The duration of the prodrome represents the rate and extent of VZV replication in the ganglion and subsequent descent in the sensory nerve to the dermal-epidermal junction, where VZV replicates in the skin to induce the characteristic rash. The appearance of skin lesions reveals the origin of the prodromal pain and provides the diagnosis. Mild constitutional symptoms are infrequent (10% to 20%). The rash of HZ in immunocompetent patients characteristically involves a single dermatome; hence, the lesions do not cross the midline (see Fig. 65.1).[82,83] Several contiguous dermatomes may develop lesions, or individual variation in innervation may give this impression. Infection of epithelial cells causes a varicelliform rash that is limited to the dermatome involved. After brief macular and papular stages, the characteristic rash (i.e., vesicles on an erythematous base) appears. New vesicles appear for 3 to 4 days in groups that tend to cluster where there are branches of the involved cutaneous sensory nerve. Pustulation of vesicles begins within 1 week, followed 3 to 5 days later by lesion ulceration, crusting, or both. The lesions may evolve over a longer time or become hemorrhagic in patients with advanced age or immune suppression.[1] The rash is usually accompanied by the same pain experienced during the prodrome, but this acute phase pain can worsen, improve, or appear for the first time after the skin lesions appear.[88] The acute pain and the preceding prodrome can be very severe, disabling, and a barrier to employment and activities of daily living. The nociceptive pain, which accompanies extensive skin involvement, is additive to the neuropathic pain. Itching may also increase in prominence.[85,89]

VZV frequently gains access to the bloodstream, as demonstrated by VZV DNAemia during the early stages of HZ.[51,90,91] This is of little consequence to most patients, but in immunocompromised patients, extensive viremia in the absence of a vigorous immune response can result in a disseminated form of HZ that includes severe, multiorgan disease.[39,92–94] VZV is also present in the saliva shortly after the onset of HZ.[51]

Additional insight into the age-related decline in VZV-CMI is gained from the observation that elderly patients with HZ frequently have cutaneous VZV lesions at a distance from the involved dermatome.[1] This reflects their inability to muster adequate VZV-CMI in a timely manner after VZV reactivation, thereby permitting more extensive viremia, unimpeded VZV replication at distant sites, or both.

In addition to the acute pain, complications occur in approximately 8% of patients with HZ who are 50 to 59 years

old and in more than 12% of persons 70 years of age or older.[87] Complications include bacterial superinfection of the skin (2%); segmental motor nerve damage, including nerves of the face, limb weakness, and other neurologic complications (3–5%); and dysfunction of bowel or bladder when sacral nerves are involved.[83,87]

The presence of motor involvement may exceed 10% if this finding is carefully sought by a neurologist.[95] Motor deficits are rarely permanent, although recovery is less likely to be complete in older patients. The occurrence of motor deficits is consistent with data that VZV often extends through the ganglionic root to the central nervous system.

Lymphocytic pleocytosis and VZV DNA are commonly found in the cerebrospinal fluid of patients with HZ, and magnetic resonance imaging studies obtained during HZ often demonstrate inflammation in the spinal cord at the level of HZ involvement.[96] Spread to the spinal cord has been confirmed histologically in patients who had HZ when they died of unrelated diseases.[26,57,97] While these abnormalities are generally inconsequential, they probably explain why contiguous dermatomes are often involved and why the uncommon complications of transverse myelitis and bilateral dermatomal involvement are occasionally seen in both immunocompetent and immunocompromised patients.[98,99] VZV meningitis and meningoencephalitis can occur with HZ.[26,100,101] Because the ophthalmic branch of the trigeminal nerve is involved in 10% to 15% of cases, damage to ocular structures is a common occurrence (5% of HZ in older patients).[87,102,103]

The most common complication of HZ is the persistence of significant pain for months after onset of the rash.[88,89,104–106] The frequency of this postherpetic neuralgia (PHN) is strongly influenced by the age of the patient. PHN has been defined as pain persisting for an extended period after the onset of HZ (i.e., prodromal pain) or after the onset of HZ rash. Thus, the age-specific frequency of PHN varies with its definition. The postevent interval used to define PHN has most often been between 30 and 90 days. Because the onset of rash is easily recognized and remembered, most investigators now use this starting point and many now define PHN as pain being present at 90 days after the rash appears.[83,84,106,107]

Age is the strongest prognostic factor for the occurrence of PHN, which is uncommon for people younger than age 40 years, but becomes common when HZ occurs in people older than age 50 years. The various definitions have led to estimates of PHN ranging from 7% to 25% of HZ cases. HZ cases that occurred during a prospective zoster vaccine trial in subjects at least 60 years old resulted in significant pain lasting or beginning (sometimes pain occurs after the rash appears) at least 30 days after rash onset in 30% of placebo recipients; for 60 days in 17%; and for 90 days in 12%.[107] In some patients, PHN may last for a year or longer.

PHN may be intermittent or constant, stabbing or lancinating, deep burning or throbbing, or allodynia, which is a painful sensation resulting from an otherwise normal stimulation of the skin. It is the third most common cause of chronic neuropathic pain in the United States, with a point estimate of 500,000 cases annually.[108] Acute and chronic pain strongly influence the quality of life, with effects on physical, psychological, social, and functional domains. These effects are particularly profound in elderly patients.[109–112]

EPIDEMIOLOGY

HZ is of endogenous origin, resulting solely from reactivation of latent VZV in sensory ganglia. Thus, the at-risk population includes more than 95% of U.S.-born adults 20 to 29 years old and more than 99.6% of persons older than 40 years of age who have anti–VZV antibody.[12] The risk of HZ may change in future years as a result of the 1995 recommendation for universal immunization with the varicella vaccine. Although recipients of the varicella vaccine can develop HZ with the vaccine strain VZV,[20,76,113] the frequency and the severity of this occurrence are believed to be three- to fivefold less than after natural infection.[76,114,115]

In the seminal study by Hope-Simpson, who recorded 16 years of HZ in his medical practice, the frequency of HZ correlated closely with increasing age.[116] These findings have been replicated in many countries during an extended observation period. The age-specific incidence of HZ is similar worldwide (Fig. 65.2).[87,117–119] HZ is 5- to 10-fold more likely to occur after

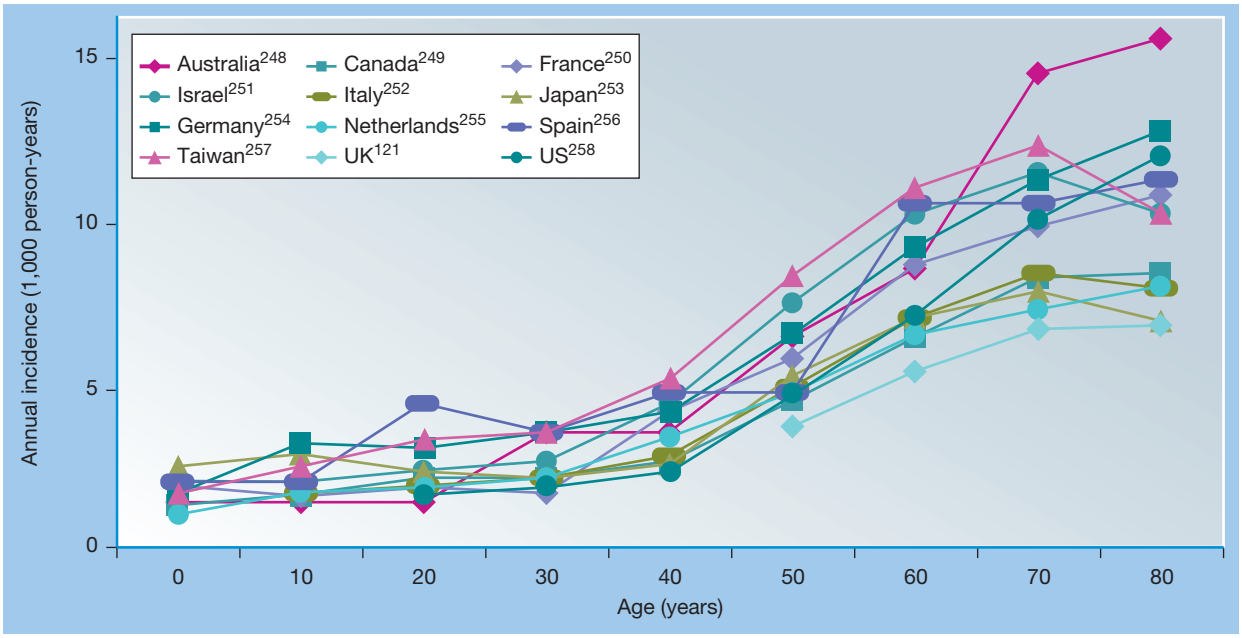

Figure 65.2. Age-specific incidence of herpes zoster as a function of age. *(Courtesy J. Pellissier and M. Brisson, Merck & Co, Inc.)*

60 years of age than in childhood. Thus, although the frequency of HZ in the general population has been reported to be 1.2 to 4.8 per 1000 person-years, the frequency increases to 7.2 to 11.8 per 1000 person-years for people at least 60 years old.[87,118,120] Using current census data and these age-specific rates, it is likely that more than 1 million cases of HZ occur annually in the United States. Of these, 45% to 50% occur in people 60 years of age or older; almost 20% occur in people 50 to 59 years old.[87] The lifetime risk of HZ approaches 50% for people who reach 80 years of age. The annual risk of HZ in people older than 60 years is greater than 1.1 per 100 persons.[107,121] Female gender and a family history of HZ increase the risk of HZ, whereas the risk is decreased in black individuals.[122–124] The severity of HZ also increases with age, as shown by the greater frequency and duration of PHN with age and the increase in complications with age.[87,106,118,120,125] In addition to age, another important risk factor for HZ is immune compromise from disease or immunosuppressive therapy, but this probably contributes less than 10% of the societal burden of HZ.[36,86,126] Other strong risk factors repeatedly identified for PHN and other complications of HZ include the intensity of the prodromal pain, the intensity of the acute pain, and the extent of the rash.[83,87,89,105,127] Each of these is probably a marker for the inability of the patient to rapidly mobilize VZV-CMI responses early after VZV reactivation occurs, and thereby fail to limit virus-induced damage within the involved ganglion.[128]

TREATMENT

The acute phase of HZ should be treated as soon as possible with nucleoside analogs (e.g., acyclovir, valacyclovir, famciclovir).[106,129] These are excellent antiviral drugs that inhibit VZV in vitro and limit virus replication in vivo (i.e., reduce duration of shedding). Their use is invariably suboptimal because of the delay in appreciating the diagnosis, during which time the ganglionitis proceeds. Nevertheless, six placebo-controlled clinical trials with these antivirals administered within 72 hours of rash onset significantly limited new lesion formation, shortened the time to healing, and decreased the severity and duration of acute pain.[83,130,131]

Valacyclovir and famciclovir have superior bioavailability to that of acyclovir and, therefore, can be dosed less frequently, but the clinical superiority of one of these drugs has not been established. The effect of antiviral drugs on PHN is controversial. Three metaanalyses and some (but not all) controlled trials failed to determine that antivirals reduced the incidence of PHN, but some suggested that the duration of prolonged pain was shortened for some patients.[83,106,130–132] Positive results on acute and chronic pain were obtained under ideal prospective trials conditions, which would be difficult to achieve in routine practice, especially because fewer than 60% of patients receive antiviral drugs within 72 hours after rash onset, as mandated by the successful trials. Moreover, the proportion of advanced elderly patients participating in the clinical trials was generally lower than found in most practices. There may be some value in beginning antiviral drugs even later than the 72-hour window after rash onset recommended for administration, especially in very old patients whose immune response may be delayed.[83]

Additional treatment in the acute phase of HZ often requires the use of strong analgesics for pain.[83] Opioids are effective in the early phase of HZ and are a mainstay for persistent pain.[133–135] Corticosteroids shorten the duration of healing and acute pain and hasten the return to a normal quality of life when used with concomitant antiviral therapy, but their use must be weighed against potential side effects.[136,137] Corticosteroids do not prevent PHN. Drugs that act on nerve transmission, such as amitriptyline and gabapentin or pregabalin, are under study for use in the acute phase of HZ.[133,138,139]

Other than analgesics, the clinical impact of drugs used to treat HZ in the acute period, although statistically significant, is modest when applied to PHN. Many patients get additional relief from gabapentin or pregabalin and another class of neural-active drugs, tricyclic antidepressants.[106,140,141] Significant PHN often requires multiple drugs.[83,106,142] Strong analgesics, usually opioids, are often required, although there is controversy about their efficacy.[83,133–135,140,143] Some patients benefit from topical application of lidocaine patches, which inhibit skin sensations that are perceived as allodynia.[144] Capsaicin is a topical therapy that desensitizes receptors on sensory nerve axons and inhibits initiation of pain transmission. Because capsaicin initially causes a local burning sensation, it is difficult to study in controlled trials, but there are credible reports that topical capsaicin ameliorates PHN in some patients.[145,146] More complex treatment approaches for unresponsive PHN can be provided by pain specialists.[82,83]

Despite these numerous therapies, the management of acute HZ pain in the acute phase, and especially PHN, is difficult.[106] In general, only approximately 50% of patients benefit from each of the therapies mentioned and they experience only partial relief. Moreover, many of these drugs frequently produce disabling side effects, especially in elderly patients who are most likely to get HZ and PHN. Some of the side effects, such as difficulty concentrating, difficulty with balance, and bowel or bladder dysfunction, are preexisting problems for many older patients. Furthermore, adverse drug effects are more common when combinations of drugs are required for intractable pain, when they are metabolized more slowly in older patients, and when they are used for patients already receiving many other drugs with potent side effects or with the potential for drug interactions. The therapy for severe PHN is time consuming for treating physicians and is expensive. *As with any infection, prevention is preferable to treatment.*

PASSIVE IMMUNIZATION

Given the epidemiology of HZ, passive immunization would not be feasible as a preventive measure. Furthermore, neither prevention nor treatment of HZ with VZV-specific antibody is successful, as indicated by the frequency of HZ in patients after allogeneic hematopoietic cell transplantation, even though they receive large amounts of VZV-specific antibody contained in the intravenous immunoglobulin typically administered for many months after transplantation. In addition, older people who frequently develop HZ have high levels of VZV-specific antibody.[62–64,147–150]

ACTIVE IMMUNIZATION

Rationale for a Zoster Vaccine

When Hope-Simpson showed in his seminal monograph that the frequency of HZ increased with age, he also suggested that this was the consequence of an age-related decline in VZV-specific immunity.[116] His conclusion was consistent with the clinical information available at that time, since corroborated, that immunocompromising diseases and therapies are associated with a large increase in the frequency and severity of HZ. We now know that the essential component in protection against HZ is VZV-CMI. Distinct humoral and T cell–mediated immunity had not been defined when Hope-Simpson discerned the relationship between age and HZ frequency. The hypothesized progressive decline in VZV-specific immunity has been identified repeatedly as VZV-CMI, and not as

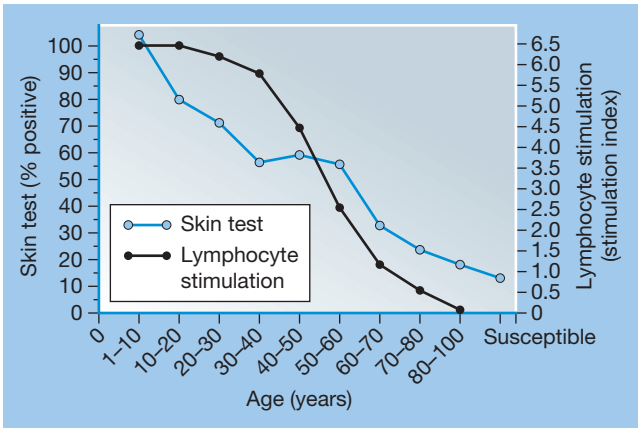

Figure 65.3. Herpes zoster and aging worldwide. *(Courtesy E. Bresnitz, Merck Vaccine Division.)*

antibody, as conjectured by Hope-Simpson. This *immunosenescence* is now considered to be one characteristic of the normal aging process (Fig. 65.3).[62–64,66,151,152] The close relationship between the decline in VZV-CMI and the increasing frequency of HZ with aging is assumed to represent cause and effect. This relationship and the continuing decline in VZV-CMI are maintained into the sixth, seventh, and eighth decades.[65,67] Anti–VZV antibody levels do not decline with age.[62–64,147,148] In addition, Hope-Simpson noted that second cases of HZ were rare in elderly patients, suggesting that the occurrence of HZ in most cases sufficiently stimulated VZV-specific immunity to prevent second attacks. Many investigators have documented that second attacks of HZ are uncommon (2% to 5%),[87,107,116,118,120,153] although a recent study questioned this conclusion.[154] Overall, the data available in the 1980s led many investigators to suggest that a vaccine capable of boosting VZV-CMI in elderly subjects might prevent or attenuate HZ in this population.[155] A similar hypothesis, suggested for transplant recipients at high risk for HZ, was confirmed by boosting VZV-CMI with an inactivated VZV vaccine.[46,47]

Preliminary Trials of Live Varicella-Zoster Virus Vaccine to Prevent Herpes Zoster in Older People

Relevant trials with a live VZV vaccine were undertaken from 1984 to 1999.[155] It was appreciated that the subjects had preexisting VZV-specific immunity and that an investigational vaccine would be unique *in preventing reactivation of an endogenous latent infection, rather than preventing a new infection*. Thus, there were considerations that preexisting immunity in vaccinees might limit replication of the administered live vaccine, while there was also concern that this live attenuated vaccine was being administered by a nonnatural subcutaneous route to a host population known to have waning immunity to VZV.

Two studies of vaccine immunogenicity were especially important. The first, by Trannoy and associates, involved vaccination of 200 subjects at least 55 years old with doses of 3200 to 41,000 plaque-forming units (PFU) of Oka strain VZV.[156] By comparison the amount of VZV in the current varicella vaccine is 1340 PFU/dose. A boost of approximately 2.5- to threefold in VZV-CMI was documented by two assay methods; no dose–response relationship was observed. The second study, by Levin and associates, involved 240 subjects at least 60 years old who received from 3000 to 12,000 PFU of Oka/Merck strain VZV.[157] The number of VZV-specific $CD4^+$ memory T cells in vaccinees was increased approximately twofold. A dose–response effect was not observed, but an important observation was that the duration of the response correlated with the titer of vaccine virus administered. For all age groups combined, the half-life for the booster effect was 56 months. At the highest dose, the vaccine effect declined little over 5 years.[147,157,158] Injection-site reactions were similar in frequency and severity to those occurring with the pneumococcal vaccine.[156] No age effect on the vaccine-induced boost was observed in these pilot studies.

By the late 1990s, a body of work had established that the vaccine was safe and well tolerated in elderly vaccinees. The Phase I/II studies demonstrated that an increase in VZV-specific $CD4^+$ T cells, measured by a variety of techniques, could be achieved and that the booster effect persisted for long periods, although it was not known whether the VZV-CMI responses elicited were biomarkers for protection against HZ.

Subsequent studies determined that cytotoxic $CD8^+$ T cells were also increased in number following vaccine.[159] An inactivated VZV vaccine induced a $CD4^+$ T-cell memory response similar in magnitude to that induced by the live vaccine, but the cytotoxic T-cell response was greater with the live attenuated vaccine. Prior to embarking on a definitive efficacy trial of a zoster vaccine, a questionnaire to record HZ pain and discomfort was validated and laboratory methods were chosen and validated for measuring VZV-CMI.[160–163] A study to inform the choice of dose for a definitive trial determined that approximately 25,000 PFU of the Oka/Merck strain (at expiry) was practical from the manufacturing perspective and would provide optimal boosting of VZV-CMI with minimal side effects.[163] Safety was demonstrated in older subjects with comorbidities, specifically persons with controlled diabetes mellitus or chronic obstructive pulmonary disease.[163,164]

Composition of the Zoster Vaccine

The zoster vaccine contains the Oka strain of VZV developed for the varicella vaccine (see Chapter 62).[165–167] It is produced by Merck & Co, and marketed as Zostavax. It was licensed in the United States in May 2006 and is licensed in the European Union, Canada, Australia, and much of Asia and the Middle East (>50 countries).

In the United States, the zoster vaccine is a lyophilized preparation designed to improve stability during prolonged storage, but elsewhere is provided as a refrigerator-stable vaccine.[168] This formulation is being considered for the United States. When reconstituted (0.5 mL of diluent), it contains at least 19,400 PFU (calculated for final expiration date) (14 times more potent than the licensed varicella vaccine) in 0.65 mL. Diluent is provided with the lyophilized vaccine. Incipient substances include porcine gelatin, L-glutamate and stabilizing salts, trace DNA and proteins from MRC-5 cells, and trace quantities of neomycin and bovine calf serum. There are no preservatives.

Immunologic Response to Zoster Vaccine

An immunologic substudy of 1200 subjects from the pivotal efficacy trial (1999–2004) was undertaken at two study sites to measure VZV-specific antibody titers and VZV-CMI before vaccination and at intervals thereafter for 3 years in vaccinees and placebo recipients.[65] At baseline the level of antibody was not influenced by age, whereas there was a strong correlation between increasing age and a decline in the magnitude of VZV-CMI responses. This finding confirmed that the age-related decline in VZV-CMI continues into the eighth decade of life and beyond and explains why the frequency of HZ continues to increase with increasing age. It also explains why

HZ becomes increasingly more severe with advancing age and explains the increased frequency and severity of PHN.

Both antibody and several measures of VZV-CMI responses in the immunologic substudy were significantly boosted after administration of the zoster vaccine.[65] The roughly twofold increase in VZV-CMI that resulted from vaccination was similar to that reported by Trannoy and colleagues[156] and Levin and colleagues[157] in the pilot studies. However, the magnitude of the vaccine-induced boost in antibody and VZV-CMI responses was also a function of age, and overall the boost in immune response was significantly less in persons 70 years of age or older than in younger vaccinees (Fig. 65.4). This finding is consistent with, and probably explains, the results of the vaccine trial (described in the next section) in that significant efficacy was observed in both age groups, but greater protection occurred in the younger vaccinees. The immunologic data also could explain why the efficacy in younger vaccinees was primarily achieved by preventing HZ, since it is likely that the boosted VZV-CMI in most younger vaccinees was sufficient to completely eliminate any clinical consequences of VZV reactivation in their ganglia (i.e., remained subclinical). In contrast, in older vaccinees, the lesser boost in VZV-CMI from zoster vaccine might not be sufficient to prevent early reactivation events in their ganglia, but would still be sufficient to support timely and adequate mobilization of immune defenses sufficient to limit ganglionitis and thereby attenuate the HZ. This relationship between severity of HZ and ambient VZV-CMI responses has been confirmed in subjects who developed HZ.[128]

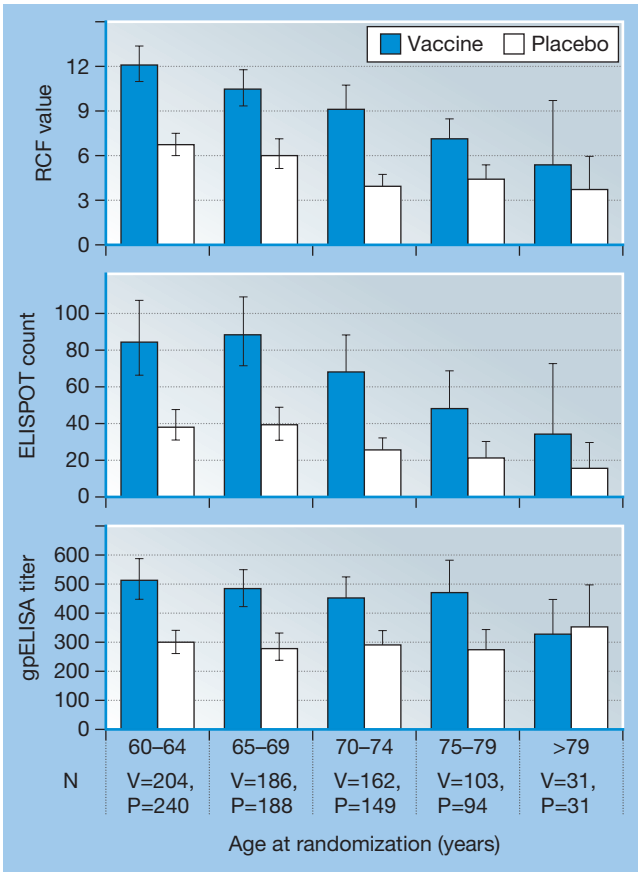

Figure 65.4. Varicella-zoster virus–specific immune responses at 6 weeks after vaccination in the pivotal zoster vaccine trial by age group. Among vaccinees there was a significant linear age effect (age slope) for the week 6 responses for RCF and ELISPOT ($P < .001$). There was a lesser association of age and gpELISA response (slope is 1% per year of age with $P = .034$). *Responder cell frequency (RCF) value*, number of responding cells per 10^5 peripheral blood mononuclear cells (PBMCs); *ELISPOT (enzyme-linked immunosorbent spot) counts*, number of spot-forming cells per 10^6 PBMCs; *glycoprotein-based enzyme-linked immunosorbent assay (gpELISA) titer*, gpELISA units/mL. *Error bars*, 95% confidence intervals for the geometric mean. *N*, number of subjects who had blood samples collected in the age group. *V*, number of subjects in the vaccine group. *P* values for differences between age groups are shown below the graphs. *(From Levin MJ, Oxman MN, Zhang JH, et al. Varicella-zoster virus–specific immune responses in elderly recipients of a herpes zoster vaccine.* J Infect Dis. *2008;197:825–835.)*

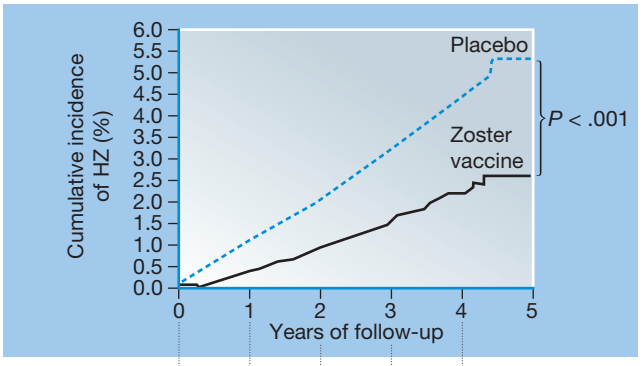
The peak boost in VZV-CMI occurs at 1 to 3 weeks after zoster vaccination.[169] This is consistent with unpublished information from the HZ vaccine trial that demonstrated prevention of HZ (approximately 50%) was observed within the initial month after vaccination. The immunology substudy of the clinical trial also indicated that the magnitude of the boost in VZV-CMI declined by 40% to 50% in the first year post-vaccination and then remained constant in the second and third years.[65] These observations are consistent with the trial results wherein vaccine efficacy was greatest in the 6 months after vaccination, and thereafter a lower efficacy was established and maintained for the remainder of the 3-year study (Fig. 65.5).



A subsequent immunologic study measured VZV-CMI in elderly versus young subjects before and after zoster vaccine. Before zoster vaccine, elderly subjects had significantly fewer VZV-specific T-helper types 1 and 2 $CD4^+$ T cells, fewer early effector $CD4^+$ T cells, and fewer $CD8^+$ early effector and effector memory T cells than a young comparator population. These differences in older subjects were largely abolished by administration of zoster vaccine.[55] Intradermal administration of zoster vaccine has also been evaluated. This was dose-sparing, in that a two-third reduction in dose administered intradermally induced VZV-specific antibody and VZV-CMI responses equivalent to a standard dose of vaccine.[170]

Efficacy of the Zoster Vaccine

Persons 60 Years of Age or Older

The efficacy trial of the zoster vaccine was a randomized, double-masked, placebo-controlled study involving 38,500 subjects 60 years of age or older; 46% of whom were at least 70 years old and 6.5% of whom were at least 80 years old.[107] Equal numbers received either a single subcutaneous injection containing a median potency of 24,600 PFU of the Oka/Merck strain of attenuated VZV or a placebo containing excipients without VZV or cell components; all had a history of varicella or resided in the United States for at least 30 years. They were taught by video at each study site to recognize HZ and instructed to immediately contact the study site if they suspected HZ. Each month, the subjects called an automated telephone response system that queried them about interval symptoms suggestive of HZ, reeducated them about the clinical signs and symptoms of HZ, and reminded them to contact the study site if they suspected HZ. The automated telephone response system notified the study site when suspected HZ was reported or if there was no contact.

Site investigators examined subjects as soon as possible after suspected HZ was reported and described each suspected episode in detail. Samples for PCR (also local culture at the site's discretion) and digital photographs were obtained. Pain was assessed with a questionnaire that measured typical pain, as well as allodynia and disturbing pruritus.[161] Pain assessment was repeated at defined intervals as long as the pain remained

at 3 or greater (scale of 1 to 10) up to a maximum of 181 days. A prior validation of the pain instrument indicated that pain scores less than 3 were inconsequential with respect to quality of life. Complications of HZ were recorded. Subjects with HZ were offered a standard course of antiviral therapy and provided symptomatic care per local standard.

The prespecified primary end point for efficacy analysis was burden of illness (BOI). BOI was defined as the sum for each treatment group of the area-under-the-curve measurements from plots of pain severity over time for each individual case of HZ. Subjects without HZ contributed nothing to this sum. Thus, BOI was a metric that encompassed frequency, duration, and severity of HZ in a population, and in this trial represented the average severity of illness from HZ among all subjects in the vaccine and placebo groups. PHN, defined as the presence of pain with a score of 3 or greater at least 90 days after the onset of rash, was the secondary end point. The incidence of HZ, which was not initially chosen as an end point, was later added as an end point. The mean time in the study was 3.13 years; 95% of subjects completed the study; 1% were lost to follow-up or withdrew; and 4% died during the study.

A low threshold for suspecting HZ was adopted by the study sites. There were 1308 suspected cases of HZ: 481 were in the vaccine group and 827 in the placebo group. Of the suspected cases, 315 vaccinees and 642 placebo recipients were confirmed as HZ by prespecified criteria, which excluded HZ occurring during the 30-day postvaccination period (Table 65.1). Confirmation of the diagnosis was made by PCR in approximately 93.5% of cases,[171] by local culture in approximately 1% of cases, and (in the absence of a laboratory diagnosis) by an experienced central clinical evaluation committee in 5% to 6% of cases. Clinical adjudication was the basis of an HZ diagnosis only when definitive laboratory testing was not available.

The overall vaccine efficacy against HZ (VE_{HZ}) was 51.3% (5.42 cases/1000 person-years vs 11.12/1000 person-years; Table 65.2; $P < .001$). The efficacy was the same for either sex. The overall vaccine efficacy for BOI (VE_{BOI}) was 61.1% (2.21 vs 5.68 score; $P < .001$). The overall vaccine efficacy against PHN (VE_{PHN}) was 66.5% (27 vs 80 cases; $P < .001$). The VE_{PHN} was not altered when the definition of PHN was varied for intervals between 30 to 180 days after rash onset in a sensitivity analysis. In a time-to-event analysis, the cumulative incidence of HZ was significantly lower in the vaccine group (see Fig. 65.5A) for 5 years, as was the cumulative incidence of PHN (see Fig. 65.5B).

The effectiveness of zoster vaccine against HZ was confirmed in three retrospective studies. One study undertaken in a managed care setting, which included almost 76,000 vaccinated persons 60 years of age or older, showed a 55% reduction in HZ (hazard ratio, 0.45; 95% confidence interval [CI], 0.42–0.48) compared with more than 227,000 matched unvaccinated control subjects.[172] Zoster vaccine also reduced the number of complications, including hospitalization and

ophthalmic HZ, but unlike the controlled trial, no age effect was noted on the protection provided by the vaccine. Additional studies using a Medicare database and smaller private insurance database had similar findings, including an effectiveness against postzoster pain of 48% to 61%.[173,174] These studies specifically addressed the value of zoster vaccine in a community setting with routine clinical practices.

Persistence of the Efficacy of Zoster Vaccine

The persistence of vaccine-induced protection is a major issue for elderly vaccinees. The 51.3% efficacy against HZ determined in the pivotal zoster vaccine trial was based on approximately 58,000 subject-years (s-y), with subjects followed for a mean of 3.1 years (range, 0.0–4.1 years). A subsequent short-term persistence study included approximately 10,000 s-y with follow-up for 3.3 to 7.8 years, which determined an overall efficacy against HZ of 39.6%.[175] This was complicated by a commitment to provide zoster vaccine to placebo recipients, resulting in the placebo control group diminishing over the course of the study. An additional approximately 25,000 s-y, with subjects in follow-up for 7 to 11 years, determined an overall efficacy against HZ of 21.3% (Table 65.3).[176] This result was hampered by the absence of a placebo control group, thereby requiring that a control group be generated with a statistical model based on age-specific HZ rates observed throughout the pivotal trial; this was further adjusted for the calendar effect observed on those rates. In addition, the estimates for the latest years of follow-up have wide confidence intervals. Efficacy against BOI and PHN was somewhat higher, 35% to 37%.

Prevention Versus Attenuation

The effect of aging on vaccine efficacy in elderly people has been repeatedly demonstrated for other vaccines, such as influenza vaccine and pneumococcal vaccine, reflecting age-related immune senescence.[152,177] This effect for zoster vaccine is shown in Table 65.2. The VE_{HZ} decreased from 64% (CI, 56–71%) in the 60- to 69-year-old group to 41% (CI, 28–52%) in vaccinees 70 to 79 years old, and 18% (CI, –29% to 48%) in vaccinees 80 years of age or older.[165] However, the VE_{BOI} was similar in 60- to 69-year-old vaccinees and in vaccinees older than 70 years of age, indicating that VE_{BOI} was largely achieved by preventing HZ in the younger age group, while attenuation of incident HZ was a major contributor to reducing BOI in the older age group. Confirmation of this attenuation is provided by the VE_{PHN}, which was preserved at least through 79 years of age. Individual HZ pain scores of 600 or more (equivalent to the worst imaginable pain for 60 days, or less pain for longer periods) occurred with HZ in one vaccinee in the 60- to 69-year-old group compared with nine placebo recipients in this age group; HZ cases with this pain intensity in subjects 70 years of age or older occurred in 10 vaccinees compared with 31 placebo recipients.[178]

The importance of attenuation against HZ in elderly persons is also demonstrated by measuring the practical consequences of the acute and chronic effects of HZ on elderly people. This was done by recording the effects of HZ on the activities of daily living (e.g., work, mood, relationships, sleep, self-care, grooming) in subjects in the zoster vaccine efficacy trial.[111] These data demonstrated (Table 65.4) that zoster vaccination had a small effect on the HZ-related loss in activities of daily living in younger vaccinees who developed HZ despite vaccination, whereas the efficacy of zoster vaccine in preventing this loss was greater in the older age cohorts that developed HZ. Ultimately, the absolute benefit of zoster vaccine for attenuating HZ is greater in older subjects because the frequency and severity of HZ, including PHN, increase disproportionately with age.

Correlates of Immunity

The clinical and laboratory information previously described indicates that VZV-specific CMI is not only sufficient, but also necessary, to maintain latency of VZV. The extent of pain

associated with HZ is also closely correlated with this specific CMI and not with antibody.[128] Nevertheless, in the large pivotal vaccine trial for older subjects, the magnitude of the antibody boost (measured by glycoprotein-based enzyme-linked immunosorbent assay) and the magnitude of the two measures of VZV-CMI (responder cell frequency and enzyme-linked immunosorbent spot assay) all correlated with protection against HZ.[65] The interpretation of these correlations is uncertain because these two types of immune responses were not correlated with each other. At best, antibody responses to zoster vaccine may be a nonmechanistic correlate of immunity, indicating responsiveness to the vaccine, although not the final path to protection. Antibody responses alone were measured in the large trial of zoster vaccine in subjects 50 to 59 years old. The boost in antibody in these younger vaccinees also correlated with protection against HZ.[179] A further analysis of their antibody responses to zoster vaccine revealed that the rise in antibody titers 6 weeks after vaccination inversely correlated strongly with the likelihood of developing HZ; more so than the magnitude of the response.[180]

Safety of the Zoster Vaccine

Deaths and all serious adverse events were similar in frequency in both treatment arms.[107,181] Reactions at the injection site were more frequent in vaccine recipients (48%) than in placebo recipients (16%), but the severity and frequency of these reactions were similar to those observed with other vaccines administered to older people. A single or small group of vesicle(s) occurred at the inoculation site in 0.11% of vaccinees compared with 0.04% of placebo recipients. Mild systemic events, such as headache, were also more common in vaccinees (6.3% vs 1.4%), but there was no difference in the occurrence of fever.

A prespecified substudy (6000 subjects) in the 42-day postvaccine period recorded more serious adverse events in vaccine recipients (1.9% vs 1.3%; $P < .03$), but there were no significant differences in the distribution of these events according to body system or type of event, and no clinically meaningful differences between the groups were observed in the pathophysiology, nature, timing, intensity, or outcome of these events. A time-to-event analysis did not suggest any temporal clustering of vaccine-associated serious adverse events. When all 38,500 subjects were considered in the 42-day postvaccine interval, the incidence of adverse events was similar (1.4%) in the two treatment groups.

In the 42-day postvaccine period, there were seven cases of HZ in vaccine recipients and 24 cases in placebo recipients, indicating that the vaccine did not cause or induce HZ and that zoster vaccine was effective shortly after administration. Moreover, no vaccine strain VZV (as typed by PCR) was recovered from 321 samples of DNA from HZ cases that occurred in vaccine recipients. Vaccine safety was confirmed in an additional placebo-controlled study and an analysis of eight managed-care organizations encompassing 193,000 older adults.[182,183] Five cases of optic neuritis, uveitis, or keratitis were reported as occurring within 2 weeks of zoster vaccination, usually in patients with prior quiescent disease.[184] A causal relationship has not been established. A single case of HZ caused by zoster vaccine has been confirmed (>20 million doses).[185]

Administration of Zoster Vaccine at 50 to 59 Years of Age

Zoster vaccine was licensed for this age group in the European Union, based on bridging experiments that showed a boost in VZV-specific antibody responses comparable to that observed in vaccinees 60 years of age or older. Subsequently, in a double-blind, placebo-controlled trial of almost 22,500 subjects 50 to 59 years old in the United States and Europe, the efficacy of zoster vaccine was demonstrated to be 69.8% and the safety profile was excellent.[186] The vaccine is now licensed for this age group in the United States. This is important because almost 20% of HZ cases (170,000 to 210,000) occur in this age group in the United States, compared with 47% of cases occurring in persons 60 years of age or older. More than 11% of all PHN occurs in the 50- to 59-year-old group.[87] The severity of acute disease, the complications, and the costs are similar to those experienced by older people; it is primarily the severity and duration of prolonged pain that distinguishes older patients with HZ. Moreover, 70% of people 50 to 59 years old are employed; approximately 3.4 days of employment are lost when HZ occurs at this age.[187,188] The prevention of work lost strongly influences the cost-to-benefit analyses of administration of zoster vaccine to persons 50 to 59 years old.

INDICATIONS

Zoster vaccine was licensed in May 2006 for people at least 60 years of age who had not had prior HZ for the prevention of HZ and related morbidity and subsequently recommended for these individuals by the Advisory Committee on Immunization Practices (ACIP). The target age was lowered to 50 years of age in 2011, but 50- to 59-year-old individuals were not added to the ACIP general recommendation. The vaccine is administered as a single subcutaneous dose.[165] The U.S.–licensed vaccine must be stored frozen (less than −15°C) in a lyophilized form and must be used within 30 minutes of reconstitution, except this formulation may be stored and/or transported at refrigerator temperature (2°C to 8°C) for up to 72 hours before reconstitution.

CONTRAINDICATIONS

Zoster vaccine should not be given to immunosuppressed persons; pregnant women; persons with active tuberculosis; or persons with a history of anaphylactic/anaphylactoid reactions to any of the vaccine components. The Oka/Merck strain

of VZV used in the zoster vaccine has caused severe or fatal disease in at least 23 people, but all but one were VZV-naive susceptibles receiving the varicella vaccine.[189] The vaccine should not be given to people who are receiving or have recently received (i.e., within 48 hours) antiviral drugs active against herpesviruses because these drugs may interfere with the protective effect of zoster vaccine. These drugs should be avoided for 10 days after zoster vaccine administration.[190] National blood bank policy is to delay blood donation until 30 days after zoster vaccine.

Prior Episodes of Herpes Zoster

The ACIP reaffirmed the indications stated at licensure, except for indicating that the vaccine is recommended for persons at least 60 years old (current age for licensure is now 50 years of age and older) regardless of a prior episode of HZ.[190] Considerations for this change include the following: (1) the incidence of second cases of HZ is uncertain, but it is 2% to 5% in some reports[87,116,118,120]; (2) by age 60 years, approximately 15% to 20% of the target population will have had HZ; (3) misdiagnosis and erroneous recall of past HZ are likely to be substantial and often not possible to confirm; (4) safety issues are unlikely[190]; and (5) the vaccine is likely to add protection, especially when the initial HZ was remote.[192]

Most likely, a prior attack of HZ will confer substantial protection against subsequent attacks for some years.[128] This boost in immune response is also likely to wane with aging, although the interval after an attack of HZ at which administration of zoster vaccine should occur is undefined. Some experts recommend that vaccination be given 3 to 5 years after prior HZ. The safety and immunogenicity of vaccinating in this setting was studied in 101 subjects.[192] Moreover, after the completion of the zoster vaccine efficacy trial, 420 placebo recipients who developed HZ received a dose of zoster vaccine without experiencing any vaccine-related serious adverse events.[193]

CONCOMITANT ADMINISTRATION

Although it might be convenient to administer zoster vaccine at the same visit as the annual influenza vaccine, administration of zoster vaccine should not be delayed for this purpose and should be given to qualifying adults as soon as an opportunity is available. In general, administration of widely used live attenuated and inactivated vaccines has not resulted in an increase in adverse events or a reduction in immunogenicity of the concomitantly administered vaccines.[194] In fact, simultaneous administration studies of HZ vaccine with trivalent inactivated influenza vaccine in more than 750 subjects showed that the immunogenicity of either vaccine was not reduced.[195] Concomitant administration with the quadrivalent inactivated influenza vaccine is under study.

One report of simultaneous administration with pneumococcal polysaccharide vaccine demonstrated a significant reduction in VZV-specific antibody responses.[196]Although there were some inconsistencies in the clinical trial, and effects on VZV-CMI were not evaluated, the U.S. Food and Drug Administration requested a revision to the zoster vaccine package insert stating that the HZ and pneumococcal vaccines should not be administered concomitantly and should be separated by 30 days.[165] However, in a retrospective cohort study involving almost 76,000 vaccinees in a managed care setting, the efficacy of zoster vaccine was not affected by concomitant pneumococcal polysaccharide vaccine administration.[172] These two vaccines are now frequently administered together. Concomitant use studies with the adult acellular pertussis-tetanus-diphtheria vaccine have not been done.

PUBLIC HEALTH CONSIDERATIONS

Burden of Herpes Zoster and Complications in Various Age Groups

The pain in the acute phase of HZ has a profound effect on the quality of life of many patients.[197–200] The effect of HZ on a typical older patient is quantitatively similar to that of congestive heart failure, severe depression, acute myocardial infarction, and uncontrolled diabetes.[201] In younger employed patients, the ability to work is often severely affected by the acute pain.[187] An average of 27 hours is lost from work after HZ and 34 hours of additional decreased effectiveness.[202,203] Chronic pain has even more substantial effects on quality of life, such that physical disability and emotional distress are common in patients with PHN. The effect of PHN is most marked in older patients, in part because they may have more intense pain and in part because of frailty and comorbidities. They experience physical consequences (e.g., fatigue, anorexia, weight loss, and insomnia), psychological consequences (e.g., depression and difficulty concentrating), social consequences (e.g., decreased social interaction and change in social role), and functional impairment (e.g., dressing, bathing, mobility, and shopping).[109,111,197,199,204] These consequences in older patients, which often are not readily appreciated, can lead to a downward spiral that ends with dependent care or even death. Table 65.4 indicates that zoster vaccine significantly reduces the loss of routine activities of daily living in people who develop HZ despite vaccination.[111] This attenuation effect is greater for older patients.

Societal Value of Zoster Vaccine

Administration of zoster vaccine to 1 million people in the target population will prevent approximately 70,000 cases of HZ, 20,000 cases of PHN, 250,000 visits to a medical office, 350,000 prescriptions, 8700 emergency department visits, and 8000 hospitalizations.[126] There are 54 million Americans in the 60- to 79-year-old age group (64 million in 2020); an additional 12 million are 80 to 100 years old (13.1 million in 2020). A case of HZ generates a cost (as of 2014) of about US$500 in a 50-year-old patient and more than US$1000 in a 70-year-old patient. Complications such as eye involvement (US$1500), neurologic involvement (US$2100), and skin superinfection (US$2115) add to the medical costs.[126,203] Hospitalization for HZ, especially cases occurring in an immunosuppressed patients, greatly increases the cost.[203,205] Total cost of HZ in the United States is almost US$2.2 billion.[203]

There have been more than 15 analyses of the cost effectiveness of zoster vaccine, including three from the United States, two from Canada, and eight from Europe, as well as Australia and Korea. Most of these rely, in large part, on published information from the HZ vaccine trial.[119,126,205–208] Most, but not all studies support the widespread administration of zoster vaccine. The strength of support in individual studies is very sensitive to assumptions about prevention of complications (especially PHN), age of vaccination, effect of age on vaccine efficacy, durability of protection, local healthcare costs, cost of vaccine, and utilities used to determine quality-adjusted life-years.

Until recently, the data on durability were limited, and most studies did not fully incorporate the vaccine effect on severity of illness. Some of these studies have influenced national policies on vaccine usage. For example, the United Kingdom recommends zoster vaccine for people who reach 70 years of age with a gradual catch-up program that includes people each year who reach 79 years of age.[209] Younger and older people are not covered by the vaccine program.

In the United States the cost per quality-adjusted life-year was calculated as US$86,000 when vaccination is undertaken at age 60 years and US$37,000 for vaccination at age 70 years.[210]

Barriers to Vaccine Uptake

The currently licensed zoster vaccine costs US$118 to the federal government and US$188 in the private market (the most expensive vaccine recommended for adults), not counting an administration fee. Thus, coverage by health maintenance organizations and governmental providers is essential for wide use. Although approximately 85% of the target population for the vaccine has some coverage from these sources, coverage is often partial and most people are left with a significant copayment. This and other barriers are responsible for an approximate zoster vaccination coverage of less than 25%, although in some managed care organizations coverage has exceeded 60%.

The largest barrier is financial, including the difficult Medicare Part D reimbursement procedures for physicians and patients. Other factors are the following: (1) lack of a strong recommendation by the caretaker (<50% for zoster vaccine vs >90% for vaccination against influenza and pneumococcus); (2) lack of patient awareness; (3) expense of stocking zoster vaccine and the requirement for storage in a freezer; and (4) the lack of a strong medical culture for vaccination of adults.[211]

Potential Effects of Universal Varicella Vaccination on the Epidemiology of Herpes Zoster and Use of the Zoster Vaccine

It has been suggested that administration of zoster vaccine at a younger age could become necessary if the age-specific incidence of HZ shifted toward younger ages as a consequence of universal vaccination against varicella. This concern was raised because environmental exposure of adults to varicella was known to boost VZV-CMI, and could be important in maintaining latency of VZV.[50,53,54] The absence of this environmental exposure was hypothesized to lead to a more rapid decline in VZV-CMI and occurrence of HZ at a younger age. This was the conclusion of two case control studies examining the effect of potential varicella exposure to the age of onset of HZ.[50,212] There are two studies in which mathematical modeling predicted the magnitude of this presumed negative effect of universal varicella vaccination.[213,214] These results have influenced public health vaccine policies concerning varicella immunization in some countries. The validity of this concern is difficult to assess by epidemiologic means because the data quality and surveillance methods vary greatly between prevaccine and postvaccine periods. In addition, there are potential biases from longitudinal changes that have occurred in the medical care system and study populations. Many studies have demonstrated an increase in incidence in HZ that began *before* the varicella vaccine era ("calendar effect") or failed to show an increase in incidence in the current era,[87,118,120,215,216] but most have found that HZ has been increasing over an extended period that *preceded the introduction of varicella vaccine*, and has increased in countries where the vaccine is not used.[217,218] A detailed analysis of a Medicare database of 3 million older adults found no significant change in the rate of HZ increase after the introduction of varicella vaccine (which was rising prior to its introduction), and also found that HZ incidence did not vary with individual state coverage for varicella vaccination.[219] This finding was replicated using a private medical insurance database of equal size.[220] Nuns and monks who were cloistered for decades without contact with children had the same incidence of HZ as age- and gender-matched villagers from the same locale.[221]

OTHER CONSIDERATIONS

Immunization Before Immunocompromise

There are additional settings in which zoster vaccine might be administered to patients younger than the currently approved age of 50 years. These include younger patients with latent VZV (i.e., prior varicella) who are likely to become immunosuppressed, such as patients scheduled for organ transplantation, therapy for autoimmune diseases, or chemotherapy for malignancy. The efficacy of this approach has not been demonstrated. However, zoster vaccination of immunocompetent older people who subsequently develop an unexpected immunocompromising illness are protected for at least several years after vaccination.[222]

While zoster vaccine is contraindicated for immune compromised patients, this definition of immunocompromise is not rigorously defined. For example, treated patients in the early stage of HIV infection (with ≥15% $CD4^+$ cell count) are likely candidates for zoster vaccine, including those younger than age 50 years.[223] Zoster vaccine was safe and immunogenic for patients receiving 5 to 20 mg of prednisone-equivalent on a chronic basis.[224] Moreover, there are likely to be levels of mild immunosuppression, or windows between cycles of immunosuppressive therapy, when patients might benefit from zoster vaccine despite the current general contraindication. This paradigm works for administration of the same Oka/Merck VZV strain as varicella vaccine in susceptible persons, such as in children scheduled for renal transplantation.[225] This type of off-label use should proceed with caution, since this strain of VZV can be very morbid in severely immunocompromised patients.[189] Mitigating the risk are the following factors: this proposed use of zoster vaccine is likely to occur in patients with preexisting immunity, which adds a large measure of safety, and the vaccine strain of VZV is sensitive to nucleoside analog antiviral therapy. Investigations are underway to establish the safety of administration to patients in a variety of clinical settings to determine if a significant boost in VZV-CMI is safely induced and maintained. It would be prudent to administer the zoster vaccine at least 2 weeks after the most recent immunosuppressive therapy and 2 weeks before anticipated additional immunosuppression.[190] This window should be broader when high-dose corticosteroids are a component of therapy for an extended period.

Unintended Administration of Zoster Vaccine to an Elderly Person Without Prior Varicella

This occurrence should be infrequent because most adults have preexisting immunity to VZV. In the two zoster vaccine efficacy trials (50–59 years of age; ≥60 years of age), subjects were recruited on the basis of a history of varicella or of residence in the United States for at least 30 years. In these two trials, five of 3754 serum samples lacked serologic evidence of past VZV infection. Even if a VZV-susceptible person were to receive zoster vaccine, it is unlikely to cause any serious adverse event given the attenuated nature of the vaccine virus, as demonstrated by approximately 150 VZV-susceptible subjects older than 13 years of age who received zoster vaccine in clinical trials; approximately 20 of them were older than 30 years. There were no significant systemic events, including the absence of signs or symptoms suggesting rash or dissemination of the administered virus.[226]

Elderly Persons Who Are Household Contacts of Varicella-Zoster Virus–Susceptible Immunocompromised Patients and Pregnant Women

It is especially important that elderly persons receive zoster vaccine if they are in regular contact with people who are VZV-naïve and at high risk to develop severe varicella.

Investigational Vaccines and Additional Studies to Improve Prevention of Herpes Zoster

The problem of immunosenescence complicates efforts to develop a vaccine with improved efficacy to prevent HZ. The administration of two doses of the current vaccine was not significantly more immunogenic than a single dose in boosting VZV-CMI responses.[169,227] However, the outcome measure, VZV antibody responses, was evaluated 4 weeks after the second dose, whereas some earlier experiments indicated that increasing the dose did not increase peak VZV-CMI responses, but greatly increased persistence of those responses.[158] Much higher doses—up to fivefold—can be safely given, but it is unclear that these will significantly improve VZV-CMI responses (Levin et al, unpublished data),[228] and this may not be commercially feasible. Given the significant waning of zoster vaccine protection after 7 to 8 years, a booster dose of zoster vaccine was safely administered to 200 subjects 10 years after a first dose. This trial indicated that VZV-CMI had declined substantially in the 10-year interval, but was still higher than levels measured in age-matched controls who had never received zoster vaccine. The booster dose restored the loss of VZV-CMI, and the immune response after 1-year in the boosted group was higher than that achieved in the control group.[229]

Heat-Inactivated Vaccine

Given that the live zoster vaccine cannot be used in patients with significant immunosuppression, an inactivated formulation (Merck Research Laboratories) was prepared by heating infectious Oka-Merck strain VZV. The initial controlled experiment used 2900 PFU of 50°C heat-inactivated VZV (4.5 U of antigen) to vaccinate patients undergoing autologous bone marrow or hematopoietic stem cell transplantation or allogeneic bone marrow transplantation.[46] A single-dose regimen was ineffective. Three monthly doses resulted in early restoration of VZV-CMI. Although this regimen did not prevent HZ, disease severity was markedly reduced. A subsequent controlled trial was performed in patients with lymphoma undergoing autologous transplantation.[47] Four monthly doses (6115 PFU, inactivated) were administered starting 1 month prior to transplantation. VZV-CMI recovered significantly sooner in the vaccinated patients, which correlated with significant efficacy against HZ. The four-dose regimen (now 4.8 U antigen) was evaluated in additional hematopoietic stem cell transplantations and immunosuppressed patients.[230] Significant increases in VZV-CMI were elicited in immunosuppressed patients with solid tumors or hematologic malignancies, autologous stem cell transplantation, and HIV with 200 or fewer $CD4^+$ cells/mm^3, but not in allogeneic bone marrow transplant recipients. Efficacy was not an end point. Additional studies are in progress (new proprietary inactivation procedure) in patients with a variety of immune compromising conditions, including biological response modifiers, with or without methotrexate, but not in immunocompetent older individuals who manifest age-related decline in immunity.

Recombinant Varicella-Zoster Virus Glycoprotein E Vaccine

Recombinant subunit vaccines provide another alternative for immunocompromised patients and, together with appropriate adjuvants,[231] may also provide an alternative for preventing HZ in elderly people. VZV glycoprotein E (gE) is a major component of the VZV capsid; the most abundant glycoprotein expressed on VZV-infected cells; the major target for neutralizing antibodies; required for replication and cell-to-cell spread; and a primary target of VZV-specific B- and $CD4^+$ T-cell responses.[52,232–237] The investigational recombinant subunit vaccine contains 50 μg of VZV gE and the AS01B adjuvant system. The vaccine combines gE antigen with monophosphoryl lipid A (a Toll-like receptor 4 agonist prepared from bacterial lipopolysaccharide) and QS-21 (a plant-derived triterpene glycoside) in a liposomal formulation. Phase I/II and Phase II clinical trials conducted in older adults showed that this vaccine administered in a two-dose schedule (60-day interval) elicited robust immune responses that were significantly elevated for at least 3 years.[238–240] The responses included stimulation of VZV- and gE-specific antibody in much greater quantities than a comparator live VZV vaccine. Importantly, multifunctional gE- and VZV-specific $CD4^+$ T cells were stimulated to high levels, including cells with a memory phenotype. These effects have been linked to a transient stimulation of the innate immune system and generation of a high number of efficient antigen-presenting dendritic cells.[241] Strikingly, in the Phase I and II trials, age had no significant effect on these responses. Strong immune responses did not occur when the adjuvant was omitted. Local and systemic side effects were reported more frequently than had been observed with the licensed live vaccine, but these were mostly transient, mild to moderate, and well tolerated.

A randomized, Phase III, placebo-controlled trial of this vaccine (Shingrix; GlaxoSmithKline) was undertaken in 15,400 subjects, stratified by 50 to 59 years, 60 to 69 years, and 70 years of age and older.[242] The vaccine was greater than 97% effective in preventing HZ, with very similar efficacy for all the three age strata (Table 65.5). Local and systemic reactions were significantly more frequent and severe than observed with some other commonly administered vaccines, including the licensed zoster vaccine. In general, these were well tolerated and 96% of subjects received the second dose of study vaccine. However, 9.4% had grade 3 systemic reactions (unable to perform usual daily activity) that lasted 1 to 2 days.

The efficacy of this vaccine alters our current paradigm about vaccination of older individuals, including results with the live zoster vaccine. Namely, that efficacy was strikingly better and did not decline with increasing age. These two outcomes mirror the immunologic profiles obtained in the Phase II studies. Persistence studies continue.

A confirmatory placebo controlled trial of 14,800 subjects 70 years of age and older (2850 subjects 80 years of age or older) was subsequently reported.[243] Data from subjects 70 years of age and older from the two trials were combined to determine the efficacy of the investigational vaccine in these older subjects (Table 65.6). Efficacy was 90% for subjects 70 to 79 years of age and was 89% for subjects 80 years of age and older. The safety profile was similar to that of the initial study. Efficacy declined very little during a 4-year follow-up. Efficacy against PHN was 88.8% in subjects 70 years of age and older. Information on durability of protection is not yet available. The efficacy from both studies may be too good to determine a correlate of protection against HZ or PHN. The vaccine protection against PHN was predominantly from prevention of HZ.

Year 4 (n = 5896)	6	1.1	Year 4 (n = 5776)	39	7.1	85.1 (64.4–94.9)

[a]Herpes zoster vaccine is the recombinant gE vaccine (Shingrix; GlaxoSmithKline).
[b]According to protocol.
CI, confidence interval; gE, glycoprotein E; HZ, herpes zoster; "n" denotes sample size; p-y, person-years.
Data from Cunningham AL, Lal H, Chlibek R, Hwang S-J, Diez-Domingo J, et al. Efficacy of the herpes zoster subunit vaccine in adults ≥70 years of age. N Engl J Med. *2016;375:1019–1032.*

Additional information will be desirable on the persistence of this protection against HZ and on the long-term safety, given that a strong adjuvant is being administered in this older population. AS01B adjuvant is not present in any vaccines licensed in the United States, although it has been studied for many years as a component of a hepatitis B vaccine[244] and a malaria vaccine.[245] To date, the committee monitoring the safety of the two pivotal trials did not find any apparent safety signal.

The adjuvanted recombinant gE vaccine may be especially valuable for immunosuppressed patients who cannot receive the live attenuated vaccine. The immunogenicity and safety of the recombinant gE vaccine was demonstrated in HIV-infected patients and after autologous hematopoietic stem cell transplantation.[246,247] For these studies a third dose was administered 6 months after the first dose. Acceptable tolerability was observed. No alteration in the status of HIV infection or the hematopoietic transplant was attributed to vaccination, and gE-specific VZV-CMI and antibody responses were robust. At least eight additional studies are planned or ongoing to include special clinical situations (such as prior live zoster vaccine or prior HZ) and additional immune compromising conditions.

SECTION 3 New Technologies

66 Technologies for Making New Vaccines

S. Sohail Ahmed, Ronald W. Ellis, and Rino Rappuoli

The technological approaches for making new vaccines have been growing rapidly in recent decades owing to significant advances in a broad range of interrelated fields, including next-generation sequencing and antibody repertoire analysis, molecular and structural biology, genetics (reverse vaccinology), protein and polysaccharide chemistry, immunology, virology, bacteriology, fermentation, macromolecular purification, and formulation.

The majority of available vaccines have been for the prevention (prophylaxis) of infectious diseases. However, new technologies have extended this scope to vaccines for noninfectious diseases (e.g., autoimmune diseases, cancer, allergy, drug addiction) and therapeutic vaccines (e.g., certain infectious and noninfectious diseases). This broadening of scope is continuing to redefine the term *vaccine*.

There are two broad categories of vaccination, *active* and *passive*. Active vaccination stimulates the immune system to produce specific antibodies or cellular immune responses or both and prevents or protects against, ameliorates, or eliminates a disease. Passive vaccination uses a preparation of antibodies that neutralizes a pathogen or binds to a human cellular antigen and is administered before or around the time of known or potential exposure to a pathogen or to a subject with disease or infection. References to the term *vaccine* generally refer to vaccines administered by active immunization. Nevertheless, passive vaccination is desirable or essential in specific cases, particularly if no active vaccine is available or feasible, for immunocompromised persons, for certain types of cancer treatment, and for the immediate efficacy of immunotherapy in acute situations when the immune response to active vaccination will not be rapid enough to prevent a new disease. Passive vaccination is discussed under "Antibody Preparations" later.

Vaccines are stored in solution (liquid or frozen) or in freeze-dried (lyophilized) form depending on their stability and physical characteristics. Lyophilized vaccines are resuspended in diluent (resuspending fluid) at around the time of administration. The vaccine solution and diluent may contain the following additives: (a) preservatives or antibiotics to prevent bacterial growth in multidose containers; (b) stabilizers, including proteins or other organic compounds, to extend the dating period or shelf life for the product; (c) adjuvants for enhancing immune responses (see "Adjuvants" later); and (d) delivery systems for presenting the vaccine antigen(s) to appropriate cells of the immune system or for preserving or stabilizing the integrity or conformation of antigen(s) in vivo (see "Delivery Systems" later). The vaccine and the respective added components comprise the *vaccine formulation*.

This chapter summarizes the major technologies, key issues associated with their development, and immunological objectives underlying different kinds of vaccines. The status of development of key vaccines made by each approach is identified, whether licensed or in preclinical or clinical evaluations (Table 66.1). While most examples are for viruses and bacteria, there also are licensed vaccines and new developments for noninfectious diseases (Table 66.2). The technologies and examples should provide readers with an appreciation of the diversity of approaches being taken in the research and development of vaccines for new targets not previously approachable.

ACTIVE VACCINES

The protective immunity elicited by an active vaccine ideally would be lifelong and robust after one or a few doses with minimal side effects (reactogenicity). Available vaccines and vaccines under development generally fall short of this ideal, which continues to stimulate new research and development initiatives in this field. The term *immunogen* refers to the property of eliciting an immune response, whereas the term *antigen* denotes the property of in vitro immunological reactivity.

There are three general categories of active vaccines; Table 66.3 outlines the salient features. A *live* vaccine generally is a microorganism that replicates on its own in the host or infects cells and functions as an immunogen without causing disease. An *inactivated* vaccine contains an immunogen that cannot replicate in the host as the disease-causing microbe has been killed with chemicals, heat, or radiation.[1] A *nucleic acid–based* vaccine (usually DNA), also incapable of replicating in humans, is taken up by cells and directs the synthesis of the vaccine antigen(s).

The strategic choice for developing a live, inactivated, or nucleic acid–based vaccine should take into account the pathogenesis, epidemiology, and immunobiology of the target infection or disease and the technical feasibility of alternative vaccine designs. Epidemiology dictates the target population for the vaccine. The age and state of health of this population may favor certain designs as more appropriate for eliciting protective immunity. In the case of a vaccine intended for healthy subjects (especially infants), minimizing acute reactogenicity is critically important as is minimizing the risk of chronic autoimmune disease development in genetically susceptible subjects. Toxicology studies address the former while in regards to the latter, bioinformatics technologies have been developed to help identify microbial antigens that may lead to a cross-reactive immune response to normal human tissue (self) through molecular mimicry (discussed in greater detail in "Adjuvants" later and in "Bioinformatics Technologies and Vaccine Safety" later). On the other hand, the tolerance for reactogenicity and other potential adverse events is greater for a therapeutic cancer vaccine as the benefit far outweighs the risk. Finally, knowledge of immunobiology should enable the identification of the type(s) of immunity that should be elicited by the vaccine to be effective.

[a]This denotes the single most advanced status achieved by each example.
[b]These categories are presented in the same order and outlined as in the text.
[c]Not yet evaluated in a human clinical trial.
[d]In clinical trial but not yet licensed, whereby "xx" denotes large-scale or Phase III trials on the path to licensure.
[e]Licensed in one or more major countries in the world, whereby "xx" denotes widespread use in multiple countries.
[f]These are representative examples for each vaccine strategy and not a comprehensive list of all examples, with key reference(s) illustrative of each example.
[g]Withdrawn postlicensure.
[h]Expressing more than 50 different foreign polypeptides, especially including HIV and colorectal cancer.
[i]Expressing foreign polypeptides, including HIV-1 *gag* and *env* genes.
[j]Expressing foreign polypeptides including Ebola and Marburg virus glycoproteins.
[k]Expressing foreign polypeptides include toxoids from *E. coli, V. cholerae,* and *C. tetani* and cancer-specific antigens.
[l]Fusion partner is hepatitis B surface antigen (HBsAg).
[m]Conjugate carrier is tetanus toxin (TT).
[n]Conjugate carriers are TT, diphtheria and tetanus toxoids–pediatric (DT), CRM_{197} (cross-reactive material 197), and an outer membrane protein complex.
[o]Conjugate carrier is CRM_{197}.
[p]Expressing foreign polypeptides, especially including HIV.

Live Vaccines

Some live vaccines are close to ideal in their capability to elicit lifelong protection in one or two doses with minimal reactogenicity. Such vaccines may be feasible in cases in which the natural infection or disease confers lifelong protection on the host. Live vaccines (with the exception of dendritic cell vaccines; see "Dendritic Cells as Autologous Vaccines" later) consist of viruses or bacteria that replicate to a limited degree in the host in a manner resembling that of the natural microorganism, thereby eliciting an immune response similar to that elicited by the natural infection. The live vaccine is attenuated; that is, its disease-causing capacity has been reduced by biological or technical manipulations. The live vaccine needs to be balanced by being neither overattenuated (no longer infectious enough to function as a vaccine) nor underattenuated (retaining pathogenicity even to a limited extent). Such vaccines usually elicit both humoral (antibodies) and cellular immunity (e.g., cytotoxic T lymphocytes [CTLs]).

Live vaccines are not technically feasible for most vaccines currently under development. The balance between incomplete attenuation (and consequent disease-causing capability) and complete attenuation (inadequately immunogenic) is delicate and, for some viruses or bacteria, technically unachievable at present. Because a live vaccine can replicate, it may be possible for it to revert to its more naturally pathogenic form unless there are multiple attenuating mutations. Moreover, some live vaccines can be transmitted from a vaccinee to a nonimmunized person, which can be quite serious if the recipient has an immune deficiency (e.g., AIDS or as a result of cancer chemotherapy). In cases in which the natural viral infection per se fails to induce a protective immune response, an attenuated virus would not be expected to be protective without further engineering. As is discussed in the following sections, live vaccines may be produced using either a classic strategy or one using recombinant technology.

TABLE 66.2 Targets for Vaccines Outside the Field of Infectious Diseases

Target Cancer	Condition
Bladder cell surface	Superficial bladder cancer
Prostatic acid phosphatase	Prostate cancer
GM_2 ganglioside	Melanoma
MUC-1 mucinous glycoprotein	Non–small cell lung carcinoma
HER2 glycoprotein	Breast cancer
CD20 glycoprotein	Non-Hodgkin lymphoma
Carcinoembryonic antigen	Carcinoma
ADDICTION	
Cocaine	Drug dependency
Nicotine	Cigarette smoking Cardiovascular
Angiotensin	Hypertension
Cholesterol ester transfer protein	Hypercholesterolemia
GASTROINTESTINAL	
Gastrin 17	Gastroesophageal reflux disease
AUTOIMMUNE	
Myelin basic protein	Multiple sclerosis
Tumor necrosis factor α	Crohn disease
Insulin, proinsulin, others	Diabetes
Ragweed, others	Allergy
TOXICITY	
Digoxin	Toxicity
REPRODUCTION	
Human chorionic gonadotropin	Fertility

Classic Strategy for Viral Targets

Attenuation in Cell Culture. The production of live viral vaccines depends on efficiently propagating virus in cell culture. The approach is empirical, in that wild-type virus isolated from a natural human infection is passaged in vitro through one or more cell types, with the goal of attenuating its pathogenicity. In contrast, a strategy to increase pathogenicity is to passage a viral or bacterial strain serially in a host species. The mechanism by which a mutation is introduced during the course of empirical attenuation is not well understood. In some cases (e.g., poliovirus),[2] it has been possible to demonstrate attenuation in a primate species, whereas in most cases, attenuation is proven only through extensive clinical trials. The success of this empirical approach, which has been applied to oral vaccines (oral poliovirus vaccine[2] and

TABLE 66.3 Comparative Properties of Active Vaccines

Characteristics	Advantages	Challenges
LIVE VACCINES		
• Able to replicate in the host • Attenuated in pathogenicity • Elicit antibodies and cell-mediated immunity	• May elicit broader immune responses • May require fewer doses • Generally longer lasting protection	• Uncertain window for attenuation • Uncertain safety before large-scale use • Stability • Ability to analyze the final product
INACTIVATED VACCINES		
• Unable to replicate in the host • Elicit mostly antibodies	• Cannot multiply or revert to pathogenicity • Nontransmissable to another person • Generally less reactogenic • Usually more feasible technically	• May require adjuvant • May require delivery system • Immunogenic potency • Variable efficacy
NUCLEIC ACID–BASED VACCINES		
• Stimulate synthesis of antigens only in cells • Elicit mostly cell-mediated immunity	• Standardized method of production and analysis • Potential sustained immunological stimulation	• Establishing proof-of-principle • Immunogenic potency

rotavirus[3]) and to injected (parenteral) vaccines (measles,[4] mumps,[5] varicella[6]), has been borne out by the significant number of available licensed vaccines. The reactogenicity of such vaccines has been low enough that some of them (polio, measles) are broadly accepted worldwide for routine pediatric use. Measles, mumps, and rubella (MMR) vaccines have been widely used for decades as the trivalent MMR vaccine. More recently, following many attempts to achieve a stable and immunogenic formulation, the MMR and varicella vaccines have been combined into the measles-mumps-rubella-varicella vaccine.[7] By means of intensive immunization programs with oral poliovirus vaccine, polio is approaching worldwide eradication. As a striking example of the challenge to proving attenuation, the Urabe strain of mumps virus was licensed after showing apparent safety in clinical trials. After several years of use in millions of children, vaccination with this strain was observed to cause aseptic meningitis at a rate of approximately 1 : 10,000.[8] Given the availability of an alternative mumps vaccine without this serious effect, the Urabe strain was withdrawn and is no longer available as a result of the manufacturer's exit from the vaccine market.[9] Another highly relevant example is vaccine-associated paralytic poliomyelitis which is a very rare adverse event (estimated at one case per 2.4 million doses administered) associated with the live-attenuated oral poliovirus vaccine. It is still the vaccine of choice for controlling poliomyelitis in many countries because of its ease of use, low cost, and superiority in conferring intestinal immunity in immunologically naïve individuals.[10]

Variants From Other Species. An animal virus that causes a veterinary disease similar to human disease can be isolated and cultivated, anticipating that the animal virus will be attenuated for humans yet be sufficiently related to elicit protection against the human virus. Smallpox, the first vaccine, is the prototype of this approach. More than 200 years ago, Jenner discerned that persons exposed to cows were resistant to smallpox, so he used the virus isolated from cows (vaccinia virus) for human vaccination against smallpox (caused by variola virus). The immunization program was applied worldwide using vaccinia virus grown in vivo in the skin of calves[11] and resulted in the complete eradication of smallpox worldwide by the mid-1970s, the only infectious disease ever eradicated. Unfortunately, the vaccine had to reenter production in a modern cell culture–based process[12] for potential use as a safeguard against the dissemination of variola virus as a weapon of bioterrorism.

Similarly, first-generation vaccines for rotavirus consisted of nonreassortant animal viruses isolated from rhesus monkeys[13] and cows. However, such rotavirus vaccines were not reproducibly efficacious as human vaccines and, thus, new vaccines were developed that incorporated the VP7 and VP4 proteins associated with disease protection and recovery.[14] RV1 is a live attenuated oral vaccine licensed in the United States since 2008.[14] RV5, a live vaccine containing reassortants, is discussed in the following section.

Reassorted Genomes. A reassortant virus, which contains genes from two parental viruses, is derived following coinfection of a cell with two viruses with segmented genomes. To improve the efficacy of animal rotaviruses, reassortant rotaviruses were isolated containing mostly animal rotavirus genes, which confer the attenuation phenotype for humans, and the gene(s) for human rotavirus surface protein(s) that elicit serotype-specific neutralizing antibodies for human rotavirus.[15,16] These reassortant rotaviruses have elicited higher efficacy rates as vaccines than their nonreassortant parental animal viruses. The same approach has been applied to influenza vaccines, in which a virulent human influenza virus provides the genes that encode the immunogenic surface glycoproteins (hemagglutinin and neuraminidase), and an attenuated virus provides all other genes with an attenuated phenotype.[17] The quadrivalent reassortant rhesus rotavirus vaccine[15] is another example of the challenge in establishing the attenuation profile of a live vaccine. After 1 year of commercial distribution in the United States, it was observed that the vaccine was associated with an increased incidence of intussusception of approximately 1 : 10,000 immediately postvaccination. Although the overall benefit-to-risk remained very high, the vaccine was withdrawn from distribution by the manufacturer. A pentavalent reassortant bovine rotavirus vaccine has been licensed since 2006.[3,18]

Temperature-Sensitive Mutants. Viral mutants can be selected according to their relative growth properties at different temperatures. Such viruses are called temperature-sensitive, being unable to grow at elevated temperatures, or cold-adapted, having been selected for growth in vitro at lower than physiological (37°C) temperatures, that is, down to 25°C. The strategy behind this approach is that cold-adapted or temperature-sensitive viruses will be less vigorous in their in vivo growth than their wild-type parental virus, hence less virulent and phenotypically attenuated. A cold-adapted rubella vaccine[19] has been widely used as part of MMR vaccine. A cold-adapted influenza vaccine based on reassortants[20] was the first live vaccine licensed for intranasal administration and one has been used widely in Russia.[21] A double temperature-sensitive respiratory syncytial virus (RSV) vaccine has been tested clinically,[22] and the use of a double mutant (one that contains two independent mutations) is an important additional refinement resulting in a much lower frequency of reversion to wild-type virulence than for a single mutant.

Recombinant Technology-Based Strategies for Viral Targets

Specific modifications or deletions can be made in viral genes so that the virus is more stably attenuated. The increased stability of the attenuation phenotype results from making the modification(s) extensive enough that reversion through back-mutation is impossible or unlikely. In contrast, attenuated viruses derived by classic strategies may have only point mutations and therefore retain the capability to revert. In attempts to generate a new vaccine, herpes simplex virus (HSV) was genetically engineered in three ways[23]: (a) to be attenuated, (b) to provide for antibody markers of vaccination that are differentiable from those of wild-type HSV infection, and (c) to protect against both HSV-1 and HSV-2. In another example, a particular HSV glycoprotein gene was deleted, resulting in an HSV strain that cannot replicate; this recombinant virus is produced in vitro in a cell line that supplies the deleted glycoprotein gene in *trans*, and the resultant virus can initiate infection in the host without further replication[24] (termed *replication-defective*).

A new molecular strategy for attenuation is to create deoptimized codons with the goal of generating a replication-defective strain. Polioviruses with deoptimized codons in the capsid region produce less infectious virus and are more highly attenuated, yet still efficiently elicit neutralizing antibodies that are protective in a mouse challenge model.[25]

Recombinant technology also has been applied to developing live vaccines in which foreign polypeptide antigens from pathogens have been engineered into carriers or vectors. The strategy in creating such vectors is to present the foreign antigen to the immune system in the context of a live virus infection to stimulate the immune system to respond to the foreign polypeptide antigen as a *live* immunogen, with the

expectation of developing a broader immunity (humoral and cellular) to the corresponding human pathogen than that attainable by a subunit polypeptide vaccine. The foreign polypeptide is expressed within the infected cell and is transported to the cell surface to stimulate antibody production or is broken down into peptides, which are transported to the cell surface where they may elicit CTL responses. This strategy also has the potential advantage of amplification of the immunogenic signal when the live vector initiates multiple rounds of replication (nonreplicating vectors are discussed in "Delivery Systems" later). If the vector virus is a commonly used vaccine, one could immunize simultaneously against the vector virus and another pathogen, ideally in a single dose. However, the preexisting or induced immune response to the live viral vector per se ordinarily limits the effectiveness of revaccination.[26]

DNA Viruses

The prototype viral vector is vaccinia virus in which dozens of different foreign polypeptides have been expressed.[27] Immunizations of animals in a wide range of infection and oncology models have protected against the pathogen encoded in the foreign polypeptide or against tumor development. Recombinant vaccinia virus expressing HIV-1 gp160 has been tested clinically[28] for prophylactic and therapeutic applications.

Given the known adverse events after vaccinia (which are more serious in immunocompromised persons) observed in the worldwide eradication program, vaccinia virus itself has been engineered to reduce its virulence without compromising its efficacy as a live viral vector.[29,30] By passaging vaccinia virus several hundred times in chicken embryo fibroblasts, the highly attenuated strain modified vaccinia Ankara was developed that, owing to its safety under conditions of immune suppression in animal studies, has also led to its use in clinical trials with recombinant HIV vaccines,[31] including modified vaccinia Ankara expressing monomeric gp120.[32,33] Modified vaccinia Ankara has also been used to express antigen 85A from *Mycobacterium tuberculosis* and was well tolerated and immunogenic, but not efficacious, in infants and adults.[34,35] Two other members of the poxvirus family, fowlpox and canarypox viruses, are being developed as naturally attenuated live virus vectors that can infect human cells but not produce infectious viral progeny. This inability to spread makes fowlpox and canarypox viral vectors classifiable as DNA-based vaccines (see "Nucleic Acid–Based Vaccines" later). Recombinant vaccinia and fowlpox viruses expressing carcinoembryonic antigen have shown clinical activity against tumors bearing this antigen.[36]

Other mammalian viruses have also been engineered into live vectors. Adenoviruses are attractive candidates for vaccine vectors as the genome is well characterized, easy to manipulate, causes mild disease in immunocompetent human adults, and can be rendered replication-defective to reduce unwanted side effects.[37] Fifty-one serotypes have been isolated from humans and 27 serotypes from simians (including seven from chimpanzees). The human serotypes are subdivided into six subgroups (serotypes A to F) of which group B contains adenoviruses 7 and 35 and group D contains adenoviruses 4 and 26. Vectors based on adenoviruses 4 and 7 are replication-competent and have been used for oral vaccination of military personnel to prevent acute respiratory disease, whereas vectors based on adenoviruses 26 and 35 are nonreplicating.[37] These vectors have been engineered to express foreign polypeptides, especially for HIV vaccine, and have elicited protective immunity in several viral challenge models in animals[38] and have been tested in clinical studies.[39] As previously described, HSV also has been engineered into a live vector[23] and so has CMV.[40] Optimizing foreign polypeptide expression for all these live viral vectors remains an important immunological objective.

RNA Viruses

RNA viruses also can be engineered into vectors for expressing foreign polypeptides. Lymphocytic choriomeningitis is one example of an RNA virus used as a vector.[41] Sindbis and other alphaviruses have received extensive attention owing to their broad host range, ability to infect nondividing cells, and potential high-level expression per cell.[42] Sindbis has been developed into a viral vector–DNA-based vaccine (see "Nucleic Acid–Based Vaccines" later). Vesicular stomatitis virus vectors expressing filovirus proteins have been shown to protect against lethal challenge by Ebola or Marburg viruses,[43] and alphavirus expressing cytomegalovirus (CMV) glycoprotein has been developed as a candidate CMV vaccine.[44] The versatility of alphavirus vectors as a vaccine strategy is further manifested for noninfectious-disease targets, in that a vector encoding a grass pollen allergen is able to prevent allergic sensitization in a mouse model.[45]

Given the Ebola outbreak that started in Africa in May 2014, global vaccine efforts were accelerated leading to the entry of two vector-based vaccine candidates into efficacy trials in humans. One is derived from a chimpanzee adenovirus engineered to express glycoproteins of ebolavirus, and the other is based on the vesicular stomatitis virus vector that has been engineered to express ebolavirus glycoproteins.[46] Recent results from a Phase III study using the vaccine based on the vesicular stomatitis virus vector demonstrated an efficacy of 100%.[47] Another growing threat that has made the development of an effective vaccine an international priority is dengue disease. Vaccine development programs in both academic and industry settings have investigated various technologies, and the only successful dengue vaccine to date (recently reporting positive Phase III efficacy data)[48] is a recombinant, live, attenuated, tetravalent dengue vaccine (CYD-TDV). This vaccine consists of four recombinant dengue vaccine viruses (CYD 1 to 4), each constructed by replacing the genes coding for the premembrane and envelope proteins of the yellow fever 17D vaccine virus with those from the wild-type dengue viruses, generating chimeric complementary DNAs that are individually transcribed to RNA, and then RNA transfection in Vero cells.[49] Results from a long-term follow-up interim analysis and an integrated efficacy analysis demonstrated lower risk for hospitalization in vaccinated children 9 to 16 years of age and a pooled rate of efficacy during the first 25 months of 60.3% for all participants.[50]

Classic Versus Recombinant Technology-Based Strategies for Bacterial Targets

It has been difficult to develop live attenuated bacterial vaccines by classic strategies because attenuation is difficult to achieve without reversion. Also, bacteria could stop expressing virulence factors in vitro, then turn on expression when in the host.

Serial Passage

The one widely available live bacterial vaccine is a live attenuated strain of *Mycobacterium bovis*, also known as bacille Calmette-Guérin (BCG).[51] Early in the 20th century, this bovine strain was attenuated by 231 successive in vitro subculturings over 13 years; there are many strains of BCG vaccine available worldwide that are derived from this original strain. These vaccines vary in terms of tolerability, immunogenicity, and rate of protective efficacy for tuberculosis in clinical trials

(range: 0% to 80% protection) for reasons that may relate to the actual vaccine strains used or to differences in clinical study designs or populations. BCG vaccines have been inoculated into more than 3 billion people worldwide, have a generally acceptable tolerability profiles, and have an important role in protection against childhood tuberculosis.[52] BCG vaccines also have been administered orally.[53,54] Following the observation that patients with tuberculosis have reduced rates of cancer, BCG vaccine was developed into the first cancer vaccine, being indicated for the treatment of superficial bladder cancer by intravesicular instillation.[55] BCG vaccine also has been used as an adjuvant for the priming doses of certain cancer vaccines.

Mutagenesis

Chemical mutagenesis followed by selection was used to derive the attenuated Ty21a strain of *Salmonella typhi*.[56] This vaccine was licensed for preventing typhoid fever based on its record of safety and efficacy (approximately 60% for several years) after a regimen of three or four doses.[57]

Recombinant DNA (rDNA) technology would be expected to be applied to attenuating any new bacterial strain that had promise as a live attenuated vaccine. Therefore, it seems unlikely that a new live bacterial vaccine attenuated by a classic strategy, alone, will be currently developed.

Recombinant Bacteria

The engineering of bacteria for attenuation is much more complex than for viruses because bacterial genomes are approximately 100-fold larger than those of viruses. The strategy for attenuation, like that for viruses, is to identify the gene(s) responsible for the virulence of bacteria or for their ability to colonize and survive in particular tissue(s) in the host and then eliminate the gene (preferred) or abolish or modulate its in vivo expression. As is the case for modification mutants of viruses, there must be a balance between the virulence of a bacterial strain and its activity as a vaccine, and it is possible to overattenuate a bacterial strain to the point that it no longer replicates sufficiently in vivo and is no longer immunogenic. *Vibrio cholerae* strains have been developed as live cholera vaccines; attenuation has been accomplished by rDNA-directed deletion of genes encoding virulence factors (e.g., cholera toxin [CT]).[58] To ensure attenuation by reducing the probability of reversion, deleting at least two independent genes or genetic loci that contribute to virulence is highly desirable. There have been attempts to develop *Shigella* strains into live vaccines through particular chromosomal or plasmid-based gene mutations to reduce pathogenicity.[59]

Recombinant Bacterial Vectors

Suitable bacterial strains have been engineered into live vectors for expressing foreign polypeptides. The most common development has been to engineer enteric pathogens for inducing mucosal immunity against the foreign polypeptide following oral delivery. *S. typhi* vectors have been the most commonly developed strains in terms of immunology, molecular design, and clinical testing.[60] Strains of *V. cholerae*,[61] *Shigella flexneri*,[62] and *Listeria monocytogenes*[63] have also been engineered. The challenges for these vectors are to retain sufficient virulence for replication in the gut while achieving sufficient attenuation and expressing appropriate levels of foreign polypeptides. The BCG vaccine strain also has been engineered as a live vector to express foreign polypeptides[64]; one aspect of the versatility of BCG is its efficacy in mice by different routes of administration (oral, intranasal, and intradermal).[65] The first human clinical trials of a recombinant BCG vaccine (rBCG30) were initiated with BCG30 (Phase I), which is a recombinant BCG Tice strain derived from the *Mycobacterium–Escherichia coli* shuttle vector pSMT3 and expresses approximately fivefold more of the *M. tuberculosis* 30-kDa protein than the parental BCG strain.[66] rBCG30 was found to be well tolerated and more immunogenic than BCG.[67] The ability of some bacterial species to replicate intracellularly may augment the ability of expressed foreign polypeptides to elicit broad and vigorous immune responses against their respective pathogens.

Streptococcus gordonii, a gram-positive commensal (nonpathogenic) bacterium, has been engineered to express foreign polypeptides on its surface by genetic fusion to attachment sequences of *S. gordonii* M protein.[68] One significant challenge is whether the foreign polypeptide will be sufficiently immunogenic given that this bacterial species does not naturally elicit an immune response that clears them.

Dendritic Cells as Autologous Vaccines

Dendritic cells (DCs) can be exploited as potent professional antigen-presenting cells for tumor-specific antigens by isolating these from the patient and mixing ex vivo with mixed antigens from a person's tumor or alternatively with a recombinant immunostimulatory protein. The DCs ingest and process the antigens and reexpress them on the DC surface. The cells then are reintroduced into the patient for antigen presentation and immune stimulation of T cells.[69] DCs loaded with prostate-specific antigen genetically linked to the granulocyte-macrophage colony-stimulating factor cytokine have shown evidence for clinical efficacy in immunotherapy of prostate cancer[70–72] and were licensed in 2010. The mixed-antigen approach has shown promise for glioblastoma.[73,74] Because autoimmune diseases are characterized by the loss of immunological tolerance to self-antigenic determinants, it may be possible to exploit DCs as antigen-presenting cells to achieve tolerance, as has been demonstrated in animal models of diabetes, multiple sclerosis, and autoimmune encephalitis[75] and for which clinical trials have commenced (e.g., diabetes and rheumatoid arthritis) since 2011.[76,77]

Inactivated Vaccines

Inactivated vaccines have safety advantages as they are unable to replicate (see Table 66.3). Such vaccines are generally well tolerated, especially those that are purified to remove other macromolecules (i.e., subunit vaccines). Subunit vaccines include primarily the antigens that best stimulate the immune system and in some cases, use very specific parts of the antigen (epitopes) that antibodies or T cells recognize and bind. Because subunit vaccines contain only the essential antigens and not all the other components of the microbe, the chances for adverse reactions are less.[1] Subunit vaccine technology is discussed in greater detail later in "Protein-Based/Subunit Vaccines." Given the broad range of available approaches, it is generally easier to produce an inactivated vaccine than a live vaccine. The immunogenicity of such vaccines generally is enhanced by administration with adjuvant or delivery system (see "Adjuvants" later). Nevertheless, this type of vaccine usually requires multiple doses, often followed by booster doses, for attaining long-term protective immunity. In one case, short-term protection was demonstrated following a single dose of a formalin-inactivated hepatitis A vaccine in children 2 to 16 years of age who remained free of infection at 10 months follow-up.[78] These vaccines usually function by stimulating humoral immune responses and by priming for immunological memory and may stimulate CTL immunity when administered with certain adjuvants and delivery

systems. Multiple approaches exist for developing inactivated vaccines; they are discussed below starting with the classic approaches, followed by recombinant strategies.

Whole Pathogen

The earliest technology in the 20th century was the only one technically feasible at that time when there was essentially no definition of specific antigens and their role in immunity. The inactivation of whole bacteria or whole viruses had the objective of eliciting the formation of antibodies to many antigens, from which some antibodies presumably would neutralize the pathogen or its virulence determinants.

Inactivated Bacteria. These vaccines are prepared by cultivating the bacteria (e.g., *Bordetella pertussis*) and inactivating the whole cells with heat or chemical agents (e.g., thimerosal or phenol[79]) without further purification. Owing to their highly crude nature, the reactogenicity of such vaccines when given parenterally was greater than that of other types of vaccines. This led to the development of a series of new acellular vaccines (subunit vaccines) which is described in Chapter 44. On the other hand, inactivated whole-cell *V. cholerae*[80] and enterotoxigenic *Escherichia coli* (ETEC)[81] vaccines are well tolerated by the oral route. Even though the ETEC vaccine is now under active development, it seems less likely that new bacterial vaccines will be made in this manner given the number of alternative technologies available for preparing purified vaccines and the more exacting regulatory standards that have developed over time.

Inactivated Virus. Inactivated viral vaccines, prepared by this old technology, have been available for many decades, and are usually very well tolerated. Viruses are shed into cell culture media, cell-free media from infected cultures is collected, and the large size of the virus particles relative to other macromolecules in the media enables the particles to be enriched readily by straightforward purification techniques. Successes include poliovirus,[82] influenza virus,[83] rabies virus,[84] and Japanese encephalitis virus[85] vaccines. Alternatively, in the case of killed hepatitis A virus vaccine, infected cells are lysed, and virus particles are purified.[86] Virus particles are inactivated chemically, typically by treatment with formalin, and then may be adjuvanted by adsorption onto an aluminum salt. The key epitopes on the surface of many nonenveloped small viruses that elicit a protective immune response (protective epitope) often are conformational, being formed by the highly ordered assembly of viral proteins into precise structures. For most of the viruses from which inactivated vaccines have been developed,[82–86] it is not possible to mimic the conformation of such epitopes by other technologies (e.g., recombinant polypeptides). Inactivated viral vaccines tend to be highly potent immunogens. Thus, this classic strategy, which has an excellent track record of producing well-tolerated and efficacious vaccines, remains the technology of choice for many viral vaccines. Similar to live vaccines, there have been inactivated vaccines associated with rare adverse events including atypical measles seen with measles vaccine[87] (characterized by febrile illness with headache, photophobia, cough, and unilateral pulmonary infiltrates) and enhanced pulmonary disease with formalin-inactivated RSV vaccine.[88] A newer inactivated adjuvanted influenza vaccine produced using a split-virus approach (where the virus has been disrupted by a detergent)[89] has demonstrated a significant association to a very rare adverse event, narcolepsy, which is not seen with another adjuvanted influenza vaccine produced using a subunit approach (a process that removed/reduced the amount of other influenza viral components besides hemagglutinin and neuraminidase) and is discussed in greater detail later in "Adjuvants."

Whole Human Cells

Some of the designs for cancer vaccines are based on the use of individual tumor-specific antigens, either purified or expressed in a vector. A concern regarding using individual antigens in a vaccine is that the induced immune response following vaccination or administration of antibodies may stimulate antigenic modulation and diminished expression of the target antigen or loss of major histocompatibility complex class I expression or loss of other T-cell receptor–associated signaling, thereby reducing efficacy. The advantage of inactivated allogeneic whole-tumor-cell vaccines is the opportunity to present a wide array of tumor-specific antigens to the immune system. Tumor cell lines are expanded in vitro, pooled, and inactivated. A melanoma vaccine derived from two tumor cell lines and given with a synthetic adjuvant is licensed[90] in Canada, but further development for the European and U.S. market was discontinued.[91] In addition, autologous tumor cells modified with the hapten dinitrophenol and adjuvanted with BCG have shown evidence of clinical benefit for melanoma and was initially licensed in Australia but subsequently withdrawn and eventually discontinued because of financial constraints and subsequent decision to discontinue manufacturing.[92,93]

Tumor cells also can be genetically modified to express immunomodulators that may enhance antigen-specific antitumor immune responses. Irradiation of cells transduced with the recombinant vector renders them unable to proliferate, yet still able to secrete the immunomodulator. Autologous melanoma cells are transduced with a recombinant adenovirus expressing granulocyte-macrophage colony-stimulating factor; cells then are irradiated and reinfused to patients with melanoma, resulting in an antitumor effect.[94] Likewise, autologous plasma cells transduced with recombinant adenovirus expressing interleukin-2 are irradiated and reinfused to patients with multiple myeloma.[95]

Protein-Based/Subunit Vaccines

Given the complexities discussed previously for inactivated vaccines, developing a (purified) protein-based vaccine is the favored strategy for many pathogens in which the isolated polypeptides contain the protective epitopes. Protein-based approaches have relied on genetic, biochemical, and immunological analyses to identify the specificity of protective antibodies to polypeptide antigens. Genomics also has enabled the identification of new vaccine antigens. Once the complete sequence (or portions thereof) of the genomic DNA or RNA becomes available, open reading frames are identified. Then, the derived amino acid sequences are inspected for features suggestive of surface localization (e.g., homologies with other proteins that are vaccine candidates or a hydrophobic N-terminal sequence). The genes are expressed in a recombinant host cell (typically *E. coli*), and the recombinant polypeptide is purified and used to immunize animals. Alternatively, the gene is injected into mice as a DNA vaccine (see "Nucleic Acid–Based Vaccines" later). The derived antisera can be used in biological assays (neutralization of viruses, opsonization of bacteria, or binding to the pathogen or human cancer cell surface) to see whether the protein may be an attractive vaccine candidate. The new protein is also used in animal challenge models. One of the earliest applications of genomics technology to viruses was to hepatitis C virus following the cloning of its viral genome.[96] The application of genomics to *Neisseria meningitidis* was accompanied by the analysis of approximately

600 putative proteins, resulting in the identification of several leading candidate vaccine antigens through a process now termed *reverse vaccinology*.[97] This meningococcal vaccine has now been licensed for use in Europe, Canada, the United States, and Australia.[98]

Numerous discovery technologies have been used to identify human proteins (or carbohydrates) that are candidate cancer vaccine antigens, including unique tumor-specific and tissue-specific antigens and shared disease-related antigens expressed in a range of tumors but not in normal adult tissues.[99] These antigens have been engineered and formulated into vaccines based on their polypeptides (or carbohydrates) by means of many of the technologies described subsequently.

Viral Targets for Protein-Based Approaches. The first protein-based vaccines relied on natural sources of antigens. In this regard, the first hepatitis B vaccine is unique in using a human source (plasma) for the vaccine antigen. Liver cells of persons chronically infected with hepatitis B virus (HBV) shed excess viral surface protein into the blood; that is, hepatitis B surface antigen (HBsAg). HBsAg was identified as a 22-nm lipoprotein particle antigen with protective epitopes. To develop a vaccine, plasma was harvested from long-term chronic hepatitis B carriers, HBsAg purified, and the final preparation subjected to one to three inactivation techniques (depending on the manufacturer) to kill HBV and any other adventitious human agents possibly present in the starting plasma.[100] This vaccine was well tolerated and highly efficacious, but is no longer used as the vaccine can now be made by recombinant technology.

Bacterial Targets for Protein-Based Approaches. Proteins purified from cultures of *B. pertussis* have been combined to formulate acellular pertussis vaccines, which have replaced whole-cell pertussis vaccine for routine pediatric vaccinations in most developed countries. Depending on the number of different protein antigens, these licensed acellular pertussis vaccines are referred to as one-, two-, three-, four-, or five-component vaccines.[101–103] These vaccines all contain pertussis toxoid,[104] which when combined with other pertussis antigens, comprises the acellular pertussis vaccines. One preparation of the pertussis toxoid component is described in "Genetic Inactivation" later.

Tumor Cells. Proteins isolated from individual tumors have been used as cancer vaccines. In one application, individual tumors were isolated, the autologous gp96 heat-shock protein was purified from each tumor, and the heat-shock protein preparation was injected into the respective subject, resulting in stimulation of CTL responses.[105]

Chemical Inactivation. Many bacteria produce protein toxins that are responsible for the pathogenesis of disease, including tetanus and diphtheria. The toxin molecules are purified from bacterial cultures (*Clostridium tetani* [T], and *Corynebacterium diphtheriae* [D]), and then detoxified by incubation with a chemical such as formalin or glutaraldehyde. These detoxified toxins, referred to as *toxoids*, are included in the diphtheria, tetanus, and pertussis (DTP) combination vaccine.[106,107]

Genetic Inactivation. The chemical "toxoiding" procedure has the disadvantages of potential alteration of protective epitopes (with ensuing reduced immunogenicity) and the potential for reversion to a biologically active toxin. However, rDNA technology can be used to produce a stable toxoid. For example, pertussis toxin was mutated (in two locations to ensure stability) to reduce its enzymatic activity. The altered gene was substituted for the native gene in *B. pertussis*, resulting in an immunogenic but stably inactivated pertussis toxoid.[108] This double-mutant pertussis toxoid (which also is treated with formalin under mild conditions to improve its immunogenicity or stability) is a component of one particular acellular pertussis vaccine,[101] which is not in use clinically at this time, while other acellular pertussis vaccines use nonrecombinant pertussis toxoid and are described in more detail in Chapter 44. A genetic approach to derive a D toxoid also was successful following the mutation of *C. diphtheriae* cultures and screening for enzymatically inactive yet antigenic toxin molecules. This genetic toxoid (CRM_{197})[109] is the protein carrier for a licensed *Haemophilus influenzae* type b (Hib) conjugate vaccine and pneumococcal conjugate vaccine (see later section). This technology also has been applied to *V. cholerae* toxin and ETEC toxin to produce candidate mucosal adjuvants (see later section).

Recombinant Polypeptides. The expression of recombinant polypeptides as subunit vaccines arguably has been the most extensively used and widely accepted application of rDNA technology to the development of new vaccines and these approaches are summarized.

