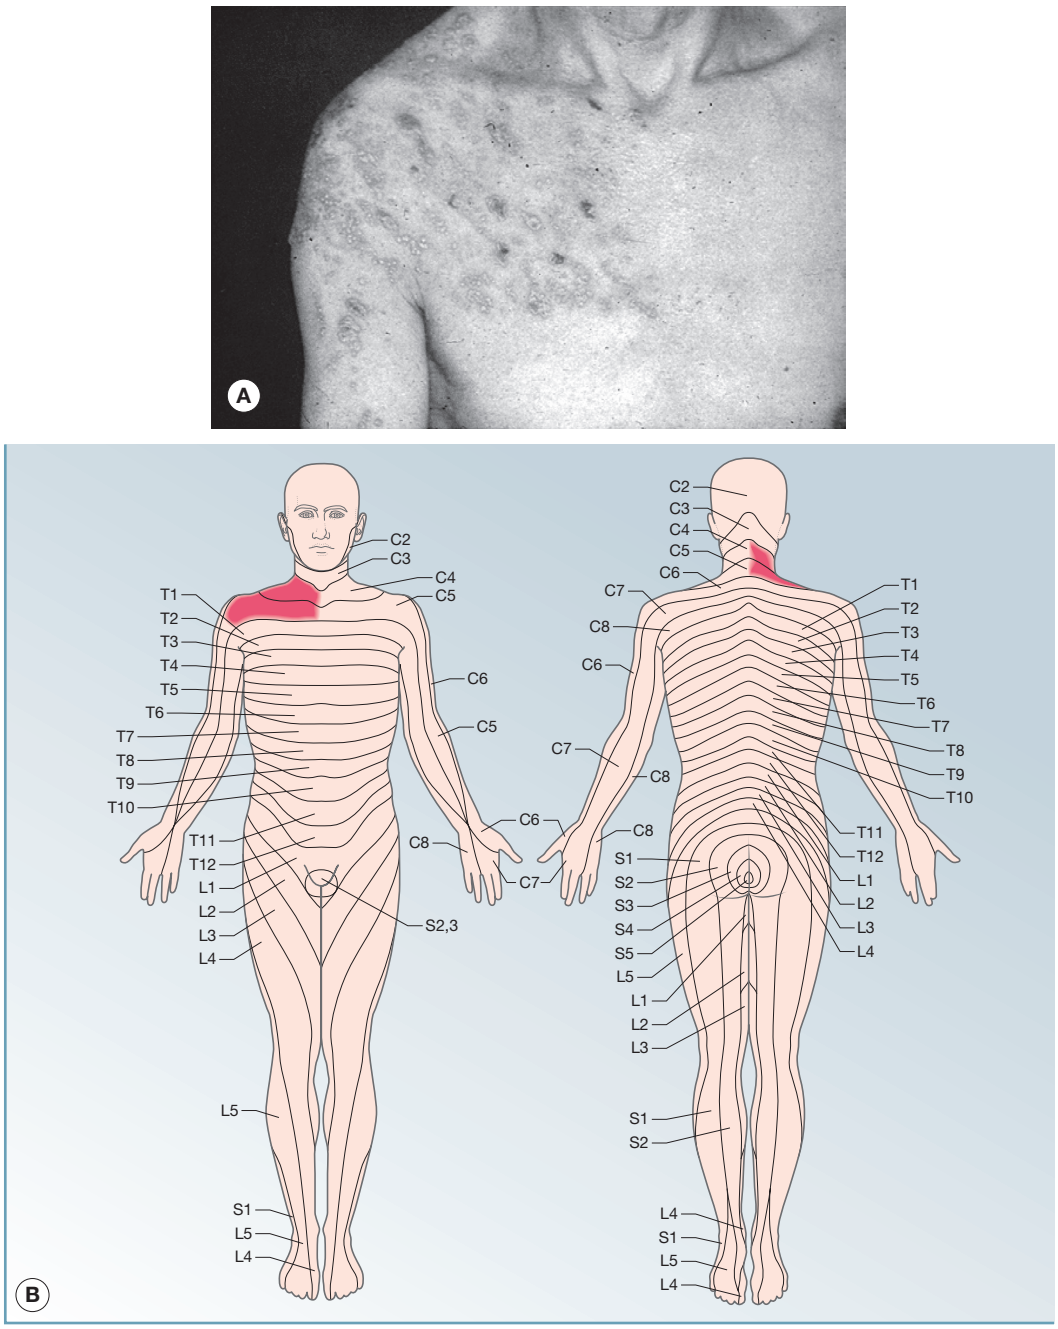

Figure 65.1. A, Herpes zoster in the right C4-C5 dermatome. **B,** Dermatome map indicates the area of skin innervated by individual sensory ganglia; gradation indicates dermatomes involved in **A**.