Particle-Based Vaccines. The first application of rDNA technology to the production of a vaccine was for hepatitis B through the expression of the HBsAg gene in baker's yeast *Saccharomyces cerevisiae*,[110] giving rise to 22-nm HBsAg particles. In contrast, expression of the HBsAg gene in *E. coli* gave rise to HBsAg polypeptides but not HBsAg particles. These HBsAg virus-like particles (VLPs) were very similar in structure to HBV virions. Purified yeast-derived HBsAg is adjuvanted with aluminum salts and this vaccine has largely supplanted the equally efficacious and well-tolerated plasma-derived vaccine that was initially approved by the U.S. Food and Drug Administration in 1981 and subsequently discontinued in 1990 (no longer available in the United States). With the goal of an edible vaccine, HBsAg also has been expressed in transgenic potato tubers and has been shown to be safe and immunogenic in clinical trials.[111]

Particles are almost always more immunogenic than individual polypeptides (Fig. 66.1). Furthermore, particles (including VLPs) usually elicit antibodies to conformational epitopes on the particle (and on the respective virus), whereas isolated surface polypeptides of the particle might not. Examples of such particle immunogens are hepatitis A virus virions (immunogenic in humans at dosage levels as low as 50 ng) and VLPs for human papillomavirus (HPV). The HPV virion is a highly ordered structure whose major protein is L1 and when expressed in eukaryotic cells, results in the formation of VLPs that elicit HPV-neutralizing antibodies. Bivalent, quadrivalent, and nonavalent vaccines have been shown to be highly effective and have been licensed.[112–114]

Natural Protein Sequences. There are innumerable ongoing applications of rDNA technology to produce natural proteins as candidate vaccine antigens for viral, bacterial, and parasitic infections. The major *Borrelia burgdorferi* surface protein (OspA [outer surface protein A]), expressed in *E. coli* as a recombinant lipoprotein,[115] was licensed for the prevention of Lyme disease, but is no longer produced. Recombinant HIV-1 gp120 (rgp120) expressed in Chinese hamster ovary (CHO) cells[116] has been formulated into a vaccine that was in Phase III clinical studies and was reported to have no efficacy in the populations studies.[117,118] Similarly, CHO cell–derived recombinant HSV glycoproteins were evaluated in Phase III clinical trials[119] and demonstrated overall efficacy of 9%, with no effect on the duration of the first clinical episode of genital HSV-2 or the frequency of subsequent recurrences. A *N. meningitidis* serogroup B vaccine composed of two recombinant lipidated

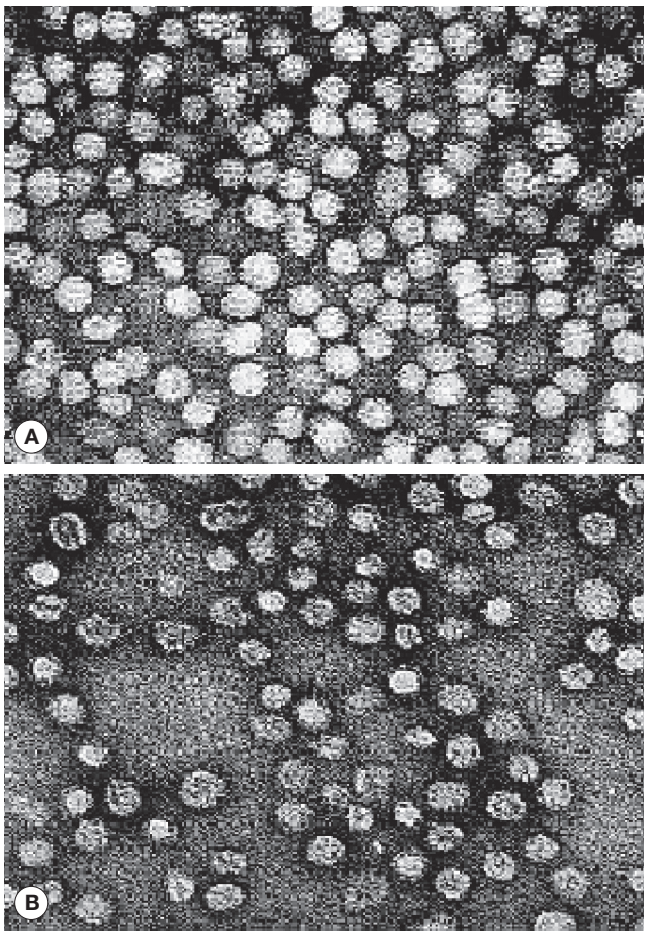

Figure 66.1. A, Recombinant hepatitis B virus–like particles. **B,** Recombinant human papillomavirus virus–like particles.

factor H binding protein variants individually produced in *E. coli* was licensed in the United States for individuals 10 to 25 years of age.[120] Finally, an AS01 adjuvanted[121] subunit vaccine containing recombinant varicella-zoster virus glycoprotein E has demonstrated 97% efficacy in a Phase III clinical trial for reducing the risk of shingles in adults older than 50 years of age[122] and provides a safer alternative for subjects with impaired cellular immunity (and at greatest risk for herpes zoster) for whom the previously approved live attenuated herpes zoster vaccines is contraindicated.[123]

Fusion Proteins. Recombinant fusion proteins containing multiple peptide sequences have been expressed as multiepitope vaccine antigens. A fusion protein containing the extracellular domains of two *Streptococcus pneumoniae* surface proteins has been evaluated in clinical studies.[124] A recombinant *Streptococcus pyogenes* vaccine consisting of 26 M protein type-specific peptide sequences integrated into four recombinant fusion proteins has been shown to stimulate responses to all 26 included *S. pyogenes* serotypes.[125] Similarly, the expression of four of five antigens, as fusion proteins, in the *N. meningitidis* serogroup B (MenB) vaccine increased immunogenicity,[126,127] and has been licensed for use in individuals from 2 months of age and older.[128]

Some of these vaccines are the products of the application of a new technology called *structural biology*. Purified proteins are grown into crystals whose X-ray diffraction pattern reveals the structure of these proteins. As of 2017, more than 126,000 biological molecular structures have been deposited into online protein data banks. Some of these structures for purified proteins help develop better vaccines by revealing their function and molecular interactions, while other structures, such as those for protective antibodies in subjects controlling their infections, help researchers understand why they are effective and what immunogens they are specifically recognizing so that recombinant immunogens can be designed that specifically reelicit these antibodies.[129] Two noteworthy efforts highlighting the power of structural biology are HIV-1 and RSV vaccine development. For example, structural biology has been used in the design of vaccines for HIV-1 by deciphering how neutralizing antibodies recognize the viral spike which targets the virus to specific receptors on host cells, an approach also being used for influenza and Ebola vaccines.[130–133] For RSV, structural biology revealed that RSV neutralization by the humanized monoclonal antibody motavizumab (which is 10-fold more potent than the licensed antibody palivizumab and differs only by 13 residues) was likely because of the recognition of a different quaternary configuration of the fusion (F) glycoprotein.[134] Motavizumab either binds to or induces a conformation of the trimeric F glycoprotein that is different from that observed in the PIV5 F prefusion structure. Subsequent structural biology studies on the RSV F glycoprotein identified prefusion-specific antibodies that were more potent than the licensed monoclonal antibody palivizumab and bound to a newly identified site of vulnerability named antigenic site ∅.[135] These effort led to the design of a fusion glycoprotein vaccine maintaining this newly identified site that elicited levels of RSV-specific neutralizing activity many times the protective threshold in immunized mice and macaques.[136]

Noninfectious Disease. Vaccine applications for allergy, oncology, and autoimmunity have also been evaluated. Because crude extracts from allergens such as ragweed can be administered to ameliorate allergic symptoms, allergen-encoding genes, expressed in a heterologous host cells, have also been designed. A recombinant dust-mite allergen polypeptide has been engineered to reduce its capacity to induce in vivo skin-test reactivity and in vitro histamine release from basophils of allergic patients, while retaining essential T-cell epitopes.[137]

Before the clinical symptoms of type 1 diabetes develop, autoantibodies become detectable to pancreatic β-cell autoantigens (e.g., insulin), following which β cells are destroyed by autoimmune attack. A range of recombinant autoantigens can prevent the development of type 1 diabetes in mouse models. Subsequent clinical trials have shown that subcutaneous injection of recombinant *E. coli*–derived insulin into prediabetic patients resulted in a significant delay in the development of clinical type 1 diabetes.[138] Studies of the intranasal instillation of recombinant insulin have also been promising.[139] An initial Phase I/II study using an engineered DNA plasmid encoding proinsulin has been demonstrated to preserve β-cell function in type 1 diabetes through the reduction of insulin-specific T cells.[140] While promising, the effects of this DNA-based vaccine need to be confirmed in larger clinical studies which are planned.

Custom Design. Recombinant fusion proteins can be custom designed for specific immunological purposes. Based on the observation that microbial heat-shock proteins can induce $CD8^+$ CTLs, immunization of mice with a fusion of *M. bovis* BCG heat-shock protein-65 with HPV-16 E7 protein was shown to induce $CD8^+$ therapeutic efficacy against HPV $E7^+$ tumor cells.[141] This fusion protein has advanced into clinical trials for treatment of HPV-associated malignancies.

DNA Shuffling. Rather than creating a specifically designed molecule, it is also possible to iteratively create new recombinant molecules and screen and select the ones with desired

immunological properties as vaccine candidates. This *DNA shuffling* method has been applied to a range of vaccine candidates including *Plasmodium* falciparum, dengue virus, HIV-1, and hepatitis B but have not entered clinical testing.[142]

Host Cell Expression Systems. Many host cells have been used for the expression of heterologous recombinant genes (Box 66.1), including a range of bacterial and yeast cells and mammalian continuous cell lines (CCLs), such as CHO and African green monkey kidney (Vero). Smaller proteins not requiring posttranslational modifications generally can be expressed in immunogenic form in microbial expression systems. In 2013, an influenza vaccine was licensed that contains recombinant hemagglutinin protein produced in a continuous insect cell line using a baculovirus vector and is approved for use in people 18 to 49 years of age,[143] the first licensed pharmaceutical product made in insect cells.

Other nonvaccine proteins produced in microbial expression systems have been developed and licensed for human therapeutic applications; such proteins include insulin, growth hormone, interferons, and interleukin-2. In contrast, polypeptides that require appropriate folding and posttranslational modifications (e.g., glycosylation) for optimal immunogenicity or activity are expressed in mammalian CCLs. Licensed nonvaccine therapeutic proteins produced in mammalian CCLs include tissue plasminogen activator, erythropoietin, colony-stimulating factors, and monoclonal antibodies (MAbs). Whole animals (sheep, cattle, and goat) and plants (e.g., tobacco) also can be used as hosts for recombinant protein expression.[144,145]

Peptide Based

B-cell epitopes against which neutralizing antibodies are directed (neutralization epitopes) usually can be identified in a polypeptide. Some B-cell epitopes are conformational (as in VLPs), being formed by the juxtaposition in three-dimensional space of amino acid residues from different portions of the polypeptide, meaning that such epitopes require the full polypeptide for proper immunogenicity. In contrast, other peptide epitopes are linear, being fully antigenic as sequences of between six and 20 amino acid residues. Many linear epitopes are weakly immunogenic when presented in the context of the full polypeptide, such that the full or partial polypeptide containing a neutralization epitope might not be an effective immunogen for that epitope (a hypothetical mechanism for a pathogen to escape immunological surveillance). For example, a linear neutralization epitope has been defined for the *P. falciparum* (malaria) circumsporozoite protein (repetitive four-amino-acid sequence).[146] The circumsporozoite polypeptide contains a linear epitope that is recognized by neutralizing antibodies, yet the whole polypeptide elicits such antibodies only weakly. However, several approaches have addressed the immunogenicity of peptides containing B-cell epitopes and peptides with T-cell epitopes and are listed in Table 66.1, including fusion proteins, fusion peptides, and conjugation for example.

B-Cell Epitopes

Aggregate. Some peptides have the ability, under appropriate incubation conditions, to form small or large aggregates that are more immunogenic. The Aβ protein, associated with the development of Alzheimer disease, is processed into a 42-amino-acid peptide that forms large fibrils and soluble aggregates in vivo. A candidate Alzheimer disease vaccine was formulated by incubating Aβ peptide (1 to 42) into insoluble fibrils. This vaccine was shown to prevent the development of dementia in a transgenic mouse model of Alzheimer disease.[147] In initial clinical studies in humans, vaccination induced cellular immune responses that were associated with serious adverse events[148] (e.g., aseptic meningoencephalitis) such that the design of the vaccine is being refined.

Fusion Protein. The immunogenicity of peptide epitopes can be increased by genetic fusion to a carrier protein particle. Two such fusion partners are HBsAg[149] and hepatitis B core antigen,[150] a 28-nm HBV-encoded particle. The peptide fusion can be at the N- or C-terminus or at an internal sequence of the carrier protein, depending on which location provides the best immunogenic presentation while maintaining particle formation. A fusion of a circumsporozoite peptide to HBsAg has shown clinical promise as a malaria vaccine and results from an 18-month follow-up postvaccination demonstrated that three doses of this AS01-adjuvanted vaccine resulted in a vaccine efficacy of 46% in children and 27% in infants, and could be an important addition to current malaria control in Africa.[151] A positive opinion has been received from the European Medicines Agency's Committee for Medicinal Products for Human Use (CHMP) on July 24, 2015, for use outside the European Union despite its limited efficacy because the benefits of the vaccine outweighed the risk in both age groups studied (especially to children in high transmission areas in which mortality is very high).[152] Melanoma-associated antigen 3 (MAGE-A3) is a tumor-specific protein identified on melanoma cells, non–small cell lung cancers, and hematologic malignancies.[153] A cancer vaccine composed of a fusion protein of MAGE-A3 and *H. influenzae* protein D and a proprietary immunoadjuvant was developed as a therapeutic vaccine against lung cancer, but development was recently halted after results from a Phase III study showed that it did not meet its primary end point in significantly extending disease-free survival.[154]

Fusion Peptide. A B-cell epitope from the target protein can be rendered immunogenic by fusion to a T-helper (Th) epitope. A 16-amino-acid peptide from cholesterol ester transfer protein fused to a 14-amino-acid Th epitope from tetanus toxoid (TT) increases plasma high-density lipoprotein and

decreases aortic lesions in rabbits fed a cholesterol-rich diet. It also has been shown to induce anti–cholesterol ester transfer protein antibodies in humans.[155] The Phase II study, however, did not meet the primary end point of increasing plasma high-density lipoprotein–cholesterol concentrations in the vaccine-treated groups as compared to the placebo groups, so further preclinical studies using adjuvanted vaccines are ongoing.[156]

Conjugate. The peptide is synthesized with a reactive amino acid residue, through which it can be covalently linked or conjugated to a carrier protein. The most commonly used carrier proteins in conjugates are bacterial proteins that humans commonly encounter such as TT, for which a conjugate with the malarial circumsporozoite epitope has been tested clinically.[157] Conjugation technology also has been applied to the formulation of a fertility vaccine based on human chorionic gonadotropin (hCG) or luteinizing hormone–releasing hormone. Antibodies to these peptide hormones have been shown to inhibit fertilization, although both luteinizing hormone–releasing hormone and hCG are poorly immunogenic. Conjugates of hCG or luteinizing hormone–releasing hormone to TT elicit antibodies that inhibit fertilization in laboratory animals and have been evaluated clinically as fertility vaccines.[158] Furthermore, because hCG is expressed on pancreatic and prostate tumor cells, an hCG conjugate vaccine has been evaluated clinically as a therapeutic cancer vaccine.[159] A peptide from the tumor-specific antigen MUC-1 conjugated to keyhole limpet hemocyanin has been evaluated for immunotherapy of non–small cell lung carcinoma.[160]

Complex Peptide. Multimers of the peptide sequence, such as multiple antigen peptides, can be synthesized for linkage in repeated arrays with resultant increase in peptide immunogenicity,[161] as shown with the malarial circumsporozoite peptide epitopes.[162] The application of the four aforementioned strategies to weakly immunogenic peptides has resulted in immunogenic presentations that elicit substantially increased titers of neutralizing antibody compared with those elicited by the epitope presented alone as a peptide or in the context of its natural full-length polypeptide. Nevertheless, the most effective strategy in terms of ultimate clinical usefulness is established on a case-by-case basis.

Mimotopes. By screening peptide libraries with antisera, peptides (mimotopes) can be identified that antigenically mimic the immunogen reactive with such antisera. This approach is a way to create an immunogen that cannot be produced readily by recombinant or synthetic methods. A peptide mimotope on the HBsAg S polypeptide, which reacts with antibodies to HBsAg, elicited antibodies to HBsAg when fused with a carrier protein.[163] The LeY antigen is a neolactoseries carbohydrate expressed on human tumor cells. Given the difficulty in isolating or synthesizing sufficient quantities of this carbohydrate for use as a vaccine immunogen, a peptide mimotope was isolated that mimics LeY; immunization of mice with a multiple antigen peptide mimotope elicited anti-LeY antibodies and reduced tumor growth in a mouse tumor model.[164] It also has been possible to use peptides that mimic carbohydrate epitopes on HIV-1 to elicit HIV-1–neutralizing antibodies.[165]

T-Cell Epitopes. Effective immune prophylaxis or therapy for some diseases requires CTL or other T-cell immunity rather than neutralizing antibodies. T-cell epitopes elicit various T-cell immune functions and have been applied mostly to therapeutic vaccines

Cytotoxic T-Lymphocyte Epitopes. Peptide epitopes recognized by CTLs may be useful immunogens for HIV and *M. tuberculosis* or immunotherapy for chronic diseases such as hepatitis B. CTL peptide epitopes generally are poor immunogens. Thus, for an immunotherapeutic hepatitis B vaccine, a CTL epitope from the HBV core protein was modified by covalent linkage to a Th epitope (from TT) and two palmitic acid molecules.[166] This vaccine was shown in clinical studies to be effective in eliciting HBV-specific CTLs and memory CTLs. T-cell epitope peptides conjugated to the cytosine phosphate guanine (CpG) oligonucleotides adjuvant show enhanced CTL activity against HIV.[167]

T-Cell Activation. Peptides that bind to human leukocyte antigen on the tumor surface can be formulated as mixtures of tumor-associated peptides. Injected tumor-associated peptides can activate T cells to attack and destroy tumor cells. The most advanced vaccine is in a Phase III clinical study for kidney cancer.[168]

T-Cell Receptor. Therapy of autoimmune disease can involve *T-cell vaccination*,[169] for which the target antigen is the T-cell receptor and the goal is to reduce T-cell–mediated autoimmune activity. This approach has been applied successfully for glatiramer acetate,[170] a peptide copolymer of alanine, lysine, glutamic acid, and tyrosine that is licensed for the immunotherapy of multiple sclerosis. It may function by inducing a shift from Th1 responses to glatiramer acetate–specific Th2 cells, which can mediate bystander suppression and, thus, ameliorate autoimmune antimyelin responses.

Carbohydrate and Polysaccharide Based. Many bacteria have an outer polysaccharide capsule. Antibodies directed against capsular polysaccharide are protective for most encapsulated bacteria, thus establishing capsular polysaccharide as leading vaccine antigens. Components of lipopolysaccharide, another abundant surface molecule on gram-negative bacteria, also may be vaccine antigens. Carbohydrates specific to the surface of certain types of cancer also have been used as vaccine antigens.

Polysaccharide. The natural capsular polysaccharide contains up to hundreds of defined repeat units distinct for each bacterial species and antigenic subtype; each monomer consists of monosaccharides, phosphate groups, and other small organic moieties. The polysaccharide is shed by the organism during its growth and is harvested and enriched from the culture medium. These polysaccharide preparations are usually immunogenic in adults and children older than age 2 years. The polysaccharide elicits antibodies that may mediate bacteriolysis or opsonization of the organism, thereby protecting against infection. Polysaccharide vaccines have been licensed for Hib[171] (monovalent), *N. meningitidis*[172] (quadrivalent), and *S. pneumoniae*[173] (tridecavalent). The shortcomings of these vaccines are that the polysaccharides, being T-cell–independent immunogens, are poorly immunogenic in children younger than age 2 years owing to the immature status of their immune systems, and polysaccharides do not elicit immunological memory or booster activity in older children and adults.

Conjugated Polysaccharide. Infants and children younger than age 2 years respond immunologically to T-cell–dependent immunogens such as proteins. Conjugation of a polysaccharide to a carrier protein converts the polysaccharide from a T-cell–independent to a T-cell–dependent immunogen. Consequently, polysaccharide conjugate vaccines can elicit protective immunoglobulin (Ig) G and immunological memory in infants and young children. Thus, conjugate vaccines using different carrier proteins display one or more differences in the following properties: response of 2-month-old infants to the first dose of vaccine, responses of 4- and 6-month-old infants to the second and third doses, response of children older than age 1 year to a booster dose, kinetics of decay of antibody levels, peak antibody titer, and age at which protection first can be shown. This strategy is important

particularly for encapsulated bacteria such as Hib, *S. pneumoniae* (pneumococcal), and *N. meningitidis* owing to the preponderance of invasive diseases caused by these bacteria in children younger than age 2 years.

The Hib bacteria are a single serotype (b). There are several licensed Hib conjugate vaccines[174] with different carrier proteins (TT, diphtheria toxoid, CRM_{197}, and an outer membrane protein complex from *N. meningitidis*) of different sizes, distinct polysaccharide chain lengths, and distinct conjugation chemistries that result in different immunological characteristics. For example, even though the Hib conjugate vaccine using outer membrane protein generates a rapid response, the Hib conjugate vaccine using CRM_{197} generates a much higher response.

Pneumococcal bacteria consist of approximately 90 serotypes, as reflected in distinct capsular polysaccharide structures. For designing a pediatric pneumococcal conjugate vaccine, seven serotypes have been established as responsible for approximately 60% to 75% of the major pediatric pneumococcal diseases (acute otitis media, pneumonia, meningitis) in developed countries, and a heptavalent pneumococcal conjugate vaccine was the first pneumococcal conjugate vaccine licensed for pediatric use.[175] A tridecavalent conjugate vaccine (PCV13) consisting of a mixture of 13 individual pneumococcal polysaccharide conjugates was licensed in 2010, and represents the vaccine with the most conjugate antigens included.[176–178] There was also licensed in 1983 a 23-valent pneumococcal polysaccharide vaccine (PPSV23) that contains more antigens, but these are not conjugated. Therefore, PPSV23 potentially affords broader protection against invasive pneumococcal disease because it covers a larger proportion of serotypes (85% to 90% compared to PCV13's greater than 60%) but does not demonstrate the higher immunogenicity seen with the conjugated vaccine.[179]

Invasive meningococcal disease is caused by *N. meningitidis* strains expressing one of five diverse capsular polysaccharides: A, B, C, W135, or Y. A quadrivalent meningococcal conjugate vaccine (A, C, W135, or Y) has been available for use in people in the United States and Canada based on the diphtheria toxoid carrier protein. A conjugate vaccine based on the mutant diphtheria toxin (CRM_{197}) also has been developed to provide immunity in children younger than age 2 years and is currently indicated for use in adolescents and adults.[180,181]

A conjugate of group B streptococcal polysaccharide has been used to immunize pregnant women[182] for the prevention of neonatal group B streptococcal meningitis. In this case, the polysaccharide conjugate vaccine would be advantageous over a polysaccharide vaccine in terms of eliciting high enough anti–polysaccharide antibody titers to enable sufficient protective IgG to cross the placenta to the fetus.

Other Carbohydrate. Tumor cells have specific carbohydrate structures lacking or deficient in other cell types. Such carbohydrates may have usefulness as cancer vaccines. Examples include the use of STn carbohydrate for ovarian and breast cancer[183] and GM_2 ganglioside for melanoma.[184] Such carbohydrates are rendered more immunogenic by conjugation to carrier proteins, as is done for capsular polysaccharide vaccines.

Other

Other technologies include those related to antiidiotypic antibodies and the conjugation of derivatives of drug substances to the B subunit of CT. Anti–idiotypic antibodies[185] represent a feasible vaccine strategy as demonstrated by the immunization of chimpanzees with anti–idiotypic antibodies mimicking HBsAg that protected from HBV infection.[186] Applications of this strategy to cancer therapy have involved the use of the anti–idiotypic antibodies as a mimic of a tumor antigen (but not identical and therefore not a self-antigen) to elicit an immune response against the tumor antigen.[187] Similar applications have been developed for metastatic breast cancer[188] and for parasitic infections caused by *Schistosoma mansoni*.[189] A highly novel approach has been to develop a vaccine to counter addiction to cocaine based on preclinical observations that antibodies can bind and clear cocaine. A derivative of cocaine conjugated to the B subunit of CT has been shown to induce anticocaine antibodies in cocaine abusers and in cocaine-abstinent subjects, with some indication of attenuation of cocaine's euphoric effects.[190]

Nucleic Acid–Based Vaccines

A technology that became fashionable during the 1990s was the use of DNA encoding vaccine antigens. The in vitro model for this technology lay in the transformation of cells in culture with a plasmid that directs the synthesis of a vaccine antigen. After cells in vivo take up DNA encoding vaccine antigens, the antigens can be secreted or associated with the cell surface in a way that triggers both humoral or cellular immune responses. DNA uptake was facilitated by chemical formulation, electroporation, or delivery by a nonreplicating virus or bacteria; the nonreplicating virus or bacteria approach fits the definition of a DNA-based vaccine (nonreplicating in vivo). Although this approach awaits clinical proof of principle, it is considered to have much long-term potential. Because the principles for both DNA and RNA approaches are similar in nature, the following examples focus on DNA but conclude with a summary of nonviral delivery approaches focusing on RNA.

Naked DNA

The initial strategy has been to inject intramuscularly a solution of uncoated or *naked* DNA encoding a vaccine antigen.[191] Cells take up the DNA, transcribe its expression cassette, and synthesize the antigen, which may be processed similarly to a live viral infection. Humoral or cellular immune responses to the encoded antigen are elicited (Fig. 66.2). The advantages of DNA vaccines are the relative technical ease of production and the ability to direct the synthesis of multiple copies of messenger RNA, hence amplification of antigen synthesis and

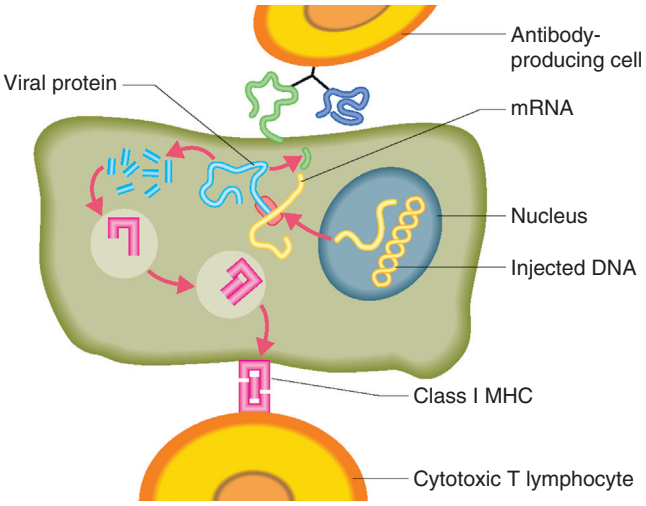

Figure 66.2. Injection of DNA encoding a foreign protein can elicit antibodies and cytotoxic T lymphocytes. MHC, major histocompatibility complex; mRNA, messenger RNA.

immune responses. Such vaccines have been shown to be effective in many animal models of infection, especially virus models.[192] Theoretical safety-related issues needed to be addressed for DNA vaccines as a novel technology. Preclinical studies showed that these vaccines did not induce detectable anti-DNA antibodies. Furthermore, the frequency of integration of plasmid DNA into chromosomal DNA was undetectable and was calculated to be much less than the rate of spontaneous integration events.[193]

Clinical studies with naked DNA vaccines for influenza, HIV, and malaria have shown these vaccines to be well tolerated.[194,195] This first generation of DNA vaccines was shown to elicit low and sporadic levels of specific antibodies and was ineffective. Subjects receiving approximately 1 mg of malaria DNA vaccine generated specific CTL activity. Beyond an excellent safety profile, these initial clinical data have shown that the immunogenicity of naked DNA vaccines needed to be augmented to be clinically effective, as discussed in the next section. These vaccines may have their best usefulness for inducing cell-mediated immune (CMI) responses or as priming doses in prime-boost regimens (see later section).

Facilitated DNA

Delivery. Facilitation can be at the level of cellular uptake of DNA, expression of messenger RNA, or immunological activation. DNA has been incorporated into microprojectiles that then are "shot" directly into cells, which then produce the encoded antigen that stimulates an immune response. DNA can be coated onto gold microparticles and delivered as dry powder into the epidermis with a needle-free device; such a hepatitis B vaccine was shown to be immunogenic.[196] For increasing uptake, DNA has been coated with cationic lipids, lipospermines, or other molecules that neutralize its charge and have lipid groups for facilitating transfer across membranes.[197] Such formulations also are being investigated for alternative routes of injection (besides parenteral) that may elicit mucosal immunity. The anesthetic bupivacaine given in conjunction with DNA enhances DNA uptake and expression.[198]

Composition. The base composition of the DNA may affect its potency. Unmethylated CpG dinucleotides, which are present in bacterial but greatly underrepresented in mammalian DNA, represent structures that stimulate innate immunity in response to bacterial infection. As part of DNA vaccines or as adjuvants per se (see later section), CpG dinucleotides have been shown to induce B-cell proliferation and Ig secretion, thereby modulating immunogenicity.[199]

While DNA vaccines elicit specific antibodies, they are particularly proficient at eliciting cellular immune responses, including CTLs. Therefore, naked (or facilitated) DNA vaccines may be useful in cancer immunotherapy as is being investigated with a plasmid DNA-lipid complex for metastatic renal cell carcinoma[200] or with interleukin-2 cytokine delivery as a plasmid formulation for treating melanoma which moved into Phase III studies.[195] A Phase I clinical trial for metastatic melanoma using plasmid pUMVC3-hIL-12-NGVL3 and electroporation to deliver antigens/cytokines directly into tumors demonstrated varying levels of tumors regression in patients.[201]

Viral DNA Vector

A variation on the design of the expression plasmid is to use a virus-based DNA expression system that can amplify the level of RNA and protein expression as occurs in a live virus infection. Such a system has been developed based on Sindbis virus DNA vectors.[202]

Viral RNA Vector

A self-replicating RNA encoding a tumor antigen can be used as a nucleic acid–based vaccine. Plasmids encoding RNA replicase of Semliki Forest virus and antigens of interest are subsequently digested to generate a DNA fragment which undergoes in vitro transcription into RNA. When injected, this RNA mediates the production of the replicase polyprotein and drives the replication of the antigen of interest. Using this approach, prophylactic and therapeutic RNA immunization elicited antibodies and CTL activity protecting mice from tumor challenge or prolonging survival, respectively.[203] Efficacy correlated with apoptotic death of transfected cells, followed by DC uptake of dead cells, which could provide a mechanism for enhanced immunogenicity.

Noninfectious RNA can be used to mimic immunization with a live flavivirus[204]; following transfection to host cells, noninfectious subviral particles are secreted. The delivery to mice of gold microparticles coated with RNA elicits neutralizing antibodies and protection against lethal challenge.

Viral Delivery

For DNA vaccine delivery by fowlpox or canarypox virus, the expression cassette for the recombinant protein is integrated into the viral genome. Although able to productively infect avian cells, these poxviruses can infect mammalian cells and produce protein products but not infectious virus.[205,206] This single round of self-limiting infection may suffice to elicit broad immunity to a pathogen whose recombinant polypeptide is expressed by these avian poxviruses in infected cells, while reactogenicity would be less than that associated with vaccinia virus (given the inability of the avian poxviruses to spread). Fowlpox virus has been tested as part of a DNA prime (pHIS-HIV-B) and a recombinant fowlpox virus (rFPV-HIV-B) boost regimen.[207,208] Canarypox virus (see "Viral RNA Vector" above) expressing HIV-1 rgp160 or rgp120 has been used as part of a prime-boost HIV-1 vaccination regimen (see later section).[209,210]

Bacterial Delivery

Bacteria that replicate intracellularly can be engineered to deliver plasmid DNA into host cells for expressing vaccine antigens.[211] *S. flexneri* has been attenuated by a deletion mutant in the *asd* gene, an essential gene. While such a strain can be propagated in vitro in the presence of diaminopimelic acid and can invade cells (as long as it maintains a plasmid encoding invasion- associated polypeptides), it cannot replicate in vivo, where diaminopimelic acid is unavailable. A plasmid harboring a eukaryotic promoter and recombinant gene was transformed into this strain. The resultant recombinant *S. flexneri* strain was able to invade mammalian cells in vitro and to express the plasmid-encoded protein as a vaccine antigen. Because *S. flexneri* replicates in the intestine and stimulates mucosal immunity, this vector may be delivered orally for delivering DNA to cells where mucosal immunity is stimulated. Other bacterial species that can invade mammalian cells but not divide also may be able to deliver recombinant plasmids to different cell types for expressing recombinant proteins as vaccine antigens.

Nonmicrobial RNA Delivery

Injection of naked messenger RNA or self-amplifying RNA generates immune responses but has limited potency because of RNA instability in vivo.[212] Therefore, messenger RNA vaccines have been formulated with delivery vehicles including

liposomes and cationic polymers for increasing potency,[213,214] and preclinical studies using this approach have demonstrated prevention of progression and metastasis of melanoma.[215] Based on innovations in systemic delivery of short interfering RNA using lipid nanoparticles, self-amplifying RNA vaccines have also been developed that contain an alphavirus genome encoding only the RNA replication machinery and with the structural protein genes being replaced with the protein antigens of interest. This approach has been found to elicit broad, potent, and protective immune responses comparable to viral delivery technology.[216]

Additional Considerations and Strategies for Active Vaccines

Formulation

The immunogenicity of inactivated, subunit, and DNA-based vaccines may be enhanced by their formulation, which refers to the final form of the vaccine to be administered. In addition to the vaccine *active substance* (antigen or DNA), the formulation also may contain an adjuvant and/or delivery system. The adjuvant is a substance that stimulates an increased humoral and/or CMI response to a coadministered antigen. The delivery system is a vehicle for ensuring the presentation of the vaccine in vivo to appropriate cells of the immune system or for stabilizing and releasing the antigen during an extended period. Many future vaccines are expected to contain new adjuvants and/or delivery systems. There are reviews[217,218] with extensive bibliographies for the wide variety of available experimental adjuvants and delivery systems. Some experimental adjuvants stimulate primarily antibody responses, whereas others stimulate primarily CMI responses, including CTLs. Table 66.4 outlines a range of benefits and challenges associated with the use of novel adjuvants and delivery systems.

TABLE 66.4 Adjuvants and Delivery Systems

Potential Benefits	Key Challenges
Dosage level ↓	Species-specific differences in cells, receptors, signaling pathways, and tissue distribution of common components of the immune system targeted by adjuvants may lead to erroneous conclusions regarding human safety and tolerability
Number of doses ↓	Long-term safety is difficult to ascertain given the indolent nature of chronic adverse events (e.g., autoimmune diseases), the lack of feasibility of long-term follow-up of subjects, and the contribution of differences in human leukocyte antigen genetics to certain safety signals
T-cell responses ↑	Demonstrated need for inclusion in prophylactic vaccines targeting healthy or young subjects has a different benefit-to-risk perception compared to patients with cancer or difficult-to-treat infectious diseases
Antibody level ↑	Analytical definition of adjuvants is complex and impacted by their classification based on source, mechanism of action, or physiochemical properties (e.g., active immunostimulants, carriers, vehicles, route of administration, salts, tensoactive agents, emulsions, particulates, lipopeptides)
Antibody quality ↑	Stability of adjuvants, long shelf life, and biodegradability are ideally expected but not always easily obtained
Responses ↑ for impaired persons	Pharmaceutical definition of what they really are, where the antigen is, and potential for long-term stability for all components
Mucosal immunity	Formulation needs to take into account route of administration and potentially adds complexity/costs to the manufacturing process

Adjuvants

Aluminum Salts. Aluminum salts (hydroxide or phosphate) are the only adjuvants broadly licensed for inclusion in human vaccines. They have been widely used for 70 years and injected into more than 1 billion people worldwide. The vaccine antigen binds ionically to the aluminum salt[219] and preferentially promotes a Th2-type immune response (i.e., antibody-based) and, thus, is not useful for inducing a CMI response. While aluminum salts improve immunogenicity for a number of licensed vaccines (e.g., hepatitis B, pertussis), they do not enhance immune responses to all vaccines.

Given the need to improve on the adjuvanting properties of aluminum salts, many chemicals, biochemicals from natural sources, and proteins with immunomodulatory activity (cytokines) have been studied as potential adjuvants. The adjuvanticity of most known formulations is associated with local or systemic side effects that may be mechanism-based or nonspecific.[220] The ideal adjuvant needs to achieve a balance between safety and immune enhancement. The immunobiology of the particular vaccine application dictates whether one would prefer an adjuvant that would enhance antibody responses or CMI responses.

Other Licensed Adjuvants: MF59, AS03, AS04, Liposomes, and AS01. MF59 (an oil-in-water emulsion) formulated with inactivated subunit influenza vaccine shows increased immunogenicity and acceptable clinical tolerability and has been licensed in Europe since 1997.[221] Another squalene-based oil-in-water emulsion called AS03, was widely used in vaccines for the 2009 H1N1 influenza pandemic.[222,223] Approximately 1 year following the influenza pandemic, reports from some European countries confirmed an association of an AS03-adjuvanted pandemic vaccine with the development of a neurologic sleep disorder, narcolepsy, in vaccinated individuals.[224,225] As of January 2015, more than 1300 cases of vaccine-associated narcolepsy have been spontaneously reported to the European Medicines Agency EudraVigilance database.[226] In contrast, no increased risk has been reported for the MF59-adjuvanted pandemic vaccine,[227] which could lead one to speculate about the safety of certain adjuvants used in vaccines. However, a study published in July 2015 may have established an immunologic link between influenza virus and narcolepsy through antigenic molecular mimicry, thus making the independent role of AS03 in triggering narcolepsy less likely.[228] Specifically, molecular mimicry was identified between a fragment of one of the influenza antigens (nucleoprotein) contained in the AS03-adjuvanted pandemic vaccine and a portion of the human brain receptor (hypocretin receptor 2) promoting wakefulness. The authors additionally demonstrated the presence of antibodies capable of cross-reacting with both influenza nucleoprotein and the hypocretin receptor which theoretically could disrupt wakefulness signaling triggered by binding of hypocretin protein to the hypocretin receptor 2. Using mass spectrometry, influenza nucleoprotein was demonstrated to be present in significant amounts in the AS03-adjuvanted inactivated split-virion pandemic vaccine compared to the MF59-adjuvanted inactivated subunit

pandemic vaccine (not associated with narcolepsy) that contained approximately 73% less influenza nucleoprotein as a result of an additional subunit purification step (see "Inactivated Vaccines" earlier). These findings and the association of narcolepsy also with influenza infection make the direct role of adjuvants alone in triggering autoimmune disease in genetically susceptible subjects less likely. This is attested to by both AS03- and MF59-adjuvanted pandemic vaccines not triggering or exacerbating disease activity in patients with established or active autoimmune disease, respectively.[225] Other adjuvants include AS04 (deacylated monophosphoryl lipid A [MPL] plus aluminum) formulated with recombinant yeast-derived hepatitis B vaccine that elicits significantly increased antibodies to HBsAg antibody responses[229] and is approved as formulations for HBV and HPV vaccines in Europe and, recently, in the United States.[222] Liposomes (virosomes) are another adjuvant technology that has gained approval and has been licensed as a component of a seasonal influenza vaccine and a hepatitis A vaccine.[230,231] AS01 is a liposome-based vaccine adjuvant containing 3-O-desacyl-4′-monophosporyl lipid A and the saponin QS-21 and is included in the RTS,S malaria vaccine and the subunit glycoprotein E varicella zoster vaccines.[121]

Adjuvants in Development. As noted previously, oligonucleotides containing unmethylated CpG structural motifs have been shown to enhance protein and peptide vaccine responses in diverse clinical experiences.[232]

Certain bacterial toxins with adenosine diphosphate (ADP)-ribosylating activity have been engineered as mucosal adjuvants. In particular, CT was shown to be active as a mucosal adjuvant for a coadministered antigen[233] when presented by the oral, nasal, vaginal, or rectal route, as was shown subsequently for the heat-labile toxin of ETEC. These toxins are composed of a catalytic A subunit and a pentameric B subunit that binds to GM_1 ganglioside on many cell types. CT and labile toxin are toxic in humans, especially by the oral route (through which they induce diarrhea); there also has been concern about the use of these adjuvants by the nasal route, given the development of Bell palsy after administration of an influenza virosome vaccine containing labile toxin in humans.[234] Consequently, point mutations have been made to create toxoids with reduced or eliminated ADP-ribosylating activity, and hence toxicity, while retaining adjuvanticity in mice.[235] An alternative approach has been to eliminate the B subunit of CT and substitute a synthetic dimeric peptide derived from *Staphylococcus aureus* protein A (DD) that binds to Ig. The fusion of the CTA subunit with the DD domain binds to Ig-positive cells, appears devoid of toxicity, retains ADP-ribosylating activity, and is active as an adjuvant in mice.[236] The tolerability and effectiveness of these engineered adjuvants needs to be evaluated in humans.

Novel adjuvantation has been applied to cancer vaccines. A 25-amino-acid peptide from the MUC-1 tumor-associated antigen is formulated with MPL and three lipids into a liposomal product. Vaccination of subjects with non–small cell lung and prostate cancer has shown positive clinical effects.[237]

Bioinformatic Technologies and Vaccine Safety

As mentioned in the previous section on "Adjuvants," the association of vaccine-associated narcolepsy in 2010 with one pandemic influenza vaccine containing a squalene-based adjuvant but not another pandemic influenza vaccine containing a squalene-based adjuvant suggested a primary role for the vaccine antigen as the trigger for developing this chronic sleep disorder.[225] This antigen-related hypothesis is also consistent with the association of narcolepsy with the 2009 pandemic influenza infection.[238] Adjuvants are not intrinsically linked to autoimmunity, but may instead uncover potential cross-reactivity mediated by B or T cells to similar epitopes contained in microbes and normal human tissue. Computational tools have now been developed to help uncover the potential cross-reactive epitopes and avoid vaccine components that could induce potentially deleterious immune responses to self-tissue. In addition to the bioinformatics tools for comparing microbial peptides for similarity to human proteins (i.e., Basic Local Alignment Search [BLAST] algorithms and sequence alignments), there are databases containing the structures of human leukocyte antigen molecules that are associated with certain autoimmune diseases and are important to consider as these molecules provide the context in which T cells can recognize cross-reactive peptides.[228] T-cell epitopes are now rapidly discoverable by cutting edge computer algorithms which can now find cross-reactive epitopes that induce autoimmunity or immune regulation by looking at the T-cell receptor "side" of the epitope.[239,240] While the approach for future vaccines will undoubtedly evolve with innovations in technologies, what is clear is that some difficult targets will require adjuvants to elicit the necessary immune response to provide protection. Such vaccines have the potential to uncover cross-reactive epitopes that may lead to immune-mediated diseases in genetically susceptible subjects. The computational tools are now approaching maturity that may enable vaccines to be refined to precise formulations containing the exact proteins or epitopes that contribute to protective immunity and from which cross-reactive epitopes have been removed.

For example, in the case of influenza vaccine (where a cross-reactive epitope has been identified from influenza nucleoprotein with high similarity to the human hypocretin receptor implicated in narcolepsy), one could apply some of the technologies discussed in this chapter to reduce or remove this cross-reactive epitope as follows: (a) applying subunit purification steps that are known to effectively minimize the total amount of influenza nucleoprotein transferring into the final vaccine product[228] or (b) genetically engineering influenza virus reassortant strains (similar to the approach used for some live-attenuated HSV vaccines[23,24]) such that the cross-reactive epitope is deleted or mutated enough so that its similarity to the human hypocretin receptor is lost (thus enabling vaccine manufacturers to continue using their preferred technology for producing their specific influenza vaccine, i.e., live-attenuated, inactivated split-virion, or inactivated subunit). Alternatively, the recombinant influenza vaccine produced in a continuous insect cell line and licensed in 2013 only contains influenza hemagglutinin[143] but is not approved for use in people younger than 18 years of age. When such hemagglutinin-only vaccines receive approval for younger ages, yet another possible solution to the problem of vaccine-associated narcolepsy (mediated by cross-reactivity to a fragment of influenza nucleoprotein) will be within arm's reach. However, any advantages (e.g., generation of cross-clade protection/development of a "universal" influenza vaccine) afforded by other epitopes contained in the highly conserved influenza nucleoprotein or other nonhemagglutinin influenza proteins would not be retained in hemagglutinin-only vaccines. The dilemma illustrated by this particular example is applicable to other vaccines and illustrates the continuous challenge facing vaccine developers trying to balance vaccine safety with vaccine efficacy.

Delivery Systems

Besides presenting an antigen, DNA, or RNA to their in vivo target cells, a delivery system may mediate other key activities. There may be a depot effect, whereby the antigen

is maintained in an appropriate site for continual immune stimulation. There may be an enhancement of in vivo stability of DNA or antigen. The delivery system may enable efficient presentation of mucosally delivered vaccines for uptake by M cells, followed by transcytosis into Peyer patches and presentation to lymphocytes for inducing mucosal immunity.[241–243] Certain formulations may maintain the vaccine inside a physical structure for a significant in vivo period, during which the vaccine is released slowly or in a pulsatile manner to function as a one-dose vaccine. No delivery systems have yet been widely licensed. Gaining clinical and pharmaceutical experience with new delivery systems and adjuvants remains a key goal in the field. A few specific viral and bacterial proteins have been shown to have adjuvanting and mucosal delivery properties in preclinical studies. A reovirus protein complexed with poly-L-lysine can adjuvant and present DNA for mucosal immune responses.[244] The *S. pyogenes* Sfp-1 protein has been reported to provide for mucosal adjuvantation.[245]

Comparing Specific Vector Technologies. The development of specific technologies for delivering vaccines by different routes of immunization (e.g., oral, nasal, transcutaneous) also has been a rapidly growing field. Once the vaccine has been delivered to the appropriate region of the human body, sufficient quantities of the antigen (and adjuvant) must gain access to appropriate cells to activate the immune system. The vehicles or vectors that may be used for this purpose include live attenuated viruses, live attenuated bacteria, commensal bacterial vectors, virosomes, VLPs, liposomes, lipopeptides, immune-stimulating complexes, microparticles, and nanoparticles.[246–250] Viruses are prototypical antigen delivery vehicles because they enter and commandeer cells to replicate themselves, thus multiplying the available antigen that they encode and inducing a natural adjuvant effect through activation of chemokines and cytokines. Recombinant viruses acting as vectors by incorporation of a gene expressing a heterologous antigen have similar advantages as conventional attenuated live virus vaccines. They deliver the foreign DNA or RNA into cells and get it replicated to activate the immune system. Viruses used as vaccine vectors ideally should have very low pathogenic potential, even in immunocompromised persons, and the capacity to hold the necessary foreign genes expressing the desired antigens and adjuvants. Bacteria have a major advantage over viruses as vaccine vectors because of their higher capacity for insertion of the heterologous genes expressing antigens, adjuvants, or plasmids for DNA vaccination. DNA vaccination involves the delivery of eponymous plasmids directly into host cells to express the desired antigens.

Nonreplicating vaccine delivery systems, including immune-stimulating complexes, liposomes, microparticles, nanoparticles, virosomes, and VLPs, mimic live viruses in the manner they deliver antigen and adjuvant. They are particles about the same size as viruses, allowing similar uptake by antigen-presenting cells. Many include a lipid component to increase cell membrane permeability and viral or bacterial proteins to activate the immune system. Liposomes are vesicles composed of a phospholipid bilayer membrane. Antigen can be packaged in its aqueous core, inside the lipid bilayer, or on the outside of the membrane.[251–253] Immune-stimulating complexes are cage-like structures roughly 40 nm in diameter composed of 12 subunits of saponin (such as Quil A) and cholesterol. Delivery can also be enhanced by packaging antigens and adjuvants into microparticles or nanoparticles composed of polymers of biodegradable materials such as polylactide and polylactide coglycolide or into biopolymers such as chitin or chitosan.[254–260] Microparticles can be designed to slowly release antigens to increase the duration of antigen presentation. Many recombinant bacterial vectors are administered orally. Antigen mixed with CT, heat-labile toxin, or their toxoid derivatives and applied to the skin can stimulate transcutaneous immunization.[261]

Adapting Strategies

Vaccine development historically has used the direct approach of a vaccine made by a single technology delivered in one or more doses. More recently with increased appreciation of the immunobiology of particular infections and diseases that are resistant to conventional single-technology vaccine approaches, regimens have been developed that use mixtures of vaccines made by different technologies (mixed vaccines) or different types of vaccines given during the overall dosing regimen (prime-boost regimens).

Mixed Vaccines

Oral inactivated whole-cell cholera vaccine, which lacks CT and its toxic effects, is well tolerated and efficacious.[80] To elicit CT-neutralizing antibodies, recombinant CT B subunit (rCTB) is independently expressed, purified, and added back to the whole-cell cholera vaccine. This combined whole-cell cholera + recombinant CT B subunit vaccine has been shown to have a higher rate of efficacy than whole-cell cholera vaccine alone.[262] Since CT B subunit is immunologically cross-reactive with the B subunit of labile toxin, the combined vaccine also shows some clinical efficacy against labile toxin–positive strains of ETEC.

Kinoids are a derivative of inactivated cytokines, of which the second-generation kinoids are also coupled to a molecule of keyhole limpet hemocyanin (immunomodulatory foreign carrier protein). This heterocomplex enables a T-cell response against the foreign carrier protein, thereby helping a B-cell response against the selected cytokine. This strategy induces elevated titers of neutralizing antibodies to counteract the pathological effect of local overproduced cytokines. Tumor necrosis factor-α–kinoid vaccines have been tested in early phase clinical trials in patients with Crohn disease,[263] Phase II/III studies in asymptomatic HIV-1–infected patients,[263] and in a Phase II study in tumor necrosis factor antagonist–resistant rheumatoid arthritis patients.[264] An interferon-α–kinoid vaccine has also been tested in Phase I/II studies in systemic lupus erythematosus patients.[265] These studies have demonstrated safety/tolerability and a trend toward clinical improvement warranting further studies.

Prime-Boost Regimens

Vaccination regimens with a sequence of different vaccines has shown that some vaccines are more efficient at priming and others at boosting immunological memory; these prime-boost regimens have been evaluated, particularly for HIV-1 vaccines. Canarypox virus expressing recombinant HIV-1 rgp160 or rgp120 has been administered in two priming doses followed by boosting with rgp160 protein[266]; this regimen induced higher levels of neutralizing antibodies than immunizing with rgp160 protein alone. A regimen consisting of a canarypox-vector prime plus a protein-subunit boost was responsible for the first demonstration to date of protection against HIV infection in Thailand[267] and the administration of the same vaccination protocol to 100 volunteers in South Africa generated similar results.[210] Likewise, clinical studies of two priming doses of rgp160 followed by boosting with a peptide from the major type-specific neutralization epitope of gp160 demonstrated higher levels of HIV-1–neutralizing antibodies than those elicited by rgp160 alone.[268] Priming with adenovirus expressing HIV-1 gp160 followed by boosting with HIV-1

rgp120 elicited persistent titers of virus-neutralizing antibodies and CTL activity and protected chimpanzees from HIV-1 challenge.[269]

The aforementioned studies have demonstrated that using a vaccine with superior priming characteristics followed by boosting with the appropriate related vaccine may be an improved regimen for eliciting higher antibody titers. Such a regimen is more complicated to develop technically and clinically and would not be generally useful in a case where a one-vaccine regimen is effective,. However, it may be useful for targets such as HIV-1 or malaria that have proven refractile to more conventional vaccine approaches.

Combination Vaccines

The increasing number of vaccines available and the desire for fewer needle sticks at the time of vaccination has fostered the use of *combination vaccines*, which are defined as two or more vaccines given in a physically mixed preparation. Combination vaccines are of two types: (a) *multidisease*—mixtures of different types of vaccines, and (b) *multivalent*—mixtures of different serotype vaccines for the same vaccine target. Some combination vaccines are multidisease *and* multivalent. There are numerous challenges in successfully developing novel combination vaccines, which include physical compatibility, stability, and potential immunological interference. For example, the success in developing measles-mumps-rubella-varicella vaccine[8] came only after numerous attempts spanning almost two decades. Combination vaccine technology is a complex discipline that is beyond the technical scope of this chapter. Other chapters in this volume and in the textbook *Combination Vaccines*[270] present a plethora of technical issues associated with developing such vaccines.

ANTIBODY PREPARATIONS

Antibody preparations can be monoclonal or polyclonal. Table 66.5 lists some examples of polyclonal antibody preparations and licensed monoclonal antibody therapies providing immediate immunological activity necessary to prevent or treat certain infections, cancer, or pathological conditions. Examples include (a) postexposure prophylaxis for known or suspected exposure to HBV[271] or varicella-zoster virus[272] in persons who are unvaccinated or in immunosuppressed individuals; (b) preexposure prophylaxis for at-risk persons with an underlying pathology (transplant recipients infected with CMV)[273] or infants with pulmonary pathologies to prevent RSV infection[274]; and (c) administration to pregnant mothers who are viremic for CMV[273] for potential modulation of perinatal viral infection in newborns. The protective effect

[b]The Antibody Society. www.antibodysociety.org/news/approved-antibodies/.

mediated by most of these antibody preparations is to (a) neutralize virus infectivity; (b) bind to bacteria, which then are destroyed by phagocytic cells; or (c) bind to and neutralize molecules such as toxins elaborated by the pathogen (e.g., tetanus[275]) or therapeutic agents like digoxin.[276]

Polyclonal Antibodies

Human Immunoglobulin and Antibody Fragment

The earliest preparations of antibody or Ig were made in species such as horses that had been injected with bacterial toxoids. Although such antisera were therapeutically effective as antimicrobials, the xenogeneic antibody elicited serious side effects, such as serum sickness, in recipients. A newer product, equine rabies globulin, is widely used as a lifesaving therapy in developing countries (giving approximately 2% allergic reactions). Nevertheless, such Ig preparations tend not to be used in humans, especially in developed countries, except in emergencies when no alternative therapy is available.

A range of human polyclonal Ig products has been available for more than 20 years (see Table 66.5). Depending on the Ig under consideration, these products are prepared by pooling plasma from healthy volunteers (with known titers of the specific target antibody) who would have acquired high titers by vaccination or natural infection with possible silent boosting by the pathogen. The pooled plasma is fractionated with alcohol to enrich for antibody. The preparations are heat treated under conditions that are known to destroy the infectivity of human pathogens such as HIV-1. The final product is released on the basis of standardized specific antibody content. These products are generally efficacious for preventing infectious diseases.[271–275] However, the large injection volumes (normalized for body weight) and the high protein (antibody) content (as high as 1 g per administration) can result in adverse reactions in recipients. Polyclonal antibodies can be processed for clinical use into F_{ab}, that is, antigen-binding fragments of the whole Igs (Fig. 66.3).[276]

Monoclonal Antibodies

MAbs have been evaluated for cancer immunotherapy.[277,278] The underlying immunological mechanisms for such MAbs would include antibody-dependent cytotoxicity, direct CTL activity, the binding to tumor cells to mark them for attack and destruction by phagocytic cells, and stimulating apoptotic destruction. Another area in which there is renewed activity is HIV where first-generation monoclonal antibody combinations were found to be largely ineffective but new-generation antibodies derived using single-cell-based antibody cloning methods have revealed more potent broadly neutralizing activity against HIV-1.[279] These include MAbs to host cellular receptors, including CD4 and CCR5.[279,280]

The use of MAbs offers the prospects of avoiding human sources of Igs; improving the tolerability of passive vaccines by substantially reducing protein content and injection volume; and providing an antibody source of unlimited supply with unique specificity, absolute standardization, and high reproducibility. In some cases, a mixture of MAbs may be required to provide multiple epitope recognition akin to that of polyclonal sera. The invention of hybridoma technology in the mid-1970s provided for a source of murine MAbs (mMAbs) that required only the availability of the specific immunogen for mice.[281] Many developments in rDNA technology in the 1980s and 1990s have enabled the expression of high levels of recombinant MAbs in defined CCLs, the chimerization or humanization of mMAbs (Fig. 66.4), the isolation of human MAbs (hMAbs) from transgenic mice, and the screening for specific hMAbs from a "library" of MAbs developed in lieu of having enough antigen for immunization.

Furthermore, the development of next-generation sequencing technologies has enabled high-throughput DNA sequencing and characterization of functional antibody repertoires including both protective and pathogenic immune responses. Blood samples obtained from patients successfully responding to an infection (either quickly clearing or chronically sequestering an involved site) can be compared to patients unsuccessfully responding to an infection (either rapid mortality or requiring a much longer time to clear an infection). Bioinformatic identification of clonal families of antibodies uniquely associated with successful response to infection can narrow down representative antibodies for recombinant expression of therapeutic antibodies "passive vaccines/antibody preparations" in addition to identifying the antigen targets of functional immune responses relevant to vaccine development ("active vaccines").[282] The many technologies for

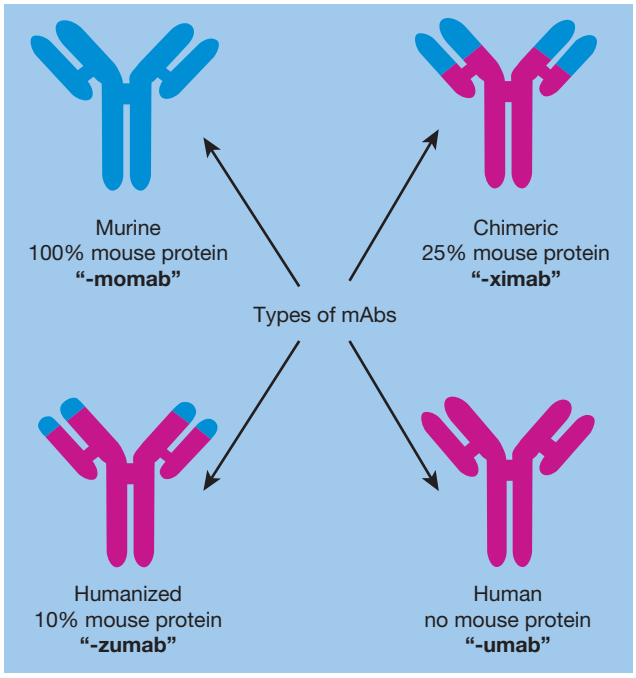

Figure 66.4. Comparison of the different types of monoclonal antibodies from murine to human and the nomenclature used to identify their composition.

developing whole MAbs or fragments or multimers thereof have been reviewed.[283]

Nonhuman

The first licensed therapeutic MAb of any type was a murine IgG_{2a} CD3-specific renal transplant rejection drug OKT-3 in 1986.[284] Given the technologies available to produce human, humanized, or chimeric MAbs and in light of issues regarding the tolerability of nonhuman antibodies, additional nonhuman mMAbs (see Fig. 66.4) are unlikely to become available for use as passive vaccines. A potential exception to this principle is a mMAb that stimulates a tumor-directed anti-Ig immune response by virtue of the presence of xenogeneic murine sequences.[285]

Natural Human

The first-generation technology for making hMAbs was adapted from murine hybridoma technology.[286,287] B lymphocytes are harvested from persons vaccinated for (or recently infected with) the desired pathogen; alternatively, B lymphocytes from healthy persons are cultured in vitro in the presence of the desired pathogen or antigen. Such B lymphocytes are immortalized by transformation in vitro with Epstein-Barr virus or by fusion with a human or murine myeloma cell. The resultant cell population is cloned and screened for the hMAb of the desired specificity. The positive cells are single-cell cloned, expanded, and preserved. The immortalized cells can be adapted to the desired growth medium and expanded to the scale necessary to manufacture a product. Alternatively, the hMAb genes can be cloned and expressed in a CCL to derive a recombinant hMAb. Given the technical challenges of maintaining the stability and large-scale consistent growth characteristics of the hybridoma cells in contrast with the reliable expression levels and stability of recombinant MAbs secreted from defined CCLs, the recombinant CCL-based route is generally preferred as a source of product.

Recombinant Human

Human Derived. The genes for the hMAb heavy (H) and light (L) chains from such hybridoma cells[288] are cloned and coexpressed in a CCL (e.g., CHO or NS0 cells) with known capability for high levels of recombinant MAb expression. Alternatively, human B lymphocytes are harvested, and the variable (V) regions of the IgG L and H chains are cloned en masse to produce an *E. coli* combinatorial V-region expression library, in which all combinations of different H and L chains are coexpressed in individual *E. coli* cells.[289] This combinatorial expression library is screened for specific antigen binding. The identified V genes of interest are recloned, reassembled with constant (C) regions into complete human H and L chain genes, and then coexpressed in a CCL (per natural hMAbs). Alternatively, the identified V regions may be used as less-than-complete antibody molecules (e.g., F_{ab} or single-chain F_v molecules) (see Fig. 66.3). Such a MAb fragment is being investigated for therapy of *Candida albicans* infections.[290] The efficiency of the combinatorial approach offers the advantages of flexibility of soliciting human B-lymphocyte donors without the need for antigen and the ability to find MAbs of higher affinity than found in a polyclonal antibody preparation. A recombinant hMAb binding to the CTLA-4 has been demonstrated to augment T-cell activation and proliferation of tumor infiltrating T-effector cells and reducing T-regulatory cell function and was licensed for the treatment of melanoma in 2011.[291] In 2014, two other hMAbs were licensed for the treatment of melanoma and block the inhibitory effect of either one or both of the programmed death (PD) receptor ligands (PD-L1 or PD-L2) on the PD-1 receptor expressed on the surface of activated T cells.[292]

Mouse Derived. A more recent and versatile technology that has attracted widespread use is the *XenoMouse*, which is a transgenic mouse into which transcriptionally active human Ig gene loci have replaced murine Ig loci.[293] MAbs derived from such mice through conventional hybridoma technology are fully hMAbs. Balancing the great versatility of deriving such hMAbs is the limitation that the human Ig gene repertoire in such XenoMice is incomplete. Such MAbs are advancing in clinical development for indications such as colorectal and kidney cancer.[294]

Recombinant Humanized

A mMAb can be changed into a *humanized* MAb (see Fig. 66.4) of the same antigenic specificity. The human immune system would not recognize the humanized MAb as foreign and, therefore, would not produce antibodies against it (other than antiidiotypic). The V regions of H and L chains contain three hypervariable regions or complementarity determining regions (CDRs), each five to 18 amino acid residues long. The six CDRs in an intact molecule come together in three-dimensional space to form the specific antigen-binding region of the antibody molecule (this region contains the idiotype and paratope, as discussed earlier). The three CDRs in each chain fall in linear sequence in the midst of four V-region less-variable framework regions. Humanization is accomplished by substituting on the DNA level the three CDRs from each murine H and L chain gene for the human CDRs in four human framework regions from individual H and L chain genes[295] (human framework region domains with sequence homology to the murine framework region domains are chosen for recombination). The substituted H and L chain V regions are reassembled with human H and L chain C regions, which are coexpressed in a CCL for scale-up and development as for any recombinant hMAb. The resultant humanized MAb contains only human-derived sequences except for the murine-derived CDRs and, consequently, has generally low immunogenicity, other than for an antiidiotypic response that may be elicited by any antibody.[296]

Humanized MAbs have been developed and licensed for applications in cancer, allergy, and infectious disease (see Table 66.5). Palivizumab, a humanized MAb that was developed based on its neutralizing activity, prevents RSV infections in at-risk newborns and is the first licensed MAb-based passive vaccine licensed for preventing an infectious disease.[297] Trastuzumab, which is specific for the HER2 (human epidermal growth receptor 2) protein, is licensed for immunotherapy of HER2-positive breast tumors.[277] Omalizumab, which binds to IgE, reduces symptoms of allergy by its ability to bind IgE and prevent IgE binding to mast cells and consequent histamine release.[298]

Recombinant Chimeric

There are potential technical limitations to being able to produce human or humanized MAbs; thus, chimeric MAbs (see Fig. 66.4) have been produced. The V region genes from mMAb H and L chains are combined with human C-region H and L chain genes, which then are expressed in CCLs as chimeric MAbs. Such MAbs have more murine-derived sequences than do humanized MAbs. Nevertheless, such MAbs have been shown to be well tolerated and effective in a range of applications. Rituximab, a chimerized MAb specific for CD20, is licensed for immunotherapy of non-Hodgkin lymphoma.[278]

CONCLUSION

The number of approaches for making new vaccines should continue to expand in the future such that almost all antigens or epitopes could be presented in a highly immunogenic form in the context of a live or inactivated vaccine or be expressed through a DNA-based vaccine. Further understanding of gene function in viral and bacterial pathogens should enable live vaccines to be more stably and predictably attenuated as vaccines and as live vectors for vaccinating against other pathogens. Adjuvant and delivery system technologies should provide formulations that are more potent than aluminum salts, yet are safe and well tolerated, and enable delivery by routes other than injection. Bioinformatics tools should enable the refinement of vaccine antigens to exclude those that are potentially cross-reactive with antigens found in normal human tissue thus limiting the generation of pathogenic autoimmune responses related to molecular mimicry. Similarly, formulations of DNA may improve potency and the ability of DNA to be delivered by routes that elicit mucosal immunity. MAb technologies will provide for finer epitope specificity and for increased diversity of antigen recognition. There also should be significant further developments in applications to noninfectious diseases, such as cancer and autoimmune diseases, building on successes to date in the fields of multiple sclerosis, whole-cell cancer vaccines, and MAbs for non-Hodgkin lymphoma and breast cancer (see Table 66.2).

67 Development of Gene-Based Vectors for Immunization

David B. Weiner and Gary J. Nabel

Vaccines can confer immune protection against infectious agents through divergent arms of the adaptive immune response. The elaboration of antibodies through the humoral immune system has been highly effective in the neutralization of many bacteria, viruses, fungi, and parasites. The cell-mediated immune response also plays a major role in containment of infectious agents as well as in eliminating pathogenic cells. T lymphocytes comprise a diverse set of cells, and their functional activity depends on helper T cells, which elaborate a variety of cytokines and stimulate B cells to produce antibodies and modulate the induction and expansion of cytotoxic T lymphocytes (CTLs). CTLs recognize processed antigen in combination with major histocompatibility complex (MHC) molecules and release cytokines that can influence pathogen replication as well as lyse infected cells. In addition, T-regulatory cells are induced as part of an immune response and can play a negative role in the clearance of chronic infectious agents and in preventing clearance of pathogenic cells.

Both humoral and cellular immunity are elicited by vaccines, each with their own effector functions that can inactivate pathogens in different ways (Box 67.1). Although the humoral immune response is well known to confer protection, the role of CTL in protective immunity against viral infections has been recognized more recently. The function and specificity of CTLs have provided the foundation for understanding MHC restriction and its importance in protection against viral infection.[1,2] Cellular immune responses help control infectious diseases, in concert with antibody responses or when it is difficult to generate neutralizing antibodies, as in patients with AIDS, malaria, hepatitis C virus, or tuberculosis. Humoral immunity is readily induced by protein antigen preparations or inactivated viruses together with appropriate adjuvants. Gene-based vaccines, the engineering of nonviral RNA- or DNA-based systems, or viral recombinant systems to express foreign antigens when delivered to a host appear to be particularly effective at inducing T-cell responses, both CD4 and CD8. At the same time, some gene-based vaccines can induce humoral immune responses when used with specific vectors or in specific prime-boost combinations, or through enhanced delivery and formulation. A variety of vectors, nonviral and viral, have been developed for these purposes (Fig. 67.1), the most studied with a focus of being in or entering the clinic are reviewed here.

The majority of conventional adjuvants that have been previously used in vaccine development affect humoral immunity and enhance antibody responses without inducing cellular immunity. In contrast, gene-based vaccine vectors can stimulate both humoral and cellular immunity, thus providing greater selective pressure on infectious agents. In this chapter, the major gene-based vaccines progressing in clinical trials are discussed, together with the advantages and disadvantages of the individual vectors and their influence on the different effector arms of the immune system. Although there is considerable experience with inactivated viruses and protein-based vaccines, there is less experience with gene-based vaccine vectors as they are more recent developments. Their ability to induce both humoral and cellular immunity and their safety and mode of antigen presentation are attractive features that must be balanced with the limitations in knowledge about clinical efficacy, production methodology, and concerns about antivector immunity (Box 67.2). However, there is a growing clinical experience that is guiding the analysis of these approaches as well as recent compelling vaccine efficacy data. Based on their early successes and advantages in conceptual development, it is likely that these vectors will make important future contributions to vaccinology.

NONVIRAL VECTORS AND DNA VACCINES

Vaccination with plasmid DNA generated excitement in the early 1990s when four independent groups simultaneously reported that plasmid gene delivery resulted in in vivo antigen expression with resulting immune responses to the plasmid-encoded antigens. Stephan Johnson's laboratory used a device called the gene gun to "shoot" gold beads coated with a plasmid encoding human growth hormone into mice.[3] The animals generated antibody to growth hormone with this approach. Other groups also attempted to harness the power of plasmids for vaccination purposes and presented their work in a session at the Cold Spring Harbor Vaccines meeting in the fall of 1992. The laboratories of Margaret Liu (Merck) and Harriet Robinson (University of Massachusetts) vaccinated mice intramuscularly with plasmids expressing influenza antigens and demonstrated the generation of antigen-specific immunity.[4,5] In addition, David Weiner (University of Pennsylvania) reported that formulations of plasmids containing either HIV envelope or tumor antigens were capable of stimulating both cellular and humoral immune responses in mice or in the case of the tumor antigen formulations, impacting tumor growth.[6] These novel results, combined with the simplicity and ease of manufacturing, spawned research into DNA vaccines for a plethora of viral, bacterial, parasitic, and cancer targets.[7–12]

At this time the DNA vaccine platform was perceived by the scientific community to be an important new approach, as conceptually, DNA has multiple advantages over traditional live attenuated, killed, peptide-based, and viral vector vaccines.[13,14] For example, DNA is easy to manipulate, it combines the simplicity of synthetic chemistry or bacterial production with the power of genomics, and it allows the rapid design and construction of multiple potential vaccines by removing entirely the need to develop vaccines using pathogen-derived materials. In addition, DNA vectors are extremely stable, reducing the need for a cold chain and increasing product shelf life. Therefore, the ease of production, stability, and cost-effectiveness of this platform made it ideal for producing vaccines for the developing world. DNA vectors themselves are not immunogenic, which allows repeat administration without developing immune interference. Importantly, DNA vaccines combine the appeal of live replicating vaccines that induce broad cellular and humoral immune responses with the safety and ease of manufacturing of a nonlive, nonspreading platform.[15,16] As DNA vaccines are nonreplicating, they eliminate the risk of attenuation reversions in the host, dissemination in the recipient, the unintended consequences of secondary infections by transfer to unvaccinated populations, and they can be delivered to high-risk groups, including immunocompromised subjects. In the clinic, DNA vaccines

BOX 67.1 Mechanisms of Immune Protection by the Adaptive Immune Response

CELLULAR

- Lysis of infected cells
- Elimination of source of production of viruses and intracellular pathogens
- Elaboration of antimicrobial cytokines
- Recruitment of innate immune effector cells
- Induction of long-term immune memory
- Elaboration of chemokines to recruit inflammatory responses
- Secretion of proteins that block pathogen receptors

HUMORAL

- Reduction of initial microbial inoculum
- Direct neutralization of pathogen
- Complement-mediated lysis of bacteria and parasites
- Lysis of infected cells through antibody-dependent, cell-mediated cytotoxicity
- Recruitment of inflammatory cells via complement-dependent mechanisms
- Generation of secretory immunoglobulin A to facilitate mucosal elimination of pathogens

BOX 67.2 Advantages and Limitations of Gene-Based Vectors for Vaccines

ADVANTAGES

- Potent immunogenicity in animal and human infectious diseases
- Ability to induce cellular immunity with or without humoral immunity
- Relative ease of production for many viral and nonviral vectors
- Ease of analysis and screening in the laboratory
- Favorable safety profile and lack of persistence in vivo
- Efficient transduction of cells and reasonable production capability
- Many potential prime-boost combinations

LIMITATIONS

- High level of immunity to some vectors in humans
- Need for qualified packaging cell lines
- Induction of antivector immunity after initial injection of viral vaccines, limiting efficacy of homologous boost
- Potential complexity with multiple vectors in prime-boost
- Limited long-term safety data
- Need to develop large-scale manufacturing processes

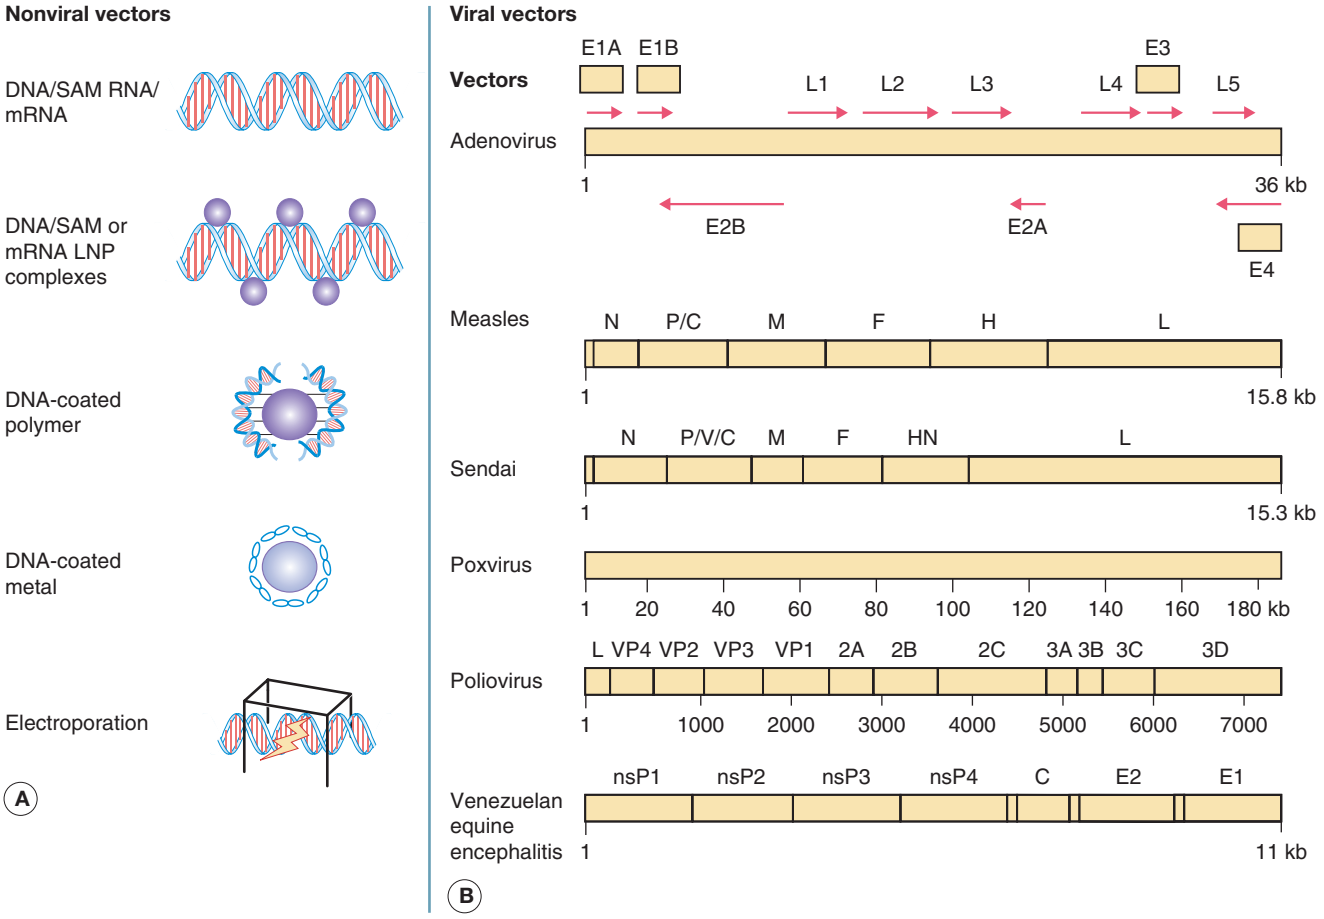

Figure 67.1. Representative vector platforms for gene-based vaccines that have advanced into clinical trials. Vaccination by gene delivery with nonviral **(A)** and replication-defective recombinant viral gene-based **(B)** vectors are shown. **B** shows the genetic organization and virus structure of the natural replication-competent virus.

have provided an unparalleled safety profile over the past decade and a half of study.[17] With some constraints, DNA vaccine products can be developed in repeat-use manufacturing facilities, thus providing enormous savings in product development and manufacturing.

Mechanism of Action

The mechanisms surrounding the generation of antigen-specific immunity with gene-based vaccines are important to understand. An antigen sequence of interest is designed to target a particular antigen or set of antigens of a pathogen or tumor antigen, potentially subjected to additional modifications (as described below), and inserted into a mammalian expression plasmid vector.[18–25] For use in humans, such vectors often share common features, including a high-copy-number origin of replication to enhance production, a human cytomegalovirus immediate-early promoter to drive in vivo expression, an RNA polyadenylation sequence that can be derived from bovine growth hormone or created synthetically to facilitate ribosome function, and a plasmid growth selection sequence such as a limited kanamycin bacterial gene or a nonantibiotic selection sequence to monitor the expression of the plasmid of interest during production.[15,17] The plasmid vaccine is then delivered to the skin by intradermal injection or intramuscularly by one of several delivery methods. Once inside the cytoplasm of the cell, the plasmid enters the nucleus of transfected cells (e.g., myocytes, keratinocytes, or local resident antigen-presenting cells [APCs]),[26–28] where the plasmid-encoded sequences drive host cell transcription, producing the foreign antigen in vivo. The host-synthesized antigens then become the subject of immune surveillance in the context of both MHC class I and class II molecules of the vaccinated host.

There are very specific differences between DNA vaccination and infection with the pathogen that the vaccine is intended to prevent. With DNA vaccines, antigen delivery remains local after plasmid transfection into cells, with little spreading of antigen expression to other regions of the body. The plasmids themselves represent a focused antigen, epitope, or multiple antigens of the pathogen and not the entire pathogen capable of dissemination.

The exact details of DNA vaccine-induced immunity remain a subject of debate. IM injection of the DNA vaccine has been shown to induce $CD8^+$ T-cell responses with more limited antibody production.[7] After IM injection, myocytes are likely transfected and dendritic cells present in the transfected muscle efficiently cross-present antigens to activate MHC class I–restricted T cells.[27] Alternatively, APCs in the muscle could be directly transfected and express antigen via the MHC class I pathway to activate CTL.[29] In contrast, intradermal (ID) administration has been reported to result in a more robust humoral response consisting of immunoglobulin (Ig) G_1 antibody production.[4,30] Because the dermis is rich in APCs, such as Langerhans and dendritic cells, ID vaccination, could result in APC transfection and antigen secretion, with either MHC class I or MHC class II presentation. APCs are also constantly sampling the environment through endocytosis, resulting in the uptake of secreted antigen predominant expression on MHC class II cells. It is thought that plasmid-encoded DNA triggers immune activation through stimulation of innate immune sensors, which include PAMPS (pathogen-associated molecular patterns) or the STING (stimulator of interferon genes)–TBK1 (TANK-binding kinase 1) pathways.[31,32] Such activated APCs express chemokines and cytokines that enhance immune cell trafficking and inflammation.

Animal Studies

Several DNA vaccines have been licensed for use in animals,[33–36] including dog melanoma immunotherapy, porcine recombinant growth hormone, vaccine for the prevention of rhabdovirus disease in fish, and West Nile virus vaccine for horses. These promising outcomes have yet to be translated to humans.

Prime-Boost Emergence

The success in preclinical models by DNA vaccines led to clinical studies in humans, initiated in the early 1990s. The goals of these human studies were to evaluate the safety, tolerability, and immune potency of the platform. Diverse DNA vaccines for a variety of prophylactic and therapeutic applications were studied, including HIV-1,[37] influenza, cancer antigens, hepatitis B, malaria,[38–42] and others.[43] Although the initial DNA vaccine studies in humans demonstrated excellent tolerability and safety,[15,43] the immune responses they elicited were much weaker than expected based on the preclinical data. Concerns about the ability of the technology to stimulate robust immune responses led to the development of the prime-boost strategy which sought to take advantage of properties of both DNA as well as recombinant viral vectors when combined resulting in focused immunity to the transgene (see below).[44]

Highly attenuated live recombinant poxviruses, including NYVAC, the modified vaccinia Ankara (MVA), the ALVAC canarypox-based vector,[45–49] and recombinant adenoviral platforms[50–52] were of great interest. Although these viral platforms induced strong antigen-specific cellular responses in preclinical models, preexisting poxvirus or adenovirus immunity diminished the immune responses induced by immunization with these recombinant vaccine vectors,[53–55] limiting the potency of the vectors in multidose regimens. Furthermore, other issues regarding preexisting immunity are also possible and problematic; these are further discussed below.[56]

Early DNA approaches induced small but focused immune responses that could be expanded with subsequent boosting with a recombinant vector encoding the same antigen as the DNA vaccine, with the prime boost strategy providing a more robust immune response.

This strategy was first suggested by studies in a murine model of malaria, in which DNA priming followed by MVA or NYVAC boost consisting of specific preerythrocytic antigens of *Plasmodium berghei*, induced higher CD8 T-cell responses than either platform delivered alone.[57,58] Schneider and coworkers, using a malaria vaccine, reported that priming with DNA and boosting with MVA vectors encoding the same antigen, led to enhanced immunity and greater protective efficacy than that achieved with either vaccine preparation alone.[57] These findings were quickly extended to many other DNA and recombinant vector combinations.

Important SHIV (simian-human immunodeficiency virus)/SIV (simian immunodeficiency virus) model vaccine studies using DNA priming followed by recombinant MVA boosts were reported to induce cell-mediated immune responses of improved magnitude in nonhuman primates and result in decreased viremia after viral challenge.[59–63] Accordingly, these heterologous-DNA-prime-followed-by-viral-vector-boosting for immunization became popular, as they presented a simple and available option to improve the immune response of two different vaccine platforms, resulting in a more robust level of vaccine-specific cellular and humoral immunity.

An early clinical evaluation of heterologous prime-boost vaccination by McConkey and colleagues is illustrative of these benefits.[64] This study of malaria antigen vaccination tested vaccination with a plasmid antigen cassette encoding

a preerythrocytic malaria antigen, thrombospondin-related adhesion protein (TRAP), followed by ID delivery of recombinant modified MVA containing the TRAP antigen as well. The DNA–MVA combination was safe, and induced cellular immune responses that provided partial protection against an irradiated-sporozoite malaria challenge in humans.

Studies by GeoVax (a biotechnology company) using HIV antigen cassettes showed that DNA priming followed by MVA boosting can be attractive as a combined vaccine modality.[65] The authors studied DNA and recombinant MVA HIV antigen vaccines which encode Gag, protease, reverse transcriptase, and the native, membrane-bound trimeric forms of envelope (Env) as vaccine antigens. They reported that DNA priming followed by recombinant poxviral boosting resulted in superior CD4 and CD8 T-cell immunity than poxviral vaccination alone. A follow-up study by these same investigators compared the data from an HIV gp120 env protein vaccination protocol where the protein vaccine was administered three times (group 1) versus a second group (group 2) which received four administrations of the immunizations with the HIV poxviral vector followed by two administrations of the HIV protein vaccination, versus a group (group 3) which received three administrations of the immunizations with an HIV env-encoding plasmid vaccine followed by boosting with gp120 protein twice.[66] The studies reported significant antibody response differences in the three arms. Group 2 exhibited the lowest neutralizing antibody titers, but a high level of binding antibody responses. Group 1 exhibited high neutralizing titer antibodies as did group 3. Interesting, the DNA prime–protein boost group (group 3) exhibited the highest level of broadly neutralizing titers observed suggesting a unique benefit of the DNA prime in the context of protein boosting.

The National Institutes of Health (NIH) Vaccine Research Center reported on several Phase I trials with the goal of developing a DNA prime followed by a recombinant adenovirus serotype 5 (rAd5) vector boost protocol for HIV.[67] For these studies both vector systems, the plasmid and the adenovirus serotype 5 (Ad5) contained similar inserts. The VRC-HIVDNA009-00-VP vaccine consisted of a four-construct mixture of plasmids encoding subtype B Gag-Pol-Nef fusion protein and three modified Env constructs from subtypes A, B, and C. Plasmid doses of 4 or 8 mg were studied but these appeared similar. The adenoviral vectors were delivered at 10^{10} particle units (PU) in a 1-mL volume, in the deltoid and as a single immunization in the prime-boost study. They observed that while each platform was capable of inducing immune responses as a standalone platform,[55,67,68] when the platforms were combined (DNA prime administered three times followed by Ad5 boost) improved immunogenicity was observed. The sequential DNA/rAd5 administration resulted in 7-fold higher magnitude Env-biased HIV-1-specific $CD8^+$ T-cell responses and 100-fold greater antibody binding titers measured by enzyme-linked immunosorbent assay.

An additional possible advantage of a heterologous prime-boost regimen is induction of responses that differed from those induced by repeated dosing of either vaccine modality. Specifically, a report by Cox and colleagues[69] showed that the cellular responses to an HIV vaccine expressing Gag, Pol, and Nef in a heterologous DNA/rAd5 regimen induced a greater Gag-specific CD4 T-cell response than that induced by the homologous rAd5/rAd5 regimen in humans.[70] Furthermore, studies by Schneider and coworkers[71] and Robinson and colleagues[72] of heterologous DNA/poxvirus prime-boost immunization strategies found that T-cell responses generated with a heterologous DNA/poxvirus strategy produce immune responses 10 times higher than either platform given separately.[64,73,74] Together these studies established that heterologous DNA prime-boost immunizations elicited immune responses of greater breadth than could be achieved by priming and boosting with the same vector (Fig. 67.2).

Specific studies, however, have provided unexpected and less-positive results. A focused Phase II study evaluated the regimen of an HIV-1 DNA prime followed by a rAd5 boost, to prevent infection or to reduce viral loads in study participants who became naturally infected after vaccination.[75] This study was designed after an earlier study entitled STEP, which tested an rAd5 vector that encoded gag pol and nef antigens of HIV. The STEP trial was ended early because of futility and a possible concern that persons in the vaccine arm acquired HIV infection more often than those in the control arm. The new trial was specifically designed to avoid potential risks observed in the STEP study, such as inclusion of env antigens in the 505 study as part of the vaccine. However, this trial also ended early because of futility,[76] supporting the conclusion that this prime-boost approach with these vaccine platforms was not effective. It has been speculated that rAd5 may not be the best genetic vaccine platform for HIV as its strong immune cell activation may work against the vaccine during HIV field challenge. An outcome of this study is a shift to other nonhuman adenoviral vectors, such as chimpanzee adenoviral vectors.[77] Overall, the prime boost strategy continues to have a central role in many vaccine efforts targeting diverse difficult pathogens, but as illustrated above, many challenges remain, and there is a major interest in further improving the immune potency of these approaches.

Improved Immune Potency of the DNA Platform

Many approaches have been taken to improve the immune responses induced by the DNA vaccine platform (Table 67.1). These start from reengineering the plasmid vector to better deliver and express antigens in vivo and include optimization of the promoter region and transcriptional elements to enhance antigen expression levels,[78–88] improved leader sequences,[89–95] and optimization of the plasmid backbone itself; development of improved gene sequences[26,28,96]; inclusion of molecular adjuvants in the formulation or as immune modulators; and development of a variety of next-generation delivery approaches.[97–108] Many of these areas have been reviewed,[15,109] and some are highlighted below in more detail.

DNA technology is highly malleable and a much-improved DNA vaccine immune profile has been described. Major areas of improvement are plasmid construction and design, including the optimization of promoters and enhancer elements; polyadenylation[78–88]; incorporation of novel leader sequences[89–95]; vector design; antibiotic resistance and selection sequences; origin of replication choices for production; and efficient and slimmer backbone designs deleted of extraneous DNA sequences, all of which may contribute to improved platform performance. An important consideration for increasing plasmid-driven immune potency involves sequence optimization.[18–26,28,96] Bacterial RNA is rich in AU sequences, whereas mammalian DNA is rich in GC. Therefore, the pool of transfer RNAs needed for translation in human cells is favored for sequences enriched in GC. Because of the redundancy in codon usage, unique transcriptional differences exist between bacteria, diverse viruses, parasites, and even host tumor antigens, which may benefit from attention to genetic design. DNA sequences can be codon-optimized to favor the transfer RNA pools available in human cells, allowing the encoded messenger RNA (mRNA) to be more efficiently translated.

An important modification for increased immune potency is RNA optimization, where changes are made to the RNA sequence that do not affect the amino acid sequence of the

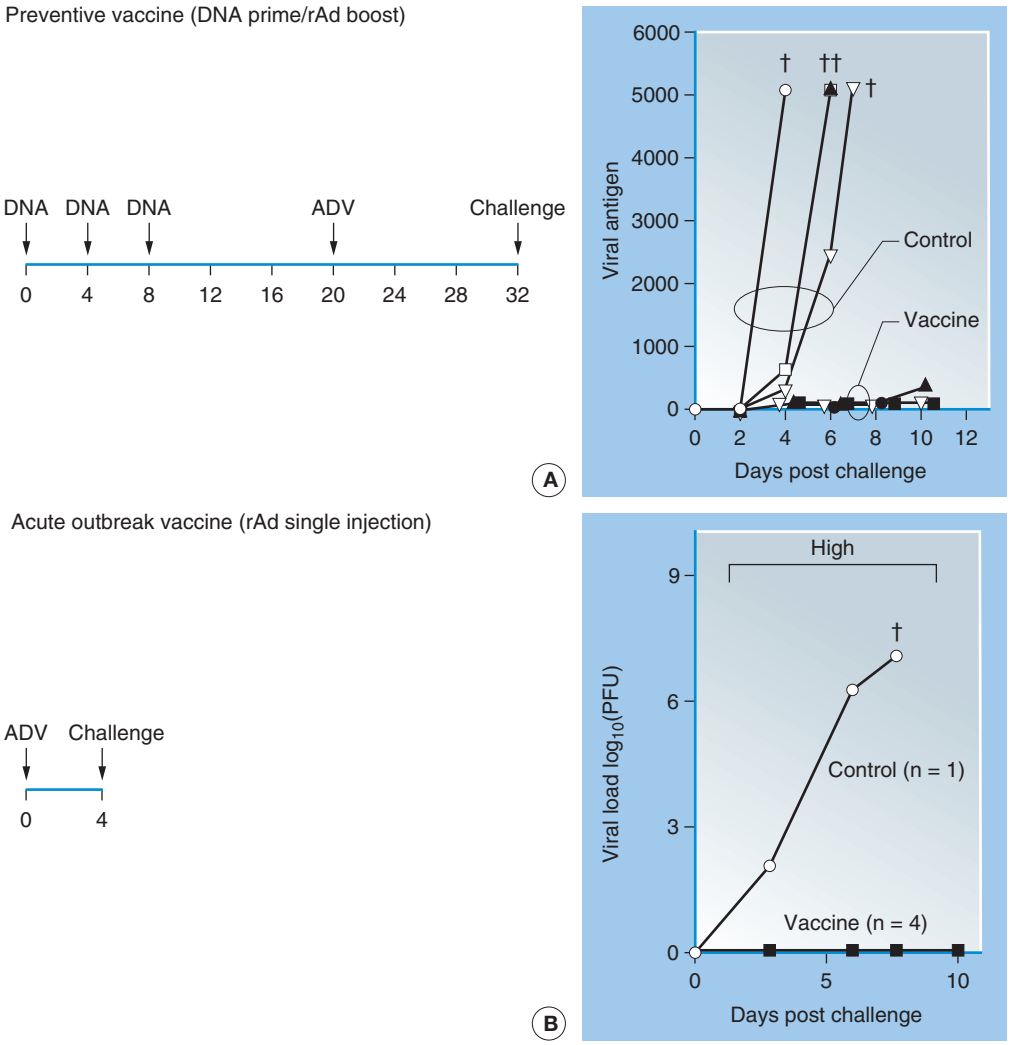

Figure 67.2. Prime-boost versus single shot in models of an Ebolavirus vaccine. Alternative approaches for vaccination can be used depending on the intended use of the vaccine. **A,** In the nonhuman primate challenge model, a DNA prime with recombinant adenoviral vector (rAd) boost of *GP* and *NP* genes confers protection in a lethal challenge model 8 months and longer after the initial immunization. **B,** In contrast, a single shot of an rAd vector encoding these genes stimulates a less potent immune response, but this rapid vaccination produces sufficient immunity to be useful during an acute outbreak. Symbols indicate individual subjects from experimental vaccine and control groups as labeled. The time frame shows the week of vaccination with DNA or ADV vector and subsequent challenge *(left)*. *(Modified from Sullivan NJ, Sanchez A, Rollin PE, et al. Development of a preventive vaccine for Ebolavirus infection in primates.* Nature*. 2000;408:605–609; and Sullivan NJ, Geisbert TW, Geisbert JB, et al. Accelerated vaccination for Ebolavirus haemorrhagic fever in non-human primates.* Nature*. 2003;424:681–684.)*

final vaccine antigen. For example, sequences rich in GC are more likely to form secondary structures and slow translation, lowering in vivo protein production. RNA optimization also involves removing internal *cis*-acting motifs such as TATA boxes, repeat sequences that can cause instability, cryptic splice sites, and unwanted ribosomal binding sites. A combination of these and other gene optimization strategies can have a dramatic positive effect on protein expression and vaccine immunogenicity.[110–112] A recent study of a West Nile virus vaccine DNA using an improved promoter induced relevant antibody responses in most of the 30 trial participants.[113] This study extended the findings reported in trials of severe acute respiratory syndrome (SARS) and Ebola plasmid vaccines, which resulted in low but positive serology induced by the vaccine, with however low T-cell responses suggesting more improvement is still important for this platform to be stand alone.[114,115]

A major advantage of the DNA platform is the ability to rapidly customize the vaccine antigens with high precision to address specific vaccine design limitations. For example, the diversity in HIV's Env sequence can reach greater than 15% within a subtype and greater than 30% between clades. Similar diversity issues plague influenza, hepatitis C virus, and malaria vaccine development, among others. Therefore, vaccination with a single viral sequence is unlikely to drive the diversity of responses necessary for cross-protection from the variety of sequences circulating in the population. Approaches to overcome these limitations combine computer predictions for immunogen design with synthetic chemistry to generate vaccine antigens that improve on nature. Important approaches include consensus antigen, ancestor gene, and center-of-tree designs[116–119]; mosaic antigens[120–122]; and epitope string approaches.[123–128] All these approaches seek to focus the immune response induced by a synthetic gene cassette to

TABLE 67.1 Some Major Approaches[a] in Plasmid Vaccine Optimization

Plasmid Modification	Sequence Modifications	Gene Adjuvants and Formulations	Delivery Enhancement
• Promoter choice • Backbone size • Enhancer elements • Transactivation sequences • Internal termination sequence • Poly AAA tract • Optimized ORI for production • Antibiotic selection sequence for stable production	• Modification of GC/AT content • Species codon optimization • RNA optimizations • Strong Kozack start sequence • Leader sequence • Termination sequence • Localization sequences • Glycosylation sequences • Immunogen sequence optimization • Epitope strings • Consensus • Mosaic • Center-of-tree • Matrix immunogens • Polyvalency or particle formation • Localization sequences • Designer immunogens	• Molecular adjuvants • Cytokines • Chemokines • Toll-like receptors • HSP • Costimulatory genes • Transcription factors • Adhesion molecules • Formulations • Alum • Saponin • Nanoparticles • Liposomes • Polymers	• Electroporation • Jet injector • Gene gun • Skin abrasion • Microneedle • Topical patch • Needle-free systems • Hydrodynamic delivery

HSP, heat shock proteins; ORI, origin of replication (site where DNA replication is initiated).

specific epitopes or regions of a native antigen or an antigen predicted by computer analysis to be more conserved or invariant in the population of divergent viruses. Such targeting would, in theory, preferentially expand the most desired T- and B-cell responses that nature would not drive. These strategies seek to maximize cross-reactivity of the T-cell responses induced against divergent strains of the pathogen. Consensus antigens, mosaic antigens, and epitope strings are currently being studied in the clinic for hepatitis C, hepatitis B, and HIV, among others. Data from HIV as well as human papillomavirus (HPV) are discussed further below.

Molecular Adjuvants

DNA vaccine approaches are particularly suited to deliver gene-encoded adjuvants to modulate the resulting immune response. As these adjuvants are derived from host genes with known biology, they allow an unprecedented level of insight into adjuvant choice. Unlike traditional adjuvants, molecular adjuvants are delivered as plasmid-encoded vectors as part of, or along with, the antigen-encoded vector.[93,129–139] On vaccination, the molecular adjuvant vector transduces cells at the site of vaccination that can then secrete the adjuvant molecule locally, thus coordinately and temporally targeting the same regional APCs[28,29] and draining lymph nodes as the vaccine antigen.

Granulocyte-macrophage colony-stimulating factor (GM-CSF), a white blood cell growth factor with considerable adjuvant properties, was one of the first gene adjuvants to clearly demonstrate that a cytokine plasmid could modulate DNA vaccine-induced immunity.[129] In mice vaccinated with a rabies virus antigen DNA, the addition of GM-CSF delivered as DNA increased antibody production, $CD4^+$ T-cell responses, and protection after lethal challenge. Accordingly, GM-CSF became a widely studied DNA molecular adjuvant that has been examined in macaques and in human clinical studies of a malaria vaccine.[140] However, in human studies, the adjuvant effect was not as clear as in the initial animal studies. It remains under investigation as part of a new delivery format in a prime-boost protocol.[139]

Another cytokine gene, interleukin (IL)-12, has also received a great deal of attention as a DNA vaccine adjuvant.[131,135] IL-12 is a strong T-helper cell type 1 adjuvant that expands T-cell immunity, including $CD8^+$ T-cell function. In mouse models, IL-12 increased $CD8^+$ T-cell lysis of target cells 4.5-fold.[131] Using an HIV-1 DNA vaccination of nonhuman primates (NHPs) along with plasmid encoded IL-12 demonstrated increased cellular responses that corresponded with control of viremia and improved clinical outcomes from a chimeric SHIV virus. The NHP challenge virus consists of SIV core antigens as well as an HIV-1 Env antigen and is designated SHIV98.6P. The ability of plasmid IL-12 vector to increase HIV-1–specific responses against an HIV-1 DNA vaccine is currently being studied in humans, where the adjuvant effect of the plasmid codelivered with IL-12 appears to significantly enhance the immune response, expanding both the CD4 and CD8 T-cell responses induced by the vaccine.[136] Additionally, IL-2–Ig, a T-cell growth expansion factor, administered with an HIV antigen DNA vaccine showed positive results in mouse and macaque model systems and was moved to human testing.[134] In the study of 70 persons which compared an HIV DNA vaccine alone to the HIV DNA vaccine given with IL-2–Ig either with the vaccine or 2 days later, the group receiving the IL-2–Ig adjuvant 2 days later exhibited improved enzyme-linked immunosorbent spot (ELISPOT) results compared to either of the other groups.[141] In a study of a DNA vaccine in the SIV model using a checkpoint inhibitor, anti–CTLA-4 or 41BB Ig adjuvants were reported.[142] This study showed that the 41BB adjuvanted groups showed superior CD8 T-cell responses to DNA alone or DNA + CTLA-4 adjuvanted groups. Furthermore, when the macaques were challenged with a highly pathogenic SIVmac251 monkey virus in the 41BB arm, seven of 14 animals showed several logs lower peak viremia and significant control of infection. The ease and specificity of such combination adjuvant approaches in the DNA vaccine arena has generated an enormous amount of data regarding vaccine effects of important cytokine genes, costimulatory molecules, chemokine genes, heat shock antigens, and other immune modulating molecules. It is likely that this area will continue to receive a great deal of attention,

particularly on the basis of the early positive effects that are being reported in the clinic.

Increased Vaccine Dose

As DNA vaccines are delivered without the benefits of a viral vector coat to facilitate host cell attachment and entry, they suffer intrinsically with a limited transfection efficiency, which compounds their lack of replication and spreading potential. Therefore, a major area of research has focused on improving DNA entry into target cells in vivo. To some extent, the efficacy of DNA vaccination in humans can be improved by increasing the dosage of plasmid delivered. Early studies in humans used doses of 1 mg or less but newer studies use doses of 8 mg, which increase the consistency and frequency of antibody production.[114] Formulations with doses as high as 12 mg, together with cytokine expression vectors and electroporation, have stimulated increased T-cell responses[143] and are promising approaches.

Novel Transfection Reagents

Formulations including novel transfection reagents were a major focus in early studies. In addition, physical delivery has become an important area of research. An important area for DNA delivery is the formulation of DNA into or on biodegradable polymeric microparticles (see a review[105]) as well as contained in liposomes.[97,101,108] Microparticle- and liposome-based DNA vaccine delivery systems are being studied for their utility of delivery and enhanced immunogenicity in several different host and antigenic vaccine platforms in small animals,[99,100,103,106] NHPs[97,104] and in humans in cytomegalovirus (CMV) and influenza DNA vaccines. These compounds can have dual roles, facilitating plasmid entry into the cell as well as providing an adjuvant effect. Polyethyleneimine, amine-functionalized polymethacrylates, cationic poly (β-amino) esters, poloxamers, and polyvinylpyrrolidone polymers are additional examples of molecules that can enhance DNA vaccine immune potency in specific systems.[103,106] The poloxamer CRL1005 has demonstrated improved immune potency in preclinical models for simian HIV vaccines.[97,108] In addition, ongoing studies show that liposome vehicles can improve DNA vaccine-induced immune responses. Studies with liposomes, in general, support an improved, but still modest, impact on antibody responses and lesser impact on T-cell responses. As liposomes have structural versatility with regard to the resulting vesicle surface charge (both cationic and anionic liposomes can be made), size, lipid content, and codelivery with other adjuvants, they offer the ability to be customized for specific DNA applications.[99,100,103–106]

The formulation of DNA vaccines in polyamine gels or nanoparticles[106,144,145] has also been reported to increase the uptake of plasmid vectors and increase antigen expression in vivo. Although there is increasing research in this area, they are not as well studied as the liposome and polymer approaches in their clinical development trajectories. However, alone none of these formulations appear capable of inducing immune responses from the DNA platform that rival the responses induced by viral vectors.

Vaccine Delivery Methods

Another major area of productive research has been in combining DNA vaccines with physical delivery methods. By physically forcing more plasmid DNA into cells, as well as increasing the number of transfected cells, expression levels should improve. Improvements in immune responses have been reported with physical delivery devices such as the gene gun or biolistic jet injection.[146–155] Jet injection involves using high pressure to deliver a liquid formulation of DNA just centimeters below the skin surface. The major limitations to clinical use of jet injection are the requirement for large amounts of DNA and the DNA degradation from the high-pressure delivery. However, it is a relatively simple technique that has shown improved immune responses when compared with IM injection in experimental model systems. The gene gun uses high pressure to deliver DNA-coated gold nanoparticles to the dermis and has demonstrated high transfection efficiency and enhanced antibody responses in several species including humans.[152,153] In contrast, it has had relatively little effect on improving cellular immunity.

Electroporation (EP) has been used to transfect cells in vitro for 3 decades and has more recently been used in vivo to increase the transfection efficiency of DNA vaccines.[17] EP involves applying a small electric field across the site of injection to cause temporary membrane instability and create an electric gradient, which increases plasmid uptake by cells in the field.[18,24] This technique has been studied for 2 decades as a method to improve delivery of chemotherapy drugs to kill specific tumor cells[147–149] and in several animal species (e.g., dogs, pigs, cattle, NHPs) to deliver genes that encode a variety of hormones, cytokines, enzymes, or antigens.[146,150–152,156] However, the conditions required for EP were initially considered too harsh for adoption into vaccination strategies. Yet, over the past 10 years, EP technology has developed more benign delivery devices that are computer controlled and capable of enhancing delivery through IM, ID, and microneedle transfection.[20,21] These approaches use lower voltage and are more tolerable. An exciting development is that in large-animal models, delivery of DNA vaccine by EP has led to both increased cellular and humoral immune responses,[22,23] rivaling those seen with viral vectors.[157] When these newer EP approaches are combined with other DNA optimization approaches, the magnitude of the immune responses generated by the combined DNA approach has increased more than a log.[110,156,158–164] EP technology can also be tailored to a particular DNA vaccine, using devices that control current, voltage, and timing settings. Combinations with molecular adjuvants also look highly promising,[136,165,166] and delivery to the skin, muscle, and the mucosal has been reported. Data from multiple primate challenge models have demonstrated much improved immunogenicity and efficacy against challenge by such delivery of plasmid vaccines.[167,168]

Clinical Studies

The initial studies of DNA vaccines in the clinic demonstrated safety and ease of production, but immune responses were not adequate. The initial fear regarding the use of DNA vaccines was the risk of integration into the host chromosome with subsequent activation of oncogenes or inactivation of tumor suppressor genes. However, studies have demonstrated that the rate of DNA integration in vivo is actually three times lower than the rate of spontaneous mutagenesis. In addition, no negative effects, such as induction of autoimmunity or transfer of antibiotic resistance markers, have been observed. With the renewed clinical interest in this approach, thousands of volunteers have received DNA vaccines without significant vaccine-related adverse events being reported. In fact, the number of DNA vaccines being tested in clinical studies compared with all other recombinant platforms has increased from just 4% in 2000 to comprise 18% of all such trials as of December 2016. Table 67.2 summarizes several pivotal trials of DNA vaccines.

One area that can serve as a barometer of the interest in an experimental platform is HIV vaccine trials. Seven of the

TABLE 67.2 Current DNA Vaccine Clinical Trials as of August 2015

Phase	Approach	No. of Trials	Vaccine Targets
I	DNA alone	17	Cancer, infectious disease
	Prime/boost[a]	3	Cancer, infectious disease
II	DNA alone	3	Cancer, infectious disease
	Prime/boost[a]	3	Cancer, infectious disease

[a]Boost studies include poxviral boosts, recombinant protein boosts, adenoviral boosts; seven DNA-only studies using electroporation. Genetic adjuvants, including granulocyte-macrophage colony-stimulating factor and interleukin-12, are found in multiple DNA studies. Both ID and cancer studies are recognized.

18 clinical trials sponsored by the HIV Vaccine Trials Network (HVTN) are evaluating DNA vaccines to elicit immune responses, either alone or in combination with multiple viral vectors as boosts. Additionally, new studies of EP-delivered DNA alone build on the data observed in HVTN 080 and EP DNA prime-boost strategies are being developed. An alternative approach uses a DNA prime to stimulate both T-cell and B-cell responses, followed by a recombinant protein-boost to generate more-potent antibody responses. DNA vaccines are also being studied in non–prime-boost settings using enhanced physical delivery. For example, in HVTN protocol 080, multiple-codon and genetically optimized DNA plus plasmid IL-12 as an adjuvant is delivered by EP to healthy volunteers. This study reported induction of T-cell immunity in 90% of study volunteers. In fact, this three-immunization protocol induced overall T-cell responses as high as responses previously reported to a DNA prime followed by poxviral or adenoviral boosts consisting of five immunizations. Furthermore, induced CD4 and CD8 T cells were still detectable at 6 months after the final immunization.[169] This was the first study to show that the combination of both EP and IL-12 can dramatically improve the T-cell responses in humans.

A Phase I study of a multioptimized (synthetic) consensus DNA-VGX3100 delivered by EP for treatment of early HPV disease was recently conducted in 18 women with precancerous cervical disease (Cin2 or Cin3). Participants were vaccinated with synthetic DNA encoding two different HPV oncogenes (E6 and E7) and two different oncogenic HPV strains (types 16 and 18) at week 1, week 4, and week 12. Three dose groups (0.6 mg, 3.0 mg, and 6.0 mg) of the plasmid vaccine were studied. Subjects were evaluated for induction of antibodies as well as CTL. In contrast to prior DNA vaccine studies, 100% of women in this study seroconverted, irrespective of dose group, greater than 90% after the second dose of vaccine. Antibodies persisted for at least 6 months after the final immunization. Cellular responses were demonstrated in 78% of women by ELISPOT and in more than 80% of women by cytotoxic assays. In the high-dose group six of six women exhibited killing capacity against targets.[167] Based on these encouraging data, a Phase IIB study was conducted in 147 women with cervical disease (CIN2 or CIN3) testing the same schedule as the Phase I study using the highest dose of vaccine. The primary end point was regression of disease, and the secondary end point was regression of disease as well as viral clearance. The study reported that 50% of the study participants had regression of their cervical disease, with 40% completely clearing the HPV infection ($P = .001$). Similar to the Phase I study, close to 100% of women seroconverted to the vaccine antigens, and greater than 90% exhibited strong T-cell responses. Furthermore, T cells were elevated in cervical samples examined from women who cleared their disease.[168]

It will be important to study optimized DNA vaccines delivered by EP in additional settings to extend these findings to additional targets, expanding the applications of the DNA platform. As with the report of the first efficacy data, it is clear from the preceding discussion that improvements in technologies are driving the field (see Table 67.2). The progress of clinical trials will have to be closely watched, as they will present an exciting picture over the next few years as various DNA approaches come to fruition.

Animal Studies

Several DNA vaccines have been licensed for use in animals. Products licensed for veterinary use[33–36] include a dog melanoma immunotherapy, porcine therapy, a porcine recombinant growth hormone, vaccine for the prevention of rhabdovirus disease in fish, and West Nile virus vaccine for horses based on successful field trials of DNA vaccines. The important safety record of this technology in animal health and in humans, the growing database regarding consistency of immune responses in the clinic, the first efficacy data reported in humans now reported, and the successful licensure of veterinary products suggest that DNA vaccination is well positioned to become an important platform for continued vaccine and immune therapeutic development.

RNA VACCINES

The application of nucleic acid encoded genes (nucleic acid vaccines) delivered in vivo adds another novel approach to the vaccine/immunotherapy pipeline. The use of plasmid DNA for in vivo antigen production and mRNA to deliver encoded antigens was first reported more than 2 decades ago.[170,171] Initially, DNA vaccines took center stage because of their ease of production and stability but problems with immunogenicity were soon appreciated. However, RNA-based approaches have reemerged as an important genetic vaccine platform. RNA-based vaccine approaches allow for infinite boosting because they are not subject to neutralization by the host immune response, even in previously seropositive individuals. RNA vaccines are produced, customized in vivo, and processed by the host. They are naturally folded and can be further modified by the endogenous host cell systems. Similar to DNA vaccine approaches the antigens produced in vivo can be presented on endogenous APC and stimulate both CD4 and CD8 T-cell responses, mimicking the immune responses induced by live infection. Mixtures of RNAs were also tested.[172] However, similar to the poor immunogenicity seen with DNA vaccines, the early studies using RNA vaccines were also plagued by low immunogenicity in small animals, as well as manufacturing issues resulting in low production yields and product instability.

Over the last decade, RNA vaccines have improved through ex vivo transfection studies.[173,174] RNA immunization by transfection of patient-derived dendritic cells showed induction of immunity in vivo. Based on these data, there was interest in cancer immune therapy using patient-derived cells, which are modified by transfecting them with either mRNA derived from their own cancer cells or antigen-specific synthesized mRNA to focus the immune response. These approaches were tested in pancreatic cancer, neuroblastoma, melanoma, colorectal cancer, lung cancer, and prostate cancer, among others. The early studies were well tolerated. Additionally, RNA-based approaches are being investigated for delivery of chimeric T-cell receptors for functionally targeting tumor antigens

directly.[175,176] This ex vivo approach is preferred because of difficulties in RNA production and storage, among other difficulties.

As a result of technological advances, the direct injection of RNA for vaccination purposes is growing in importance.[177] This reemergence is the result of separate advances in the field of RNA vaccines. One advance is the ability to stabilize mRNA during production. The second is the existence of more potent self-amplifying RNA vectors based on the alphavirus platform. In a recent study using a synthetic mRNA encoding influenza antigens, optimized for RNA GC content and complexed with protamine, mice or ferrets vaccinated with this formulation seroconverted to influenza antigens and were protected against influenza challenge[178] after a single immunization. The formulation was also immunogenic in animals as large as pigs, and while not fully protective after influenza challenge in pigs, the disease was attenuated. mRNA vaccines are now being tested in humans, with a focus on therapy of cancer, particularly prostatic cancer.[179–182] A prostate cancer mRNA vaccine containing "self-adjuvanted" mRNA encoding antigens of relevance to prostate disease, including prostate specific antigen, prostate stem cell antigen, prostate specific membrane antigen, and six transmembrane epithelial antigens of the prostate, was evaluated for immunogenicity and safety in 44 patients with advanced castration-resistant prostate cancer. These mRNA-based vaccines contained free and protamine-complexed mRNA to support the stability and delivery of the mRNA. In mice, the vaccine was immunogenic and suggested that these vaccines drove innate immune stimulation that was mediated in part via Toll-like receptor 7 activation. In clinical studies, the mRNA vaccines were administered with five ID injections at a recommended dose of 1280 µg. Results showed that immune responses could be detected against at least one vaccine antigen in 26 of 33 evaluable patients, with 15 of 33 patients responding to more than one of the vaccine antigens. Treatment-related adverse events were experienced by 39 (89%) patients, including injection-site erythema and injection-site reactions, fatigue (18%), pyrexia (16%), chills (11%), and influenza-like illness (11%). Although most of these reactions were considered mild in nature, additional safety studies are needed. The outcome results were interesting as the immune responders showed a trend toward increased survival compared to the non-immune responders. There was also a trend to better clinical outcome based on induction of more antigenic responses; patients who responded to three antigens had better outcomes than those who responded to only one or two antigens. Antibody responses induced by the vaccine were not as robust as the T-cell responses as only four of the patients showed increased titers to tested vaccine antigens. Additional studies in the mRNA vaccine area will be important to follow.

An additional area of importance in the RNA vaccine field is the reemergence of the alphavirus system as a nonviral RNA vaccine delivery platform.[183,184] For example, studies reported from Novartis have described this self-amplifying RNA technology.[185] In this approach the alphavirus genes encoding the RNA replication machinery along with the recombinant viral target antigens are synthesized in the laboratory. Users of this technology to vaccinate mice against respiratory syncytial virus F protein have reported rapid induction of potent antibody responses. This group also reported responses in an NHP study of HIV immunogenicity.[186] The self-amplifying HIV vaccine induced both T cells, measured by ELISPOT, and antibody responses, and were further boosted by MF59 adjuvanted HIV env antigen. Overall, the data clearly illustrate that this platform can induce immune responses. As with mRNA vaccine it will be important to monitor self-amplifying vaccines as they enter clinical evaluation.

RNA approaches have conceptual advantages as they are simple focused immunogens and do not require nuclear localization to generate expression. The replicating vectors such as self-amplifying vectors expand mRNA copies by providing the replication machinery from alphaviruses to maximize expression. The newer stabilized mRNA approaches exhibit a longer half-life compared to earlier-generation mRNA vaccines. These advances improve delivery and expression. Furthermore, RNA approaches strongly stimulate the host innate defense system in part through activation of the Toll-like receptor 3 and Toll-like receptor 7/8 pathways.[187] Innate activation may be an advantage for immune priming that needs further investigation. Overall, even though the RNA field has to catch up to other genetic vaccine platforms, this next generation of RNA vaccines presents interesting opportunities as a standalone platform or as part of prime-boost protocols.

VIRAL VECTORS

Advances in molecular virology have facilitated an understanding of the regulation of viral replication, gene expression, and molecular pathogenesis. At the same time, this understanding has enabled the development of novel viral vectors useful for vaccination. A variety of such vectors have now advanced to preclinical and clinical studies (see Fig. 67.1). Depending on their ability to target APCs, the ease of developing packaging lines, the inherent immunogenicity of both the vector and insert, and other factors (see Box 67.2), these viral vectors are helping to improve vaccine efficacy in a variety of infectious disease models. The properties of promising vectors and current progress in their development are summarized in the following sections.

Replication-Defective Adenoviral Vectors

Among the viral vectors that have been studied, recombinant adenoviral vectors have demonstrated immunogenicity and protective immunity in a variety of animal models. These vectors have been genetically modified so that they can deliver and express specific recombinant gene products but are unable to grow on their own and thus are replication-defective. Like DNA vaccines, these vectors transduce cells that can synthesize native gene products, and they appear to be quite potent in their ability to induce not only helper but specifically CTL immunity.[188] The majority of clinical vectors have been derived from Ad5, although more than 51 human serotypes in six subfamilies (A to F) are known. Ad5 is derived from the C subfamily and is the most common and best-studied serotype; however, the relatively high prevalence of immunity to Ad5 in human populations may pose limitations to the use of these vectors.[189]

Preexisting anti-Ad5 immunity may inhibit the response to rAd5 vaccine immunization, so alternative serotypes and chimeric vectors have been developed to circumvent this. The attraction to rAd5 for immunization has followed from its success with a variety of preclinical animal models and with human trials in Phase I or Phase II. With respect to animal models, the replication-defective adenovirus elicits potent immune responses and protection against Ebolavirus, administered either alone as a single injection, or in prime-boost combinations (see Fig. 67.2).[190,191] The prime-boost approach induces a more potent and durable immunity, desirable for a preventive vaccine in routine use, whereas a single rAd5 vaccination induces a more rapid response that is sufficient for immediate protection (see Fig. 67.2). This rAd5 approach may be useful in containing acute outbreaks of Ebola infection and could be applicable to other pathogens.[39] In addition, both rAd5 vaccines and DNA prime/rAd5 boost combinations

confer partial protection in rhesus macaques against multiple HIV isolates, including SHIV-89.6P,[37,192] SIVmac239,[193] and SIVmac251.[194–196] Replication-defective adenovirus has also been used in a variety of additional animal models of infectious disease, including plague, anthrax, influenza, and malaria.[51]

Phase I and Phase II clinical studies with replication-defective adenoviral vectors for HIV-1 have been conducted by several groups. The STEP trial, a clinical efficacy study of an rAd5 vector encoding *Gag*, *Pol*, and *Nef* genes of HIV-1, evaluated the effect of vaccine-induced T-cell responses on controlling viral load. Although the vaccine was immunogenic, there was no reduction in HIV acquisition or long-term control of postinfection viremia.[197] Further analyses revealed that persons with specific human lymphocyte antigen types, as well as those who developed a $CD8^+$ T-cell response to certain *Gag* and *Nef* HIV epitopes, selected against viruses that contained the vaccine epitope in vivo.[198] There was also an unexpected association between infection in vaccine recipients and those who were both uncircumcised and immune to Ad5 before vaccination. The rate of HIV infection during the first 18 months after the immunization regimen appeared higher in this subgroup, although this result remains controversial.

The clinical utility of the 505 DNA prime/rAd5 boost vaccines is as discussed above in the prime-boost section. The 505 trial was similar to the Merck STEP study, which also was ended early because of futility. The results support that improvement to Ad5 vector approaches must be considered for improving the outcome in the clinic. This could be a vector issue as the inclusion of env antigens did not impact positively on efficacy in the 505 trial. The serology issues associated with Ad5 vectors, as well as the controversy regarding whether there is an increased risk of HIV infection,[199] have driven interest in other non-Ad5 adenoviral vectors.

Effect of Preexisting Antivector Immunity and Alternative Adenovirus Serotypes

Despite the ability of rAd5 to induce potent and sustained immune responses against a variety of infectious pathogens, concerns remain that preexisting immunity against rAd5 may compromise its efficacy. In certain regions of Africa, the Ad5 seroprevalence is greater than 90% with a high degree of neutralizing antibody, limiting the use of this vector. Although both cellular and humoral immune responses contribute to anti-Ad5 immunity, it is likely that the Ad5 neutralizing antibodies play a major role in suppressing rAd5-induced immunogenicity, as seen in humans. This preexisting immunity has been shown to reduce the immunogenicity of Ad vaccines in mice,[200,201] rhesus monkeys,[202] and potentially in humans,[203,204] but it is not clear that preexisting immunity in humans will completely block vaccine immunogenicity.

Several strategies have been developed to overcome the potential problem of rAd immunity. Novel methods to deliver existing recombinant Ad vectors are being explored. For example, it is possible that the administration of higher doses of recombinant Ad5 vectors may overcome anti-Ad5 immunity, although this strategy may be limited by increased toxicity with dose escalation.[204–206] Ad boosting after DNA priming may potentially reduce its immunosuppressive effects, too, although this was not seen in the described HVTN 505 study.[200,201] Finally, the administration of Ad5 vectors through mucosal routes may help circumvent this problem.[207] However, the safety of this approach, particularly for intranasal delivery, has yet to be determined.[208] In addition, several investigators have explored the possibility of coating rAd5 particles with chemicals such as polyethylene glycol, which may block access of antibodies to the viral surface.

Alternative approaches to evasion of Ad5 immunity include engineering of the vectors to evade dominant Ad5 immune responses. A variety of chimeric fiber or hexon proteins have been described that maintain immunogenicity and can evade neutralizing antibodies, both against the fiber,[209–212] or through the use of hexon chimeras, which appear to be the targets of the major neutralizing antibody response.[213,214] Another approach to antivector immunity involves the development of novel vectors from alternative serotypes. To develop such vectors, investigators have evaluated rAd vectors from low-seroprevalence human adenoviruses, as well as from NHPs. Recombinant Ad vectors from human serotypes have been well described.[215–217] Seroprevalence of the 51 Ad serotypes suggests that the Ad11 and Ad35 subfamilies, as well as adenoviruses from subfamily D, including Ad26, are uncommon in humans,[218] and thus may offer advantages over Ad5 as vectors. Novel vectors based on rAd35 and rAd11 have been developed, and preclinical studies suggest that they are resistant to anti-Ad5 immunity in mice.[54,219] Some of the alternative vectors show less-potent antibody responses than seen with rAd5. There also appear to be regional differences in seropositivity to diverse "rare" serotype rAd vectors. For example, although the rAd26 and rAd28 B serotypes have shown promise in early clinical trials and their seroprevalence is low in North America, seropositivity to these viruses approaches 80% in parts of Africa,[220,221] complicating development and regulatory issues for such vectors.

In addition to these replication-incompetent Ad vectors, attenuated replication-competent vectors from Ad4 and Ad7 have been used as vaccine vectors to prevent adenoviral mediated disease in the military where there is a high incidence of this disease among recruits. These live vaccines appear well tolerated and highly effective against Ad4 and Ad7.[222,223] These serotypes have also been developed as recombinant vectors platforms—for example, against HIV.[222,224] These vaccines not only offer the potential of alternative serotypes but when used orally can deliver immune stimulus to the gut mucosa, which may have potentially desirable effects in protection against some viral challenges. Finally, recombinant Ad vectors have been developed from alternative species, including sheep, pigs, cows, macaques, and chimpanzees.[190,225–233] In particular such chimp adenoviral vectors appear to be gaining traction for clinical evaluation. Specifically, the Ad5 Ebola vaccine was superseded by a new chimp adenoviral vaccine.[234] A chimpanzee-derived replication-defective adenovirus (chAd) vaccine induced uniform protection against acute lethal Ebolavirus challenge in macaques. However, the protection was short lived. When chAd3 was boosted with a MVA Ebola vaccine, much more durable protection against lethal Ebolavirus challenge was generated. In human studies, the vaccine induced antibody responses were detected in 68% of vaccine recipients in the highest dose group studied (5×10^{-10}vp) with 100% of vaccinated persons responding in ELISPOT assays.[235] Overall, the data were encouraging. Surprisingly, preexisting neutralizing antibodies were observed against chimp adenoviral vectors in sub-Saharan Africa suggesting that at some level chimp adenoviruses or related viruses have crossed into the human population with some frequency. This finding has consequences beyond HIV vaccines as the chAd3-EBO-Z viral vaccine developed by the NIH is among the important new vaccine candidates being studied in the context of the recent Ebola outbreak in West Africa. The impact of preexisting immunity on this vaccine or others being developed will require additional investigation.[235,236]

In conclusion, the immunogenicity of rAd vectors has prompted their development as candidate vaccines for a variety of infectious diseases. These vectors are well tolerated and highly immunogenic at moderate doses. The concerns

over preexisting Ad5 immunity has generated a number of new approaches for Ad vectors. Novel delivery vectors, molecularly engineered rAd5, and alternative Ad serotypes from other species provide a number of options for clinical study in a variety of infectious disease as well as cancer immune therapy settings.

Poxvirus Vectors for Immunization

The efficacy of vaccinia virus against smallpox represents one of the best examples of the impact of vaccination on infectious disease. However, safety issues using vaccinia strains against smallpox were substantial,[237–240] and a number of alternative vaccinia virus strains have been developed as immunization vehicles (summarized in Box 67.3). These attenuated vaccinia viruses have also been used as delivery vectors for gene products against specific pathogens other than smallpox.

One of the two major attenuated strains of poxvirus is MVA, developed by repeated passaging of the Ankara vaccinia strain on primary chicken embryo fibroblasts (CEFs), as a safer alternative as a vaccine against smallpox. This resulted in multiple genetic changes that enabled the virus to replicate efficiently on a variety of nonavian cell types. A second alternative attenuated strain, the New York vaccinia strain (NYVAC), was developed by genetic modification including the deletion of 18 open reading frames associated with virulence and host range in the Copenhagen strain.[241–244] NYVAC, like MVA, is attenuated in animal models and shows favorable safety and immunogenicity in animals and humans.[242,245,246] NYVAC has a block at an early stage of replication, although it is able to replicate productively in African green monkey kidney cells and primary CEFs.

ALVAC, derived from a plaque-purified virus isolated from an existing canarypox strain, canapox,[247] is able to express inserted transgenes and is immunogenic in both animal and early clinical trials.[245,246,248–251] Additional avipox vectors include fowlpox and canarypox. These vectors have been evaluated both alone and in prime-boost combinations in a variety of infectious disease and cancer models (see review[245]).

In general, poxviruses are notable for their large genome size and their ability to express recombinant genes without an effect on their replication capacity. Polyvalent recombinants have been used to immunize experimental animals and have proved useful in a variety of infectious disease models, including rabies, measles, SIV, canine distemper, respiratory syncytial virus, malaria,[57,252] and influenza.[253] In addition, these vectors have been studied in a variety of HIV challenge models in animals. Human studies have also been conducted [45,254–258] with vaccinia,[259–267] NYVAC,[268–271] and ALVAC,[268,269,271–276] and have advanced into efficacy studies in humans. The ALVAC-EnvGag/Pol (clade B and AE) was evaluated in combination with gp120 protein boosting in a Phase III study in Thailand and demonstrated a 31% reduction in the frequency of acquisition of HIV infection among vaccinated heterosexual men and women when compared with placebo recipients.[277] This study represented a landmark trial, providing a proof of concept that a vaccine could prevent HIV-1 infection, although the degree of efficacy was modest. Although attenuated poxvectors have been evaluated in a variety of human studies, it is clear that developing these vaccines for use in humans has been challenging. In part, because the recombinant transgenes represent a small minority of gene products expressed in this otherwise large vector. Thus, there is no certainty that the immune response will be focused to the foreign transgene rather than to gene products synthesized endogenously by the poxvirus. In addition, as seen with rAd, antivector immunity remains problematic, although to a lesser degree with canarypox vectors.

Poxvirus vectors show thermostability, an ability to incorporate a large foreign transgene, a lack of persistence or genomic integration, and a demonstrable success in smallpox eradication. However, the difficulties in manufacturing virus in high yields from primary CEFs, as well as their antigenic complexity, reactogenicity and poor immunogenicity, possibly impacts their effect in multiple immunization regimens. A poxviral vaccine was tested in a human malaria challenge model.[278] The vaccine expressed a polyprotein insert which consisted of a string of six preerythrocytic antigens designed from *Plasmodium falciparum*. Following safety assessment of single doses, 15 volunteers received a heterologous prime-boost vaccination regime involving two difference poxvirus malaria subunit vaccines containing the insert, FP9-PP and MVA-PP. Following immunization the subjects underwent malaria sporozoite challenge. The vaccines were safe; however, T-cell interferon-γ ELISPOT responses were low and there was no vaccine efficacy observed. A novel MVA vaccine expressing the antigen 85A of *Mycobacterium tuberculosis* was evaluated in a placebo-controlled Phase IIb trial in South Africa in infants.[279] Infants who had previously received bacille Calmette-Guérin (BCG) vaccination were randomized to receive either the MVA85A or placebo intradermally and then followed for immune responses and protection against tuberculosis. Although the vaccine was safe and the immunogenicity was modest, there was no efficacy against tuberculosis infection or disease. Both of these studies with malaria and tuberculosis suggest that much more potent immune responses will be needed to impact these two infections. Thus, prime-boost strategies are being pursued.

In addition to studies in the infectious disease arena, poxviral vectors have been important tools in multiple cancer immune therapy protocols[280] targeting diverse tumor types. In these studies, T cells have been induced; however, the poxviral vectors appear to induce modest antibody responses. The first positive efficacy outcome has been reported in a Phase IIb study using a recombinant poxviral vector. Prostvac-V/F is a candidate, anticancer immunotherapy for therapy of prostate cancer which was originally championed by the National Cancer Institute. It was developed for men with asymptomatic or minimally symptomatic metastatic castration-resistant prostate cancer. Therapy consists of priming with a vaccinia recombinant poxviral vector followed by up to five monthly immunizations with a fowlpox vector. The vectors contain the identical gene inserts. The inserts include a gene sequence encoding a modified immune stimulatory prostate-specific antigen cassette along with additional gene cassettes for three human immunostimulatory molecules (known as TRICOM), leukocyte function–associated antigen-3, intercellular adhesion molecule-1, and B7.1. In clinical trials, the treatment generated clear anti–prostate-specific antigen CTL responses in up to 57% of vaccinees, but almost no antibody responses.[281]

BOX 67.3 Poxvirus Strains Used as Immunization Vehicles

VACCINIA VIRUS

- New York vaccinia strain (NYVAC) (18 ORFs deleted)
- Modified vaccinia Ankara (MVA) (adapted to CEF)

AVIPOXVIRUS

- Fowlpox—FPV/TROVAC
- Canarypox—CPV/ALVAC (adapted to CEF)
- Canarypox—ALVAC (2) (+ *E3L* and *K3L* genes)

CEF, chicken embryonic fibroblasts; ORF, open reading frame.

These CTLs were shown to have the ability to lyse tumor targets.[282] In a randomized, placebo-controlled, double-blind, Phase II clinical trial (NCT00078585), Prostvac-V/F increased overall survival in patients with metastatic castration-resistant prostate cancer by 8.5 months which translated to a 44% reduction in risk of death.[283] Bavarian Nordic in conjunction with the National Cancer Institute is currently testing Prostvac with or without a GM-CSF adjuvant in a global, double-blind, randomized, Phase III efficacy trial dubbed PROSPECT (NCT01322490). It will be interesting to clinically evaluate this immune therapeutic vaccine in the context of checkpoint inhibitor therapy as well. Further improvement in poxviral immunogenicity remains important.

Adeno-Associated Viruses

The adeno-associated viruses (AAVs) were defined initially as "helper" viruses that facilitated the propagation of wild-type adenovirus in cell culture. In contrast to the large genome sizes of rAd and vaccinia vectors, AAV's genome sizes are much more limited in size, with an insert size of approximately 5 kb. Like other replication-defective viruses, these particles can be produced in packaging lines that provide complementary structural proteins made constitutively by the cell rather than the virus. A variety of serotypes have been defined,[284] and an HIV vaccine expressed in AAV2 has been evaluated in Phase I human studies, with poor immunogenicity results. Alternative serotypes, including AAV1, are currently under development and may be assessed both alone and in prime-boost combinations for efficacy in humans. An entirely unique use of these vectors has also been described recently. Recombinant adeno-associated virus vectors have been studied as a platform to deliver recombinant antibody genes for direct in vivo production of antibodies. This strategy, vector immune prophylaxis, allows previously identified rare neutralizing antibodies to be engineered into an Recombinant adeno-associated virus vector, which, upon infection, results in in vivo antibody production of protective antibodies. Vector immune prophylaxis also allows for production of protective antibodies in vivo that have not been achieved with vaccination.[285] Several studies have demonstrated the effectiveness of this delivery strategy in protecting NHPs against SIV,[285,286] humanized mice against HIV,[287,288] and mice and ferrets against influenza.[289,290] The first vector immune prophylaxis approach has reached the clinic to inhibit HIV infection. A similar approach has been described using DNA vectors delivered by EP. This DNA monoclonal antibody delivery approach showed in vivo production of broadly neutralizing HIV antibodies,[291] as well as antibodies that can protect against Dengue challenge.[292] Collectively the vector immune prophylaxis and related platforms are clearly exciting, even though they are early and have many hurdles to overcome. They illustrate how gene vectors are revolutionizing the way we think about traditional vaccination for protection against infectious disease.

VECTORS IN DEVELOPMENT

Alphaviruses are negative-stranded RNA viruses that can be modified to express foreign recombinant genes without producing pathogenic infections. Prototypes include Venezuelan equine encephalitis virus,[293,294] Sindbis virus,[295,296] and Semliki Forest virus. Replication-defective herpes simplex virus (HSV) can be produced using packaging cell lines similar to those described for replication-defective rAd5, AAV, or alphavirus vectors. These vaccines have been developed not only to deliver foreign genes as potential immunogens, but also to be vectors against HSV itself, including both HSV1 and HSV2.[297] Vesicular stomatitis virus, dengue virus type 4, yellow fever virus, and alphavirus have been modified to express heterologous viral genes for vaccines for infectious disease targets including HIV, West Nile virus, filoviruses, CMV, and other pathogens.[298–305]

Although not yet in the clinic, interesting data have been generated in NHP challenge models by a novel recombinant replicating simian CMV vector (RhCMV/SIV). This is engineered to contain SIV antigens env, gag, pol, vpr/vpx in four separate RhCMV vectors. The concept is that CMV infection is a potent T-cell memory driving infection, therefore recombinant antigens expressed from this vector may represent a novel CTL-inducing vaccine platform.[306] In an illustrative example, animals were vaccinated twice at 98-day intervals with the RhCMV/SIV vectors, then rested for 545 days and subjected to repeat low-dose pathogenic SIVmac[293] challenge. Over time, 50% of the vaccinated challenged animals exhibited close to complete control over the SIV challenge.[307] Surprisingly, CD8 T-cell responses were not responsible for this impressive control, rather it appears that CD8 T-cell killing is redirected in the context of MHC II molecules.[308] Important issues, such as development of a more field-ready vaccine protocol, understanding why protection is observed in specifically 50% of the animals, understanding the role of the observed CD8 class II killing and its relevance to humans, development of similar acting human appropriate vectors for study, as well as the unique differences between simian CMV and human CMV vectors will require more investigation. However, the interesting impact in the difficult SIV challenge model and the associated control and immune-based clearance is an important avenue for research for control of HIV and other chronic infections.

An unique vector that has moved quickly into the clinic is based on the vesicular stomatitis platform (VSV). The VSV Ebolavirus vaccine (rVSV-ZEBOV) was developed by the Public Health Agency of Canada and consists of a recombinant, replication-competent VSV engineered to express the surface glycoprotein from the Zaire strain of Ebolavirus (Fig. 67.3). Preclinical testing in mice and NHPs demonstrated that IM injections of rVSV-ZEBOV induced neutralizing antibodies that were capable of protecting the animals from a challenge with a lethal dose of Ebolavirus.[309] Phase I clinical trials studying the safety of this vaccine reported that vaccination with rVSV-ZEBOV at doses ranging from 3×10^5 to 50×10^6 plaque forming units (PFU) resulted in no serious adverse events with the only reported side effects being mild fever, joint pains, and vesicular dermatitis in some vaccines.[310] Importantly, vaccination resulted in a transient systemic infection that generated antibodies against Ebolavirus that were capable of neutralizing the virus in vitro (described more fully in the Chapter 20). This vaccine was deployed during the current outbreak. A Phase III study was designed using a ring vaccination strategy and a single immunization protocol. Excitingly, the preliminary results of this Phase III clinical trial of rVSV-ZEBOV in Guinea revealed that the vaccine was 100% effective in protecting close contacts of Ebolavirus patients from becoming infected when the vaccine was administered immediately as opposed to when it was delivered 3 weeks following the patient's diagnosis.[311] Based on these encouraging preliminary data, the World Health Organization approved the continuation of the trial with the elimination of the 3-week postexposure vaccination arm of the study. Further testing is needed to qualify and quantify the anti-Ebolavirus immune response(s) generated in vaccinees, to determine the longevity of protection, and to evaluate the protection generated against different strains of Ebolavirus. Nonetheless, these data are impressive and important for in the context of Ebola and other pandemic outbreaks.

The VSV Ebola is an example of pressing into service a recombinant platform resulting from the urgency of a serious

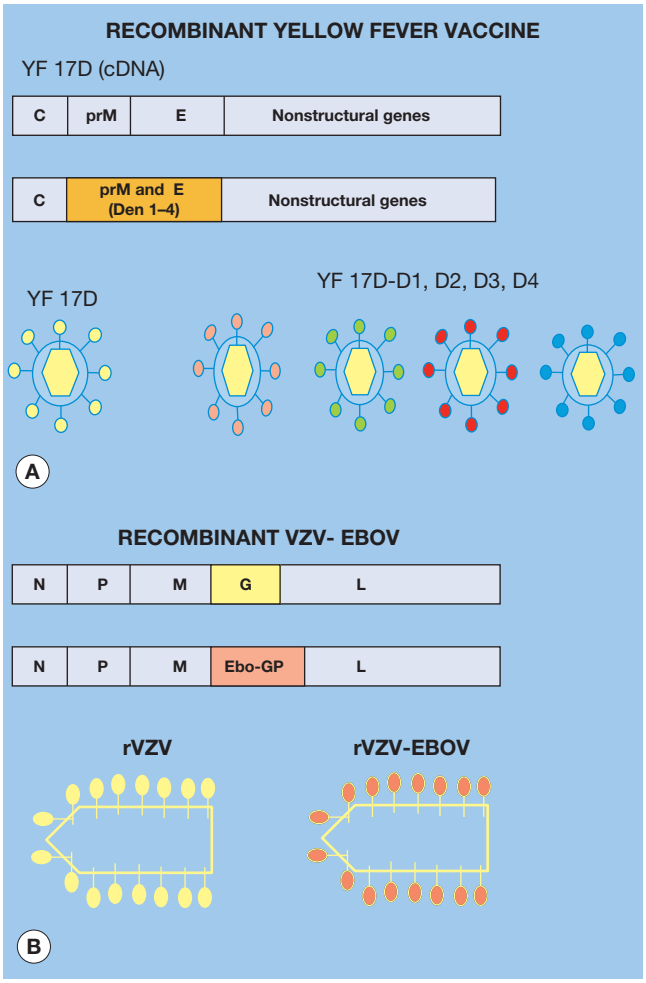

Figure 67.3. A, Recombinant chimeric dengue vaccine. The figure depicts the genome of the attenuated yellow fever vaccine *(top)* versus the chimeric vaccines genome, which has the *prM* and *E* genes *(in orange)* inserted in their place, one each in four different backbones. The *prM* and *E* genes associate to form a complex for env transport and correct surface orientation allowing attachment of the E antigen allowing infection and replication of the attenuated vaccine. The E antigen contains the important immune targets for protection. As there are four different Dengue viral serotypes *(Den 1-4)*, a different chimeric virus was constructed to contain each serotype. This is depicted in the schematic on the bottom of the figure to the left of the attenuated YF17D viral particle cartoon. **B,** Varicella zoster virus–Ebolavirus (VZV-EBOV). The figure depicts the genome of attenuated VZV *(top)* versus the genome of the attenuated VZV with the Ebola glycoprotein inserted upstream of the L antigen. *Yellow*, glycoprotein from VZV; *orange*, glycoprotein from Ebola strain. The glycoprotein switch between the attenuated vesicular stomatitis backbone and the constructed VZV-Ebolavirus vaccine as a viral particle is shown in the schematic below. To construct the vaccine the gene for the native envelope of VZV was deleted. The glycoprotein from the Ebolavirus Zaire-Kikwit 1995 strain is inserted into the recombinant viral genome.

life-threating emerging disease. In contrast, the development of chimeric attenuated yellow fever virus vector expressing dengue viral antigens is a story reminiscent of the development of recombinant poxviral vaccine vectors. The live attenuated 17D strain of yellow fever vaccine is considered one of the world's most effective and safest vaccines. It has been deployed since the 1950s with millions of doses administered. Originally developed by Max Theiler in 1937 through passage, a single dose of the vaccine can confer lifelong immunity. This passed virus has been used as the basis for construction of the new chimeric tetravalent dengue vaccine (CYD-TDV or ChimeriVax) which consists of four recombinant, live, attenuated yellow fever virus 17D vaccine backbones in which the surface Env and premembrane genes were swapped out for those of one of the four serotypes of dengue virus (see Fig. 67.3).[312] The administered vaccine dose consists of 1×10^5 CCID50 (median end point of the cell culture's infectious dose) of each chimeric vector, and each vaccinee receives three doses of vaccine, 6 months apart. Phase IIb clinical trials reported that the vaccine was 30% effective at preventing any dengue infection, and that the vaccine primarily provided protection from dengue serotypes 1, 3, and 4, and offered no protection from serotype 2.[313,314] In two Phase III trials in dengue endemic regions ChimeriVax was found to be 56% to 60% effective in preventing dengue virus infections including infections with dengue serotype 2. Additional testing and research are needed to determine the immune correlates of protection for the vaccine, and a Phase IV clinical trial will likely be needed after licensure to monitor the continued safety, efficacy, and feasibility of large scale vaccination with ChimeriVax. An important fact is that development of this vaccine cost more than $1.5 billion and more than 20 years of research to get to this milestone. Importantly, ChimeriVax is poised to be one of the first examples of successful licensure of a recombinant gene-based vaccine.

Cell Substrates

The progress of more recent viral vectors has depended on the development of appropriate packaging cell lines and cell substrates for viral production. Changes in regulatory requirements that allowed the advancement of transformed cell lines for virus production have proved invaluable in facilitating this effort. For recombinant adenoviral production, the PERC6 and GV11 cell lines have supported production of clinical-grade Ad5, and these have progressed into trials for HIV and are under study for other infectious agents, such as Ebolavirus, Marburg virus, tuberculosis, and malaria. Once approved, these cell lines can be used for diverse vectors. The PERC6 cell line has been used to develop a number of vaccines, including those for West Nile and influenza viruses. In these latter cases, the propagated virus is subsequently inactivated before administration to humans.

For the generation of replication-defective viral vectors, these cell lines allow the production of vectors that can be used in human vaccine studies. Of the viruses developed for such vaccines, representative members (summarized in Fig. 67.1B) include recombinant Ad, poxviruses, measles, Venezuelan equine encephalitis virus, and AAV, all of which have progressed into human trials. The development of transformed cell lines that are capable of propagation, in contrast to the previous standard, avian leukosis–free primary CEFs, represents a major advance in vaccine production technology. These cell lines facilitate the production of replication-defective viral vectors in stably transfected cell lines and offer potentially improved yields and stable production capacity. The development of these lines has taken years to implement because of regulatory concerns regarding adventitious agents, tumorigenicity, and other safety and consistency considerations. Oversight and evaluation of the strengths and limitations of these cell substrates continues,[315] based on guidelines created several years ago,[316,317] with an increasing number of such lines becoming better characterized and available.

Bacterial Vaccine Vectors

Because many infectious agents replicate at mucosal membranes and transit through the gastrointestinal tract for primary infection, the ability to elicit effective immune responses at these sites is desirable. A variety of bacteria are able to replicate at mucosal sites of natural infection, and it has been proposed that attenuation of these microorganisms and modification to facilitate the delivery of antigen might allow the development of improved vaccines to protect against pathogens that enter through the mucosa. Development of live bacterial vectors has therefore focused both on their ability to induce mucosal IgA responses and on cytolytic T-cell responses at mucosal sites. The synthesis of proteins in mammalian cells delivered by bacterial vectors has the potential to induce the cellular immunity that is the goal of many gene-based viral and nonviral vaccines. These approaches have been reviewed in detail elsewhere[318–320] and are summarized briefly here.

Among the live bacterial vectors used for antigen delivery, there are mucosal pathogens that have been attenuated, including strains of *Listeria monocytogenes*, *Salmonella*, *Vibrio* cholera, *Shigella*, *Mycobacteria bovis*, *Yersinia enterocolitica*, and *Bacillus anthracis*. In addition, there are commensal strains such as *Streptococcus gordonii*, lactobacilli, and staphylococci that have been used for the induction of humoral and cellular responses. For gene-based vaccination, *L. monocytogenes* has been a particular focus of research. This gram-positive intracellular pathogen has been studied as a model for understanding class I MHC-restricted immune responses. These responses are normally seen against the bacterial proteins or coexpressed antigens. This microorganism uses a specialized system to introduce proteins into cells and facilitate processing and presentation through MHC class I, and different mutations have been used to develop attenuated strains that retain the ability to deliver antigens. Similarly, *Salmonella* bacterial strains are intracellular pathogens that become restricted to the endosomal compartment of eukaryotic cells, where they are resistant to lysis.[321] A variety of mutations have been introduced into *Salmonella* to generate several different live vaccine carriers, and these vaccine prototypes have undergone further development for vaccine delivery. Among the other bacterial carriers, *M. bovis* Calmette-Guérin (bacille Calmette-Guérin) has been a widely used bacterial vaccine; for example, this organism has been used to express HIV antigens.[322,323] In some instances, expression of mammalian genes has required modification of codons more consistent with the host cell type, which has improved immunogenicity.[18,324] At present, however, the ability of such microorganisms to induce cellular immunity at levels similar to adenoviral or poxviral vectors in humans is still under investigation.

An area of intense interest has been the use of live bacterial vectors for the delivery of DNA vaccines. In this instance, the aim is for the bacteria to deliver plasmid DNA into the cytoplasm of infected cells; organisms such as *Shigella* and *Listeria* have been used for this purpose.[325,326] In addition, attenuated *Salmonella* has been evaluated for these purposes and has shown some promise in both infectious disease and tumor models in experimental animals.[327–329]

Although the use of such bacterial vectors is attractive in theory, it is more difficult to reduce this method to practice. Among the concerns is the possibility of reversion or reactogenicity of these potentially pathogenic bacteria to wild-type forms, the stability of the recombinant bacteria, and the possibility that preexisting immunity from exposure to natural pathogens may limit their infectivity. A variety of host genetic factors can modulate the immune response induced by the bacterial carrier, and variability in the innate immune responses to such pathogens may limit their consistency in vivo. Finally, perhaps the most challenging problem has been the ability to effect a gene transfer from bacteria into mammalian cells. It is likely that very specialized transport pathways are required for the successful implementation of this technology, and if additional improvements will be necessary to improve the efficacy of this approach remains to be established in the clinic.

CLINICAL APPLICATIONS OF GENE-BASED VECTOR TECHNOLOGY

There has been substantial work in animal models of genetic vaccine efficacy. Until very recently there were no reported successes in human studies for guidance; rather there were several failures that brought into question the potential of the technology. However, this status is rapidly changing. Some of the oldest of the recombinant vector platforms have been in clinical evaluation for close to 2 decades. Several trials using the poxvirus technology have been studied in efficacy trials. These include canarypox, MVA, and NYVAC, which have been evaluated in various Phase I to III human studies. As the production technology for poxviruses is well researched, and good-manufacturing-practice procedures for amplification of these viruses followed protocols similar to those developed for vaccinia virus, the path toward clinical studies appeared relatively straightforward. Over the past 3 decades efficacy data were elusive, but recently there has been some positive news. The "Thai" trail of a canarypox vector engineered to carry HIV antigens in which patients were boosted with gp120 antigen provided a possible glimpse of efficacy in a prime-boost platform study, with approximately 31% protection from infection reported.[277] Subsequently, the ProstaVac immune therapy efficacy trial using two different poxviral backbones in prime-boost fashion demonstrated overall increased survival in patients with metastatic castration-resistant prostate cancer of 8.5 months. These important results are supportive of potential impact of these vectors in other targets in the future. It is also important to remember that studies of recombinant MVA technology have given rise to a potentially safer next-generation vaccine for smallpox.[31]

Similarly, DNA vaccines have undergone Phase I testing targeting a diverse collection of infectious diseases, including Ebolavirus, West Nile virus, the SARS coronavirus, MERS, Zika, and influenza virus as well as in cancer studies. Proof-of-concept studies against these viruses have been performed first in animal models with either DNA or in prime-boost combinations or using newer synthetic EP systems. In such studies, impressive protection has been demonstrated in animals.[75,330] Based on these findings, several Phase I trials were completed for Ebola, SARS, and West Nile virus disease targets.[113–115]

In the case of influenza, both naked DNA and DNA adjuvanted with gold microparticles (by biolistics) have advanced into clinical testing. Of particular interest is the development of prime-boost strategies to stimulate the production of broadly neutralizing antibodies to influenza viruses, demonstrated initially in mice, ferrets, and monkeys.[331] Phase I studies testing this concept in humans revealed that even a single injection of a DNA vaccine can prime for an effective traditional vaccine boost against the H5N1 virus. This regimen also showed that more broadly neutralizing anti-stem antibodies can be elicited by vaccination in humans.[332]

A Phase IIb efficacy trial testing a synthetic DNA delivered by EP (VGX-3100) in cervical disease reported that 50% of the women in the vaccine arm regressed disease, and 40% of them cured their underlying infection, providing the first efficacy outcome for the DNA vaccine field.[333] It is likely that additional studies building off these more potent approaches will

be important to study. As previously discussed, DNA vaccines have been approved for veterinary use, including a DNA vaccine for West Nile virus in horses[334] and a DNA vaccine for infectious hematopoietic necrosis virus for protection of farm-raised fish. An additional vaccine is being developed against viral hemorrhagic septicemia virus in farmed salmon. In these studies, a single injection of microgram amounts of DNA induces rapid and long-lasting immune protection.[335]

Among many research and early clinical accomplishments, the efficacy data reported in multiple gene-based studies is a refreshing change. The protection reported for rVSV-ZEBOV vaccine studies which prevented Ebola transmission in West Africa, the efficacy of tetravalent ChimeriVax lowering hospitalizations and improving outcome in dengue endemic regions, the impact of ProstaVac for extending life of cancer patients, and the ability of VGX 3100 to regress and clear some women with neoplastic cervical disease serve as major milestones for gene based vaccine technologies. These efficacy outcomes have come to fruition only in the last few years suggesting that specific gene based platforms appear to be coming of age. The precedent set by these studies provide hope that additional gene-based vaccines will become available for human use and may contribute to the development of protective immunity for a variety of challenging infectious diseases as well as providing new therapies for cancer.

68 Technologies to Improve Immunization

Mark J. Papania, Darin Zehrung, and Courtney Jarrahian

NEW TECHNOLOGIES NEEDED TO REDUCE IMMUNIZATION LOGISTICS HURDLES

Immunization can be described as the process of delivering carefully packaged antigen to the appropriate destination in a vaccine recipient to produce a desired immune response. In this sense, immunization programs are package delivery systems: they manage the flow of antigens, formulated in vaccines and packaged in different presentations, between the point of origin at the vaccine manufacturer and the point of consumption, inside antigen-presenting cells (APCs) of the vaccinee. This simple concept of delivering antigen packages from point to point can help elucidate the complex logistical challenges inherent in the preservation, packaging, storage, transportation, and administration of vaccines.

Immunization is one of the most powerful tools for health, but many current vaccines are not affordable, accessible, and acceptable to everyone who needs them. Continual sharpening of this public health tool is needed to achieve the full potential of immunization for improving health. Some advances will come in the form of better vaccine antigens; however, significant potential also lies in improving the way vaccines are packaged and delivered. Reviewing immunization as a package delivery process and recognizing critical hurdles, bottlenecks, and barriers to vaccine flow is a first step toward making immunization programs more efficient and effective. Managing vaccine flow around those obstacles is the day-to-day work of immunization programs, which often requires heroic effort. This chapter briefly describes key restrictions to vaccine flow logistics in terms of complexity, cost, human resources requirements, distributability, and sources of errors in the immunization process. It reviews new technologies in various stages of development that have the potential to eliminate or reduce restrictions to vaccine flow. These new technologies have the potential to increase the capacity and efficiency of immunization programs and make immunization safer and more effective, affordable, accessible, and acceptable for everyone.

POINT-TO-POINT ANTIGEN PACKAGE DELIVERY

The four key points in the antigen package delivery system are the point of origin, storage and distribution point, the point of care (POC), and the final destination point in the recipient. The points of origin are the dozens of vaccine manufacturing plants where antigens are produced and, along with other components, formulated into vaccines, and where the vaccines are further packaged in multiple layers of containers for storage and distribution. The distribution and storage points form the network of thousands of sites from vaccine plants through national, regional, and local centers tasked with safely storing and transporting vaccines to the POCs. The POCs are the millions of hospitals, clinics, health posts, and homes where a competent vaccinator, an informed and willing vaccinee, and a safe and effective vaccine can be brought together for vaccine administration. The final destination points for antigen package delivery are the APCs inside the IM, subcutaneous (SC), cutaneous, or mucosal tissues of the billions of people who will benefit from immunization. Each of the four points along the package delivery system has distinct logistical challenges.

Points of Origin: Vaccine Manufacturing Plants

Purity and Stability

The antigen package delivery system originates in the vaccine manufacturing plant. The formulation, manufacture, and packaging of vaccines are well described in Chapter 5; this chapter highlights key factors relevant to immunization logistics. Vaccine manufacturing plants are highly capitalized, multimillion-dollar facilities that use sophisticated technology to mass-produce the billions of doses of vaccines used globally each year. Two critical vaccine flow logistics requirements start in the plant and span the entire immunization process up to vaccination of the individual: (a) maintenance of vaccine purity and (b) maintenance of vaccine potency by keeping it within the prescribed temperature range. These impose significant restrictions on vaccine flow logistics.

To maintain purity, the vaccine plant environment is highly regulated and monitored: people, equipment, and materials are introduced into the facilities in a precisely controlled manner. Expensive, high-speed filling equipment enables sterile packaging of bulk vaccine into specific-dose packages at low costs. Each step is carefully orchestrated, and even minor modifications to procedures or material may require approval from national regulatory authorities. Any change to the process implies regulatory consequences with significant associated economic costs (see Chapter 5).

For almost all currently licensed vaccines, the required storage conditions include constant maintenance at 2 °C to 8 °C (or −20 °C for several vaccines). This requirement, which is met by the system known as the cold chain, constricts the flow of vaccine to facilities and delivery mechanisms that have refrigeration or cold pack storage capabilities. Some vaccines, especially those that include aluminum adjuvants, are susceptible to damage from freezing temperatures. Others, especially live attenuated vaccines, are more susceptible to loss of potency at elevated temperatures. Through the addition of stabilizers and, in some cases, the additional step of lyophilization (freeze drying), vaccines maintain minimum potency under the required storage conditions, throughout the listed shelf life. When breaks in the cold chain are detected, valuable vaccines are discarded. When undetected, cold chain failures can result in administration of ineffective vaccine.

Presentation

Vaccine presentation affects flow logistics. In contrast to many pharmaceuticals, all currently licensed vaccines are administered as liquids—by needle and syringe injection, oral delivery, or nasal spray. Most vaccines are formulated, packaged, and shipped as liquids in single- or multidose vials or prefilled syringes. All others are first formulated as liquids, packaged in vials, and then lyophilized to enhance their stability. Although they are shipped in a dry format, lyophilized vaccines must be accompanied by a liquid diluent and reconstituted before on-site filling of the administration device and vaccination.

Liquid diluents increase the volume and weight of the vaccine, which may increase shipping costs and require more cold chain storage capacity. There is also the risk of spilling and leakage. Thus, the lyophilized format of vaccine with liquid diluent can slow down efficient vaccine flow.

There are three basic vaccine presentation schemes: prefilled delivery devices, liquid vaccine in vials or ampules, and lyophilized vaccine in vials. Prefilled delivery devices simplify the logistics at the POCs because they minimize on-site preparation. They also reduce the number of components to be shipped; eliminate the need for a separate supply chain for vaccine, diluent, and administration devices; and reduce filling overage required for vials and ampules. However, packaging vaccines in prefilled delivery devices is expensive, and the larger volumes of some devices increase the space needed in cold chain storage.

Liquid vaccines packaged and shipped in vials or ampules typically cost less per dose and occupy less cold chain space than prefilled vaccine presentations, but they require filling of the administration device at the POCs. This increases delivery complexity and creates an opportunity for errors, such as withdrawing the wrong dose amount from the vial or contamination of the vaccine. Vaccines in vials can be in single- or multidose format. Multidose vials typically cost less per dose and occupy less cold chain space than single-dose vials; however, vaccine wastage may be increased with multidose vials if a vial is opened when there are fewer people needing vaccine than the doses in the vial. Vaccinators also may be reluctant to open a 10-dose vial if only one or two people need vaccine, leading to missed opportunities to vaccinate those people. Repeated entry into a multidose vial and time lapse between vaccine withdrawals increase the risk of bacterial or fungal overgrowth, with subsequent injection of a contaminated vaccine. Single-dose vials avoid some of these problems but cost more per dose, occupy more cold chain space, and still require on-site filling of the delivery device.

Lyophilized vaccines can be packaged in single- or multidose vials, and they share the same problems as liquid vaccines in vials. The reconstitution step needed for lyophilized vaccines adds further complexity to delivery, creating the opportunity for errors such as use of a wrong amount of diluent or the wrong diluent. Other challenges with reconstitution include the potential for mismatched amounts of dry vaccine and diluent—which are often shipped and stored separately, with vaccine in the cold chain and diluent at ambient temperature—and a temperature difference between the diluent and the dried vaccine, which may render some vaccines ineffective upon reconstitution.

Inability to overcome the challenges presented by multidose liquid vial presentation and by lyophilized presentations can result in failure to immunize a vaccinee; cross-contamination of infectious pathogens among persons receiving vaccinations; and adverse reactions, including local abscesses, toxic shock syndrome, or even death.[1–9] Although rare, these errors can have grave consequences and may significantly undermine public confidence in vaccines. A recent example of a reconstitution error occurred in Syria in 2014, when an anesthetic agent was mistakenly used for a vaccine diluent, resulting in 15 infant deaths and many hospitalizations.[10]

Distribution and Storage Points

Complex networks of storage and shipping facilities manage the distribution of vaccines from dozens of manufacturers to millions of POCs. The challenges associated with timely ordering, purchase, inventory, and monitoring are staggering and result in ongoing attempts to improve immunization programs and develop software to assist with the logistics.

Vaccine distributability, a key logistics concept, is how easily a vaccine can be transported to POCs and administered to vaccine recipients. Cold chain requirements at every level of storage and distribution can significantly reduce vaccine distributability. In general, the complexity and difficulty associated with cold chain management increase with distance from the manufacturer. It is relatively easy to keep large quantities of vaccine refrigerated and monitored in cold rooms at vaccine plants or large national or regional storage facilities, and economies of scale reduce the per dose cost of storage. However, maintaining the refrigerated storage with around-the-clock monitoring and backup energy sources for the smaller quantities of vaccine present at each district and at the local level can be a daunting task.[11]

Package shipping must avoid delays that could allow vaccine temperatures to rise. Transporting vaccines at cold temperatures at the end of the cold chain, where transport is often by unrefrigerated vehicles, requires insulated boxes with cold packs, which significantly increase weight, expense, and difficulty.

Vaccination by needle and syringe injection requires highly skilled staff, which combined with limited staff supply can restrict distributability. Self-administered vaccines could significantly increase distributability, but only oral typhoid vaccine has been approved for self-administration.[12] Thermostable[13] self-administered vaccines distributed through regular mail systems and self-administered are a conceptual example of ideal distributability.

Points of Care: Vaccine Administration Settings

The POCs are the settings where three essential components meet: vaccine, vaccinator, and vaccinee. Ideally, a caring and competent vaccinator administers a safe and effective vaccine to an informed and willing vaccinee. While this chapter focuses on the logistics of getting vaccines safely to the POCs and technologies for vaccine administration, getting vaccinators and vaccinees to the POCs is equally important. As the complexity of the vaccination process increases, the skill level required of the vaccinator increases as well: safe injection requires highly trained staff, while oral vaccine delivery can be performed by minimally trained volunteers. Many pharmaceuticals and other treatments can be self-administered, but oral typhoid is currently the only vaccine approved for self-administration. Self-vaccination—enabling the vaccinee to be the vaccinator—could overcome the substantial logistical bottleneck resulting from skilled vaccinator shortages.

Getting potential vaccinees to the POCs can also be difficult, so these places need to be as close and convenient to everyone who needs vaccines as feasible. The vaccinee's home may be the most convenient POC, and many mass immunization campaigns in low-resource settings are conducted house-to-house to achieve maximum coverage. However, logistical challenges increase with rising numbers of POCs and with distance from distribution points. Vaccine hesitancy resulting from lack of confidence in vaccines or the health system, complacency about the risk of vaccine-preventable disease, or inconvenience of immunization can be another limiting factor in getting potential vaccinees to the POC. This is a multifaceted problem that must be addressed at many levels.[14] The pain associated with injection and needle phobia is one issue that may cause people not to seek vaccination. Many adults and children suffer from needle phobia.[15–17] Needle-free vaccine delivery technologies may increase the acceptability of vaccination.[12]

Vaccination, vaccine delivery, and vaccine administration are all terms that may refer to the act of transporting a vaccine across the skin of the vaccinee into the cutaneous, SC, or IM

tissue, or into an orifice to contact mucosal tissue. The vaccine delivery systems used for administration, such as injection by needle and syringe, jet injectors, or microarrays, may be considered *macrodelivery* systems. In contrast, vaccine *microdelivery* systems are the molecular antigen packaging technologies, such as viral vectors, microparticles, or virus-like particles (VLPs), that help transport the antigen to APCs once it has been administered to the vaccinee. Currently, most vaccines are administered by needle and syringe injection into the IM, SC, or intradermal (ID) tissues. Other vaccines are delivered mucosally by the oral or intranasal (IN) routes. Vaccine administration methods and devices are critical aspects of immunization logistics and many of the new immunization technologies described in this chapter focus on vaccine macrodelivery systems.

Current Vaccination Methods: Description and Logistical Hurdles

Vaccination by Injection. Hypodermic injection with a needle and syringe dates back to the mid-19th century and is such a predominant vaccine administration method that "shots" or "jabs" are often considered synonymous with vaccinations. Mass production of needles and syringes results in extremely low costs for these devices. Injection breaches the skin's stratum corneum, the protective layers of dead keratinized epithelial cells, to deposit vaccine in direct contact with the underlying dermal, SC, or muscle tissues. IM and SC delivery of vaccines by needle and syringe provides highly consistent dosing. For ID injection, because the dermal layer is so thin, precise targeted deposition is more difficult, so ID needle injection may provide less consistent delivery to the targeted tissues. Overall, needle and syringe vaccination produces excellent immune responses and is extremely safe when proper procedures are followed by trained vaccinators.

However, significant logistical limitations are inherent in needle and syringe injection. The high level of skill required for safe injections limits the availability of vaccinators. Reuse of contaminated syringes and needles is common in some developing countries and can lead to transmission of bloodborne diseases such as hepatitis and HIV.[18–22] Inexpensive autodisabling syringes and needles can prevent reuse and mitigate this problem. However, while autodisabling devices are used in many developing countries, risk of needlestick injuries to healthcare workers remains a concern and increases healthcare costs.[23,24] Safety syringes which include needlestick protection features, described later in this chapter, can reduce the risk of needlestick injuries. Finally, the cost and complexity of safe disposal of sharps in the medical waste stream represent major logistical challenges.

To overcome many of the difficulties of needle and syringe injection, multiuse nozzle jet injectors (MUNJIs) were commonly used in the past for IM and SC injection. However, repeated use of the jet injection nozzles without cleaning between patients was shown to have a risk of transmission of bloodborne pathogens, and use of these devices was discontinued.[25] Disposable syringe jet injectors (DSJIs) eliminated this contamination problem and are discussed in detail later in this chapter.

Mucosal Vaccination. In addition to vaccination by injection, current macrodelivery methods include mucosal vaccination via oral ingestion or nasal spray delivery. Both methods share the advantages of being needle free and present the possibility for simple administration methods. Mucosal vaccination mimics the route of entry, through portals to mucosal tissues, of many infectious agents and typically provides higher levels of mucosal immunity. The major challenge of mucosal vaccination is that delivery of antigen to the target tissues can be much less consistent than IM or SC vaccination by injection. Mucosal vaccination deposits vaccine on internal surfaces of the body. Although the vaccine is inside the body, it still must evade a variety of defense mechanisms to penetrate the mucosal surface and contact target tissues. Mucus flow, gastric acid, mucosal antibodies, and other antimicrobial substances continually destroy or remove substances on mucosal surfaces. As a result, mucosal vaccination generally requires higher doses of antigen, macrodelivery technologies to assure tissue contact, and more specialized antigen microdelivery packaging to reach APCs consistently.

Destination Points: Inside the Vaccinee's Antigen-Presenting Cells

Vaccination delivers the antigen package into the person receiving the vaccine, but delivery is not complete until APCs internalize the antigen. Immunization involves mimicry: vaccines must never be pathogenic, but must cause the APCs to respond to antigens as pathogens. One of the first principles of this mimicry is that the antigen package should be "pathogen-sized." Free antigen in solution is typically ignored by immune cells; however, APCs readily take up microparticle packages that are in the size range of pathogens, such as viruses and bacteria, by phagocytosis and endocytosis. These microparticle antigen packages are likely to be assessed as threatening and to initiate an immune response. Molecular antigen packages may include adjuvants, which are nonantigen components designed to trigger or modify an immune response. Some adjuvants act as package "warning labels" to alert activation of the innate immune system. Other adjuvants create a depot effect, which causes the antigen package to be opened gradually, prolonging the presence of antigen at the delivery site. Another molecular antigen packaging strategy is inclusion of specific cellular address labels. Typically, vaccine macrodelivery systems place the molecular antigen package in or near the tissues where APCs reside or traverse. For some vaccines, using molecules that match receptors on APCs such as dendritic cells or M cells increases the likelihood of delivery specifically to these cells. Many molecular packaging strategies for antigen delivery that are in use or in development are described in detail in Chapters 64 and Chapter 65, and examples are described briefly later in this chapter. Once the APCs have received the antigen package, the next step is processing of antigen and presentation to lymphocytes to initiate the immune response, which is well described in Chapter 2.

Logistical Hurdles in Special Settings

Emergency Settings

Preparation for emergencies should be included in every national immunization program plan. National programs in developed and developing countries have had varying degrees of success achieving high routine vaccine coverage rates, and strengthening routine systems is a key step for emergency immunization preparedness. Special situations and high-risk populations increase immunization logistical challenges and create the need for rapid delivery of vaccines to vastly increased numbers of people. War and other armed conflicts interrupt routine vaccination services and displace large populations away from available services, often concentrating people in refugee settings that significantly increase the risk of disease and the need for vaccines. Natural disasters such as earthquakes, tsunamis, or hurricanes disrupt local infrastructure, including transportation, electricity needed to maintain the

cold chain, and vaccine supply. Emergency situations expand the demand for skilled vaccinators and often the supply is diminished as vaccinators are personally affected by the emergency or pulled to other emergency duties. Reducing logistical barriers to routine vaccine delivery is critical to assuring the barriers are not insurmountable in an emergency situation.

Low- and Middle-Income Countries

All low- and middle-income countries (LMICs) have national immunization programs, and most provide vaccines recommended by the World Health Organization (WHO) for the following diseases: diphtheria, hepatitis B, *Haemophilus influenzae* type b (Hib), measles, pertussis, poliovirus, tetanus, and tuberculosis.[26] For routine immunization, vaccines can be administered at health posts or clinics (fixed post), or in communities through mobile outreach on a daily, weekly, or monthly schedule. Many countries also provide vaccines against pneumococcal disease, rotavirus, and other pathogens.[26] Supplemental immunization activities include mass campaigns that can be fixed post (often including extra posts), mobile outreach, or house-to-house campaigns. Three critical immunization delivery hurdles in LMICs are the cold chain requirement, the need for skilled vaccinators, and sharps safety.

The 2°C to 8°C cold chain storage requirement is especially challenging in countries with high ambient temperatures or with unreliable access to electricity.[27,28] Keeping vaccines tethered to refrigeration limits the capacity to distribute them to everyone in need because transporting them to remote locations requires cold packaging equipment many times larger and heavier than the vaccine itself. In a cold chain study in Vietnam, 46% of community health centers assessed did not have refrigeration.[11] This limits vaccination to days when vaccine can be transported from district facilities in cold boxes to the health centers for immediate use.

In many countries, cold chain equipment is antiquated and storage capacity is stretched to the limit, restricting the implementation of new vaccinations and eliminating surge capacity for mass-vaccination storage in case of an epidemic. For many immunization programs, purchase and maintenance of cold chain equipment consumes a significant portion of the immunization budget. One study estimated that cold chain equipment and overhead costs would account for 23% of the $25.4 billion needed for non-vaccine immunization program costs for low- and lower-middle-income countries from 2011 to 2020.[29]

Some vaccines may have thermostability that allows them to be managed outside the cold chain for limited periods of time. For example, a major reason for the successful MenAfriVac campaigns in Africa was the relaxation of the cold chain requirements in a number of countries for the last miles of delivery.[30,31] In these countries, a controlled temperature chain was implemented, allowing the vaccine to be shipped and stored at ambient temperatures for up to 4 days. In addition to increasing access to difficult-to-reach areas, a modeling study estimated that use of the controlled temperature chain could potentially reduce cold chain and associated logistics costs.[29] Additional studies based on field implementation are required. Research on the thermostability of other vaccines may enable their use under a controlled temperature chain to simplify logistics for the last difficult miles of delivery, improve vaccine access in remote areas, and potentially reduce costs.

The second hurdle for immunization programs in many LMICs—and often the rate-limiting factor—is the shortage of skilled vaccinators. There is a global shortage of all healthcare workers,[32] and safe and effective vaccination requires highly skilled workers for many vaccines, particularly for needle and syringe injection. Needle-free vaccines that could be administered by minimally trained staff or volunteers, or that could be self-administered, would significantly increase vaccine delivery capacity.

The third important logistics factor for immunizations in LMICs is sharps safety. Needlestick injuries are common; however, unlike in high-income countries, needlestick protection devices and prophylaxis to prevent bloodborne disease transmission following these injuries are often not available in low-resource settings because of cost. Safe disposal of used needles requires an expensive biowaste disposal infrastructure that is not always present. In some countries, used needles are harvested from the common waste stream and repackaged to the unsuspecting for reuse, presenting a high risk for transmission of bloodborne pathogens.

In the long run, thermostable needle-free vaccines could significantly reduce these logistical hurdles to vaccine delivery in developing countries and extend the benefits of immunization to all people. In the short term, intermediate technologies that are in development can improve cold chain shipping and storage and provide needlestick injury protection.

Bioterror and Pandemic Settings

The United States—used here as an example of a developed country—has a relatively strong immunization program infrastructure, which is reflected in high vaccination coverage rates (except for certain communities where vaccine hesitancy by parents has led to historically low coverage rates). In the United States, POCs include doctors' offices, health clinics, and, within the last several years, pharmacies. However, in an emergency, new vaccination POCs may be established—such as sports arenas, schools, convention centers, and other nontraditional locations—to allow mass vaccination to reach large populations rapidly.[33–35] At-risk individuals are a key consideration and include children, pregnant women, people with disabilities, and the elderly, among other groups.

In the event of a pandemic or bioterror event, local, regional, and even national healthcare resources and infrastructure may be overwhelmed. From the immunization logistics perspective, key factors will include ensuring vaccine supply and distribution, establishing accessible POCs for large numbers of people, and providing sufficiently skilled vaccinators to meet the vaccine demand. The U.S. Strategic National Stockpile maintains supplies of key vaccines. Cold chain logistics may become an issue in emergency settings if there is collateral damage to the power infrastructure, as in a natural disaster such as a hurricane, or if massive increases in vaccine volumes overwhelm local cold chain capacity.

In contrast to many developing countries, the United States has little recent experience with mass vaccination campaigns. In a pandemic setting or a bioterror event involving an infectious agent, gathering masses of people in central locations for vaccination may represent an increased risk for transmission of the disease; thus, more discrete methods of vaccine distribution may be preferable.

Summary: Desirable Features of Practically Ideal Vaccine Delivery Systems

The major immunization logistical challenges to vaccine flow include the following: distribution of multicomponent products, purity and sterility requirements, cold chain requirements, availability of highly skilled vaccinators, on-site filling and reconstitution, needle safety issues, and transfer of antigen into APCs.

Technologies described in this chapter address some or many of these challenges. Overall, a "practically ideal vaccine

delivery system" would be a thermostable vaccine in a prefilled unit dose for needle-free delivery with minimal waste. The vaccine would be optimized for shipping, even by mail in some cases, and would be self-administered or administered by minimally trained personnel. The molecular antigen packaging would ensure safe delivery of the antigen into the APC and induction of the immune response with minimal adverse reactions.

NEW TECHNOLOGIES FOR VACCINE STABILIZATION, PACKAGING, STORAGE, SHIPPING, AND ON-SITE PREPARATION: POINTS OF ORIGIN AND DISTRIBUTION POINTS

Maintaining the integrity, potency, and safety of vaccines from their point of origin at the vaccine manufacturer, through the point of preparation and use, requires attention to the vaccine's formulation, packaging (primary, secondary, and tertiary containers), and reconstitution.

Formulation

The development of vaccine formulations includes the chemical and physical characterization of the antigen, potency assays for lot release and to demonstrate stability, preclinical and clinical evaluation of the optimal administration route to include the potential use of adjuvants, and formulation stability development.[36] Current live-attenuated vaccines are not formulated with an adjuvant. Nonreplicating vaccines, including inactivated viruses and bacteria, VLPs, carbohydrate antigens, and purified or recombinant subunit protein antigens, are typically presented as liquid solutions or suspensions and usually contain adjuvants to induce the desired immune response.

A vaccine's formulation consists of the antigen as well as the other supporting ingredients, called excipients. Excipients include preservatives to prevent contamination and adjuvants to enhance potency. A carefully developed formulation can also increase the thermostability of the vaccine and avoid damage to the antigen due to freezing or high temperatures. Live-attenuated vaccines are often lyophilized and freeze stable but tend to be more heat sensitive for long-term storage (months to years) in the cold chain and immediately after reconstitution.[37] Nonreplicating vaccines can be more stable in high temperatures compared with live-attenuated vaccines, but can also be damaged by freezing, particularly if they include aluminum adjuvants.[37]

Preservatives

Thimerosal, an organic mercury preservative (approximately 50% by weight in the form of ethyl mercury), is used in some inactivated vaccines for multidose vial formats to prevent microbial growth in opened and partially used vials. It is also used during some vaccine manufacturing processes as an inactivation agent. Thimerosal is intended to kill or prevent the growth of a broad spectrum of pathogens (bacteria, fungi). The safety of thimerosal has been evaluated by the Global Advisory Committee on Vaccine Safety as well as other national-level expert groups and regulatory bodies, such as the European Agency for the Evaluation of Medicinal Products, the American Academy of Pediatrics, and the U.S. Food and Drug Administration (FDA). These evaluations concluded that, given the short biological half-life of ethyl mercury—which is excreted via the gut and does not accumulate in the body—evidence of long-term toxic effects has not been demonstrated.[38] In 1999, however, the U.S. Public Health Service urged vaccine manufacturers to reduce or eliminate thimerosal from vaccines as a precautionary measure. Currently in the United States, routine vaccines are thimerosal-free or have levels less than or equal to 1 µg of mercury per dose.[39] Two other preservatives in WHO prequalified vaccines are 2-phenoxyethanol, used with inactivated poliovirus vaccine (IPV), and phenol, used for inactivated typhoid vaccine.

Many industrialized countries, such as the United States, have switched to single-dose vials for use in routine immunization, and thimerosal is not used because the vial is accessed only once. However, in multidose vial formats for seasonal influenza vaccines and vaccines for epidemic or pandemic response, preservatives such as thimerosal continue to be used. Furthermore, many vaccines used in LMICs still contain thimerosal, including diphtheria, tetanus, and pertussis, hepatitis B, Hib, influenza, and meningococcal vaccines. LMIC use of single-dose vial presentations is limited by vaccine manufacturer production capacity, the increased cold chain volume, and cost, which many countries cannot absorb.

Thermostability

Extended exposure to elevated and freezing temperatures—those temperatures outside of the recommended range (normally 2°C to 8°C)—can damage vaccines. Heat can denature or otherwise alter the protein tertiary structure; this may reduce viability of live-attenuated vaccines or, in the case of polysaccharide conjugate vaccines, result in increased rates of hydrolysis of the polysaccharide from the protein in the vaccine formulation. Formation of ice crystals can result in freeze damage to the antigen, and freezing of vaccines containing aluminum adjuvants can reduce potency from agglomeration of the adjuvant.[40] Thermostability (resistance to high ambient temperatures or freezing) could reduce potency loss and have positive impacts on vaccine efficacy.[27,41] It could also allow removal of vaccines from the cold chain, reduce costs, and lead to increased coverage by allowing flexibility in time to reach remote populations. Some thermostable products could be dry cakes similar to lyophilized vaccine and would require reconstitution prior to injection. Other dry formulations could be incorporated into unit-dose dry-format delivery systems such as microarray patches, or dry powder aerosols for respiratory administration (see "Cutaneous Vaccination" and "Mucosal Vaccination" later). These formats would have the combined benefits of being needle free and thus simple to administer or self-administer. They would not require refrigeration or reconstitution.

Protection From High Ambient Temperatures. Enhanced thermostability of liquid formulation vaccines can be achieved through selection of buffering agents and by the use of excipients (vaccine formulation ingredients other than the antigen) that can further stabilize the formulation. Examples include nonreducing sugars, nonionic surfactants, and polymers or protein stabilizers. Excipient stabilization can enhance protection from shifts in pH, decrease antigen loss as a result of surface adsorption and aggregation, and prevent or reduce protein-to-protein interactions.[41]

Freeze Protection. Propylene glycol, polyethylene glycol, and glycerol have been used to protect aluminum-adjuvanted vaccines from freezing. Various concentrations of propylene glycol have prevented vaccine freezing or loss of potency and have prevented destructive particle aggregation if physical freezing occurred.[41]

Dry-Format Delivery. Alternative processes to lyophilization for vaccine drying (removing water molecules from the vaccine

suspension) include spray drying, spray-freeze drying (SFD), vacuum-foam drying, and supercritical fluid drying. These processes have been evaluated for increasing vaccine thermostability.[42] Research with aluminum-hydroxide–adjuvanted hepatitis B surface antigen (HBsAg) or human papillomavirus (HPV) vaccines and aluminum-phosphate–adjuvanted diphtheria and tetanus toxoids has been conducted using alternative freeze-drying processes. These studies have typically found aluminum coagulation and difficulty in reconstitution for lyophilized adjuvanted vaccines, although additional excipients and a thin film freeze-drying process may provide freeze protection.[43,44] The SFD method produced a homogenous suspension, indicating the feasibility of this approach for aluminum-adjuvanted vaccines.[45] Evaluation of SFD of HBsAg without aluminum in combination with inulin or dextran/trehalose stabilizers demonstrated enhanced thermostability (up to 60°C). However, preclinical immunogenicity studies of this formulation demonstrated immunoglobulin (Ig) G immune responses that were lower than responses to aluminum-adjuvanted HBsAg.[46] SFD has also been assessed for meningitis A and measles vaccines.[47,48]

In addition, alternative delivery or packaging methods, such as dry powder inhalation, microarray patches, biodegradable implants, or integrated reconstitution technologies (discussed later in this chapter), are currently being developed or used for biologics or pharmaceuticals and could be adapted for vaccines. Primary excipients include nonreducing sugars such as trehalose or sucrose because of the high glass-transition temperatures they exhibit. Glass (amorphous solid) is formed instead of crystals when these excipients are dried, which contributes to vaccine stability.[41]

Packaging

Vaccine packaging is the collection of components that surround the vaccine and protect its integrity (potency/stability/shelf life), from production through the supply chain to the POCs. Vaccine packaging is typically divided into three categories: primary, secondary, and tertiary.[49,50] Primary packaging protects against light, oxygen, and moisture vapor ingress, and it must not allow pH shifts that could affect vaccine stability or antigen binding to the material of the container that could reduce the available dose. The packaging also provides information and identification of its contents.[51] Labeling to identify the product must be integral to the packaging, or affixed to it. Primary containers are nested together in secondary packaging, and larger containers such as boxes or cartons provide tertiary packaging.

Primary Packaging

Vial and Ampoule (Vaccine and Diluent). Primary packaging, such as ampoules, vials, prefilled syringes, and prefilled oral dispensers, comes into direct contact with the vaccine product or diluent and may affect the vaccine formulation itself. The WHO has issued guidelines covering vaccine formulation, presentation, labeling, and packaging to ensure that vaccines submitted for prequalification have been optimized to address LMIC needs. These guidelines include mandatory, critical, unique and innovative, and preferred characteristics. Mandatory and critical characteristics must be met to achieve WHO prequalification. In the case of critical characteristics, some deviation from defined values may be allowed when taking into account public health needs. Unique and innovative characteristics may be vaccine specific and are reviewed as such. Preferred characteristics are not required, but they represent the buyer preference (procurement agencies and national immunization programs).[52]

Vaccines must be WHO prequalified for purchasing by UN agencies. The WHO requirements on vaccine quality, safety, and efficacy are included in the prequalification process, as well as compliance requirements for manufacturing and specifications for packaging and presentation. Prequalification provides assurance that vaccines used by national immunization programs are safe, effective, and meet quality standards.[53]

The Vaccine Presentation and Packaging Advisory Group (VPPAG) is a WHO and United Nations Children's Fund (UNICEF)-led forum for both the public sector and industry to discuss and provide advice on vaccine presentation and packaging. VPPAG has developed a generic preferred product profile for vaccines for LMIC use, which recommends "ready-to-use" presentations that do not require mixing (i.e., reconstitution) and formats that reduce the number of user steps (and potential errors). Vaccine formulations with improved heat and freeze stability also are recommended, to provide for higher temperature storage (target threshold 40°C) and potential use beyond the cold chain. Prefilled syringes or injection systems should reduce the volume required in the cold chain and should incorporate an autodisable feature that prevents reuse. These designs are designated as compact prefilled autodisable injection devices (cPADs). The generic preferred product profile also includes vaccine vial dimensional recommendations that conform to ISO 8362 and are the most efficient size for the cold chain. Vial labeling should include a vaccine vial monitor (per UNICEF and WHO recommendations), which consists of a temperature-sensitive material and serves as a visual indicator of cumulative heat exposure. Labeling should also include standard product, date, and lot information, among other requirements.

Unit Dose Versus Multidose Formats. Multidose presentations are common in LMICs, a result of both lower cost and reduced per-dose volume compared with single-dose presentations. Industrialized or high-income countries are less vaccine-price sensitive and have been switching to single-dose presentations for adult and childhood vaccines. The shift to single dose was accelerated by public concerns regarding thimerosal,[54–58] healthcare provider preference for single-dose presentations including prefilled syringes, and increased awareness of injection safety.[58] In the United States, the awareness of safety issues came in response to the Needlestick Safety and Prevention Act and subsequent revision of the Occupational Safety and Health Administration (OSHA) Bloodborne Pathogens standard. This led to requirements for workplace reporting and maintenance of a log of needlestick injuries as well as broader implementation of engineered safety features to reduce or prevent the risk of needlestick injury.[59]

The use of single-dose and small multidose presentations also has increased in LMICs, in part because of the higher costs of vaccine wastage for newer vaccines.[60,61] The use of preservatives in multidose vials is critically important for vaccines that are used in more than one immunization session because repeated access of the vial through the septum, as well as storage between sessions, presents potential contamination risk from pathogen ingress. The WHO's multidose vial policy permits open vials of vaccine with preservative that have been handled under specific conditions to be used for up to 28 days after the first dose is withdrawn.[5] These guidelines are consistent with U.S. recommendations, which also require that an open vial be discarded in 28 days except if there are different manufacturer requirements in the product labeling, which may specify an alternative number of days.[63]

These policies apply only to liquid vaccines that contain preservative; lyophilized live attenuated vaccines—such as measles-containing vaccines, bacillus Calmette-Guérin (BCG), and yellow fever vaccines—generally do not contain preservatives and must be discarded at a maximum of 6 hours after

reconstitution, per the multidose vial policy. Because of vaccine wastage concerns, some healthcare workers are hesitant to reconstitute a multidose vial if there are insufficient numbers of people available to be vaccinated.

Preservative-Free Multidose Primary Packaging. MEDInstill, Inc., a U.S.-based firm, has developed a primary packaging pharmaceutical filling and dispensing technology called Intact that may reduce or eliminate the need for preservatives in multidose vaccine vials. The technology is designed to reduce the risk of contamination during both filling and dispensing from a primary container. To maintain sterility during the filling process, a closed-system valve is used for the filling needle. The prevention of contamination allows for sterile filling in a nonaseptic facility.[64]

In addition, the Intact design has been incorporated into the dispensing port for MEDInstill primary containers. The valve allows multiple withdrawals from the container, maintaining sterility of the contents even in the presence of external contaminants. Multidose vials (Fig. 68.1A) and pouch designs are undergoing evaluation for pharmaceuticals and vaccines.[65]

Prefilled Syringes. Prefilled syringes represent a fully integrated vaccine presentation. Multiple studies comparing prefilled syringes with standard vial presentations have demonstrated increased efficiency and improved vaccination throughput with this packaging format. For example, a study of U.S. nurses preparing and delivering influenza vaccine reported that the time necessary for providing an injection was 12.4 seconds for a prefilled syringe compared with 49.7 seconds for a multidose vial.[66] The increased efficiencies possible with prefilled syringes for both parenteral and nonparenteral administration (oral/nasal) could greatly enhance pandemic/epidemic outbreak response capacity.

Glass Prefilled Syringes. Glass prefilled syringes are manufactured from type 1 borosilicate glass, which has high chemical resistance, low alkali content, and barrier properties appropriate for long-term storage of vaccines and other pharmaceuticals.[67] A leading example is the Becton, Dickinson and Company (BD) Hypak SCF (sterile, clean, ready to fill) glass prefilled syringe used widely in the United States and Europe (see Fig. 68.1B). This design comes in different models to include fixed-needle, Luer slip, and Luer-Lok varieties. Other manufacturers include Gerresheimer, Schott, Nuova Ompi, Nipro, and Catalent. Glass has been used for decades for a variety of primary containers (prefilled syringes, vials, cartridges). Problems associated with its use include the possibility of cracks or breakage.

Plastic Prefilled Syringes. Various plastic materials have been used as alternatives to glass, for both prefilled syringes and other primary container technologies. Plastic syringes are injection molded, allowing for tighter dimensional tolerances and ability to generate alternative geometries. Plastic prefilled syringes are lighter in weight and more resistant to breakage than glass during production, fill/finish, shipping, and programmatic use. Polypropylene (PP) is a polymer used for standard- and large-volume prefilled syringes (up to 50 mL) and vials.[68] Cyclic olefin copolymer and cyclic olefin polymer (COP) are highly transparent polymers that have been used increasingly for prefilled syringes.[69,70] Compared with PP, cyclic olefin copolymer and cyclic olefin polymer have lower water vapor and oxygen permeability, allowing long-term storage of vaccines[71] and have been demonstrated to be biocompatible, resistant to heat, and compatible with various terminal sterilization processes.[68]

The selection of glass or plastic is determined by the formulation or stability requirements of the pharmaceutical, needs of the patient/user, and other requirements. Plastic prefilled syringes are typically more expensive than glass.[72] Examples include the BD Sterifill SCF, SCHOTT TopPac, Gerresheimer ClearJect, Baxter Clearshot, and West Daikyo Crystal Zenith Ready-to-Use silicone-free syringes. Cyclic olefin copolymer and cyclic olefin polymer have also been used for vials; for example, Aseptic Technologies, Inc.'s, AT-Closed Vial composed of cyclic olefin copolymer (see Fig. 68.1C) has been validated for use with GlaxoSmithKline's Synflorix pneumococcal vaccine and was approved by the European Medicines Agency.[73]

Compact Prefilled Autodisable Devices. A cPAD is a prefilled single-dose injection system comparable to a prefilled syringe, but with an autodisable feature that prevents reuse. Like prefilled syringes, cPADs provide accurate doses, fast injection preparation, and quick delivery time (ready to use). In addition, because they are typically smaller than standard syringes, they bring the logistical benefits of decreased volume and weight.[74]

The BD Uniject injection system (see Fig. 68.1D) is a cPAD technology with a small reservoir prefilled with vaccine or other pharmaceutical. It has four main components: reservoir, port, needle assembly, and needle shield. The reservoir is a three-layer laminate film with linear low-density polyethylene in contact with the contained fluid. The port and valve are in contact with the fluid in the reservoir and are also constructed of low-density polyethylene. The needle assembly connected to the port consists of a polystyrene hub and a steel needle. The PP needle shield is removed from the needle for administration. Typically, a foil-laminate secondary pouch maintains stability of the material in the Uniject units. Crucell has developed a novel hybrid secondary packaging for the Uniject system that can store up to 20 filled devices.[75] A needleless version of the Uniject platform, designated "Uniject DP," also has been developed by BD for oral delivery and is commercially available.

To deliver the prefilled dose, after removal of the needle shield and insertion of the needle, the plastic reservoir of the Uniject system is squeezed between the thumb and fingers. The Uniject system is available in four dose-volume sizes: 0.25, 0.5, 1.0, and 2.0 mL. It is available with various needle gauges and lengths, ranging from 18 to 26 gauge and needle lengths of ⅜ to 1.5 inches (for SC or IM injection). The container is provided sterile in "ready-to-fill" reels of 1500. The sterile reel is loaded onto a custom filling machine where the containers are filled and then heat sealed. They are kept on the reel throughout the process and either accumulated in reel form or transferred out of the sterile area for final packaging.[76]

Hepatitis B and tetanus toxoid vaccines made by PT Bio Farma (Indonesia) have been WHO-prequalified in Uniject formats, and Crucell developed a new presentation of Quinvaxem fully liquid pentavalent vaccine in Uniject, which was prequalified but is not being commercialized.[77] A time-and-motion study in Kenya comparing the average time for health workers to prepare and inject 20 doses of pentavalent vaccine in five different presentations found that the prefilled Uniject system was faster to deliver than fill-onsite presentations (single-dose or multidose vials, liquid or lyophilized).[78]

Novel Primary Container Technologies. Blow-fill-seal (BFS) ampoules are plastic primary containers manufactured from polyethylene or PP and used for a variety of pharmaceuticals (see Fig. 68.1E). The containers are extruded, blown, filled, and sealed in an automated, continuous process. Although these ampoules have not yet been approved for vaccines, they have been evaluated with MedImmune's live attenuated influenza vaccine (LAIV)[79] and are being evaluated by rotavirus vaccine manufacturers.[80] For parenteral delivery, a Luer interface can be incorporated into the neck of the ampoule, allowing for connection of a Luer-tip needle. A needle and syringe can also simply withdraw a dose from a standard BFS ampoule

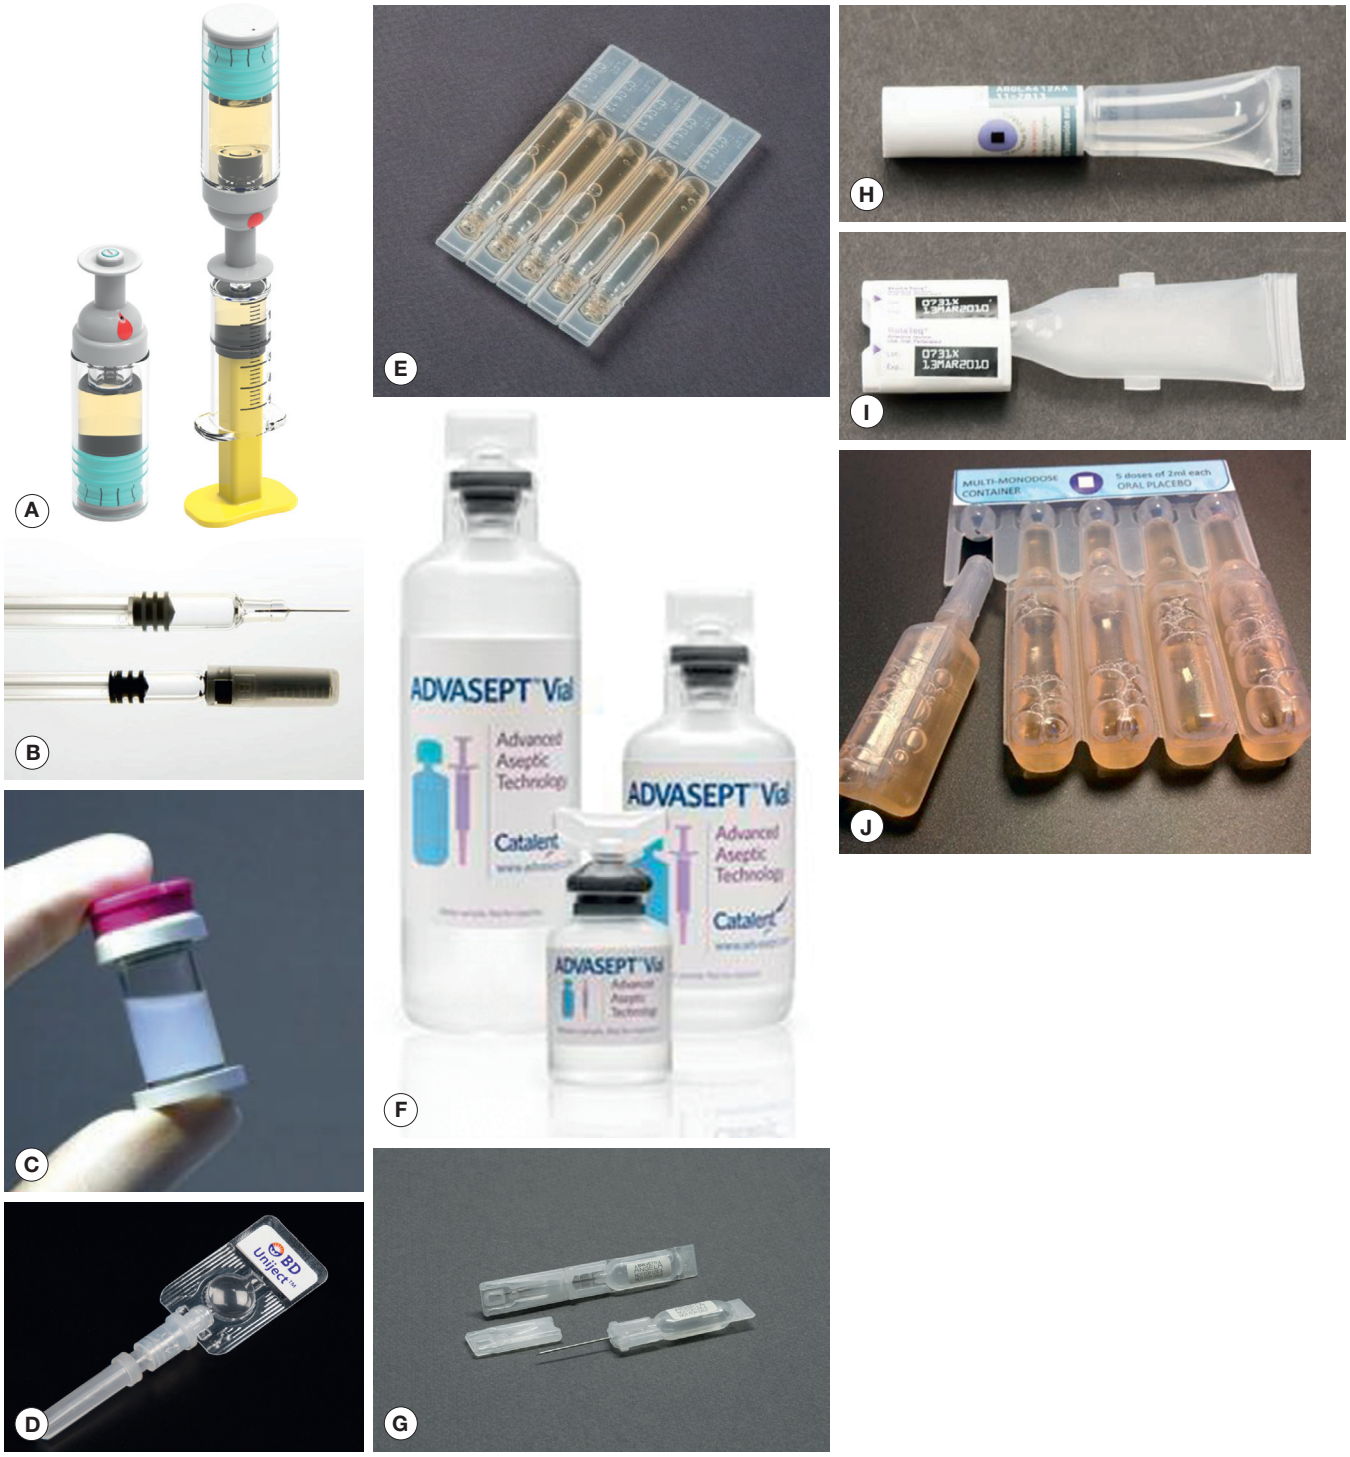

Figure 68.1. Vaccine primary containers. A, MEDInstill vial represents a preservative-free technology that incorporates a novel valve to prevent contamination. **B,** BD Hypack SCF is a widely used prefill glass syringe used for a variety of pharmaceutical applications. **C,** The Aseptic Technologies AT-Closed Vial uses cyclic olefin copolymer, an alternative material to glass. **D,** Uniject is the only WHO-prequalified compact prefilled autodisable (cPAD) technology. **E,** Rommelag produces blow-fill-seal (BFS) technology for small- and large-volume pharmaceuticals. **F,** Catalent ADVASEPT Vial technology uses the advanced aseptic manufacturing process of BFS to incorporate a septum through an insertion to form fill and seal the primary container. **G,** Brevetti Angela has also developed an integrated needle design for use in parenteral delivery, the SECURE-JECT- SQUEEZABLE. **H,** GlaxoSmithKline uses a polymer tube manufactured by Rexam for use with its Rotarix vaccine. **I,** Merck RotaTeq comes in a plastic injection molded tube composed of polyethylene. **J,** PATH in cooperation with Rommelag has developed a multi-mono-dose design with a single vaccine vial monitor to maximize cold chain volume. *(**A,** Courtesy of MEDInstill [Debashis Sahoo]. **B, D, E,** and **H–J,** Courtesy PATH. **C,** Courtesy Aseptic Technologies, Inc. **F,** Courtesy Catalent [Bill Hartzell]. **G,** Courtesy Brevetti Angela [Rajeev Kabbur, Daniel Martinez].)*

or vial with integrated septum such as Catalent's ADVASEPT Vial Technology (see Fig. 68.1F). Rommelag, Weiler Engineering, and Brevetti Angela are leading examples of BFS machine manufacturers. Brevetti Angela and Rommelag have BFS systems with integrated needles incorporated during the forming process (see Fig. 68.1G).