Episomal DNA also characterizes the physical state of latent herpes simplex virus in sensory ganglia. The number of copies of VZV DNA in a neuron is 1000-fold lower than the burst size in infected fibroblasts, indicating rapid shut off of VZV replication in infected neurons.[27,28,30] VZV DNA serves as an active template during latency from which five or six immediate-early or early genes of VZV are transcribed during latency and their gene products detected.[24,31] Some of the latency gene products, many of which are strong transactivators, are not transported to the nucleus during latency, whereas they are found in the nucleus during lytic infection. It is hypothesized that this failure to translocate one or more of the early gene products prevents the cascade of events in the nucleus that normally leads to viral replication.[32]

Maintenance of Latency by Varicella-Zoster Virus–Specific Immune Responses

Although the mechanism of latency is not understood, strong evidence exists that it is related to a decline in the VZV-specific immunity of the host that initially developed at the time of, or shortly after, the appearance of skin lesions with varicella.[33] These immune responses include polyclonal VZV-specific antibody and T-cell–mediated immune (VZV-CMI) responses, including $CD4^+$ and $CD8^+$ effector and memory T cells. These persist lifelong to protect the host against subsequent cases of varicella and to prevent HZ.[34,35]

The relationship between VZV-CMI and HZ is evident from numerous and varied clinical observations. It was recognized

early that the age-specific incidence and severity of HZ was greatly increased in patients with immune compromise resulting from underlying illness (e.g., HIV infection) or immunosuppressive therapies for malignancy, autoimmune disease, or organ transplantation.[36–40] Natural and iatrogenic experiments indicate that VZV-CMI is necessary *and* sufficient to maintain latency of VZV and prevent HZ.[41] For example, children born with isolated γ-globulin deficiencies do not develop severe varicella or experience an increased incidence or severity of HZ, whereas children with severe combined immune deficiency often have severe morbidity with VZV infections.[42,43] The likelihood of chemotherapy-treated patients with lymphoma developing HZ correlated with the preservation or recovery of VZV-CMI and was not influenced by the presence of anti-VZV antibody, and anti–varicella antibody before bone marrow transplantation was not predictive of the occurrence of HZ.[40,44] Moreover, recipients of allogeneic hematopoietic stem cell transplants, who have their immune responses totally ablated and then receive replacement therapy with intravenous γ-globulin (which has high levels of anti–VZV antibody), nevertheless have a high incidence of HZ, often with severe manifestations. The risk of HZ in this setting abates only with engraftment and return of the potential for pathogen-specific CMI.[45] The essential role of VZV-CMI in maintaining latency is verified by the success of an experimental, inactivated vaccine that boosted VZV-CMI (but not anti–VZV antibody) after stem cell transplantation and thereby reduced the frequency and severity of HZ.[46,47]

Clinical Manifestations

VZV, because of the global endemicity of varicella, is latent in many ganglia in most humans and has the potential to reactivate intermittently in a subclinical manner. This is suspected because unexplained increases in VZV-specific antibody and activated VZV-specific T cells occur intermittently, and VZV DNA is intermittently detected in the blood of asymptomatic immunocompromised and immunocompetent people.[38,48–52] Presumably these random events, *of unknown frequency*, are of no consequence because the VZV-CMI present when they occur is sufficient to prevent propagation of VZV infection in the ganglion. The subsequent boost in immunity that accompanies subclinical reactivation may be a factor in maintaining VZV-CMI throughout life (termed "endogenous boosting"). When an immune person is exposed to someone with varicella or HZ, VZV-specific immunity may also be boosted (termed "exogenous boosting").[53,54] The accumulation of activated VZV-specific $CD4^+$ T cells in older people may be a reflection of these phenomena.[55]

HZ occurs following reactivation caused by the waning of some (unknown) critical level of VZV-CMI. In this scenario, the appearance of infectious VZV in a ganglion, unchecked by the ambient VZV-CMI, leads to ganglionitis, during which many neurons and supporting cells are damaged by the widespread infection and/or the intense inflammatory response that follows.[56–61] An alternative potential role of VZV-CMI is to directly prevent (rather than limit) VZV reactivation. There is insufficient information to distinguish between these two possibilities. Although the inadequate immune response to a VZV reactivation that culminates in HZ may result from therapy-related or disease-related immune suppression, much more often it is the result of the decline in VZV-CMI that accompanies the normal aging process.[62–67] It is also likely that the level of VZV-specific immunity, at any age, can be temporarily blunted by changes in sense of well-being,[68] depression,[69–71] stress,[72] or intercurrent infection with viruses that can alter CMI responses, such as Epstein-Barr virus and cytomegalovirus.[73,74] Trauma to a dermatome may also lower the threshold for symptomatic reactivation in the ganglion innervating that dermatome.[75] These additional factors explain why children sometimes develop HZ.[76,77] Race and family history may also influence the age-specific incidence of HZ and its complications.[70,78–81]

The ganglionitis and related neuronal damage that accompany extensive VZV reactivation cause the neuropathic prodromal pain in the dermatome where skin lesions subsequently appear. Prodromal pain accompanies 70% to 80% of HZ cases in older adults.[1,82–84] The prodromal pain typically lasts 3 to 4 days, but may last a week or longer. Its character varies with the patient: shooting, boring, aching, and throbbing are some descriptors. The pain may be constant or intermittent. Intense itching is common.[85] The cause of this localized pain in the involved dermatome is initially unclear to the medical provider, often leading to a search for visceral disease suggested by the location of the pain, such as myocardial infarction when a left upper thoracic dermatome is involved; renal stone or intervertebral disk disease when a lumbar dermatome is involved; or intraabdominal disease (e.g., cholecystitis or appendicitis) when right-sided mid-lower thoracic dermatomes are involved. Approximately 12% of medical costs for HZ in the United States occur before the appearance of skin lesions.[86,87]