Plastic tubes that are injection molded or extruded have been developed primarily for oral administration. These containers are manufactured, terminally sterilized, and shipped to the pharmaceutical manufacturer for filling and heat sealing. Examples are the Rexam dispenser tube, used for GlaxoSmithKline's Rotarix vaccine, and the Lameplast tube, used for Merck's RotaTeq vaccine (see Figs. 68.1H and I). Under funding from the Bill & Melinda Gates Foundation, PATH, in collaboration with Rommelag, has developed a multi-mono-dose BFS container design targeted for rotavirus vaccine delivery. The design has individual containers conjoined by a shared tab. When one container is separated from the tab, it is rendered open and must be used to deliver the vaccine. This attribute provides key advantages compared with single-dose presentations, including cold chain volume reduction and potential cost savings (see Fig. 68.1J).

Safety Syringes. The Needlestick Safety and Prevention Act, signed into law in 2000, led to the standard use of syringes with engineered safety features for vaccine and drug delivery in the United States. One study found that beginning in 2001, this resulted in a drop of more than one-third in needlestick injuries—with approximate annual reductions of 100,000—and a cost savings of $69 million to $415 million.[81] However, a Cochrane review concluded there was no clear evidence of benefit with use of these devices, despite their increased costs.[82]

To achieve WHO prequalification, vaccines in prefilled syringes are required to have an autodisable or reuse-prevention feature.[52] Autodisable syringes have attached needles and a method to prevent reuse of needle and syringe after delivery of a fixed dose. A reuse-prevention feature syringe allows variable dosing, necessary for volume diluent transfer, for vaccine reconstitution. The WHO recommends autodisable syringes or other syringes with reuse-prevention features for vaccine administration.[84]

WHO also recommends syringes with a sharps injury protection (SIP) feature for immunizations.[85] A sharps injury protection feature covers, shields, or retracts the needle into the syringe barrel to prevent needlestick after use or during disposal. Multiple self-shielding needle technologies have been introduced to reduce the risk of needlestick injuries.[86,87] Currently, the costs of such syringes limit their use in LMICs.

The Unifill safety syringe (Unilife Medical Solutions) has a reuse-prevention feature that retracts the needle after delivery. Other developers, including Tip-Top, Safety Syringes, and Credence MedSystems, have prefilled syringe-compatible sharps injury protection designs that can be incorporated into the syringe after filling.[86,88] Merck's Gardasil HPV vaccine is delivered in a single-dose prefilled syringe with UltraSafe needle guards.[89] Clip-on prefilled syringe safety mechanisms also include the BD Preventis, the West Clip'n'Ject, and the Specialized Health Products International LuproLoc.

Secondary and Tertiary Packaging

Secondary packaging, such as cartons, trays, or foil pouches, hold one or more primary containers, such as vials or prefilled syringes of vaccine. These packages generally represent the volume for calculation of cold chain storage requirements.[52] Secondary packaging is important for vaccine stability; for example, a foil pouch protects a polymer-based primary container such as the Uniject system from water vapor loss, oxygen ingress, and light.

Tertiary packaging includes cartons or cases that enclose multiple secondary packaging units. Insulated shipping boxes with internal walls of polystyrene, isocyanurate panels, or polyurethane foam also maintain cold chain temperatures and prevent shifting during shipment. Pallets are used for international shipment of these containers. In the GS1 General Specifications, these are designated as export packaging or shipping containers, whereas the WHO puts them into the category of tertiary packaging.[90,91]

VPPAG secondary package recommendations include minimizing weight, volume, and the need for in-country repackaging for distribution in the cold chain. Specific vial arrays (rectangular) by number of vials for packing are also recommended. Tertiary packaging recommendations also include minimizing dimensions as well as limiting the need for repackaging, with vials in multiples of 100 for easier inventory control. Weight and width dimension recommendations are also included, with reference to ISO pallet sizes. Labeling recommendations also include the use of bar codes that conform to GS1 standards. Materials used for packaging (primary, secondary, tertiary) should minimize environmental impact.[92]

Environmentally Friendly Secondary Cartons and Tertiary Shipping Containers. Numerous companies have developed insulation products to replace polystyrene. Green Cell Foam technology is a biodegradable, starch-based polymer that can break down within four weeks, dissolves in water, and can be incinerated or burned cleanly (Fig. 68.2A). It maintains temperatures for 24 to 48 hours.[93,94] Ecovative is developing compostable plastics derived from agricultural byproducts and mushroom mycelium.[95] Wool packaging uses this renewable and compostable material for thermal insulation.[96] The Coldpack AirLiner is an inflatable insulation liner that can be shipped flat when empty for space saving and deflated for landfill disposal.[97] Placon plastics (polyethylene terephthalate) for secondary packaging are composed of at least 35% postconsumer content.[98] Softbox has developed a new thermal insulation foam with 100% recyclable materials that has increased thermal efficiency compared with Styrofoam. Softbox maintains the cold chain for more than half the world's top 50 pharmaceutical companies.[99]

The Credo container from Pelican Biothermal has been used for influenza vaccines and other temperature-sensitive drugs (see Fig. 68.2B).[100] Repeat flu vaccine shipments and alternative logistics/distribution models of use have been successfully demonstrated with this technology.[103] Container reuse could provide reduced environmental impact and disposal burden at the program level.[103] The Sonoco ThermoSafe Greenbox is another reusable container technology, composed of 100% biodegradable, bio-based materials.[105] A plant-based phase-change material allows cold chain temperature maintenance of up to 6 days.[96] The phase-change material can be reconditioned and used repeatedly, replacing the need for other refrigerants. Approximately 20,000 repeat uses have demonstrated the thermal management properties of this material.

On-Site Reconstitution and Filling

While shipping vaccines in lyophilized form has advantages such as improved thermostability, reconstitution can introduce errors noted earlier, such as using the wrong diluent. For reconstitution, diluent is withdrawn from its container, typically with a needle and syringe, and injected into the primary vaccine container for mixing. Then the reconstituted vaccine is withdrawn from the vaccine container for administration. Vaccines currently available in lyophilized form include yellow fever,

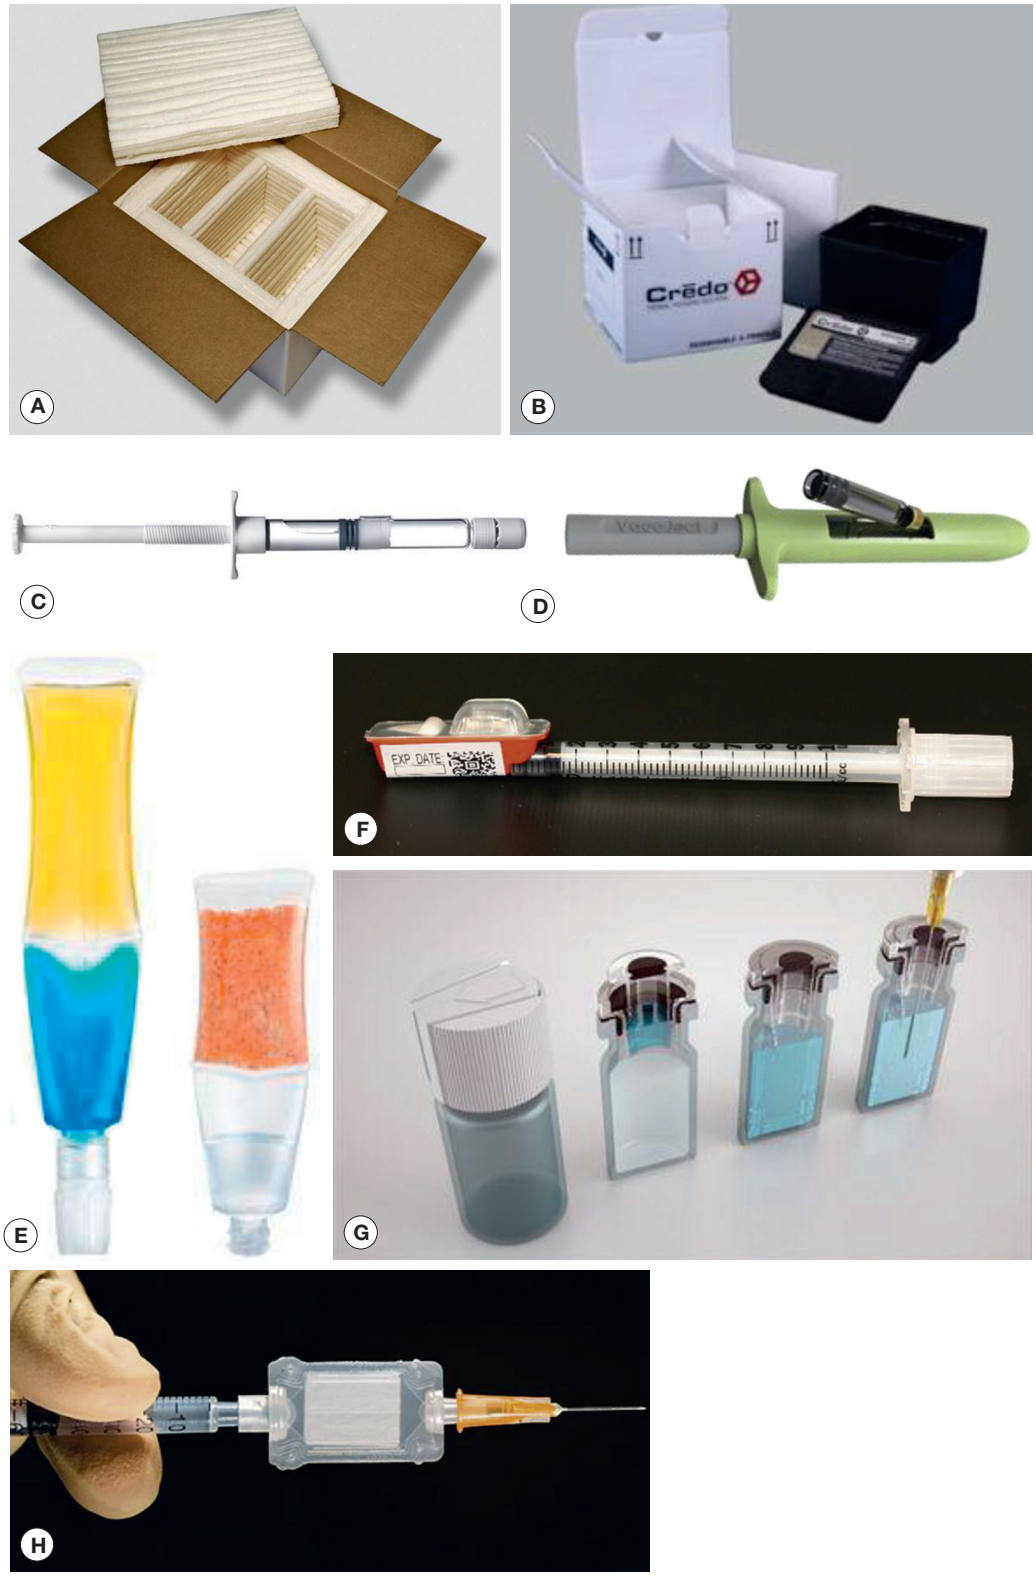

Figure 68.2. Vaccine packaging and reconstitution technologies. A, Landaal Green Cell Foam is a biodegradable polymer that can be easily disposed of by dissolving or incinerating. **B,** Credo Container from Pelican BioThermal can be repeatedly reused and has been used for influenza vaccines and other temperature-sensitive drugs. **C,** The Vetter Lyo-Ject (syringe) is a dual-chamber technology for simplified reconstitution. **D,** Duoject VaccJet is a cartridge-based technology that uses dual-sided needles for parenteral injection. **E,** Neopac's Fleximed Easymix uses a frangible seal separating the wet and dry compartments. Pressurizing (squeezing) one end breaks the seal allowing for reconstitution. **F,** AktiVax's ARCH design uses blisters with frangible seals to separate the dry vaccine from diluent prior to mixing. **G,** Eulysis' SVS is a vial-based design with a compartment that separates the dry powder/lyophilized pharmaceutical from the diluent, which is pierced by a piston cap allowing for mixing. **H,** HydRIS from NOVA Laboratories, is distal hub/attachment for prefilled diluent syringes that is filled with the lyophilized pharmaceutical in a sugar glass based membrane. Reconstitution occurs upon expelling the diluent from the syringe into the compartment during the process of delivery. measles, rubella, varicella, measles-containing combination vaccines (measles-rubella, measles-mumps-rubella [MMR], and measles-mumps-rubella-varicella), BCG, Hib (standalone and in some combination vaccines), rabies, rotavirus, Japanese encephalitis, meningococcus, and LAIVs. Vaccines in development, including those for cholera, dengue, enterotoxigenic *Escherichia coli*, influenza, tuberculosis, and rotavirus, will likely be available in a format requiring reconstitution.[37]

Preparation and delivery of reconstituted vaccines requires more vaccinator time than preparation and delivery of liquid vaccines. A time-motion study conducted in Kenya, comparing the amount of time required for vaccinators to prepare and deliver mock injections with various single-dose and 10-dose vaccine presentations, found that more time was required to administer lyophilized vaccines than liquid vaccines. The difference was greatest for single-dose, lyophilized presentations, since reconstitution is done once for each vial.[78]

Novel reconstitution technologies might be useful for current or future lyophilized vaccines. A variety of reconstitution technologies have been developed to reduce the chance of user error and simplify delivery. These technologies can be grouped into several categories: (1) fully integrated reconstitution technologies, which include primary packaging, diluent transfer, reconstitution, and delivery features; (2) partially integrated reconstitution technologies that include everything but the delivery device; (3) diluent transfer devices that facilitate reconstitution of existing lyophilized vaccine vials; and (4) hybrid reconstitution technologies that incorporate one or more features. Some of these technologies are currently in use for high-cost pharmaceuticals, particularly those intended for self-administration by patients at home. For vaccines, except diluent transfer devices such as vial adapters, reconstitution technologies are in varying stages of development, and no vaccines are available currently in these formats.

Fully Integrated Reconstitution Technologies

This type of technology incorporates packaging, reconstitution, and delivery and represents the most complex of the reconstitution technologies. Some technologies incorporate valved stoppers that are actuated with plungers in a glass syringe or a cartridge. Others use polymer tubes, pouches, or blister packs with frangible seals that rupture when pressure is applied.

Syringe- or Cartridge-Based Technologies. In this reconstitution technology, a prefilled syringe or cartridge contains both the dry and liquid components separated by an elastomeric internal stopper. Reconstitution occurs when mechanical pressure is applied to either overcome a valve in the plunger or push diluent through a bypass channel in the syringe. Parenteral delivery is possible with these technologies. These technologies may be more suitable for vaccine-drying methods other than lyophilization, which may represent a barrier to consideration because alternative drying methods are not currently in use for vaccines.

Examples of syringes include the Vetter Lyo-Ject Syringe (see Fig. 68.2C) and the LyoGo Dual Chamber Pre-Filled Syringe technologies. The commercially available Vetter Lyo-Ject Syringe incorporates a standard stopper with a bypass channel that is accessed upon advancement of the plunger, allowing diluent to flow through the channel into the dry powder chamber.[106] Vetter has also developed and marketed the Vetter V-LK Reconstitution Cartridge, which has a similar mechanism of action.

The LyoGo Dual Chamber Pre-Filled Syringe, currently in development,[107] has a chamber-separating stopper with a novel valve. Advancement of the plunger creates a pressure differential that opens the valve, allowing the diluent to enter the dry powder chamber. LyoGo also is developing a dual-chamber cartridge version of their novel valve technology. Another manufacturer, Unilife, has developed the dual-chamber syringe EZMix Genesis, which incorporates its retractable needle feature.[108]

Cartridge-based reconstitution technologies require incorporation into a separate novel delivery device. Duoject's VacJect technology is designed for single-use delivery using a retractable needle that allows cartridge access (see Fig. 68.2D). A reconstitution-capable version of the VacJect has been developed with a feature to allow for diluent transfer from one cartridge to a cartridge containing the lyophilized vaccine or drug.

Frangible Seal–Based Technologies (Tubes, Pouches, Blister Packs). An alternative to syringes and cartridges for reconstitution is the use of tubes, pouches, or blister packs with a frangible seal separating the diluent from the lyophilized or dry powder vaccine. Frangibility refers to property of breaking up into fragments when deformed or otherwise placed under sufficient stress. The frangible seal is ruptured upon application of pressure, allowing the diluent to mix with the pharmaceutical. Materials used for the seal must be compatible with heat sealing and can include PP, polyesters, or coextruded laminates.[98] Water vapor and oxygen transfer rates related to these different materials must be considered because they will affect product stability. An aluminum dual-chamber foil pouch was used for oral cholera vaccine (Orochol from Crucell [formerly Berna Biotech]); however, this product is no longer available. Frangible seal pouches have been used in non-pharmaceutical point-of-use component mixing.[109]

An example of a commercially available tube with a frangible seal is the Neopac Fleximed Easymix, a two-compartment, coextruded, polymer-based tube with the seal separating two compartments containing the dry and liquid or two liquid components (see Fig. 68.2E). Reconstitution occurs when the user applies pressure to rupture the seal between compartments. Nozzles for oral delivery are available, or a Luer interface can allow filling into a syringe or attachment of a Luer-fit needle. The pharmaceutical must be in dry format and dispensed into the tube and sealed. Use of this technology for vaccines may require shifting to a drying technique other than lyophilization (e.g., SFD).

The AktiVax ARCH (aseptic reconstitution cartridge hybrid) is a polymer prefilled syringe incorporating a flexible package on a solid backing (see Fig. 68.2F).[109a] The ARCH package can accommodate one or more constituents of the pharmaceutical, stored in adjacent high-barrier compartments separated by a frangible seal, which can be broken by depressing with a thumb for reconstitution just prior to injection. The mixed pharmaceutical is drawn into the attached syringe for injection. The ARCH syringe can incorporate a staked needle or Luer interface. As for the other technologies discussed above, use of flexible packaging may require updated vaccine lyophilization or other drying techniques. An integrated needle-based design using ARCH features—the Immunoject—also has been developed by AktiVax. In this design, the two-compartment blister is attached to a needle and a foldable plastic backing. The plastic backing shields the needle before use and allows compression of the blister compartments to rupture the frangible seal for reconstitution. Once reconstituted, the integrated needle allows parenteral administration, and refolding the plastic backing disables and covers the needle.[109b]

Partially Integrated Reconstitution Technologies

These technologies are characterized by an integrated primary container with a reconstitution feature such as a dual chamber, but they are without an integrated delivery feature for parenteral

delivery. The Eulysis Single Vial System (SVS) is composed of two compartments: the lyophilized or dry powder pharmaceutical is in a thin plastic cup resting on a glass vial that contains the diluent (see Fig. 68.2G). Actuation of a piston-like cap punctures the base of the plastic cup, causing the contents to fall into the diluent and permitting reconstitution; a needle and syringe must be used to withdraw a dose from the vial. A tamper-evident cap protects the piston cap from activation during shipment. This technology is in early-stage development and may potentially have wide-ranging applications for all freeze-dried injectable products. The Pfizer Injectable Act-O-Vial System demonstrates a similar concept. A rubber septum separates diluent and dry compartments of a nonstandard glass vial. Pushing down on the plastic cap dislodges the septum, forcing it into the lower dry compartment where reconstitution occurs. The Act-O-Vial is used with Pfizer's glucocorticoids Solu-Cortef and Solu-Medrol.[110,111]

Diluent Transfer Technologies

Diluent transfer technologies facilitate mixing of dry and liquid components of a pharmaceutical from two separate primary containers. These technologies eliminate the reconstitution needle to improve safety and reduce user error. An example, the Duoject E-Z-Link, incorporates a Luer lock fitting with a socket-style plastic spike vial adapter (socket sizes 13 mm and 20 mm) that can be used only once. A prefilled diluent syringe can be used to dispense into a standard-sized vial with lyophilized or dry powder pharmaceutical and draw from the contents once reconstituted. The E-Z-Link contains a protective disk to prevent contamination and shield the plastic spike.[112]

The Mix2Vial from West Pharmaceutical Services, Inc., allows connection of two vials with diluent and lyophilized pharmaceutical via two vial-adapter sockets with plastic spikes. The Mix2Vial requires the dry powder vial to be manufactured under vacuum to facilitate the transfer from the diluent vial. After reconstitution, a needle and syringe are used for dosing and delivery.[113] The West Needle-free Transfer Device has a Luer fitting to allow the attachment of a Luer lock syringe, which can be used to transfer the diluent from its vial into the lyophilized pharmaceutical vial and then back into the syringe. The syringe is then detached and a needle attached for parenteral delivery.[114] The West MixJect consists of a capped needle, a 13-mm vial adapter, and a Luer lock fitting for a prefilled syringe attachment. Diluent from the syringe is transferred into a vial of lyophilized pharmaceutical through the vial adapter, reconstituted, and drawn back into the syringe. The vial is then detached and the device is ready for drug administration.[115]

Hybrid Reconstitution Technologies

Some technologies present a fully or partially integrated hybrid approach to primary packaging, diluent transfer, reconstitution, and delivery. The Integrity Bio LyoTip distal hub incorporates a spiral-shaped channel to facilitate mixing of diluent and lyophilized pharmaceutical. The hub requires a Luer lock needle and syringe for delivery. The NOVA Laboratories Hydration Rehydration Injection System (HydRIS) is similar to the LyoTip: it is an attachment filled with lyophilized pharmaceutical for a prefilled diluent syringe (see Fig. 68.2H). A unique feature of the HydRIS is use of a stabilization technology based on sugar glass (an amorphous solid, clear crystallized form of the sugar): the pharmaceutical is dried onto a membrane, which is then integrated into the distal hub. The sugar-based membrane dissolves when it contacts the diluent, allowing the instantaneous mixing of diluent and lyophilized pharmaceutical.

Duoject has designed several reconstitution formats. One example is the PEN-PREP EVO device used to transfer reconstituted pharmaceuticals from a vial into multidose cartridges for use with traditional pen injectors. An integrated vial adapter incorporates a protective disk to shield the user from sharps injuries and to prevent contamination prior to use.[116] The Duoject Inter-Vial and the Duoject Smart-Rod XR combine a prefilled diluent syringe and a vial adapter. The vial adapter on the Inter-Vial detaches from the device once the drug is reconstituted and drawn back into the syringe. Detaching the vial adapter exposes a standard Luer lock for needle attachment. The vial adapter on the Smart-Rod is located on the plunger and cannot be removed for reuse. The Duoject Inter-Vial Plus and Duoject Smart-Rod Plus are nearly identical to the Inter-Vial and Smart-Rod XR except for the location of the diluent and lyophilized contents. The syringe components are prefilled with a lyophilized drug and attached to a diluent-filled vial.

Reconstitution Aids

Bundling or copackaging lyophilized vaccine and diluent in the same secondary packaging is common for many pharmaceutical applications as well as for select vaccine applications such as rabies vaccine. For the Rabipur rabies vaccine that is produced by CSL (formerly Chiron), the secondary package contains the vaccine vial, the diluent ampoule, and a syringe.[117]

Both vaccines and diluents can be supplied in vials or ampoule primary container presentations, and diluent can be provided in a prefilled syringe or other container such as a BFS ampoule. GlaxoSmithKline's Tritanrix HB+Hib vaccine presentation included a one-dose vial containing diphtheria, tetanus, pertussis (DTP)-hepatitis B (HepB) (liquid) and a one-dose vial of lyophilized Hib. A plastic clip bound both vials together to aid in easier reconstitution in that the "diluent" vial (the DTP-HepB vial) was immediately adjacent to the lyophilized vaccine vial.[118] The plastic clip binding either vial–vial or vial–ampoule combinations could reduce adverse events associated with incorrect diluent use.

Summary

The traditional glass vial and needle and syringe continue to be used with standard vaccine formulations and pharmaceutical filling techniques; however, new technologies are available that represent paradigm shifts in manufacturing and healthcare worker use. The use of polymer materials has enabled design and development of new primary packaging technologies, and alternative materials are informing new research in secondary and tertiary containers. Given the challenges of vaccine shipment and storage in the cold chain, new technologies that can reduce volume or the need for the cold chain would be of great benefit to high-income countries as well as LMICs.

NEW TECHNOLOGIES FOR VACCINE ADMINISTRATION: VACCINE MACRODELIVERY SYSTEMS AT THE POINTS OF CARE

New vaccine administration technologies are classified here into three major categories: SC and IM injection, cutaneous vaccine delivery, and mucosal vaccine delivery.

Subcutaneous and Intramuscular Injection

Most vaccines are delivered via SC or IM injection with needles and syringes. As described previously, in high-income–country

markets, immunizations are increasingly provided in prefilled syringes or single-dose presentations, while in lower-income countries serviced by UNICEF, vaccines are commonly delivered from multidose vials using autodisable needles and syringes, although use of single-dose vials and prefilled devices is increasing. An alternative to needle and syringe administration for SC and IM delivery is the jet injector, which can deliver vaccines in their current formulations. Another method in an early stage of development is solid dissolving needles, for which vaccines are reformulated as biodegradable implants.

Anatomy

The SC tissue (also known as the hypodermis) lies below the dermis of the skin and consists mainly of lobules of adipocytes as well as connective tissue (see Fig. 68.3A). Blood and lymphatic vessels transiting this layer serve the dermal layer of the skin. The thickness of the SC tissue layer varies widely between individuals of different age and body mass and at different body sites. For SC injection of vaccines, a $\frac{5}{8}$-inch needle (23 to 25 gauge) is recommended. The skin should be pinched up to avoid injecting intramuscularly and the needle inserted at a 45-degree angle. In infants younger than 12 months of age, SC injections are typically given in the thigh, while for adults and children older than 12 months, SC injections are given in the back of the upper arm, over the triceps.

Beneath the SC layer are skeletal muscles. Individual muscle cells are arranged into bundles called fascicles. These fascicles in turn are grouped in bundles within a layer of connective tissue to form muscles. For infants and toddlers up to 2 years of age, the vastus lateralis muscle in the anterolateral thigh is the preferred IM injection site, and the deltoid muscle in the upper arm is used for older children and adults. Recommended needle lengths vary by age, injection site, and body mass, because of the variation in thickness of the SC layer.

Immunological Rationale

The SC and IM routes of administration are typically used for vaccines because they are relatively convenient to access using a needle and syringe, enable consistent delivery, and provide adequately reproducible immunogenicity among individuals. However, compared with internal and external body surfaces that are more frequently in contact with the environment, SC and IM tissues have relatively fewer immune cells. Following injection of a vaccine, the antigen or adjuvant generates a local innate immune response, attracting APCs which ingest the vaccine package. These infiltrating dendritic cells (see Fig. 68.3B) and monocytes migrate to local draining lymph nodes and induce B- and T-cell immune responses. In general, SC and IM injection of vaccines tends to be less effective at producing mucosal immunity than mucosal vaccination.[119]

Jet Injection

Jet injectors force liquid under high pressure through a tiny orifice, producing a focused stream that penetrates the skin to deliver medication into targeted tissues without needles. Most modern jet injectors are powered by the release of energy stored in a compressed metal spring, and a few use compressed gas such as CO_2 or N_2. The velocity of the jet stream exceeds 100 meters per second. The depth achieved depends primarily on the power imparted to the liquid and then on variables such as orifice diameter, distance from the nozzle to the skin, and angle of injection.[120–125] This section focuses on jet injectors for SC and IM delivery of vaccines; devices capable of ID delivery are discussed "Cutaneous Vaccination" later.

Over the past half-century, jet injectors have been used to administer hundreds of millions, if not billions, of vaccine doses for mass campaigns in humans against smallpox,[126–132] measles,[133–135] polio,[136,137] meningitis,[138–140] influenza,[141,142] yellow fever,[143,144] cholera, and other diseases.[128,129,145–149] During the swine influenza mass campaign of 1976–77 in the United States, a substantial proportion of the approximately 43 million doses administered were by jet injection (Centers for Disease Control and Prevention [CDC], unpublished data).[150,151] Jet injectors have also been used for a wide variety of therapeutic drugs.[152–171] In recent years, the devices have been used to administer antigens to humans and animal models for a variety of investigational vaccines, including dengue,[172–175] herpes simplex type 2,[176] HIV/AIDS,[177–179] Japanese encephalitis,[180] malaria,[181] and melanoma.[182] A wide variety of investigational recombinant nucleic acid vaccines are being delivered in preclinical and clinical trials using various jet injectors.[183–198]

Because of safety issues with the earlier generation of MUNJIs, a new generation of DSJIs has been developed, many with features designed to be suitable for global immunization programs.

Multiuse Nozzle Jet Injectors. Jet injector technology was invented in France in the 1860s[199,200] and reintroduced in the 1940s as the Hypospray[157] for patient self-injection with insulin. In the 1950s, the U.S. military developed a high-speed system called the Ped-O-Jet[201] (Fig. 68.4A), and the units once referred to as jet guns were widely used for mass-vaccination programs.[127,202–206]

A large body of clinical literature shows the immunogenicity of vaccine delivered by jet injectors to be usually equal to, and sometimes better than, that induced by conventional needle and syringe for a wide variety of vaccines.[207,208] The pain associated with jet injection depends on the medication or vaccine involved. Insulin, other nonirritating drugs, and vaccines without adjuvants are usually reported to result in reduced or equivalent pain compared with needles,[121,124,133,141,154,171,209,210] but not always.[211] Vaccines with aluminum adjuvants or other irritating components tend to result in higher frequencies of mild, transient, local reactions (e.g., soreness, edema, erythema) when jet injected, probably because small amounts remain in the track left through the skin.[212–224] Bleeding and, less often, ecchymosis are reported to occur at the jet injection site more frequently than with needle injections.* Rarely, the jet stream causes a laceration if the injector moves during injection.[132,195,200,204] Safety features on some modern DSJIs reduce this risk.

Beginning in the 1960s, concerns arose for potential iatrogenic transmission of bloodborne pathogens by MUNJIs, which use the same nozzle to inject consecutive patients without intervening sterilization.[229,230] Bench and animal studies indicated cross-contamination could occur because blood or virus remained in nozzle orifices despite recommended alcohol swabbing between injections.[231–233] Fact superseded theory when a Med-E-Jet caused an outbreak of several dozen cases of hepatitis B among patients in a California clinic.[234] Subsequent clinical,[235] field,[236,237] bench,[238] animal,[239,240] and epidemiologic[241,242] studies added more evidence that MUNJIs could transmit pathogens between patients. This led to warnings and discontinuation of their use by public health authorities[24] and to market withdrawal of the Ped-O-Jet and discontinuation of its U.S. military use in 1997.[243,244]

Figure 68.4. Selected devices for subcutaneous and intramuscular vaccine delivery. A, Ped-O-Jet (Keystone Industries), the most widely used multiuse nozzle jet injector (MUNJI) worldwide, before withdrawal from public health use by the 1990s for cross-contamination risk. Its metal spring is compressed by hydraulic fluid pumped by a foot pedal in its carrying case (**A,** *inset*) or by electric pump (not shown). Depth of delivery determined by removable nozzle used, either a subcutaneous (SC)/IM nozzle (shown here) or an intradermal (ID) nozzle (see Fig. 68.3E). **B,** Bioject Biojector 2000 DSJI, powered by gas. It has Food and Drug Administration (FDA) clearance for SC, IM, and ID delivery. **C,** PharmaJet Stratis DSJI, for 0.5-mL dose delivery. Delivery IM or SC set by vaccinator technique (fat layer pinched up for SC). Spring is reset using separate carrying case. Syringe is filled by pulling back and breaking off its blue shaft and thumb tab from conventional single-dose and multidose vials using needle-free vial adaptor (not shown). On insertion into device, any excess liquid is returned to vial to minimize wastage of overfill. Cleared for U.S. marketing by the FDA in 2011 and received World Health Organization (WHO) prequalification in 2013.[715,716] **D,** Biojet ZetaJet metal-spring-powered DSJI, features built-in crank for manual recocking of metal spring (Bioject Medical Technologies). Uses different autodisabling cartridges for SC, IM, and ID injections (SC and IM delivery was licensed by U.S. FDA in 2009; ID use is investigational). **E,** Investigational LectraJet HS (high-speed) motorized DSJI (D'Antonio Consultants International) features built-in motor and rechargeable battery for rapidly compressing metal spring between injections at rates exceeding 600 per hour, with battery capacity of >3000 injections per charge. Capable of rapid loading and unloading of single-use syringes from (**E,** *inset*) a sterile-packaged, 30-unit magazine for mass vaccination. **F,** Med-Jet H4 DSJI (Medical International Technology), gas-powered with entirely disposable single use fluid path. Licensed in Canada in 2014. A manually powered DSJI, the Dart (not shown), is in development and uses the same disposable cartridges. **G,** Investigational Solid Dose Injector (SDI) from Glide Pharma is powered by a compressed metal spring, which is released as the disposable drug cassette (white component extending beyond blue hub) is pressed fully against the skin. It inserts a (**G,** *inset*) pointed, hardened, approximately 1-mm-diameter drug formulation (shown compared with conventional matchstick tip) into subcutaneous tissues, where it dissolves. (***A*** *and* ***inset,*** *Courtesy James Gathany, Greg Knobloch [CDC Photographic Services].* ***B*** *and* ***D,*** *Courtesy Bioject Medical Technologies.* ***C,*** *Courtesy PharmaJet, Inc.* ***E,*** *Courtesy D'Antonio Consultants International, Inc.* ***F,*** *Courtesy Medical International Technologies [MIT Canada] Inc. In the mid-2000s, a MUNJI was reengineered with disposable caps to try to prevent contaminating blood or tissue fluid from splashing back onto the reusable nozzle. However, after injections with saline of volunteers who carried hepatitis B virus, 8% of subsequent injections into vials—representing the next vaccinees in a clinic or mass campaign—were found to contain hepatitis B antigen.[245] High-speed microcinematography also revealed extensive splash back from the skin during injection with MUNJIs.

This body of evidence supports the conclusion that the design of MUNJIs is inherently unsafe for use in immunization settings, and any reuse of fluid pathways or unsterile components that are in direct or indirect contact with consecutive patients should be abandoned.[25] Even if contamination could be shown to be extremely rare, it is unlikely that policy makers could be convinced to set any level of acceptable risk.[246] Although public health authorities recommend against MUNJI use for vaccination,[25,247] MUNJIs continue to be used in the United States and other countries in clinical specialties such as dentistry, urology, and podiatry where cleaning and sterilization (such as autoclaving) of the entire device fluid path between patients is possible. Also, the Med-Jet line of MUNJIs has received licensure in multiple countries including Canada, China, and Russia for human applications including physiatrics, dermatology, and mesotherapy indications.[248] MUNJIs allowed a single health worker to vaccinate 600 or more patients per hour.[132] The withdrawal of the device posed challenges for conducting mass-immunization campaigns for disease control programs and in response to pandemic or bioterrorism threat.

Disposable-Syringe Jet Injectors. To overcome concerns about MUNJIs and their withdrawal, a new generation of safer DSJIs has been developed since the early 1990s.[249–252] Each sterile syringe (or cartridge) has its own orifice and nozzle and is discarded between patients. Although some are used for self-administration of insulin, other hormones, and drugs such as sumatriptan for migraines,[253] others are targeted for vaccine administration.

One early system, developed by predecessor companies of Sanofi Pasteur, was the manufacturer-prefilled Imule syringe for use in the Mini-Imojet DSJI.[254,255] Although demonstrated in the clinic and field to be immunogenic and safe for several vaccines,[256] the system was eventually abandoned upon corporate merger. The pioneering DSJI for the vaccine market was the Biojector 2000 (see Fig. 68.4B), introduced in the United States in the 1990s. During the first decade of the 2000s, it delivered approximately 1 million IM and SC vaccine doses per year at private, public, and U.S. Navy and Coast Guard immunization clinics in the United States, and it has been used in many vaccine studies, including a number of investigational recombinant nucleic acid vaccines.*

To meet developing-world needs, several DSJIs have been developed that are economical, autodisabling to prevent reuse, and suitable for mass campaigns and routine immunization. PharmaJet entered the market in 2009 with licensure of its eponymous device for IM and SC injections. A recent study with this now-discontinued DSJI found that delivery of MMR vaccine did not meet noninferiority criteria in comparison with needle and syringe delivery.[267] PharmaJet subsequently received market clearance for the Stratis device (see Fig. 68.4C), which was the first DSJI to receive WHO prequalification, in 2013. Various PharmaJet models have been studied for veterinary[186–188,268] and human[164,165,255,257,258,269–271] applications. In a bench study testing injection of MMR vaccine through pig skin into a vial with three PharmaJet injectors, there was no loss of measles or mumps vaccine virus infectivity but some loss of rubella infectivity with two of the devices.[271a] Other examples of DSJIs developed for vaccine delivery include the Bioject ZetaJet (see Fig. 68.4D),[272] the DCI Lectrajet (see Fig. 68.4E),[273,274] and the MIT Med-Jet H-4 (see Fig. 68.4F) and Dart.[248]

Use of DSJIs in the United States was curtailed by a 2011 FDA communication advising that vaccines should be delivered with a needle and syringe unless specifically labeled for jet injector delivery. Following consultation with the FDA, PharmaJet and bioCSL conducted a clinical trial demonstrating noninferiority of delivering bioCSL's Afluria influenza vaccine with a DSJI compared with a needle and syringe.[271] Based on these data, in 2014 Afluria was licensed by the FDA for delivery with the PharmaJet Stratis device. This "vaccine relabeling" has enabled DSJIs to reenter the U.S. market; however, the FDA-approved language limits delivery to a specific manufacturer's DSJI device.

Advantages of DSJIs are the elimination of needlestick injuries associated with possible transmission of bloodborne pathogens to health workers as well as reduction in the volume of sharps waste disposal, which is not required for used DSJI syringes. They also have the potential to increase acceptability and immunization coverage rates. Reduced crying has been observed when vaccines are delivered to infants with jet injection compared with needle and syringe injections.[258,267] However, like syringes with needles, DSJI syringes require onsite filling following vaccine reconstitution (if required). Prefilled DSJI syringes in development by PharmaJet and other manufacturers may enable greater efficiency and speed of administration, similar to that of the old generation of MUNJIs. Use of DSJIs likely will entail higher costs because of the higher cost of manufacturing a DSJI syringe and the cost of the durable injector, but modeling indicates the potential for overall cost savings compared with needles and syringes when the indirect costs of iatrogenic disease resulting from the latter are included.[257,275] As with all vaccination systems that require a durable administration device, distributability of the vaccine is restricted by the need to have a device available at every POC when vaccine is delivered. The cost of a jet injector can be negligible if amortized over many doses in high-vaccination–volume settings. However, in POCs with low-vaccination volumes, the cost of these devices may be prohibitive.

Solid Dissolving Needles

Dissolving needles are a novel biodegradable implant technology consisting of solid doses of vaccine that are administered subcutaneously. A disposable cartridge containing the implant is loaded into a reusable handheld applicator that uses gas or spring pressure to insert the implant into the skin. Once the implant is in the tissue, it begins to dissolve and the vaccine is released.

The Bioneedle Technologies Group (The Netherlands) has developed Bioneedles, small implants of biodegradable polymer (extruded starch) filled with concentrated liquid vaccine, which are freeze-dried. After insertion into the SC tissue, the implants have been shown to break down within a few hours and dissipate from the delivery site within 3 days. Administration of a placebo Bioneedle implant in a clinical trial found adequate safety and acceptability of the technology and no histological findings at the implantation site. Administration of tetanus toxoid, hepatitis B, influenza, and IPVs via Bioneedles has been studied in animal models.[276–279] In Wistar rats, the same dose of IPV given by SC or IM liquid injection or by Bioneedle implantation was found to produce similar antibody titers after two immunizations.

*References 154, 160, 161, 175–179, 182–185, 188–191, 198, 211, 214, 217, 254, 256a, 258–266.

Glide Pharma (United Kingdom) has also developed a solid-dose injector. It uses a spring-loaded device to quickly push into SC tissue a sharp, biodegradable implant the size of a grain of rice (see Fig. 68.4G). The solid-dose injector has been tested with influenza, diphtheria, and *H. influenzae* vaccines and is in development with an anthrax vaccine.[282]

Potential benefits of this technology class include dry-format unit-dose administration; increased thermostability of the solid vaccine formulation in comparison to a liquid formulation; reduced cold chain footprint because of the small dose and package size; avoidance of needles and syringes with reduced risk of needlestick injury and reuse; and potential for reduced number of booster doses if slow release is successfully demonstrated to provide improved immunogenicity. Challenges to development include demonstrating the feasibility of the formulation and manufacture of solid vaccine implants, acceptability, and the complexity and costliness of the administration device.

Cutaneous Vaccination

Cutaneous administration of vaccines includes delivery to either the dermis or epidermal layers of the skin. The skin was one of the first tissues into which variola (smallpox) virus and, later, cross-protecting cowpox virus were introduced to prevent smallpox. The cutaneous route for variolation involved breaking the skin with a sharp instrument, and it was used in India and China at least as early as the 16th century. Variolation was supplanted by safer cutaneous application of material from cowpox lesions (vaccinia virus), the 18th-century method first given the term *vaccination* and first published by Edward Jenner. The cutaneous route remains the standard for smallpox vaccine (see Chapter 33) as well as for administering BCG to prevent tuberculosis (see Chapter 54). Vaccines for poliovirus[284] and yellow fever[285] were also delivered by this route in the past. The cutaneous route has demonstrated and hypothetical advantages over other delivery methods, including the potential to enable dose-sparing.[286–307] Cutaneous delivery is often associated with an increase in mild local reactions, because of the visibility of the administration site, but is less likely to result in unanticipated serious adverse reactions than other routes. Mixed results for the immunogenicity of the ID route have been reported for a variety of live attenuated, inactivated, and subunit vaccines, including those from dose-sparing studies for currently available vaccine formulations as well as for investigational vaccines, particularly DNA vaccines.

In a classical ID injection, a bolus of liquid is deposited into the dermis to raise a visible bleb, as in the traditional Mantoux method. A variety of novel delivery methods and technologies have been developed to deliver vaccines into the skin with the goals of (a) improving the ease, acceptability, and safety of vaccination, and (b) taking advantage of the potential for skin tissue to enhance immunogenicity or enable dose-sparing.

Anatomy

The outermost layer of the skin is the epidermis (see Fig. 68.3A), a stratified squamous epithelium that is usually about 0.1-mm thick but can be from 0.8 to 1.4 mm on the palms and soles. The stratum Malpighi layer is the primary component of the epidermis, and its dividing and growing keratinocytes serve both a structural function—limiting the passage of water and other molecules—and an immunologic role. Keratinocytes germinate just above the basement membrane, which demarcates the boundary between epidermis and deeper dermis. These cells then grow, flatten, mature, and senesce in increasingly superficial strata until they reach the surface and are sloughed. The main product of this cell is keratohyalin, a dense lipid that helps form a waterproof barrier. The lateral edges of adjacent keratinocytes are tightly linked by desmosomes, which maintain the strength of the epidermis and also contribute to its resistance to the passage of foreign matter or molecules.[308,309]

The topmost horny layer of the epidermis is the stratum corneum, composed of staggered courses of dead keratinocytes—also known as corneocytes—in a lipid bilayer matrix. This stack of 10 to 20 cells, 10 to 20 µm thick, is the principal obstacle to the introduction of vaccine antigen for cutaneous vaccination. Below the epidermis and basement membrane lies the dermis, approximately 1.5 to 3.0 mm thick, in which fibroblasts, fine collagen, elastic fibers, and most skin organelles—including small blood vessels, lymphatic vessels, nerves, hair follicles, and sweat and sebaceous glands—are found.

Skin thicknesses have been mapped in children to identify the histologic suitability of sites for cutaneous vaccination. Equally important is selecting skin sites that are easily accessed so as to minimize disrobing and loss of privacy. In smallpox eradication, the volar surface of the forearm was commonly used because it was quickly accessible.[126]

Immunological Rationale

The specific mechanisms that produce an immune response when vaccine antigen is introduced into the skin are not entirely clear. With stimulation, keratinocytes can produce proinflammatory cytokines (e.g., interleukin-1) and can function as APCs by displaying major histocompatibility complex class II antigens (human leukocyte antigen–DR) as well as intercellular adhesion molecule-1. Epidermal Langerhans cells—a type of APC—are believed to play a key role in cutaneous immunization (see Fig. 68.3C), although dermal dendritic cells and other well-known immune system components such as $CD8^+$ and $CD4^+$ T lymphocytes, mast cells, and macrophages also circulate or reside in the epidermis or dermis.[298,299,302,310–314]

The immature Langerhans cells reside like sentinels among the keratinocytes in the epidermis, composing about a quarter of the skin surface area,[315] where they efficiently capture foreign antigens by phagocytosis or endocytosis. Like dendritic cells in other tissues (see Chapter 2), on activation (see Fig. 68.3C) these professional APCs process the antigen as they migrate to draining lymph nodes. There, now mature, they express high levels of class II major histocompatibility complex molecules and present the antigen brought from the skin to T-helper lymphocytes, a critical step for the subsequent immune responses orchestrated by the latter cells.

Macrodelivery of vaccines precisely into the extremely thin epidermal tissue or the dermis layer creates a technological challenge that has resulted in a wide array of cutaneous delivery methods and devices. Researchers investigating cutaneous delivery of existing vaccines and those in development have used the Mantoux method of injection by needle and syringe (see "Mantoux Method" later) as well as a variety of novel devices such as ID jet injectors, mini-needles, microneedles, electroporation devices, and microarray patches.

Traditional Methods

During the more than 200 years of cutaneous vaccination against smallpox (see Chapter 54), a variety of sharp

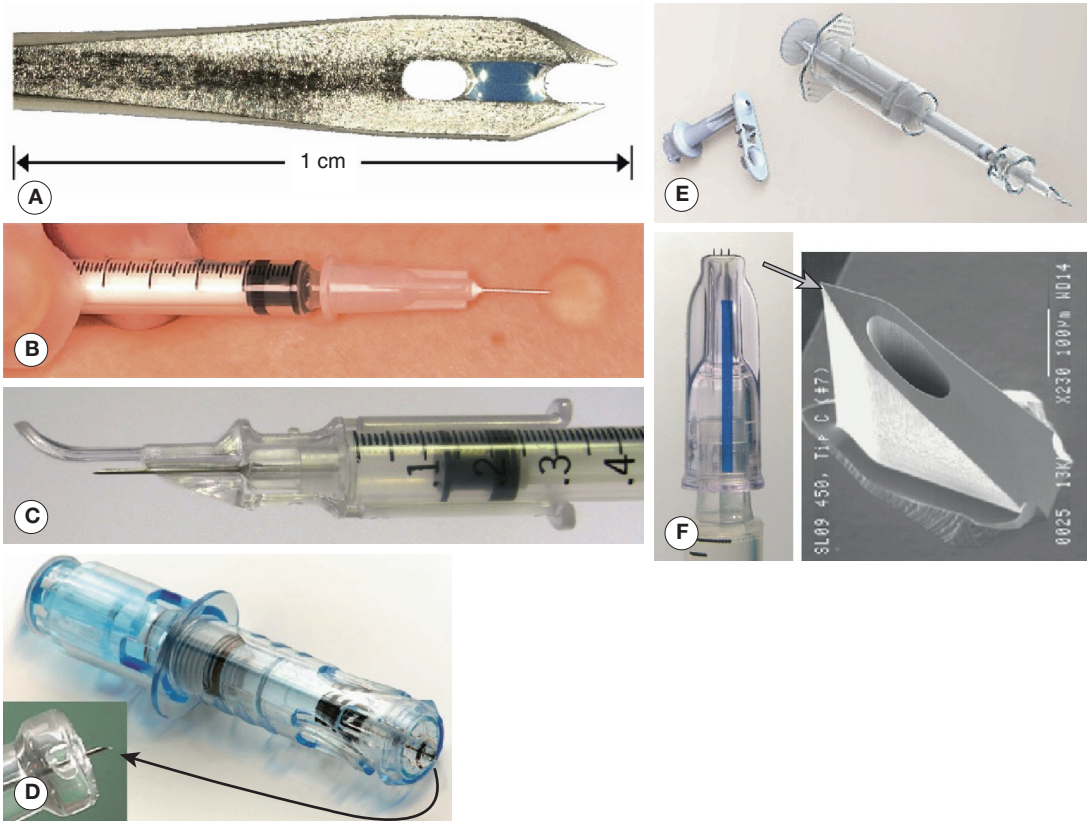

Figure 68.5. Selected needle-based technologies for cutaneous vaccine delivery. A, Pronged end of bifurcated needle (full length is 5 to 7 cm), which is the current preferred device for smallpox vaccination, holds between its tines approximately 2.5 μL of fluid by capillary action. **B,** Traditional Mantoux method for creating intradermal (ID) wheal using 26-gauge hypodermic needle and conventional 1-mL syringe. **C,** ID adapter for conventional needle and syringe for quick and consistent Mantoux ID injection (West Pharmaceutica Services), the length and depth of the protruding needle underneath the "Ski-tip" guide manipulates the skin to optimize needle placement regardless of bevel orientation.[338,339] **D,** Prefilled version of Soluvia mini-needle ID syringe (BD Micro-Delivery System; Becton, Dickinson and Co.). Used for ID delivery of Sanofi Pasteur brands of inactivated influenza vaccine (Intanza, IDflu,[717] Fluzone Intradermal[718]).[719] **D** *inset,* The 30-gauge staked mini-needle projects 1.5 mm beyond its hub to limit the depth of injection upon perpendicular insertion into the skin. Marketing of vaccine-device combination product approved in European Union in 2009 and in United States in 2011. **E,** ID syringe in development (Star Syringe) with an autodisable feature and an integrated plastic spike for filling from a vial, and a mini-needle adapter for providing an ID injection. **F,** MicronJet hollow microneedle device with Luer fitting onto conventional syringe for ID delivery (NanoPass Technologies Ltd). Cleared for marketing in the European Union and the United States. Safety and efficacy of a novel microneedle device for dose sparing intradermal influenza vaccination in healthy adults.* Vaccine. *2009;27[3]:454–459.)*

instruments have been used to penetrate the epidermis (and avoid penetrating unnecessarily deeper into the dermis) for inoculation of cowpox or vaccinia virus. These included scarification with a needle, scalpel, lancet, or knife and rubbing vaccine into the resulting lesion; twirling a rotary lancet in a drop of vaccine on the skin; and the multiple-pressure method of pressing a straight surgical needle sideways into the skin through a drop of vaccine. Multitine devices consisting of multiple short needles in a circular or square array dipped in solution and pressed into the skin have also been used.[316,317]

The BCG vaccine for the prevention of disease from *Mycobacterium tuberculosis* was originally administered orally in the 1920s (see Chapter 60). Safety concerns prompted a shift to cutaneous administration by ID needle injection using the Mantoux technique in 1927. BCG has also been delivered cutaneously by multiple puncture devices,[318–321] scarification, jet injectors,[322] bifurcated needles (Fig. 68.5A),[323] and multitine devices,[316,324] but the Mantoux method remains the standard delivery method (see Fig. 68.5B).

Bifurcated Needle. In the 1960s, Benjamin Rubin invented the bifurcated needle (see Fig. 68.5A), for which Wyeth waived the royalties so that the WHO could produce it for smallpox eradication. The device holds approximately 2.5 μL of fluid by capillary action between its tines and is applied perpendicularly into the skin. This uses one-fifth of the typical dose volume needed by earlier multiple-pressure methods, but it

requires a higher virus concentration. Its simplicity, portability, and economy greatly facilitated the latter half of smallpox eradication, particularly in Asia and East Africa.

Mantoux Method. The needle technique for classical ID injection, as used for BCG, was developed in the early 20th century by Felix Mendel and separately by Charles Mantoux for the administration of tuberculin (now replaced by purified protein derivative) used for diagnosis of tuberculosis infection. Now referred to as the Mantoux method (see Fig. 68.5B), this procedure has become the common route for ID injection of both BCG and rabies vaccines. Although the latter was typically delivered intramuscularly, research found that reduced doses of rabies vaccines delivered via ID are similarly effective for both postexposure and preexposure prophylaxis regimens.[325–333] Because of the high cost of cell-culture rabies vaccines, the WHO has recommended ID delivery for resource-constrained settings since 1991, and this route is widely used in the developing world, particularly in Asia.[333a,334–336]

In the Mantoux technique, a short-bevel, fine-gauge needle, usually 27 gauge, is inserted, bevel up, at a 5- to 15-degree angle into slightly stretched skin, often the volar surface of the forearm. The tip is advanced approximately 3 mm until the entire bevel is covered. Upon injection of fluid, proper location of the bevel in the dermis creates a bleb, or a wheal, as the basement membrane and epidermis above are stretched by the fluid (see Fig. 68.5B). Leakage onto the skin indicates insufficient penetration to cover the bevel. Failure to produce a bleb indicates an improperly deep location of the fluid in the SC tissue. Drawbacks to the Mantoux method are the training, skill, and extra time needed to accomplish it correctly.

Needle-Based Technologies

Intradermal Adapters. A novel ID adapter (see Fig. 68.5C), designed to improve ease and consistency of the traditional Mantoux technique (see Fig. 68.5B), fits over a conventional syringe with a fixed needle and guides the needle to its appropriate position in the skin to produce the desired bleb. The device is marketed by West Pharmaceutical Services[337] and has FDA clearance. In clinical studies, the ID adapter has been found to reliably produce blebs, regardless of the orientation of the needle bevel during injection.[338,339] Similar to a fill-on-site mini-needle device, the ID adapter has the potential to be a relatively low-cost option to increase the ease and reliability of ID injections. Because the angle of injection mimics the Mantoux technique, it may also serve as a training tool for users inexperienced with Mantoux. One challenge is that the device design is syringe specific and must be paired with a particular brand of syringe.

Mini-Needles. As for cutaneous vaccination in general, a diverse terminology is applied to microscopic projections for perforating the superficial skin to deliver the drug or vaccine.[340–343] This chapter uses the term *mini-needles* for hollow projections of 1 mm or longer for liquid delivery. The term *microneedles* refers to hollow projections shorter than 1000 µm. Microarray patches are arrays of solid projections (without lumens) shorter than 1000 µm. These patches deliver vaccine in a dry format and are not classified as needles.

To circumvent the amount of skill and time needed for successful Mantoux injection, BD developed a prefilled glass syringe with a staked 30-gauge mini-needle that projects only 1.5 mm beyond its depth-limiting hub for intuitive perpendicular insertion into the skin (see Fig. 68.5D). Termed the Soluvia Micro-Delivery System, it was licensed exclusively by Sanofi Pasteur for certain vaccine applications. Sanofi Pasteur undertook a series of clinical trials with trivalent inactivated influenza vaccine,[345–349] which led to marketing approval in Europe in 2009 for ID delivery of its Intanza and IDflu products. These contained either 9 µg of viral hemagglutinin per strain per 0.1 mL for adults through age 59 years,[350] or a full (non–dosage-sparing) 15 µg for those age 60 years and older.[345–347] Sanofi Pasteur's U.S. brand of ID influenza vaccine (Fluzone Intradermal), similarly containing 9 µg per strain, was found to induce geometric mean titers of hemagglutination-inhibiting antibody that were noninferior to those of control patients receiving conventional Fluzone by the IM route with 15 µg per strain. In 2011, the FDA licensed the vaccine and its unique prefilled delivery system with an indication that it be used only for patients 18 to 64 years of age. Several other countries (e.g., Canada, Australia, and New Zealand) have also licensed a Sanofi influenza vaccine in the Soluvia mini-needle delivery system.

A fill-on-site version of the Soluvia mini-needle syringe was used in a rabies vaccine clinical trial and demonstrated protective seroconversion comparable to a full dose by the IM route. In preclinical animal experiments, delivery with this device produced good immune responses to anthrax recombinant protective antigen,[351–353] conventional hemagglutinin and plasmid DNA antigens for influenza, and live recombinant yellow fever vector for Japanese encephalitis vaccines.[354]

Novosanis has developed another prefilled mini-needle device, the VAX-ID, which was tested for delivery of saline in humans.[355] Star Syringe has developed a fill-on-site mini-needle ID syringe (see Fig. 68.5E). The Star ID device is designed to be low cost and suitable for use with existing vial formats, is filled through an integrated plastic spike, and has an autodisable feature. A clinical study assessing the injection performance with this device is planned.

Mini-needle devices can facilitate ID delivery and enable the dose-sparing potential of some vaccines while retaining the familiar interface and use method of common IM needle and syringe injections. ID injections with the Soluvia device frequently do not produce the characteristic wheals in the skin that are indicative of correct Mantoux injection technique,[356,357] so some education for healthcare workers may be needed. Prefilled presentations such as the Soluvia and VAX-ID offer additional benefits in ease of use and dose accuracy, but they are more expensive and require much more cold chain storage space than vial presentations. The recent development of low-cost fill-on-site devices such as the Star ID syringe, if demonstrated to perform clinically, could be more appropriate for the requirements of LMIC immunization programs.

Hollow Microneedles. Hollow microneedles, which deliver liquid vaccines intradermally, share attributes with the needle-based technologies for ID delivery described previously (see "Mini-Needles" and "Intradermal Adapters" earlier). Hollow microneedles are designed to inject therapeutic liquids through their tiny lumens and are used with either a syringe or a small wearable pump.[292,303,305,342,358] Flow rates of microneedles have been measured up to a remarkable 1 mL/min per cannula. Common lengths of 200 to 1000 µm are short enough, in theory, to be painless because they would not reach nerve endings in the dermis.[294,358–360]

The MicronJet 600 device developed by NanoPass is unique in its availability as a licensed, sterile, disposable microneedle device. It consists of three hollow microneedles 600 µm in height in a beveled pyramidal shape. These are mounted on an adapter with a Luer interface for fitting onto a conventional syringe for liquid vaccine or drug (see Fig. 68.5F). In 2010, it was cleared by the FDA for injection of any drug approved for ID delivery. It also holds a CE mark for marketing in Europe.

Adult volunteers vaccinated intradermally with a similar MicronJet version (four microneedles 450 µm in height)

received reduced single doses of 3 or 6 µg per strain, or full 15-µg doses by IM route, of licensed alpha-Rix (Fluarix, GlaxoSmithKline) 2007–08 seasonal influenza vaccine. By day 21, all three study arms developed comparable increases in antibody titers.[361] Local reactions were more frequent with MicronJet than by the IM route, but they were mild and transient. Similar dosage-sparing trials for 2009–10 monovalent H1N1 influenza vaccine and 2010–11 trivalent vaccine confirmed comparable or superior immune responses for the ID route versus IM. The MicronJet has also been studied for reduced-dose delivery of IPV[362,363] and varicella-zoster vaccine.[364]

Another hollow microneedle system is 3M's hollow microstructured transdermal system (hMTS).[289,369] Its patient-contact surface contains 18 microneedles of 500 to 900 µm in height, whose lumina of 10 to 40 µm in diameter delivers liquid volumes ranging from 0.3 to 1.5 mL. A spring-powered device contains liquid drug prefilled into a glass dose chamber. Upon triggering, a spike pierces the stopper of the chamber through which the dose passes and is forced slowly, over a period of 5 to 40 minutes, through the microneedles into the skin of the upper arm or thigh. Adhesive keeps the system in place until delivery is complete. Delivery of equine tetanus antitoxin to swine as a model for delivery of monoclonal antibodies resulted in pharmacokinetic profiles of tetanus antitoxin similar to dosages via SC injection.[369] Other industry and academic groups have pursued development of hollow microneedles, including Debiotech and the Georgia Institute of Technology.[249,370]

Hollow microneedles have advantages similar to those of other needle-based ID devices for delivery of liquid vaccines: they can increase reliability and ease of ID injection, potentially enabling vaccine dose-sparing. A clinical study found that delivery of influenza vaccine with the NanoPass MicronJet hollow microneedle device enhanced immunogenicity compared with the same dose of vaccine delivered ID by the Mantoux method, which suggests that the reliability and shallower depth of delivery of some hollow microneedle devices may enable superior immune responses.[371] However, separate needles or vial adapters are required to fill the syringes for hollow microneedle devices from a conventional vial, adding to the steps required for injection. Prefilled hollow microneedle technologies in development would simplify usage but are likely to increase costs and cold chain requirements.

Electroporation. Electroporation uses very short electrical pulses to produce temporary pores of nanometer-range diameters in the intercellular lipid matrix of the stratum corneum, which remain open and permeable for hours.[294,372–376] In vitro and in vivo preclinical studies of this technique demonstrated skin entry of larger molecules, such as heparin (12 kDa), peptides, proteins (such as luteinizing hormone–releasing hormone), and nucleic acids,[260,377–380] with potentially extensive use for investigational DNA vaccines in animals and humans.[194,381,382]

Inovio's CELLECTRA series of electroporation devices[383] and Ichor's TriGrid delivery system[385] are capable of ID and IM delivery. A hollow needle injects the drug conventionally, while parallel solid needles surrounding the injected dose create the current to generate pores in the target muscle tissue.[376,386,387] These devices have been tested preclinically and clinically for delivery of several DNA vaccines, including those for HPV,[388] HIV,[389,390] malaria,[391] and tuberculosis, with results demonstrating improved immunogenicity of the DNA antigen when electroporation is applied. Noninvasive surface electroporation devices have also been developed by Inovio and may have better acceptability.[392]

The Easy Vax and related Derma Vax epidermal electroporation systems combine the application of antigen- or drug-coated mini-needles 2 mm long, followed by electroporation. Smallpox antigen in plasmid DNA was dried onto the tips of arrays and inserted into the skin of mice, and when followed by six electric pulses, it induced protection from smallpox challenge.[393] A prostate cancer DNA vaccine was similarly administered.[394]

Electroporation has promise as an enabling technology for DNA vaccines, which have lower efficacy by traditional delivery methods. Acceptability is a challenge, particularly for IM electroporation devices, although ID devices have been found to be more tolerable.[395] The cost and complexity of the devices could preclude use in most low-resource settings.

Needle-Free Technologies

Jet Injection. Since the 1960s, multiuse nozzle jet injectors (see "Subcutaneous and Intramuscular Injection: Jet Injection" earlier) have allowed ID delivery of smallpox, BCG, and other vaccines via specialized nozzles or standoffs to achieve the shallower penetration required compared with IM or SC injection.[396,397–399] With discontinuation of the use of MUNJIs, DSJIs have been used for some ID injections.[128,129,249,400–402] For some of these devices, such as the Biojector 2000 and the Bioject ZetaJet, spacers can be added to a nozzle intended for SC delivery, creating a gap between orifice and skin, which weakens the jet and provides space for a bleb that leaves the dose in the skin. Other designs, such as the MIT Med-Jet line of gas-powered jet injectors and the MIT Dart spring-powered DSJI, can achieve ID delivery with variable pressure settings that allow the user to reduce the force of the injection stream. The PharmaJet Tropis (Fig. 68.6A) and the Bioject ID Pen (see Fig. 68.6B) are two new spring-powered DSJIs designed solely for ID delivery of 0.05 and 0.1-mL volumes.

The Ped-O-Jet (and, to a much lesser extent, other MUNJIs) administered tens of millions of smallpox vaccine doses for the first half of the WHO Smallpox Eradication Program in South America and West Africa from the late 1960s to the early 1970s, until invention of the simpler and swifter bifurcated needle.[126,132,399] MUNJIs also delivered yellow fever[128,143,404,405] and BCG vaccines[405a,406–410] by the ID route, as well as various tuberculosis skin testing antigens.[401,411–417] However, variations in subsequent tuberculosis skin testing reaction sizes when delivered by MUNJIs[322,418] led the WHO to discourage jet injector use for BCG and tuberculosis skin testing.[419,420]

To achieve polio eradication goals, injectable IPV is being introduced worldwide to supplement use of oral poliovirus vaccine (OPV). However, IPV is more expensive to produce and more difficult to deliver in campaign settings than OPV, promoting a search for cost-saving strategies that also avoid the introduction of needles into the polio eradication program. Recent clinical research has compared full doses of IPV given intramuscularly (0.5 mL) with ID delivery of 0.1 mL by either needle-free jet injectors or the Mantoux technique. In studies evaluating a primary series of immunizations in infants, some have found equivalent seroconversion rates, while others have shown reduced responses with ID jet injection.[258,259,421] In all the trials conducted in infants, ID delivery of reduced doses of IPV has resulted in lower titers of neutralizing antibodies, whether reported as geometric mean titers or median titers, and whether or not the study was performed in poliovirus-naïve infants or in infants receiving supplemental doses of IPV.[258,259,420,422] It has been suggested, however, that any detectable neutralizing antibody titer should be sufficient to prevent paralytic disease.[258] Clinical trials using a single dose of IPV for boosting immunity in previously immunized children and adults generally have found that ID delivery of a 20% (0.1 mL)

Figure 68.6. Selected needle-free technologies for cutaneous vaccine delivery. dose is immunogenic but often does not meet noninferiority criteria compared with full-dose IM delivery.[266,269,270]

A recent clinical trial of BCG vaccine given via ID found that DSJI delivery and Mantoux method delivery were similar in safety and immunogenicity.[423] Other vaccines that have been studied for ID delivery by DSJIs include those for HIV,[179,198] influenza, dengue,[424] and HPV.[425] Jet injectors for ID delivery offer the advantage of speed, simplicity, and patient acceptability as well as the ability to use off-the-shelf vaccines without reformulation. Challenges include developing devices that reliably deliver small ID doses to the correct depth,[266,269] obtaining clinical data to license vaccines for ID delivery by DSJIs, and the higher cost of DSJI devices compared with an ID needles and syringes.

Microarray Patches. Microarray patches (also referred to as microneedle patches) deliver solid formulations of vaccines into the skin and have a different set of potential benefits and development challenges from the liquid-delivery technologies for cutaneous vaccination that have been described. Microarray patches meet many of the criteria for a practically ideal vaccine delivery system because they are needle free in a prefilled unit-dose dry format, with potential for increased thermostability. They also can be shipped by common shipping methods such as mail and can potentially be self-administered or administered by minimally trained personnel. Microarray patches can be further subdivided into solid-coated and dissolving types.

Solid-Coated Microarray Patches. A common strategy pursued by a number of commercial and academic teams to carry antigens across the stratum corneum is to coat the vaccine onto solid microscopic projections, which are held for variable periods of time in the dermis or epidermal layer (depending on height) while the antigen (or other drug) elutes and diffuses.[290,293–295,297,301–305,342,343,426] Some microarray patch technologies have been designed for application by finger pressure, while other developers have found that a mechanical applicator is needed for consistency of skin penetration. To date, therapeutic drug applications have reached a more advanced stage of development than those for vaccines; nevertheless, a substantial amount of preclinical research has been conducted with vaccines, and several early-stage vaccine clinical trials are in progress.

One example of drug-coated microarray patches is the investigational Zosano Pharma ZP Patch platform (formerly known as Macroflux). Its titanium projections vary from 225 to 600 µm in height and are packed into an area of 1 to 2 cm^2 at densities from 140 to 650 tines/cm^2. They are inserted by a spring-mounted applicator and held in place by an adhesive patch. The most advanced applications for these microarray patches are delivery of parathyroid hormone to treat osteoporosis,[427] already studied clinically, and erythropoietin to treat anemia. Regarding vaccine applications,[428] Zosano Pharma's ZP-Flu influenza vaccine patch, applied for 5 or 10 minutes onto the skin, trended toward increased titers and seroprotection compared with an IM control injection.[430] Other preclinical studies of the system demonstrated delivery of ovalbumin,[428,431] oligonucleotides,[432] and the peptide hormone desmopressin.[433] The company reports animal work with tetanus, diphtheria, Lyme disease, and hepatitis B (DNA) vaccine antigens.

Another coated microarray patch platform is the solid microstructured transdermal system from 3M.[289,434] Its drug-coated pyramidal projections vary from 250 to 750 µm in height, in arrays of 300 to 1500 microarray patches mounted on an adhesive patch at a density of 1300 per square centimeter.[435–438] Application to the skin is by a manual finger-thumb Press&Patch device[439–441,480] or by a spring-powered applicator, shown elsewhere.[249] Coatings of the microarray patches are said to hold up to 0.5 mg of active pharmaceutical ingredient. In a rabbit model, coatings of tetanus toxoid and aluminum adjuvant in various ratios induced antibody using just a fraction of the standard IM dosage.[443] In swine, a model virus-like protein (HBsAg) demonstrated dosage sparing via solid microstructured transdermal system compared with antigen delivered by IM control route.[442] A more recent public registration described a safety trial without antigen.[444]

The Georgia Institute of Technology, a pioneering center for microarray technology, has worked with Emory University to conduct numerous studies of coated microarray patches[342,444a] in animal models for cutaneous vaccine delivery. In a series of murine studies using solid metal microarray patches coated with inactivated influenza viruses, cutaneous vaccination induced robust immune responses—often better than equivalent dosages in controls injected by the SC route—as well as protection against lethal viral challenge.[445–454]

When coated with BCG, the same microarray platform was highly immunogenic in guinea pigs, with robust cell-mediated responses in lungs and spleen, comparable to those with Mantoux injection.[455] Similarly, plasmid DNA antigen for hepatitis C, coated on needles 500 µm in length, primed specific cytotoxic T lymphocytes in vaccinated mice more readily than conventional needle.[456] Inactivated rotavirus vaccine—developed to avoid the inhibitory effect of maternal antibodies on live oral vaccines[457]—was coated onto this microarray platform and found immunogenic in an animal model.[458]

Another center for microarray research, the University of Queensland and the nearby company Vaxxas in Australia,[459,460] developed a novel nitrogen gas jet-drying method for coating antigen onto silicon that overcomes the challenges of dip-coating closely spaced projections,[444a,459,461] but still allows antigen to elute within 2 to 3 minutes upon skin entry. This Nanopatch technology has among the smallest projections (less than 300 µm in length) with more than 20,000 projections per square centimeter on silicon chips (see Fig. 68.6C). It has achieved $\frac{1}{30}$ to $\frac{1}{100}$ dosage-sparing compared with the IM route in a mouse model for influenza.[462,463] Other antigens studied with good results in murine models with this platform include HPV, chikungunya, DNA plasmid vaccines (herpes simplex virus 2, West Nile virus), and viral vector DNA vaccine (malaria).[463–470] Research on and development of coated microarray patches for vaccination are also underway by many other groups.[340,381,471]

Experimental placement of the solid microstructured transdermal system microarray patches device on human volunteers found it to be "well tolerated" and "nonintimidating and not painful." The Georgia Institute of Technology microarray patch (without coating) has been used in clinical studies to assess usability and completeness of skin penetration when applied by self-administration, and study participants indicated they would be more willing to be vaccinated with influenza vaccine if microarray patches were available.[12] In focus group discussions, both public and private healthcare providers were also positive toward microarray patches as a change from conventional needle and syringe delivery.[472] Microarray patches can also allow use of dry formulations, which improve vaccine thermostability and reduce the need for cold chain storage. For example, in formulations prepared at Georgia Institute of Technology, a key ingredient of the carboxycellulose matrix of the dried coating was trehalose, one of several sugars, including sucrose, that have been found useful in protecting protein antigens from damage by drying and freezing, thereby improving vaccine thermostability.[473,474] Microarray patches have the potential to enable dose sparing of some vaccines, and some patches may also provide an adjuvant-like effect themselves by increasing local cell death.[475]

Although they have the potential to be a transformative technology for vaccine delivery, microarray patches are in an early stage of development for use with vaccines, and challenges include generating clinical evidence and scaling up manufacturing processes. The required wear times for microarray patches are not yet fixed and differ among designs. In preclinical studies, wear times for some microarray patches for vaccines have been greater than 5 minutes but can also be around 2 minutes. Ideally, delivery times would be sufficiently rapid to allow for quick application, removal, and proper disposal by a healthcare worker. If longer wear times are required for successful delivery, early removal is a risk, leading to possible insufficient antigen delivery as well as disposal of vaccine antigen outside the location of the supervised immunization session. If the vaccine recipient remains in the clinic

or otherwise-supervised environment of delivery, increased vaccination time and thus reduced throughput might have a negative impact on overall program efficiencies. Coated microarray patches might be considered both sharps and infectious waste material after they have been used and in contact with bodily fluids, so the risk of needlestick injury remains a consideration. The need for an applicator (whether separate or integrated with the patch) to reliably apply the microarray patches is another key question, as are cost and logistical implications for immunization programs. A visual or auditory indicator may also be important to reassure users and recipients that the vaccine has been delivered correctly.[472,476]

Dissolving Microarray Patches. An elegant strategy to decrease risk from intentional reuse of, or inadvertent contact with, used microarray patches is for the sharps to dissolve in the skin with hydration, thus releasing the antigen.[249,305,477–481] The most common matrix for dissolvable microarray patches hard enough to penetrate skin is carboxymethylcellulose, "generally recognized as safe" for parenteral delivery by the FDA, among other compounds.[477,478] Georgia Institute of Technology and Emory University have encapsulated inactivated influenza vaccine virus into biocompatible polymer, which dissolves within minutes after its application to skin (see Fig. 68.6D). Robust antibody and cellular immune responses provided complete protection from lethal challenge in mice, and a clinical trial is in progress.[481a,482] Several sugars, such as trehalose, sucrose, and maltose, have been found to be key ingredients in stabilizing and maintaining the potency of antigen during the process of forming dissolvable microarray patches, and studies have shown up to 4 months of stability at 40°C for measles vaccine in a microarray patch.[473,483–485] Formal thermostability studies will be needed to assess whether such formulations would resist heat degradation and allow transport and storage outside the cold chain.

Corium International has developed the MicroCor dissolvable microarray patch, with an integrated applicator that adheres to the skin (see Fig. 68.6E). TheraJect has developed the DrugMAT and VaxMAT dissolvable microarray patches, which have been investigated preclinically for delivery of several pharmaceuticals, including influenza vaccine. TheraJect's patches are designed for manual application without an applicator, but an applicator is also in development if needed for reliable delivery. In Japan, CosMED markets a cosmetic MicroHyala microarray patch containing hyaluronate, which dissolves in 60 to 90 minutes, and a Phase I clinical trial using this technology to deliver influenza vaccine has been conducted.[486] Many others also pursue dissolvable microarray patches.[486a,487,488]

Advantages and challenges for dissolving microarray patches are similar to those for solid-coated patches (see "Solid-Coated Microarray Patches" earlier). An important distinction is that dissolving patches leave no sharps waste.

Powder Injection. The transfection of cells by kinetic methods to deposit DNA-coated gold particles into them was pioneered in the 1980s. The Helios or PDS 1000/He gene guns170 and the Accell injector[518] have become standard bench tools for biolistic delivery of nucleic acid plasmids into a wide variety of plants and animals to transfect them to express the coded genes.[304,489,490] Delivery of DNA into the skin overcomes the usual polarized T-helper cell type 1 response when DNA is delivered into muscle.[293,491,492] These devices are unavailable for human vaccination (patent rights are held by PowderMed). The proprietary terms "epidermal powder immunization" and "particle-mediated epidermal delivery" (PMED) refer to the use of helium gas to blow powdered proteins, polysaccharides, or inactivated pathogens (epidermal powder immunization) or DNA-coated particles (PMED) into the epidermis at supersonic speeds. This unique method of vaccination was developed in the early 1990s by Oxford BioSciences, which over the years was renamed PowderJect, acquired by Chiron,[493] spun off as PowderMed, and finally acquired by Pfizer[494] in 2006. Delivery is by either reusable (XR series) or single-use disposable (ND series) devices (see Fig. 68.6F), with the ND series targeted for commercialization.

Conventional protein antigens for delivery by epidermal powder immunization are spray-dried into powders of suitable density and size (20 to 70 μm),[495,496] but the economics of manufacturing such formulations may be an obstacle.[293] For DNA vaccines delivered by PMED, plasmids coding for desired antigens are coated onto gold beads (1 to 3 μm in diameter) and, when deposited into epidermal APCs, they are eluted and transcribed.[497] A number of preclinical studies in various animal models have been conducted.[495,498–500]

Human trials of DNA vaccines containing up to one order of magnitude less antigen than the amount used for IM routes have induced humoral and cellular immune responses for hepatitis B in subjects both naïve and previously vaccinated with conventional vaccine.[501,502] PMED vaccination has also been studied for DNA priming in trials of malaria vaccine,[503,504] has produced seroprotective immune responses by DNA vaccine for seasonal strains of influenza,[505] and has reduced influenza symptoms and viral shedding after human challenge.[506]

In the hepatitis B and influenza trials cited earlier, there were no severe local reactions, but erythema, swelling, and flaking or crust formation occurred in nearly all subjects, albeit resolving by day 28. Skin discoloration, however, persisted through day 56 in 29 (97%) of 30 subjects,[510] through day 180 in 21 (25%) of 84 injection sites,[511] and beyond 12 months in 5 (25%) of 20 patients with long-term follow-up.[510] No anti–double-stranded DNA antibodies were detected. The deposition of the gold particles was studied in pigs, in which most were deposited in the stratum corneum and epidermis and were eventually sloughed by exfoliation by 28 days.[512] At days 56 and 141 after administration, a few particles remained in the basal epidermal layer and in macrophages in the dermis and regional lymph nodes.

Preclinical studies of epidermal powder immunization or PMED in murine, porcine, and primate models have shown immunogenicity or protection for either powdered or DNA plasmid antigens for various other pathogens, including Eurasian encephalitic viruses,[514] hantaviruses,[515] HIV,[516,517] influenza H5N1,[499] malaria,[518] severe acute respiratory syndrome (SARS) coronavirus,[519] smallpox,[393] and Venezuelan equine encephalitis.[520]

Abrasion/Transcutaneous Delivery. Various commercial patch delivery systems developed since 1981 have demonstrated the ability of certain therapeutic agents (e.g., scopolamine, nitroglycerin, clonidine, estradiol, fentanyl, nicotine, testosterone) to diffuse passively into bare, untreated skin without the use of active technologies or enhancers. However, such passive diffusion usually works only for small molecules with certain physical characteristics. Thus, there are but a few animal models of immunization onto bare, untreated skin.[521–523]

Newer methods to facilitate antigen delivery to the epidermis involve painlessly stripping or abrading the skin to increase the permeability barrier of the stratum corneum. A variety of simple tools have been used to remove the stratum corneum. Common cellophane adhesive tape may be applied to the skin and pulled away, carrying away dead keratinocytes with each repetition. Such tape-stripping has been shown to enhance cytotoxic T-cell and cytokine immune responses on subsequent application of various antigens and adjuvants

to the skin in mice.[524–530] Similarly, rubbing gauze, emery paper, or pumice on the skin removes cells by their abrasive effects, and this has been found to enhance immune responses in humans. Application of cyanoacrylate glue followed by stripping the skin to apply antigen to the exposed hair follicles has been described,[531] but its practicality has been questioned.[299]

Among methods that strip the skin, perhaps the most advanced is one that combines this step with the use of a remarkably potent adjuvant, the heat-labile enterotoxin (LT) of *Escherichia coli*. This effort was originally championed by Gregory M. Glenn, first at the Walter Reed Army Institute of Research, then at Iomai Corporation, and later at Intercell. The vaccinator or the patient holds against the skin a device, the Skin Preparation System (see Fig. 68.6G). With the push of a button and the pull of a tab, a controlled pressure is applied to a sandpaper strip, which gently abrades and removes approximately 25% of the stratum corneum.[532] Then, a patch containing LT as antigen alone, or LT as an adjuvant for another antigen, is applied to the skin; the process is called transcutaneous immunization.[534–537] LT alone is intended to induce immunity against enterotoxigenic *E. coli* (ETEC), the cause of traveler's diarrhea, or against *Vibrio cholerae*, with[538] or without[539,540] ETEC colonization factor.

An initial randomized, blinded field trial among travelers to Guatemala and Mexico found 75% efficacy for the patch with LT alone in protecting from moderate to severe diarrhea.[541] In 2010, Intercell reported mixed results from two follow-up field studies. In a pivotal Phase III trial for traveler's diarrhea (N = 2036), again in Guatemala and Mexico, the trial's primary target end point of greater than 60% efficacy against moderate to severe ETEC diarrhea was not met, finding only approximately 35% protection. Nor was there an effect on the frequency of all causes of diarrhea. However, there was a 60% reduction in the incidence of LT-positive diarrhea of all degrees of severity, along with a significant reduction in duration and severity of all diarrhea causes. The patch also induced measurable immune responses and was well tolerated.[542]

In a smaller Phase II trial in India (N = 723), the LT patch also did not reach its targeted end point, perhaps because of a low attack rate (approximately 1%) for LT-positive ETEC.[543] As a result of these two trials, Intercell discontinued work on the LT patch for traveler's diarrhea but still pursues its use with the Skin Preparation System device for other applications.

Applying the Intercell LT patch near the site of injection of parenteral influenza vaccine (an application referred to as a vaccine enhancement patch) was found to improve hemagglutination inhibition titers in the serum and mucosa of both young and aged mice[544,545] and increase the hemagglutination inhibition titer or show an improving trend for adult human volunteers older than 60 years of age.[546] In preclinical studies of other applications, use of LT or a structurally similar cholera toxin as cutaneous adjuvants resulted in improved immune responses or challenge protection in animal models for tetanus,[547] anthrax,[548,549] malaria, *Helicobacter pylori*, and Shiga toxin–producing strains of enterohemorrhagic *E. coli*.[550,551]

Other methods take advantage of low-cost fabrication techniques adapted from the microelectronics industry to convert silicon, metal, or other material into arrays of micrometer- to millimeter-sized microrasps designed to abrade the stratum corneum.[294,297,301–303,325,552] One example is the microenhancer array (also known as Onvax), an investigational technology that scrapes the skin before or after topical application of the antigen or therapeutic agent.[553] The microenhancer array consists of a square or round chip containing about a 1-cm^2 area of silicon or plastic microprojections mounted on a finger-held applicator.[249,342,353] Preclinical studies of the microenhancer array device have been conducted using hepatitis B, anthrax, and Japanese encephalitis vaccines.[288,354] A human trial, however, in which rabies vaccine was applied before or after four "rubs" of the device over four separate deltoid skin sites did not detect any immune response after three dosings.[325]

Technologies for abrading the skin to enhance transdermal delivery have the potential to be low cost, acceptable to users, compatible with vaccines, and suitable for use in a variety of vaccination settings, although device design must ensure ease of correct use. Reproducibility of dosing and effectiveness of vaccination has been a challenge for this technology, particularly the disappointing results of the Intercell ETEC vaccine. As a result, the field of cutaneous vaccination has focused mainly on technologies that inject or deliver the vaccine into the skin, rather than relying on passive diffusion.

Microporation. Microporation, also termed thermoporation, uses heat to vaporize tiny openings in the stratum corneum.[294,295,377,554,555] In the PassPort system, developed by Altea and now owned by Nitto Denko,[289,556] this heat is generated by a disposable array of metallic filaments held momentarily against the skin by a device the size of a computer mouse (see Fig. 68.6H). At activation, electric pulses are induced to heat the filaments. An adhesive patch containing vaccine or therapeutic agent is then applied over the micropores just created. In a hairless mouse model, this technique elicited 10- to 100-fold greater cellular and humoral responses to an adenovirus vaccine than intact skin, as well as 100% protection to surrogate tumor challenge (27% for intact skin).[377] In the same model, adenovirus-vectored melanoma antigen applied to the micropores roughly doubled the average onset time of tumors after challenge, and it protected one of six mice compared with none of eight vaccinated controls with intact skin. Microporated recombinant influenza H5 hemagglutinin protected BALB/c mice from challenge with a lethal H5N1 strain.[557] Skin micropores also permitted the passage of insulin in pharmacokinetic human trials with historical controls, and in the other direction allowed interstitial fluid to be extracted for potential glucose monitoring.[558]

Another device similarly generates micropores with heat induced by radiofrequency waves (ViaDerm). A different technique uses short, 100-microsecond pulses of superheated steam in microliter amounts to remove the stratum corneum.[559] Pantec Biosolutions has developed a laser microporation platform that could also be used for cutaneous vaccine delivery.

Microporation systems provide a reliable means of forming pores in the stratum corneum to enhance transdermal delivery, although the dose and reproducibility of vaccine delivered across the skin following this procedure remain to be verified. Devices can be designed for rapid use and acceptable levels of local reactivity, but for any microporation system, the cost and distribution of the reusable device could be a challenge in low-resource settings, particularly due to electrical power requirements.

Mucosal Vaccination

Most human pathogens initiate infection through mucosal portals of entry—the respiratory, gastrointestinal, and genitourinary tracts. Mucosal immunity can prevent these infections. In contrast, systemic immunity clears infection only after successful invasion, by limiting replication and destroying the pathogens. Ideally, both mucosal and systemic immunity should be raised against targeted pathogens. Strong mucosal immunity may enhance the benefits of immunization for some diseases. For example, by preventing the initial infection, mucosal immunity can reduce the risk of transmission to

others in addition to preventing clinical disease. Prevention of infection at the mucosal surface may be especially important for diseases for which effective systemic immunity has been difficult to achieve, such as tuberculosis and AIDS.

Anatomy

As described above, the external surfaces of the human body are protected by the keratinized stratified squamous epithelium, which composes the outermost layer of the skin. In contrast, the internal surfaces of the mucosal tracts are protected by a variety of epithelial types commensurate with the different functions of the gastrointestinal, respiratory, and genitourinary tracts. Nonkeratinized stratified squamous epithelium predominates in the oral cavity, oropharynx, vagina, and anal canal. Ciliated and nonciliated pseudostratified epithelia line the nasal airway, nasopharynx, and bronchi. Various specialized simple (single layer) epithelia are found at other mucosal sites. For example, the enterocytes of the gastrointestinal tract have microvilli at their apical surfaces to facilitate nutrient absorption, and the pulmonary squamous alveolar cells are extremely thin to permit diffusion of oxygen and other gases between the alveoli and the vascular systems.

Lacking the skin's protective layer of keratin, mucosal epithelial surfaces are protected from pathogen invasion by several alternative mechanisms. First, a complex dynamic mucus coat restricts access to most mucosal epithelial surfaces. Next, proteolytic enzymes are abundant on many mucosal surfaces and the highly acidic gastric environment degrades most pathogens before entry into the small intestine. Mucosal systems also dynamically move potential threats to limit the duration of exposure. For example, the ciliated epithelia of the upper and lower respiratory tract continually drive the mucus layer and its contents to the oropharynx to be swallowed and degraded by gastric acid. Peristalsis and other gastrointestinal mechanisms result in the eventual expulsion of gastrointestinal contents. Finally, the importance of mucosal microbiota to the prevention of infection and promotion of healthy immune responses is becoming increasingly realized.[560–562]

In addition to the physical defenses described above, mucosal immunity provides additional defensive layers to prevent infection. Innate mucosal immune factors include endogenous antimicrobial peptides such as defensins and cathelicidins. Proteins such as lysozyme and lactoferrin also reside in many mucosal surfaces and inhibit pathogen incursions. Each of these pathogen invasion defenses is a barrier that mucosal vaccine delivery systems must overcome to deliver the antigen package to host cells and elicit a consistent protective immune response.

Anatomical features of the upper respiratory tract affect IN delivery of medications. Particles are first filtered by the hairs in the nostrils, whose surface is covered with keratinized stratified squamous epithelia. Next, the particles must traverse the external nasal valves, slit-like passages that limit airflow from the nostrils into the internal nasal airways. Djupesland and colleagues estimated that only 25% of large, high-speed droplets (average: 43 μm) of a traditional nasal spray reach beyond the external nasal valve.[563] Almost all large, high-speed particles that transit the nasal valve deposit in the internal nasal airway, which has an average of approximately 150 cm^2 (0.015 m^2) of surface area covered with columnar epithelia, most of which is ciliated. In the internal nasal airway, particles deposit on the nasal mucosa and then join the flow of mucus that is swept by ciliated epithelia toward the pharynx, where it is swallowed. Immune surveillance of antigens in the flow of mucus begins as they are taken up into epithelial cells, intraepithelial dendritic cells, surface macrophages, and M cells (see Fig. 68.3D).

For delivery into the lower respiratory tract, small particles inhaled via nose or mouth share a common pathway through the pharynx, larynx, and trachea. The bifurcation of the trachea into the right and left bronchi starts a series of bifurcations, providing further surfaces to trap airborne particles. Only very small, slow-moving particles succeed in navigating the tortuous passages to deposit in the lower airways. The smallest particles (≤3 μm) may reach the alveoli, where they can be rapidly absorbed into systemic circulation. The complex branching of the lung passages also results in an astonishing alveolar surface area, exceeding 100 m^2 in a human adult male. The lower airways in humans do not typically have organized lymphoid tissues, but they do have abundant intraepithelial dendritic cells and alveolar macrophages that process antigens (see Fig. 68.3E).[564]

Immunological Rationale

While IM, SC, and ID vaccine delivery can induce both mucosal and systemic immunity, administration of vaccines to mucosal tissues tends to induce the strongest mucosal response. Several cell types are active in the mucosal antigen surveillance system. Although epithelial cells may play a role in the immune response, critical targets include the professional APCs, such as dendritic cells and macrophages, which are present in all mucosal tissues (see Figs. 68.3E and F), and in the case of alveolar macrophages, on the mucosal surface (see Fig. 68.3E). Phagocytosis of foreign microparticles is an important component of innate mucosal immunity and of mucosal antigen surveillance. Because mucosal surfaces are exposed to a myriad of nonpathogenic macromolecules, there are mechanisms for downregulating the immune response to antigenic exposure. Thus the potential for inducing immunologic tolerance must be considered when developing mucosal immunization strategies.

Dendritic cells are active throughout mucosal tissues and are present in high concentrations in the mucosal-associated lymphoid tissue, which include the tonsils, adenoids, and Peyer patches (see Fig. 68.3F). Mucosal-associated lymphoid tissue are also rich in microfold (M) cells, specialized epithelial cells with apical surfaces that take up macromolecules, viruses, and bacteria by endocytosis. On their basal surfaces, M cells have invaginated pockets that communicate with the extracellular space and host collections of lymphocytes and dendritic cells (see Fig. 68.3D). M cells transfer the endocytosed materials to these APCs for processing.[565–568]

APCs from the mucosa track to regional lymph nodes, where B-cell activation occurs. These B cells preferentially switch to IgA plasmablasts that "home" back to the exposed mucosal tissue to provide antigen-specific IgA protection. T cells also home back to mucosal sites and play a major role in mucosal immunologic memory responses. Lymphocytes exposed to antigen from one mucosal site, such as the respiratory tract, will migrate to provide protection at remote mucosal sites, such as the vagina. This integrated network of immune cells and tissues is known as the common mucosal immune system.[119,569] In some studies, IN vaccination has resulted in higher vaginal IgA titers than has vaginal vaccination.[570]

Almost every mucosal surface available for administering vaccines has been studied with a variety of antigens in animal models, including oral, respiratory, rectal, vaginal, and ocular tissues. In general, the respiratory and gastrointestinal tracts have more organized lymphoid tissue sites and more capacity for induction of immune responses.[571]

Several human vaccines are licensed and have been used successfully for delivery to the enteric tract by oral ingestion. Preclinical studies have investigated the potential utility of administering oral vaccines that target the oral mucosa rather

than the enteric tract. IN LAIVs are the only respiratory-delivered vaccines in use. However, multiple clinical trials have assessed vaccine delivery to the respiratory tract.

Challenges for Mucosal Delivery of Vaccines

Many of the technologies in development for mucosal vaccination target the oral or respiratory route and these will be the major focus of this section. Although vaginal and rectal vaccines may be effective, they could have limited acceptability for social, cultural, and practical reasons.

The first challenge in mucosal immunization is determining the appropriate target tissue. The optimal target tissues are not fully understood and may vary for different vaccines. Oral and respiratory vaccination strategies each have two discrete target areas. Vaccination via the oral route may target the oral mucosa or the intestines. Respiratory vaccination may target the upper respiratory tract (nasal passages, pharynx and larynx) or the lower tract (trachea, bronchi, bronchioles and lungs). For both nasal and oral mucosal delivery, the pharyngeal tonsils are likely target tissues. Some respiratory vaccines may require deposition in the lower airways for uptake by alveolar macrophages and dendritic cells. Lower airway deposition can be achieved by oral or nasal inhalation. Scientific methods for evaluating and comparing different target tissues are not yet well developed.

A second challenge is selecting animal models and extrapolating results to human mucosal vaccine delivery. Interspecies differences in immunologic tissue limit interpretation of animal target-tissue research results for humans. Moreover, the size and anatomy of common research animals differ greatly from those in humans. For example, in small animals such as rodents, nose drops may deposit to the entire respiratory tract, which would not be the case in humans. Balmelli and colleagues estimated that 30% of 20 µL of vaccine given to mice as IN drops deposited into the lungs.[572] Many viruses and bacteria that infect humans do not grow well in animal models. For example, species-specific differences in the distribution of sialic acid receptors on cell surfaces is a crucial factor in tissue and host specificity of influenza A viruses, which limits the number of animal models suitable for influenza research. Such species-specific differences can make it difficult to use animals to study live attenuated vaccines or vaccine vectors, and difficult to challenge animals to assess protection. This impedes the development of safe and effective mucosal vaccines for humans.

A third hurdle for mucosal immunization is assuring delivery of an accurate dose to the target tissue. The mass or volume of the antigen delivered depends on many factors. For intestinal delivery, gastric acids may destroy much of the antigen dose. For respiratory delivery, variability in performance by delivery device, the technique of the vaccinator, and differences in the anatomy and physiology of persons being vaccinated affect the dose delivered.[573] Fortunately, for many vaccines there is a wide margin between the dosage necessary to induce protection and the dosage at which the risk of adverse events increases.

A fourth challenge is the lack of accepted correlates of protection for mucosal immunity. For many diseases, laboratory assays have well-established criteria for systemic immunity—such as antibody titers above certain cutoffs—that have served for many years to predict protection from disease. In the absence of accepted serologic or cellular correlates of protection induced by mucosal vaccines, clinical trials must use specific disease-prevention end points, which can make the studies required for licensure much larger and more expensive.

Several immunization safety concerns represent further challenges for mucosal vaccines. Live virus or bacterial vaccines might pose an increased risk to immunocompromised persons if administered mucosally. Live-attenuated vaccines that revert to more virulent genotypes can adversely affect the vaccinee and be spread to contacts in the community. For nasal vaccines, another risk is that vaccine antigen (live or inactivated), adjuvant, or excipients might affect nearby cranial nerves[574] or travel along the olfactory nerve through the cribriform plate into the brain, with resulting adverse nervous system effects. Vaccines targeting the lower airways may induce or exacerbate bronchospasm or pulmonary inflammation, which can be life threatening. Another risk is cross-contamination: respiratory pathogens from one patient may contaminate the respiratory immunization device and be spread to subsequent patients.[575] Also, vaccine aerosols may spread beyond the intended recipient and affect other persons in the vicinity.

With so many challenges, new delivery technologies to achieve mucosal immunization are required if this route is to become practical and acceptable. In this young field, published research on delivery systems in animals or humans is limited. In most reported animal studies, the delivery system is not mentioned at all. For most systems designed for human respiratory systems, testing is very difficult or impossible in an animal model.

Finally, perhaps the most significant challenges to implementation of novel vaccine delivery systems in routine immunization practice are the regulatory requirements needed to ensure that the systems are safe and effective. The required studies and clinical trials can be extremely expensive. Vaccine manufacturers typically are reluctant to assume such cost and risk to relicense an existing product already delivering profits unless the potential benefits and market advantages will be significant. The best opportunity to bring alternative delivery into routine practice may be to use new delivery systems—from the start—for new vaccines early in development and licensure processes.

Oral Vaccination

Oral Ingestion (Intestinal Delivery). Several human vaccines are licensed and have been used successfully for delivery by ingestion, including those for polio, cholera, rotavirus, typhoid, and adenovirus (see Chapters 10, 14, 48, 49, 52, and 61). OPV, a prototypical mucosal vaccine, demonstrates the key advantages and challenges of mucosal vaccination. The ease of delivery of OPV drops enables minimally trained volunteers to distribute it in house-to-house campaigns that have been essential for the current successes of the global polio eradication effort. OPV is a live attenuated vaccine, as are most successful mucosal vaccines to date. Vaccination results in increased mucosal immunity, particularly in the intestine, as evidenced by increased secretory IgA and decreased shedding of vaccine poliovirus on subsequent challenge compared with IPV given by injection (see Chapter 48). However, even minor shedding of vaccine virus can result in transmission of the vaccine virus to others. This is especially concerning because the vaccine virus has the potential for reversion to virulence, which can result in vaccine-associated paralytic poliomyelitis in vaccinees and their contacts, and even in sustained outbreaks of circulating vaccine-derived polioviruses. Another concern regarding mucosal vaccine delivery demonstrated by OPV is the inconsistency of the immune response across different populations. OPV produces immunogenic responses less consistently in children in developing countries than in children in industrialized countries. This may be caused by differences in intestinal microbiota (see Chapter 48).

Because intestinal delivery by oral ingestion is simple, especially for liquids such as OPV drops, there is little

technology development required for macrodelivery of oral vaccines. Most of the new technologies for intestinal vaccination focus on microdelivery systems, which are reviewed in a separate section. One of the biggest hurdles to consistent delivery of vaccine antigen to APCs in the intestinal tract is ensuring that the antigen survives degradation from gastric acids. Like wild poliovirus, OPV is stable in acid environments for several hours. Other enteric vaccines, such as cholera and rotavirus vaccine, are delivered with a buffer solution to neutralize gastric acid. Typhoid fever vaccine is delivered as a lyophilized powder protected in an enteric coated capsule. However, capsules are not appropriate for infant vaccination.

Oral Mucosal Vaccination (Sublingual or Buccal Delivery). Preclinical studies have been conducted to explore the potential of administering vaccines via the sublingual (SL) or buccal mucosa. These routes have long been used for low-molecular-weight drugs such as nitroglycerin SL tablets. Several SL immunotherapy vaccines are marketed in Europe to suppress allergic hypersensitivity.[576] The major advantages of oral mucosal immunization are the ease of administration, including the potential for self-administration, and the probability of inducing robust mucosal immunity. In contrast to intestinal delivery, orally absorbed antigens are not subjected to degradation by gastric acid.

The oral cavity is lined with stratified epithelium. Like the skin, the oral epithelium is replete with Langerhans cells, the principal target APCs for oral vaccination. Some oral surfaces, such as the hard palate, have a keratinized upper layer, while the epithelia of the buccal and SL mucosa are nonkeratinized.[576] The lack of keratin increases permeability and potential for transportation of antigen to the mucosal APCs without the disruption or penetration of the stratum corneum required for cutaneous vaccination. As an example, Fig. 68.3G demonstrates wild-type measles virus replication in the oral mucosa. However, salivary and mucus flow rapidly moves substances on oral surfaces toward the pharynx to be swallowed and digested, and many salivary components initiate the processes of digestion and degradation. The oral cavity does not have organized lymphoid tissue such as the intestinal Peyer patches; however, movement of antigen across the pharyngeal tonsils may play a role in induction of an immune response.[577] Unlike nasal delivery, oral delivery does not have the potential of exposing the cribriform plate to vaccine. Shim and colleagues reported that SL vaccination with a recombinant replication-deficient adenovirus expressing SARS-associated coronavirus antigen induced protective immunity against SARS-associated coronavirus comparable to that seen with IN vaccination. Adenoviral DNA was detected in the olfactory bulbs of the mice vaccinated intranasally, but not in those mice vaccinated sublingually.[578]

In addition to immunotherapy vaccines, two novel SL vaccines are commercially available in Spain for the prevention of recurrent infections. One of these, Uromune, is a mixture of inactivated whole bacteria of selected strains that are common causes of urinary tract infections (UTIs). The vaccine is self-administered as a daily SL spray, maintained under the tongue for a period of 1 to 2 minutes, and then swallowed. In a clinical study of 319 patients with recurrent UTIs, subjects who received the vaccination daily for 3 months had significantly reduced occurrence of UTIs compared with subjects who received the standard therapy of sulfamethoxazole/trimethoprim for a period of 6 months. The reduced incidence of UTIs persisted for 12 months after completion of vaccination.[579]

Immunotherapy for allergy patients and use of polyvalent inactivated bacterial preparations to suppress recurrent infections are the major focus of published clinical trials for oral mucosal vaccination.[580–583] There are few clinical data on traditional prophylactic vaccines delivered via the SL or buccal route, although studies are registered on ClinicalTrials.gov for influenza, cholera, and HPV.[584,585] Preclinical studies of SL vaccines have demonstrated immunogenicity in mice using viral vectors such as adenovirus-based vaccines[586–588] and bacterial vectors such as *Bacillus subtilis*.[589,590] For example, SL immunization of mice with recombinant adenovirus-based vaccine expressing influenza virus hemagglutinin induced significant levels of sustained hemagglutinin-specific mucosal IgA and IgG, and provided complete protection from challenge with a lethal dose of homologous virus.[590a]

Despite the potential benefits of oral mucosal immunization, significant challenges have delayed progress toward commercially available prophylactic vaccines. First, antigens presented to the oral mucosa may result in immune tolerance, as evidenced by the success of the SL immunotherapy products designed to induce tolerance. Producing the desired protective immune response may require manipulation of the antigen formulation and dose, as well as addition of adjuvants. Another problem is that the rapid flow of saliva limits the residence time of antigen in the mouth and the opportunity for contact with APCs. Several formats have been designed or adapted from oral drug delivery systems to increase oral residence time.[576] For preclinical testing of vaccines, oral delivery is complicated by the extremely small oral cavities in small animal models: delivery of liquid vaccines to the mouth in mice is limited to 5 to 15 μL and alternate delivery formats are extremely difficult to use. Also, unlike humans, most rodents have keratinized epithelia in the buccal mucosa, which limits comparability of antigen uptake.[576]

To overcome the inherent mucosal tolerance for antigens, a variety of mucosal adjuvants have been studied.[576,591–594] For example, mice sublingually immunized with influenza vaccine (hemagglutinin split vaccine) with a lipopolysaccharide adjuvant demonstrated both hemagglutinin-specific IgG (systemic) and IgA (mucosal) antibody responses, which led to a significant increase in survival rate against lethal influenza virus challenge compared with SC vaccination.[591] Two mucosal adjuvants—α-galactosylceramide, a potent stimulator of natural killer T cells, and cytosine phosphate guanine–oligodeoxynucleotide a Toll-like receptor-9 agonist—effectively increased gp140-specific serum IgG and vaginal IgA levels following SL vaccination in mice. Combining both significantly improved these responses, and serum and vaginal washes collected 60 days after immunization had significant neutralization activity against simian/human immunodeficiency virus.[595]

To enhance residence time on the oral mucosa, a thermoresponsive gel—which changes from aqueous solution to viscous gel upon contact with the mucosa at body temperature—was combined with a double mutant of a bacterial heat-labile toxin. SL immunization of mice with a trivalent IPV with the gel delivery system produced both mucosal and serum antibodies, including IgA.[596]

Interest in SL vaccination has accelerated significantly: a 2015 PubMed search of "sublingual vaccine" returned more than 175 published articles since 2010 compared with 115 prior to 2010.

Progress of candidate oral mucosal vaccines through clinical trials to commercialization will require significant additional research to increase our understanding of the pharmacokinetics and pharmacodynamics, as well as immunological mechanisms, of this route of delivery. Because of the inherent mucosal tolerance of antigens and limited oral residence time,[576] development of optimized delivery formulations and predictive assays for mucosal immunity are particularly challenging.

Respiratory Vaccination

Background. The earliest known route of vaccination was IN insufflation of powdered scab material from smallpox patients, reportedly practiced in China as early as the 10th century AD. However, IN LAIVs are the only respiratory vaccines in modern use (see Chapter 54). In contrast, the respiratory route is used to deliver a wide and expanding variety of pharmaceutical products.[597,598] Respiratory drug administration typically targets one of two major areas: the upper airway or the lower airway. Most common products, such as nasal decongestants and inhaled asthma medications, are intended for local therapy in the target area. Newer products, such as inhaled insulin, target deposition in alveoli to achieve systemic delivery. The first inhalable insulin (Exubera) was a commercial failure, partly because of a cumbersome delivery device.[599,600] However, another product for insulin inhalation, Afrezza, was approved by the FDA in 2014.[600a] Afrezza uses a small, simple dry powder inhaler, the Mannkind Dreamboat.[600b] Efficient and effective delivery to respiratory target tissues is determined largely by the aerodynamic size and speed of the vaccine particles, which are functions of the device engineering and the product formulation.

Devices for upper respiratory tract drug delivery include droppers, nasal sprayers, nasal nebulizers, and dry powder inhalers. Very few are designed for or have been tested with vaccines. Most drug devices deliver repetitive doses to a single patient. In contrast, vaccination delivers single doses to multiple patients, which raises the issue of device cross-contamination. Although unit-dose disposable devices or disposable components could solve this problem, they must be inexpensive to be cost-effective. Many drug-delivery devices are designed for self-administration; however, this requires a level of patient cooperation difficult to achieve in young children and impossible in infants.

With mucosal vaccination in general, the optimal target tissues are not yet understood for most potential respiratory vaccines, and they vary for different antigens. Liquid droppers for IN delivery are perhaps the simplest devices, and inexpensive prefilled single-use droppers are commonly used for administering drugs to the upper respiratory tract. However, drops administered intranasally tend to drip out of the nose or roll back to the pharynx where they are swallowed, resulting in less residence time in the nasal passages and nasopharynx and less contact with mucosal surfaces. Recumbent patient positioning may increase nasal residence time but may not be practical at all POCs. Prefilled and fill-on-site nasal spray devices generate smaller particles, typically in the 50- to 100-μm range, and nasal nebulizers generate even smaller (20 to 30 μm) particles. While these devices may increase mucosal surface contact and residence time, there are no definitive studies to their effect on immunogenicity.

Deposition of liquid vaccines in the lower airways requires a nebulizer device that generates the very small droplets required to pass the vocal cords and reach the trachea and bronchi (<10 μm) or the alveoli (<5 μm). Nebulizers are durable devices that require an energy source to generate aerosols. The device transits aerosol to the patient through a mask, oral prong, or nasal prongs. Single-use disposable components, including patient interfaces, are needed to prevent cross-contamination.

Dry powder aerosols can also be used to deposit vaccine in the upper or lower respiratory tract. Liquid delivery has the advantage of being the standard format: all currently licensed aerosol vaccines are in liquid presentation. Generating sprays and aerosols from existing liquid vaccine formulations could accelerate respiratory vaccination research. In contrast, a number of obstacles must be overcome to produce vaccines as dry particles of sizes suitable for upper or lower respiratory tract deposition.[601–603] First, formulating powders requires significant and extensive changes in manufacturing methods. Second, many potential dry-formulation ingredients are extremely hygroscopic and become sticky when exposed to humidity. Third, once the powders are deposited in the respiratory tract, they must be sufficiently hygroscopic to dissolve and release the vaccine for uptake. However, if these challenges can be met, dry aerosols have several advantages over liquid aerosols. Doses can be filled into inexpensive single-use presentations and delivered without on-site aqueous reconstitution. Secondary packaging that seals the dose container in an impermeable overwrap, such as metal foil, could maintain low humidity to prolong potency and increase shelf life. Minimal energy is required for powder dispersion compared with liquid droplet generation, so electromechanical devices are not necessary.

Upper Airway Vaccine Deposition

Nasal Sprays. The only vaccine currently licensed and in use in the United States for respiratory delivery is the cold-adapted LAIV FluMist, delivered with the AccuSpray IN syringe. LAIV development, testing, and licensure are reviewed in detail in Chapter 32. LAIV demonstrates several potential benefits of respiratory delivery. It produces both mucosal and systemic immunity, and it generally has been found to provide higher protective efficacy than injected inactivated vaccine in young children.[604–612] It also provides heterotypic immunity against nonvaccine strains.[604] IN delivery of LAIV may reduce the risk of influenza transmission because it reduces respiratory shedding among immunized children challenged later with a vaccine virus.[604] Finally, modest coverage with LAIV among schoolchildren reduced influenza-related illness rates in unvaccinated adults in a community.[612] However, despite the previous positive results for LAIV, vaccine effectiveness data for the 2015–16 influenza season found that FluMist did not provide protective benefit for children, and the Centers for Disease Control and Prevention (CDC)'s Advisory Committee on Immunization Practices has recommended that FluMist not be used in the United States.[613]

The AccuSpray device is a sterile, single-patient–use, disposable, prefilled glass syringe fixed with a nonremovable plastic nozzle (Figs. 68.7A and B). Its total dose is 0.2 mL of which 0.1 mL is sprayed consecutively into each nostril. An attachment on the plunger stops the first dose to allow the user to switch nostrils. FluMist vaccination delivered by AccuSpray is highly effective in most populations (see Chapter 54). Key advantages of AccuSpray delivery are that it is simple to use, low cost, capable of disposed without needing to use a sharps container, and has a low possibility of refill and reuse. The large particle sizes generated by the sprayer minimize deposition to the lower airways, reducing the risk of adverse pulmonary events. A limitation of the system is that the particle size emitted depends on the speed at which the vaccinator depresses the plunger. The median diameters of the particles can range from 200 μm or greater at plunger speeds of up to 33 mm per second to 50 μm or less at speeds of 80 mm per second and greater.[614] Although this wide variability might in theory affect the efficiency of vaccine deposition, LAIV by AccuSpray typically produces a high rate of protective immunity at the current dosage.

An IN LAIV developed in Russia has been in use in that country for more than 50 years (see Chapter 54). The vaccine is lyophilized and must be reconstituted and filled into the syringe at the POC. Each dose comes with a Lindal Group atomizer tip that fits the syringe, after removal of the reconstitution needle, for delivery into the nostril. No dose divider is provided and the 0.25-mL dose for each nostril must be drawn

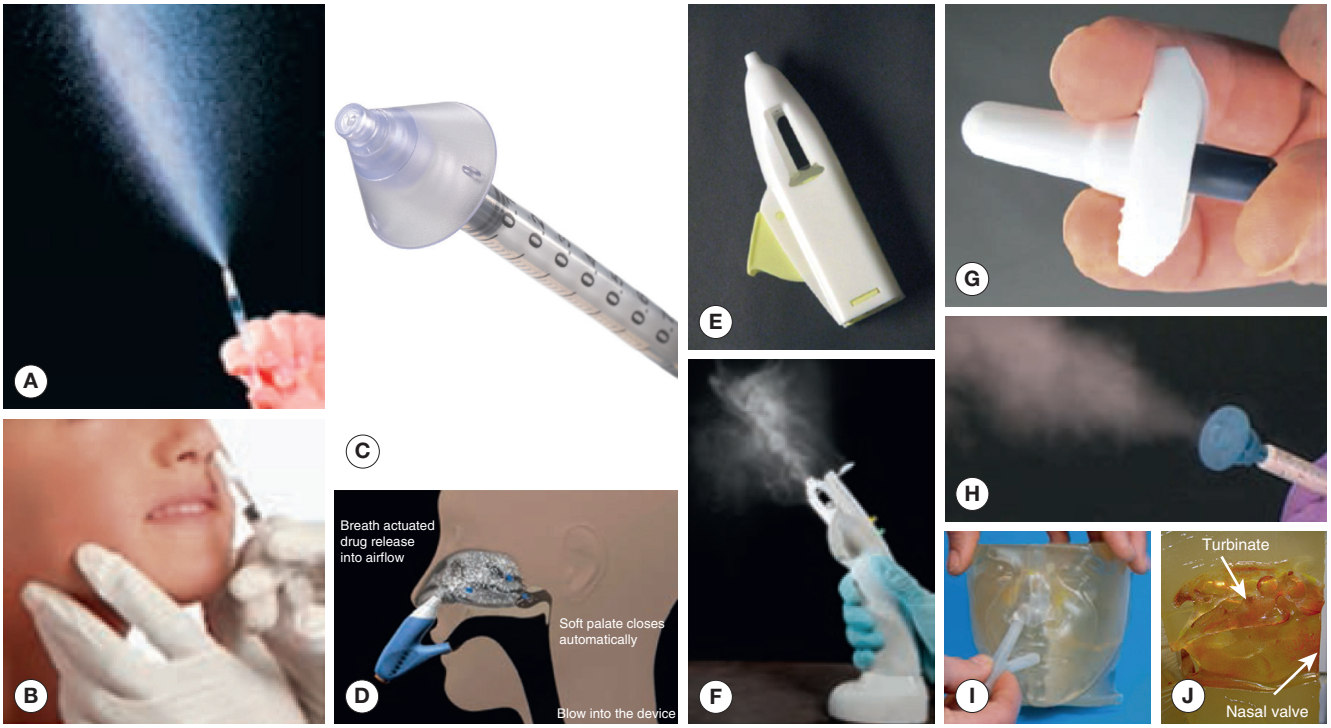

Figure 68.7. Selected devices for upper respiratory tract vaccine delivery. A and **B,** AccuSpray nasal spray syringe (Becton, Dickinson and Co.) **A,** AccuSpray produces an aerosol plume of particles reported from 50 to 200 μm in diameter, depending on plunger speed. **B,** AccuSpray used for intranasal delivery of FluMist influenza vaccine (MedImmune, Inc.). Prefilled liquid vaccine is stored refrigerated for single patient use. The total volume is 0.2 mL. A dose separator interrupts delivery at 0.1 mL and, when removed, allows the remaining 0.1 mL to be administered into the opposite nostril. **C,** Teleflex VaxINinator nasal spray device currently used to deliver Serum Institute of India Ltd's Nasovac-S influenza vaccine. The conical spray tip is attached to the syringe by a Luer fitting. **D,** Sagittal computer-assisted image illustrating intranasal delivery by the OptiNose delivery device (OptiNose, Inc.). **E,** Dolphin side-activated nasal spray disposable unit-spray device designed to deliver 200 μL of product in two 100 μL sprays. **F,** Investigational AeroVax prototype (Creare, Inc.) uses battery-powered piezoelectric energy to drive an aerosol from a disposable drug cartridge via a microperforated mesh plate through a disposable patient interface, such as nasal prong in patient nostril, oral prong, or mask (not shown). Droplet diameters can be tailored from <5 μm to 10 to 25 μm for upper or lower airway delivery, respectively. **G,** BesPak, UniDose DP a dry powder prefilled unit-dose device which can deliver up to 10 μg of medication. Requires a predefined amount of pressure to be applied to the plunger before the device will operate, thus ensuring proper dispersion. **H,** Investigational Solovent (Becton, Dickinson and Co.) dry powder inhaler prototype, adaptable for intranasal or pulmonary formats. The Solovent is a small cylindrical plastic capsule open on both ends. One end has a Luer fitting for attachment to any standard syringe to provide air flow, while the other end is the patient interface, either a nasal prong or a snap-fit adapter to mate with a mask or reservoir. The capsule contains the powder dose between two burstable plastic membranes, which rupture when airflow is provided by the syringe. Plume of powder upon release from Solovent in open air for visualization purposes. **I,** Investigational nasal dry powder inhaler developed by the CDC and Creare, Inc. A prefilled cup (shown between right thumb and forefinger) containing the powdered vaccine is opened by its attachment to the device. The breath of the patient blowing into the device tube carries the dry powder into the nose. Dispersion during patient exhalation limits pulmonary deposition from the posterior nasal space. The plastic face is a phantom model of the airway of a 5-year-old child (CFDRC, Inc.). **J,** Medial section of the right internal nasal airway of a plastic, phantom model shown and described in **I**. The external nares and face (not shown) are to the right, proximal to the nasal valve. The pharynx (not shown) is to the left, distal to the nasopharyngeal opening. The red-pigmented powder indicates the deposition pattern from the investigational nasal dry powder inhaler shown in **I**. *(**A**–**B,** Courtesy Nuphar Rozen-Alder [Becton, Dickinson and Co.]. **C,** Courtesy Teleflex Medical Europe Limited. up separately by reattaching the fill needle. Potential reuse of the device with cross-contamination is a risk.

BioDiem has commercialization rights for the Russian LAIV outside of Russia and has licensed the technology to the Serum Institute of India Ltd. The Serum Institute of India Nasovac-S vaccine is currently delivered with the Teleflex VaxINator, a single-use device that consists of an atomization spray tip compatible with any standard Luer lock fill-on-site syringe (see Fig. 68.7C). A dose divider attached to the syringe plunger separates the 0.5-mL dose for delivery of 0.25 mL per nostril. One advantage of the VaxINator is that the conical tip fits any nostril size and limits the depth of

insertion, providing the vaccinator with physical guidance to device placement. The device is potentially reusable. Teleflex offers an optional autodisable syringe, which automatically disables both the syringe and the VaxINator after the drug is delivered.

An inactivated virosomal-subunit influenza vaccine (Nasalflu, Berna Biotech) was licensed in Switzerland in 2000 for administration as a nasal spray. Nasalflu contained *E. coli* heat-labile toxin as a mucosal adjuvant. The vaccine was withdrawn from the market after an increased incidence of temporary paralysis of the seventh cranial nerve (Bell palsy), which was considered to be related to the heat-labile toxin adjuvant.[574,615]

Multiple clinical trials have been conducted with other LAIVs in addition to the licensed vaccines.[616,617] Clinical trials of other types of influenza vaccines—including inactivated, virosomal, live replication-deficient, and proteasome vaccines—also have demonstrated promising immune responses.[618–621] Most studies used standard nasal spray or did not describe the IN delivery method. One study used a novel breath-actuated nasal spray device, OptiMist, which delivers liquid or dry powder aerosols only during oral exhalation. Because this method raises the soft palate to close the connection between nose and throat, pulmonary deposition is avoided and delivery to the posterior nasal segments is increased (see Fig. 68.7D).[563] Inactivated influenza vaccine self-administered using the OptiMist resulted in significant increases in virus-specific IgA in nasal secretions, as well as protective levels of virus-specific serum antibodies, after two doses in more than 80% of subjects.[622]

Other IN vaccines for which clinical trials demonstrate encouraging immune responses include live attenuated respiratory syncytial virus, parainfluenza, *Bordetella pertussis* vaccines,[623–626] a Norwalk virus VLP vaccine, and hepatitis B vaccine. For example, live attenuated respiratory syncytial virus vaccines administered as IN drops to seronegative infants 5 to 24 months of age produced a functional immune response in 59% of subjects.[626] Riddle and colleagues reported that a *Shigella flexneri* subunit vaccine was safe and well tolerated, producing robust levels of antigen-specific intestinal IgA when administered IN with a Dolphin spray device (see Fig. 68.7E).[627]

Nasal Drops. Multiple clinical trials and almost all preclinical studies of IN vaccines have been conducted with nasal drops. Unfortunately, the dropper device and delivery method is often not described. Several studies compared LAIV delivery by nasal spray with liquid dropper delivery.[628] In a multicenter study of children 18 to 71 months of age, King and colleagues detected no statistically significant differences in reactogenicity or immunogenicity between subjects who received LAIV by drops or spray at four different doses.[628] In another study, four weekly doses of inactivated influenza vaccine were given as drops, 250 µL per nostril, with the vaccinee in a supine position on a tilted couch with the head lowered for 1 minute in order to retain the vaccine within the nasopharyngeal area. IN vaccine drops produced hemagglutination-inhibiting antibody titers ≥40, considered protective in more than 80% of subjects.[618]

Nasal Nebulizer. Several nebulizers have the capacity to deliver IN aerosols. Live attenuated measles vaccine administered via nasal prong with the AeroVax nebulizer (see Fig. 68.7F; Creare, Inc.) was shown to be safe and immunogenic in macaques.[629] AeroVax delivery of LAIV to ferrets elicited high levels of serum-neutralizing antibodies and protected them from homologous virus challenge at conventional (median tissue culture infective dose [$TCID_{50}$]: 10^7) and significantly reduced ($TCID_{50}$: 10^3) dosages, and it provided a significant level of subtype-specific cross-protection.[630]

Intranasal Dry Powders. Multiple clinical trials of an IN powder vaccine including chitosan as a mucoadhesive have demonstrated robust immune responses.[631,632] Two doses of a combination dry powder *Neisseria meningitidis*–diphtheria IN vaccine administered by a 5-mL Combitips Plus syringe produced protective antibody titers for both pathogens comparable to those generated by conventional injection. The Combitips is a sterile PP syringe with a solid displacement plunger that expels powder without residual airspace and has a very narrow opening that generates a fine aerosol. The tip of the syringe was placed as far into the nostril as possible without causing discomfort, with the subject in a semireclined position. One-third of IN vaccinees reported mild side effects compared with two-thirds of injection vaccinees who reported mild injection pain.[631] In another clinical study, IN powder diphtheria vaccine formulated with chitosan significantly augmented systemic T-cell responses compared with the same vaccine without chitosan.[632] An IN norovirus VLP vaccine that included chitosan and monophosphoryl lipid A as adjuvants significantly reduced the frequency of Norwalk virus gastroenteritis in human subjects following viral challenge with a homologous strain. The vaccine was delivered intranasally using the Bespak Unidose DP (dry powder) device[633,634] (see Fig. 68.7G), a single-use unit-dose design that allows for IN delivery of up to 100 µg of medication.

IN dry powder vaccines have been formulated and tested in preclinical studies for influenza, anthrax, diphtheria, meningococcus, measles, hepatitis B, plague, and Norwalk virus. The BD Solovent device has been used in several preclinical studies (see Fig. 68.7H). Live attenuated measles vaccine delivered intranasally to macaques with Solovent provided an immune response equivalent to SC injection, including protection from virus challenge.[635] Anthrax vaccine by the IN route with Solovent provided complete protection against inhalational challenge with roughly 90 times the median lethal dose in rabbits, while providing better stability than liquid formulations.[353,635a,636] Solovent IN delivery of a whole inactivated influenza virus product in rats elicited high titers of nasal antiinfluenza IgA, as well as serum antibody titers equivalent to those obtained with injected vaccine.[637] No loss of potency was found when it was stored at 25°C and 25% relative humidity for up to 12 weeks and at 40°C and 75% relative humidity for 2 weeks.[637]

An investigational nasal powder delivery device developed by Creare, Inc., operates by patient exhalation through the mouth, blowing the powder into the nose while simultaneously generating air flow that limits entry to the lower respiratory tract. In three-dimensional plastic models developed from computerized tomography airway anatomy of children ages 2, 5, 7, and 12 years of age, the device consistently delivered a significant fraction (>66%) of a fluorescein powder dose to the target IN airways (see Figs. 68.7I and J).

To increase nasal residence time, a dry powder formulation, GelVac, was developed with an inert in situ gelling polysaccharide. IN vaccination with GelVac Norwalk-virus VLPs induced systemic and mucosal antibody titers in rats and guinea pigs equal to or greater than those achieved by liquid VLPs plus adjuvant.[638] The GelVac powder vaccine was administered using a laboratory-constructed delivery device using a 5-mL syringe to provide airflow through a modified pipette tip, which served as a nasal prong. Although many dry powder and liquid-spray nasal devices are in use for drug delivery in humans, testing them in vaccine studies in animals is difficult or impossible because of the nostril size.

Lower Airway Vaccine Deposition. The vast alveolar surface area and abundant APCs make the lungs an attractive target for vaccine delivery. However, inflammatory adverse reactions in this vital organ could have grave consequences, so a high degree of caution is required. Significant development in

pulmonary drug delivery has been achieved, which might be adapted for vaccine delivery.

Pulmonary Liquid Aerosols. Measles vaccine is the most widely studied vaccine targeting pulmonary delivery. Early clinical studies of drops or sprays delivered to the conjunctiva, or the oral or nasal mucosa, produced inconsistent immune responses,[639–648] prompting researchers to consider aerosol pulmonary delivery. Albert Sabin was an early pioneer and advocate of this delivery method.[649–652] A significant body of clinical research in aerosol measles has been published and summarized in review articles and metaanalyses.[653–656] The primary finding is that delivery of nebulizer-generated small-particle liquid aerosols via pulmonary inhalation to children 10 months of age or older typically produced immune responses in very high proportions of subjects, usually equivalent to or greater than responses to injected vaccines.[630–632,640–642,656–671] For example, Dilraj and colleagues found that 96%, 94%, and 86% of schoolchildren who received the aerosol measles vaccine had antibody titers of greater than 300 IU/mL at 1, 2, and 6 years after vaccination, respectively, compared with 91%, 87%, and 73% among those receiving the injected vaccine.[659,669,672] In contrast, generally lower immune responses were found for the aerosol route compared with parenteral injection, among children younger than 10 months.[649–652,673–675] For example, Wong-Chew and coworkers found vaccination of 12- and 9-month-old infants by injection induced immunity in 100%, but by aerosol route in only 86% and 23%, respectively.[673,674] One hypothesis was that the very low respiratory volume of infants results in an inhaled dose of aerosol vaccine that is too small in that period. A follow-up study by Wong-Chew and colleagues demonstrated that increasing exposure time to aerosol measles vaccine elicits immune responses that are comparable to those seen by the SC route in 9-month-old infants.[676]

With regard to vaccine safety, the same reviews and metaanalyses[653–655] noted that no severe adverse events were reported after aerosol measles vaccination in any of the studies. Rates of minor adverse events, when reported, were typically less than or the same as vaccination by injection.[659,666,668,673,674] Experience in mass campaigns was similar, with de Castro and colleagues reporting no serious adverse events among more than 3.7 million children in Mexico vaccinated by aerosol.

The jet nebulizer system known as the Classic Mexican Device (see Figs. 68.8A and B) was used in many measles aerosol clinical studies and during mass campaigns in Mexico.[659,669,672,674,677] The system consists of a general-use (non–medical-grade) compressor that delivers air to a jet nebulizer, which holds the vaccine in crushed ice to maintain potency during the vaccination session. The vaccine aerosol is delivered through reusable plastic tubing to a single-use disposable paper cone (modified from a drinking cup), which is held close to the patient's face for 30 seconds. Typically, the aerosolized dose volume is roughly 0.15 mL, and the mass median aerosol diameter of droplets is 4.3 μm.[678] In a study that assessed the distribution of viable vaccine virus across the range of droplet sizes emitted from a Classic Mexican Device, Coates and coworkers estimated that 30% of infective viral particles were contained in droplets with diameters of 5 μm or less, and 23% were in droplets of greater than 10 μm. As with all vaccine delivery to the lower respiratory tract, it has not been possible to identify which target tissues are essential for production of an immune response. Although the Classic Mexican Device has demonstrated a level of safety and immunogenicity, it is heavy, cumbersome, and noisy, and it requires outlet (mains) electricity and crushed ice. It is thus not practical for routine vaccination.

Because of the encouraging results of early measles aerosol vaccine trials, in 2002 the WHO, in partnership with the CDC and the American Red Cross, initiated the Measles Aerosol Project. Its goal was licensure of at least one live attenuated measles vaccine and its associated aerosol delivery system in the developing world. The project documented immunogenicity and safety (i.e., the lack of local or systemic toxicity) in animal studies.[629] Three existing therapeutic nebulizers were used for Phase I clinical trials: the AeroEclipse, the CompAIR, and the Aeroneb.[679,680] Measles vaccine delivery by the three devices, delivered to 145 subjects in India, was reported to be safe, well tolerated, and immunogenic.[681] A modified version of the battery-operated Aeroneb vibrating mesh nebulizer (Aerogen) device (see Fig. 68.8C) was selected for use in the Phase II/III pivotal trial initiated in 2009 by the Measles Aerosol Project. The study was a randomized, open-label, active-control, noninferiority trial of the measles vaccine in unvaccinated healthy infants from 9 to 11.9 months of age. For aerosol delivery, vaccine was reconstituted in 2-mL diluent and administered as a single 0.2-mL dose, nebulized for 30 seconds through a single-use nonvented face mask. The nebulizer generated aerosol with a median diameter of 5.1 μm. In the full-analysis set, 673 (85.4%) of 788 children in the aerosol group and 754 (94.7%) of 796 children in the SC group were seropositive at day 91, a difference of 9.3 percentage points (95% confidence interval, 12.3 to 6.4), which failed to meet the predetermined 5% noninferiority margin. No serious adverse events were attributable to measles vaccination and adverse-event profiles were similar in the two groups.[682]

In other recent clinical studies, rubella and mumps vaccines have been used in combination with measles vaccine for aerosol delivery. Bennett and colleagues found that aerosol vaccination of preschool children with a combination MMR vaccine produced antibody responses to all antigens equivalent to those produced by injection.[658] Sepúlveda and coworkers found that aerosolized measles-rubella combination vaccine in school-age children produced levels of measles and rubella antibodies equivalent or higher than levels seen after SC injection.[666] Fewer adverse events were reported in the aerosol group. Diaz-Ortega and colleagues found that MMR vaccination by aerosol in college students produced immune responses similar to those produced by injection, with seropositivity retained in all vaccinees 1 year after vaccination.[670,671]

Few clinical trials of pulmonary aerosol delivery of other vaccines have been reported. In a small Phase I double-blind trial, aerosol delivery was compared with ID delivery for a modified vaccinia Ankara–vectored vaccine delivering the *Mycobacterium tuberculosis* Ag85A antigen. The aerosol was administered as a 1-mL liquid dose using an Omron MicroAIR U22 vibrating mesh nebulizer. Both administration routes were well tolerated with few adverse events and were immunogenic with Ag85A-specific systemic responses similar across groups. Ag85A-specific CD4 T cells were detected in bronchoalveolar lavage cells from both groups, and responses were higher in the aerosol group than in the ID group.[683]

Pulmonary Dry Powders. Measles vaccine has been a pathfinding application for respiratory dry powder vaccination. Early formulations were finely milled and retained adequate potency, but immune responses were poor when delivered to the respiratory tract of macaques.[601,603] Aktiv-Dry was awarded a Grand Challenges in Global Health grant in 2005 for a measles vaccine dry powder (MVDP) project. The project goals were to refine a dry powder measles vaccine formulation, establish production capacity at the Serum Institute of India, and complete preclinical and Phase I clinical testing[684] A novel spray-drying system was used to manufacture inhalable MVDP with minimal potency losses in the drying process.

Figure 68.8. Selected devices for lower respiratory tract vaccine delivery. A–B, Investigational Classic Mexican Device for aerosol vaccine delivery, illustrated by component diagram **(A)** and use in clinical trials **(B)**. A nonmedical electric compressor (not shown) delivers roughly 9 L of air per minute at a pressure of 30 to 40 psi (207 to 276 kPa) to a jet nebulizer that is kept in crushed ice to maintain vaccine potency. The vaccine aerosol (roughly 0.15 cm^3 of particles averaging 4.3 μm in diameter) is delivered through a disposable paper cone held close to the patient's face for 30 seconds. **C,** Aerogen Aeroneb GO battery powered vibrating mesh nebulizer used as the basis for the Measles Aerosol Project clinical trials device. Cap (between thumb and finger) is removed to fill upper chamber. Microperforated vibrating mesh disk at the base of the chamber aerosolizes dose into lower chamber. Patient inhales aerosol through the mouthpiece or attached mask (not shown). Cord connects to battery control pack. **D,** Investigational Solovent dry powder inhaler prototype pulmonary delivery format (Becton, Dickinson and Co.). Air from the empty syringe ruptures the membranes of the vaccine container, releasing into the cardstock spacer a plume of dry powder. Patient inhales from the cardstock spacer directly or via a mask. The vaccine container (capsule), spacer, and mask are single-use disposables. **E** and **F,** Investigational PuffHaler dry powder inhaler (Aktivdry, LLC). **E,** Air from the squeeze bulb lofts vaccine powder from the disperser into the reservoir once the pressure threshold of the burst valve is exceeded. **F,** Patient inhales from the single-use-only reservoir of PuffHaler after detachment from the device, either directly (as shown) or via a disposable mask (not shown). **G,** Investigational Twincer single-use, disposable, dry powder inhaler for pulmonary delivery (University of Groningen). The drug formulation is stored in the snap-together plates of the device in an aluminum blister for maximal moisture protection. The powder becomes available for inhalation upon pulling a foil cover that protrudes from the rear of the inhaler (not shown). *(**A–B,** Courtesy José Luis Valdespino [Instituto Nacional de Salud Pública, Mexico] and from Valdespino-Gómez JL, de Lourdes Garcia-Garcia M, Fernandez-de-Castro J, et al. Pulmonary delivery of the vaccine powder with the Solovent device (see Fig. 68.8D) and the Aktiv-Dry developed PuffHaler device (see Figs. 68.8E and F) demonstrated robust immune responses in macaques, including serum antibody, T-cell responses, and protection from viral challenge. Both devices delivered aerosol into reservoirs for mask delivery.[635] Toxicology studies found no test-article–related effects or delayed onset of toxicity after inhalation by Sprague Dawley rats and no effects in mortality, clinical observations, respiratory function, clinical pathology, or histopathology in rhesus macaques.[685]

A Phase I MVDP safety trial of the vaccine was conducted in adults in India, with subjects randomly assigned in 1 : 1:1 ratio to receive MVDP via PuffHaler device, Solovent device, or the licensed SC measles vaccine. No adverse events were reported. MVDP produced serologic responses similar to SC vaccination.[686]

Other vaccines in development for pulmonary powder delivery include influenza, tuberculosis, and hepatitis B.[687] For example, a pulmonary powder formulation produced by SFD, with influenza subunit viral antigen and inulin stabilizer, induced humoral (IgG), cell-mediated (interleukin-4, interferon-γ), and mucosal (IgA, IgG) immune responses in BALB/c mice.[688] When tested separately with a novel dry powder inhaler, the single-use disposable Twincer (see Fig. 68.8G), inulin-based dry powder subunit influenza vaccine was dispersed with an aerodynamic particle size distribution suitable for pulmonary administration.[689]

VACCINE MICRODELIVERY SYSTEMS: ANTIGEN DELIVERY TO DESTINATION-POINT ANTIGEN-PRESENTING CELLS

Once vaccine has been delivered to the appropriate target tissue, sufficient quantities of the antigen must gain access to APCs to activate the immune system. The microdelivery vehicles or vectors that can be used for this purpose include live attenuated viruses (including those acting as vectors for exogenous antigen), live attenuated bacteria (including vectors), commensal bacterial vectors, virosomes, VLPs, liposomes, lipopeptides, immune stimulating complexes, microparticles, nanoparticles, and dendritic cells.[690–696] These vaccine microdelivery systems are described in detail in Chapter 64. Here we include an abbreviated description of these systems to complete the discussion of immunization as an antigen package delivery system.

Replicating Systems

Live Viruses and Bacteria

Viruses and bacteria are prototypical antigen delivery vehicles for several reasons: (a) the package size is optimal for cellular uptake; (b) viral surfaces are coated with molecules that attach to cellular receptors, a process that "rings the package delivery bell" (i.e., cells recognize them as potential pathogens, activating innate immunity and increasing cellular uptake); (c) once inside, viruses commandeer cellular systems for replication, multiplying exponentially the vaccine antigen that they encode; and (d) bacteria self-replicate, in tissues or inside cells, multiplying the vaccine antigen available to APCs. Live attenuated strains of pathogenic viruses and bacteria are among the most common type of vaccines and have been used for every delivery route. The major risks of attenuated pathogens as vaccines are potential pathogenic effects, which may occur in immunocompromised persons, following viral reversion to a virulent form, or with exposure of an unintended tissue, such as neurotoxicity following exposure via the olfactory route.[697]

Recombinant viruses and bacteria act as vaccine vectors by incorporation of genes that express a heterologous antigen. Some recombinant vectors also express adjuvants. The replicating systems have advantages similar to those of conventional live attenuated virus vaccines. They deliver the genetic code for the vaccine antigens and adjuvants to host cells for replication, and the cells manufacture the vaccine components to activate the immune system. Viruses and bacteria used as vaccine vectors should, ideally, have very low pathogenic potential, even in immunocompromised people, and they should have the capacity to incorporate the necessary foreign genes for desired antigens, promoters, and adjuvants. As vectors, bacteria have an advantage over viruses because of their higher capacity for insertion of heterologous genes expressing antigens, adjuvants, or plasmids (for DNA vaccination). One caveat for the use of vectored vaccines is that preexisting immunity to the vector may reduce vaccine effectiveness.[698]

DNA Vaccines

DNA vaccination involves the delivery of eponymous plasmids directly into host cells to express the desired antigens and adjuvants. Naked DNA lacks cellular entry mechanisms, so the critical hurdle is getting the DNA into the cells without degradation. Live attenuated bacteria, especially *Salmonella* and *Shigella*, have been vectored to produce DNA for IN vaccination.[699–704] Virosomes, liposomes, and microparticles have also been used to deliver DNA vaccines.[705–708]

Nonreplicating Vaccine Delivery Systems

Synthetic constructs, including liposomes, VLPs, virosomes, immune stimulating complexes, microparticles, and nanoparticles, are nonreplicating delivery systems that mimic live viruses in the way they appear to the immune system to enhance antigen delivery. They may also carry adjuvant. The particles are about the size of viruses, allowing similar uptake by APCs. Many include a lipid component to increase cell membrane permeability and may contain unrelated viral or bacterial proteins to activate the immune system.

One of the most novel methods of delivering antigen into a recipient's APCs is to extract the APCs, by peripheral blood draw for example, culture them with the antigen, and then administer the autologous antigen-laden APCs via intravenous, IM, or SC injection. Autologous dendritic cell-based vaccines are under development as curative cancer vaccines.[695,696]

Adjuvants

Nonreplicating antigens are typically poorly immunogenic and may require adjuvants to stimulate an appropriate immune response. One mechanism of adjuvant action is to provide "warning labels," implying the antigen package is a potential pathogen, to alert cells and induce innate immunity. Adjuvants studied for this purpose include pathogen components such as bacterial toxins and their derivatives, other bacterial components, and bacterial DNA motifs. Other adjuvants include the cytokines and chemokines that cells produce to induce innate immunity. Another adjuvant mechanism is to increase the residence time of the antigen in the target tissue, prolonging the opportunity for the antigen package to be taken up by APCs. Aluminum adjuvants provide this depot effect for many inactivated vaccines delivered intramuscularly or subcutaneously. For mucosal delivery, nanoemulsions and natural polymers such as chitosan have mucoadhesive properties that delay mucosal antigen clearance.[621,708a,708b,709–712]

CONCLUSION

New technologies for delivering antigen packages have the potential to overcome logistical hurdles that impede delivery of vaccines to all populations in need. Practically ideal vaccines would be safe, effective, and inexpensive. They would have these characteristics: (1) packaged as single-unit doses to minimize wastage and missed opportunities to vaccinate; (2) thermostable at ambient temperatures to make vaccines easy to store and ship, even via routine delivery systems such as postal services; (3) available in prefilled dose format to obviate on-site reconstitution or filling; (4) simple to administer or self-administer to reduce dependence on highly skilled healthcare workers; and (5) needle-free to reduce the risks of sharps injuries, needle reuse, and the burden of sharps waste disposal.

Combining new technologies for stabilizing and packaging vaccines with new vaccine administration technologies, new molecular antigen delivery systems, and adjuvants could yield practically ideal vaccines in the next few decades. However, the promising technologies described in this chapter face daunting obstacles to (1) bridge the gap between successful proof of principle and the expensive and complicated series of clinical trials, related studies, and regulatory steps to ensure that the novel systems are safe and effective, and (2) achieve licensure and general availability.

The initial costs of developing, licensing, and supplying practically ideal vaccines are very high. To encourage financing, a clear demand—a willingness to pay—must be expressed in advance by key stakeholders, including public health and immunization program policy makers, vaccine purchasers, and independent philanthropic entities. To create this demand, stakeholders must be aware of the potential of new technologies and convinced that the cost of developing practically ideal vaccines is outweighed by the benefit of reducing the long-term costs of current inefficiencies in the immunization system. In February 2014, the WHO held a meeting on Next-Generation Vaccine Delivery Technologies to conduct a rapid review of existing and future technologies, provide a vision for the future of vaccine technologies, and determine the strategic next steps to guide and enable the development, introduction, and uptake of new technologies with potential positive public health impact. Integrated products that would eliminate the need for reconstitution, provide improved thermostability, and offer needle-free delivery were all highlighted as priority technology development areas.[713]

DISCLOSURE

Mark Papania is a coinventor with corresponding financial interests in the AeroVax (CDC, Creare, Inc.) and dry powder inhaler (CDC, Creare, Inc.) devices illustrated in Figs. 68.7F and I.

Acknowledgments

We thank Bruce Weniger, coauthor of previous editions of this chapter, for the research and content that informed this edition. We are grateful to the following organizations and individuals for photographs, prepublication manuscripts, reference material, fact-checking, and other assistance for this and previous editions: Aerogen (Elaine Lesnak), AktiVax, Inc. (Amir Genosar); Becton, Dickinson and Co. (Roderick Hausser, Nuphar Rozen-Alder, Vincent Sullivan); BesPak (Ian Anderson); Brevetti Angela (Rajeev Kabbur, Daniel Martinez); CDC Photographic Services (James Gathany, Greg Knobloch); Catalent (Bill Hartzell); Corium International, Inc. (Bobby Singh); Creare, Inc. (Darin Knaus); Duoject (Simon Williams); Georgia Institute of Technology (Mark Prausnitz); Instituto Nacional de Salud Pública, Mexico (José Luis Valdespino); Intercell AG (Andi Bruckner); Medical International Technologies (MIT Canada) Inc. (Karim Menassa); MEDInstill (Debashis Sahoo); Neopac (Ralf Künzi); OptiNose (Per Gisle Djupesland); PharmaJet (Chris Cappello); Phillips Respironics (Brian Groskopf); Star Syringe Ltd (Paul Mallins); University of Groningen (A. H. de Boer); and the University of Queensland/Vaxxas (Mark A. F. Kendall). We also gratefully acknowledge the contributions of our colleagues at PATH (Sarah Sterner, Marge Murray, Gene Saxon, Annie Rein-Weston, Savitha Swaminathan, Mike Ruffo, Joe Little, Patrick McKern, Scott Brown, and Debra Kristensen) for their support with information, photography, and editing.

SECTION 4

Vaccination of Special Groups

69 Vaccination of Immunocompromised Hosts

Per Ljungman

Over the past decades, the number of immunocompromised patients has increased rapidly. These patients are vulnerable to a number of vaccine-preventable diseases and new vaccines are in development such as cytomegalovirus (CMV) vaccines—the "troll of transplantation"—and inactivated varicella vaccines.[1–3] The 2009 H1N1 influenza A pandemic also showed the need for rapid development of vaccination strategies in immunocompromised populations.[4–7] Thus, increased knowledge regarding responses to vaccinations in the immunocompromised host is needed. Yet, the issue is complex because the characteristics of the immunosuppressed states and their management differ greatly between the various patient groups and many immunosuppressive therapies are being developed and used in expanding numbers of patients.

PATIENTS WITH CANCER

Cancer chemo- and radiotherapy has changed substantially over the past several decades with the introduction of monoclonal antibodies and targeted anticancer drugs such as tyrosine kinase inhibitors. However, the number of clinical trials assessing vaccination responses in patients receiving these modern therapies is limited. Most vaccine studies have been performed in patients with hematological malignancies, and studies assessing immune responses in adult and pediatric solid-tumor patients are few. Many patients with non-Hodgkin lymphoma or chronic lymphocytic leukemia (CLL) will have received the monoclonal antibodies, rituximab or alemtuzumab, as part of their therapy and both of these agents persist in the circulation for prolonged periods impairing vaccine responses.[8–10] These complexities must be considered in interpreting the recommendations for immunizations, which are summarized in Table 69.1.

Inactivated Vaccines (Nonlive Vaccines)

These agents pose less risk to the patient because they are incapable of replicating in the immunocompromised subject. Several of the inactivated vaccines used in immunocompromised patients are summarized below.

Pneumococcal Vaccines

Pneumococci are important causes of infection in patients with hematological malignancies, particularly B-cell malignancies such as CLL, Hodgkin lymphoma, and multiple myeloma. Early studies were performed with the polysaccharide-based vaccine (23-valent pneumococcal polysaccharide vaccine [PPSV23]) in multiple myeloma patients and less than 40% had a serological response to vaccination.[11] The response to PPSV23 in patients with Hodgkin lymphoma varies with the time when therapy is delivered. Patients immunized after chemo- and/or radiotherapy have a severe impairment of the antibody response.[12,13] In contrast, improved responses to PPSV23 are obtained if immunizations are performed before therapy is initiated.[13,14] In children with Hodgkin disease, immunogenicity is improved if immunizations are administered prior to splenectomy.[15] Repeated vaccinations with PPSV23 given before and after splenectomy in patients with Hodgkin lymphoma induced antibody responses and were not associated with serious side effects.[16]

Pneumococcal conjugate vaccines (PCVs) have also been studied in patients with hematological malignancies. Molrine and colleagues showed that a single dose of the seven-valent PCV (PCV7) gave suboptimal responses in patients being treated for Hodgkin disease.[17] CLL patients responded to PCV7 but with lower responses than seen in healthy controls and with decreased responses later in the disease course.[18] Administering a single dose of the 13-valent PCV (PCV13) early after the diagnosis in patients with CLL resulted in an immune response in only 58% of CLL patients compared to 100% of healthy controls.[19] Whether repeated doses would enhance the immune response has not been studied.

In a noncontrolled follow-up study to the study by Molrine and colleagues, Chan and colleagues showed that priming with PCV7 improved the subsequent booster response to the PPSV23 in patients with previously treated Hodgkin lymphoma.[20] This prime-boost strategy has been successfully used in patients with sickle cell anemia[21] and HIV infection. The booster dose of PPSV23 broadens the coverage of additional pneumococcal serotypes and is recommended by the Centers for Disease Control and Prevention's Advisory Committee on Immunization Practices (ACIP).[22,23] It is unclear how effective this strategy is in patients with other hematological malignancies. Immunization against pneumococcal infections is recommended as early as possible after diagnosis and preferably before therapy is initiated in patients with hematological malignancies.[24,25]

Haemophilus influenzae Type B Vaccine

Severe infections with *Haemophilus influenzae* type b (Hib) in cancer patients are quite rare. Immunization with a conjugated Hib vaccine resulted in lower antibody responses than in normal children, and a booster dose was ineffective. Longer duration and intensity of antileukemic chemotherapy were associated with a poorer response.[26,27] Children undergoing therapy for solid tumors also have lower-than-normal responses to vaccination with an Hib vaccine.[28]

Very limited data are available regarding the risk for severe Hib infections and the response to vaccination in adult patients with cancer. Patients with multiple myeloma have antibody responses to Hib conjugate vaccines comparable to those of healthy adults.[11] Molrine and colleagues showed that

TABLE 69.1 Recommendations for Immunizations in Cancer Patients

Vaccine	Recommendation	Comments
Pneumococcal conjugate vaccine	Yes	Lymphoma and CLL patients. Responses <6 months after rituximab unlikely to be effective.
Pneumococcal polysaccharide vaccine	Yes	Lymphoma and CLL patients. Preferably before initiation of chemotherapy. Could be given at least after priming with conjugate vaccine. Responses <6 months after rituximab unlikely to be effective.
Conjugated Hib	Yes	Children with cancer. Patients with Hodgkin disease. Preferably before initiation of chemotherapy.
Inactivated influenza vaccine	Yes	Seasonal to all cancer patients.
Varicella	Yes	Seronegative children and young adults in remission from malignant disease. Not during active chemo- or radiotherapy.
Zoster	No Possible	During active therapy. At least 3 months after active therapy but at least 12 months after rituximab.
MMR	Yes Individual consideration	Children with cancer not previously vaccinated. Not during active chemo- or radiotherapy. Seronegative adults depending on the local epidemiological situation. Not during active chemotherapy or radiotherapy.
Tetanus toxoid, diphtheria toxoid acellular pertussis, poliovirus	Yes	Children to complete primary schedule. Booster dose after finishing intensive chemotherapy can be considered to retain long-term immunity.

CLL, chronic lymphocytic leukemia; Hib, *Haemophilus influenzae* type b; MMR, measles, mumps, and rubella.

99% of patients with Hodgkin lymphoma in whom therapy had been discontinued responded to vaccination.[17] In contrast, patients with CLL respond rather poorly to Hib conjugate vaccine, with response rates around 50%.[29,30] It is preferable for vaccination to be performed before the start of therapy.

Influenza Vaccine

Patients with cancer were more likely to die during hospitalization for influenza, especially if elderly and with comorbid conditions. The morbidity in adult patients is highest in patients with hematological malignancies, especially those with acute leukemia. Patients with lung cancer had the highest influenza-related case-fatality rates among patients with solid tumors.[31] Influenza disease can also interrupt scheduled chemotherapy with a negative impact on the ultimate disease outcome. Earle showed that in patients with colorectal cancer, patients who were immunized had fewer chemotherapy interruptions and were more likely to survive 1 year.[32] Efficacy data in adult patients with solid tumors are limited. In a study of lung cancer patients, the vaccination response was similar to that of healthy controls.[33] Patients with breast cancer vaccinated during ongoing chemotherapy had significantly lower responses than healthy controls, but these patients responded better if vaccinated early rather than late after chemotherapy.[34]

Most studies show that adult patients with hematological malignancies respond poorly to influenza vaccination. In a study of patients with multiple myeloma, the response rate to one dose of vaccine was 19%.[11] Similar results have been seen in patients with lymphoma.[35] In a study of patients with non-Hodgkin lymphoma, 32 patients were vaccinated, half with ongoing therapy (type not specified) and half without therapy. The immune responses were similar between the groups, although the responses tended to be more robust in patients without ongoing therapy but lower when compared to healthy controls.[36] A larger study from the same group gave similar results after influenza immunization comparing previously treated (within 2 months of vaccination) with untreated patients and controls.[37]

It may be possible to improve responses by giving repeated doses. Adults with lymphoma receiving a two-dose influenza vaccine schedule showed responses of approximately 30% after one dose and approximately 45% after two doses.[38] In a study of patients with multiple myeloma, two doses gave good seroconversion and seroprotection rates against H1N1 and H3N2 serotypes (27% and 34% seroconversion after first dose; 63% and 54% after the second dose, respectively) while the responses to influenza B were less.[39] However, the two studies failed to show an enhanced response after the second dose in patients with various hematological malignancies[9] or CLL.[40] De Lavallade and colleagues reported results of two doses of an adjuvanted pandemic H1N1 vaccine in patients with chronic myeloid leukemia and B-cell malignancies compared to one dose given to healthy controls.[8] The study showed improved seroconversion rates after the second dose compared to the first dose (39–68% in B-lymphoid malignancies; 85–95% in chronic myeloid leukemia) although lower than in healthy controls. The response rates were better in patients with an interval from end of chemotherapy of at least 12 months. They also showed that influenza vaccination was able to induce a T-cell response in approximately 33% of patients compared to 50% in controls.[8]

Patients who have received rituximab as part of their therapy regimen respond very poorly to influenza vaccination for prolonged periods after the end of rituximab therapy. None of 67 lymphoma patients responded to adjuvanted H1N1 vaccine within the first 6 months after the conclusion of rituximab therapy.[10] Furthermore, in lymphoma patients who had completed a rituximab-containing regimen, the response to influenza vaccine was even further impaired if they had been treated with fludarabine.[41]

Studies of influenza vaccination in children with acute lymphoblastic leukemia (ALL) show that the proportion of children reaching "protective" antibody levels varied between 45% and 100% for the different influenza subtypes included in the vaccines.[42–45] A Cochrane review analyzing influenza vaccination in children with cancer summarized that immune responses were weaker in children receiving chemotherapy than in those who had completed chemotherapy and in

healthy controls.[46] In a study of children with solid tumors or lymphoma, who were given one or two doses of vaccine, the overall results regardless of chemotherapy were lower, with only 38% achieving protective antibody levels to all three influenza strains.[47] It has been reported that an antibody titer protective in healthy controls failed to prevent influenza in 24% of children with cancer, but the severity of the influenza infection may have been reduced by the vaccine.[33,48] Vaccination against pH1N1 was studied in a group of 54 children with different types of malignancies.[49] The seroconversion rate was 44%; significantly lower in univariate analysis in children with hematological malignancies compared to those with solid tumors and in children with ongoing chemotherapy. In multivariate analysis, children with ongoing chemotherapy had lower responses ($P = .05$) with a trend for lower responses in children with hematological malignancies ($P = .10$). One way to improve outcome would be to immunize with a vaccine containing higher doses of influenza antigen. A Phase I study was performed in children with ALL and showed safety but no difference in the immune responses, although the study was not powered to assess efficacy.[50]

Despite the lower serological responses in cancer patients, a systematic review showed that vaccinated cancer patients had a reduced risk for influenza-like illness,[51] and a Cochrane review found lower mortality in influenza-vaccinated patients but no difference in infection-related outcomes.[52] Yearly influenza vaccination with the trivalent or quadrivalent inactivated vaccine is recommended for cancer patients.[53,54] Despite these recommendations, the uptake of vaccination is limited and strongly influenced by the attitude of treating oncologists.[55] However, it must be recognized that the protection is likely to be low in those patients who are at highest risk of severe complications. Elting and colleagues reported that influenza in acute leukemia patients undergoing chemotherapy was commonly nosocomially acquired.[56] Immunization of family members and hospital staff is therefore recommended. Only limited data exist with the live attenuated vaccine given to mild to moderately immunocompromised children with cancer.[57] Currently live attenuated vaccine is not recommended in immunocompromised patients.

Tetanus Toxoid, Diphtheria Toxoid, and Inactivated Poliovirus Vaccine

The protection against tetanus, diphtheria, and poliovirus is frequently low in cancer patients undergoing chemotherapy. Hammarström and colleagues showed that 41% of nontransplanted acute leukemia patients were not protected against tetanus.[58] Risk factors for loss of immunity were ALL versus acute myelogenous leukemia, more advanced disease, and increasing age. Lymphoma patients are also likely to have deficient immunity. In children treated for cancer, the antibody titers against tetanus, diphtheria, and poliovirus were lower than in an age-matched healthy population.[59,60] The loss of specific immunity is related to the intensity of given chemotherapy. Children with high-risk ALL were more likely to become nonimmune to tetanus and diphtheria than were patients with low- or standard-risk ALL.[61] In contrast, Nordoy and colleagues reported that treatment of low-grade non-Hodgkin lymphoma patients with radioimmunotherapy did not influence specific immunity to tetanus.[62]

The responses to diphtheria toxoid and tetanus toxoid vaccinations in adult cancer patients have not been systematically studied. Most children respond well to vaccination after chemotherapy for malignancies.[60,63] However, children treated for high-risk ALL had poor responses (22% protected against tetanus; 56% against diphtheria).[61] Stenvik and colleagues reported on 14 children with leukemia who were given a booster dose of vaccine, with 12 of 14 responding.[64] No data exist regarding the vaccination of adults with cancer. Despite the absence of data, it seems logical to recommend an investigation of poliovirus immunity and booster immunization for cancer patients traveling to areas of the world that are still endemic for poliovirus. Inactivated poliovirus vaccine is the only vaccine that should be used in immunocompromised patients as paralytic disease can result in the immunocompromised and transmission of the live vaccine strain has occurred.[64] In the United States and in most countries in Europe, only inactivated polio vaccine is available.

Hepatitis B Virus

Hepatitis B virus (HBV) infection is a major cause of morbidity in many parts of the world. Several studies have been performed regarding the efficacy of HBV vaccination in children[65–71] and these results are summarized in Table 69.2. In general, these vaccines are safe and moderately immunogenic.

Other Nonlive (Nonreplicating) Vaccines

Vaccinations could be considered against pertussis although data are limited regarding if there is an increased risk for severe infection in cancer patients. Age-group–appropriate vaccination against meningococci should be performed according to national guidelines.[24,25] There are also vaccines for cancer patients living in certain areas of the world or traveling to these areas. These include hepatitis A vaccine and vaccines against tickborne encephalitis and Japanese encephalitis. Although there are very limited data regarding serological responses to these vaccines, the risk for significant side effects should be similar to the normal population as they are nonreplicating agents.

The number of long-term survivors after cancer treatment is increasing. These patients might be at increased risk for late complications driven by human papillomavirus infections. The immune response to existing papillomavirus vaccines have not been systematically studied in cancer patients although patients have been vaccinated as part of their age-appropriate routine schedules.[72] Despite this lack of information human papillomavirus vaccination should be considered, especially in survivors after cancer during childhood to be given at the appropriate and recommended age.[24,73]

Live Vaccines

Varicella Vaccine

Primary varicella has previously caused high mortality in children with cancer. With the increased use of acyclovir prophylaxis and treatment, the risk for severe disease seems to have decreased. A recent analysis estimated the mortality to be 0.057% with the mortality varying between regions (0.027% in North America, 0.041% in Asia, and 0.08% in Europe).[74] The existing vaccine is live, attenuated, and based on the Oka strain.[75] The vaccine was shown to be effective and safe in children with leukemia who were in remission,[76] but it should be recognized that the type of leukemia therapy was less intensive in the 1980s. The rate of varicella infection in vaccinees was 8%, but all infected children had mild disease.[76] The frequency of side effects from the vaccine is low, and breakthrough vaccine disease can usually be treated effectively with acyclovir.[76,77] However, there have been fatal vaccine-associated infections reported.[74] Cakir and colleagues investigated single dose versus double dose of varicella vaccine and found a much higher rate of seroconversion (75% vs 29%) and better persistence of specific antibodies in patients receiving a double dose.[78] Furthermore, reinfections in previously vaccinated

TABLE 69.2 Results of Hepatitis B Virus Recombinant Vaccine Studies in Children With Malignancies

ALL, acute lymphoblastic leukemia.

children with cancer have been reported[79] and might become an increasing problem in the future with more adult cancer and leukemia patients having been vaccinated during childhood. The risk for herpes zoster after vaccination is lower than after natural varicella disease.[80,81] In a small randomized study, varicella vaccine was given to children with newly diagnosed cancer before starting chemotherapy. There was a high rate of seroconversion and no severe side effects were found, but the number of included patients was low.[82]

Household exposure to varicella is associated with more-severe varicella disease. An option is to immunize healthy seronegative family members when the child with cancer is undergoing intensive therapy and a live vaccine cannot be given. Diaz and colleagues showed that the attenuated varicella vaccine virus cannot be isolated from oropharyngeal secretions of the immunized siblings.[83] None of the children with cancer showed clinical or serologic evidence of vaccine virus transmission. Immunization with the varicella vaccine is indicated in seronegative patients with cancer when the cancer chemotherapy schedule allows safe immunization, but it would generally not be indicated to interrupt maintenance therapy to allow vaccination considering the relatively low risk for severe and fatal varicella with available antiviral therapy.[74]

Zoster Vaccine

Most cancer patients are elderly and develop zoster more commonly than in age-matched healthy controls.[84] Current recommendations are not to vaccinate during cancer therapy. However, Naidus and colleagues vaccinated 31 patients with hematological malignancies with the zoster vaccine.[85] Eighteen of these patients had previously received cancer therapy and two had ongoing therapy at the time of vaccination; no severe side effects were reported. A case report of a death resulting from dissemination of a vaccine strain occurring 4 years after an autologous stem cell transplant in a patient with untreated lymphoma relapse clearly shows that care is needed in administering live varicella vaccine to immunosuppressed patients.[86] On the other hand, zoster vaccine given before diagnosis and treatment of cancer has a protective effect for cancer patients after chemotherapy.[87]

There are two new inactivated varicella-zoster vaccines in development that offer a solution to the live vaccine dilemma, a subunit vaccine and a heat-inactivated vaccine. The subunit vaccine was reported to be effective in older healthy adults, but has not been studied in elderly cancer patients.[3] A Phase II study with four doses of the heat-treated vaccine in patients with solid tumors and hematological malignancies demonstrated immunogenicity without important side effects.[88] A Phase III study has been fully recruited, but data are not yet available.

Measles, Mumps, and Rubella

Measles disease in cancer patients has a high mortality. Kaplan and colleagues reviewed 27 published cases, among whom 20 (74%) developed pneumonitis and eight (30%) died.[89] The clinical consequences of rubella and mumps infections in cancer patients appear to be of less significance.

Loss of immunity to measles is common in children previously vaccinated with measles, mumps, and rubella (MMR) and then treated for leukemia and other cancers.[61,90,91] Risk factors for loss of measles immunity include younger age and female gender in leukemia patients[61] and younger age in other childhood malignancies.[91] Immunization with the live attenuated vaccine has been contraindicated because of the risk of severe side effects in cancer patients undergoing chemotherapy. Koochakzadeh and colleagues studied MMR vaccination

3 to 12 months after cessation of therapy and reported that it was safe and gave high response rates to mumps (80–100%) but lower (50–71%) to rubella and measles (41–63%).[92] Immunization with live attenuated MMR vaccine should be considered in seronegative cancer patients who are not receiving active chemotherapy and in epidemiologic situations when the risk for measles is high.

Other Live Vaccines

Very limited data exist on immunization with bacille Calmette-Guérin (BCG), yellow fever, or rotavirus vaccines in cancer patients. The use of these live vaccines is not recommended during active cancer therapy.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION PATIENTS

In allogeneic hematopoietic stem cell transplant (HSCT) recipients, four components combine in the production of the immunodeficient state of the patient: (1) the immunosuppressive activity of the primary disease and treatment, (2) the chemotherapy and radiotherapy used to eradicate the host's immune system, (3) the immunologic reactivity between the graft and the host (graft-versus-host disease [GVHD]), and (4) the immunosuppressive therapy given after transplantation to prevent or treat GVHD. The technology of allogeneic HSCT is developing rapidly with the introduction of new stem cell sources (peripheral blood stem cells, cord blood cells, and mesenchymal stem cells), new donor categories (haploidentical donors, unrelated donors), and innovative conditioning regimens using the graft-versus-malignancy reactivity from the donor grafts rather than the chemo- and radiotherapy to clear the recipient's immune system and allow engraftment of the donor's immune system.

Immunity to infectious agents is transferred by the graft and can be detected in the patient early after the HSCT.[93–98] The transferred immunity is usually of a finite duration and over time an increasing number of patients becomes susceptible to infections because of declining immunity to tetanus,[95,99,100] poliovirus,[99,101] and measles.[102,103] The immune status of the donor is important for the short-term transfer of immunity and can be boosted by immunizing the donor before transplantation[97,104–106] combined with early posttransplantation vaccination of the recipient with inactivated polysaccharide–protein conjugate vaccines or protein-based vaccines.[107–109]

The transplantation period can be divided into three distinct phases, each with its unique combination of risks and benefits of immunization. The early phase is characterized by neutropenia, and the characteristic infections are caused by bacteria and fungi. Other infections during this phase are caused by respiratory viruses and herpes simplex virus. The only window of opportunity to vaccinate either the donor or the patient occurs before HSCT. The currently available vaccines that could be of clinical importance are influenza and PCV. The risk for infections during the period from 1 to 6 months after HSCT is strongly influenced by the presence of GVHD and the typical infections during this period are caused by CMV and mold, but influenza and pneumococcal infections can also be important.[6,110,111] During the late phase, infections caused by pneumococci, influenza, and varicella-zoster virus (VZV) are important and potentially preventable by vaccination.[6,110–112] With the reappearance of measles, immunity to this virus is of increased importance. However, long-term protection against other infectious agents such as tetanus, diphtheria, poliovirus, and vaccines to protect travelers is also of importance.

The current recommendations do not take the different types of allogeneic HSCT into account even though we know that the speed of immune reconstitution is different between cord blood graft recipients and recipients of bone marrow or peripheral blood grafts. There is a paucity of studies in the different patient groups. However, certain factors are important when deciding on the timing and schedule of vaccinations. One such factor is the speed and completeness of immune reconstitution. It has been reported that the number of $CD4^+$ cells can be used as a marker for when vaccinations can be started with better responses in patients with $CD4^+$ cells above 200/μL.[113,114] Another important factor to consider is whether patients have GVHD. Patients with GVHD clearly should not be vaccinated with live vaccines because of the risk for severe side effects; additionally, patients with severe GVHD who are receiving intensive immunosuppression should have vaccinations deferred. Existing data support that patients with GVHD have lower response rates or more rapidly lose immunity to some vaccines,[115–119] but there are also studies showing no negative effect of GVHD.[120,121] Patients with GVHD are at risk for severe infections and could benefit from vaccination. The risk for activation of GVHD seems to be low based on the reported safety data from prospective vaccination studies[7,116,122] and clinical experience, can be triggered with adjuvanted vaccines.[123]

Table 69.3 summarizes the recommendations for allogeneic HSCT recipients and is in part based on recently published Infectious Diseases Society of America recommendations.[24,25]

Nonlive Vaccines

Pneumococcal Vaccines

Pneumococcal infections can be severe in HSCT patients especially in patients with chronic GVHD.[124–126] Immunization with the PPSV23 can elicit antibody responses from 6 months after HSCT in patients without GVHD, but was shown to be ineffective in patients with chronic GVHD.[105,115,127,128] In particular, the specific immunoglobulin (Ig) G_2 responses have been poor.[115,129] Children given PPSV23 developed short-lived responses and low avidity,[130] in contrast to adults.[131] Thus, responses to vaccination with PPSV23 are suboptimal in many patients.

PCV7 has been evaluated in several studies in HSCT patients including those with chronic GVHD. Kumar and colleagues conducted a randomized study of one dose of either PPSV23 or PCV7 given to donors before and 6 months after HSCT. PCV7 improved the likelihood of an immune response compared to PPSV23, but neither approach was optimally effective.[132] Molrine and colleagues performed a randomized study with the PCV7 comparing pretransplant vaccination of patients and their donors with no vaccination given pretransplantation. All patients were given three doses of the vaccine at 3, 6, and 12 months after transplantation. The majority of patients (72–100% for the different serotypes) developed protective antibody levels at 12 months after HSCT.[133] There was also an improved response (67% vs 36%) to the first dose of PCV7 when compared to the polysaccharide vaccine. Cordonnier and colleagues compared early (starting at 3 months) with late (starting at 9 months) vaccination with three doses of PCV7 and showed that good protection could be achieved as early as 3 months after HSCT.[116] Furthermore, PCV7 increased the functional antibodies assessed by an opsonophagocytic assay.[134] However, there was a tendency for patients who were immunized early to have a shorter duration of immunity and for patients with chronic GVHD to benefit from a booster dose.[116] It was also shown that a dose of PPSV23 given 9 months after the first PCV7 dose increased the response rates and extended the serotype coverage.[135] Studies also have been

TABLE 69.3 Recommendations for Immunizations in Stem Cell Transplant Patients

Vaccine	Recommendation	Comments
Tetanus toxoid + diphtheria toxoid	Yes	Three doses (DT) starting at 6–12 mo after transplantation
Inactive influenza	Yes	Seasonal, beginning at 4–6 mo after transplantation depending on season
Inactivated poliovirus	Yes	Three doses starting at 6–12 mo after transplantation
Conjugated Hib	Yes	Three doses starting at 6–12 mo after transplantation
Pneumococcal conjugate	Yes	Three doses started at 3–6 mo after transplantation; booster at 12 mo in patients with chronic GVHD
Pneumococcal polysaccharide	Yes	Booster at 12 months in patients without GVHD
Acellular pertussis	Yes	Children <7 y started at 6–12 mo after transplantation
Hepatitis B virus	Yes	In countries where it is recommended to the general population starting at 6 mo after transplantation
Papillomavirus	Can be considered	As in the general population starting at 6 mo after transplantation; three doses
Meningococcal conjugate	Can be considered	As in the general population starting at 6 mo after transplantation; two doses
MMR	Individual consideration	Children and seronegative adults. Not before 24 mo after HSCT; not to be given to patients with GVHD
Varicella vaccine	Individual consideration	Seronegative patients, not before 24 mo after BMT; not to be given in patients with GVHD
Zoster vaccine	Not recommended	

BMT, bone marrow transplantation; DT, diphtheria and tetanus toxoids; GVHD, graft-versus-host disease; Hib, *Haemophilus influenzae* type b; HSCT, hematopoietic stem cell transplantation; MMR, measles, mumps, and rubella.
Modified from Ljungman P, Cordonnier C, Einsele H, et al. Vaccination of hematopoietic cell transplant recipients. Bone Marrow Transplant. *2009;44:521–526.*

performed in children showing good immune responses.[114,136] It also has been shown that the degree of immunological immune reconstitution influenced the immune response, with CD4 cells greater than 200 and normal immunoglobulin levels predicting an improved response.[114]

The current recommendations are to start vaccination with three doses of PCV13 at 3 to 4 months after HSCT followed by either a PPSV23 dose in patients without chronic GVHD or PCV13 in patients with chronic GVHD.[24,25] A prospective, but uncontrolled, trial studied the effect of four doses of the PCV13 and showed very strong immune responses to the fourth dose although associated with more side effects.[122] In this study, there was no beneficial effect of a subsequent dose of PPSV23, but this dose was probably given too early after the fourth PCV dose. It is also most likely necessary to give additional pneumococcal vaccine doses during follow-up to maintain immunity to pneumococci but the exact schedule needs to be defined by further studies.[137] There is also a PCV10 vaccine available but this has not been studied in HSCT recipients.

Haemophilus influenzae Type B Vaccine

Immunization with Hib conjugate vaccines can elicit protective immune responses.[105,128,138] It has been reported that time after transplantation is important for the immune response to Hib vaccine in transplanted children.[114,139] A good immune response could be elicited when the donor was immunized before transplantation and the recipient at 3 months after transplantation.[140] Immunization with a Hib vaccine is indicated in all allogeneic HSCT recipients.[24,25]

Influenza Vaccine

Influenza A and B infections can be severe and life-threatening in HSCT recipients[111,141,142] and can occur up to several years after HSCT.[6,141] The time after HSCT is important for vaccine efficacy, with patients vaccinated more than 6 months after HSCT having better responses in most,[8,117,121,143] but not all, studies.[7]

Ambati and colleagues conducted a prospective, randomized study of the impact of pretransplantation immunization of the donor or the recipient followed by influenza vaccination of the patient at 6 months after HSCT and showed an impact on antibody levels by pretransplantation vaccination of the recipient. It is, however, possible that an earlier post-transplantation dose would have increased the immune response.[109] Machado and colleagues found that influenza vaccination performed at least 6 months after stem cell transplantation (SCT) had an 80% efficacy in preventing influenza.[144] Furthermore, T-cell responses after influenza vaccination can be elicited already at 3 to 4 months after HSCT.[145,146]

During and after the H1N1 pandemic, several studies were performed in HSCT recipients. Issa and colleagues studied 82 patients vaccinated a median of 19 months after transplantation (range: 2.5 to 94 months) with one dose of unadjuvanted influenza vaccine.[121] Protective titers were found in 51% of the patients with better responses seen in patients vaccinated later after HSCT (odds ratio [OR], 1.79/year) and poorer responses if the patient had received rituximab during the last year.[121] There was no effect by conditioning or chronic GVHD. Engelhard and colleagues studied 55 patients vaccinated a median of 27 months after HSCT (1–290 months) with two doses of an AS03-adjuvanted vaccine (Pandemrix, GlaxoSmithKline). The protection rate after two doses was 48.7% and the seroconversion rate 41.9%.[7] Factors influencing seroconversion were the absolute lymphocyte count (OR, 3.04) and donor type (OR, 14.0) with better responses in patients receiving grafts from human leukocyte antigen–identical donors but with no effect of time of influenza vaccination after HSCT.[7] De Lavaillade and colleagues studied 26 allogeneic HSCT recipients receiving two doses of the same adjuvanted vaccine

at a median time from HSCT of 39 months (range, 6 to 127 months).[8] The seroprotection rates were 45% after one and 73% after two doses, but significantly lower than found in healthy controls. The only factor influencing the response was time after HSCT. T-cell responses to influenza were observed in 40% of the patients. Dhédin and colleagues reported comparable immune responses after two doses of adjuvanted pH1N1 vaccine to those seen after natural infection when analyzed 6 months after vaccination.[123] All four studies reported that the vaccines were safe. Dhédin and colleagues reported, however, that four patients developed worsened chronic GVHD.[123]

Influenza vaccination with the inactivated vaccine is recommended for all allogeneic HSCT recipients starting at 6 months after HSCT and starting as early as 4 months after HSCT during a community outbreak. Children 6 months to 8 years of age should be given a second dose. The live attenuated influenza vaccine should not be used in HSCT recipients. Another recommended strategy is to immunize family members and hospital staff, thereby reducing the risk for transmission of the infection.[24,25,147]

Hepatitis B Virus Vaccine

Severe primary HBV infections are rare after HSCT unless an HBV-positive donor is used for a seronegative recipient. Loss of preexisting immunity is quite common and can result in virus reemergence with or without signs of hepatitis. Immunization early after HSCT is likely to be ineffective unless the donor is immunized. Jaffe and colleagues based start of vaccination on grade of immune competence.[118] Of 292 patients who were vaccinated, 187 (64%) seroconverted, a rate lower than in age-matched controls. Older age and history of chronic GVHD were associated with lower responses. In another study, the rate of seroconversion after vaccination was higher when the patient, the donor, or both had been vaccinated before HSCT.[148] The immunization of the marrow donor allows a transfer of immunity to the recipient[104,106] and can be long lasting in at least 50% of patients.[149] Case reports further suggest that transfer of immunity from an HBV-immune donor can clear the virus from an HBV antigen and DNA-positive recipient.[150,151] Another important issue is to prevent HBV seroreversion in seropositive individuals. Vaccinated patients are significantly less likely to experience HBV reactivation compared to unvaccinated controls.[152,153] HBV seropositive patients should receive antiviral prophylaxis until vaccinations can be given after HSCT to prevent seroreversion and viral replication. Vaccination is recommended after allogeneic HSCT.[24,25]

Tetanus Toxoid, Diphtheria Toxoid, and Inactivated Poliovirus Vaccines

Several studies of immunization with these vaccines have been published.[99–101,120,154] A new primary schedule with repeated doses of these vaccines is needed to obtain stable protective immunity.[99–101,120,154] Gerritsen and colleagues immunized children before bone marrow transplantation (BMT) followed by revaccination as early as 6 weeks after BMT. Thirty percent of the patients responded to early immunization.[107] The inactivated poliovirus vaccine should be used. It has been shown that robust and lasting immune responses to poliovirus vaccine can be obtained when immunizations are started at 6 months after HSCT.[154] It was shown that more than 90% of allogeneic HSCT recipients remained protected against poliovirus at 10 years after vaccination with a three-dose schedule.[155] The vaccination of allogeneic HSCT recipients with three doses of tetanus toxoid, diphtheria toxoid, and inactivated poliovirus vaccine is recommended.[24,25] Because posttransplantation patients should be viewed as "never vaccinated" they should receive full doses of toxoids, DT vaccine, and not with the vaccines normally used for booster doses to adults.

HSCT patients might be vulnerable to pertussis although the documentation for severe infections is limited.[156,157] In young children, it is logical to vaccinate against pertussis together with diphtheria, and tetanus since many available vaccines include the pertussis component (diphtheria, tetanus, and acellular pertussis [DTaP]) as well as the Hib and inactivated polio vaccine components. The immune response to tetanus, diphtheria, and pertussis (Tdap) is poorer than to DTaP.[158] Pertussis vaccination can be considered in older children and adults but then it is most likely more effective to use a vaccine with higher pertussis content (P) although these vaccines are not licensed for adults.[24,25]

Human Papillomavirus Vaccine

HSCT patients are prone to develop papillomavirus complications such as cervical dysplasia.[159] The vaccines are safe and efficient in immunocompetent individuals. No study has been performed to show efficacy in HSCT patients, but it is logical to vaccinate HSCT recipients at similar age as in the general population. There are no data supporting vaccination of already human papillomavirus–infected HSCT recipients, but this could be a topic for future studies.

Cytomegalovirus Vaccine

CMV is one of the most important pathogens encountered by patients after HSCT. Vaccines based on new vaccine technologies, such as DNA plasmid–based vaccines, subcomponent vaccines, and vaccines using other viral vectors, are currently in clinical development. A Phase II study of a DNA plasmid vaccine containing plasmids for glycoprotein B and pp65 elicited T-cell responses and reduced the rate of CMV DNAemia[160,161] and a Phase III study is ongoing.

Other Nonlive Vaccines

Vaccination with a meningococcal polysaccharide vaccine can elicit good responses in HSCT recipients against both serogroups A and C.[162] Mahler and colleagues studied the tetravalent conjugated meningococcal vaccine in 46 patients, mainly children, at a median of more than 2 years after HSCT.[163] The response rate to the different serotypes varied between 30% and 52%. Seven of 46 patients (15%) responded to all serotypes and 16 (35%) did not respond to any serotype. Sixteen patients received a second dose and eight (50%) of the 16 responded to responses against all serotypes. Meningococcal vaccination is recommended to older children and teenagers after allogeneic HSCT[24,25] but can be considered in other age groups in countries were vaccination for the general population is recommended.[164]

There are also vaccines for HSCT patients living in certain areas of the world or traveling to these areas. These include vaccines against hepatitis A, tickborne encephalitis, and Japanese encephalitis. There are very limited data regarding serological responses to these vaccines but the risk for significant side effects should be similar to the normal population.

Live Vaccines

Varicella Vaccine

Primary VZV infections can be very severe after HSCT. The existing vaccine is live and attenuated and should not

be used early in the posttransplantation period. A seronegative patient should, if possible, be immunized before transplantation, providing that enough time can elapse from the vaccination to the transplantation procedure. No data exist regarding the interval needed between vaccination and start of conditioning but rash after vaccination has been noted up to 60 days after vaccination in patients with cancer undergoing chemotherapy and in children with acute leukemia in remission.[82,165] Children with acute leukemia who have been immunized with the varicella vaccine have subsequently undergone allogeneic HSCT. The care of varicella-seronegative HSCT recipients is frequently problematic; exposure to varicella-infected individuals is not uncommon and either prophylactic zoster immunoglobulin or antiviral prophylaxis is needed. Vaccination of seronegative family members of allogeneic HSCT recipients is recommended.[164] A few uncontrolled studies have been performed and reported that varicella vaccination is safe and can result in seroconversion if performed more than 2 years after HSCT in patients without chronic GVHD and without ongoing immunosuppression.[113,166,167]

A high proportion of HSCT patients develop herpes zoster that occasionally becomes severe. Redman and colleagues used heat-inactivated varicella vaccine and showed that immunization conferred no reduction in the risk but a reduced severity of the herpes zoster.[168] Inactivated varicella vaccines are currently in development. However, the immune response in allogeneic HSCT recipients was poor in a Phase II study with a heat-treated vaccine.[88] Issa and colleagues gave one dose of live zoster vaccine to 58 allogeneic HSCT recipients and did not note any significant side effects.[169] Because of the proven efficacy and safety of acyclovir prophylaxis,[170] vaccination with the live zoster vaccine is not recommended during at least the first 2 years after HSCT.

Measles, Mumps, and Rubella Vaccine

With the return of measles in many countries, protection against this infection is important because a majority of allogeneic HSCT patients will become seronegative to measles during extended follow-up.[103,171,172] The loss of immunity is more rapid in patients previously vaccinated against measles compared to those having experienced natural infection.[172] There are documented cases of fatal measles in BMT recipients.[89,173] In an outbreak in Brazil, one of eight patients with measles developed interstitial pneumonia but all survived.[171] Immunization can only be considered in a patient without chronic GVHD or without ongoing immunosuppression. Existing data indicate that measles vaccine can be given safely at 2 years after HSCT.[102,174] During the outbreak in Brazil, patients were vaccinated at 1 year after HSCT without serious side effects.[175] The reported effect of vaccination varies between different studies with a seemingly higher response rate in adults than in children.[102,130,175,176]

Rubella vaccine could be indicated in female patients who have retained the potential for becoming pregnant. Existing data indicate that rubella vaccine can be given without severe side effects at 2 years after BMT in patients without chronic GVHD or without ongoing immunosuppression.[102] The effectiveness of the vaccine is high.[102,176] The risk for severe infections with mumps virus in HSCT recipients is likely to be very low, although a case report of a fatal infection in a HSCT recipient has been published.[177] Furthermore, the efficacy of mumps vaccination to induce long-lasting serological immunity is rather poor.[176] Vaccination with MMR is recommended in children and seronegative adults. A second dose of MMR is recommended in children younger than 9 years old.[24,25]

Other Live Vaccines

Other vaccines that can be considered in allogeneic HSCT recipients are BCG and yellow fever. The possible benefits must be weighed against the risk for side effects. Rio and colleagues have reported three patients who were immunized with yellow fever vaccine at 5 years after HSCT without severe side effects[178] and this experience has been expanded to 25 patients without any serious side effects (B. Rio, personal communication, 2001). Immunization could be considered in patients, who live in or must visit areas where yellow fever is endemic at least 2 years after HSCT and if the patient is without GVHD and without ongoing immunosuppression. The BCG vaccine can cause severe infections in patients with depressed T-cell function and is not recommended in HSCT recipients.[24,25]

Autologous Hematopoietic Stem Cell Transplantation Recipients

In autologous HSCT recipients, the immune regeneration is faster than after allogeneic HSCT. Autologous HSCT patients are usually not prone to severe vaccine preventable infections during the early phase after transplant. Several studies have shown that autologous transplant recipients will also lose protective immunity to tetanus, poliovirus, and measles during a long-term follow-up.[101,179–182] Many patients undergoing autologous HSCT for lymphoma will have received rituximab, which negatively influences the responses to vaccination.[8,9]

Nonlive Vaccines

Influenza Vaccine. Influenza virus vaccination is recommended starting at 4 to 6 months after autologous HSCT.[24,25] However, the response is likely to be suboptimal early after transplantation.[7,117,143] It has been shown that rituximab blocks the immune response to influenza vaccine for at least 6 months after HSCT and probably longer in many patients.[9,10,41] No data exist with the live attenuated vaccine since it is contraindicated in this population.

Pneumococcal Vaccine and Conjugated *Haemophilus influenzae* Type B Vaccine. Autologous HSCT patients are less prone than allogeneic patients to develop severe infections with Hib or pneumococci and the infections are more likely to occur early after the transplantation when the response to immunization is poor. The response to a single dose of PPSV23 is poor regardless of the stem cell source,[105,183] and remains decreased compared to controls for several years after transplantation for lymphoma.[182] Vaccination with the PCV7 was shown to be effective and induced protective antibody levels in more than 60% of the patients.[184] Vaccination before stem cell harvest resulted in significantly higher antibody levels at all studied time points up to 12 months after HSCT. Vaccination with PCV13 is recommended starting at 3 to 6 months after autologous HSCT.[24,25] It is likely that treatment with rituximab will decrease the responses, but it has not been systematically studied.

Tetanus Toxoid, Diphtheria Toxoid, Pertussis, and Poliovirus Vaccine. Autologous HSCT recipients have an increased risk compared to the normal population to lose protective immunity to poliovirus,[180,182] diphtheria,[182] and tetanus.[179] Reimmunization with repeated doses of inactivated poliovirus vaccine, diphtheria toxoid, and tetanus toxoid effectively restores protective immunity.[101,180,182,183] There was no difference in response to tetanus toxoid in autologous bone marrow or peripheral blood stem cell graft recipients.[183] The immune

response early after the autologous HSCT can be improved by immunizing the patient before the stem cell harvest followed by tetanus toxoid given repeatedly after the autologous HSCT.[185] Vaccination with reduced-dose pertussis vaccine (Tdap) failed to induce immune responses in most autologous HSCT recipients.[186] Immunization with tetanus toxoid, diphtheria toxoid, and inactivated poliovirus is recommended after autologous HSCT.[24,25] Vaccines included pertussis antigen DTaP is recommended in children.

Live Attenuated Vaccines

Measles, Mumps, and Rubella Vaccine. Individuals who have been immunized against measles before autologous HSCT frequently become seronegative during follow-up, whereas patients having experienced natural measles infection usually remain immune.[181] The risk for side effects after immunization seems to be low if the vaccine is administered later after transplantation.[181] MMR vaccination is recommended for children and seronegative autologous patients not earlier than 24 months after HSCT.[24,25] Two doses are recommended in children younger than age 9 years.

Varicella-Zoster Virus Vaccine. In seropositive patients undergoing autologous HSCT for lymphoma, a randomized study was performed with heat-inactivated varicella vaccine given in four doses: within 30 days of vaccination, and 30, 60, and 90 days after the first vaccination. During the 12 months posttransplantation, the rate of zoster was 13% in vaccinees and 33% in unvaccinated patients, giving an efficacy of 61%.[187] Sasadeusz and colleagues gave one or two doses of the live varicella vaccine 4.5 to 6 months after HSCT and showed that the immune responses were rather poor but no severe side effects occurred.[188] Issa and colleagues vaccinated 52 autologous HSCT recipients with the live zoster vaccine around 2 years after transplantation and did not note any significant side effects.[169] There is, however, one death reported with the vaccine strain 4 years after autologous HSCT in patient with untreated non-Hodgkin lymphoma relapse.[86] The safety of live varicella or varicella-zoster vaccines after autologous HSCT must be balanced against other options such as acyclovir/valacyclovir prophylaxis or the potential receipt of the inactivated varicella vaccine when it is available.

Two studies have reported on inactivated vaccines in development. Stadtmauer and colleagues reported on a Phase I/II placebo-controlled study in which 121 adult patients were vaccinated with three doses of an adjuvanted subunit varicella vaccine.[189] Patients receiving the vaccine had improved $CD4^+$ and antibody responses compared to those given placebo. Mullane and colleagues studied four doses of a heat-inactivated vaccine. The vaccine was able to induce both antibody and cell-mediated immune responses.[88] Phase III studies are ongoing.

SOLID-ORGAN TRANSPLANT RECIPIENTS

The need for immunization in solid-organ transplant (SOT) recipients can arise from three factors, each causing a suppression of the immune system: the immunosuppressive activity of the underlying disease (e.g., chronic renal failure), rejection of the organ graft, and the immunosuppressive therapy given after the transplantation. It is recommended that immunizations be given to candidates awaiting transplantation as the patient is more likely to respond to the vaccine pretransplantation than after the transplantation.[24,25,190] Children awaiting transplantation should complete vaccination schedules appropriate for their age.[24,25]

The optimal time to begin vaccine administration after transplant is not well defined. The immunosuppressive therapy is often most intense during first couple of months and likely will influence the immune response to vaccination. However, this has not been well studied. Table 69.4 summarizes the recommendations.

Nonlive Vaccines

Pneumococci and *Haemophilus influenzae* Type B

Both transplantation candidates and SOT recipients are at an increased risk for invasive pneumococcal infection.[191] Protective titers can be attained after PPSV23 in most candidates,[192] although these titers can wane within 2 years.[193] Children, who are candidates for SOT, should receive pneumococcal vaccine and vaccine against Hib according to their age-appropriate schedules.

There have been conflicting reports regarding the efficacy of the PPSV23 after transplantation. In some studies it was reported to be similar to that in healthy controls after liver,[194] heart,[194,195] and renal transplantation.[196] In other studies, the antibody responses were reported to be suppressed after heart[197] and liver transplantation.[198] Furthermore, the antibody levels declined faster than in controls.[199] Kumar and colleagues conducted a double-blind, randomized study of conjugate and a polysaccharide pneumococcal vaccine in adult renal transplant recipients[200] and found no clear differences in immune responses between the two vaccines. At the 3-year follow-up the antibody concentration declined significantly in both groups.[201] However, adult liver transplant recipients did not have an enhancement in response to PPSV23 when they received a prior dose of PCV7. Similar results were seen in adult renal transplant recipients.[202] Barton and colleagues found that two doses of PCV7 was enough to give twofold or more titer increases in all types of patients, but heart and lung recipients appeared to benefit from a third PCV7 dose.[203] The PPSV23 dose gave significantly higher antibody levels to some PCV7 serotypes. Another study using two doses of PCV7 followed by PPSV23 in children found that rises in serotype-specific antibody occurred after the first dose of PCV7, although at lower titers than in controls.[204] The ACIP recommends one dose of PCV13 followed by a dose of PPSV23 at least 8 weeks later to immunocompromised patients including SOT patients ("prime-boost" strategy).[22,23]

Influenza

Influenza can cause severe infections in SOT patients. In one survey of patients infected with the H1N1 pandemic virus, the risk for pneumonia was reported to be 32% and the mortality 4%.[4] The reported results of immunization vary with the age of the patients, time after transplant, and type of immunosuppression given. Adults recipients of renal,[205] liver,[206,207] heart,[195,208] and lung transplantation[209] have poorer antibody responses than immunocompetent controls. Similar results were found with the pandemic H1N1 vaccine.[210,211] The responses were reported to be better in patients awaiting liver transplantation than in patients after the transplantation.[212] Some but not all studies have noted increased responses with repeat doses of influenza vaccine.[207] In contrast, studies showed normal responses in children after renal[213–215] and liver transplantation.[216] One study showed that the frequency of influenza-specific antibody-secreting cells in peripheral blood was significantly reduced in stable transplant recipients compared to healthy controls.[217]

The immunosuppression given posttransplantation influences the response. In lung transplant recipients, mycophenolate mofetil was associated with a poorer response and

TABLE 69.4 Recommendations for Immunizations in Solid-Organ Transplant Recipients

Vaccine	Recommendations for		Comments
	Candidates	Recipients	
NONLIVE VACCINES			
Pneumococcal polysaccharide	Yes	Yes	Children >2 y and adults
Pneumococcal conjugate	Yes	Yes	Children and adults
Conjugated Hib	Complete schedule	As in the normal population	
Influenza	Yes	Yes	Adults and children; annually
Hepatitis A virus	Yes	Yes	Adults and children undergoing liver transplantation
Hepatitis B virus	Yes	Yes	Adults and children
Inactivated poliovirus	Complete schedule	Complete schedule	Boosters can be considered posttransplantation
Tetanus and diphtheria toxoid	Complete schedule (children)	Complete schedule (children)	Boosters can be considered posttransplantation
Acellular pertussis	Yes	Older children and adults	
Papillomavirus	Yes	Yes	As in the general population
Meningococcal	Yes	Yes	As in the general population
LIVE VACCINES			
MMR	Complete schedule	No	
Varicella	Yes	No	Before transplantation in seronegative patients
Zoster	Age dependent	No	

Hib, *Haemophilus influenzae* type b; MMR, measles, mumps, and rubella.
Modified from Avery RK, Ljungman P. Prophylactic measures in the solid-organ recipient before transplantation. Clin Infect Dis. *2001;33(Suppl 1):S15–S21; and Danzinger-Isakov L, Kumar D. AST Infectious Diseases Community of Practice. Guidelines for vaccination of solid organ transplant candidates and recipients.* Am J Transplant. *2009;9(Suppl 4):S258–S262.*

sirolimus with a better response.[209] It has been suggested that intradermal vaccination can improve the immune response in renal transplant patients,[218] but a randomized study did not confirm the improved immunogenicity in all groups.[219] A Phase I study in children having undergone SOT with high-dose influenza vaccine has been performed. The study showed a higher risk for mild local and systemic side effects and a higher seroconversion rate to one of the antigens although the study was not powered to assess the latter.[220] Also the cellular immune responses to influenza vaccine have been studied and found to be impaired in some,[221,222] but not all, studies.[223]

Despite systematic reviews showing that SOT patients respond more poorly to influenza vaccine than healthy controls,[51,224] vaccinated transplantation patients had a lower risk for influenza-like illness and laboratory-verified influenza compared to nonvaccinated controls.[51] Magnani and colleagues also reported that vaccination of heart transplant recipients reduced the proportion of patients developing influenza-like symptoms.[225] In a retrospective analysis of pediatric liver transplant patients during the H1N1 pandemic, the frequency of infection was 4% in vaccinated patients when compared to 25% in unvaccinated patients.[226]

Several studies have analyzed the risk for graft rejection after vaccination with influenza vaccine and found no increased risk.[195,206,208,225,227–231] However, case reports do exist that report organ rejection after vaccination.[232–234] There are also reports of increased alloreactivity after influenza vaccination.[235] On the other hand, a large cohort study of more than 50,000 renal transplant recipients showed a reduced risk for allograft loss and death during the first year after transplantation in patients receiving influenza vaccine.[236] Given all the available data, the benefits with influenza vaccination are far greater than the possible risks.[190]

Inactivated influenza vaccine is recommended to be given annually to SOT recipients.[24,25] Because influenza can be severe in patients with end-stage organ disease, influenza vaccination with the inactivated seasonal influenza vaccine is recommended also to transplantation candidates.[24,25] No data exist with the live attenuated vaccine and it is contraindicated in this population.[24,25,190]

Tetanus, Diphtheria, and Pertussis Vaccines

Less than 50% of patients with chronic kidney disease have protective titers against tetanus. Although the response rates after vaccination were decreased,[237] vaccination of transplantation candidates is recommended either to complete the primary schedule (young children) or with a booster dose of Tdap (older children and adults).[24,25,190]

In children who had undergone renal transplantation, persistent immunity to diphtheria was found in 38% and to tetanus in 90%.[238] After vaccination, 35% and 32% of patients were protected against diphtheria at 1 and 5 years, respectively.[238] A booster dose gave protective antibody levels to diphtheria in 95% of patients, but at 12 months only 76% remained protected[238] while all patients remain protected against tetanus. Pertussis vaccination after SOT has not been studied, but continuation of the recommended immunization with DTaP is recommended.[24,25]

Hepatitis B Virus Vaccine

Protection against HBV infection can be transferred to a SOT recipient either by an HBV-positive organ graft or through transfusions. HBV vaccination is recommended in HBV-negative candidates because there is an increased risk of severe

HBV infections in transplantation patients. Furthermore, patients receiving grafts from HBV immune donors have a lower risk for posttransplantation de novo HBV infection.[239] The efficacy of HBV vaccine was low in patients on hemodialysis[240,241] and in patients with end-stage liver disease waiting for transplantation.[242,243] Different schedules have been used in attempts to improve the response to vaccinations, including accelerated dose schedules and double-strength doses.[244–247] The seroconversion rates in the different studies varied from 31% to 62%. One study found a higher response rate after repeated high-dose (80 μg) vaccine doses in nonresponders.[248] Factors associated with better responses were young age,[244,249] a diagnosis of biliary atresia,[250] a milder grade of liver disease,[244] and specific human leukocyte antigen types.[244] Besides poor initial responses, the antibody levels decreased rapidly so that up to 35% of the patients who had seroconverted became seronegative after liver transplantation.[244,245,249] Despite the less-than-optimal responses, pretransplantation immunization is recommended.[190]

The efficacy of HBV vaccination was reported as being low with standard vaccine schedules in adults, with response rates between 5% and 15%.[251,252] Reports suggest that pediatric liver transplant patients can achieve better vaccination responses (70% seroconversion).[253] The immunosuppression administered to prevent rejection also influences the vaccination response. Patients receiving triple immunosuppression (cyclosporine, corticosteroids, and azathioprine) responded less well than patients receiving cyclosporine alone.[253] HBV vaccinations with the aim to prevent reactivation in patients transplanted for HBV-induced cirrhosis have given different results. Sanches-Fueyo and colleagues reported good results using a double dose of HBV vaccine,[228] whereas Angelico and colleagues reported poor results with a similar strategy.[254] Another option to improve the immunogenicity is intradermal HBV vaccination. Choy and colleagues reported a 62% response rate to intradermal HBV infection in renal transplant recipients failing intramuscular vaccination.[255] Attempts to prevent HBV reactivation in patients receiving liver transplants for HBV-related liver disease with the combination of lamivudine and a double dose of vaccine have been unsuccessful.[256,257] New vaccine approaches are needed. For example, two studies using experimental adjuvants have given promising results with response rates of 50% to 80% in subjects transplanted for HBV-related disorders.[258,259] A booster with conventional vaccine has also been shown to enhance long-term immunity.[260]

Hepatitis A Virus

Hepatitis A virus can cause decompensation and death in patients with chronic liver disease. Patients with chronic liver or renal disease awaiting transplantation are able to respond to vaccination, although the results are not as good as in healthy individuals.[261,262] Loss of immunity in seropositive patients was reported to occur in 29% of the patients at 2 years posttransplantation.[263] In a large study of kidney transplant recipients in South Korea, 19% were seronegative. Fifty-two patients received two doses of hepatitis A virus vaccine and the seroconversion rate was only 27% with lower serum creatinine and higher hemoglobin being positive predictors for improved response.[264]

Vaccination of transplantation candidates is recommended, particularly those with liver disease.[190] The combined hepatitis A/B vaccine is potentially useful in pretransplantation immunization. Vaccination results after liver or renal transplantation are poorer compared to those in healthy individuals,[249,265] and antibody levels decrease more rapidly.[265]

Papillomavirus Vaccine

SOT patients are at higher risk for human papillomavirus-related genital warts, cervical cancer, and other anogenital malignancies.[266] A small study in adolescent kidney and liver transplant recipients showed that 100% responded to vaccination with the quadrivalent human papillomavirus vaccine.[267] Indications for vaccination against papillomavirus should be the same as for the general population but because of an increased rate of warts, the quadrivalent vaccine might be preferable in SOT candidates and recipients.[24,25]

Cytomegalovirus

CMV is an important pathogen in patients after SOT. A live attenuated virus vaccine based on the Towne strain showed a reduction in the severity of CMV disease and a reduction in graft rejection primarily in seronegative recipients getting organs from seropositive donors,[268,269] but this vaccine is no longer available. In a Phase II study, a glycoprotein B–based subunit vaccine was given before and twice after liver and renal transplantations. The vaccine induced glycoprotein B–specific antibodies and was associated with fewer days of CMV viremia and fewer days of ganciclovir therapy in seronegative patients receiving grafts from CMV seropositive donors.[2] Further studies are necessary to determine if inactivated CMV vaccine will be clinically useful in SOT recipients.

Other Nonlive Vaccines

A study performed in heart transplant patients reported lower vaccine response to tickborne encephalitis vaccine compared to healthy controls.[270] There are no data regarding meningococcal vaccine specifically in transplantation candidates or recipients. Many SOT recipients travel, and there might be indications for "travel vaccines." However, there are no data supporting efficacy for most of these vaccines, making it important to get expert advice before traveling to countries where there is need for specific vaccines.

Live Attenuated Vaccines

Immunization with live vaccines is not recommended after SOT because of the risk of vaccine-associated complications.[24,25] The risk of vaccine-associated disease from pretransplantation administration of live vaccines has not been defined but is likely to be time-dependent with lower risks if the interval from vaccination to transplantation is longer.

Varicella Vaccine

VZV can cause severe and potentially fatal disease in patients after transplantation. It is important to consider the vaccination of seronegative candidates prior to transplantation. Varicella vaccine given to uremic children prior to transplantation was shown to be safe and reduced the posttransplantation risk for varicella.[271] A follow-up showed that the protection was long lasting, with 42% of the patients still having antibodies at more than 10 years after immunization. Furthermore, the risk for varicella was lower and if disease occurred, it was significantly less severe in previously vaccinated subjects.[271] A large study of more than 700 children showed that vaccination before renal transplantation reduced the incidence of both varicella and zoster.[272] A two-dose schedule was given to 50 children awaiting renal transplantation and the seroconversion rate was 98%.[273] Similar results of a single vaccine dose were seen in a study of children with chronic liver disease, with a vaccination efficacy of 100% and no severe side effects.[274]

In another study, 95% of pediatric liver candidates given vaccine prior to transplant seroconverted.[275] A small number of adults who are seronegative to VZV would also benefit from vaccination.

The zoster vaccine decreases the risk for zoster reactivation in elderly individuals for up to 8 years after vaccination.[276] Whether pretransplant zoster vaccination would reduce the risk for posttransplant zoster is unknown but could be considered in candidates fulfilling standard criteria for zoster vaccination.

Vaccination of VZV seronegative patients after transplantation might be contemplated. There have been a number of small studies suggesting safety of varicella vaccine given after transplant.[275,277–281] In one study that included 17 renal transplant recipients, the authors reported an 85% seroconversion rate and only three posttransplant patients developed mild varicella.[277] In another study, booster doses of varicella and MMR vaccine were administered to 15 pediatric liver recipients whose titers had waned, and augmentation of seroresponse was noted without severe adverse effects or rash.[275] However, these patients are likely to have retained some cell-mediated immunity. In a study of 16 pediatric liver and small bowel transplant recipients, 87% of the patients developed both humoral and cell-mediated immunity.[278] Three of the 16 patients were given acyclovir for vaccine induced rash. However, there are also reports of significant varicella virus disease after varicella vaccination in transplant recipients[282,283] and further studies are needed to assess both efficacy and safety of this approach. The availability of inactivated varicella-zoster vaccines will provide new opportunities to evaluate vaccination in transplant recipients.

Measles, Mumps, and Rubella

MMR vaccine has been given to infants awaiting renal transplantation with good responses: 88% of the patients developed immunity to all three components of the vaccine.[284] Analyzing the components separately, 89% developed immunity to measles, 88% to mumps, and 100% to rubella. In another study, 42 seronegative pediatric candidates were vaccinated with measles vaccine with a seroconversion rate of 97% and no significant side effects.[285] Children who are transplantation candidates and not yet vaccinated with MMR should be vaccinated, unless transplantation is imminent.

Other Live Vaccines

There are no data regarding vaccination with other live vaccines such as rotavirus, yellow fever, or BCG either prior to or after transplantation. In general, live vaccines should not be used after solid-organ transplantation.[24,25] However, children awaiting transplantation should receive age appropriate vaccines including that infants waiting for solid-organ transplantation should be vaccinated with rotavirus vaccine starting at 2 months of age.[24,25] It was shown that antibodies to yellow fever were retained in 98% of SOT recipients at a median of 3 years after solid-organ transplantation.[286] However, it is likely that the interval between vaccination and transplantation is important for the risk of postvaccination disease and an interval from vaccination to transplantation of at least 4 weeks is recommended.[24,25]

PRIMARY IMMUNODEFICIENCY DISEASES

Primary immunodeficiency diseases (PIDs) include genetic disorders affecting the functioning of either the innate or the adaptive immune systems. Many different types exist whose causes are now rapidly being detected by molecular genetic analysis. These disorders increase the risk for infections, making it important to vaccinate these children when it is possible and safe. The sensitivity to and spectrum of infections seen in these patients and thereby the need, effectiveness, and risks of vaccination are determined by the genetic defect. The less pronounced of the defects are frequently diagnosed later during childhood and routine pediatric immunizations have been administered to many. Other immune defects, such as disseminated BCG infections, are diagnosed as a result of a vaccination. Most PIDs are rare to very rare and therefore clinical trials in patients with each defect are impossible to perform. The defects can be broadly classified as:

- Defects of the innate immune system including diseases with complement deficiencies, defects in the phagocytic cell functions, and diseases associated with cellular receptors and signaling pathways involving cytokine production.
- Defects of the adaptive immune system including major defects in antibody production such as X-linked agammaglobulinemia, common variable immunodeficiency as well as more minor defects such as IgA deficiency or Ig subclass deficiencies and specific polysaccharide antibody deficiency. The most severe of these patients require lifelong immunoglobulin substitution therapy and are rarely candidates for vaccination.
- Combined defects that involve T-cell function. These include many different disorders such as severe combined immunodeficiency, Wiskott-Aldrich syndrome, DiGeorge syndrome, X-linked hyper-IgM syndrome, severe ataxia-telangiectasia, familial hemophagocytic lymphohistiocytosis with perforin mutations, and several other very rare disorders.

Nonlive vaccines pose no increased risk for side effects, but immunogenicity and efficacy are problematic. Consequently, the recommendation is to give nonlive vaccines according to the same schedule as for healthy children. Regarding live vaccines, the summaries given below must be seen as generalizations and expert advice should be solicited before vaccinating children with specific rare defects. The use of oral poliovirus vaccine has resulted in paralytic disease in some patients with PIDs although it can be argued that many patients have received this vaccine before the diagnosis of the immune defect was made. However, this vaccine is no longer available in many countries including the United States. Family members of immunodeficient patients should also receive the inactivated vaccine.

Defects of the Innate Immune System

Nonlive Vaccines

Pneumococcal, *Haemophilus influenzae* Type B, Meningococcal Vaccine. Patients with primary complement deficiencies are at a very high risk for invasive meningococcal disease.[287] A deficiency of the early complement components C2 to C4 also increases the risk for pneumococcus and Hib disease. Vaccination with the quadrivalent meningococcal polysaccharide vaccine gives good serological responses in patients with complement deficiencies.[288–290] These patients also need to be revaccinated regularly to maintain protective antibody levels.[288,290] There is no study specifically addressing efficacy of the meningococcal conjugate vaccine. Because of its improved immunogenicity, however, it is recommended for use in patients with complement deficiencies.[24,25,291] In ataxia-telangiectasia there is known to be a poor response to PPSV23 in the majority of patients. In three small studies, PCV7 was immunogenic in most ataxia-telangiectasia patients, although not comparable to normal controls.[292–294] The same is suggested for patients with specific polysaccharide antibody

deficiency. Vaccination with PCV13 and Hib conjugate vaccines should be given to patients with defects in the innate immune system.[24,25]

Tetanus Toxoid, Diphtheria Toxoid, Inactivated Poliovirus, and Acellular Pertussis Vaccine. These vaccines should be given to children with complement deficiencies, phagocyte defects, and defects in cytokine production in a similar schedule as in normal children.

Influenza. Inactivated influenza vaccine should be given to children with complement deficiencies, phagocyte defects, and defects in cytokine production.[24,25]

Live Attenuated Vaccines

Varicella Vaccine and Measles, Mumps, and Rubella. Live attenuated varicella vaccine and MMR can be given to children with chronic granulomatous disease and early or late complement defect disorders.[295] A number of molecular genetic changes can result in defects of the antiviral immunity. Consequently, expert advice should be solicited before vaccinating children with phagocytic or cytokine generation disorders.

Other Live Vaccines. There are a number of case reports of disseminated BCG in patients with cytokine generation disorders[296–298] and in patients with other defects in the innate immune system.[299,300] BCG should generally be avoided in patients with PIDs. Patients with cytokine generation disorder are at increased risk for *Salmonella* infections.[301] Therefore, oral typhoid vaccine should also be avoided. There are very limited data regarding the oral rotavirus vaccine in patients with PID.

B-Cell Defects

Nonlive Vaccines

Pneumococcal and *Haemophilus influenzae* Vaccines. Patients with mild to moderate defects in the B-cell function, including IgA deficiency, should be vaccinated against pneumococci and Hib similarly to healthy children. Children with specific polysaccharide antibody deficiency or ataxia-telangiectasia should receive PCV13 and those older than 2 years of age should also receive a dose of PPSV23.[24,25] Patients with more substantial defects in Ig production and on Ig supplementation therapy are unlikely to respond. In cases of specific polysaccharide antibody deficiency, the use of conjugate vaccines might to some extent overcome the defect and produce some antibody response.[302] Studies of patients with common variable immunodeficiency using polysaccharide and conjugate vaccines showed that a subset of patients produce immune responses correlated with the clinical severity of the underlying disease.[303–305]

Tetanus Toxoid, Diphtheria Toxoid, Inactivated Poliovirus, and Acellular Pertussis. These vaccines should be given to children with patients with IgA deficiencies and to other patients with mild to moderate B-cell defects, including subclass deficiencies, although the antibody responses might be suboptimal. Patients with more complete lack of B-cell function are unlikely to respond but there are no risks.

Influenza. Individuals with mild/moderate defects in B-cell function, including IgA deficiency, can receive inactivated influenza vaccine. The efficacy of vaccination has not been studied. Live attenuated influenza vaccine should not be administered to patients with major B-cell defects.

Live Attenuated Vaccines

Varicella and Measles, Mumps, and Rubella. Varicella and MMR vaccines should not be given to patients with significant B-cell deficiencies as it is unlikely that the patients will mount an antibody response and there is a possibility of side effects from the vaccine. In patients with less-severe defects in B-cell function, vaccination with these vaccines can be considered.[295] However, the possibility that patients with B-cell deficiencies also can have defects in the T-cell function, thereby increasing the risk for side effects, should be considered.

Oral Poliovirus Vaccine. Individuals with IgA deficiency can develop vaccine associated poliomyelitis.[306–308] Patients with major B-cell deficiencies should not receive oral poliovirus vaccine.

Combined Immunodeficiency Disorders

Nonlive Vaccines

Pneumococcal, *Haemophilus influenzae*, Inactivated Influenza, Tetanus Toxoid, Diphtheria Toxoid, Inactivated Poliovirus, and Acellular Pertussis. Patients with combined immunodeficiencies can be vaccinated using the same routine immunization schedule as that used for healthy children; however, the more severely affected children are unlikely to respond.

Live Attenuated Vaccines

The data regarding safety and efficacy of vaccinating children with combined immunodeficiencies with live vaccines are limited. Complications from vaccination of T-cell–deficient children receiving live viral vaccines, such as vaccine-associated poliomyelitis[309] disseminated measles infection, and chronic rotavirus infection, have been described.[310–313] Patients with severe combined immunodeficiency, Wiscott-Aldrich syndrome, complete Di George syndrome, and inherited hemophagocytic lymphohistiocytosis should not receive live vaccines, including live attenuated influenza vaccine. In other, less-severe diseases, such as partial DiGeorge syndrome, it has been shown that MMR and varicella vaccines can result in high rates of seroconversion and no severe side effects.[314,315] The number of circulating T cells as well as responses to in vitro T-cell assays have been suggested as markers reflecting the safety of administration of live vaccines in patients with immune defects. Decisions regarding vaccination must be made on an individual basis after assessment of the immune system and consultation with an expert in PIDs.

PATIENTS WITH CHRONIC INFLAMMATORY DISORDERS

Disorders resulting in chronic inflammation include inflammatory bowel diseases (Crohn disease and ulcerative colitis), rheumatological diseases (rheumatoid arthritis, systemic lupus erythematosus [SLE], systemic sclerosis, dermatomyositis), neurological diseases (multiple sclerosis and other autoimmune neurological diseases), and hematologic diseases (autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura). These patients are treated with a wide variety of antiinflammatory agents, including corticosteroids, cytotoxic drugs such as methotrexate and cyclophosphamide, calcineurin inhibitors such as cyclosporine and tacrolimus, and, with increasing frequency, monoclonal antibodies such as tumor necrosis factor (TNF)-blockers or anti–B-cell antibodies including rituximab. Vaccinations of patients with rheumatologic and autoimmune disorders must be

considered from three viewpoints: the response to vaccination during immunosuppressive therapy, the risk for side effects from the vaccines, and the potential risk for flare-up of the underlying disease. Decreased responses to vaccination in rheumatoid arthritis patients treated with rituximab have been shown.[316] In general, patients should be immunized before immunosuppression, if possible, with age-appropriate vaccinations.[24,25]

Nonlive Vaccines

Pneumococcal and *Haemophilus influenzae* Type B Vaccine

The incidence of severe pneumococcal infections is increased 13-fold in patients with SLE.[317] PPSV23 is effective in patients with rheumatoid arthritis and SLE.[318–320] However, Battafarano and colleagues reported that patients on active immunosuppressive therapy had lower immune responses[320] and Elkayam and colleagues demonstrated that 20% to 33% of patients failed to respond to at least one of the analyzed serotypes.[319] PPSV23[318–321] and conjugated Hib vaccines[320] have been shown to be safe and tetanus toxoid and Hib have been shown to be immunogenic in SLE patients.

The effect of TNF blockers on vaccine responses has been studied in patients with rheumatoid arthritis,[322] with no negative impact noted. In contrast, patients treated with methotrexate had a lower response rate to pneumococcal vaccination.[323] Rituximab had a negative impact on the antibody response to PPSV23.[324] There are no reports of disease flares or significant side effects after vaccination with PPSV23 in patients with rheumatoid arthritis. Antibody responses to PPSV23 in 190 adults with rheumatoid arthritis were not adversely affected by treatment with tocilizumab, an anti–interleukin-6 receptor antibody.[325] Nagel and colleagues reported a registry study of the effects of PCV7 and found a nonsignificant reduction in serious pneumococcal infections in patients with rheumatoid arthritis and spondyloarthropathy. The ACIP of the Centers for Disease Control and Prevention has recommended routine use of PCV13 for immunocompromised persons followed by PPSV23 including those receiving immunosuppressive medications.[22,23] However, this regimen has not been studied in patients with inflammatory disorders.

Influenza

Patients with chronic inflammatory disorder (CID) are included in the general recommendations for influenza vaccination of immunosuppressed patients.[24,25] The immunogenicity of influenza vaccine has been studied in patients with SLE. Most patients are able to respond, although the responses tend to be lower in patients compared to healthy controls[326–328] and correlated with the intensity of steroid therapy.[326] Lu and colleagues studied the response to pandemic H1N1 in patients with SLE and found responses similar to controls.[329]

Elkayam and colleagues showed in a study of patients with rheumatoid arthritis and ankylosing spondylitis that patients receiving infliximab responded to vaccination, although the response in patients vaccinated 3 weeks after infliximab had less of an immune response.[330] Van Assen and colleagues studied responses early (1 to 2 months) and late (6 to 10 months) after rituximab and compared them to methotrexate-treated rheumatoid arthritis patients and healthy controls.[331] They found much reduced responses in the rituximab treated patients although there were some increases in geometric mean titer in the group vaccinated later after rituximab therapy. Patients receiving tocilizumab for treatment of rheumatoid arthritis or juvenile idiopathic arthritis had antibody responses to inactivated influenza vaccine that were similar to those of the comparator groups.[332]

Children with rheumatologic diseases respond well to influenza vaccination with seroprotection rates similar to healthy children.[333] Two prospective trials of inactivated influenza vaccine in children with inflammatory bowel disease[334,335] showed that vaccination is safe and effective, although immunogenicity may be decreased in patients treated with TNFα antibodies. Children receiving lower amounts of immunosuppression had seroprotection rates comparable to immunocompetent controls for all three strains in the vaccine. Children treated with TNFα antibodies, however, had normal seroprotection rates to influenza A strains, but lower seroprotection and seroconversion rates to the type B vaccine strain.

In patients with SLE, studies show no increased rate of flare-ups in disease activity in influenza-vaccinated patients than in the controls.[326,327,336,337] Similar results were seen in patients with rheumatoid arthritis and ankylosing spondylitis,[329–331] and in mixed groups of patients with rheumatology disorders.[338,339] As the efficacy is adequate and there are no evident risks, annual influenza vaccination with the inactivated vaccine is recommended for both adults and children with CIDs.

Other Vaccines

Patients with CID respond similarly as healthy controls to tetanus toxoid.[324] A prospective study of HBV vaccination in patients with rheumatoid arthritis demonstrated immune responses in the majority of patients without significant side effects.[340] A large study of meningococcal conjugate vaccine in 234 children and young adults with juvenile arthritis showed that the patients responded well regardless of type and intensity of immunosuppression.[341] Two studies of the quadrivalent papillomavirus vaccine in patients with SLE both showed a high rate of antibody response and no risk for significant side effects.[342,343] Finally, it was shown that two doses of hepatitis A vaccine was required to give protective antibody levels in patients with rheumatoid arthritis treated with TNFα blockers.[344]

Live Attenuated Vaccines

Varicella

Two studies have been published on varicella vaccination in children with CID. Pileggi and colleagues reported varicella vaccination of 25 children with juvenile rheumatoid diseases (20 seronegative children and five children with borderline antibody titers) and compared the results to 18 healthy controls.[345] All 25 patients were receiving methotrexate; 13 were also receiving prednisone and five were also receiving other therapeutic agents. Half the patients responded compared to 72% of the controls, but the responses were not significantly different. The vaccine was well tolerated without signs of dissemination or other side effects. A case series reported results from six children with inflammatory bowel disease where five had received their initial dose of varicella vaccine prior to initiating the immunosuppressive therapy followed by a booster dose after start of therapy. There were no significant side effects seen.[346]

The risk for zoster is increased in patients with CID. Although there are no studies addressing vaccine safety in this population, the Infectious Diseases Society of America guidelines recommend zoster vaccine in patients older than 50 years of age on mild immunosuppression; but zoster vaccine is contraindicated for patients receiving more intensive immunosuppression, including TNFα inhibitors.[24,25]

Other Live Vaccines

There are no data regarding other live vaccines given to adults with CID, but they are not recommended in adults with rheumatoid diseases treated with immunosuppressive therapy. MMR revaccination of patients with juvenile idiopathic arthritis resulted in a good immune response to all three viruses without serious adverse effects despite continued therapy with methotrexate or recent therapy with etanercept or anakinra; however, data are lacking on the safety of primary MMR vaccination in this population. An increase in disease activity was observed in seven patients with multiple sclerosis who were vaccinated with yellow fever vaccine.[347] However, the Committee on Infectious Diseases of the American Academy of Pediatrics states that children who have been given moderate doses of corticosteroids (<20 mg prednisolone in children weighing >10 kg) can receive live vaccines.[295]

HOUSEHOLD CONTACTS OF IMMUNOCOMPROMISED PATIENTS

Household and other close contacts of immunocompromised patients can receive all age-appropriate live vaccines except live oral poliovirus vaccine.[295] Limited data are available regarding the potential for transmission of live attenuated influenza vaccine. However, it is recommended that live influenza vaccine should be avoided in contacts of severely immunocompromised patient groups such as allogeneic HSCT patients early after HSCT or those who are receiving intensive immunosuppression because of GVHD.

FUTURE DIRECTIONS

The number of patients with immunosuppressed states is increasing. The advances in medical technology result in constant changes in groups of patients undergoing intensive immunosuppressive therapy; for example the increase in age of patients undergoing HSCT. At the same time new immunosuppressive agents are being introduced and the types of therapies given to these patients change. Therefore, prospective clinical trials need to be performed to assess the safety, immunogenicity, and efficacy of vaccinations in these new cohorts. These technologies are spreading throughout the world and few if any studies have been performed with vaccines against infectious agents more common in tropical areas. The epidemiology in these countries, and thereby the risks, are different. For example, a high risk for tuberculosis in highly endemic areas, and the risks for yellow fever and hepatitis A virus must be taken into account when assessing the risk-to-benefit and cost-to-benefit of vaccination.[348] The recent outbreak of pandemic H1N1 showed the vulnerability of the immunocompromised populations to new and rapidly spreading infections.[4,6] New vaccines are in development against CMV, varicella, and influenza. These vaccines should be evaluated in immunocompromised hosts because they are vulnerable to both infection and disease.

70 Vaccination of Human Immunodeficiency Virus–Infected Persons

Catherine G. Sutcliffe and William J. Moss

In the absence of effective antiretroviral therapy, HIV-1 infection results in a progressive decline in CD4 T lymphocytes, decreased ability to mount protective responses to new antigenic stimuli, loss of prior immunity, and increased risk of complications from infections. As with other causes of serious immune suppression, HIV-1 infection can impair the effectiveness of vaccines and increase the risk of serious adverse events from live vaccines. Fewer HIV-1–infected children and adults develop protective antibody levels after vaccination than do HIV-1–uninfected persons. The magnitude of the antibody response often is inversely correlated with the CD4 T-lymphocyte count.[1,2] In general, HIV-1–infected adults with CD4 T-lymphocyte counts less than 200 cells/mm^3 and HIV-1–infected children with CD4 T-lymphocyte percentages less than 15 have poor serologic[1,2] responses to vaccines. Of those who develop an initial antibody response following vaccination, antibody concentrations frequently wane at a faster rate in HIV-1–infected persons than in HIV-1–uninfected persons. Live viral and bacterial vaccines pose an increased risk to immunosuppressed HIV-1–infected persons because of the potential for disease caused by uncontrolled replication of the vaccine strain, and this risk increases with severe immune suppression. T-lymphocyte proliferation induced by vaccination can transiently increase plasma HIV-1 RNA levels, but an effect of vaccination on HIV-1 disease progression has not been found.[3]

Vaccination is generally safe and effective early in infancy before HIV-1 infection causes significant immune suppression.[4,5] The rate of progression to clinically apparent immune suppression is variable and depends on factors related to the host and the virus. Accordingly, the safety and effectiveness of vaccines in HIV-1–infected children vary with age at vaccination and immune status of the HIV-1–infected child. Partial or protective immunity usually persists until immune suppression becomes severe, although antibody concentrations to some antigens (measles virus, tetanus toxoid, and hepatitis B virus [HBV]) may wane with lesser degrees of immune suppression.[6] In older HIV-1–infected children and adults, the immune response to primary immunization may be impaired, but protective immunity to vaccines received before HIV-1 infection is usually maintained. Antiretroviral therapy can improve immune responses to vaccines in HIV-1–infected children[7,8] and adults,[9] but probably not to levels found in HIV-1–uninfected persons. Antiretroviral therapy, however, does not restore immunity lost prior to treatment. Deferring vaccination in HIV-1–infected persons with advanced immune suppression until HIV-1 replication is controlled and the immune system reconstituted by highly active antiretroviral therapy (HAART) should result in improved responses to vaccination[1,10] and should be considered if they are not at immediate risk of contracting the vaccine-preventable diseases. As an increasing number of HIV-1–infected children start HAART in early infancy, and even prior to vaccination, their immune responses may more closely approximate those of uninfected children. However, serologic responses may wane even in HIV-1–infected persons receiving effective HAART.

Multiple immunologic abnormalities have been described in HIV-exposed but uninfected children, including reductions in the number of naïve CD4 T lymphocytes, although the clinical significance of these changes is unclear.[11] Consistent with these findings, several studies reported lower vaccine responses among HIV-exposed but uninfected infants compared to unexposed infants, including responses to tetanus toxoid, poliovirus, hepatitis B, and bacille Calmette-Guérin (BCG) vaccines.[12–14] Not all studies, however, identified differences in antibody responses to vaccines between HIV-exposed, uninfected children and HIV-unexposed children,[15,16] and the clinical and public health significance of these observations remain unclear. Assessing vaccine efficacy in exposed, uninfected children is complicated by multiple confounding factors. Whether these infants are less likely to develop protective immunity after vaccination remains to be determined.

GUIDELINES FOR USE OF VACCINES IN HIV-INFECTED PERSONS

Guidelines for vaccination of HIV-1–infected persons consider the risks of vaccination, the risks of exposure to diseases, and the risks of complications from the diseases.[17–20] The World Health Organization recommends administering almost all routinely recommended vaccines for asymptomatic HIV-1–infected children and adults.[18] The exception is BCG vaccine, which is not recommended for children known to be HIV-1–infected because of the increased risk of disseminated BCG disease, although the difficulty of identifying HIV-1 infection shortly after birth is recognized.[21,22] When the diagnosis of HIV-1 infection cannot be made in early infancy, BCG vaccine should be administered at birth to all infants regardless of HIV-1 exposure, and infants exposed to HIV-1 should be closely followed for signs and symptoms of disseminated BCG disease.[21] For HIV-1–infected persons who are severely immunocompromised, yellow fever and measles vaccines are not recommended because of the potential for increased risk of complications,[23,24] although additional safety data are needed. In the United States, varicella and zoster vaccines also are not recommended for HIV-1–infected persons who are severely immunocompromised.[19,20] All other vaccines are recommended for HIV-1–infected persons regardless of symptoms. The World Health Organization and the Advisory Committee on Immunization Practices in the United States recommend measles revaccination of HIV-1–infected children after immune reconstitution with antiretroviral therapy because of waning immunity prior to treatment. In settings where the risk from exposure to disease may be less and testing for immunologic status or alternatives to live vaccines are available, more specific recommendations have been made by advisory committees such as the Advisory Committee on Immunization Practices and the Committee on Infectious Diseases of the American Academy of Pediatrics (Table 70.1).

TABLE 70.1 WHO/UNICEF and ACIP Recommendations for Immunization of HIV-1–Infected Children and Adults[17–20]

Vaccine	HIV-1 Infection	Severe Immune Suppression	Comments
WHO/UNICEF			
BCG	Not recommended	Not recommended	HIV-1 infection can be difficult to identify in early infancy
DTP	Recommended	Recommended	
OPV/IPV	Recommended	Recommended	IPV may be used if symptomatic
Measles	Recommended	Not recommended	Administered at 6 and 9 mo; revaccination after immune reconstitution with antiretroviral therapy
Hepatitis B	Recommended	Recommended	
Hib	Recommended	Recommended	
Pneumococcal	Recommended	Recommended	
Rotavirus	Recommended	Not recommended	
Tetanus toxoid	Recommended	Recommended	5 doses
Yellow fever	Recommended	Not recommended	Until safety is further evaluated
Vaccine	**Children With HIV-1 Infection or AIDS**	**Adults With HIV-1 Infection or AIDS**	**Comments**
ACIP			
DTP	Recommended	Not applicable	
OPV	Contraindicated	Contraindicated	
IPV	Recommended	Use if indicated	
MMR	Recommended	Recommended	Not if severe immune suppression (CD4 % T cells <15%) Revaccination with two doses after effective antiretroviral therapy
Hib	Recommended	Considered	Consider risk of disease in adults
Hepatitis B	Recommended	Recommended	
HPV	Considered	Considered	
Pneumococcal	Recommended	Recommended	
Meningococcal	Recommended	Use if indicated	Two doses of conjugate vaccine for all 11–18-year-olds
Rotavirus	Considered	Not applicable	
Varicella	Recommended	Recommended	Not if severe immune suppression (CD4 % T cells <15%)
Influenza, inactivated	Recommended	Recommended	Not for infants <6 mo old
Influenza, attenuated	Contraindicated	Contraindicated	
Td		Recommended	
BCG	Contraindicated	Contraindicated	
Yellow fever	Contraindicated	Contraindicated	Consider if exposure is unavoidable
Rabies	Use if indicated	Use if indicated	
Vaccinia	Contraindicated	Contraindicated	
Anthrax	Use if indicated	Use if indicated	
Plague	Use if indicated	Use if indicated	

ACIP, Advisory Committee on Immunization Practices; BCG, bacille Calmette-Guérin vaccine; DTP, diphtheria and tetanus toxoids and pertussis vaccine; Hib, *Haemophilus influenzae* type b vaccine; HPV, human papillomavirus; IPV, inactivated poliovirus vaccine; MMR, measles-mumps-rubella vaccine; OPV, oral poliovirus vaccine; Td, tetanus-diphtheria toxoid; UNICEF, United Nations International Children's Emergency Fund; WHO, World Health Organization.

NONREPLICATING VACCINES

Diphtheria and Tetanus Toxoids and Pertussis Vaccine

Children

Following primary immunization in infancy, 62% to 100% of HIV-1–infected children not receiving HAART respond to tetanus and diphtheria toxoids by developing protective concentrations of tetanus and diphtheria antitoxins, although geometric mean antibody titers are sometimes lower than in healthy control children and are more likely to wane over time (Table 70.2).[25] However, responses to booster doses are similar to those of uninfected children. Data on the immunogenicity of pertussis vaccines are more limited and interpretation is more difficult because serologic correlates of protection have not been identified. The limited data suggest that the proportion of children who seroconvert and the geometric mean antibody titers to pertussis toxin are lower in HIV-1–infected

TABLE 70.2 Immunogenicity of Diphtheria and Tetanus Toxoids and Pertussis Vaccines in HIV-1–Infected Children and Adults

Vaccine	Reference	Country	No. of Subjects	HAART	Age	HIV-1–Infected Persons Developing Protective Antibody Titers
CHILDREN						
DT	28	United States	5	No	2–6 y	40% to tetanus booster; titers lower than in control subjects
DT	29	France	13	No	4–24 mo	62% to tetanus and 57% to diphtheria; lower titers in children with opportunistic infections
TT	30	Italy	17	No	18–84 mo	77% to tetanus; titers lower than in control subjects
DTP	31	United States	17	No	11–90 mo	60% to tetanus; 18% to diphtheria; CMI in some children without protective antibody titers; titers lower than in control subjects
DTP	32	United States	33	No	<4 y	100% to tetanus; 88% to diphtheria; better responses early in life
DTP	33	Zaire	48	No	<4 mo	96% to tetanus; 71% to diphtheria; titers lower than in control subjects for diphtheria
TT	34	United States	15	Yes	Median, 12.6 y	92%; titers lower than in control subjects
TT	35	Kenya	24	Yes	Median, 4.9 y	75%
DTP	36	United States	11	Yes	3–14 y	90% to tetanus
DTP	37	United States	37	Yes	2–11 y	74% to tetanus; no difference in response by time receiving HAART
DTP	38	United States	46	Yes	3–17 y	94% to tetanus; no difference in response by time receiving HAART
Acellular pertussis	26	Italy	12	No	6–107 mo	75%; titers lower than in control subjects; correlated with CD4 cell count
ADULTS						
TT	39	France	25	No	Adults	77%; no difference in GMT titer from control subjects
TT	40	Switzerland	10	No	Adults	Increase in GMT; correlated with CD4 cell counts
TT	41	Netherlands	47	No	Adults	84%; correlated with CD4 cell count
TT	42	Chile	26	No	Adults	23%; decline in antibody titers at 1 y
TT	42	Brazil	21	No	Adults	Titers lower than in control subjects
TT	42	Brazil	61	No	Adults	Titers lower than in control subjects but increased after booster dose

CMI, cell-mediated immunity; DTP, diphtheria and tetanus toxoids and pertussis vaccine; GMT, geometric mean antibody titer; HAART, highly active antiretroviral therapy; TT, tetanus toxin.

children compared with healthy control children.[26] However, there is no evidence that HIV-1–infected children have higher vaccine failure rates than uninfected children following diphtheria, tetanus, or pertussis immunization.[27]

Because many HIV-1–infected children start antiretroviral therapy at older ages, few data exist on the response to primary immunization among children receiving HAART. In South Africa, infants beginning HAART shortly after diagnosis, and approximately 1 week prior to beginning the primary vaccine series, had similar responses to tetanus (92.3%) and diphtheria (100%) toxoids 1 month after the third dose of vaccine compared to those of HIV-1–uninfected children (tetanus toxoid: 100%; diphtheria and tetanus toxoids–pediatric: 100%). Responses to tetanus, but not diphtheria, toxoids were higher than among HIV-infected infants who started HAART at a later age (tetanus toxoid: 82.7%; diphtheria and tetanus toxoids–pediatric: 100%).[44]

Among previously vaccinated children starting HAART, 74% to 94% responded to a booster dose of tetanus toxoid in the first few months after vaccination,[34–38] although antibody titers waned over time in some children (see Table 70.2).[34,36–38] Responses tended to be higher for children with better immunological recovery and virological control after HAART initiation for tetanus toxoid and pertussis.[34,45] For tetanus toxoid, the age of HAART initiation may be important, as children in whom HAART was initiated in early infancy had responses comparable to those of healthy control children.[46] However, the duration of HAART at the time of revaccination did not influence vaccine responses in one study.[38]

Adults

Mean antibody titers to tetanus and diphtheria toxoids were lower in HIV-1–infected Brazilian women than uninfected women, but titers increased following revaccination.[43] In an uncontrolled study, 48% of 31 HIV-1–infected adults developed a fourfold increase in antibody titers to tetanus toxoid after receiving antiretroviral therapy for at least 48 weeks.[47] Ensuring immunity to tetanus is important for men undergoing voluntary medical circumcision in regions of high HIV prevalence.

Inactivated Poliovirus Vaccine

Despite the global transition to inactivated poliovirus vaccine as part of the Global Polio Eradication Initiative, few studies

have evaluated the immunogenicity of inactivated poliovirus vaccine in HIV-1–infected children and adults. Several early studies measured poor antibody responses in HIV-1–infected children with low CD4 T-lymphocyte counts.[48,49] In a more recent study, intradermally administered inactivated poliovirus vaccine, using a reduced dose, was as immunogenic as intramuscular injection in HIV-1–infected adults.[50]

Hepatitis B Vaccine

Children

HIV-1 shares common risk factors for HBV infection, and HIV-1 infection increases the risk of chronic hepatitis B surface antigen carriage and liver failure, heightening the need for HBV vaccination in persons at risk of HIV-1 infection.[51] Serologic response rates have varied, but only 25% to 70% of HIV-1–infected children not receiving HAART developed protective antibody concentrations following hepatitis B vaccination in most studies (Table 70.3). Attempts to overcome the decreased response by administering higher doses or extra doses of hepatitis B vaccine have not been promising.[52,53] HIV-1–infected children who respond to hepatitis B vaccine have a more rapid decline in antibody titer than do uninfected persons.[54]

Among children previously vaccinated against HBV, HAART did not result in higher antibody levels.[88,89] However, administration of booster doses after HAART initiation improved responses, with serologic response rates ranging from 46% to 100% (see Table 70.3). Waning immunity may occur even after booster doses of hepatitis B vaccine.[64]

Administration of the primary vaccine series after HAART initiation among older children resulted in better antibody

TABLE 70.3 Immunogenicity of Hepatitis B Vaccines in HIV-1–Infected Children and Adults

Reference	Country	Vaccine and Dose	No. of Subjects	HAART	Age	HIV-1–Infected Persons Developing Protective Antibody Titers
CHILDREN						
55	Italy	Engerix-B (20 μg)	18	No	Mean: 1.8 y	78%; titers lower than in control subjects; no correlation with CD4 cell count; poor response to booster dose
56	United States	<11 y: Engerix-B (10 μg) or Recombivax HB (2.5 μg); >11 y: Engerix-B (20 μg) or Recombivax HB (5 μg)	24	No	5–115 mo	25%; correlated with CD4 cell count
57	United States	Recombivax HB (2.5 μg)	17	No	1 day to 11 mo	35%; no correlation with CD4 cell count
58	Spain	Engerix-B (10 μg)	17	No	0–63 mo	41%; response lower than in control subjects; no correlation with CD4 cell count
53	United States	Booster doses: <11 y: Engerix-B (20 μg); >11 y: Engerix-B (40 μg)	14[a]	No	21–129 mo	14% after 1 booster dose; 0 of 7 developed antibody response after second booster dose; correlated with CD4 cell count
54	Italy	Engerix-B (10 μg)	20	No	1–102 mo	45%; not correlated with CD4 cell count; 73% of 11 responded to booster dose
59	Thailand	Engerix-B (10 μg)	14	No	0–12 mo	71% after 3 doses; titers lower than in 3 subjects
60	Poland	10 μg	45	Yes	—	91% >100 mIU/mL
61, 62	Thailand	20 μg	63	Yes	Mean: 10.1 y	92% 1 month after 3 doses; 70% after 3 years; not correlated with CD4 cell count
63	Tanzania	HBVaxPro (5 μg)	48	Yes	Median: 4.7 y	71%
64	United States	Recombivax HB (5 μg)	204	Yes	Median: 9.1 y	46%; correlated with CD4 T-cell percentage
65	South Africa	—	73	No	5–24 mo	78%

TABLE 70.3 Immunogenicity of Hepatitis B Vaccines in HIV-1–Infected Children and Adults *(Continued)*

Reference	Country	Vaccine and Dose	No. of Subjects	HAART	Age	HIV-1–Infected Persons Developing Protective Antibody Titers
ADULTS						
70	United States	Plasma-derived	16	No	Adults	56%; titers lower than in control subjects
71	Belgium	Recombinant	32	No	Adults	28%; titers lower than in control subjects
72	Spain	Recombinant	21	No	Adults	24%; titers lower than in control subjects
73	United Kingdom	Engerix-B (20 μg)	12	No	Adults	17%; poor response to additional dose
74	Australia	Plasma-derived	14	No	Adults	43% or recombinant
75	France	GenHevac B (20 μg)	20	No	Adults	55% after 3 doses; 78% of 9 nonresponders after 3 additional doses
76	Brazil	Engerix-B (20 μg):		No		% seroconversion by dose and CD4%:
		CD4 <350	38		Adults	26%
		CD4 ≥350	56		Adults	39%
		Engerix-B (40 μg):				
		CD4 <350	42		Adults	24%
		CD4 ≥350	56		Adults	64%
77	United States	Engerix-B or Recombivax (40 μg)	116	Most	Adults	53%; all receiving dialysis; most receiving HAART
78	United States	Engerix-B or Recombivax	57	Most	Adults	37%; most receiving HAART
79	Brazil	Euvax (40 μg)	47	Some	Adults	64%
80	Thailand	Engerix-B (20 μg)	65	Most	Adults	46%
81	Canada	Recombivax (40 μg) intradermal	12	Most	Adults	50%; all previously failed to respond to 6 intramuscular doses
82	Thailand	Engerix-B (20 μg)	28	Yes	Adults	71%
83	United States	Engerix-B or Twinrix (20 μg)	97	Some	Adults	44%; better response in patients receiving HAART
84	United States	Not available	626	Some	Adults	35%; 49% receiving HAART
85	United States	Recombivax (40 μg)	363	Some	Adults	35%; 85% of 40 who received 3 double doses
86	Thailand	Hepavax-Gene:		Yes	≥18 y	% with anti-HBs ≥10 mIU/mL 6 m after last dose:
		3 doses (20 μg)	44			70%
		4 doses (20 μg)	44			86%
		4 doses (40 μg)	44			89%
87	Kenya	Euvax B, Revacc B or Shanvac B (20 μg)	310	No	≥18 y	64% 6 months after last dose; 71% of nonresponders responded to revaccination; lower response than among HIV-uninfected participants

[a]Follow-up study of children previously described by Diamant EP, Schechter CB, Hodes DS, et al. Immunogenicity of hepatitis B vaccine in human immunodeficiency virus infected children. *Pediatr Infect Dis J*. 1993;12:877–878.

DPT-HB, diphtheria, pertussis, tetanus–hepatitis B; HAART, highly active antiretroviral therapy; HAV, hepatitis A virus; HBV, hepatitis B virus; rDNA, ribosomal DNA.

responses.[69] With improvements in early infant diagnosis and initiation of HAART at younger ages, infants may receive the primary vaccine series while receiving treatment. In South Africa, infants initiating HAART approximately 1 week prior to beginning the primary vaccine series had similar serologic responses to HBV (98.8%) as HIV-uninfected (100%) and HIV-exposed-but-uninfected (99.2%) infants.[44]

Adults

Most HIV-1–infected adults have poor responses to hepatitis B vaccine.[90,91] Doubling the dose of hepatitis B vaccine increased the antibody response among HIV-1–infected adolescents and adults,[76,92–96] but may be less effective among persons with lower CD4 counts.[76] In other studies, 85% to 100% of previous HBV nonresponders developed protective antibody titers after three double doses of hepatitis B vaccine.[85,97] HAART was associated with better short-term and long-term responses to hepatitis B vaccine in some, but not all, studies of HIV-1–infected adults.[83,84,98] Higher CD4 counts and lower HIV viral loads at vaccination are also associated with better responses in some, but not all, studies.[70,92,99–103] Other novel strategies to improve responses to hepatitis B vaccine, such as use of adjuvants and intradermal administration, as well as accelerated schedules, have been explored with some success.[93,102,104–106]

Hepatitis A Vaccine

Children

As with hepatitis B vaccine, HIV-1–infected children not receiving HAART are less likely to develop a protective antibody response following vaccination against hepatitis A and have lower antibody titers than do HIV-1–uninfected persons (76% vs 100% 6 months after third dose).[107]

Among children receiving HAART, vaccine response rates were high, with approximately 72% to 100% of children developing protective antibodies to hepatitis A virus 1 month after primary vaccination.[38,108–111] However, immunity waned over time.[38,109] A third dose of vaccine induced higher antibody concentrations than after two doses. Immune status at the time of vaccination was correlated with response to hepatitis A vaccine.[109,110,112]

Adults

HIV-1–infected adults not receiving HAART are less likely to develop a protective antibody response following vaccination against hepatitis A and have lower antibody titers than do HIV-1–uninfected persons. Approximately 90% of immunologically normal adults, but only 48% to 90% of HIV-1–infected adults not receiving HAART, seroconverted following two to three doses of hepatitis A vaccine.[113–123] In one study, the likelihood of seroconversion was associated with a higher CD4 T-lymphocyte count.[120] In an uncontrolled study, 73% of 31 HIV-1–infected adults developed antibodies to hepatitis A vaccine after receiving antiretroviral therapy for at least 48 weeks.[47] Serologic responses persisted 6 to 10 years after vaccination in adults with suppressed HIV viral loads.[124]

Inactivated Influenza Vaccine

Children

Most studies of inactivated influenza vaccine have been conducted among children receiving HAART and found seroprotection rates (as defined by each study) of 57% to 100% for influenza A/H1N1 (including pH1N1 2009),[125] 50% to 100% for influenza A/H3N2, and 56% to 76% for influenza B.[126–131] The proportion of children developing protective immunity seems to be similar in HIV-infected and HIV-uninfected children,[128,129,131] although geometric mean titers were sometimes higher in uninfected children.[128,129,131,132] Few predictors of response were consistently identified.[128–130,133] Influenza vaccine efficacy was only 18% in a double-blind, placebo-controlled trial of influenza vaccine conducted in South Africa among HIV-1–infected children, perhaps attributable to poor immunogenicity and genetic drift of the H3N2 wild-type virus.[134]

Adults

Limited data suggest that influenza vaccine is effective in preventing symptomatic influenza infection in many HIV-1–infected adults.[135–137] In a double-blind, randomized clinical trial of the safety, immunogenicity, and efficacy of trivalent inactivated influenza vaccine in 506 HIV-1–infected South African adults, vaccine efficacy was 76% against confirmed influenza illness and seroconversion rates as measured by hemagglutination inhibition antibody titers (>1 : 40 if baseline titers were <1 : 10 or a greater than fourfold increase in those with baseline titers >1 : 10) were 53% for H1N1, 61% for H3N2, and 54% for influenza B virus.[138] Influenza vaccine was most effective in HIV-1–infected persons with CD4 T-lymphocyte counts greater than 100 cells/mm^3 during an outbreak at a residential facility in New York City.[139] In persons with severe immune suppression, a second dose of influenza vaccine did not result in greater immunogenicity.[140,141] In general, HIV-1–infected adults developed protective antibody titers after receipt of the 2009 pandemic H1N1 influenza vaccine, particularly in conjunction with adjuvants[142–147] and with higher antigen content.[148] A systematic review of influenza vaccination of HIV-1-infected persons concluded that inactivated influenza vaccine is effective in preventing influenza infection in HIV-infected adults but not in HIV-infected young children.[149]

Vaccination of HIV-1–infected pregnant women against influenza is a potential strategy to protect both mother and child. Influenza vaccination of HIV-1–infected pregnant women receiving antiretroviral therapy in the United States is safe and immunogenic[150]; however, a large trial in South Africa failed to demonstrate protection of infants born to influenza vaccinated HIV-1–infected women.[151] HIV-exposed infants had lower antibody levels at birth but similar antibody levels after 8 weeks of life.[152]

Haemophilus influenzae Type B Polysaccharide-Protein Conjugate Vaccines

Children

A wide range of 16% to 86% of HIV-1–infected children not receiving HAART developed protective antibody responses following three doses of *Haemophilus influenzae* type b conjugate vaccines, and geometric mean titers were lower than in HIV-1–uninfected children of similar ages (Table 70.4).[153,154] Vaccine effectiveness was lower in HIV-1–infected South African children (44%) compared with uninfected children (95%),[154] and the estimated risk of vaccine failure was 35-fold (95% confidence interval, 15 to 84) higher in HIV-1–infected than uninfected children.[155] Antibody concentrations waned more rapidly in HIV-1–infected children.[156] However, booster doses of vaccine can induce rapid increases in antibody in some HIV-1–infected children.[157–160]

Few studies of immune responses to *H. influenzae* type b vaccine have been conducted among children receiving HAART. In one study of 18 previously vaccinated children, 78% had detectable antibodies after HAART initiation.[36] In South Africa, HIV-infected infants initiating HAART approximately 1 week prior to beginning the primary vaccine series experienced similar responses 1 month after the last dose (99.4%) compared to HIV-uninfected (97.4%) and HIV-exposed, uninfected (99.2%) infants.[44] HIV-infected infants initiating HAART at older ages also had similar responses (97.3%).[44]

Pneumococcal Polysaccharide and Polysaccharide-Protein Conjugate Vaccines

Children

Antibody responses to pneumococcal conjugate vaccines among children not receiving HAART were high, with the proportion of children with antibody levels above a specified threshold ranging from 63% to 93% by serotype, but were generally lower than among uninfected children (see Table 70.4). The quality of antibodies as measured with an opsonophagocytic assay was deficient among HIV-1–infected children in South Africa,[154] and significant waning of antibody concentrations was found 5 years after vaccination, such that the proportion with antibody concentrations ≥0.35 μg/mL ranged only from 5% to 24%.[174] Provision of a booster dose improved responses for only three of seven serotypes.[174] Vaccine efficacy was lower in a clinical trial of HIV-1–infected South African

TABLE 70.4 Immunogenicity of *Haemophilus influenzae* Type B and Pneumococcal Conjugate Vaccines in HIV-1–Infected Children and Adults

Reference	Country	Vaccine	No. of Subjects	HAART	Age Group	Immunogenicity or Effectiveness
***HAEMOPHILUS INFLUENZAE* TYPE B CONJUGATE VACCINES**						
Children						
157, 159	United States	PRP-CRM_{197}	19	No	15–56 mo	16% immune 4–85 mo after vaccination; 77% after revaccination
153	United States	PRP-CRM_{197}	23	No	1–5 mo	82% of asymptomatic and of 33% symptomatic children immune; similar responses in asymptomatic and control children
156, 161	United States	PRP-tetanus toxoid	56	No	1–13 y	86% with protective titers compared with 100% of uninfected children after 1 mo; 57% at 1 y
158	United States	PRP-CRM_{197}	39	No	Mean: 16.6 mo at booster	46% immune after primary series; 63% after booster; titers lower than in control subjects
162	United States	PRP-CRM_{197}	18	No	6–19 mo	28% immune after primary series; 45% after booster dose
163	United States	PRP-CRM_{197}	35	No	9 mo	74% immune after primary series; 76% after booster dose; no difference with control subjects
155	South Africa	PRP-CRM_{197}	[a]	No		Reduced effectiveness with HIV-1 infection
36	United States	PRP-CRM_{197}	4	Yes	3–14 y	75% with detectable antibodies
164	Thailand	PRP-tetanus toxoid	41	No	24–84 mo	67% with anti-PRP ≥0.15 μg/mL
165	South Africa	PRP-CRM_{197}	66	No	Mean: 3.7 mo at third dose	52% immune compared with 95% in control subjects; correlated with disease stage
Adults						
166	United States	PRP and PRP-CRM_{197}	181	No	Adults	Better antibody response to PRP-CRM_{197} except in people with AIDS
167	Netherlands	PRP-tetanus toxoid	54	No	Adults	Poor antibody response in people with low CD4 cells
168	Brazil	PRP-OMP	60	No	Adults	38% immune; titers lower than in control subjects
PNEUMOCOCCAL CONJUGATE VACCINES						
Children						
169, 170	United States	5-valent CRM_{197}	17	No	≤2 y	78% immune compared with 88% in control subjects
171	United States	7-valent CRM_{197}	30	70%	56–180 days	Variable antibody response by serotype (88% to 100%); good response to booster
172, 173	South Africa	9-valent CRM_{197}	[a]	No	0–3 y	Efficacy 65% compared with 83% in control subjects after 2 y; efficacy 39% compared with 78% in control subjects after 6 y
165, 174	South Africa	9-valent CRM_{197}	30	No	Mean: 3.7 mo after third dose	Variable antibody response by serotype (63% to 93%); similar GMT but lower functional antibodies than control subjects
160	Greece	7-valent CRM_{197}	14	78%	20–163 mo	29% immune compared with 57% in control subjects; no effect of booster dose
175	Spain	7-valent CRM_{197}	56	Yes	3–19 y	Variable antibody response by serotype (29% to 50%)
176, 177	United States	7-valent CRM_{197} + PPV	225	Yes	2 to <19 y	Variable antibody response by serotype (76% to 96%); some waning over 5-year follow-up but good response to booster with either PCV7 or PPV; correlated with immune status and viral load
178	Brazil	7-valent CRM_{197}	40	Yes	2–9 y	65% immune; variable response by serotype (45% to 90%)

TABLE 70.4 Immunogenicity of *Haemophilus influenzae* Type B and Pneumococcal Conjugate Vaccines in HIV-1–Infected Children and Adults *(Continued)*

Reference	Country	Vaccine	No. of Subjects	HAART	Age Group	Immunogenicity or Effectiveness
179, 180	South Africa	7-valent CRM_{197}	249	Yes	6–12 wk	Variable antibody response by serotype (92% to 100%) for infants receiving HAART; similar antibody response for non-HAART status and control subjects; lower functional antibodies for non-HAART
181	United Kingdom	13-valent CRM_{197}	48	Yes	2 mo to18 y	Variable antibody response by serotype (65% to 98%); lower than HIV-uninfected adult controls; correlated with viral load
182	South Africa and Romania	13-valent CRM_{197} + PPV	150	98%	6–17 y	Increase in IgG GMCs for all serotypes
183	Thailand	7-valent CRM_{197}	59	90%	2 mo to 9 y	Antibody response varied by serotype (85% to 98%); similar to HIV-exposed but uninfected children
Adults						
184	United States	5-valent CRM_{197}	141	No	Adults	Similar GMT to polysaccharide vaccine
185	United States	7-valent CRM_{197} + second dose or PPV	67	42%	≥17 y	Increase in GMCs after 1 dose; no increases observed with second dose of either conjugate or polysaccharide vaccine
186	Uganda	7-valent CRM_{197}	109	No	Adults	Antibodies correlated with CD4 cell counts
187	United States	13-valent CRM_{197}	329 (all previously vaccinated with PPV)	95.4%	≥18 y	Increase in GMCs after 3 doses for all serotypes
182	South Africa and Romania	13-valent CRM_{197} + PPV	151	97%	≥18 y	Increase in IgG GMCs for all serotypes
188	Brazil	PPV or 7-valent CRM_{197} or 7-valent CRM_{197} ± PPV	331	77%	18–60 y	Good antibody response to PPV or 7-valent CRM_{197}; no added benefit of second dose of PPV
189	Taiwan	7-valent CRM_{197} or PPV	208	86%	≥20 y	Better antibody response with PCV7 than PPV; correlated with viral load
190	Taiwan	7-valent CRM_{197} or PPV	221 (all previously vaccinated with PPV)	96%	≥20 y	Better antibody response with 2 doses than 1 dose of PCV7 or 1 dose of PPV
191	Taiwan	7-valent CRM_{197}	230	72%	≥20 y	Better antibody response with 2 doses than 1 dose
192	Malawi	7-valent CRM_{197}	219	41%	Adults	74% vaccine efficacy

[a]Population-based study.

GMC, geometric mean concentration; GMT, geometric mean antibody titer; HAART, highly active antiretroviral therapy; IgG, immunoglobulin G; PPV, pneumococcal polysaccharide vaccine; PRP-OMP, polyribosylribitol phosphate–outer membrane protein.

children (65%) and decreased over time (39%) compared with uninfected children (83%).[172,173] Vaccine effectiveness was not demonstrated in a matched case-control study of HIV-1–infected children[193] in South Africa.

Among children receiving HAART, responses to pneumococcal vaccines varied by serotype, ranging from 29% to 100% based on antibody levels above specified thresholds or an increase from baseline, with some evidence of waning immunity.[160,171,177] The benefits of a booster dose are unclear because studies have reported conflicting results.[160,171,175–177] Immune responses by immunological status and viral load suppression were also inconsistent.[154,171,175,176,181] Children in whom HAART was initiated in infancy had responses similar to uninfected children and better responses than children in whom HAART was initiated later in childhood.[46] Another study of early and deferred HAART among infants found similar responses between the two groups and similar to uninfected children, but lower levels of functional antibodies among infants in the deferred HAART group.[179,180]

Adults

Response to 23-valent pneumococcal polysaccharide vaccine is poorer in HIV-1–infected than in uninfected persons, but better in persons receiving HAART.[194–197] However, antibody responses declined even in persons receiving HAART.[198] The 23-valent pneumococcal vaccine reduced the risk of pneumococcal disease in 305 HIV-1–infected adult vaccine recipients

receiving HAART in Taiwan[199] and the risk of pneumonia in a cohort of 23,255 HIV-1–infected adults in the United States.[200] However, in HIV-1–infected Ugandan adults, the 23-valent polysaccharide pneumococcal vaccine was found to be ineffective in preventing first episodes of invasive pneumococcal disease.[201]

The antibody response to a glycoprotein conjugate pneumococcal vaccine was better than that of the polysaccharide vaccine in HIV-1–infected persons, except for adults with CD4 T-lymphocyte counts less than 200 cells/mm^3.[184,202,203] However, the antibody response to specific pneumococcal polysaccharide serotypes varies, with some serotypes eliciting poor antibody responses in HIV-1–infected persons with CD4 T-lymphocyte counts less than 200 cells/mm^3.[204] In a placebo-controlled trial of seven-valent pneumococcal vaccine in predominantly HIV-1–infected adults in Malawi, all of whom had prior invasive pneumococcal disease, vaccine efficacy against invasive pneumococcal disease was 74%.[192] Revaccination with conjugate pneumococcal vaccine resulted in a higher proportion of HIV-1–infected adults with protective antibody levels than adults vaccinated with polysaccharide vaccine, but this difference was not sustained after 6 months.[205] Studies of the benefits of a second dose of conjugate pneumococcal vaccine or polysaccharide vaccine have produced inconsistent results.[206]

Meningococcal Polysaccharide and Conjugate Vaccines

Few data are available regarding responses to meningococcal polysaccharide vaccine in HIV-1–infected children. The proportion of children achieving a fourfold or greater increase in rabbit serum bactericidal antibody titers in a trial (International Maternal Pediatric Adolescent AIDS Clinical Trials [IMPAACT] P1065) of the immunogenicity of a meningococcal polysaccharide diphtheria toxoid conjugate vaccine among 319 HIV-1–infected adolescents 11 to 24 years old, the majority of whom were receiving HAART, were 86% for serogroup A, 55% for serogroup C, 72% for serogroup W-135, and 73% for serogroup Y, although some level of immunity also was detectable at baseline.[207] Response rates were positively correlated with better immunological status and inversely with HIV-1 viral load. In the same trial, vaccine immunogenicity among 59 HIV-1–infected children 2 to 10 years of age was assessed and seroprotective titers were achieved in 78% for serogroup A, 46% for serogroup C, 93% for serogroup W-135, and 91% for serogroup Y by 72 weeks after vaccination.[208] Improved responses were seen with a second dose administered 6 months after the initial dose.[209] Studies of the meningococcal C conjugate vaccine in HIV-1–infected children demonstrated significantly lower serologic responses than those seen in uninfected children.[210,211] The Advisory Committee on Immunization Practices recommends a primary series of two doses of the meningococcal conjugate vaccine for HIV-infected adolescents 11 through 18 years old.[212]

Rabies Vaccine

Antibody responses to an eight-site intradermal rabies vaccination regimen using the purified chick embryo cell rabies vaccine resulted in good antibody responses among 27 HIV-infected adults regardless of CD4 T-lymphocyte count,[213] although another study suggested poor antibody responses to the human diploid cell rabies vaccine in HIV-infected persons with low CD4 T-lymphocyte counts.[214] Antiretroviral therapy may improve the immunogenicity of rabies vaccine but not to levels found in those of uninfected persons.[215]

Human Papillomavirus Vaccines

The human papillomavirus vaccine is recommended for HIV-1–infected and uninfected children.[19] The quadrivalent human papillomavirus vaccine was found to be safe and immunogenic in a study of 126 HIV-1–infected children 7 to 12 years old[216] and stimulated mucosal antibodies and cytotoxic T lymphocytes.[217] Studies in HIV-infected girls and women showed the quadrivalent human papilloma vaccine to be safe and immunogenic,[218–221] with one study finding poorer responses in women with HIV viral loads greater than 10,000 copies/mL and CD4 T lymphocyte counts less than 200 cells/μL.[222]

Japanese Encephalitis Vaccine

HIV-1–infected children have a poor response to mouse brain–derived, inactivated Japanese encephalitis vaccine, but a higher proportion responded to revaccination while receiving HAART[223,224] and levels of protective antibodies persisted for at least 3 years.[225] A cell culture–based vaccine for Japanese encephalitis is available, although no data are available on its use in HIV-infected persons.

Safety of Nonreplicating Vaccines

Nonreplicating vaccines are not associated with increased risks of complications in immunocompromised persons. However, a study of HIV-1–infected Ugandan adults found an increased incidence of pneumonia in recipients of 23-valent pneumococcal polysaccharide vaccine compared with unvaccinated HIV-1–infected adults.[201] The authors hypothesized that immunization resulted in destruction of polysaccharide-responsive B-cell clones, but no specific data to support this hypothesis were provided and this observation has not been corroborated in other studies. Surprisingly, 6-year follow-up of this same population confirmed excess all-cause pneumonia, but an overall survival advantage persisted among vaccinated persons.[226]

Activation of T lymphocytes following immunization could potentially augment HIV-1 replication and result in more rapid progression of HIV-1 disease. Several studies, but not all, described transient elevations of HIV-1 RNA plasma levels lasting several days following immunization with tetanus toxoid,[227,228] influenza,[229–233] pneumococcal,[234,235] and hepatitis B[103,236] vaccines. None of these investigations found prolonged elevation of HIV-1 RNA viral load, decreased CD4 T-lymphocyte counts, or accelerated HIV-1 disease progression following immunization. Although the transient rise in HIV-1 viral load following administration of tetanus toxoid to pregnant women could theoretically affect the risk of maternal-infant HIV-1 transmission, an increased risk of transmission is unlikely if vaccination occurs at least 4 weeks before delivery.[237]

LIVE BACTERIAL VACCINES

Bacille Calmette-Guérin Vaccine

The BCG vaccine is not recommended for children known to have HIV-1 infection because of the increased risk of disseminated BCG disease many months, or even years, after vaccination.[21,22] The effectiveness of BCG in HIV-1–infected persons may be lower than in uninfected persons, and there are numerous reports of regional lymphadenitis, poorly healing ulcers, fistulas, and disseminated disease developing in HIV-1–infected infants, children, and adults.[238,239] HIV-exposed, uninfected infants may have impaired cellular immune responses

to BCG[13] (although findings are not consistent)[240] and may benefit from delayed administration until 8 weeks of age[241] and after HIV infection is excluded.

Typhoid Vaccine

Few studies of live typhoid vaccine in HIV-infected individuals have been published. An increased risk of diarrhea was reported following administration of the oral typhoid vaccine Ty21a to 42 HIV-infected Zambian adults.[4]

LIVE VIRUS VACCINES

Oral Poliovirus Vaccine

Children

The proportion of HIV-1–infected children who responded to three doses of live attenuated poliovirus vaccine was greater than 90% in many studies, although titers tended to be lower compared to those in HIV-1-uninfected children (Table 70.5). Few studies of the immune response to oral poliovirus vaccine have been conducted among children receiving HAART. In addition, no direct estimates of poliovirus vaccine efficacy have been conducted in HIV-1–infected children. However, all three wild-type polioviruses have been successfully eliminated from countries with high prevalence of HIV-1 infection.

Safety of Oral Poliovirus Vaccine in HIV-1–Infected Persons

The risk of vaccine-associated paralytic poliomyelitis (VAPP) is increased in persons with primary B-cell immunodeficiency disorders.[248] Nevertheless, more than 1000 HIV-1–infected children received at least one dose of oral polio vaccine without complications in the United States before it was known that they or their mothers were HIV-1–infected, and millions of HIV-1–infected children in other countries have been vaccinated. Only two HIV-1–infected children have been reported to have VAPP following receipt of oral polio vaccine (Table 70.6): one 2-year-old, HIV-1–infected Romanian girl[246] and one child in Zimbabwe.[247] In Romania, the rate of VAPP in all children was approximately 10-fold higher than the estimated 1 case per 2.5 million doses administered in the United States and Europe, most likely related to simultaneous administration of multiple injections.[249] Thus, HIV-1 infection in these two children with VAPP could be chance associations and not evidence of an increased risk associated with HIV-1 infection. If the risk of VAPP is increased in HIV-1–infected persons, the attributable risk is very low.

Persons with inherited B-cell deficiency disorders can excrete vaccine-derived polioviruses for more than 2 decades.[268] However, prolonged shedding of polioviruses among HIV-infected children[269,270] and adults has not been observed.[269,271,272] A study in Zimbabwe of 92 HIV-1–infected children found

TABLE 70.5 Immunogenicity and Safety of Poliovirus Vaccines in HIV-1–Infected Children

Reference	Country	Vaccine	No. of Subjects	HAART	Age	Safety	HIV-Infected Persons Developing Protective Antibody Titers After ≥3 Doses
29	France	OPV	15	No	4–24 mo	No adverse events	40% to type 2; 33% to types 1 and 3
242	United States	OPV	23	No	1–180 mo	No adverse events	91%; lower titers with advanced disease
243	United States	OPV	180	No	1–132 mo	No adverse events	Immunogenicity not studied
49	Italy	IPV	9	No	3–13 mo	No adverse events	100% to types 1 and 2; 88% to type 3
30	Italy	OPV and/or IPV	12	No	18–84 mo	No adverse events	100% to type 2; 92% to types 1 and 3; decrease in titers over 2 y in 4 children studied
33	Zaire	OPV	48	No	<4 mo	No adverse events	97% to all types; titers lower than in control subjects
244	Zimbabwe	OPV	21	No	2 mo to 2 y	No adverse events	52% to type 1; 62% to type 2; 33% to type 3; lower titers than HIV-exposed but uninfected children
14	Zambia	OPV	17	No	18 mo	No adverse events	65% to type 2; lower titers than HIV-uninfected children
245	Zimbabwe	OPV	92	67%	9 mo	No adverse events	69% to type 1, 74% to type 2, 37% to type 3; lower titers than HIV-uninfected children
246	Romania	OPV	1	No	26 mo	Flaccid paralysis; vaccine strain type 2 in stool	Lacked antibody titers to all 3 types despite receipt of 4 doses of OPV
247	Zimbabwe	OPV	1	No	4 y	Paralysis of right leg	Lacked antibodies to polioviruses types 1 and 3 wk after second OPV despite having received OPV during first year of life

IPV, inactivated polio vaccine; OPV, oral polio vaccine.

HAART, highly active antiretroviral therapy; NA, not available.

significantly higher titers of poliovirus shedding in HIV-1–infected children within 42 days of three or more doses of vaccine, but no evidence of prolonged vaccine virus shedding.[245] Persistent excretion by HIV-1–infected persons is unlikely to be a source of poliovirus transmission to others.

Measles Vaccine

Children

The antibody response to measles vaccine is impaired in HIV-1–infected children not receiving HAART (see Table 70.6).[273] In a metaanalysis of studies of measles vaccination of HIV-1–infected children, levels of serologic response varied.[274] One study of standard-titer measles vaccine at 6 and 9 months of age found 59% of HIV-1–infected children were seropositive after vaccination at 6 months but only 64% after vaccination again at 9 months of age.[260] In contrast, 88% of 50 HIV-1–infected children in Zambia developed antibody levels of 120 mIU/mL or more within 6 months of vaccination compared with 94% of 98 HIV-seronegative children and 94% of 211 HIV-seropositive but uninfected children (P = .3).[259] However, these HIV-1–infected children had lower antibody avidity[275] and experienced waning antibody levels and lower frequency of protective antibody titers by 2 to 3 years of age.[259] The response to a second dose of measles vaccine in five studies of children not receiving antiretroviral therapy was variable, but generally poor.[273] In cross-sectional studies among HIV-infected children, the prevalence of measles antibody after vaccination varied widely, ranging from 17% to 100%.[16,266,273,274,276] An association between lack of measles virus-specific antibodies after vaccination and low CD4 T-lymphocyte count was documented in some studies.[273,274,276]

Placental transfer of maternal antibodies, including antibody to measles virus, is impaired in HIV-1–infected women[277–281] and was associated with high maternal HIV-1 viral load in one study.[282] The lower levels of maternal antibody correlated with an improved response of their HIV-1–infected and –uninfected infants to measles vaccine administered at 6 months of age.

Few data exist on the primary immune response to measles vaccine among children receiving HAART. Initiation of HAART before primary vaccination may result in higher production and maintenance of antibodies and protective immunity. A cross-sectional study in Italy found that children in whom HAART was initiated in infancy, likely before measles vaccination, maintained high levels of protective antibodies (82%) compared with children in whom HAART was initiated later in childhood (40%), and levels were similar to those found in healthy HIV-uninfected control children (100%).[46] Several studies have been conducted on the response to vaccination or revaccination after initiating HAART (see Table 70.6) and suggest that children receiving HAART are more likely to respond to revaccination than are children not receiving HAART.[258] Within the first 3 months after vaccination, the proportion of children responding to revaccination, as defined by each study, was 64% to 90%.[35,36,258,262] A study of 428

HIV-1–infected children 7 to 15 years of age in the United States found that the number of vaccine doses received while on antiretroviral therapy was positively associated with seroprotection.[16] However, antiretroviral therapy does not restore immunity lost prior to treatment. In a prospective study of 169 HIV-1–infected Zambian children, subsequent HAART was not associated with seroconversion.[266] Children vaccinated while receiving HAART may experience waning immunity,[36] although in Thailand the prevalence of protective antibodies to measles virus 3 years after revaccination of HIV-1–infected children receiving antiretroviral therapy was 85% compared with 88% 1 month after revaccination.[263] HIV-1–infected children receiving HAART would likely benefit from revaccination.[283] In 2012, the Advisory Committee on Immunization Practices recommended measles revaccination of HIV-1–infected children who were vaccinated before treatment with two doses of measles vaccine once effective therapy had been established.[284] The World Health Organization made a similar recommendation in December 2015.[284a]

Adults

The majority of HIV-1–infected adults vaccinated as children were seropositive.[285,286] Waning immunity was observed among revaccinated HIV-1–infected, measles-seronegative adults, despite HAART.[287]

Safety of Measles Vaccine in HIV-1–Infected Persons

Prospective studies revealed no increased risk of adverse events in the few weeks following immunization with standard- and high-titer measles vaccines for HIV-1–infected children not receiving antiretroviral therapy compared with uninfected children.[259,260,273] A retrospective survey conducted by the New York City Department of Health found no complications following measles immunization of HIV-1–infected children,[243] and no evidence of persistent measles vaccine virus excretion was found in 10 HIV-1–infected children immunized with measles-mumps-rubella (MMR) vaccine.[254] A systematic review concluded that measles vaccines appear to be safe in HIV-1–infected children, but the evidence is limited.[274]

Only one fatal adverse event has been reported following administration of measles vaccine to an HIV-1–infected person.[288,289] A 20-year-old HIV-1–infected man, who had a very low CD4 T-lymphocyte count at the time he received a second dose of MMR vaccine, developed cough and progressive pulmonary infiltrates 10 months after immunization. An open lung biopsy showed giant cell pneumonitis, and measles vaccine virus was identified in the lung tissue. He died several months later of encephalitis, presumably from cytomegalovirus and progressive pneumonitis attributable in part to measles vaccine virus. An HIV-1–infected child with a CD4 T-lymphocyte count of 340/μL who received MMR vaccine developed rash and interstitial pneumonia, from which he recovered, and vaccine-strain measles virus RNA was present in his blood.[290]

Mumps and Rubella Vaccines

Children

Several studies suggested that HIV-1–infected children not receiving HAART are as likely to develop protective antibody titers to mumps and rubella vaccines as HIV-1–uninfected children.[253,291,292] However, HIV-1–infected children 7 to 15 years of age in the United States were less likely to have serological evidence of protection against mumps (59% vs 97%) and rubella (65% vs 98%) than HIV-exposed uninfected children,[16] with receipt of antiretroviral therapy a strong predictor of immunity. No cases of measles, mumps, or rubella were observed in vaccinated HIV-1–infected children followed in the European Collaborative Study,[27] and no serious adverse events resulting from mumps or rubella vaccines have been reported in HIV-1–infected children. Revaccination has not been found to have a significant effect on mumps and rubella antibody concentrations.[254,291]

Limited data are available on the response to mumps and rubella among children receiving HAART. A study from Brazil evaluated antibodies to mumps among children in whom HAART was initiated in infancy, likely before primary vaccination. HIV-1–infected children had lower responses (80%) compared with HIV-uninfected children (94% to 100%), although responses were higher among children without severe immunosuppression than those with it (100% vs 62%).[293] Another study in Thailand evaluated the response to revaccination among children receiving HAART and found that 100% and 69% of children without detectable antibodies at baseline developed protective antibodies to rubella and mumps viruses 1 month after revaccination, respectively.[262] After 3 years, the proportion of children with protective antibodies decreased to 79% for rubella and 61% for mumps.[263]

Adults

A cross-sectional survey in the United Kingdom found that 12% of HIV-1–infected adults lacked protective antibodies to mumps virus, but the study lacked a comparison group of HIV-uninfected persons.[294]

Rotavirus Vaccines

Few studies have assessed the efficacy, immunogenicity, or safety of rotavirus vaccine in HIV-1–infected children, and limited data suggest rotavirus infection is not more frequent or more severe in HIV-1–infected children.[295] Two multicountry trials of rotavirus vaccine in Africa included HIV-1–infected infants, although estimates of vaccine efficacy or immunogenicity were not reported separately for infected and uninfected the children.[296,297] Three doses of human rotavirus vaccine RIX4414 were found to be safe and immunogenic in a placebo-controlled study of HIV-1–infected infants in South Africa.[298] Serious adverse events were not significantly more common among 37 HIV-1–infected Kenyan children following receipt of the pentavalent rotavirus vaccine than among HIV-uninfected children, although the study power was limited.[299]

Varicella Virus Vaccine

Children

Varicella vaccine was safe and immunogenic (60% with detectable antibodies), as determined by antibody and lymphocyte proliferation assay responses, in mildly symptomatic American HIV-1–infected children.[300] However, disseminated vaccine-strain varicella virus was reported in an HIV-1–infected child with a CD4 T-lymphocyte count of 8 cells/mm^3.[301] Based on these findings, HIV-1–infected children with CD4 T-lymphocyte percentages of 15 or more should receive two doses of varicella vaccine.[19,302]

Varicella vaccine has been found to be safe and immunogenic among children receiving HAART. No serious adverse events have been reported, and 67% to 79% of children had an antibody response within the first 3 months after vac-

cination, although waning immunity was found, with only 30% to 65% having persistent antibody 1 year after vaccination.[303–305] Children receiving HAART were as responsive to vaccination as asymptomatic and untreated HIV-infected children,[304] but they were less likely to respond than HIV-uninfected control children.[306] Providing booster doses to improve immunity did not result in sustained antibody titers among children with a history of varicella infection.[307] In a study that observed children for the development of varicella or herpes zoster in the prevaccine and postvaccine eras, vaccine effectiveness was determined to be 82% against varicella and 100% against herpes zoster.[308]

Adults

In a randomized, placebo-controlled study of two doses of varicella vaccine in 67 HIV-1–infected adults and 15 uninfected adults, the vaccine was found to be safe but only moderately immunogenic as measured by cellular immune responses.[309] Disseminated varicella resulting from the vaccine strain has been reported in HIV-1–infected adults.[310] The herpes zoster vaccine was reported to be safe and immunogenic in HIV-1–infected adults.[311,312]

Yellow Fever Virus Vaccine

Children

Limited data suggest that HIV-1–infected children respond poorly to yellow fever vaccine. Only 17% of 18 HIV-1–infected children developed an antibody response to yellow fever vaccine compared with 74% of 57 HIV-1–uninfected children.[313] No data are available on children receiving HAART or on protection against disease following yellow fever vaccination.

Adults

A Cochrane review of yellow fever vaccination of HIV-1–infected persons identified three cohort studies involving 484 patients and concluded that HIV-1–infected individuals developed significantly lower concentrations of neutralizing antibodies in the first year after vaccination compared to uninfected patients.[314] Lower HIV viral load and higher CD4 T lymphocyte counts were associated with higher antibody titers.[314–316] Within the Swiss HIV Cohort Study, 83% of 78 HIV-1–infected adults seroconverted following receipt of yellow fever vaccine compared with 97% of 66 uninfected adults.[317]

Safety of Yellow Fever Virus Vaccine

Few severe complications have been reported as a result of inadvertent immunization of yellow fever vaccine to immunocompromised persons, but experience is limited.[23,318,319] No serious adverse events were reported among 102 HIV-1–infected adults who received yellow fever vaccine,[317] and no adverse events were observed following yellow fever vaccination of 14 other HIV-1–infected adults.[320,321] However, fatal myeloencephalitis caused by yellow fever vaccine was reported in a 53-year-old HIV-infected man in Thailand who was asymptomatic but had high plasma HIV viral load levels and low CD4 T lymphocyte counts.[322]

Live Attenuated Influenza Virus Vaccine

Children

The trivalent, cold-adapted, live, attenuated influenza vaccine was shown to be safe in studies of HIV-1–infected children receiving antiretroviral therapy.[130,323,324] After two doses of vaccine, 77% of the HIV-1–infected children and 83% of the control children had a fourfold or greater rise in influenza antibody in response to at least one of the three vaccine strains.[323] HIV-infected children receiving the inactivated influenza vaccine tended to have higher antibody responses than children receiving the live attenuated influenza vaccine.[130] Shedding of vaccine virus was detected in 67% of HIV-1–infected and 50% of uninfected children up to 28 days after receiving attenuated influenza vaccine.[325]

Adults

The trivalent, cold-adapted, live, attenuated influenza vaccine was shown to be safe in small studies of HIV-1–infected adults.[126,323,326] Few HIV-1–infected and –uninfected adults developed a seroresponse to the live attenuated influenza vaccine, although most had preexisting titers to the vaccine strains before vaccination.

SUMMARY

HIV-1 infection poses some risk from live vaccines in untreated immunosuppressed patients, and vaccines may be less immunogenic and efficacious than in uninfected persons, but most HIV-1–infected persons can benefit from vaccines.

71 Vaccines for International Travel

Elizabeth D. Barnett, Phyllis E. Kozarsky, and Robert Steffen

INTERNATIONAL TRAVEL

People travel for many reasons, including tourism, business, educational experiences, or to flee from war, famine, or other intolerable situations. In 2016, international tourist arrivals exceeded 1.2 billion. The World Tourism Organization predicts that international tourist arrivals may exceed 1.8 billion by 2030.[1] International migrants, a category of traveler not captured in the tourism statistics, included more than 240 million refugees, asylum seekers, migrant workers, illegal migrants, and internally displaced persons in 2015.[2]

Given the growth of international travel, it is likely that many health providers will be called on to offer advice about pretravel immunizations. The International Society of Travel Medicine was started in 1991 to promote healthy and safe travel through education, service, and research activities in the field, and in 2006, the Infectious Diseases Society of America published guidelines on the practice of travel medicine.[3] Although travel health clinics specializing in pretravel advice and immunization are present in many locations, most travelers will not be seen in these clinics before travel. Health professionals of all kinds must be able to provide basic pretravel services and identify patients in need of specialized advice. This chapter focuses on disease risks specific to travelers to destinations where disease risk may be greater than in their home countries and considerations taken in choosing whether a traveler is a candidate for travel-related vaccines. Information about disease epidemiology and vaccine characteristics is presented in detail in other chapters. Because national standards for licensure differ, not all vaccines are available in all countries. Similarly, vaccines against the same disease and recommended vaccine schedules may differ somewhat by manufacturer and national authority.

GENERAL INFORMATION ABOUT IMMUNIZATIONS FOR INTERNATIONAL TRAVEL

Approach to Travel Immunizations

The two steps in immunizing travelers are to update routine immunizations and provide travel-specific immunizations. To do the first, knowledge of a patient's previous immunizations and medical history is necessary. For the second, detailed information about the patient's itinerary, living conditions during travel, mode of travel (e.g., adventure travel or chaperoned luxury tour), and purpose of travel (e.g., medical or veterinary work, tourism, visiting relatives) is needed. Although sometimes mistakenly regarded as a rote selection of vaccines based on destination country, choice of vaccines more often requires thoughtful consideration based on the patient's medical history, vaccine interactions with other vaccines or medications, limitation of time until departure, magnitude of risk of vaccine-preventable diseases, and patient preferences. Cost is a growing factor in a traveler's decision-making process about which vaccines to receive. Travelers with limited means and incomplete insurance coverage may be forced to make decisions about which family members to protect (often choosing children, leaving adults vulnerable) or may choose, because of cost, to limit vaccines to those such as yellow fever vaccine because it is required for entry into some countries. Finally, incremental risk during the voyage needs to be considered. Travelers are originating from countries previously considered only as destination countries, leading to situations in which risk of disease is lower in the destination country; for example, the risk of acquiring typhoid for someone originating in Kolkata, India who plans to visit relatives in East Africa is likely to be lower than at home.

Sources of Information on Travel Vaccines

Sources of health information for international travel include International Travel and Health-Vaccination Requirements and Health Advice; while the print edition has not been available since 2012, electronic updates, especially of the vaccine chapter, are available through the World Health Organization (WHO)[4], Health Information for International Travel (Yellow Book), published by the Centers for Disease Control and Prevention (CDC), Atlanta, GA, and available at the CDC travel health website,[5] and other local and national publications. Many countries publish national guidelines regarding travel health information, and readers are encouraged to base their recommendations on those. Other sources of information are textbooks[6,7] and review articles.[8–16] Many sites on the Internet provide travel health information for health providers and the public, although not all are reliable.

The CDC publishes downloadable vaccine information statements for vaccines available in the United States.[17] These handouts are useful when discussing with patients risk of disease, indications and contraindications for vaccine, adverse events associated with vaccines, and need for and timing of booster doses. Detailed technical recommendations of the Advisory Committee on Immunization Practices (ACIP) for many travel-related vaccines are also available.[18] More comprehensive information on each vaccine can be found in individual chapters in this textbook.

General Considerations Regarding Immunizations

Simultaneous Administration of Vaccines and Immunoglobulin

Scheduling multiple vaccines for the traveler can be challenging, especially when departures are imminent. Although scheduling a consultation at least 4 to 6 weeks before travel is ideal, few travelers allow as long as a month, and many come for consultation only a few days before departure. Whenever the traveler is seen, there is potential for helpful information to be given, and some agents (e.g., hepatitis A vaccine, influenza vaccine when available, updates on routine vaccines), can be given with good effectiveness even on the day of departure. Immunization schedules can be accelerated, or vaccines limited to those most appropriate to the infectious disease risks likely to be faced by the traveler. Although many patients and providers are concerned about the likelihood of adverse reactions to multiple vaccines administered simultaneously, studies performed in travel clinics that evaluated simultaneous

administration of multiple vaccines, including travel vaccines, reported that adverse events were generally minor and not incapacitating.[19,20] The ACIP encourages simultaneous administration of all needed vaccines including settings such as preparation for travel.[21]

Inactivated vaccines can be given concurrently or at any interval before or after other inactivated or live vaccines (see Chapter 9). Live vaccines (such as yellow fever, measles-mumps-rubella [MMR], and varicella) should be administered either simultaneously or at least 28 days apart. When live vaccines are given less than 28 days apart, the second should not be counted as valid and should be repeated at least 28 days from the first administration.[21] Some data exist to support exceptions: oral poliovirus vaccine (OPV), no longer used in most industrialized countries, may be given at any interval before or after parenteral live vaccines; yellow fever vaccine may be given at any interval with respect to monovalent measles vaccine; and Ty21a oral typhoid vaccine may be given at the same time as or at any interval relative to parenteral live vaccines (MMR, varicella, yellow fever).[21,22]

Antibody responses to MMR and varicella vaccines may be impaired if given at the same time as immunoglobulin. MMR and varicella vaccines should be administered at least 2 weeks before immunoglobulin, although they can be administered at the same time, if necessary.[23] If immunoglobulin is given before MMR or varicella vaccines, the appropriate time interval after immunoglobulin for giving these vaccines depends on the dose of immunoglobulin administered; a helpful table detailing appropriate intervals is available.[24] Immunoglobulin has not been shown to interfere with responses to polio, yellow fever, or oral typhoid vaccines.

Immunization of Persons With Altered Immunocompetence

Detailed recommendations regarding immunization of immunocompromised persons are published elsewhere (see Chapters 67 and 68) and are available from the CDC[25] and from the Infectious Diseases Society of America.[21,26,27] Information specific to immunocompromised travelers is available from the CDC.[28] In general, immunocompromised persons should not receive live viral vaccines, but there may be some exceptions. Information specific to travel vaccines is presented in the sections on individual vaccines below.

Effect of Antimalarials and Antimicrobial Agents on Vaccine Response

When antimalarials in the chloroquine/mefloquine family are administered simultaneously with human diploid cell rabies vaccines, they may interfere with immunogenicity of the vaccines.[29] It does not appear that these antimalarials interfere with immunogenicity of oral typhoid vaccine. The combination of antimicrobial agents and oral typhoid vaccine is contraindicated because they would probably interfere with the activity of this live bacterial vaccine.[30,31] Details of these interactions can be found in the sections devoted to individual vaccines below.

Routine Immunizations and Modifications Needed for Travelers

Routine childhood and adult immunizations should be brought up to date as part of preparation for international travel. Information is available from many sources about routine immunizations. In the United States, schedules are updated frequently and are available from the CDC on the Internet.[32] Readers are also referred to country-specific schedules for this information. Some travelers will require accelerated schedules because of imminent departure dates or because of immunization delays. The reader is referred to Chapter 9 for routine and accelerated schedules in the United States and to the chapters on individual vaccines for detailed information on indications, contraindications, precautions, and expected adverse events. Children in the United States are immunized routinely against 16 diseases (Table 71.1). Most diseases for which children are immunized routinely are present worldwide, although risk of contracting them varies markedly depending on travel destination. Additional information about adult immunization is available from several sources.[33–35] Indications specific to travel are given in sections referring to individual vaccines below. All adults should be up to date with routine childhood immunizations, and all (who have no contraindication) in the United States should receive annual influenza vaccination[36]; influenza immunization is recommended from age 60 or 65 years in most other industrialized countries, although the risk of influenza is worldwide. Those 65 years of age or older, or at any age with certain medical conditions, should be immunized against pneumococcal disease, and all adults older than age 60 years without contraindications should receive zoster vaccine.

VACCINES FOR TRAVEL

Selected Routine Immunizations Especially Important for Travelers

Diphtheria

Epidemics of diphtheria in the newly independent states of the former Soviet Union[37] and in Thailand, Algeria, and Ecuador in the early 1990s,[38] along with the continued endemic presence of diphtheria in many developing countries, underscore the need for attention to diphtheria immunization for travelers to these areas and for continuing to provide routine booster doses (supplied as a combination of tetanus-diphtheria toxoids) throughout adulthood. Vitek and colleagues demonstrated a significant relationship between time since the last diphtheria toxoid booster and risk of diphtheria among Russian schoolchildren.[39] Cases of diphtheria, both cutaneous and fatal respiratory disease, have been reported in travelers.[40–43] Migrant populations also may transmit the bacteria into populations in which immunity has waned because of a decrease in natural disease and lack of routine adult vaccine boosters. In the United States, 20% to 60% of adults older than 20 years of age lack diphtheria antibody,[44,45] and in Western Europe, serologic surveys have shown immunity to diphtheria to be poor among adults, particularly women; men may have been given boosters during military service.[46]

Travel consultation is an opportunity to bring every individual up to date with diphtheria immunization. For adults, a booster dose of combined tetanus-diphtheria toxoids every 10 years is recommended in the United States and some other countries, while boosters at 20-year intervals from ages 25 to 65 years, or no boosters after a complete five-dose series, are recommended by health authorities in other countries.

Poliomyelitis

The program for worldwide polio eradication is proceeding rapidly; periodic setbacks have occurred in recent years with resurgence of disease in some countries and importation into previously polio-free countries.[47] The Western Hemisphere was declared polio free in 1994, the Western Pacific region in 2000, the European region in 2002, and the Southeast Asia region, which includes India, in 2014.[48–51] The latest information on

TABLE 71.1 Vaccinations Recommended Routinely for Children and Adults in the United States, With Special Indications for Travelers

Disease	Vaccine	Age Groups	Greatest Areas of Risk	Special Indications
Diphtheria	DTaP or DTP	<7 y	Developing world, countries of former Soviet Union	
	Td	≥7 y		
	Tdap	≥11 y		May be given to those age 7–10 y who are not fully immunized against pertussis
Tetanus	DTaP or DTP	<7 y	Worldwide	
	Td	≥7 y		
	Tdap	≥11 y		
Pertussis	DTaP or DTP Tdap	<7 y ≥11 y	Worldwide circulation	May be given to those age 7–10 y who are not fully immunized against pertussis
Polio	IPV	<18 y and previously unvaccinated adults	Pakistan, Afghanistan, Nigeria	Extra dose of IPV (if previously fully immunized) for persons traveling to areas of risk
Measles	MMR, MR, MMRV, or M[b]	All ages for susceptible persons	Worldwide	2 Doses separated by ≥28 days for those age ≥12 mo; first dose may be given as early as age 6 mo but should not be counted toward the routinely recommended 2 doses for persons on or after their 1st birthday; most persons born before 1957 can be considered immune and do not need vaccination
Mumps	MMR, MMRV, Mu[b]	All ages for susceptible persons	Worldwide	
Rubella	MMR, MMRV, MR, or R[b]	All ages for susceptible persons	Worldwide	Especially for nonpregnant females of childbearing age
Haemophilus influenzae type b	Hib	<5 y	Most of the world	
Hepatitis A	Hep A	≥1-year-old children	Developing world	Children traveling for the purpose of visiting friends or relatives may be at greater risk
Hepatitis B	Hep B	Routine childhood and adolescence; older ages with special risk	Most of the world; see Fig. 71.1	Travel to areas with hepatitis B prevalence ≥2%; occupational or behavioral risk factors for disease
Pneumococcal	Pneumococcal conjugate	All children age 2–23 mo; certain children ages 24–59 mo; high-risk groups of older ages and all adults age ≥65 y	Worldwide	
Pneumococcal[a]	Pneumococcal polysaccharide	All adults ≥65 y; also younger special-risk groups, such as persons with chronic cardiopulmonary disease, asthma, or smoking	Worldwide	
Varicella	Varicella or MMRV	All ages for susceptible persons	Most of the world	
Influenza[a]	Influenza	1 Dose annually in persons age ≥6 mo; 2 doses for the first influenza season for children age <9 y	Most of the world	Northern hemisphere season December through March; southern hemisphere season April through September; tropics all year
Human papillomavirus	HPV	9- to 26-y-old females; 9- to 21-y-old males (HPV4)	Worldwide	
Meningococcal	Conjugate ACYW135	1 Dose for 11- to 12-y-olds; with booster at 16 y; adolescents at high school entry; college students	Meningitis belt in sub-Saharan Africa	Travelers to high-risk areas
Meningococcal B	Serogroup B	>10 y-olds at increased risk for meningococcal disease	Worldwide	
Rotavirus	Rotavirus	All children age 6–32 wk	Worldwide	

The most current ACIP recommended adult and childhood vaccination schedules can be found at www.cdc.gov/vaccines/schedules/hcp/.
[a]Vaccines routinely indicated for adults.
[b]Single antigen measles, mumps, and rubella vaccines are no longer available in the United States.
DTaP, diphtheria and tetanus toxoids and acellular pertussis; DTP, diphtheria and tetanus toxoids and pertussis; Hep A, hepatitis A; Hep B, hepatitis B; Hib, *Haemophilus influenzae* type b; HPV human papillomavirus; IPV, inactivated poliovirus vaccine; M, measles; MMR, measles-mumps-rubella; MR, measles-rubella; Mu, mumps; Td, tetanus and diphtheria toxoids; Tdap, tetanus toxoid, diphtheria toxoid, and acellular pertussis; R, rubella.

the status of global polio eradication can be found at the Polio Global Eradication Initiative website[52]; at the time of writing, the only three countries where polio transmission has never been eradicated are Afghanistan, Nigeria, and Pakistan. Somalia, Cameroon, Iraq, and Equatorial Guinea had cases in 2014. A 2005 case of vaccine-associated paralytic polio in an unimmunized traveler underscores the need to provide immunization against polio to protect not only against wild-type polio but also against vaccine-associated disease.[53]

Travelers to areas of the world where polio continues to occur should ensure that they have completed the recommended age-appropriate vaccine series; adults and children who have completed a basic series of polio vaccine should receive a single lifetime booster of inactivated polio vaccine (IPV). In many European countries, an IPV booster dose is recommended every 10 years if exposure to risk persists. People of all ages staying in a country identified as a poliovirus exporter for longer than 4 weeks may be required to show proof of polio vaccination before departing the country. In 2015, this focused on Pakistan and Afghanistan. The most current list of countries can be found at the Polio Global Eradication Initiative.[52] CDC recommends long-term travelers and expatriates staying in Pakistan and Afghanistan receive a dose of IPV between 4 weeks and 12 months before the date of their planned departure. This dose should be documented on an International Certificate of Vaccination or Prophylaxis (ICVP).[54] IPV is indicated for unvaccinated adults; IPV or OPV can be used for children. Partially immunized children or adults may complete the series with either IPV or OPV. The interval between doses of vaccine may be shortened to 4 weeks to allow the maximal number of doses to be administered before departure. IPV-containing combination vaccines may be used if available. In 2009, the ACIP revised recommendations for the childhood poliovirus immunization to include administration of the final dose of polio vaccine after 4 years of age, regardless of number of previous doses, and extending the interval between doses three and four from 4 weeks to 6 months.[55] Accelerated schedules, however, remain appropriate for imminent travel to polio risk areas.

Hepatitis B

Hepatitis B risk in travelers is associated with longer length of stay, contact with population groups with high carrier rates of hepatitis B (Fig. 71.1), occupations such as healthcare workers or laboratory workers, and behaviors such as injection drug use and having multiple sex partners. Risk for Swiss tourists traveling to developing countries was noted in 1987 to be 39 per 100,000 travelers for a stay of 1 month.[56] Long-stay travelers were at greater risk; unimmunized U.S. missionaries serving in Africa before 1990 had attack rates of 11% during the first 2 years of service and median annual attack rates of 1.2% over the next decade.[57] A prospective study published in 2004 of unvaccinated Dutch missionaries and their families living in rural Nigeria identified seroconversion rates of 1.7 per 1000 person-months in adults and 2.8 per 1000 person-months in children.[58]

A 2015 review of vaccine-preventable disease risk in travelers considers hepatitis B to be of intermediate risk (one to 10 cases per 100,000 travelers per month), with behaviors during travel and contact with the local population likely more important than disease prevalence at destination.[59–62]

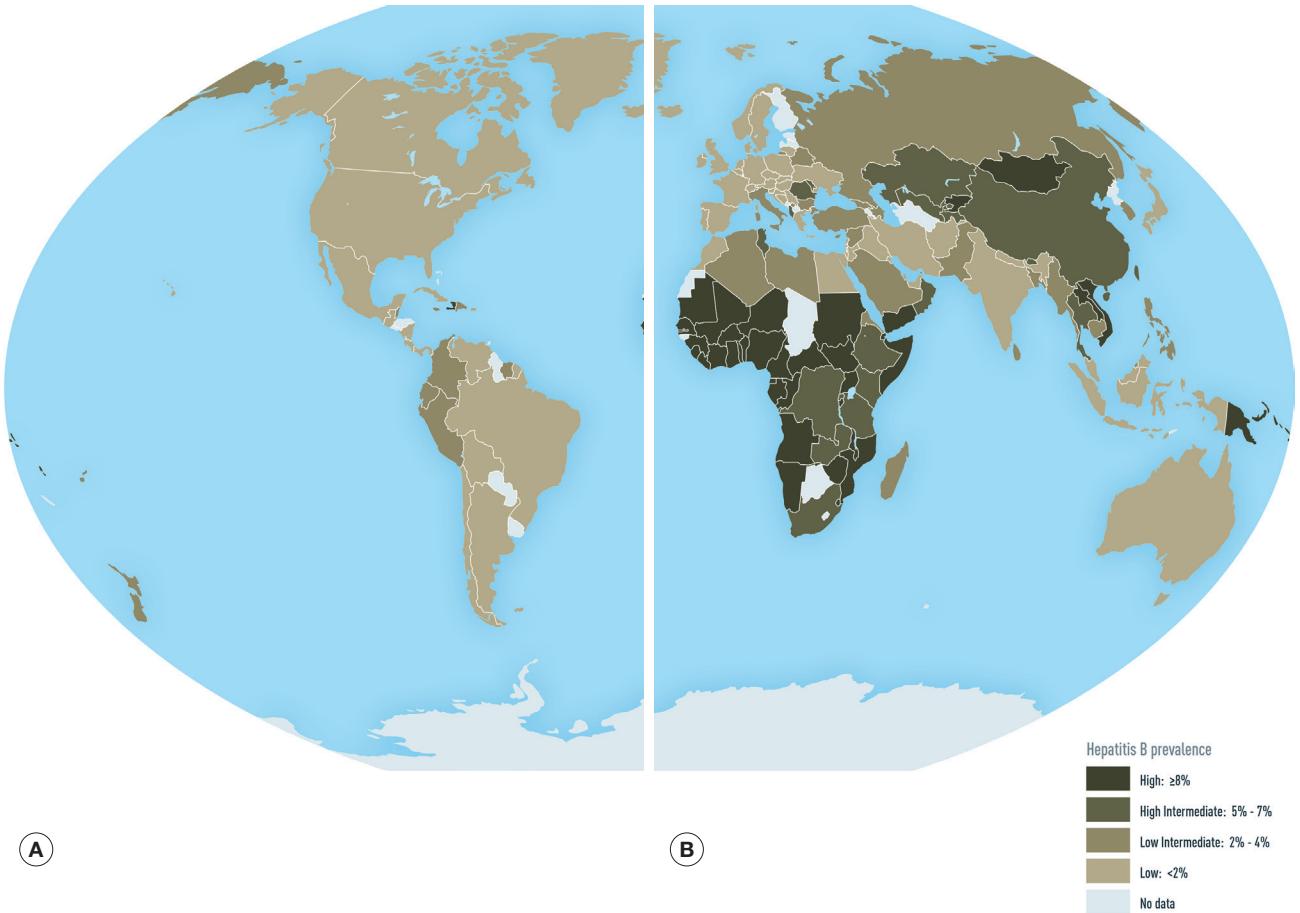

Figure 71.1. Prevalence of chronic hepatitis B virus infection among adults. *(From Centers for Disease Control and Prevention [CDC]. Health Information for International Travel 2016.)*

Immunization against hepatitis B is now a routine immunization for children and adolescents in most countries, except some in Northern Europe. The CDC recommends hepatitis B immunization for travelers to countries with prevalence of hepatitis B infection of ≥2%. The first two doses should be given 4 weeks apart and the third dose 4 to 12 months after the second. If insufficient time is available before departure, rapid seroconversion may be achieved by giving the third dose as early as 4 weeks after the second, with a fourth dose given 12 months from the first to ensure long-term protection. Other accelerated schedules are proposed for hepatitis B and hepatitis A/B combination vaccines and have been recommended and used by travel medicine clinicians, but not all have been approved by the U.S. Food and Drug Administration.

Measles

Measles continues to be an important cause of childhood morbidity and mortality worldwide; cases associated with travel have increased in recent years. In 2014, the United States experienced the largest number of cases since measles elimination was documented in 2000. Multistate outbreaks have been associated with imported cases at sporting events and amusement parks.[63,64] Cases in returning U.S. travelers and foreign visitors predominate and continue to lead to secondary cases and outbreaks primarily among unimmunized individuals.[65] Eighty percent of cases of measles in the United States in 2001 to 2003 were confirmed to be imported, import-linked, or a result of imported virus.[66] Of measles cases in U.S. residents from 2001 to 2004, 55 of 122 (45%) occurred in those who travelled internationally.[67] Outbreaks associated with air travel have been documented; in the summer of 2010, a case of measles was identified in a young unimmunized airline passenger arriving in the United States from Switzerland, exposing 31 persons, one of whom developed measles and in turn exposed 270 persons in the United States.[68] In 2013, a traveler returning from India was associated with direct and indirect transmission to 22 other individuals and investigation of exposures to approximately 1000 individuals.[69,70] Similar outbreaks and exposures have been reported from Australia, Italy, and The Netherlands.[71–73]

Two doses of MMR vaccine are recommended for all international travelers.[32,74] The first dose may be given at 6 months of age; this dose is not counted as part of the routine two dose series. Travelers 1 year of age or older who have received a single MMR vaccine should receive a second, at an interval of 4 weeks from the first, before international travel. Children younger than 6 months of age are likely to be protected by maternal antibody. Adults born in the United States before 1957 can be considered to have natural immunity, but those at increased risk of measles, such as international travelers, may be offered serologic testing or vaccine before travel; if nonimmune, such individuals should receive two doses of vaccine.[74] Mumps, rubella, and varicella vaccines should also be brought up to date, using MMR or MMR with varicella vaccines as appropriate. As seroprevalence of varicella in adult immigrants from tropic countries might be much lower compared with North America or Europe, the latter may be particularly appropriate in this population.

Pertussis

Pertussis continues to be a disease of worldwide importance, with an estimated 16 million cases and 195,000 deaths per year. In the United States there were more than 48,000 cases in 2012, the highest number reported since 1955[75]; more than 28,000 cases were reported in both 2013 and 2014.[76] Attack rates of pertussis are related directly to use of vaccine; after a decline in use of pertussis vaccines in Japan, Sweden, and Britain, a resurgence of disease occurred.[74] Acellular pertussis vaccines are now used in many countries; two vaccines are licensed in the United States.[77] The increased risk for pertussis as a result of international travel is unknown.[78] One study found an increased rate of pertussis among Hajj pilgrims.[79] Children and adolescents should complete as much of a primary series of a pertussis-containing vaccine as possible, or be given any boosters due, before international travel.[77] Adults should be given pertussis-containing vaccine (tetanus, diphtheria, and pertussis [Tdap]) once if due for boosters of tetanus and diphtheria before travel if they have never received a Tdap booster in the past. Pregnant women should receive Tdap vaccine during every pregnancy to provide additional protection to infants.[80]

Influenza

Influenza occurs worldwide; in the tropics transmission occurs throughout the year, whereas peaks of transmission usually occur from December through March in the Northern Hemisphere and April through September in the Southern Hemisphere. Experience with the H1N1 influenza pandemic heightened awareness of influenza risk and travel. Risk to travelers for contracting influenza is increased by travel to a destination during influenza season, and participation in large organized tourist groups, such as those on cruise ships. Risk for serious disease depends on underlying health status. Incidence of influenza in travelers has been addressed by three studies; the rate of serologically confirmed cases was 8.9 per 100 person-months, and rates of symptomatic cases ranged from 0.9% to 1.0%.[81–83] Risk of influenza was sevenfold higher for destinations in East and Southeast Asia compared with other destinations.[84]

Annual influenza vaccination for all persons 6 months of age or older is recommended in the United States[85] and other countries. Challenges specific to travelers are that vaccine may not be available in the traveler's country of origin at the time of travel and available vaccine may not match strains circulating at the destination. In these cases, education about risk of influenza and management of respiratory and influenza-like illness is important. Available influenza vaccines will not protect against avian influenza [A(H5N1) and A(H7N9)], so other precautions (such as staying away from live animal markets) are needed when traveling to areas that might be affected by that virus. Information about circulating virus strains by region can be obtained from CDC[86] or the WHO.[87]

Rotavirus

A three-dose rotavirus vaccine (RotaTeq; Merck, Whitehouse Station, NJ) was licensed in the United States in February 2006; a second two-dose vaccine (Rotarix, GlaxoSmithKline, Research Park Triangle, NC) was licensed in April 2008. Recommendations for use of rotavirus vaccines are available from CDC.[88] The first dose of either vaccine can be given as early as 6 weeks of age, but must be given by 14 weeks and 6 days of age. The minimum interval between doses is 4 weeks, with maximum age at the last dose of the series 8 months 0 days. It would be prudent for infants traveling to areas with high prevalence of rotavirus to complete all doses of vaccine before departure.

Human Papillomavirus Vaccine

Three vaccines against human papillomavirus (HPV) are licensed in the United States at this time. Recommendations for their use are available from CDC.[89] HPV is present worldwide. A travel medicine consultation is an opportunity to offer this vaccine at routinely recommended ages as a part of an

overall strategy to reduce risk of HPV-associated cancers and sexually transmitted diseases.

Travel Vaccines

Bacille Calmette-Guérin

Bacille Calmette-Guérin (BCG) vaccines are available in many countries but vary in efficacy. In the United States and in many European countries, a program of surveillance, using tuberculin skin testing or interferon-γ release assays and early identification and treatment of infected persons, is preferred to universal immunization with BCG.[90]

Estimates of risk for tuberculosis (TB) among travelers are difficult to obtain.[91] Dutch long-term travelers had 3.5 tuberculin skin test conversions per 1000 person-months of travel and 2.8 if healthcare workers were excluded.[92] A study in Peace Corps Volunteers found 1.436 purified protein derivative conversions and 0.084 cases of active TB per 1000 volunteer-months for those serving in "high-risk" countries.[93] Immigrants returning home to visit family are at increased risk of exposure and development of disease.[94–96] Risk to travelers is not thought to be high enough to warrant routine immunization for travel. There are rare circumstances in which BCG might be considered in the United States for long-term travelers (infants or young children) to areas where the incidence of disease is high (more than 30 to 40 per 100,000) and where occupation or living conditions may result in significant exposure. One vaccine, manufactured by Organon Teknika (Durham, NC), is licensed in the United States. Because the protective effect of BCG has been confirmed mainly in infants age 1 year or younger, there would be almost no indication for BCG for adults who are traveling, although some experts believe BCG should be administered to healthcare personnel traveling to work in environments with high TB transmission rates.

Adverse events from vaccine occur in up to 10% of persons and usually consist of local ulceration and inflammatory adenitis. BCG vaccine is contraindicated in immunocompromised persons because of risk of dissemination of infection. Decisions to immunize HIV-infected, but immunocompetent persons are controversial; bacteria are able to remain dormant for years and cause disease if an individual becomes immunocompromised. Risk of infection with TB, such as in infants in developing countries with high rates of TB, must be weighed against risk of vaccination for those who may be at risk for HIV infection. The WHO continues to recommend universal immunization with BCG for infants in areas where risk of TB is substantial, based on potential for reducing miliary and meningeal TB in the first year of life.

Cholera

Cholera cases have increased globally since 2005 and continue to occur in Africa, Southeast Asia, and Haiti.[97] Risk of severe cholera is very low for travelers; the vast majority of infections will be asymptomatic or appear just as travelers' diarrhea. Attack rates are estimated to be one per 500,000 travelers, although higher rates (five per 100,000 travelers) have been reported from Japan, where routine screening for cholera was done in returning travelers with diarrhea.[98] The mainstay of protection against cholera remains drinking and using only water that has been boiled, treated, or supplied in reliable cans or bottles, and avoidance of ingestion of high-risk foods, such as raw shellfish, and the use of precautions when making other food selections. Cholera can be treated by prompt and vigorous oral or intravenous rehydration; antibiotics can be used, especially in hospitalized patients.

Two cholera vaccines are prequalified by WHO and available in various countries outside the United States. A third killed oral cholera vaccine is produced and available only in Vietnam and is 76% protective in the setting of a cholera outbreak.[99] An oral cholera vaccine was approved by the U.S. Food and Drug Administration in 2016 and is indicated for adults aged 18 to 64 years traveling to cholera-affected areas.[99a] Previously produced whole-cell injectable and live oral cholera vaccines are no longer available. Cholera vaccine is not recommended routinely for travelers, and no country requires cholera immunization for entry at this time.[100,101] For the rare person traveling to areas of high risk and poor sanitary conditions (e.g., relief workers in the midst of cholera outbreaks), vaccine may be offered if available. Food and water precautions are the mainstay of prevention of cholera, and appropriate rehydration therapy is the mainstay of treatment.

Oral cholera vaccines available outside the United States are given on a two-dose schedule with a 14-day interval between doses. A booster dose is recommended at an interval of 10 months to 2 years. Mild gastrointestinal side effects have been observed.[100] Immunization is not recommended during pregnancy; specific safety information about the use of these vaccines during pregnancy is not available. The oral cholera vaccine available in the United States is given as single oral dose a minimum of 10 days before potential exposure. Tiredness, headache, and mild gastrointestinal side effects were the most common adverse events. No information is available about booster doses.

Oral cholera vaccine may be given concurrently with yellow fever vaccine, oral typhoid Ty21a vaccine, and OPV.[102] Immunization with cholera vaccine should be completed before initiating malaria prophylaxis with chloroquine or mefloquine because of the potential for these antimalarials to affect immune response to vaccine adversely.[103]

Hepatitis A

Hepatitis A is a common vaccine-preventable disease to affect travelers, but is decreasing because of widespread use of vaccine and improving hygienic conditions at many destinations. In the 1980s, risk was estimated to be as high as 1% for short-term travelers who did not receive immunoglobulin and traveled to highest-risk areas.[104] A study of Canadian travelers reported a rate of one case per 3000 unimmunized travelers.[105] A report from Switzerland documented a reduction in cases of hepatitis A during the years 1988 to 2004 that was variable by country; this was attributed to both improved hygiene and hepatitis A immunization.[106] Risk for disease depends on length of stay and conditions of travel, including frequency of exposure to contaminated food and water. Fig. 71.2 shows the geographic distribution of risk for hepatitis A. Cases of hepatitis A, however, have been reported in tourists staying in luxury accommodations in countries where the risk of hepatitis A is high.[107] Despite availability of both immunoglobulin and an effective vaccine, many travelers do not receive them and therefore are not protected against hepatitis A.

Persons born in Europe, North America, Australia/New Zealand, or Japan since World War II have a low prevalence of immunity to hepatitis A.[108] Rates of immunity are higher with increased age, history of jaundice, and birth or residence in areas with high rates of hepatitis A. As many as 95% of persons born and raised in developing countries with high rates of hepatitis A may be protected by naturally acquired antibody.[109] Some countries, including the United States, have adopted hepatitis A as a routine immunization for children beginning at 1 year of age.

Options for immunoprophylaxis of hepatitis A include intramuscular immunoglobulin and hepatitis A vaccine. Immunoglobulin was the mainstay of protection for many years and is 85% to 90% protective. The major disadvantage

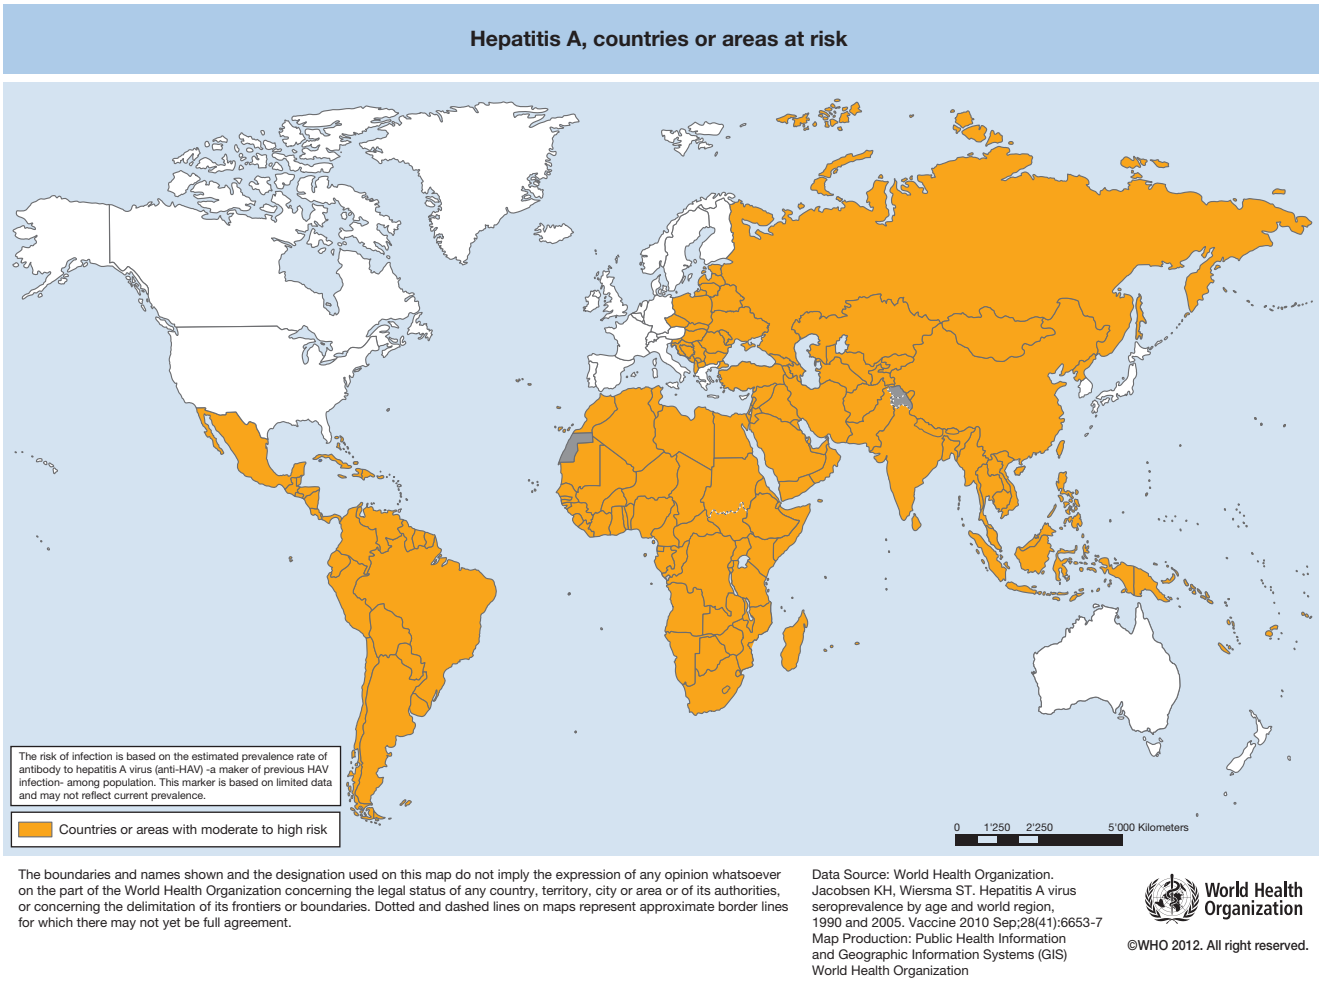

Figure 71.2. Countries or areas with moderate to high risk for hepatitis A. Note: This map generalizes available data, and patterns may vary within countries. *(From World Health Organization (WHO), 2012. http://gamapserver.who.int/mapLibrary/Files/Maps/Global_HepA_ITHRiskMap.png.)*

of immunoglobulin is that it is short acting and must be repeated for subsequent journeys, or additional doses must be given during prolonged residence in endemic areas. It does not offer effective protection against hepatitis B, C, or E. Adverse events are rare, although the large volume required may result in local discomfort. One advantage of this preparation is that it may be given to children younger than 1 year of age. Immunoglobulin has become unavailable in most countries, in part because of concern about the theoretical risk of transmission of variant Creutzfeldt-Jacob disease, and availability is limited in parts of the United States.[110] Hepatitis A vaccines have been marketed in Europe since 1992 and in the United States since 1995. Four products—Havrix (GlaxoSmithKline), Epaxal (PaxVax, formerly Crucell/Berna Biotech, currently unavailable), VAQTA (Merck), and AVAXIM (Pasteur Mérieux Connaught, Lyon, France)—have been manufactured, although AVAXIM and Epaxal, a virosomal, aluminum-free vaccine, are not licensed in the United States. A combined hepatitis A and B vaccine (Twinrix; GlaxoSmithKline) is also marketed widely. The four monovalent hepatitis A vaccines are highly immunogenic in adults, with protective antibody levels achieved in 95% to 100% of adults 1 month after the first injection, using recommended adult doses of Havrix (1440 enzyme-linked immunosorbent assay units [ELU] in 1.0 mL), VAQTA (50 units in 1.0 mL), or AVAXIM (160 units in 0.6 mL). It should be noted that because no international standardized reference exists for hepatitis A antigen content, each laboratory has expressed the antigen content using an in-house reference. One month after the booster dose, given at 6 to 12 months after the first dose, seroconversion rates of 100% were reported with all three vaccines.[111,112] Of importance for travelers with imminent departures, seroconversion rates of 87.1% (Havrix, 1440 ELU) and 95.7% (AVAXIM) were reported at 14 days after a single dose in a comparative trial.[113] Development of antibody occurred more slowly in the elderly, although similar antibody concentrations are achieved.[114] Combination hepatitis A and B vaccine demonstrated immunogenicity comparable to that of the monovalent vaccines.[115] Efficacy studies performed in Thailand (Havrix) and during a hepatitis A epidemic in the United States (VAQTA) demonstrated clinical efficacy of 94% and 100%, respectively. Havrix and VAQTA both have pediatric formulations for children 1 to 17 years of age (720 ELU and 25 units, respectively). Similar protective levels of antibody have been reported in children as in adults.[116,117] A Cochrane Database review documented clinical efficacy of preexposure prophylaxis with hepatitis A vaccines in susceptible individuals.[118]

Travelers to areas of intermediate or high prevalence should be protected against hepatitis A; some providers believe all travelers should be offered vaccine. Ideally, vaccine should be given at least 4 weeks prior to initiation of travel because of the concern that neutralizing antibody is not optimal prior to this time, although most young, healthy vaccinees will have detectable antibody response by 2 weeks, and to date there are

no reports of cases of hepatitis A, even in those immunized the day of departure. For healthy adults younger than 40 years of age, the CDC recommends a dose of hepatitis A vaccine administered at any time before departure; immunoglobulin may be used with vaccine for older persons or those with immunocompromising conditions, chronic liver disease, or other medical conditions.[119] The WHO and most other regional and national expert groups recommend a dose of hepatitis A vaccine at any interval before departure and consider immunoglobulin virtually obsolete for the purpose of prevention of hepatitis A for travelers.[120] A booster dose of vaccine at least 6 months after the initial dose is expected to provide long-term (at least 20 years) protection. Booster doses may be from the same or a different manufacturer, or may be the A/B combination vaccine, without adverse effect on reactogenicity or immunogenicity.[121] Table 71.2 lists the doses and schedules for administration of hepatitis A vaccines.

Generally, hepatitis A vaccine is well tolerated. The most common vaccine side effects include soreness at the injection site, headache, and malaise. Serious adverse events appear to be rare. Vaccine should not be given to persons with allergies to adjuvants or preservatives contained in the vaccine. Although risk from vaccination during pregnancy should be low, risk of disease must be weighed against the theoretical risk of immunization. Hepatitis A vaccines are inactivated and therefore may be used in immunocompromised persons. Simultaneous administration of hepatitis A vaccine and diphtheria, tetanus, oral and inactivated poliovirus, oral typhoid, cholera, Japanese encephalitis, rabies, or yellow fever vaccines does not impair immune response to either vaccine or increase adverse events.[122]

Children younger than 1 year of age should receive a single dose of immunoglobulin (0.02 mL/kg for up to 3 months protection or 0.06 mL/kg for up to 5 months protection), if available, because safety and efficacy of vaccine have not been evaluated adequately in this age group. Doses of immunoglobulin may be given as close as possible to the departure date; the dose depends on weight and length of stay. Serious adverse events following immunoglobulin are rare, although anaphylaxis has been reported in immunoglobulin A–deficient persons; immunoglobulin should not be used in these persons.

Immunoglobulin may interfere with response to certain live virus vaccines, such as measles, mumps, rubella, and varicella. It has been shown not to interfere with the immune response to oral polio, oral typhoid, or yellow fever vaccines. If travelers require both MMR or varicella vaccine and immunoglobulin, the vaccines ideally should be given 2 weeks before immunoglobulin. If immunoglobulin for hepatitis A has been given, subsequent immunization with MMR or varicella vaccine should be delayed at least 3 months.[23,24] If MMR or varicella vaccines and immunoglobulin must be given closer than 2 weeks apart, the MMR and varicella vaccine doses should be repeated 3 or more months after immunoglobulin unless serologic testing shows that antibodies to vaccine were produced.

Testing for susceptibility to hepatitis A before offering vaccine or immunoglobulin may be cost-effective in specific situations. Candidates for testing may include persons born and raised in high-prevalence areas and those with a history of jaundice. Other considerations include cost of testing compared with cost of immunization and assuring that testing will not delay ability to provide immunization if a person is seronegative. It is estimated that if cost of screening is one-third the cost of immunization, and the person's likelihood of immunity is greater than 33%, testing should be cost-effective.[123] Plans-Rubio has described a model to determine whether screening before immunization is cost-effective, based on calculation of a critical prevalence of antibody in the population, in turn based largely on screening and vaccination costs.[124]

Japanese Encephalitis

Japanese encephalitis (JE) is a leading cause of viral encephalitis in Asia. Although disease incidence has decreased in many countries because of immunization, improved hygiene and agricultural practices, and improved standards of living, the predominant picture remains that of expansion of the geographic range of JE over the past four decades.[125,126] JE is transmitted by mosquitoes. Risk of clinical disease in travelers is low, with estimates of risk ranging from less than one per million in civilian travelers to one per 5000 per month of exposure in the military or in the local population in rural endemic areas.

TABLE 71.2 Recommended Doses and Schedules for VAQTA, AVAXIM, Havrix, and Twinrix

Group	Age (y)	Dose	Volume (mL)	No. of Doses	Schedule (mo)[a]
VAQTA[b]					
Children and adolescents	1–17	25 U	0.5	2	0, 6–18
Adults	≥18	50 U	1.0	2	0, 6
AVAXIM[c]					
Adults[d]	≥16	160 U	0.5	2	0, 6–18
HAVRIX[e]					
Children and adolescents	1–18	720 ELU	0.5	2	0, 6–12
Adults	>18	1440 ELU	1.0	2	0, 6–12
TWINRIX[f]					
Adults	>18	720 ELU/20 μg HBsAg	1.0	3[g,h]	0, 1, 6
Children	1–15	360/10	0.5	3	0, 1, 6

[a]Zero (0) months represents timing of the initial dose; subsequent numbers represent months after the initial dose.
[b]Hepatitis A vaccine, inactivated (Merck).
[c]Hepatitis A vaccine (Pasteur Mérieux Connaught).
[d]Hepatitis A vaccine, inactivated (Crucell/Berna Biotech).
[e]Hepatitis A vaccine, inactivated (GlaxoSmithKline).
[f]Hepatitis A, inactivated, and hepatitis B, recombinant (GlaxoSmithKline).
[g]Two doses essential before departure as 720 ELU of hepatitis A would not grant sufficient protection.
[h]In some countries 2 doses of Twinrix Adult may be given to children >1 y up to the 16th birthday, scheduled at 0, 6–12 months.
ELU, enzyme-linked immunosorbent assay unit; RIA U, radioimmunoassay unit; U, unit.

Fifty-five cases of JE in travelers were reported in the literature between 1973 and 2008; none were known to have received JE vaccine.[127] Although there were only eight cases of JE reported in U.S. travelers between 1992 and 2008, the numbers have increased. Although disease in returned travelers is still quite rare, symptomatic illness is typically followed by either severe neurologic sequelae or death.[128] Most travelers have no natural immunity to the disease. Although risk is highest for persons who travel during the season of high transmission and remain in endemic areas for extended periods, many of those few cases have occurred in short-stay tourists.[129–134] Fig. 71.3 is a map of JE risk areas and Table 71.3 provides detailed information about the risk of JE by country, region, and season.[135] JE vaccines are available in many countries. Several vaccines, including a live attenuated vaccine, SA14-14-2, are licensed in Asia but are not available in the United States. The first JE vaccine to be licensed in the United States, JE-VAX, an inactivated, mouse-brain derived vaccine, has not been manufactured since 2006 and is no longer available.

An inactivated, Vero-cell culture-derived JE vaccine (Ixiaro, Jespect in Australia) was licensed for use in adults (age 17 years or older) in many countries and in the United States in 2009, and for use in children in 2013. This vaccine was licensed in the United States on the basis of the ability to produce JE virus–specific neutralizing antibody, a correlate of protection. The vaccine is given as two doses, 28 days apart; it is recommended that both doses be given before travel (Table 71.4). Some experts are using an accelerated schedule of a 1-week interval between doses.[134a] A booster dose may be given 1 year after the primary series has been completed if the traveler will be reexposed to JE. Studies of concomitant administration with other vaccines have been done only for hepatitis A vaccine; no differences were reported in safety or reactogenicity of either vaccine when given together compared with separate administration, although local reactions were reported more often in those who received the vaccines together.[136] The most common adverse events were local reactions, including pain and tenderness at the site of administration. Systemic adverse events were generally mild and included headache (26%), myalgia (21%), influenza-like illness (13%), and fatigue (13%).[127] A recent summary of adverse events reported to the U.S. Vaccine Adverse Events Reporting System (VAERS) suggests that serious adverse events to JE vaccine are infrequent.[137]

Vaccine is most appropriate for persons who will spend 1 month or longer in endemic areas, especially in rural areas during transmission season. Other travelers, such as those traveling to endemic areas during epidemic transmission or those whose occupation or living conditions will place them at increased risk of exposure (those with unprotected outdoor, evening, and nighttime exposure in rural areas, such as campers or bicyclers), may be candidates for vaccine even if traveling for less than 1 month.[138] Protective measures for persons who are not immunized include prevention of mosquito bites through the use of window screens, bed nets, and insect repellents.

Meningococcus

Invasive meningococcal disease occurs worldwide, but major epidemics occur more frequently in the meningitis belt of

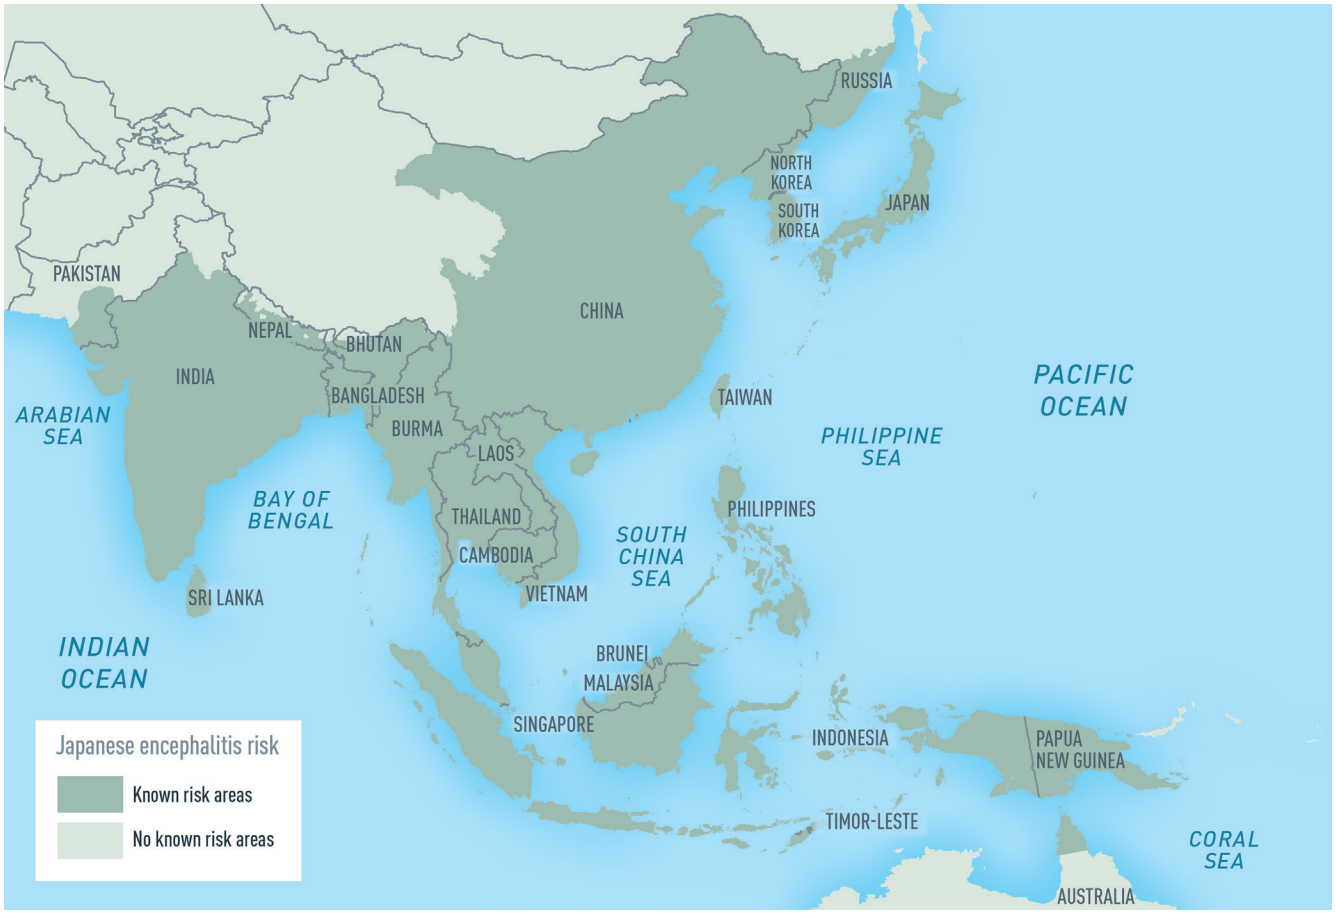

Figure 71.3. Geographic distribution of Japanese encephalitis. *(From Centers for Disease Control and Prevention [CDC]. Health Information for International Travel 2016.)*

TABLE 71.3 Risk for Japanese Encephalitis (JE) by Country[a]

Country	Affected Areas	Transmission Season	Comments
Australia	Outer Torres Strait islands	December–May; all human cases reported February–April	1 Human case reported from north Queensland mainland
Bangladesh	Presumed widespread	Most human cases reported May–October	Sentinel surveillance has identified human cases in Chittagong, Dhaka, Khulna, Rajshahi, Ranjpur, and Sylhet Divisions; highest incidence reported from Rajshahi Division; outbreak reported from Tangail District, Dhaka Division, in 1977
Bhutan	Very rare reports; probably endemic in nonmountainous areas	No data	Proximity to other endemic areas and presence of vectors suggests virus transmission is likely
Brunei	Very rare reports; presumed to be endemic countrywide	Unknown; presumed year-round	Proximity to other endemic areas suggests virus transmission is likely
Burma (Myanmar)	Limited data; presumed to be endemic countrywide	Unknown; most human cases reported May–October	Outbreaks of human disease documented in Shan State; antibodies documented in animals and humans in other areas
Cambodia	Presumed to be endemic countrywide	Year-round with peak season May–October	Sentinel surveillance has identified human cases in at least 15 of 23 provinces, including Phnom Penh, Takeo, Kampong Cham, Battambang, Svay Rieng, and Siem Reap; 1 case reported in 2010 in a traveler who visited Phnom Penh and Angkor Wat/Siem Reap only
China	Human cases reported from all provinces except Xizang (Tibet), Xinjiang, and Qinghai	Most human cases reported June–October	Highest rates reported from Guizhou, Shaanxi, Sichuan, and Yunnan Provinces, and Chongqing City; vaccine not routinely recommended for travel limited to Beijing, Shanghai, Hong Kong City/Kowloon, Macau, or other major cities
India	Human cases reported from all states except Dadra, Daman, Diu, Gujarat, Himachal Pradesh, Jammu and Kashmir, Lakshadweep, Meghalaya, Nagar Haveli, Punjab, Rajasthan, and Sikkim	Most human cases reported May–October, especially in northern India; the season may be extended or year-round in some areas, especially in southern India	Highest rates of human disease reported from the states of Andhra Pradesh, Assam, Bihar, Goa, Haryana, Karnataka, Kerala, Tamil Nadu, Uttar Pradesh, and West Bengal
Indonesia	Presumed to be endemic countrywide	Year-round; peak season varies by island	Sentinel surveillance has identified human cases in Bali, Kalimantan, Java, Nusa Tenggara, Papua, and Sumatra
Japan[b]	Rare sporadic human cases on all islands except Hokkaido; enzootic activity ongoing	Most human cases reported July–October	Large number of human cases reported until JE vaccination program introduced in late 1960s; most recent small outbreak reported from Chugoku district in 2002; enzootic transmission without human cases observed on Hokkaido; vaccine not routinely recommended for travel limited to Tokyo or other major cities
Korea, North	Limited data; presumed to be endemic countrywide	No data; proximity to South Korea suggests peak season is likely to be May–October	
Korea, South[b]	Rare sporadic human cases countrywide; enzootic activity ongoing	Most human cases reported May–October	Large number of human cases reported until routine JE vaccination program introduced in mid-1980s; last major outbreak reported in 1982; vaccine not routinely recommended for travel limited to Seoul or other major cities
Laos	Limited data; presumed to be endemic countrywide	Year-round, with peak season June–September	Sentinel surveillance has identified human cases in north, central, and southern Laos
Malaysia	Endemic in Sarawak; sporadic cases reported from all other states; occasional outbreaks reported	Year-round; in Sarawak, peak season October–December	Most human cases reported from Sarawak; vaccine not routinely recommended for travel limited to Kuala Lumpur or other major cities
Nepal	Endemic in southern lowlands (Terai); cases also reported from hill and mountain districts, including the Kathmandu valley	Most human cases reported June–October	Highest rates of human disease reported from western Terai districts, including Banke, Bardiya, Dang, and Kailali; vaccine not routinely recommended for those trekking in high-altitude areas

TABLE 71.3 Risk for Japanese Encephalitis (JE) by Country[a] *(Continued)*

Country	Affected Areas	Transmission Season	Comments
Pakistan	Limited data; human cases reported from around Karachi	Unknown	
Papua New Guinea	Limited data; probably widespread	Unknown; probably year-round	Sporadic human cases reported from Western Province; serologic evidence of disease from Gulf and Southern Highland Provinces; a case of JE was reported from near Port Moresby in 2004
Philippines	Limited data; presumed to be endemic on all islands	Year-round with peak season July–September	Outbreaks reported in Nueva Ecija and Manila; sentinel surveillance has identified human cases in other areas of Luzon and the Visayas
Russia	Rare human cases reported from the Far Eastern maritime areas south of Khabarovsk	Most human cases reported July–September	
Singapore	Rare sporadic human cases reported	Year-round	Vaccine not routinely recommended
Sri Lanka	Endemic countrywide except in mountainous areas	Year-round with variable peaks based on monsoon rains	Highest rates of human disease reported from Anuradhapura, Gampaha, Kurunegala, Polonnaruwa, and Puttalam districts
Taiwan[b]	Rare sporadic human cases islandwide	Most human cases reported May–October	Large number of human cases reported until routine JE vaccination introduced in 1968; vaccine not routinely recommended for travel limited to Taipei or other major cities
Thailand	Endemic countrywide; seasonal epidemics in the northern provinces	Year-round with peak season May–October, especially in the north	Highest rates of human disease reported from the Chiang Mai Valley; sporadic human cases reported from Bangkok suburbs; several cases reported recently in travelers who visited resort or coastal areas of southern Thailand
Timor-Leste	Sporadic human cases reported; presumed to be endemic countrywide	No data; cases reported year-round in neighboring West Timor	
Vietnam	Endemic countrywide; seasonal epidemics in the northern provinces	Year-round with peak season May–October, especially in the north	Highest rates of disease in the northern provinces around Hanoi and northwestern and northeastern provinces bordering China
Western Pacific Islands	Outbreaks of human disease reported in Guam in 1947–48 and Saipan in 1990	Unknown; most human cases reported October–March	Enzootic cycle might not be sustainable; outbreaks may follow introductions of virus; vaccine not recommended

[a]Data are based on published reports and personal correspondence. Risk assessments should be performed cautiously, because risk can vary within areas and from year to year, and surveillance data regarding human cases and JE virus transmission are incomplete.
[b]In some endemic areas, human cases among residents are limited because of natural immunity among older people or vaccination. However, because JE virus is maintained in an enzootic cycle between animals and mosquitoes, susceptible visitors to these areas still may be at risk for infection.

TABLE 71.4 Japanese Encephalitis Vaccine (Ixiaro, Jespect) Schedule

	Dose (Subcutaneous Route)	Comments
Primary series 1 and 2	0.5 mL for ages ≥3 y 0.25 mL for ages 2 mo to 2 y	Days 0 and 28
Booster[a]	0.5 mL	≥1 y after dose 2 for ages ≥17 y if still at risk; no data for ages 2 mo to 16 y

[a]In vaccinees who have completed a two-dose primary series, the full duration of protection is unknown; consequently, definitive recommendations cannot be given.

sub-Saharan Africa (Fig. 71.4). International travelers may acquire the disease, or may become colonized with epidemic strains of meningococcus and spread the disease to other parts of the world. Disease resulting from *Neisseria meningitidis* infection is caused most often by one of the five serogroups: A, B, C, Y, and W135. Distribution of serogroups may change rapidly. Serogroups C, B, and Y are predominant in the Americas and Europe. Serogroup A predominated in sub-Saharan Africa, but in the 1990s the proportion of cases caused by serogroup W135 increased significantly.[139] Vaccination campaigns conducted in the African meningitis belt with a group A meningococcal conjugate vaccines have led to variable reductions in meningococcal carriage across this region.[140]

Risk to travelers of acquiring invasive meningococcal disease is low, estimated to be less than 0.0001% per month for a stay in a developing country, and up to 2000 per million in pilgrims to Mecca before quadrivalent immunization with

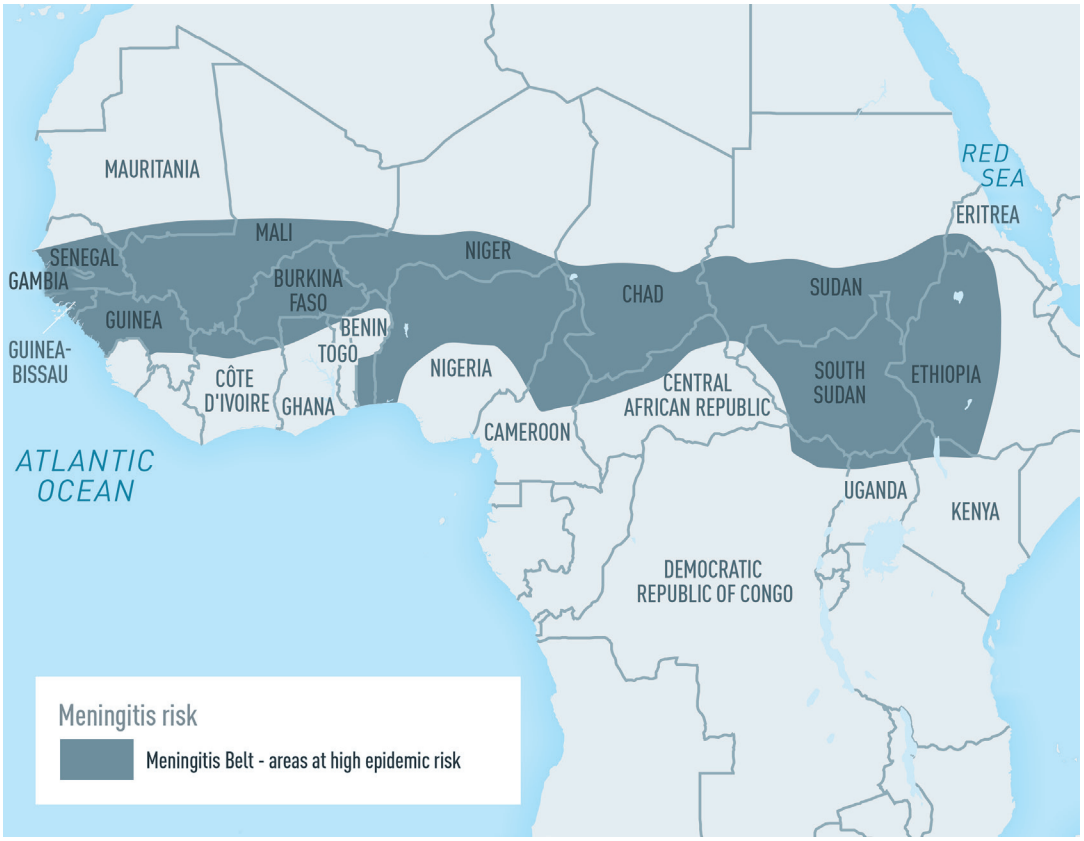

Figure 71.4. Areas with frequent epidemics of meningococcal meningitis. *(From Centers for Disease Control and Prevention [CDC]. Health Information for International Travel 2016.)*

an ACYW135 vaccine became a requirement to obtain a visa.[141,142] Outbreaks have occurred involving travelers, and travelers have become carriers of disease. American pilgrims who returned from Mecca, Saudi Arabia, after an epidemic of group A meningococcal diseases in 1987 were more than 11 times as likely to carry the organism home as travelers returning from other parts of Saudi Arabia.[143] In 2000 and 2001, outbreaks of meningitis caused by serogroup W135 among Hajj pilgrims and their contacts occurred in more than 10 countries.[144,145] Transmission of serogroup W135 strains to household contacts of pilgrims attending the Hajj and returning to Singapore was documented in seven (13%) of 54 contacts.[146] Since 1987, Saudi Arabian health authorities have required immunization against meningococcal disease for pilgrims attending the Hajj. Until 2002, bivalent serogroup A and C vaccine was sufficient; because of outbreaks of disease caused by serogroup W135, the policy was changed for the 2002 Hajj season to require immunization with quadrivalent vaccine (A, C, Y, and W135). A 2003 study of nasopharyngeal carriage of *N. meningitidis* in Burkina Faso identified serogroup W135 as the most common strain carried by the 4- to 29-year-old study population.[147] Although acquisition of meningococcal carriage has been documented in hajj pilgrims who had received polysaccharide vaccine,[147a] this risk would be reduced if the conjugate vaccine would be used.[147b] No additional Hajj-related outbreaks of meningococcal disease have occurred since the Saudi authorities requested quadrivalent vaccine.

Two cases of meningococcal disease thought to be transmitted during an airline flight have been reported.[148] A 2010 paper reviews meningococcal disease and travelers.[149] Persons traveling to countries within the meningitis belt of sub-Saharan Africa and who will have contact with the local population (persons visiting friends and relatives, healthcare workers, and long-term travelers, such as missionaries and volunteer workers) are thought to be at higher risk than tourist travelers and may benefit from immunization. Other vaccine candidates include persons at increased risk of contracting meningococcal disease, such as those with functional or anatomic asplenia or late complement deficiency. Persons who will travel to these areas and stay in tourist accommodations with little contact with the local population are at low risk and may elect not to be immunized. Immunization should be done, if possible, at least 10 to 14 days before departure.

Currently available meningococcal vaccines in the United States and elsewhere include polysaccharide and conjugate vaccines containing the four serogroups A, C, Y, and W135, bivalent A and C polysaccharide and conjugate vaccines, conjugate serogroup C vaccines, a combination vaccine with serogroups C and Y along with *Haemophilus influenzae* type b, and, most recently, serogroup B protein vaccines.[150,151] Conjugate vaccines generate equivalent or higher concentrations of protective antibody and may elicit greater duration of protective immunity than polysaccharide vaccines.[152] Additional benefits include the ability of conjugate vaccines to decrease nasopharyngeal carriage and therefore provide herd immunity.[150] Meningococcal conjugate vaccines also have the potential for greater immunogenicity in infants (and are licensed in the United States for children 2 months of age and older), as well as greater efficacy in those with underlying health problems affecting ability to respond to polysaccharide antigens.[153] It is important to choose vaccines containing serogroup A, and preferably also W135, for travel to the meningitis belt of sub-Saharan Africa. There are as of this writing no specific

recommendations for use of meningococcal vaccines for travel to other destinations, except in the setting of an outbreak. Serogroup B vaccine may be considered if travel to an area with an outbreak is anticipated.[154]

Duration of immunity of polysaccharide vaccine is at least 3 years in persons immunized when at least 4 years of age. Duration of immunity of conjugate vaccine is at least equivalent to that of the polysaccharide vaccine and is expected to be longer lasting; the Saudi health authorities grand validity for 8 years.[152,155,155a] Because of increased evidence of waning immunity, however, recommendations for revaccination have been updated by the CDC. A booster dose is recommended at age 16 years for those who were immunized at age 11 to 12 years, and a two-dose primary series, with doses 2 months apart, is recommended for those at increased risk of meningococcal disease. Children who were immunized at 6 years of age or younger who live in endemic areas or take a subsequent trip to a risk area may be given a booster dose after 3 years, and for those immunized at age 7 years or later, a booster may be given after 5 years.[150] Systemic adverse reactions were reported at similar rates in recipients of conjugate and polysaccharide vaccines; local adverse reactions were more common in those who received the conjugate than those who received polysaccharide vaccine.[150] A possible association of receipt of meningococcal conjugate vaccine and Guillain-Barré syndrome was reported in October 2005; the eight cases reported were not thought to represent an increase in incidence of this condition over what would be expected to occur by chance alone.[156] As of this writing, the CDC continues to recommend use of meningococcal conjugate vaccine for those for whom vaccine is indicated.[157] Adverse effects of immunization with meningococcal polysaccharide vaccine during pregnancy have not been documented; no data are available on the safety of the conjugate vaccine.[150] When considering immunization during pregnancy, the theoretical risk of immunization must be balanced against the risk of disease. In general, conjugate vaccines are preferable to polysaccharide vaccines when available because of superior immunogenicity, potential for reduction of nasopharyngeal carriage resulting in herd immunity, and effectiveness in individuals with conditions resulting in poor response to polysaccharide vaccines.[150,152,153]

Rabies

Human rabies causes approximately 60,000 deaths per year, mostly in Africa and Asia, with more than 95% occurring from exposure to rabid dogs.[158] The WHO estimates that more than 10 million persons receive rabies postexposure prophylaxis each year.[159] Currently there are two to three cases of human rabies per year in the United States, some acquired locally.[161] A review of 60 travel-associated cases worldwide from 1990 to 2012 identified many cases in short-term travelers and those visiting friends and relatives (predominantly immigrants returning to visit their country of origin).[162] Risk of rabies in travelers depends on destination, length of stay, and exposure to animals (especially dogs). A study in Thailand reported rates of animal bites, licks, and scratches of 1.7, 6.9, and 1.8 per 1000 person-months, respectively, in expatriates (non-Thai individuals living in Thailand for extended periods) and 43.1, 136.1, and 33 per 1000 person-months, respectively, in travelers.[163] A 2014 review of rabies in travelers concluded that the incidence of injuries to travelers caused by potentially rabid animals was 0.4% per month of stay.[164] Dogs were associated with 60% of exposures in one global study, and 66% of exposures associated with mammals in a study in Thailand.[163,165] A study of travelers seen during or after travel for rabies postexposure prophylaxis reported Thailand, Nepal, China, India, and Indonesia to be the most frequent countries of exposure for dog bites; other countries were associated with exposures to nonhuman primates (India, Vietnam, Brazil), cats (Algeria and Turkey), and bats (French Guyana, Peru, Mexico, and Surinam).[164,165] In Costa Rica, the first human rabies cases in 31 years were reported in 2001.[166] The 2008 outbreak of rabies in Bali, a popular tourist destination, highlights the importance of speaking with travelers about rabies risk.[167] Travelers should be informed about risk of rabies in the region to which they will travel and be advised to avoid contact with animals that could be rabies carriers, especially dogs but also cats, nonhuman primates, skunks, raccoons, and bats.[168] Cases of rabies in travelers highlight the importance of offering preexposure prophylaxis and counseling travelers about management of exposures while abroad.[169,170] Travelers should be aware of the need for a plan if a bite or exposure occurs because access to treatment is unpredictable globally. Three inactivated rabies vaccines are licensed for use in the United States, with others available worldwide. Vaccines may be used to provide preexposure prophylaxis (termed prophylaxis rather than immunization to emphasize that receiving this product before exposure does not obviate the need for additional injections if an exposure occurs) or postexposure prophylaxis. Travelers to countries where canine rabies is endemic or where exposures to potentially rabid animals could occur are candidates for preexposure vaccination, as are persons whose purpose of travel includes relevant animal or laboratory work; those who are likely to be hiking, bicycling, or riding motorcycles; or those whose itineraries include remote destinations where prompt medical attention is impossible.[171] Preexposure vaccination does not remove the imperative to seek definitive treatment if an exposure occurs but does alter the postexposure prophylaxis regimen. Table 71.5 lists the criteria for preexposure immunization and dosage schedules for vaccines licensed in the United States. Rabies postexposure prophylaxis consists of two doses of rabies vaccine for those who have received preexposure prophylaxis, and rabies immunoglobulin (RIG) plus vaccine for those who have not. Human RIG is necessary for such travelers, and they need to be informed that this preparation may not be available in their destination country.[172–175]

The postexposure prophylaxis series for those who have not had preexposure prophylaxis consists of four doses of vaccine at days 0, 3, 7, and 14 (CDC), and 28 (WHO)[176] The vaccine should be accompanied by a single dose of RIG, given no later than 7 days after the exposure, but ideally accompanying the first dose of vaccine. RIG should be diluted and infused directly into the wound, and vaccine given in a separate injection at a distant site. The WHO recommends intradermal rabies vaccine in places where vaccine is in short supply[177]; this regimen is not approved in the United States or many other countries. Vaccine preparations other than those listed in the table may be available in some countries; these vaccines are produced locally and have unknown safety and efficacy. If bitten by a suspect animal, an individual should receive modern tissue culture vaccine preparations, even if this means traveling to a destination where RIG and vaccine are available, or receiving additional treatment once the individual has returned to the individual's country of origin. Adverse events, such as local pain and swelling, have been reported in 30% to 74% of recipients of human diploid cell vaccine (HDCV). Systemic reactions may occur in up to 40% of recipients. Three cases of central nervous system disease have been reported following HDCV administration, but a causal relationship has not been established. Up to 6% of those receiving booster doses of HDCV may experience immune complex-like reactions. Although vaccines prepared in purified chick embryo cell culture may cause mild erythema, swelling, and pain at the injection site, serum sickness–like hypersensitivity reactions

TABLE 71.5 Rabies Preexposure Immunization[a]

Risk Category	Nature of Risk	Typical Populations	Preexposure Regimen
Frequent	Exposure usually episodic with source recognized, but exposure may also be unrecognized Bite, nonbite, or aerosol exposure possible	Rabies diagnostic laboratory workers, cavers, veterinarians and staff, and animal control and wildlife workers in rabies-epizootic areas	Primary preexposure immunization course; serologic examination or booster immunization every 2 years
Infrequent (but greater than population at large)	Exposure nearly always episodic with source recognized Bite or nonbite exposure	Veterinarians, animal control, and wildlife workers in areas of low rabies endemicity; veterinary students; and travelers visiting areas where rabies is enzootic and immediate access to medical care, including biologics, is limited	Primary preexposure immunization course; no routine booster immunization or serologic examination

[a]Preexposure immunization consists of three doses of human diploid cell vaccine (HDCV), rabies vaccine (adsorbed), or RabAvert, 1.0 mL intramuscularly (IM), one each on days 0, 7, and 21 or 28. Only HDCV may be administered by the intradermal (ID) dose/route (0.1 mL ID on days 0, 7, and 21 or 28). If the traveler will be taking chloroquine or mefloquine for malaria chemoprophylaxis, the three-dose series must be completed before initiation of antimalarials. If this is not possible, the IM dose/route should be used. Administration of routine booster doses of vaccine depends on exposure risk category. Preexposure immunization of immunosuppressed persons is not recommended.

Modified from the Centers for Disease Control and Prevention (CDC) Health Information for International Travel, 2016.

have not been problematic with these vaccines.[178] When given as postexposure prophylaxis, the series of doses should not be interrupted because of mild systemic or local reactions to vaccine; they can be managed with antiinflammatory agents.

Antimalarials such as chloroquine (and possibly mefloquine) may interfere with antibody response to HDCV rabies vaccine.[29] Other drugs (steroids or immunosuppressive agents) or conditions that affect the immune system also may impair efficacy of vaccine. HIV-infected persons, especially those with low CD4 counts, have impaired antibody response following rabies vaccine.[179] Persons taking such agents or experiencing such conditions may be candidates for testing of serum antibody levels following immunization. In addition, immunosuppressed persons who have not received preexposure prophylaxis require specific counseling about the importance of immediate wound care and administration of RIG promptly after any possible exposure, to take into account possible poor response to postexposure immunization.

Pregnancy is not a contraindication to postexposure prophylaxis with rabies vaccine, and no harmful effects to the fetus from immunization have been noted. If risk of exposure is high, preexposure prophylaxis may be offered.[180]

Tickborne Encephalitis

Tickborne encephalitis (TBE) is endemic to Central and Eastern Europe, Russia, and the Far East, and its area of endemicity is expanding.[181,182] In 2012 there were 38 reported cases of TBE in international travelers. The attack rate for an undefined period of time could be roughly extrapolated to be 0.5 to 1.3 per 100,000 population overall in Western/Central European endemic areas for the exposed at-risk population.[142] Disease occurs following the bite of an infected tick or through ingestion of infected unpasteurized milk. Although asymptomatic and mild infections occur commonly, neurologic manifestations and sequelae are significant causes of morbidity and mortality.[183] Most infections are acquired in rural locations; those working or vacationing in such locations between April and November, when tick activity is greatest, are at greatest risk. McNeil and colleagues reported an infection rate of 0.9 per 100 per month of exposure in a study of American service members of a military unit who lived and trained in a highly endemic area in Central Europe.[184] Five cases were reported in U.S. travelers to Europe and Asia from 2001 to 2008.[185]

Active immunization is the most effective means of prevention of TBE. Two vaccines, FSME-IMMUN (Baxter Vaccine AG, Wien, Austria, from 2015 Pfizer) and Encepur (Novartis Vaccine [formerly Chiron Behring], Marburg, Germany, from 2015 GlaxoSmithKline) are used widely in Europe. FSME-IMMUN's efficacy has been reported to be greater than 95%, based on data collected during active surveillance for infection following a mass immunization campaign in Austria. Several vaccines are marketed in Russia; one has been reported to be highly effective.[186] No vaccines are available in the United States or Canada. Travelers who plan extended stays in endemic areas can arrange to receive vaccine locally. TBE vaccination is most appropriate for persons traveling to high-risk TBE regions who plan to take part in outdoor activities.[186] TBE immunoglobulin, once proposed for preexposure prophylaxis, is no longer available.[187] Measures to prevent exposures to ticks, such as use of appropriate clothing and repellents containing *N,N*-diethyl-meta-toluamide (DEET), avoidance of tick habitats, immediate removal of ticks, and avoidance of unpasteurized milk, are additional strategies that can be used to prevent TBE.

The vaccine is given as a three-dose series, with the first two injections at least 4 weeks apart, and a third dose 5 to 12 months later, depending on the vaccine. An accelerated schedule of Encepur, with doses at days 0, 7, and 21 and with a booster 12 to 18 months after the third dose, may be used. Boosters are recommended at 3- to 5-year intervals in most countries, but protection may last much longer (Table 71.6). Fever is the most common side effect of vaccine; mild local and systemic reactions may also occur. Persons with egg allergy should not receive this vaccine. Data are lacking regarding use of these vaccines during pregnancy.

Typhoid

Typhoid is another common vaccine-preventable disease affecting travelers. In the United States, 1393 cases of typhoid fever were reported from 1994 to 1999, with recent travel associated with 74% of cases. In only 36 (4%) of travel-associated cases did persons report receipt of typhoid vaccine.[188] Seventy-nine percent of 1902 cases reported (with adequate information) between 1999 and 2006 were related to foreign travel.[189] There were approximately 400 cases of typhoid per year from 2007 to 2011 in the United States, with approximately 90% occurring in those returning from foreign travel; more than

TABLE 71.6 Recommended Doses and Schedules for Tickborne Encephalitis Vaccines

Group	Vaccine	Dose	No. of Doses	Schedule	Booster
Children 1–15 y old	FSME-IMMUN	0.25 mL SC/IM	3	0, 2 wk to 3 mo	5–12 mo after second dose
Individuals 16 y and older	FSME-IMMUN	0.5 mL SC/IM	3	0, 1–3 mo, 9–12 mo after second dose	3–5 y after last dose
Children 1–11 y old	Encepur	0.75 μg/0.5 mL SC/IM	3	0, 1–3 mo, 9–12 mo after second dose[a]	3–5 y after last dose
12 y and older	Encepur	1.5 μg/0.5 mL SC/IM	3	0, 1–3 mo, 9–12 mo after second dose[a]	3–5 y after last dose

[a]An accelerated schedule of days 0, 7, and 21 also may be used. In this case, a fourth dose should be given 12 to 18 months after completing the three-dose series.
IM, intramuscular; SC, subcutaneous.

TABLE 71.7 Dosage and Schedules for Typhoid Fever Vaccination

Vaccination	Age	Dose/Mode of Administration	No. of Doses	Interval Between Doses	Boosting Interval
ORAL LIVE ATTENUATED TY21A VACCINE					
Primary series (capsule)	≥6 y	1 capsule[a]	3 or 4	48 h	NA
(liquid)	≥3 y	1 packet[b]	3	48 h	
Booster	≥6 y	1 capsule[a]	4	48 h	Every 5 y[c]
VI CAPSULAR POLYSACCHARIDE VACCINE					
Primary series	≥2 y	0.50 mL[d]	1	NA	–
Booster	≥2 y	0.50 mL[d]	1	NA	Every 2 y

[a]Administer with cool liquid no warmer than 37°C.
[b]Dissolve in no more than 4 ounces of cold or lukewarm water.
[c]Every year for those taking the three-dose series.
[d]Intramuscularly.
NA, Not applicable.

75% of these travelers had returned from India, Bangladesh, or Pakistan.[190] Risk of contracting typhoid depends largely on travel destination, with greatest risk associated with travel to the Indian subcontinent.[189,191] Those traveling for the purpose of visiting friends and relatives make up a large proportion of reported cases in travelers.[190] A study showed risk of disease to be related inversely to receiving vaccine prior to travel: incidence rates per visit ranged from 16 per 100,000 in North American tourists, 92% of whom had received typhoid vaccine prior to travel, to 216 per 100,000 in Israeli tourists, 6% of whom had been immunized.[193] A study from Sweden reported rates of enteric fever of 0.42 per 100,000 travelers overall, and this study, along with most others, continues to show the highest risk for typhoid is in travelers to the Indian subcontinent (41.7 per 100,000).[194,195] Steffen and colleagues estimate rates of typhoid to be between 0.01% and 0.1% for travel to South Asia and between 0.001% and 0.01% for other destinations for a 1-month stay.[142] The Canadian Committee to Advise on Tropical Medicine and Travel assesses the risk as 33 cases per 100,000 for travel to South Asia, one to two cases per 100,000 for travel to Africa (with a negligible risk in Southern Africa), the Middle East and South America, and less than one per 300,000 for the Caribbean and Central America.[196]

Two vaccines are available in the United States to protect travelers from typhoid. While the Vi vaccine does not protect against paratyphoid fever, which accounts for a growing proportion of enteric fever in many countries, some claim that the Ty21a vaccine may offer limited protection.[190] Some travel medicine providers are recommending vaccine more frequently as a result of worsening antibiotic resistance profiles of *Salmonella typhi*. Food and water precautions should continue to be used to augment protection afforded by vaccine. Oral live attenuated typhoid vaccine (Vivotif; Crucell) manufactured from the Ty21a strain of *S. typhi* is given in a series of three (Europe) or four (North America) capsules taken every other day and has a vaccine efficacy of 67%.[197] In the United States, it is not licensed for children younger than 6 years of age, and administration of this vaccine may be limited by the ability of small children to swallow capsules.

A capsular polysaccharide vaccine (TYPHIM Vi; Sanofi Pasteur), given in a single intramuscular dose, is available for persons 2 years of age and older. Vaccine efficacy of this product ranges from 55% to 74%.[198,199] Duration of immunity is uncertain; Keddy and colleagues reported persistence of antibody for more than 10 years following immunization with this vaccine in South African schoolchildren, but acknowledge that exposure to disease may have contributed to these findings.[200]

Table 71.7 lists typhoid vaccine schedules. No vaccine is available for children younger than 2 years of age. Mothers of infants may be reassured that exclusive breastfeeding (reducing contact with contaminated food or water) reduces risk for infants when careful hand washing also is done. Booster doses are recommended every 2 years in the United States for the polysaccharide vaccine (3 years in many other countries).[203] In the United States, boosters for the oral vaccine are recommended every 5 years (every 7 years in Canada), and in countries where the three-dose series is used, every year for travelers

from nonendemic to endemic areas, and every 3 years for those living in endemic areas.[203]

Adverse reactions to the capsular polysaccharide vaccine include fever in 1% or fewer of vaccine recipients, headache in up to 3%, and local reactions in approximately 7%. Oral vaccine results in fever or headache in approximately 5% of recipients, and stomach pain, nausea, vomiting or rash occur rarely.[204] Impaired response to capsular polysaccharide vaccine occurs in HIV-infected persons, especially those with low CD4 counts.[205] Oral typhoid vaccine is a live bacterial preparation and should not be given to immunocompromised persons, including those with HIV infection. Concerns have been raised about the immunogenicity of this vaccine in persons receiving proguanil (as in the antimalarial agent atovaquone-proguanil). Growth of the live Ty21a strain is inhibited by some antimicrobial agents and by the antimalarial agent mefloquine, although there are no data to suggest that mefloquine interferes with vaccine efficacy.[30,31] Ideally, the oral typhoid vaccine series should be completed at least 2 weeks before departure. Oral typhoid vaccine should not be taken concurrently with antimicrobial agents; capsules should be taken 24 hours or more after the last dose of the antibiotic (and probably longer if an agent with a long half-life, such as azithromycin, has been taken). Oral typhoid vaccine may be given concurrently with yellow fever vaccine.[102] Concomitant administration of inactivated hepatitis A, Typhim Vi, and yellow fever vaccines resulted in adequate responses to all three vaccines without affecting the adverse event profile.[206] Data are not available regarding concurrent administration of oral typhoid vaccine and other live-virus vaccines. Vaccine may be administered at the same time as immunoglobulin. Safety during pregnancy of vaccines against typhoid has not been established; live vaccines are contraindicated in general, and the injectable vaccine administered only if clearly needed.[190]

Yellow Fever

Yellow fever continues to be a disease of importance in sub-Saharan Africa and South America. Reemergence of disease continues on both continents in 2016–17, resulting in increased attention to measures to reduce transmission and enhance immunization coverage.[207–210] Recent outbreaks occurred in Angola in 2015–16 and in Brazil in 2016–17.[210a,210b] Most cases of yellow fever occur in nonimmune, unvaccinated persons who migrate to or visit areas where transmission occurs.[211] Yellow fever can be a fatal disease, and cases have occurred in unimmunized travelers.[212–215] During the recent Angola outbreak, approximately 12 cases of yellow fever have been exported by nonimmunized workers to China and by other travelers to several other countries within Africa.[215a] Figs. 71.5 and 71.6 show the destination countries for which yellow fever vaccination is recommended. An outbreak of yellow fever in Brazil prompted updating of the yellow fever risk map in Brazil to acknowledge expansion of the risk areas in the states of Bahia, Espirito Santo, Minas Gerais, Rio de Janiero, and Sao Paulo.[215b]

Vaccination against yellow fever offers high levels of protection, with seroconversion rates of greater than 95% in children

and adults and duration of immunity of at least 10 years, and likely lifelong in healthy individuals.[216] Side effects are generally mild and include headaches, myalgia, and low-grade fever occurring 5 to 10 days after immunization in less than 25% of those participating in clinical trials of yellow fever vaccine.[217,218] Immediate hypersensitivity reactions are uncommon and are most likely to occur in those with allergy to eggs.

Serious adverse events to yellow fever vaccine include yellow fever vaccine–associated neurotropic disease (YFV-AND; formerly postvaccinal encephalitis) and yellow fever vaccine–associated viscerotropic disease (YFV-AVD). These reactions have occurred exclusively in persons receiving their first yellow fever vaccine. Encephalitis has been reported in vaccine recipients with higher rates in infants; the vaccine is contraindicated in infants younger than 6 months of age and should be used with caution, balancing carefully risk of disease with risk of severe adverse events, in those 6 to 8 months of age.[219] A syndrome of fever, jaundice, and multiorgan system failure following yellow fever vaccine was reported in 10 patients (ranging in age from 5 to 79 years) worldwide (five in the United States, two in Brazil, and one each in Australia, Switzerland, Germany, and the United Kingdom) from 1996 to 2001.[220–226] This syndrome, initially called febrile multiorgan system failure, ranges in severity from moderate disease with focal-organ dysfunction to severe multisystem failure and death, and may include neurotropic disease. In 2002, two suspected cases of viscerotropic disease and four suspected cases of neurotropic disease were reported in U.S. recipients of yellow fever vaccine.[227] A fatal case reported in 2005 involved a 22-year-old female.[228] A study of reports submitted to the VAERS in the United States identified advanced age as a risk factor for adverse events associated with yellow fever immunization.[229]

Initial estimates of rates of YFV-AND were 0.5 to four cases per 1000 very young infants and fewer than one case per 8 million vaccinees older than 9 months of age in the United States.[230] Initial estimates of incidence of YFV-AND were made based on number of doses distributed to the civilian population, safety monitoring data for doses distributed during 1990 to 1998 in the United States, and number of cases identified using enhanced surveillance of yellow fever vaccine adverse events through the VAERS database. These data yielded an estimated reported incidence of 2.5 per 1,000,000 doses distributed.[231] Limitations of this estimate include possible underreporting of cases and lack of exact information about number of doses administered. The CDC has published current estimates of risk for the three serious adverse events to yellow fever vaccine; these data are printed on the vaccine information statement for yellow fever vaccine and are useful when discussing yellow fever immunization with patients. Risk estimates are as follows: life-threatening allergic reactions: one per 55,000 doses; vaccine-associated neurologic disease: one per 125,000 doses; and vaccine-associated viscerotropic disease: one per 250,000 doses.[232] An update of advanced age as a risk factor for serious adverse events to yellow fever vaccine was published in 2005, confirming the increased risk and documenting a reporting rate ratio of 5.9 (95% confidence interval, 1.6 to 22.2) in first-time vaccinees 60 years of age or older and 10.4 (95% confidence interval, 2.7 to 40.2) in those 70 years of age or older relative to those 19 to 29 years of age (0.7/100,000).[233] Although risk factors for developing severe reactions after yellow fever vaccine are not well understood, one report identified thymus disease as present in a greater proportion of those who developed YFV-AVD after yellow fever vaccination than in the general population.[234] A case of death resulting from YFV-AVD in an individual with undiagnosed thymoma was reported from Oregon, in 2015.[235] Several articles summarize indications for yellow fever vaccine and risk of adverse events in an effort to guide appropriate recommendations for travelers.[236–239] Yellow fever vaccine must be given at official yellow fever vaccine centers and travelers should be given documentation of immunization on the ICVP. Travelers to countries or areas of countries where disease risk is present should receive a single dose of vaccine at least 10 days before departure. As of July 11, 2016, the certificate of vaccination against yellow fever as documented on the ICVP is valid for the life of the person vaccinated per Amendment 7 of the International Health Regulations (2005). The CDC ACIP has issued recommendations for use of yellow fever vaccine booster doses.[240–245] Vaccine is contraindicated in children younger than 6 months of age and should be used cautiously in children 6 to 8 months of age. Vaccine is also contraindicated in HIV-infected persons with CD4 counts less than 200/mm^3 or less than 15% of total lymphocytes for children younger than 6 years of age, and in persons whose immune systems have been altered by immunomodulating agents.[219] Precautions against use of yellow fever vaccine include: age older than 60 years; infants 6 to 8 months of age; pregnant or nursing women; and weakened immune systems. The single most important step in judicious use of yellow fever vaccine is to provide vaccine only to persons traveling to yellow fever–endemic areas: in one report, two of five persons with multiorgan system failure were traveling to areas where yellow fever had never been described.[226] Persons not protected by vaccine should use adequate personal protective measures to avoid mosquito bites.

Serologic response to yellow fever vaccine is not diminished by simultaneous administration of tetanus, diphtheria, pertussis, measles, polio, BCG, hepatitis A, hepatitis B, Vi antigen capsular polysaccharide typhoid, or oral Ty21a typhoid vaccines.[102,246] Immunoglobulin did not decrease the antibody response to yellow fever vaccine when given 0 to 7 days before immunization.[247] The antimalarial chloroquine has been shown not to affect adversely the antibody response to yellow fever vaccine.[248]

Yellow fever immunization may be given during pregnancy if risk of disease is believed to be greater than risk of adverse events to vaccine.[249] Several studies are available to inform these decisions. One documented fetal infection in one of 41 infants exposed to maternal vaccination; the infant was full-term and appeared normal.[250] A mass vaccination campaign in Brazil, in early 2000, resulted in inadvertent immunization of 480 pregnant women with 17DD vaccine; the women and infants were followed until the infants were 1 year of age. Maternal seroconversion was high, and no infants were found to be infected at birth (no immunoglobulin M antibodies detected and no placental or umbilical cord blood found to contain yellow fever vaccine strain virus by polymerase chain reaction).[251] Immunization during pregnancy may result in antibody concentrations that are inferior to those obtained following immunization of nonpregnant women; women immunized during pregnancy may be candidates for reimmunization when next at risk for yellow fever.[252] Immunization with yellow fever vaccine is not recommended for immunocompromised persons or those with symptomatic HIV infection. Vaccine has been administered with good tolerance and efficacy to asymptomatic HIV-infected persons.[253–255] Cases from Brazil and Canada of yellow fever transmitted via breast milk have been reported.[256–258]

COST-EFFECTIVENESS OF TRAVEL IMMUNIZATIONS

Travel medicine experts have long noted the willingness of travelers to accept (and pay for) multiple vaccines for diseases for which they are at minimal risk. Beutels and colleagues, in an economic evaluation of travel medicine interventions, concluded that, except for hepatitis A vaccine in specific circumstances, no travel vaccine has a favorable cost-to-benefit ratio.[259] Costs to prevent travel-related vaccine-preventable disease ranged from US$100,000 to US$300,000 to prevent a case of typhoid, US$4 million to prevent a case of JE, and US$5 to US$29 million to prevent a case of cholera.[260–263] The most studied travel-associated vaccine in terms of cost-effectiveness is hepatitis A. In one study, which also examined cost-effectiveness of typhoid immunization, neither typhoid nor hepatitis A vaccine was found to be cost-effective; societal expenditures of more than £67 million were required to prevent a single death from typhoid fever with either of the two typhoid vaccines.[264] In contrast, a study from The Netherlands suggested that cost-effective choices are available regarding hepatitis A immunization when frequency of travel, likelihood of prior immunity, and product used are taken into consideration.[265] Typhoid vaccination was found rarely to be cost-effective, with the possible exception of travel to very-high-incidence countries when the itinerary involved close contact with the local population.[266] Cost-effectiveness of preexposure rabies prophylaxis has been studied in Canada, with the conclusion that routine preexposure prophylaxis for most travelers is not indicated.[267]

Issues complicating performance of studies of cost-effectiveness of travel vaccines include difficulty estimating risk of vaccine-preventable diseases accurately; difficulties in determining vaccine efficacy, especially for travelers who will have variable exposures in endemic areas; difficulties approximating costs associated with disease; and lack of sufficient experience with some newer vaccines to allow accurate estimation of the incidence of vaccine-associated adverse events.

Finally, some practitioners may be reluctant to omit any vaccine, no matter the risk of disease, for fear of liability. Until these issues are studied in greater detail, each travel medicine provider must continue to individualize recommendations for travel vaccination, taking into account the potential for adverse reactions to immunization and the patient's risk for the disease. Current recommendations by the CDC and the WHO for travel vaccination should be followed, regardless of cost-effectiveness data.

THE FUTURE

Rapid advances in biotechnology promise a potential revolution in the development of new vaccines using diverse approaches ranging from DNA vaccines to transgenic plant vaccines, although significant technical hurdles remain.[268,269] New candidate vaccines show promise in protecting against diverse pathogens that cause diarrheal disease.[270] A dengue vaccine has been licensed in some countries, although there are currently no indications for use in travlers.[270a] Optimism remains for the eventual development of vaccines against Zika virus, Ebola virus, chikungunya virus infection, HIV, norovirus, and malaria.[271–276] In addition to the remaining technical hurdles, however, equally formidable economic hurdles remain in adequate funding of vaccine research and development against diseases that mostly afflict the poorest populations in the poorest countries.[277] The increased interest in travel and travel immunizations by more affluent travelers may provide substantial assistance in making these much-needed vaccines a reality.

72 Vaccines for Healthcare Personnel

David J. Weber and William A. Rutala

Healthcare personnel (HCP) are commonly exposed to infectious agents. The risks and methods of preventing occupational acquisition of infection by HCP have been reviewed.[1–8] Minimizing the risk of disease acquisition is based on strict adherence to five key recommended interventions: (a) adherence to standard precautions when providing patient care,[9–11] especially the performance of appropriate hand hygiene before and after patient care[12–22]; (b) rapid institution of appropriate isolation precautions for patients with known or suspected communicable diseases[9,10,23,24]; (c) proper use of personal protective equipment, such as masks, N-95 respirators, eye protection, and gowns when caring for patients with potentially communicable diseases[10,11,24,25]; (d) evaluation of personnel who were exposed to communicable diseases for receipt of postexposure prophylaxis[1,23,27–29]; and (e) appropriate immunizations.[1,7,30–32] Laboratory personnel, including hospital personnel working in microbiology laboratories, are also at risk for acquiring infectious diseases.[33–36] Prevention of laboratory-acquired infection requires adherence to recommended administrative protocols (e.g., no eating, drinking, or smoking in areas where microbiologic or pathologic samples are processed), engineering controls (e.g., containment hoods), personal protective equipment (e.g., N-95 masks when culturing *Mycobacterium tuberculosis*), and appropriate immunizations.[37–40] Vaccine-preventable diseases may be classified by their route of transmission and include airborne (e.g., varicella, measles), droplet (e.g., influenza, pertussis, meningococcal infection), contact (e.g., hepatitis A from contact with feces), and parenteral or mucosal exposure to blood or contaminated body fluids (e.g., hepatitis B).

Immunization of HCP should be included by all healthcare facilities as part of a comprehensive occupational health program. Ensuring that HCP are immune to vaccine-preventable diseases is important because it protects HCP from infections that cause potentially serious complications when acquired as an adult (e.g., rubella, varicella, hepatitis B) and prevents the HCP from serving as a source for infecting patients, especially immunocompromised patients, with diseases that may lead to serious morbidity or even death (e.g., varicella, measles).[41,42] For this reason, all new HCP should receive a prompt review of their immunization status against vaccine-preventable diseases. Immunization status also should be reviewed yearly. Other important occupational health interventions include an accessible health service, baseline and periodic testing for tuberculosis (i.e., purified protein derivative skin test or interferon-γ release assay blood test), evaluation of HCP ill with potential communicable diseases to provide appropriate treatment and work restrictions, evaluation of HCP after infectious disease exposures for postexposure prophylaxis and work restrictions, and education of HCP focusing on general infection control guidelines in addition to Occupational Safety and Health Administration (OSHA)-mandated training in the prevention of bloodborne pathogens[43] and tuberculosis.[44]

VACCINES RECOMMENDED FOR HEALTHCARE PERSONNEL

General Guidelines

General recommendations regarding vaccination of HCP have been published by the Centers for Disease Control and Prevention (CDC),[1] the Advisory Committee on Immunization Practices (ACIP),[30,45,46] the American Academy of Pediatrics,[47] the Association for Professionals in Infection Control and Epidemiology,[48] and infectious disease experts.[7,31,49,50] It is recommended that all HCP be immune to mumps, measles, rubella, varicella, pertussis, and influenza (Table 72.1).[1,7,30,31,45–48] Depending on the vaccine, preventable disease immunity may be assured by several different measures. All HCP with potential exposure to blood or body fluids should be immune to hepatitis B. Influenza vaccine should be offered to all HCP yearly. In the past few years, editorials and commentaries have recommended that yearly influenza immunization (unless contraindicated) should be a condition of employment for HCP.[51–55] New policy statements from professional societies have endorsed the requirement for yearly influenza immunization, including the American Academy of Pediatrics,[56] Association for Professionals in Infection Control,[57] Infectious Diseases Society of America,[58] American College of Physicians,[59] and the Society of Healthcare Epidemiologists of America.[60] In February 2012, the National Vaccine Advisory Committee issued a statement which provided recommendations on how to achieve the Healthy People 2020 annual influenza vaccine coverage goal (i.e., 90%) for HCP; for facilities that have implemented the recommended initial strategies but have "not consistently achieved the Healthy People goal for vaccination coverage of HCP in an efficient and timely manner" it was recommended that they should "strongly consider an employer requirement for influenza immunization."[61] However, some of these policy statements allow HCP to opt out if they sign a declination statement, have religious or personal objections, or agree to wear a surgical mask while working in a clinical area during influenza season. Detailed recommendations have been published regarding mumps, measles and rubella[62]; varicella[63]; hepatitis B[64–66]; influenza[67,68]; and Tdap (tetanus toxoid, reduced diphtheria toxoid, acellular pertussis)[69–71] vaccines. All HCP should be subject to these recommendations, including personnel with direct patient care responsibilities (e.g., nurses, respiratory technicians, physical therapists, physicians, students and other trainees), personnel without direct patient care responsibilities (e.g., environmental service workers, security), contract workers, volunteers, and emergency medical personnel. HCP should be provided vaccines that are recommended for adults,[45,46] such as human papillomavirus, herpes zoster, and pneumococcal vaccines, or referred to their local medical provider. In special circumstances, HCP or laboratory personnel should be offered immunization with other vaccines, including polio[72,73]; quadrivalent (A, C, Y, W135) meningococcal (polysaccharide,

conjugate)[74] and meningococcal serogroup B vaccines[75]; rabies[76,77]; typhoid[78]; hepatitis A[79]; anthrax[80]; and vaccinia (smallpox)[81–83] (Table 72.2).

Immunocompromised HCP require special consideration in the provision of immunizations (Table 72.3).[45,46,84,85] First, live virus vaccines (e.g., measles-mumps-rubella [MMR], varicella, live attenuated influenza) may be contraindicated. Second, vaccines not routinely recommended may be indicated (e.g., pneumococcal, meningococcal, *Haemophilus influenzae* type b). Third, higher antigen doses (e.g., hepatitis B vaccine in people with end-stage renal disease), additional doses of vaccine (e.g., rabies vaccine in immunocompromised persons), or postimmunization serologic evaluation may be indicated (e.g., anti–hepatitis B surface antigen titer after hepatitis B vaccine, antibody response to rabies vaccine) because immunization of immunocompromised people may elicit a lower antibody response. Finally, such personnel should be individually evaluated for reassignment (with the consent of the employee) depending on their job duties. Of importance, caring for an immunocompromised patient is not

TABLE 72.1 Vaccines Strongly Recommended for All Healthcare Personnel

Vaccine	Demonstration of Immunity[a]	Indications[b]	Administration[b]	Major Contraindications and Precautions[b]
Influenza	Yearly immunization needed	All healthcare personnel[c]	1 dose 0.5 mL IM (deltoid) inactivated vaccine, 1 dose intradermal, 1 dose live attenuated influenza vaccine (LAIV) via nasal instillation	History of anaphylaxis to eggs; LAIV contraindicated in HCP who work with patients housed in a "protected environment," pregnancy, immunocompromising disorder[d] or medications, ≥50 years of age
Hepatitis B	Laboratory evidence of immunity[e] unless last dose of series provided >6 months prior to evaluation, prior receipt of three doses of vaccine with appropriate schedule	All healthcare personnel with potential exposure to blood or contaminated body fluids	1.0 mL dose IM at 0, 1, 6 mo, additional doses not necessary if adequate response[h]; if response inadequate, test for HBsAg, and if negative, provide additional three doses and retest antibody response (if still inadequate consider HCP a nonresponder)	History of anaphylaxis to common baker's yeast; pregnancy should not be considered a contraindication
Measles	1. Documented administration of two doses of live measles virus vaccine (MMR)[e] *or* 2. Laboratory evidence of immunity *or* laboratory confirmation of disease *or* 3. Born before 1957[f] 4. Physician diagnosed disease with laboratory confirmation	All healthcare personnel	0.5 mL SC, second dose at least 1 mo later	History of anaphylaxis to gelatin or neomycin; pregnancy; immunocompromised disorder,[d] recent (<11 mo) receipt of antibody-containing blood product; need for tuberculin skin testing in next 4 weeks unless performed simultaneously with vaccine administration; moderate or severe acute illness with or without fever
Mumps	1. Documented administration of two doses of live mumps virus vaccine (MMR)[e] *or* 2. Laboratory evidence of immunity or laboratory confirmation of disease *or* 3. Born before 1957[f] 4. Physician diagnosed diseases with laboratory confirmation	All healthcare personnel	0.5 mL SC, second dose at least 1 mo later	As for measles (above) if provided as MMR
Rubella	1. Documented administration of one dose of live rubella virus vaccine (MMR)[e] *or* 2. Laboratory evidence of immunity or laboratory confirmation of disease *or* 3. Born before 1957 (except women of childbearing age who could become pregnant)[f]	All healthcare personnel	0.5 mL SC, no booster	As for measles (above) if provided as MMR
Tdap	Documented administration of one dose of Tdap vaccine	All healthcare personnel	0.5 mL IM	Progressive or unstable neurologic disorder or progressive encephalopathy, Guillain-Barré syndrome <6 wk after a previous dose of a tetanus toxoid–containing vaccine, moderate or severe acute illness with or without fever

Continued on following page

TABLE 72.1 Vaccines Strongly Recommended for All Healthcare Personnel *(Continued)*

Vaccine	Demonstration of Immunity[a]	Indications[b]	Administration[b]	Major Contraindications and Precautions[b]
Varicella	1. Documented receipt of two doses of varicella vaccine *or* 2. Laboratory evidence of immunity *or* 3. Physician diagnosed varicella or zoster[g]	All healthcare personnel	0.5 mL SC, second dose 4–8 wk later	History of anaphylaxis to gelatin or neomycin; pregnancy; immunocompromised disorder,[d] recent (<11 mo) receipt of antibody containing blood product; moderate or severe acute illness with or without fever

[a]Written documentation should be required.
[b]The package insert and Centers for Disease Control and Prevention (CDC)/Advisory Committee on Immunization Practices (ACIP) should always be consulted for specific recommendations regarding indications, storage, administration, precautions, and contraindications. Doses listed are for adults; CDC/ACIP guidelines should be consulted when providing vaccines for children.
[c]Persons who provide healthcare to patients or who work in institutions that provide healthcare (e.g., physicians, nurses, emergency medical personnel, dental professionals and students, medical and nursing students, laboratory technicians, hospital volunteers, and administrative and support staff in healthcare institutions).
[d]Persons immunocompromised because of immune deficiency diseases, human immunodeficiency virus infection, leukemia, lymphoma, or generalized malignancy, or immunosuppressed as a result of therapy with corticosteroids (i.e., >2 mg/kg body weight or 20 mg/day of prednisone for >2 weeks), alkylating drugs, antimetabolites, or radiation. Also see Table 72.2.
[e]The first dose should be administered on or after the first birthday; the second dose of measles and mumps–containing vaccine should be administered no earlier than 1 month (i.e., a minimum of 28 days) after the first dose. Combined MMR vaccine generally should be used whenever any of its component vaccines is indicated.
[f]For unvaccinated personnel born before 1957 who lack laboratory evidence of immunity of measles, mumps, and/or rubella or laboratory confirmation of disease, healthcare facilities should consider vaccinating personnel with two doses of MMR vaccine at the appropriate interval (for measles and mumps) or one dose of MMR vaccine (for rubella), respectively. For unvaccinated personnel born before 1957 who lack laboratory evidence of measles, mumps, and/or rubella immunity or laboratory confirmation of disease, healthcare facilities should recommend two doses of MMR vaccine during an outbreak of measles or mumps and one dose during an outbreak of rubella.
[g]An acceptable history is as follows: history of varicella disease based on healthcare provider diagnosis or self- or parental report of typical varicella disease for non-U.S.–born persons born before 1966 and all persons born from 1966 to 1997. For persons reporting a history of an atypical mild case, healthcare providers should seek either (a) an epidemiologic link to a typical varicella case (e.g., case occurred in the context of an outbreak or patient had household exposure in the previous 3 weeks) or (b) evidence of laboratory confirmation, if it was performed at the time of acute disease. When such documentation is lacking, persons should not be considered as having a valid history of disease because other diseases may mimic mild atypical varicella. For persons born during or after 1998, history of disease is no longer considered as evidence of immunity, unless the illness was laboratory confirmed.
[h]Immunity should be assessed 1 to 2 months after the third dose; if not immune, an additional three doses should be provided and immunity reassessed; if not immune, test for HBsAg, and if HBsAg is absent, provide hepatitis B immunoglobulin as postexposure prophylaxis when indicated. Immunity is indicated by an anti-HBsAg titer of ≥10 mIU/mL.
HBsAg, hepatitis B surface antigen; HCP, healthcare personnel; IM, intramuscularly; LAIV, live attenuated influenza vaccine; MMR, measles-mumps-rubella; SC, subcutaneously.

TABLE 72.2 Vaccines Available for Healthcare and Laboratory Personnel in Special Circumstances

Vaccines	Indications[a]	Administration[a]	Major Contraindications and Precautions[a]
Anthrax (AVA)	Laboratory personnel or researchers engaged in work involving production quantities or concentrations of *Bacillus anthracis* culture or in activities with a high potential for aerosol production. Healthcare personnel exposed as a result of a bioterrorist attack	Preexposure—0.5 mL IM × 5 doses (0 wk, 4 wk, 6 mo, 12 mo, and 18 mo). Annual booster to maintain immunity. PEP (available under an IND), 0.5 mL SC × 3 doses (0, 2, and 4 wk) (in conjunction with 60-day antimicrobial PEP)	History of anaphylaxis to a previous dose of vaccine or a vaccine component. Precautions: latex allergy, history of anthrax, moderate or severe illness. Pregnancy: avoid for preevent use; recommended for PEP
Hepatitis A	Not routinely indicated for healthcare personnel. May be useful in outbreak settings (administer within 2 wk of exposure or use Ig 0.02 mL/kg)	1.0 mL IM × 2 or 3 (follow manufacturer's recommendation for dosing)	History of anaphylaxis to a previous dose of vaccine or a vaccine component. Precautions: pregnancy, moderate or severe illness
Meningococcal quadrivalent (A,C, Y, W135) *and* meningococcal serogroup B (MenB)	Clinical and research microbiologists who may be routinely exposed to isolates of *Neisseria meningitides*. Others: asplenia, persistent complement deficiencies, travel to an endemic area	Microbiologists—one dose MenACWY (adult ≤55 y) or MPSV4 (adults >55 y) 0.5 mL IM. Plus either a 2-dose series of MenB-4C or a 3-dose series of MenB-FHbp. Booster dose every 5 y if still at risk. For other indications (asplenia, persistent complement deficiencies)—appropriate doses	History of anaphylaxis to a previous dose of vaccine or a vaccine component. Precautions: moderate or severe illness

TABLE 72.2 Vaccines Available for Healthcare and Laboratory Personnel in Special Circumstances *(Continued)*

Vaccines	Indications[a]	Administration[a]	Major Contraindications and Precautions[a]
Pneumococcal polysaccharide (PPSV23) and pneumococcal conjugate (PCV13)	Not routinely indicated for healthcare personnel. Indicated for immunocompromised persons 18–65 and adult ≥65 years of age, and residents extended care facilities	Revaccination recommendations depend on vaccine indication	History of anaphylaxis to a previous dose of vaccine or a vaccine component. Precautions: moderate or severe illness
Polio (IPV)	Laboratory personnel or researchers who frequently work with polio. HCP who have close contact with patients who may be excreting wild poliovirus, including HCP who travel to work in areas where polioviruses are circulating	Unimmunized adults—0.5 mL IM or SC × 2 doses (0, 4–8 wk, 6–12 mo after second dose). Immunized—0.5 mL IM or SC × 1 dose	History of anaphylaxis to a previous dose of vaccine or a vaccine component. Precautions: pregnancy, moderate or severe illness
Rabies	Laboratory personnel or researchers who work with rabies virus of potentially infected animals; PEP may be required for potential exposure despite primary immunization	Preexposure—1.0 mL (HDCV, PCECV) IM × 3 doses (0, 7, and 21 or 28 days). Booster doses may be required. Postexposure (unimmunized) —1.0 mL (HDCV, PCECV) in deltoid × 4 (0, 3, 7 and 14 days) (if immunocompromised, provide additional dose on day 28). Also administer HRIG. postexposure (previously immunized)—1.0 mL (HDCV, PCECV) × 2 (0, 3 days)	History of anaphylaxis to a previous dose of vaccine or a vaccine component
Typhoid[b]	Laboratory personnel or researchers who frequently work with *Salmonella* Typhi	Four oral doses (Ty21a; 1 capsule taken every other day) *or* one 0.5 mL-dose IM (ViCPS). Booster doses per manufacturer's recommendations	History of anaphylaxis to a previous dose of vaccine or a vaccine component. Ty21a: receipt of antibiotics or antimalarials (delay for >3 days posttherapy). Precautions: pregnancy, immunocompromised (Ty21a)[c]
Vaccinia	HCP or researchers who directly handle cultures or animals contaminated with recombinant vaccinia or orthopox viruses (monkeypox, cowpox) that infect humans; preexposure or postexposure prophylaxis for bioterrorist use of variola (smallpox)	One dose administered with a bifurcated needle; booster every 10 years	Discuss with public health authorities prior to administration. Contraindications: pregnancy, immunocompromised state in vaccine recipient or household contact, history of eczema in HCP or family contact, other acute or chronic exfoliative skin conditions
Zoster	Not specifically indicated for HCP. Adults ≥50 years of age	One 0.65 mL dose SC	History of anaphylaxis to a previous dose of vaccine or a vaccine component, immunocompromised, pregnant

[a]The package insert and CDC/ACIP should always be consulted for specific recommendations regarding indications, storage, administration, precautions, and contraindications.
[b]Two vaccines available: oral live attenuated vaccine (Ty21a) and Vi capsular polysaccharide vaccine (ViCPS).
[c]Persons immunocompromised because of immune deficiency diseases, human immunodeficiency virus infection, leukemia, lymphoma, or generalized malignancy, or immunosuppressed as a result of therapy with corticosteroids (i.e., >2 mg/kg body weight or 20 mg/day of prednisone for >2 weeks), alkylating drugs, antimetabolites, or radiation.
ACIP, Advisory Committee on Immunization Practices; AVA, anthrax vaccine absorbed; CDC, Centers for Disease Control and Prevention; HCP, healthcare personnel; HDCV, human diploid cell vaccine; HRIG, human rabies immunoglobulin; Ig, immunoglobulin; IM, intramuscular; IND, investigational new drug; IPV, inactivated polio vaccine; PCECV, purified chick embryo cell vaccine; PEP, postexposure prophylaxis; SC, subcutaneous; ViCPS, Vi capsular polysaccharide.

a contraindication to receipt of a live attenuated vaccine, although HCP receiving live attenuated influenza vaccine should not work in a protected environment (i.e., stem cell transplant unit) for 7 days postimmunization.[46,86]

Pregnant HCP also require special consideration in the provision of immunizations. The risks from immunization during pregnancy are largely theoretical.[45] The benefit of immunization among pregnant women usually outweighs the potential risks for adverse reactions, especially when the risk for disease exposure is high, infection would pose a special risk to the mother or fetus, and the vaccine is unlikely to cause harm.[45,46,87–89] Furthermore, newer information continues to confirm the safety of vaccines given inadvertently during pregnancy. Ideally, women of childbearing age, including HCP, should have been immunized against measles, mumps, rubella, varicella, tetanus, diphtheria, pertussis, meningococcus, polio, hepatitis A, and hepatitis B as children or adolescents before becoming pregnant. However, because this may not have occurred, it is especially important that all HCP be screened for rubella immunity (by serology because history is

TABLE 72.3 Recommendations on Immunization of Healthcare Personnel With Special Conditions

Vaccine	Pregnancy	HIV Infection		Immunocompromising Conditions (Excluding HIV)[a]	Diabetes, Heart Disease, Chronic Lung Disease, Chronic Alcoholism	Asplenia and Persistent Complement Component Deficiencies	Chronic Liver Disease	Kidney Failure, End- Stage Renal Disease, Receipt of Hemodialysis
		<200 cells/uL	≥200 cells/uL					
Hepatitis A	UI	UI	UI	UI	UI	UI	R[b]	UI
Hepatitis B	R	R	R	R	R	R	R	R
Influenza	R[c]	R	R	R	R	R	R	R
MMR	C	C	R	C	R	R	R	R
Polio, inactivated[d]	UI	UI	UI	UI	UI	UI	UI	UI
Pneumococcal (PPSV23 and PCV13)	UI	R[b]	R[b]	R[b]	R[b]	R[b]	R[b]	R[b]
Rabies	UI	UI	UI	UI	UI	UI	UI	UI
Tdap	–[e]	R	R	R	R	R	R	R
Typhoid, ViCPS[b]	UI	UI	UI	UI	UI	UI	UI	UI
Typhoid, Ty21a[b]	C	C	C	C	UI	UI	UI	UI
Varicella	C	C	R	C	R	R	R	R
Vaccinia	C	C	C	C	UI	UI	UI	UI
Zoster	C	C	C	C	UI	UI	UI	UI

[a]Severe immunosuppression can be the result of congenital immunodeficiency; leukemia, lymphoma, generalized malignancy, radiation, or therapy with immunosuppressive agents, such as alkylating agents, antimetabolites, and large amounts of corticosteroids.
[b]Recommendation based on the person's underlying medical condition(s) or risks (e.g., travel) rather than occupation.
[c]Recommended for women who will be pregnant during the influenza season.
[d]Immunization with IPV is recommended for unvaccinated healthcare workers who have close contact with persons who may be excreting wild poliovirus. Healthcare workers who have a primary series of OPV or IPV who are directly involved with the provision of care to patients who may be excreting poliovirus may receive another dose of IPV. Any suspected case of poliomyelitis should be investigated immediately. If evidence suggests transmission of wild poliovirus, control measures to contain further transmission should be instituted immediately, including an IPV immunization campaign.
[e]Td vaccine recommended for pregnant women who have not received a Td within the past 10 years; Tdap is specifically recommended for pregnant women more than 20 weeks' gestation (preferred to Td).
C, Contraindicated; HIV, human immunodeficiency virus; IPV, inactivated polio vaccine; MMR, measles-mumps-rubella; OPV, oral polio vaccine; R, recommended; Td, tetanus, diphtheria vaccine; Tdap, tetanus, diphtheria, acellular pertussis vaccine; UI, use if indicated; ViCPS, Vi capsular polysaccharide.

often unreliable) because of the consequences of infection for the developing fetus. Nevertheless, attenuated vaccines (mumps, measles, rubella, and varicella) or live attenuated influenza vaccine should be provided only to nonpregnant HCP and deferred for pregnant women. The ACIP has recommended that "health care personnel should administer Tdap during all pregnancies, preferably during the third or late second trimester (after 20 weeks' gestation)." If not administered during pregnancy, Tdap should be administered immediately postpartum. Women who are pregnant during respiratory virus season should receive inactivated influenza immunization.[45,46,68] There is no convincing evidence of risk from immunizing pregnant women with other inactivated virus or bacterial vaccines, or toxoids. Susceptible pregnant women at high risk for specific infections should receive, as indicated, the following vaccines: hepatitis A, hepatitis B, pneumococcal polysaccharide, meningococcal, rabies, and poliovirus (inactivated).[45] Several vaccines or immunoglobulins (Igs) are recommended as part of postexposure prophylaxis, including hepatitis A (Ig), hepatitis B immunoglobulin (HBIG), and rabies immunoglobulin (RIG). The indications for use are the same in pregnant and nonpregnant women. Pregnant women should be immunized with meningococcal vaccine when there is a substantial risk of infection, such as during epidemics. Breastfeeding does not adversely affect the response to immunization and is not a contraindication for any of the currently routinely recommended vaccines.

Before the administration of any vaccine, the HCP should be evaluated for the presence of condition(s) that are listed as a vaccine contraindication or precaution.[45] If such a condition is present, the risks and benefits of vaccination need to be carefully weighed by the healthcare provider and the HCP. The most common contraindication is a history of an anaphylactic reaction to a previous dose of the vaccine or to a vaccine component. Factors that are not contraindications to immunization include the following: household contact with a pregnant woman; breastfeeding; reaction to a previous vaccination, consisting only of mild to moderate local tenderness, swelling, or both, or a fever of less than 40.5°C; mild acute illness with or without low-grade fever; current antimicrobial therapy (except for oral typhoid vaccine) or convalescence from a recent illness; personal history of allergies except a history of an anaphylactic reaction to a vaccine component (e.g., people with a history of anaphylaxis to neomycin should not receive the MMR vaccine); and family history of allergies, serious adverse reactions to vaccination, or seizures.[45]

Postexposure Prophylaxis

All HCP potentially exposed to a communicable disease should be evaluated by the institution's occupational health service as soon as possible. General guidelines for a postexposure evaluation of medical personnel have been published.[1,30,90] In brief, the following steps should be undertaken:

- Confirm that the source has a communicable disease.
- Determine that potential transmission could have taken place (e.g., close contact for transmission of *Neisseria meningitidis* or *Bordetella pertussis*).
- Determine that the exposed healthcare provider was not protected by the use of personal protective equipment (e.g., N-95 respirator for airborne transmitted diseases).
- Determine that the exposed healthcare provider is susceptible to infection (this may require laboratory evaluation).
- Determine if effective postexposure prophylaxis is available and recommended.
- Determine that the healthcare provider has no contraindications to use of the recommended prophylaxis.
- If the healthcare provider has a contraindication to the recommended prophylaxis, determine if an alternative exists and is safe to use.
- Inform the healthcare provider of the risk of disease transmission, signs and symptoms of infection, and risks and benefits of prophylaxis.
- Obtain informed consent for prophylaxis.
- Obtain baseline laboratory tests, if indicated (e.g., anti–hepatitis B surface antigen [anti-HBsAg] titer).
- Assess whether the healthcare provider's work activities should be restricted or if the provider should be furloughed (e.g., days 8 to 21 after exposure to varicella-zoster in a susceptible employee).
- Arrange follow-up evaluations.

Vaccines that may be indicated for postexposure prophylaxis include tetanus toxoid (Tdap preferred), hepatitis B, and rabies (Tables 72.4 and 72.5). The CDC states that "unvaccinated HCP who have no other evidence of immunity and who are exposed to varicella-zoster virus (VZV; varicella, disseminated herpes zoster, and uncovered lesions of a localized herpes zoster) are potentially infective from days 8 to 21 after exposure and should be furloughed during this period. They should receive postexposure vaccination as soon as possible. Vaccination within 3 to 5 days of exposure to rash might modify the disease if infection occurred. Vaccination more than 5 days postexposure is still indicated because it induces protection against subsequent exposures (if the current exposure did not cause infection)."[30] HCP who have received one dose of vaccine and who are exposed to VZV (varicella, disseminated herpes zoster, and uncovered lesions of a localized herpes zoster in the community or healthcare setting/workplace) should receive the second dose within 3 to 5 days after exposure to rash (provided 4 weeks have elapsed after the first dose).

The ACIP now recommends that for healthy persons 12 months to 40 years of age, single-antigen hepatitis A vaccine at the age-appropriate dose is preferred to immunoglobulin for postexposure prophylaxis for persons exposed to hepatitis A virus because of vaccine advantages that include long-term protection and ease of administration.[79] Currently, there are no data regarding the relative efficacy of vaccine compared with immunoglobulin postexposure prophylaxis for persons older than 40 years of age or for those with underlying medical conditions; consequently, the ACIP states that decisions to use vaccine or immunoglobulin should take into account patient characteristics associated with severe manifestations of hepatitis A, including older age and chronic liver disease.[79] Several vaccines have been provided to persons without known direct exposure to an infected case to help contain communitywide or institutional outbreaks, including hepatitis A, meningococcal vaccine, and pertussis vaccine. Immunoglobulin preparations may be indicated as part of postexposure prophylaxis for exposure to hepatitis A (immunoglobulin), hepatitis B (HBIG), measles (immunoglobulin), rabies (RIG), tetanus (tetanus immunoglobulin), varicella (varicella-zoster immunoglobulin [VariZIG]), and vaccinia immunoglobulin). All HCP who are exposed to a communicable disease or with symptoms of an infectious disease should be evaluated with the consideration of whether work restriction or furlough is required to prevent secondary cases from developing among patients or staff (Table 72.6).

Postexposure Prophylaxis for Bioterrorism Agents

Before the intentional release of anthrax in the United States in 2001, several publications highlighted the concern about the potential for biologic terrorism.[91,92] Since 2001, the continued

TABLE 72.4 Postexposure Prophylaxis for Vaccine-Preventable Diseases

Disease	Definition of Exposure	Prophylaxis[a]	Comments
Hepatitis A	Ingestion of contaminated food; contact with feces from a hepatitis A–infected patient	One dose IM immunoglobulin 0.02 mL/kg given within 14 days of exposure (can also use hepatitis A vaccine)	Ig: avoid in persons with IgA deficiency; do not administer within 2 wk of MMR vaccine or 3 wk of varicella vaccine
Hepatitis B	Contact with HBsAg-positive blood (or body fluid) via percutaneous, mucous membrane, or nonintact skin exposure	See Table 72.5	HCP who have ever demonstrated an anti-HBsAg titer ≥10 mIU/mL do not require postexposure prophylaxis
Influenza A or B	Cohabiting confined air space or face-to-face contact in an open area (nonimmunized HCP)	Zanamivir 10 by inhaler once daily or oseltamivir 75 mg orally once daily may be used; both for 7–10 days	Zanamivir—avoid if asthmatic. Oseltamivir associated with gastrointestinal toxicity (≈ 5–10%)
Measles[b]	Cohabiting confined air space or face-to-face contact in an open area (nonimmune HCP)	Susceptible HCP should receive immunoglobulin 0.25 mL/kg (maximum 15 mL) IM within 6 days of exposure or measles vaccine	Susceptible HCP should be furloughed from days 5–21 postexposure or for 7 days after the rash appears
Meningococcus (invasive)[b]	Direct contact with respiratory secretions (e.g., resuscitating intubating, or closely examining the oropharynx) of infected persons with invasive disease (sepsis, meningitis)	Ciprofloxacin 500 mg orally × 1 dose or ceftriaxone 250 mg IM × 1 dose or rifampin 600 mg orally 2 bid for 2 days Avoid ciprofloxacin if resistant strains reported in the community	Home contacts of exposed HCP do not need to receive prophylaxis unless the HCP develops infection; rifampin and ciprofloxacin not recommended in pregnancy
Pertussis[b]	Direct contact with respiratory secretions or droplets from the respiratory tract of infected persons	Exposed HCP should receive azithromycin orally (500 mg day 1, 250 mg days 2–5) or trimethoprim-sulfamethoxazole orally 1 tablet bid for 14 days	Other acceptable alternatives are erythromycin (14 days) and clarithromycin (7 days)
Varicella[b]	Cohabiting confined air space or face-to-face contact in an open area with a patient with active lesions or within 48 hours before the development of lesions (nonimmune HCP)	For susceptible employees, VariZIG 125 U/10 kg IM (maximum dose 625 U) is indicated for immunocompromised or pregnant adults (within 10 days of exposure but it should be administered as soon as possible after exposure)	Susceptible employees should be furloughed from days 8–21 postexposure (employees who receive VariZIG should be furloughed from days 8–28 postexposure)
Zoster[b]	Cohabiting confined air space or face-to-face contact in an open area with a patient with uncovered active lesions (disseminated zoster or immunocompromised patient) (nonimmune HCP)	As for varicella	Same as varicella exposure

[a]The latest guidelines from the Centers for Disease Control and Prevention should always be consulted.
[b]HCP who was wearing a mask (surgical mask or N-95 respirator) is not considered exposed.
bid, Twice a day; HBsAg, hepatitis B surface antigen; HCP, healthcare personnel; Ig, immunoglobulin; IM, intramuscular; MMR, measles, mumps, and rubella; VariZIG varicella-zoster immunoglobulin (available via an investigational new drug).

TABLE 72.5 Recommended Postexposure Prophylaxis for Exposure to Hepatitis B Virus

Vaccination and Antibody Response of Exposed Workers[a]	Treatment		
	Source HBsAg-positive	Source HBsAg-negative	Source Not Tested or Unknown
Unvaccinated	HBIG[b] × 1 and initiate HBV vaccine	Initiate HBV vaccine series	Initiate HBV vaccine series
Previously vaccinated			
Known responder[c]	No treatment	No treatment	No treatment
Known nonresponder[d]	HBIG × 1 and initiate HBV revaccination or HBIG × 2[e]	No treatment	If known high-risk source, treat as if source were HBsAg positive
Antibody response unknown	Test exposed person for anti-HBsAg 1. If adequate,[c] no treatment is necessary 2. If inadequate,[d] administer HBIG × 1 and HBV vaccine booster	No treatment	Test exposed person for anti-HBsAg 1. If adequate,[c] no treatment is necessary 2. If inadequate,[d] administer HBV vaccine booster and recheck titer in 1–2 mo

[a]Persons who have previously been infected with HBV are immune to reinfection and do not require postexposure prophylaxis.
[b]Dose is 0.06 mL/kg intramuscularly.
[c]A responder is a person who has adequate levels of serum antibody to HBsAg (i.e., anti-HBsAg ≥10 mIU/mL).
[d]A nonresponder is a person who has inadequate response to vaccination (i.e., serum anti-HBsAg <10 mIU/mL).
[e]The option of giving one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who have not completed a second three-dose series. For persons who previously completed a second vaccine series but failed to respond, two doses of HBIG are preferred.
HBV, hepatitis B virus; HBIG, hepatitis B immunoglobulin; HBsAg, hepatitis B surface antigen.

TABLE 72.6 Work Restrictions for Vaccine-Preventable Diseases

Disease	Work Restriction	Duration
Hepatitis A	Relieve from direct patient contact and food handling	Until 7 days after onset of jaundice
Hepatitis B		
Acute	Relieve from direct patient contact	Until jaundice resolves
Chronic	No restriction unless demonstrated to transmit infection to patients or unable to practice appropriate infection control. Restrictions should be considered by SHEA guideline[a] for personnel performing invasive procedures	Counsel regarding need to follow standard precautions. Periodic reevaluation per SHEA guideline[a]
Influenzas A and B	Furlough from healthcare facility	Until fever resolves off antipyretics or 5 days (whichever is longer)
Measles		
Active	Furlough from healthcare facility	Until 4 days after rash appears
Postexposure (susceptible personnel)	Furlough from healthcare facility	From the 5th day after the first exposure through the 21st day after the last exposure or 4 days after the rash appears
Mumps		
Active	Furlough from healthcare facility	Until 9 days after onset of parotitis
Postexposure (susceptible personnel)	Furlough from healthcare facility	From the 12th day after the first exposure through the 26th day after the last exposure or 9 days after the onset of parotitis
Pertussis		
Active	Furlough from healthcare facility	From the beginning of the catarrhal stage through the third week after the onset of paroxysms or until 5 days after start of effective antimicrobial therapy
Postexposure (susceptible personnel)	No restriction, if on prophylactic antimicrobial therapy[a]	—
Postexposure (symptomatic personnel)	Furlough from healthcare facility	Same as active pertussis
Rubella		
Active	Furlough from healthcare facility	Until 5 days after rash appears
Postexposure (susceptible personnel)	Furlough from healthcare facility	From the 7th day after the first exposure through the 21st day after the last exposure or 5–7 days after the rash appears
Varicella		
Active	Furlough from healthcare facility	Until the lesions are dried and crusted
Postexposure (susceptible personnel)[b]	Furlough from healthcare facility	From the 8th day after the first exposure through the 21st day (28th day if VariZIG given) after the last exposure or if varicella occurs, until all lesions are dried and crusted
Zoster		
Localized (nonexposed area of skin); in a normal host	Cover lesions; relieve from care of immunocompromised patients	Until the lesions are dried and crusted
Localized (exposed area of the skin); localized in immunocompromised host; generalized	Furlough from healthcare facility	Until the lesions are dried and crusted
Postexposure (susceptible personnel)	Furlough from healthcare facility	From the 8th day after the first exposure through the 21st day (28th day if VariZIG given) after the last exposure or if varicella occurs, until all lesions are dried and crusted

need to be prepared for bioterrorism has been highlighted.[93,94] The CDC has categorized several agents as "high priority" because they can be easily disseminated or transmitted person-to-person, cause high mortality, and are likely to cause public panic and social disruption. These agents include *Bacillus anthracis* (anthrax), *Yersinia pestis* (plague), variola major (smallpox), *Clostridium botulinum* toxin (botulism), *Francisella tularensis* (tularemia), filoviruses (Ebola virus disease, Marburg disease), and arenaviruses (Lassa [Lassa hemorrhagic fever], Junin [Argentine hemorrhagic fever], and related viruses).[95] Characteristics of these high-priority agents include the following: they are infectious via aerosol, the organisms are fairly stable in aerosol form, there are susceptible civilian populations, infection is associated with high morbidity and mortality, several exhibit person-to-person transmission (i.e., cutaneous anthrax, pneumonic plague, smallpox, and Ebola, Marburg, Lassa, and Junin viruses), they are difficult to diagnose and/or treat, and most have previously been developed as biologic weapons. General reviews of bioterrorist agents have been published,[93,94] as well as detailed management recommendations for anthrax,[96] botulism,[97] plague,[98] smallpox,[99] tularemia,[100] and viral hemorrhagic fever.[101]

Key aspects of the management of patients infected with bioterrorism agents include decontamination before medical evaluation, proper isolation, rapid diagnosis with appropriate therapy, and postexposure prophylaxis of exposed persons. HCP may acquire infection from patients via contaminated clothes (smallpox, Q fever, plague, and anthrax) or via patient-to-HCP transmission.[23] In the event of an attack with mass casualties and widespread exposures, vaccines likely will play an important adjunctive role in limiting the impact of anthrax[102] and the critical role in containing smallpox.[103] Currently preexposure use of anthrax vaccine is recommended only for laboratory workers or researchers at risk for anthrax exposure (see Table 72.2). Vaccinia vaccine is effective as postexposure prophylaxis after smallpox exposure when used within 4 days.[99] If vaccines now in development for bioterrorist agents (e.g., vaccines for *C. botulinum, F. tularensis, Y. pestis*) become available, HCP may be included in both preexposure and postexposure recommendations.[104]

PROVIDING VACCINES FOR HEALTHCARE PERSONNEL

All HCP new to a healthcare facility should be screened for immunity to vaccine-preventable diseases within 10 working days. Unless immune, the HCP should be appropriately immunized. In general, serologic screening for immunity before immunization is neither necessary nor cost-effective. Each healthcare facility, however, needs to evaluate the cost-effectiveness of screening. Factors that determine the effectiveness of serologically screening HCP for immunity include the cost of the screening test, the cost of the vaccine, and the prevalence of immunity in the population. The prevalence of immunity in the population likely depends on age, gender, race, place of birth, and socioeconomic status. In addition, the sensitivity and specificity of the screening test must be considered.

The immunization status of all HCP should be recorded in their medical record, which should be maintained by the institution's occupational health service. Signed informed consent specific to each vaccine should be obtained before immunization. When vaccines are provided, appropriate information should be recorded in the healthcare provider's medical record (Box 72.1). All institutions should develop a readily available personnel medical record that includes the HCP immune status to vaccine-preventable diseases.

BOX 72.1 Information That Should Be Obtained When Providing Vaccines to Healthcare Personnel

- Personnel name
- Prsonnel identification number
- Date of birth or age
- Date of immunization
- Potential contraindications to vaccine:
  - Anaphylaxis to a previous dose of vaccine
  - Allergy to vaccine constituent
  - For live attenuated vaccines: possible pregnancy, immunocompromising conditions/medications
  - Vaccine-specific contraindications
- Vaccine provided
- Name of vaccine manufacturer
- Lot number of vaccine
- Site of immunization
- Route of immunization
- Date for additional immunizations (if required)
- Complications (if any)
- Name, title, and address of person providing vaccine
- Signed informed consent

IMPROVING VACCINE COVERAGE OF HEALTHCARE PERSONNEL

Despite strong recommendations from the CDC and professional organizations that HCP in the United States be immune to vaccine-preventable diseases, studies continue to demonstrate that substantial numbers of HCP lacked evidence of immunity to these diseases and that many HCP refuse immunization. The proportion of U.S. HCP that have received vaccine has been reported as the following: hepatitis B, 61.7% (2013)[105]; Tdap, 47.0% (2013)[105]; and influenza, 64.3% (2014–15 season).[106] By occupation, influenza vaccine coverage was highest among pharmacists (86.7%), nurse practitioners/physician assistants (85.8%), physicians (82.2%), nurses (81.4%), and other clinical professionals (72.0%). Influenza vaccine coverage was lowest among administrative and nonclinical support staff (59.1%) and assistants or aides (46.6%). By work setting, influenza vaccine coverage was highest among HCP working in hospitals (78.7%) and lowest among HCP working in long-term care facilities (54.4%). Serologic studies of hospital-based HCP indicate that 2% to 9% of those born before 1957 lack antibodies to measles virus.[30] Although most U.S. schools training nurses and physicians required immunity to MMR and hepatitis B (i.e., >95%), less require immunity to varicella (physicians, >95%; registered nurses, ~90%), and even less to Tdap (~89%), and influenza (<20%).[107] Schools training allied HCP (e.g., occupational therapists) are even less likely to require immunity to vaccine-preventable diseases.[108] Vaccination policies in other areas of the world, such as Europe, are less likely than the United States to require or recommend immunity to vaccine-preventable diseases for HCP.[109] A recent review of vaccine coverage of HCP which focused on influenza and hepatitis B vaccine coverage around the world reported, in general, very low rates of coverage.[110]

Barriers to receiving influenza vaccine commonly reported by HCP have included desire to avoid medications, inconvenient vaccine administration, concern about side effects, belief that influenza can be caused by the vaccine, belief that they are at low risk of infection, doubt that influenza is a serious disease, and belief that the vaccine is ineffective.[111–115] Similar concerns are voiced about hepatitis B vaccine, including the desire to avoid medications, perception that the HCP is at low

risk for occupationally acquired hepatitis B virus (HBV) infection, and concern about side effects.[111] Barriers to acceptance of influenza vaccine and measures to improve influenza vaccine compliance among HCP have been reviewed.[115] Interventions that have been demonstrated to improve vaccine uptake have included the use of mobile carts,[116,117] incentive programs,[118] educational campaigns that focus on the seriousness of influenza and address misconceptions about the vaccine,[119–121] providing vaccine at multiple sites and on the wards,[120] and weekly feedback to the staff.[121] An analysis of 50 hospitals during the 2007–08 influenza season revealed that programs with the following components had significantly higher vaccination rates: weekend provision of vaccine, train-the-trainer programs, report of vaccination rates to administrators or board of trustees, a letter sent to HCP emphasizing the importance of vaccination, and any form of visible leadership support.[122] The use of a signed declination form for HCP who refuse vaccination was not associated with an improved frequency of influenza immunization. Although some studies have demonstrated that the use of a signed declination form was associated with improved influenza coverage among HCP,[123] a systematic review found only "modest" benefit.[124] As noted above, multiple professional organizations have endorsed the position that employment for HCP should be conditional on receipt (unless contraindicated) of influenza vaccine. A systematic review of mandatory influenza vaccine for HCP reviewed eight observational studies; influenza vaccine rates in all studies exceeded 94%.[125] The National Vaccine Advisory Committee statement provides an excellent summary of strategies for improving influenza coverage of HCP.[61]

GUIDELINES FOR THE USE OF SELECTED VACCINES

Measles-Mumps-Rubella Vaccine

Epidemiology

The incidence of mumps, measles, and rubella has decreased dramatically since the widespread use of MMR vaccine. Cases reported to the CDC in 2012 were as follows: mumps, 229 (0.07 per 100,000 population); measles, 55 (0.02 per 100,000 population) of which 38% were imported; rubella, eight (0 per 100,000 population), and congenital rubella, three (0 per 100,000 population).[126] In the years between 2013 and 2015, the CDC has reported substantially more cases of measles.[127–129] The vast majority of the cases were import-associated and infected persons were unvaccinated or had an unknown vaccination status. Of note, an outbreak in California which was related to visiting two adjacent Disney theme parks involved 125 measles cases between December 28, 2014 and February 11, 2015.[130]

All three diseases represent an important health hazard for hospital personnel for the following reasons. First, all three are transmitted by the droplet route (measles is also transmitted by the airborne route). Second, in all three diseases, persons become infectious before developing a clinically recognizable illness. Third, a history of prior disease may be unreliable for determining whether HCP actually suffered a vaccine-preventable disease in the past. Hence, many unimmunized HCPs may falsely believe themselves immune.

Rubella is of special concern because of its ability to cause congenital abnormalities in up to 90% of women with confirmed infection in the first trimester of pregnancy. Hospital workers are frequently females of childbearing age. Infants with congenital rubella may be contagious until they are at least 1 year old and therefore can expose HCP.

Lessons From Hospital Outbreaks

Nosocomial outbreaks of mumps have been reported infrequently,[131–138] but transmission from patient-to-patient[131,132,136,137] and from patient-to-healthcare provider has been reported.[13,134—136] In one case, it was suggested that an asymptomatically infected hospital nurse introduced mumps into a children's hospital.[132] Community outbreaks are likely to lead to nosocomial exposures. For example, during the widespread epidemic of mumps in Tennessee from 1986 to 1987, six HCP in three different hospitals developed mumps after nosocomial exposure.[136] Men, including male HCP, are at higher risk of complications from mumps (such as orchitis) than are children.[139] Orchitis has been reported among male HCP who developed mumps as a result of hospital exposure.[140] Because of the threat of mumps outbreaks, the ACIP now recommends that HCP receive two doses of MMR vaccine.[30]

Nosocomial measles is well documented in the literature[141–191] and may aid in the propagation of community outbreaks.[160–162,173,180,189,190] Analyses of measles cases reported to the CDC revealed acquisition in a medical setting for 241 people (1.1% of all cases) between 1980 and 1984[149] and for 1209 people (3.5% of all cases) between 1985 and 1989.[163] Investigations of individual outbreaks, however, have reported that 17% to 59% of cases were acquired in a medical set ting.[144,146,150,153,157,161,165,182,184,191] Acquisition of measles has occurred in outpatient settings, including emergency departments and physician offices, and has involved patient-to-patient, patient-to-staff, and staff-to-patient transmission. In one community outbreak, the relative risk of measles in HCP compared to community adults was 18.6.[182] Transmission in the outpatient setting has occurred even though the index cases had left the waiting or examination room up to 75 minutes earlier.[144,146,147,156,168,171] Case-control studies have demonstrated that persons who visited an emergency department had a 4.9-fold[172] to 5.2-fold[162] higher risk of developing measles one incubation period later compared with those who did not have such visits. In inpatient settings, transmission also has occurred among patients, from patients to staff, and from infected staff to patients. Infected staff most commonly have been nurses, with other groups at high risk of infection being physicians and office or hospital clerical staff. Nosocomial outbreaks have led to hospitalization of infected staff,[164,181,182] severe complications in infected patients,[166] and, occasionally, death of patients.[160,164,174] Multiple generations of nosocomial cases may occur.[184] The cost of controlling a single outbreak has ranged from US$28,000 to more than US$100,000.[160,164] As noted above, although measles is an uncommon disease, there have been an increased number of cases in recent years often import-related and propagated by unimmunized or underimmunized persons.

There has been no documented transmission of rubella to HCP or other hospital staff or patients in U.S. healthcare facilities since the elimination of rubella was announced in 2004. However, as with mumps and measles, nosocomial rubella is well documented in the literature.[192–211] Sources of rubella infection have included not only persons with acute infection, but also infants with congenital rubella.[193,202,210] Hospital-acquired infection of pregnant staff members has led to the termination of pregnancy.[200,206]

Several valuable lessons have been learned from the outbreaks. First, it appears that mumps and rubella are acquired mainly via droplet transmission. Measles, however, may be acquired via airborne transmission. Furthermore, measles transmission may occur for more than an hour after an infected case has left an enclosed area. Second, history of prior disease is unreliable for determining whether

healthcare providers actually contracted measles in the past, and hence many HCP falsely believe they are immune from past illness and fail to take appropriate precautions. Third, failure to institute a mandatory program requiring immunity results in a subpopulation of susceptible HCP capable of propagating epidemics. In multiple outbreaks, three to more than five generations of disease transmission occurred. Fourth, the cost of outbreaks for these diseases is high in both monetary terms and human suffering. Fifth, patients with congenital rubella are capable of transmitting rubella to susceptible adults.

Preexposure Prophylaxis

All HCP should be immune to mumps, measles, and rubella. Immunity may be demonstrated by meeting one of the following criteria: (a) birth before 1957 (rubella except women with childbearing potential who could become pregnant, although pregnancy in this age group would be exceedingly rare), (b) laboratory evidence of immunity (persons with indeterminate levels are considered susceptible), (c) laboratory confirmation of disease, or (d) evidence of appropriate immunizations (see Table 72.1).[30,62] Physician-diagnosed disease is no longer considered adequate evidence of immunity. Appropriate immunization consists of documented administration of two doses of live measles virus vaccine, two doses of live mumps virus vaccine, and one dose of live rubella virus vaccine (use of MMR is preferred). Birth before 1957 provides only presumptive evidence of immunity to measles, mumps, and rubella, although more than 95% of newly hired workers will demonstrate serologic immunity.[212] For unvaccinated personnel born before 1957 who lack laboratory evidence of measles, mumps, and/or rubella immunity or laboratory confirmation of disease, the ACIP recommends that healthcare facilities should consider vaccinating personnel with two doses of MMR vaccine at the appropriate interval (for measles and mumps) and one dose of MMR vaccine (for rubella), respectively.[30,69] If a healthcare facility chooses not to assure immunity of HCP born before 1957 to mumps, measles, and rubella, the ACIP states that healthcare facilities should recommend two doses of MMR vaccine during an outbreak of measles or mumps and one dose during an outbreak of rubella.[30] The American Academy of Pediatrics recommends that all HCP, including those born before 1957 who lack serologic evidence of immunity to rubella, should be immunized regardless of gender. The American Academy of Pediatrics also states that healthcare facilities should consider recommending one dose of MMR for HCP born before 1957 without other evidence of immunity.

Postexposure Management of Exposed Healthcare Workers

No specific prophylaxis is effective for mumps or rubella. Exposed susceptible people should be furloughed from the hospital (see Table 72.5). Patients with incubating or active mumps or rubella should be placed on *droplet precautions.* Patients with measles should be placed on *airborne precautions.* Because of the possibility, albeit low (~1%) of measles vaccine failure in HCP exposed to infected patients, all HCP should observe airborne precautions in caring for patients with measles. Measles vaccine can be used to provide postexposure prophylaxis of susceptible personnel if administered within 72 hours of exposure. However, all exposed HCP without evidence of immunity regardless of whether they receive measles vaccine postexposure, should be excluded from work from days 5 to 21 following exposure.[30] Immunoglobulin, 0.25 mL/kg (maximum dose: 15 mL), may be used for postexposure prophylaxis for susceptible personnel who are exposed to measles but must be provided within 6 days of exposure. Measles vaccine may also be used as postexposure prophylaxis but must be provided within 72 hours. Immunoglobulin postexposure prophylaxis is especially recommended for serosusceptible pregnant women and immunocompromised persons (dose: 0.5 mL/kg; maximum dose: 15 mL).

Varicella Vaccine

Epidemiology

VZV is the causative agent of two diseases: varicella (chickenpox), the primary infection, and zoster (shingles), a secondary infection caused by reactivation of latent VZV.[213–225] The licensure of the varicella vaccine in the mid-1990s allowed primary prevention of chickenpox. With the incorporation of the varicella vaccine into the childhood vaccine schedule, the incidence of varicella disease, hospitalization, deaths, and varicella-related expenditure has declined dramatically in the United States.[226–229] Although varicella is generally a mild disease in children, serious morbidity and mortality are common if infection occurs in neonates, adults, or immunocompromised people. For these reasons, the CDC[9,30] and the American Academy of Pediatrics,[47] have published recommendations regarding the isolation of patients with VZV infection and the management of patients and HCP exposed to VZV.

In most cases, VZV appears to be transmitted from person-to-person by the droplet route, and transmission occurs most efficiently when there is close contact, but true airborne transmission also may occur. The secondary attack rate of varicella among susceptible people in the household setting has ranged from 61% to 87%.[230–233] Vaccinated persons who develop breakthrough varicella are approximately half as contagious as unvaccinated persons with primary infections.[234] Herpes zoster is also infectious, although analysis of households suggests that the risk of transmission is lower than that for varicella.

Lessons From Nosocomial Outbreaks

Control of varicella is important in healthcare facilities because varicella and zoster are highly contagious; infection in adults frequently results in complications, including hospitalization; infection in pregnant women may lead to the congenital varicella syndrome[234–244]; and severe complications, including death, may occur in immunocompromised patients and healthcare providers. Of importance for hospitals, the risk of complications appears to be higher in neonates, adults,[218,245,246] and severely immunocompromised persons.[215,216] Approximately 1% to 2% of adults who develop varicella become ill enough to require hospitalization.[245,246] Patients developing varicella while undergoing chemotherapy for malignancy or undergoing immunosuppressive therapy after organ or bone marrow transplantation have a high risk of complications (30–50%) and death (7–17%).[247–254] Current rates of morbidity and mortality are dramatically lower because of prophylactic use of antivirals, postexposure prophylaxis with VariZIG or antivirals, and availability of antivirals, such as acyclovir, for therapy.[218,219]

Nosocomial transmission of VZV has been well documented in the literature, although few outbreaks have been reported in recent years in the United States.[232,255–276] Varicella may be introduced into the hospital by infected patients, staff, or visitors. Several investigators have noted that the initial source case for an outbreak was in the incubating phase of varicella.[255,266] After nosocomial exposure to VZV infection, 2% to 16% of susceptible staff have developed clinical varicella.[255,266] Nosocomial varicella has occurred among staff and

patients who had no direct contact with the index case, supporting the airborne route as a mode of spread.[256,265,276] Epidemiologic studies using tracers[267] or measurement of VZV DNA[277] have provided definitive evidence to support airborne transmission. By using polymerase chain reaction to detect VZV DNA, Yoshikawa and colleagues[278] demonstrated extensive environmental contamination in the room of a person with dermatomal zoster. Exposure to dermatomal[255,256,261,275] or disseminated[262] zoster in immunocompromised patients and to dermatomal zoster in immunocompetent hosts has led to transmission of VZV to susceptible HCP via the airborne route or droplet route.[255,267]

The CDC/HICPAC (Healthcare Infection Control Practices Advisory Committee),[9] CDC/ACIP,[30] and the American Academy of Pediatrics,[47] have published guidelines designed to aid clinicians in the control of nosocomial exposures. Key components include the following: (1) varicella, disseminated zoster, or dermatomal zoster in immunocompromised persons should be managed using *airborne* and *contact precautions* until all lesions are dried and crusted; (2) immunocompetent patients with dermatomal zoster should be managed using contact precautions until all lesions are dried and crusted; (3) serosusceptible patients exposed to varicella or zoster should be managed using airborne precautions from day 8 after the first exposure through day 21 after the last exposure (if patient has received VariZIG, precautions should extend through day 28) regardless of postexposure vaccination with varicella vaccine; (4) susceptible HCP personnel should not enter the room of patients with varicella-zoster if immune caregivers are available; (5) either a surgical mask or N-95 respirator should be used by susceptible HCP who enter the room; and (6) susceptible HCP who have been exposed to varicella-zoster should be furloughed from day 8 after the first exposure through day 21 after the last exposure (if HCP has received VariZIG, precautions should extend through day 28) regardless of postexposure vaccination with varicella vaccine. The authors are unaware of any nosocomial outbreaks in which transmission was linked to recirculated air of infected patients placed in private rooms with negative pressure. However, it is important to keep the door closed to prevent transient airflow into the corridor, which can lead to infection of susceptible personnel.[273] Given the current incidence of varicella and tuberculosis, it is likely that many hospitals do not have adequate rooms meeting the OSHA tuberculosis requirements to use these rooms to isolate patients with VZV infections.

Preexposure Prophylaxis

The ACIP,[30] the American Academy of Pediatrics,[47] and the American Medical Association[279] have recommended that all HCP should be immune to varicella. HCP should be screened for VZV immunity at the time of initial employment, as is currently recommended for mumps, measles, and rubella. Evidence of immunity includes any of the following: written documentation of vaccination with two doses of varicella vaccine, laboratory evidence of immunity or laboratory confirmation of disease, diagnosis or verification of a history of varicella disease by a healthcare provider, or diagnosis or verification of a history of herpes zoster by a healthcare provider.[30] Birth in the United States before 1980 is not considered presumptive evidence of immunity for HCP.[30] HCP born in tropical countries are more likely to be susceptible to varicella. Healthcare providers without a vaccine contraindication or precaution should be immunized with two doses at least 4 weeks apart of varicella vaccine. The most common test for determining immunity to varicella is the enzyme-linked immunosorbent assay (ELISA) test. Performing postimmunization serology is not recommended because commercial tests (e.g., ELISA) lack the sensitivity to detect the lower antibody levels associated with immunization compared with natural infection.[30] Furthermore, the glycoprotein ELISA test (not commercially available) used by Merck and Co. (West Point, PA) suggests a seroconversion rate of 99% in adults, making postimmunization serologic testing not cost-effective. Decision and/or cost-effective analysis methods have been used to demonstrate that immunization of HCP susceptible to varicella is cost-effective for healthcare facilities.[280–282] The use of varicella vaccine has been demonstrated to effectively protect HCP from varicella, particularly from serious disease.[283]

There appears to be virtually no risk of transmission of the vaccine strain of virus from healthy people who do not develop a rash postimmunization. Furthermore, no transmission has been documented from vaccinated HCP.[30] However, HCP who develop a vaccine-related rash after vaccination should avoid contact with persons without evidence of immunity to varicella who are at risk for severe disease and complications until all lesions resolve (i.e., are crusted over) or, if they develop lesions that do not crust (macules and papules only), until no new lesions appear within a 24-hour period.[30]

Postexposure Management of Exposed Healthcare Personnel

All HCP potentially exposed to varicella or zoster should be evaluated as soon as feasible by the occupational health service. HCP with no history or an uncertain history (e.g., VZV infection in other family members) of varicella should be serologically tested for immunity. HCP with a positive test should be considered immune. Susceptible exposed HCP who are exposed to varicella or zoster (disseminated herpes zoster and uncovered lesions of a localized herpes zoster) are potentially infective from days 8 to 21 after exposure and should be furloughed during this period.[30] They should also receive postexposure vaccination as soon as possible. Vaccination within 3 to 5 days of exposure to rash might modify the disease if infection occurred. Vaccination more than 5 days postexposure is still indicated because it induces protection against subsequent exposures (if the current exposure did not cause infection). For HCP at risk for severe disease for whom varicella vaccination is contraindicated (e.g., pregnant or immunocompromised HCP), varicella-zoster immunoglobulin after exposure is recommended. The varicella-zoster immunoglobulin product currently used in the United States is VariZIG.[284] VariZIG should be administered as soon as possible after exposure and within 10 days. The adult dose of VariZIG is 125 U/10 kg (maximum dose: 625 U or five vials). VariZIG should be administered intramuscularly or as directed by the manufacturer. It should not be administered intravenously. VariZIG has been demonstrated to lead to attenuated disease in pregnant women and immunocompromised people but likely does not prevent congenital infection. VariZIG may prolong the incubation period before disease; hence all HCP treated with VariZIG should be removed from duty from days 8 through 28.

HCP who have received one dose of vaccine and who are exposed to varicella-zoster should receive the second dose as soon as feasible (provided 4 weeks have elapsed since the first dose). HCP should be monitored daily (days 8 to 21 postexposure) for fever, skin lesions, and systemic symptoms suggestive of varicella. HCP can be monitored by the occupational health program or infection control preventionists, or by self-monitoring, with instructions to immediately report fever, headache, constitutional symptoms, or atypical skin lesions. HCP should be excluded immediately from the healthcare facility if symptoms occur. HCP who have had two doses of varicella vaccine should also be monitored as above and

excluded from work if symptoms occur. After vaccination, the management is similar to that of two-dose vaccine recipients.

The American Academy of Pediatrics states that "if VariZIG is not available or more than 96 hours have passed since exposure, some experts recommend prophylaxis with acyclovir (20 mg/kg per dose, administered four times per day, with a maximum dose daily dose of 3200 mg) or valacyclovir (20 mg/kg per dose, administered three times per day with a maximum dose of 3000 mg) beginning 7 to 10 days after exposure."[47] The authors have successfully used acyclovir as postexposure prophylaxis beginning on day 8 postexposure and continuing to day 21 postexposure. The use of acyclovir postexposure prophylaxis in immunocompromised children has been reviewed.[285] The prophylactic use of acyclovir, however, was associated with a decreased rate of the development of varicella immunity as measured by seroconversion. For those that seroconverted, durable protection was produced. Failures of acyclovir prophylaxis have been noted.

All HCP with VZV infection should be evaluated and, after confirmation of infection, should be offered the recommended antiviral therapy, which should ideally be initiated within 72 hours of the onset of clinical infection. There are currently three drugs approved by the Food and Drug Administration for therapy of VZV in the normal adult: acyclovir, famciclovir, and valacyclovir. Although the safety of acyclovir in pregnant women has not been firmly established, adverse fetal events have not been described. The American Academy of Pediatrics states "that some experts recommend oral acyclovir or valacyclovir for pregnant women with varicella, especially during the second and third trimesters. Intravenous acyclovir is recommended for the pregnant patient with serious complications of varicella.[47] HCP who develop varicella may return to work when clinically well and after all lesions are dried and crusted (usually about 5 days).

Hepatitis B Vaccine

Epidemiology

Exposure to bloodborne pathogens via parenteral or mucosal contact remains a major hazard for HCP, especially those performing invasive procedures. Although more than 30 diseases have been transmitted to HCP by sharps injuries or mucosal exposure,[286] the agents of greatest concern are HBV, hepatitis C virus, and HIV.[27–30,287–289] Seroprevalence surveys conducted before the availability of the HBV vaccine in 1981 showed that HCP had prevalence rates of past or present HBV infection threefold to fivefold higher than the general U.S. population.[290–293] The risk of infection was related to both the extent and the duration of blood contact. The CDC predicted that, in 1989, an estimated 12,000 American HCP would become infected with HBV, which would result in 250 deaths.[294] With a decreasing incidence of hepatitis B, the CDC estimated that, in 1994, 1012 HCP became infected with HBV because of occupational exposures, leading to approximately 22 deaths.[295] In a more recent analysis, Mahoney and colleagues reported in 1997 that HBV infection among HCP declined from 17,000 in 1983 to 400 in 1995.[296] The 95% decline in incidence observed among HCP was 1.5-fold greater than the reduction in incidence in the general U.S. population. The decline among HCP was because of the use of HBV vaccine, institution of *universal* (now standard) *precautions*, and other preventive measures such as needleless devices. Hepatitis B acquisition remains a concern for unimmunized HCP because the virus is environmentally stable and has been transmitted by other routes than percutaneous injury, including paper cuts, human bites, and mucosal contamination with blood.

Lessons From Nosocomial Outbreaks

Hepatitis B acquisition represents a major hazard for HCP for several reasons. First, HCP have high rates of percutaneous blood contact. The 2011 EPINet Report from 32 hospitals noted that the percutaneous injury rate was 19.5 per 100 beds.[297] Second, the virus is relatively stable in the environment, as demonstrated by its survival after drying and storage at 25°C and 42% relative humidity for 1 week.[298] Third, HBV is more transmissible than either HIV or hepatitis C virus, with rates of disease transmission after a percutaneous injury with a contaminated sharp reported as between 6% and 30%.[299–301] The risks of disease transmission via mucosal contact or contact with nonintact skin have not been quantitated but appear to be much lower than for percutaneous exposure. HBV infection has been acquired via ocular exposure[302] and has been transmitted to multiple patients by a respiratory therapist with severe exudative dermatitis while obtaining arterial blood gases.[303] The high frequency of hepatitis B among hospital personnel who did not recall a percutaneous exposure in the era before HBV vaccine has been attributed to inapparent inoculation through mucous membranes or small breaks in the skin.[304] Fourth, a significant number of patients are infectious (i.e., HBsAg-positive), with their status unknown to the medical staff. Finally, many HCP remain unimmunized.

Transmission of hepatitis B via contaminated medical instruments and environmental surfaces is well described. Nosocomial outbreaks of HBV infection have been associated with a blood-contaminated jet gun injector,[305] an endoscope,[306] multidose medication vials,[307–310] electroencephalography electrodes,[311] finger-stick (i.e., capillary) blood-sampling devices,[312–322] and reuse of needles and syringes.[323] Contamination of instruments or medication vials resulted in 67 of 243 cardiac transplant patients developing infection during transvenous endomyocardial biopsies.[324] Environmental surfaces in clinical laboratories were demonstrated to be positive for HBsAg in 34% of samples,[325] and contaminated file cards have been reported to lead to transmission among laboratory technicians.[326]

Transmission of hepatitis B in hemodialysis centers, presumably via contaminated environmental surfaces, shared equipment, or common-dose medications, has been an ongoing problem.[327–330] The CDC has described the problem and provided guidelines for preventing HBV transmission in hemodialysis units.[331–334] Unsafe practices that have led to transmission of bloodborne pathogens to patients include: (1) use of a single syringe, with or without the same needle to administer medication to multiple patients; (2) reinsertion of a used syringe into a medication vial or solution container to obtain additional medication for a single patient and then using that vial or solution container for subsequent patients; and (3) preparation of medications in close proximity to contaminated supplies or equipment. Occult HBV infection and reactivation of HBV infection after cytotoxic chemotherapy or immunosuppressive therapy have led to transmission of HBV in hemodialysis centers. Occult HBV infection is defined as long-lasting persistence of HBV genomes in the liver (with detectable or undetectable HBV DNA in the serum) of individuals testing negative for HBV surface antigen (HBsAg).[335] The prevalence of Occult HBV infection in hemodialysis patients has been reported to vary from 0% to 54% according to the diagnostic techniques and HBV endemicity.[336]. Occult HBV infection has been a source of viral spread both to other patients and staff within hemodialysis units.[336] Similarly, reactivation of HBV infection has led to transmission in hemodialysis centers.[337,338] These causes of HBV transmission in hemodialysis centers emphasize why immunity to HBV is so important among hemodialysis patients and staff. The CDC

has noted that since the initiation of strict infection control practices and hepatitis B vaccination, the rate of hepatitis B infection among patients undergoing hemodialysis has declined approximately 95%.[65] In addition to standard precautions, the following hemodialysis-specific infection control practices should be used:

- HBsAg-positive patients should be isolated by room, machine, instruments, medications, supplies, and staff.
- Recommended cleaning and disinfection procedures should be followed.
- Instruments, medications, and supplies should not be shared between any patients. When sharing of multidose medication vials is necessary, medications must be prepared in a clean centralized area separate from areas used for patient care, laboratory work, or refuse disposal. Safe injection practices should be strictly followed.
- Serologic testing should be done for all markers of HBV infection (HBsAg, anti–hepatitis B core antigen antibody [HBc], and anti-HBsAg) on admission of new patients to a hemodialysis center.
- To prevent transmission in dialysis settings, hemodialysis patients should be vaccinated against hepatitis B using the high-dose vaccine and have their anti-HBsAg titers determined 1 to 2 months after the last immunization.
- Vaccine responders on hemodialysis should have their anti-HBsAg titer determined annually and be revaccinated when serum anti-HBsAg titers falls to less than 10 mIU/mL.[331,332]
- Vaccine nonresponders (<10 mIU/mL) should be tested monthly for HBsAg and these results promptly reviewed.

Because hemodialyzed patients have a diminished response to HBV vaccine, higher doses and booster doses are recommended to maintain protection against hepatitis B (see ACIP[65] age-based recommendations for hepatitis B immunization of predialysis and dialysis patients). The Centers for Medicare and Medicaid Services now requires that hemodialysis centers receiving Medicare payment for outpatient dialysis services adhere to CDC guidelines.[339]

More than 40 outbreaks have been described of healthcare provider–to-patient transmission of hepatitis B.[340] The source has most commonly been a dentist, surgeon, or gynecologist performing invasive procedures. The most important risk factors for transmission during an invasive procedure are a hepatitis B *e* antigen–positive source, degree of invasiveness of the procedure, lack of wearing gloves by the infected HCP, or injury to the infected HCP with a sharp object.[339] Guidelines for the management of HBV-infected HCP have been published.[341]

Preexposure Prophylaxis

Because of the risks posed by bloodborne pathogens, OSHA has mandated, since 1991, that HCP undergo annual training in the prevention of bloodborne pathogen acquisition and use of personal protective equipment (gloves, masks, gown, and eyewear) whenever exposure to blood or other potentially infectious body fluids is reasonably anticipated.[43] However, despite the OSHA regulations and the introduction of new technologies, such as needleless devices, percutaneous, mucous membrane, and skin exposures to contaminated body fluids continue to occur at a high frequency. The OSHA standard also required that all healthcare facilities offer HCP hepatitis B immunization. healthcare providers may refuse immunization but must sign a declination form.

Protective serum titers of anti-HBsAg (≥10 mIU/mL) develop in greater than 90% of healthy adults younger than 40 years of age who receive a series of three intramuscular doses of HBV vaccine.[30,342–346] After age 40 years, less than 90% of persons vaccinated with three doses have a protective antibody response, and by age 60 years, protective levels of antibody develop in approximately 75% of vaccinated persons.[30] Independent risk factors for failure to seroconvert in HCP after HBV vaccine include smoking, female gender, higher body mass index, and older age.[347] Protection against symptomatic and chronic HBV infection has been documented to persist for longer than 22 years in vaccine responders.[348] Two single-antigen hepatitis B vaccines, Recombivax HB (Merck & Co., Inc., Whitehouse Station, New Jersey) and Engerix-B (GlaxoSmithKline Biologicals, Rixensart, Belgium) and one combination hepatitis A and hepatitis B vaccine, Twinrix (GlaxoSmithKline Biologicals), are available in the United States.[30] Primary vaccination consists of three or more intramuscular doses of hepatitis B vaccine or of the combined hepatitis A and hepatitis B vaccine. The hepatitis vaccine series does not need to be restarted if the second or third dose is delayed. In adults, hepatitis B vaccine always should be administered into the deltoid muscle. Longer needles (up to 1.5 inches in length) might be required for obese adults. Administering three doses on an accelerated schedule (e.g., 0, 1, and 2 months) results in a more rapid antibody rise but may reduce peak titers.[349,350] Immunogenicity is not reduced when HBV vaccine is given with other vaccines. Pregnancy is not a contraindication to HBV vaccine. Persons with an incomplete series are not considered protected and should complete the three-dose series. Because higher risk has been reported during the professional training period, the vaccination series should be completed before trainees have contact with blood; vaccination should be offered in schools of medicine, dentistry, nursing, laboratory technology, and other allied health professions. Consideration should be given to using a 0-, 1-, and 2-month or 0-, 1-, and 4-month schedule for unimmunized HCP at high risk for HBV acquisition (e.g., hemodialysis workers, cardiac surgeons), but a fourth dose should be given at 12 months to ensure long-term protection.

To determine the need for revaccination and to guide postexposure prophylaxis, postvaccination serologic testing should be performed for all HCP at high risk for occupational percutaneous or mucosal exposure to blood or body fluids. Postvaccination serologic testing is performed 1 to 2 months after administration of the last dose of the vaccine series using a method that allows detection of the protective concentration of anti-HBsAg (≥10 mIU/mL). Persons determined to have anti-HBsAg concentrations of equal to or greater than10 mIU/mL after receipt of the primary vaccine series are considered immune, and the result should be documented. Immunocompetent persons have long-term protection and do not need further periodic testing to assess anti-HBsAg levels. Because approximately half the persons who do not develop a protective level of anti-HBsAg antibodies after a three-dose series do so after additional doses,[351] persons determined to have anti-HBsAg concentrations of less than 10 mIU/mL soon after receipt of the primary vaccine series should be revaccinated. For these persons, administration of a second complete three-dose series on an appropriate schedule, followed by anti-HBsAg testing 1 to 2 months after the third dose, usually is more practical than conducting serologic testing after each additional dose of vaccine.[30] Persons who do not have a protective concentration of anti-HBsAg (≥10 mIU/mL) after revaccination (i.e., after receiving a total of six doses) should be tested for HBsAg and anti-HBc to determine infection status. Those determined not to be infected but who have anti-HBsAg less than 10 mIU/mL (nonresponders) should be considered susceptible to HBV infection and should be counseled about precautions to prevent HBV infection and the need to obtain HBIG postexposure prophylaxis for any known or likely

exposure to HBsAg-positive blood (see Table 72.4).[30] Persons determined to be infected (anti–HBc-positive) and positive for HBsAg should be provided counseling regarding how to prevent HBV transmission to others and referred for further evaluation (e.g., HBV viral load testing), care, treatment, and other services, as appropriate.[332,340,341] Persons who are HBsAg-positive and who perform exposure-prone procedures should seek counsel from a review panel comprised of experts with a balanced perspective (e.g., personal physicians of HCP and infectious disease specialists) regarding the procedures that they can perform safely.[340,341] Persons who were infected in the past (anti–HBc-positive but negative for HBsAg) require no vaccination or treatment.

The CDC has provided guidance for the preexposure evaluation of HCP previously vaccinated with a complete equal to or greater than a three-dose hepatitis B vaccine series who did not have postvaccination testing within 1 to 2 months.[66] For such HCP, an anti-HBsAg quantitative titer should be obtained; if the anti-HBsAg is ≥10 mIU/mL, no action is required for hepatitis B prophylaxis even if in the future the HCP has an exposure to a source patient positive for HBsAg. If the anti-HBsAg is less than 10 mIU/mL then HCP should receive an additional dose of hepatitis B vaccine and have a postvaccination anti-HBsAg titer obtained; if the anti-HBsAg is equal to or greater than 10 mIU/mL, no action is required for hepatitis B prophylaxis. If the anti-HBsAg remains less than 10 mIU/mL after the first booster dose, then HCP should receive an additional two doses of hepatitis B vaccine and have a postvaccination anti-HBsAg titer obtained; if the anti-HBsAg is equal to or greater than 10 mIU/mL, no action is required for hepatitis B prophylaxis. If the anti-HBsAg is less than 10 mIU/mL, the HCP is considered a nonresponder and should be evaluated for HBIG after a bloodborne exposure.

Postexposure Prophylaxis

All HCP with potential exposure to blood or contaminated body fluids should be evaluated. Exposure is defined as parenteral, mucous membrane, or nonintact skin exposure to blood or contaminated fluids. In all cases, the source should be tested for HBsAg, hepatitis C, and HIV. If the source case is HBsAg-positive, postexposure prophylaxis may be indicated (see Table 72.4). HBIG is effective when provided within 7 days. Immunoglobulin should not be used because of lack of efficacy. The simultaneous administration of HBIG and HBV vaccine (at different sites) does not diminish the efficacy of the hepatitis B vaccine.[66]

Influenza Vaccine

Epidemiology

Epidemics of influenza occur nearly every year during the winter months. Influenza causes an estimated 226,000 hospitalizations each year and results in an average of approximately 6300 deaths (range, ≈ 5800 to 7500) because of influenza and pneumonia.[352–354] However, if we take into account influenza-associated deaths with underlying respiratory and circulatory causes, the number of annual deaths rises to approximately 23,000 (range, ≈ 22,000 to 28,000).[252] Older persons (i.e., older than 65 years of age), pregnant women, young children (i.e., younger than 2 years of age) and persons with underlying health problems (e.g., cardiovascular disease, pulmonary disease, certain metabolic conditions) are at increased risk of hospitalization and death. During influenza epidemics, the hospitalization rate for the elderly and persons with chronic health problems may increase twofold to fivefold compared with nonepidemic periods.

Influenza viruses are classified into subtypes on the basis of two surface antigens: hemagglutinin (H) and neuraminidase (N). Widespread human disease since 1977 has been caused by influenza A (H1N1 and H3N2) viruses, and influenza B. Immunity to these antigens, especially to the hemagglutinin, reduces the likelihood of infection and lessens the severity of disease if infection occurs. Infection with a virus of one subtype confers little or no protection against viruses of other subtypes. Over time, antigenic variation (antigenic drift) within a subtype may be so marked that infection or immunization with one strain may not induce immunity to more distantly related strains of the same subtype. The antigenic characteristics of circulating strains provide the basis for selecting the viral strains included in each year's vaccine. During 2009–10 there was a worldwide pandemic because of a novel influenza A H1N1 strain.[355–358]

Influenza virus appears to spread from person-to-person by small-particle aerosol transmission. Although aerosol transmission is well established, nosocomial transmission via fomites and contaminated hands is likely. Influenza virus is shed for at least 5 days beyond the onset of illness in adults, but shedding may occur for longer periods in children and immunocompromised persons. Humans are the primary reservoir of infection, but swine and avian (especially, ducks) reservoirs are likely sources of new human subtypes thought to emerge through mutation and/or genetic reassortment.

Lessons From Nosocomial Outbreaks

Nosocomial acquisition of influenza has been well described.[359–391] Nosocomial transmission most commonly occurs during community influenza outbreaks when patients infected with influenza are admitted to the hospital. Because up to 25% of unimmunized HCP may develop influenza during the winter months, however, infected staff may introduce infection into a healthcare facility.[392] Staff infected by patients have frequently served as the source for secondary transmission of influenza to patients and other staff.[361,362,367,368,381,384,387,390] Acquisition of influenza by HCP may cause absenteeism and significant disruption of in the healthcare system.[362,365,368,391]

Nosocomial outbreaks frequently have involved extended-care facilities for the elderly.[392–424] Such outbreaks may cause significant morbidity and mortality.[396,397,405,424] A metaanalysis assessed studies evaluating whether high rates of influenza immunization among HCP working with persons older than 60 years of age led to a decrease in the attack rate of influenza among patients in extended-care facilities and/or provided other benefits.[425] The metaanalysis included four cluster-randomized clinical trials and one cohort study. Pooled data from three trials demonstrated that HCP vaccination reduced influenza-like illness among the patients and reduced all-cause mortality in persons older than 60 years of age. Even though the coverage among HCP in the intervention facilities only reached approximately 60%, the metaanalysis demonstrated reduced patient mortality. Nosocomial outbreaks also have been reported in other types of long-term care facilities, such as institutions caring for mentally challenged persons.[426]

Important lessons from these outbreaks include the following. First, identification of all patients with influenza is problematic and incomplete. Furthermore, community indicators of influenza activity (e.g., visits to acute ambulatory care centers for upper respiratory illness) cannot be relied on to provide warning of influenza among hospitalized patients.[379] For example, a nosocomial outbreak has been reported during a period without influenza epidemic activity in the community.[381] Second, influenza infection among staff is common during the winter season and results in significant

absenteeism. Attack rates of 25% to 80% often are observed among both patients and staff during outbreaks. Third, high rates of immunization among residents cannot be relied upon to prevent outbreaks.[415] Recommendations have been published for prevention and control of nosocomial influenza in acute-care hospitals[61,67,68,427] and extended-care facilities.[428–432] The CDC guideline for the prevention of healthcare-associated pneumonia contains detailed recommendations for the detection and isolation of patients with known or suspected influenza, management of healthcare workers with known or suspected influenza, and use of antivirals in the management of healthcare-associated outbreaks.[427]

Preexposure Prophylaxis

Influenza vaccine is strongly recommended for any person age 6 months or older, especially those who are at increased risk for complications of influenza because of age or underlying medical condition. Persons at increased risk for influenza-related complications include those age 50 years or older; residents of extended-care facilities or long-term care facilities that house persons of any age who have chronic medical conditions; adults and children who have required regular medical follow-up or hospitalization during the previous year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression; children and teenagers (ages 6 months to 18 years) who are receiving long-term aspirin therapy and therefore may be at risk for developing Reye syndrome after influenza; and pregnant women.[67,68] In addition, influenza vaccine should be offered to persons who live with or care for persons with certain chronic medical conditions.

Influenza vaccine is also recommended for all HCP because, when they are clinically or subclinically infected, they can transmit influenza virus to people at high risk. In a recent study, Voirin and colleagues assessed the risk of influenza transmission in an acute care geriatric unit in an academic hospital by collecting high-resolution contact data via wearable sensors combined with virological data.[433] Voirin and associates documented three patient- and one nurse-acquired laboratory-confirmed influenza cases and concluded that infectious medical doctors and nurses are potential sources of hospital-acquired influenza for patients. In addition, infectious patients were identified as likely sources for nurses. The CDC specifically recommends immunization for the following HCP: physicians, nurses, and other personnel in both hospital and outpatient care settings; HCP of nursing homes and long-term care facilities who have contact with patients or residents; and providers of home care to persons at high risk (e.g., visiting nurses and volunteer workers).[30] The American Academy of Pediatrics,[56] the Association for Professionals in Infection Control and Epidemiology,[57] the Infectious Diseases Society of America,[58] the American College of Physicians,[59] and the Society of Healthcare Epidemiologists of America,[60] not only specifically endorse this recommendation, but also state that annual influenza immunization should be mandatory for all HCP. Current influenza vaccines may be trivalent (i.e., two A strains and one B strain) or quadrivalent (two A strains and two B strains). In modeling studies quadrivalent vaccines have been demonstrated to prevent an additional 18% to 21% of cases from influenza B strains.[434] Multiple types of influenza vaccine are available including inactivated influenza vaccine (IIV3 or IIV4) that can be administered intramuscularly or intradermally, a cell-culture based IIV (ccIIV3), a high-dose IIV, a recombinant influenza vaccine (RIIV3), and a live attenuated influenza vaccine (LAIV4). HCP providing influenza vaccines should be aware of current age restrictions for each specific vaccine, and whether the vaccine contains thimerosal and/or latex. Although the administration of thimerosal in vaccines has not been demonstrated to result in patient harm, some patients (especially pregnant women) remain concerned about receiving vaccine containing this preservative. Administration of vaccines whose vial or syringe contain latex could precipitate anaphylaxis in persons with latex allergies. Both thimerosal and latex-free influenza vaccines are available. RIIV3 is the only vaccine that is completely free of egg proteins. The CDC does not list any vaccine as being preferential. Importantly, HCP should not receive the attenuated live influenza virus vaccine if they have close contact with severely immunosuppressed persons (e.g., patients with hematopoietic stem cell transplants) during those periods in which the immunosuppressed person requires care in a protective environment.[30] If they receive the vaccine, they should refrain from contact with severely immunosuppressed patients for 7 days after vaccine receipt. An inactivated trivalent vaccine containing 60 μg of hemagglutinin antigen per influenza vaccine virus strain is an alternative inactivated vaccine for persons 65 years of age and older.

Chemoprophylaxis with an antiviral drug (amantadine, rimantadine, zanamivir, oseltamivir) has been used as both seasonal preexposure and postexposure prophylaxis to reduce the likelihood of developing influenza A (amantadine, rimantadine) or influenza A and B (zanamivir, oseltamivir) infection. Amantadine and rimantadine are no longer recommended for either prophylaxis or treatment of viral influenza because of a dramatic increase in resistance that was noted in 2005 to 2006.[435] Specific recommendations for the use of oseltamivir or zanamivir for chemoprophylaxis or treatment of influenza have been published.[435,436] Oseltamivir has been used successfully to provide chemoprophylaxis in extended-care facilities.[412,413,415,417,418] Fewer data are available regarding the use of zanamivir.[411] Zanamivir is associated with bronchospasm, and oseltamivir is associated with gastrointestinal upset. Use of antiviral agents for chemoprophylaxis or treatment of influenza is an adjunct (but not a substitute for) vaccination.

Despite these recommendations, many HCP still choose not to receive the influenza vaccine.[112,113,120,437–448] The knowledge and attitudes of HCP to influenza immunization have been reviewed.[449,450] Institutions should consider introducing innovative methods, such as provision by mobile carts on hospital wards, off-hours clinics, feedback on immunization rates to unit nursing and medical directors, and offering vaccine to medical personnel in clinics and conferences.[451] Only making continued employment conditional on influenza immunization (unless there is a medical contraindication) has succeeded in achieving high rates of influenza vaccine coverage among HCP. The ethics of "mandatory" influenza immunization have been discussed.[57–61] The Society for Healthcare Epidemiology of America has recommended the following methods of improving influenza vaccine coverage of healthcare workers.[451]

- Off-hours clinics
- Use of mobile vaccination carts
- Vaccination at staff and departmental meetings
- Provision of adequate staff and resources
- Provision of vaccine free of charge to HCP
- Targeted education, including specific information to dispel vaccine myths
- Use of live attenuated influenza vaccine for eligible HCP
- Strong and visible administrative leadership
- Visible vaccination of key leaders
- Accurate tracking of individual and unit-based compliance of HCP with vaccination
- Surveillance for healthcare-associated influenza

Postexposure Prophylaxis

During community or nosocomial outbreaks, healthcare institutions should offer and strongly encourage the use of influenza vaccine among HCP. If influenza is causing a community outbreak, consideration should be given to providing chemoprophylaxis for 2 weeks to newly immunized HCP (avoid live attenuated influenza vaccine in such cases) who are at high risk of exposure to infected patients. Prophylaxis should be considered for all HCP, regardless of immunization status, if the outbreak is caused by a variant strain of influenza that might not be controlled by the vaccine. Using antiviral drugs for treatment and chemoprophylaxis of influenza is a key component of influenza outbreak control in institutions.[435,436] When confirmed or suspected outbreaks of influenza occur in healthcare facilities, appropriate chemoprophylaxis should be started as early as possible to reduce the spread of virus. Chemoprophylaxis should be continued until approximately 1 week after the end of the outbreak. Of importance, antivirals are most effective in reducing the severity and shortening the duration of influenza illness among healthy adults when administered within 48 hours of illness onset.

Pertussis Vaccine

Epidemiology

In the United States, the highest recorded annual incidence of pertussis occurred in 1934, when more than 260,000 cases were reported.[452] After the introduction of diphtheria, tetanus, and whole-cell pertussis vaccine, the incidence declined by more than 99%. However, throughout the 1980s and 1990s, the incidence of pertussis increased, peaking in 2004 (8.9 per 100,000 population). Subsequent to this peak, the incidence declined, but is increasing again (8.97 per 100,000 population in 2010, 6.06 per 100,000 population in 2011, and 15.49 per 100,000 population in 2012). The 48,277 reported cases in 2012 is the highest number of cases reported in the United States since 1955 when 62,786 cases were reported. Provisional data for more recent years were as follows: 28,639 cases reported in 2013 and 27,878 cases reported in 2014. The number of cases as reported by the CDC is clearly an underestimate of the true incidence of pertussis as many persons, especially adults with mild disease, are not reported to public health authorities. Infants younger than 6 months of age are at the greatest risk for severe disease and death, and continue to have the highest reported rate of pertussis (124.93 per 100,000 infants younger than 6 months of age). However, children (5 to 14 years of age) accounted for approximately 45% of reported cases in 2012. Since the introduction of the Tdap vaccine for adolescents and adults in 2005, coverage among persons 13 to 17 years of age has dramatically increased, and was approximately 85% in 2014. Most cases occur in adolescents and young adults. Possible explanations for this increase in disease include (a) genetic changes in *B. pertussis*, making vaccine less effective; (b) waning immunity among children, adolescents, and adults vaccinated during childhood, especially those who received acellular pertussis vaccines; (c) lessened effectiveness of acellular pertussis vaccines compared to whole-cell vaccines; (d) greater awareness of pertussis and hence more diagnostic testing; and (e) the general availability of better laboratory tests.[453] Waning immunity after diphtheria, tetanus, acellular pertussis (DTaP) vaccine appears to be the most important reason for the increases in pertussis.[453]

Adolescents and young adults play an important role in transmitting pertussis to susceptible infants because immunization-induced immunity to pertussis wanes with increasing age and because disease in adults frequently is not diagnosed or treated because it is often mild or atypical. Studies using serologic methods have demonstrated that *B. pertussis* is a common cause of respiratory illness, causing cough in adults.[453–455]

Lessons From Nosocomial Outbreaks

At the University of North Carolina Hospitals, pertussis is now the most common source of infectious disease exposure evaluations (Weber, unpublished data, 1994 to 2015). Multiple nosocomial outbreaks have been reported in the literature.[456–485] These most often have involved residential facilities for the mentally or physically impaired or pediatric wards of acute-care hospitals. Although the source case most commonly was an infected patient in whom pertussis was unrecognized,[456,457,461,466,481] infected HCP[459,462,465,468,470,471,481,484] and the infected mother of a child with pertussis[458] also served as sources. HCP often served as vectors for additional nosocomial cases.[456,457,459,462] In several instances, infected HCP also infected members of their households.[457,459,480] Nosocomial outbreaks have occurred for several reasons: (a) failure to recognize and appropriately isolate infected patients, (b) failure to provide antibiotic prophylaxis to exposed staff, and (c) failure to furlough symptomatic staff.[486,487]

Preexposure Prophylaxis

With the licensure of a Tdap for adolescents and adults in 2005, it is now possible to provide preexposure prophylaxis to HCP. The CDC recommends that regardless of age, HCP should receive a single dose of Tdap if they have not previously received Tdap and regardless of the time since their most recent diphtheria and tetanus toxoids (Td) vaccination.[30] The CDC also recommends against HCP receiving any additional Tdap boosters.[488] Importantly, prevaccination serologic testing is not recommended and immunity cannot be demonstrated through serologic testing because serologic correlates of protection are not well established.[30] Hospitals and ambulatory-care facilities should provide Tdap for HCP and use approaches that maximize vaccination rates (e.g., education about the benefits of vaccination, convenient access, and the provision of Tdap at no charge). The benefits of immunizing HCP with Tdap have been reviewed.[488,489]

Postexposure Prophylaxis

B. pertussis is highly susceptible in vitro to erythromycin[490,491] and the newer macrolides, azithromycin, and clarithromycin.[492] It is also susceptible to trimethoprim-sulfamethoxazole.[491] *B. pertussis* is not susceptible to the first-generation cephalosporins. Erythromycin has been shown to decrease the duration of illness when administered early in the course of pertussis and to eliminate *B. pertussis* from the nasopharynx. Erythromycin also has been successfully used to provide chemoprophylaxis to individuals exposed to *B. pertussis* and to aid in preventing secondary spread in households or terminating outbreaks in institutions.[493–495] Azithromycin has been demonstrated to be effective in the prophylaxis and treatment of pertussis.[496] It is now the preferred agent because, compared with erythromycin, it requires a short period of postexposure prophylaxis or therapy (5 vs 7 to 14 days), reduced dosing frequency (one vs four times per day), and is less likely to result in gastrointestinal distress.[496] Trimethoprim-sulfamethoxazole is the recommended alternative for treatment and for chemoprophylaxis of individuals intolerant to a macrolide, although its efficacy as a chemoprophylactic agent has not been evaluated. The evidence of trimethoprim-sulfamethoxazole's efficacy is based on small studies.[497,498]

Erythromycin-resistant clinical isolates of *B. pertussis* have been reported, raising concern about the use of macrolides for therapy or prophylaxis.[499–501] However, surveys of *B. pertussis* strains demonstrate that macrolide resistance is uncommon.[502–504] Immunization of HCP with Tdap vaccine has been used along with chemoprophylaxis to control nosocomial outbreaks.[480]

Data on the need for postexposure prophylaxis in Tdap-vaccinated HCP are inconclusive.[505] Certain vaccinated HCP are still at risk for acquisition of *B. pertussis*. Therefore, Tdap might not preclude the need for postexposure prophylaxis. Postexposure antimicrobial prophylaxis is recommended for all HCP regardless of Tdap status who have unprotected exposure to pertussis and are likely to expose a patient at risk for severe pertussis (e.g., hospitalized neonates and pregnant women). Other HCP regardless of Tdap status should either receive postexposure antimicrobial prophylaxis or be monitored daily for 21 days after pertussis exposure and treated at the onset of signs and symptoms of pertussis.

CONCLUSIONS

All susceptible HCP, unless they have a contraindication to immunization, should be immunized against mumps, measles, rubella, varicella, and pertussis. If HCP have the potential for exposure to blood or contaminated fluids, they should be immunized against hepatitis B. In addition, HCP should be immunized against influenza annually. HCP also should be referred for vaccines recommended for the general public. Selected HCP may be candidates for other available vaccines, including hepatitis A, meningococcal, anthrax, polio, plague, typhoid, vaccinia, and rabies.

SECTION 5

Public Health and Regulatory Issues

73 Immunization in the United States

Amanda Cohn, Lance E. Rodewald, Walter A. Orenstein, and Anne Schuchat

A strong immunization program is critical to ensure vaccines are given at the recommended ages to all children, adolescents, and adults in the United States. The immunization system in the United States is a public- and private-sector partnership, including federal agencies, state and local health departments, healthcare providers, and vaccine manufacturers, that works toward common immunization goals and objectives. The U.S. immunization system has a formal process of establishing national immunization recommendations and uses a set of systems to monitor the health impact, coverage levels, and safety of recommended vaccines. As of 2017, routine immunizations protected the U.S. public against 17 vaccine-preventable diseases. Vaccine access is provided through private and public health insurance for all ages, and financially vulnerable children have a federal government entitlement to vaccines through the Vaccines for Children (VFC) program.

Immunization of young children in the United States has been highly effective. Most vaccine-preventable diseases of children are at record or near record lows in the United States with small or no disparities by race and ethnicity.[1] Measles, rubella, and polio have been, and remain, eliminated in the United States, and the number of young children not immunized at all remains less than 1%. Immunization of adolescents has improved substantially but lags for selected recommended vaccines (e.g., human papillomavirus [HPV]).[2] Immunization of adults continues to be a growing challenge in the United States as vaccination coverage for both older and new vaccines, such as zoster, tetanus toxoid, diphtheria toxoid, and acellular pertussis vaccine (Tdap), and HPV vaccines, is still low, while new vaccines, such as pneumococcal conjugate vaccine, are being introduced.

IMMUNIZATION RECOMMENDATIONS

Vaccines for routine immunization in the United States must be licensed prior to recommendations. The sole authority for licensing vaccines in the United States is the Food and Drug Administration (FDA), which has responsibility for ensuring the safety and efficacy of vaccines before licensure (see Chapter 81). The FDA approves vaccines for specific indications, age groups, dose amounts and schedules, and contraindications and precautions. Information about the safety and efficacy of administering a specific vaccine simultaneously with other vaccines may be obtained before or after licensure of that vaccine, but information about the safety and efficacy of combining several vaccines into one formulation must be obtained before combination vaccines are licensed.

Technical recommendations for the use of vaccines are made by the U.S. Centers for Disease Control and Prevention (CDC) with advice from its Advisory Committee on Immunization Practices (ACIP). The ACIP was chartered in 1964, and members are 15 experts in immunization and related fields selected by the Secretary of the U.S. Department of Health and Human Services to provide advice and guidance on control of vaccine-preventable diseases.[3] In its role as a federal advisory committee, the ACIP develops written recommendations, subject to approval of the CDC director, for administration of FDA-licensed vaccines to children, adolescents, and adults in the U.S. civilian population. The ACIP works closely with several liaison organizations, including the American Academy of Pediatrics, the American Academy of Family Physicians, the American College of Physicians, and the American College of Obstetricians and Gynecologists, to harmonize immunization recommendations among key professional medical organizations in the United States.[4,5] ACIP meetings are conducted three times a year and are open to the public and the media, invite public comment, and are webcast live. Presentations at ACIP are considered in the public domain and are available at the CDC's ACIP website[6] soon after the meeting. Comprehensive descriptions of the structure, role, and procedures of the ACIP are also available in the peer-reviewed literature.[5]

The ACIP is charged to conduct its work in an objective manner, and decisions are to be made without regard for budgetary implications (VFC Statement of Managers[7]). The ACIP recommends vaccines, ages of vaccination, number of doses and dosing interval, and precautions and contraindications for vaccination (Table 73.1). The ACIP considers a careful review of available scientific data, including the epidemiology of the disease in the general U.S. population and in specific risk groups; the licensed indications, safety, efficacy, and cost-effectiveness of the vaccine; and programmatic concerns and related factors. Selection of the age at which a vaccine should be administered depends on the ability of the vaccinee to respond to the vaccine, the risk of exposure to disease, and the age-specific incidence of disease and its complications.[8,9] In general, the approach has been to administer vaccine at the earliest possible age at which the vaccine is reliably effective and has sufficient duration of immunity to protect vaccinees through ages of peak disease risk or until a booster dose is recommended.

In 2010, the ACIP adopted the Grading of Recommendations, Assessment, Development and Evaluation (GRADE) framework for developing evidence-based recommendations.[10,11] In the GRADE framework, key factors include the balance of benefits and harms, type of evidence, values and preferences of the people affected, and economic analyses. Category A recommendations apply for all persons in an age group or for all persons in a risk-factor-based group. Category B recommendations direct individualized clinical decision making; category B recommendations may not apply to all members of an age- or risk-factor-based subgroup of the population, but in the context of a clinician-patient interaction, vaccination may be found to be appropriate for a person.

TABLE 73.1 Selected Major Immunization Policy Decisions, U.S. Advisory Committee on Immunization Practices: 2005–15

New Vaccine/Recommendation	ACIP Vote
Meningococcal A/C/Y/W-135 conjugate (adolescents)	February 2005
Tetanus, diphtheria, and pertussis (Tdap) (adolescents)	June 2005
Measles-mumps-rubella-varicella (MMRV), universal hepatitis A	October 2005
Rotavirus (infants)	February 2006
Quadrivalent human papillomavirus (4vHPV) (adolescent girls); varicella second dose	June 2006
Zoster (shingles)	October 2006
Influenza (universal >6 months), PCV13 children	February 2010
Meningococcal A/C/Y/W-135 conjugate second dose	October 2010
Tdap in every pregnancy	October 2012
Pneumococcal conjugate vaccine (PCV13) in persons age ≥65 years	August 2014
2-dose human papillomavirus for younger adolescents	October 2016
Meningococcal serogroup B (MenB) (adolescents, category B)	June 2015

Evidence tables are used to summarize the benefits and harms and the strengths and limitations of the body of evidence. The ACIP does not have predetermined economic valuation criteria for recommending a vaccine. The CDC provides guidance on the allowable methods for health economic studies presented to the ACIP.[12,13]

Recommendations for the use of a vaccine depend on the balance of benefits of vaccination, duration of protection, risks of disease, and risks of vaccination. This balance must be assessed periodically and when new information is available. As experience is gained with a particular vaccine, recommendations may need to be modified. Examples of modification of recommendations include transitioning from oral poliovirus vaccine to inactivated poliovirus vaccine to eliminate the risk of vaccine-acquired paralytic polio,[14] adding a second dose of varicella vaccine in the face of evidence of limited immunity after one dose of varicella vaccine,[15] withdrawing a recommendation for the rhesus rotavirus vaccine owing to evidence that this particular rotavirus vaccine caused intussusception,[16] adding a second dose of meningococcal conjugate vaccine after evidence of waning immunity,[17] and adjusting Tdap recommendations for women from the postpartum period to the third trimester of each pregnancy.[18]

ACIP recommendations are summarized in two separate immunization schedules: one for children 0 through 18 years of age, and the second for adults (19 years of age and older). There is also a catch-up schedule for children who are not appropriately immunized for their age. There are two adult immunization schedules, one based on age and the other based on underlying conditions. The most current immunization schedules are available from the CDC in a variety of formats.[19] The schedules are updated annually and published at the beginning of each year in the CDC's *Morbidity and Mortality Weekly Report* and in major medical journals, including *Pediatrics*, *Annals of Internal Medicine*, and *American Family Physician*. The schedules provide information for clinicians on routinely recommended vaccines and risk-group recommended vaccines with category A and category B recommendations. The CDC also publishes general recommendations that supplement the schedules with information about vaccination technique and storage and handling of vaccines.[20] Updates to these general recommendations can be found at the CDC website.[21] Vaccines recommended solely for international travel are not included in these schedules, but information on vaccines for travelers is available at the CDC.[22]

Fig. 73.1 shows recommended immunizations for children and adolescents, and Fig. 73.2 shows recommended immunizations for adults as of 2017. The United States currently protects children against 16 infectious diseases, and adults older than age 60 years are additionally protected against zoster. Full protection during the first 18 years of age requires more than 50 doses of vaccines, although combination vaccines can reduce the number of injections needed and may lead to higher coverage rates.[23,24] Lessons learned from making and implementing vaccine recommendations in the United States have been reviewed.[3,25]

Policy immunization recommendations are made by the Department of Health and Human Services' National Vaccine Advisory Committee (NVAC), which was established in 1986 by the National Childhood Vaccine Injury Act to focus on programmatic policies and strategies. Some important NVAC reports have focused on vaccination financing, vaccine supply, standards for immunization practices, the status of vaccine research, and a blueprint for immunization programs.[26–30]

U.S. IMMUNIZATION PROGRAM

History

In the United States, immunizations are provided through the private and public sectors. The public sector consists primarily of health departments, but also includes other clinics, such as community and migrant health centers and public hospital–based clinics supported by public funds. There was no federal support specifically for immunization activities until 1955, when inactivated polio vaccine was licensed. Through the Polio Vaccination Assistance Act, Congress appropriated funds in 1955 and 1956 to the Communicable Disease Center (now the CDC) to help states and local communities purchase and administer vaccine.

In 1962, President John F. Kennedy signed into law the Vaccination Assistance Act. The central thrust of this legislation was to allow the CDC to support mass immunization campaigns and to initiate maintenance programs. The first grants, authorized under Section 317 of the Public Health Service Act, were made in June 1963. During the more than 50 years since the Vaccination Assistance Act was signed into law, this grant program has thrived. There are now 64 grantees under what has become known as the "317" Immunization Grant Program, including all 50 states, six large cities (including the District of Columbia), and eight territories and former territories.[30] The level of grant funding has varied greatly over the years. When the grant program began in 1963, the only vaccines available were diphtheria and tetanus toxoids and whole-cell pertussis (DTP), polio, and smallpox. In 1966, a national effort to eradicate measles began.[31] The focus on measles vaccine administration ultimately led to adoption of many critical components of the program that have had impact on multiple vaccine-preventable diseases[32] and funding has since expanded to support the infrastructure underpinning the addition of new vaccines to the immunization schedule, as outlined in the NVAC report "Protecting the Public's Health: Critical Functions of the Section 317 Immunization Program."[30]

In the early 1970s, immunization programs around the country were in varying states of effectiveness. In 1977, a

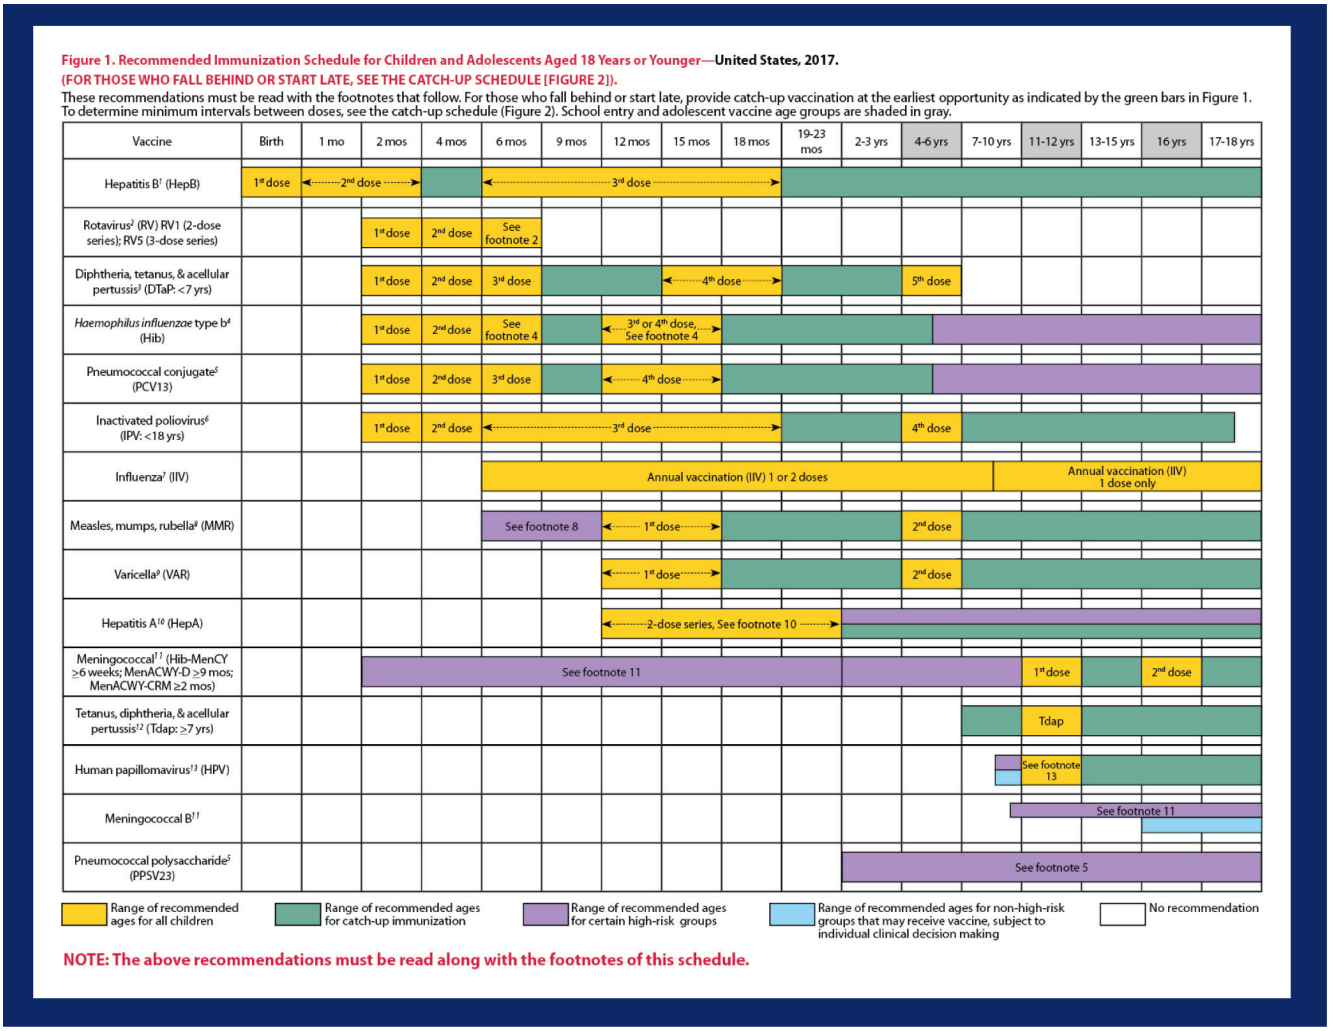

Figure 73.1. 2017 immunization schedule for birth through 18 years of age. Footnotes for each vaccine are not shown in the figure, but can be found at https://www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html.

national childhood immunization initiative was announced with two goals: attainment of immunization levels of 90% in the nation's children by October 1979 and establishment of a permanent system to provide comprehensive immunization services to the 3 million children born annually in the United States at that time.[33] (For comparison, the current U.S. birth cohort is 4.3 million.) At the time, it was estimated that nearly 20 million U.S. children were in need of at least one dose of a vaccine to be fully immunized. The poor and minority populations were disproportionately represented among the persons needing additional vaccine doses. Efforts were expended to enact school immunization requirements in states that did not have them and to enforce those already in existence. As a result of these efforts, all 50 states soon had, and were enforcing, school-entry immunization laws. Since 1981, 95% or more of children entering school have had documented immunizations. Given these levels, even with lower levels in preschoolers, the overall immunization level in children of all ages in this country was 90% or greater. Thus, the first goal of the initiative was met.

Unfortunately, the second goal of the 1977 initiative was not met. Although the overall level of support for immunization grants rose rapidly in the late 1970s and throughout the 1980s (reaching US$126.8 million in 1989), almost all the increase was to meet the increasing cost of vaccines or the addition of new vaccines or additional doses of existing vaccines. In the 1980s, the level of federal support to grantees to carry out maintenance elements did not increase significantly. Over the years, the federal government provided more existing and new vaccines within a delivery system that had remained static in the face of increasing demands. Investigations of the measles epidemics of 1989 to 1991, which especially affected unvaccinated preschool children, made it clear that the public sector delivery system was inadequate for the challenge and that it required substantial assistance.

Part of the problem was that immunization grant funds were only permitted to be used to purchase vaccines and to carry out surveillance, investigation, education, and coordination, but not to support vaccine delivery (e.g., salaries of nurses, clinic supplies, expenses associated with increasing clinic hours). In 1991, President George H.W. Bush announced the federal government's support to accomplish a major health goal—to raise immunization levels by the year 2000 so that 90% or more of the nation's children routinely completed their basic series of vaccinations by their second birthday. The President announced that model

immunization plans would be developed in several areas of the country as a beginning for the national effort to ensure adequate and timely immunization of infants and young children.[34] This began a process that ultimately resulted in the preparation of immunization action plans by all 50 states and 28 metropolitan areas. Although there was great variation in the reported needs around the country, one theme was common to most plans and that was to increase the availability of immunization services. Consequently, for the first time, federal immunization grant funds were allowed to be used for the actual provision of immunization services.

President Bill Clinton's announcement of the Childhood Immunization Initiative in 1993 and the leadership and infusion of funds associated with that initiative, coupled with the VFC program that followed, have brought the United States to the point that it is now, finally achieving 90% coverage in most vaccines recommended for preschool children.[35–37] A critical part of the Childhood Immunization Initiative was to eliminate financial barriers to vaccination and ensure children could be vaccinated at their site of usual care ("medical home"), typically a private provider's office.[38] The Childhood Immunization Initiative also established the National Immunization Survey (NIS) to assess vaccination coverage levels among young children. During the measles resurgence of 1989–91, there was no national mechanism to assess vaccination coverage. NIS was designed to estimate national, state, and selected local area coverage levels of children, 19 to 35 months of age. NIS has been in continuous operation since its establishment in 1994.

Following successful achievement of the 1996 Childhood Immunization Initiative goals, funding for the Section 317 program declined. Concerned about the adequacy of immunization infrastructure in the United States, Congress requested that the Institute of Medicine (IOM) conduct a study on the level of need for federal infrastructure support. The IOM recognized the damaging impact that the ebb and flow of infrastructure funding was having on the nation's immunization system and recommended a combined, 5-year investment of US$1.5 billion, shared between both federal and state resources. Between the publication of the IOM's 2000 report, "Calling the Shots," and 2010, federal infrastructure funding was increased by US$115 million to US$239 million.[39] Colgrove reviewed the history of two critical components of U.S. immunization efforts—public financing and immunization mandates.[40]

Figures 1 and 2 should be read with the footnotes that contain important general information and considerations for special populations.

Figure 1. Recommended immunization schedule for adults aged 19 years or older by age group, United States, 2017

Vaccine	19–21 years	22–26 years	27–59 years	60–64 years	≥ 65 years
Influenza[1]	1 dose annually				
Td/Tdap[2]	Substitute Tdap for Td once, then Td booster every 10 yrs				
MMR[3]	1 or 2 doses depending on indication				
VAR[4]	2 doses				
HZV[5]				1 dose	
HPV–Female[6]	3 doses				
HPV–Male[6]	3 doses				
PCV13[7]	1 dose				
PPSV23[7]	1 or 2 doses depending on indication				1 dose
HepA[8]	2 or 3 doses depending on vaccine				
HepB[9]	3 doses				
MenACWY or MPSV4[10]	1 or more doses depending on indication				
MenB[10]	2 or 3 doses depending on vaccine				
Hib[11]	1 or 3 doses depending on indication				

Recommended for adults who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection

Recommended for adults with additional medical conditions or other indications

No recommendation

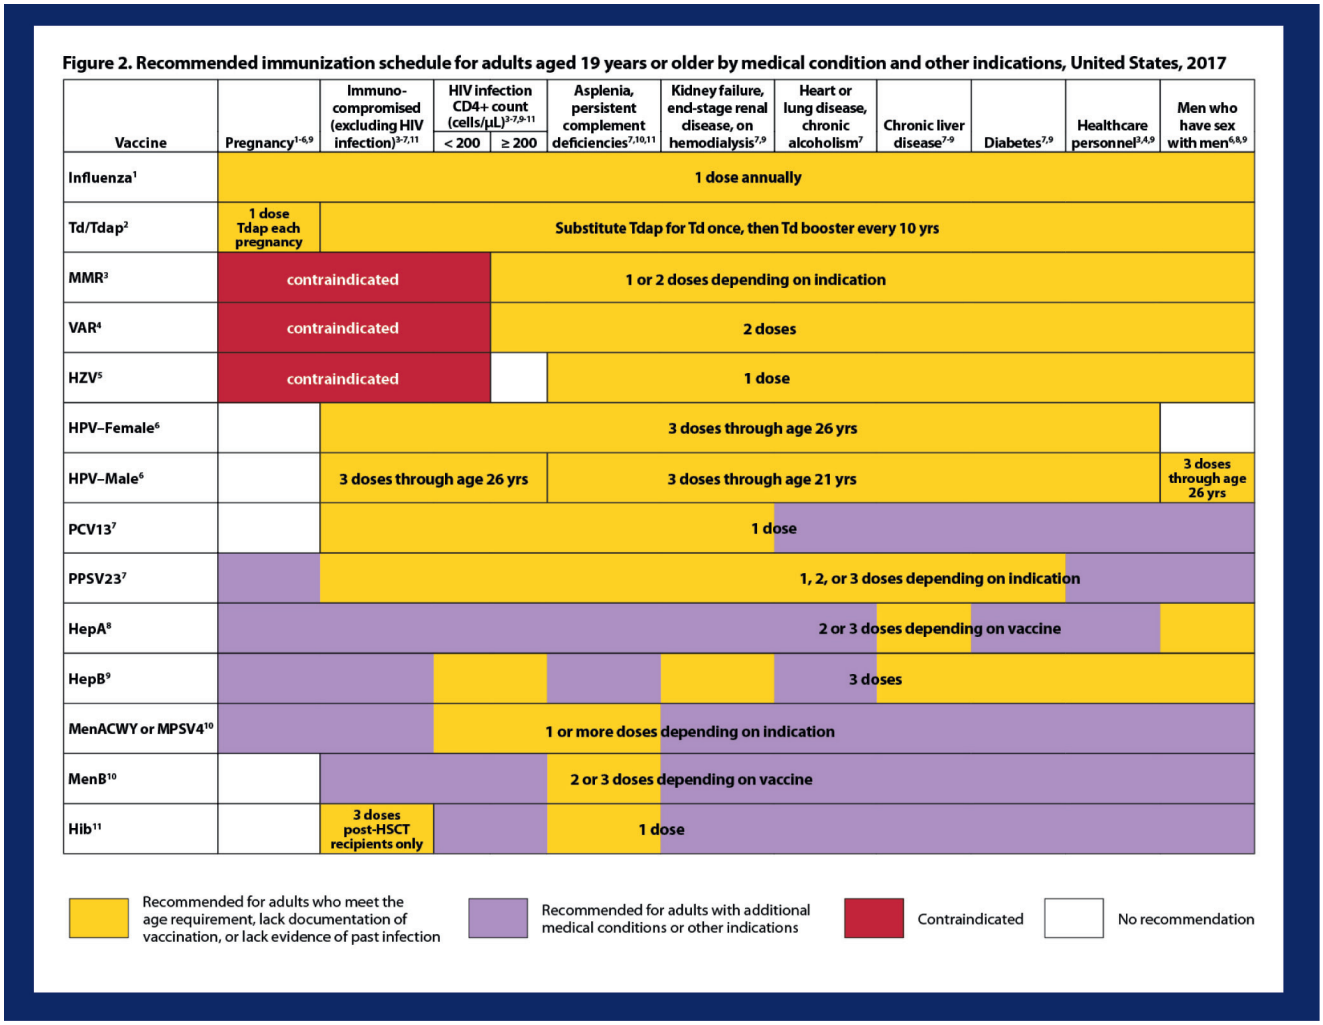

Figure 73.2, cont'd

Three major pieces of legislation have helped solidify the success of the U.S. immunization program: the National Childhood Vaccine Injury Act, the VFC program, and the Patient Protection and Affordable Care Act (ACA). Their role in vaccine successes are summarized below. In 1986, the National Childhood Vaccine Injury Act was enacted, which put in place a no-fault compensation program for persons who had been injured after receipt of a vaccine that was universally recommended for children (no matter the age of the recipient). This reduced the threat of liability for vaccine manufacturers and facilitated the availability of vaccines. The VFC program was created by the Omnibus Budget Reconciliation Act of 1993 and first implemented in 1994. The VFC program entitles eligible children 0 to 18 years of age to receive all ACIP recommended vaccines free of charge. The ACA was passed in 2010 and requires private insurers to cover all vaccines as indicated on the pediatric and adult immunization schedules. A comprehensive review of the *Morbidity and Mortality Weekly Report (MMWR)*'s documentation of the U.S. immunization program has been published.[41]

ROLES OF THE U.S. IMMUNIZATION PROGRAM

The IOM "Calling the Shots" report provided a useful conceptual framework for understanding the complex array of roles of the federal, state, and local immunization programs in collaboration with the nation's healthcare delivery system. The IOM identified five key functions in vaccine implementation: (a) assure purchase of vaccine, (b) assure service delivery, (c) control and prevent infectious diseases and measure disease burden, (d) conduct surveillance of vaccine coverage and safety, and (e) sustain and improve immunization coverage levels.[39] These functions are all needed to ensure the ultimate immunization program goal of controlling and preventing infectious diseases. The impact of immunization policies and practices is assessed through careful disease surveillance, vaccine effectiveness studies, and safety monitoring—an evidence base that is used to adjust immunization recommendations as new evidence emerges. All these activities are supported by a base of immunization finance policies and practices and through the work of health departments and other public sector agencies.

Assuring Vaccine Purchase, Supply, and Distribution

Except for a small amount of diphtheria and tetanus toxoids vaccine, all U.S. vaccines for routine use are manufactured by private sector pharmaceutical companies, with some produced by several companies and others by a single manufacturer.

Manufacturers are the sole decision makers for which vaccines they will develop and bring to the U.S. market, including new vaccines and combinations of existing vaccines.[42] However, the National Vaccine Plan of the U.S. Department of Health and Human Services proposes a government role to encourage the development of vaccines specific to U.S. public health needs.[43] One goal of the National Vaccine Plan is "to create an evidence-based list of new vaccine targets to prevent infectious diseases that are high priorities for development." The IOM, with support from National Vaccine Program Office, developed a new vaccine decision-support tool called the Strategic Multi-Attribute Ranking Tool for Vaccines, or SMART Vaccines tool. National Vaccine Program Office is developing strategies to ensure this multistakeholder decision support tool is useful and available for the public.[44]

Approximately half of the childhood vaccine supply is purchased with federal and state government funding using the CDC's vaccine contracts. These contracts allow state and local immunization programs to obtain vaccines at reduced prices and without having to negotiate separate contracts with the vaccine manufacturers. Current CDC contract prices and comparative private sector catalog prices are available from the CDC.[45] Fig. 73.3 shows the CDC vaccine contract cost to fully vaccinate a child at three points in time. The current policy allows multiple manufacturers to contract for any of the program vaccines. States and local immunization programs are allowed to select which of the vaccines they will use if there is more than one manufacturer for a given vaccine. In turn, states generally permit their providers to select which vaccines they will use to vaccinate program-eligible persons. Vaccine purchased using the CDC contracts is not allowed to be resold, and parents cannot be charged for the cost of CDC-contracted vaccine, although a state-determined administration fee can be charged to parents who can afford this fee. Approximately 90% of vaccine funding is provided by the federal VFC entitlement program, with state/local funding and the federal Section 317 funding making up the remainder. State and local immunization programs are provided a credit line of federal vaccine purchase funding that is awarded through population-based formulas for VFC and Section 317 vaccine.

The management of public-sector vaccine is accomplished with a comprehensive information technology system called VTrckS, for "Vaccine Tracking System." Public sector vaccine is delivered by a CDC-contracted distributor directly to more than 40,000 end-user immunization providers. The providers can order vaccine through VTrckS or through their state's immunization information system that, in turn, places the orders into VTrckS. State and local immunization programs have oversight and control of the vaccine orders placed by providers, and they can also enter the vaccine orders on behalf of their providers. VTrckS and its interfaces to manufacturers, the CDC-funded distributors, and state and local immunization programs now provide a unified, seamless system with complete visibility of all segments of the system. Information about VTrckS and centralized vaccine distribution is available from the CDC.[46]

The CDC maintains stockpiles of childhood vaccine that are intended to serve as a buffer against short- and medium-term vaccine supply disruptions and to control outbreaks of vaccine-preventable diseases.[47] The stockpiles are maintained as storage and rotation inventories of vaccine so that the vaccine that enters the stockpile is used before its expiration. All the vaccines that are routinely recommended for children and are included in the VFC program are included in the stockpiles. The stockpiles include a 6-month supply of each of the CDC-contracted pediatric vaccines purchased through the public sector. Because shortages of vaccine and outbreaks of vaccine-preventable diseases span private and public sectors, the stockpile also supports the private sector vaccine supply system by allowing vaccine manufacturers to borrow vaccine

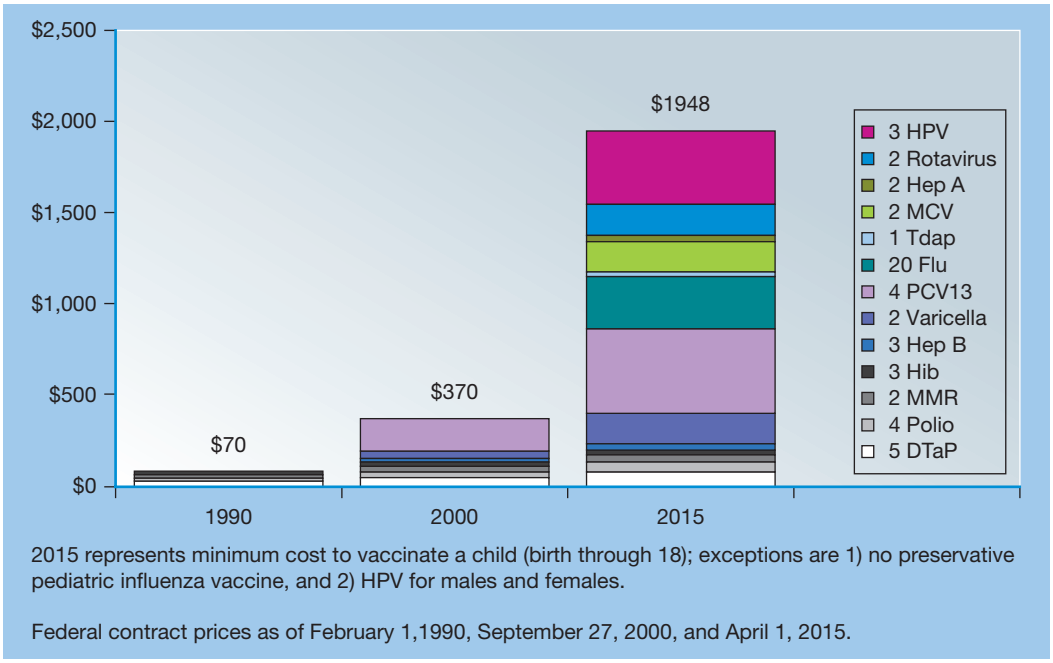

Figure 73.3. Sums of the prices of the Centers for Disease Control and Prevention (CDC) contract prices for vaccines needed to fully vaccinate a child from birth through 18 years of age. The vaccine contract prices are from February 1, 1990, September 27, 2000, and April 1, 2015. DTaP, diphtheria, pertussis, and acellular pertussis; Hep A, hepatitis A; Hep B, hepatitis B; Hib, *Haemophilus influenzae* type b; HPV, human papillomavirus; MCV, meningococcal conjugate vaccine; MMR, measles, mumps, rubella; PCV, pneumococcal conjugate vaccine; Tdap, adolescent-adult formulation tetanus, diphtheria, and acellular pertussis vaccine.

from the stockpile to sell to their private customers. Because the public sector purchases half of the childhood vaccines, CDC's stockpiles can manage a complete vaccine supply disruption of at least 3 month's duration or longer if disruptions are incomplete (e.g., a vaccine with more than one manufacturer).

Assuring an uninterrupted supply of vaccine is especially challenging during manufacturing production problems. A staged response is used to manage such supply disruptions. If there is more than one manufacturer the disruption can often be managed by increasing the use of another manufacturer's vaccine. If there is only one manufacturer, then the shortage is, by definition, a national shortage. The first step in managing such a shortage is to limit vaccine purchase in the public and private sectors so that excessive inventory is halted. If these measures are unable to address the shortage, the next step is to use CDC's vaccine stockpile to maintain the vaccine supply. If the stockpile is exhausted or is insufficient to manage the projected scope and duration of the shortage, temporary recommendations are often made to reduce vaccine use. For example, during the *Haemophilus influenzae* type b (Hib) vaccine shortage from 2007 to 2009, interim recommendations eliminated the booster dose for children unless they were at high risk such as Native American or Native Alaskans. Once the shortage resolved, routine recommendations were reinstated.[48] Following the resolution of a severe vaccine shortage, additional catch-up vaccination is often needed to ensure adequate protection. The much greater visibility of public sector vaccine with centralized vaccine distribution and VTrckS has greatly enhanced the CDC's ability to manage shortages. Current information on U.S. vaccine shortages and delays is available from the CDC.[49]

Assuring Access to Vaccines

A critically important step in the ensuring vaccine delivery is to make vaccines available with as few barriers to immunization as possible and with a minimum of missed opportunities to vaccinate. Cost of vaccines to the patient is a widely studied and recognized barrier, and one that is amenable to government programs that support the purchase of vaccine for financially vulnerable persons and government laws and regulations that require private insurance coverage for immunization—two solutions to the cost barrier that are cornerstones of the U.S. immunization system.

The 2010 ACA requires private health insurers to cover CDC/ACIP-recommended vaccines (category A and category B) on the pediatric and adult immunization schedules without cost sharing (i.e., first dollar coverage) as a benefit for persons of all ages when administered by a provider in the person's health plan network. Vaccines are required to be covered within 1 year of the publication of a new ACIP vaccine recommendation in the *MMWR*. Although health plans not covering immunization before the ACA are exempt from the immunization requirement, their exemption (grandfathered status) disappears if the plan makes any changes in coverage. Before ACA, the general practice of the health insurance industry had been to cover vaccines; 11% of young children and 20% of teens had commercial insurance that did not cover vaccines (underinsured).[50,51] The net effect of the ACA has been a decline in the number of persons with private health insurance that does not cover immunizations and a reduction in the number of persons without health insurance.

The VFC program has been critical in assuring access to vaccine for children by providing financially vulnerable children with government-purchased vaccine up to a child's 19th birthday. The VFC program is an entitlement to eligible children that has mandatory federal funding of ACIP-recommended vaccines. Four groups of children are entitled to VFC vaccine: children who are 18 years of age or younger who are either (a) eligible for Medicaid health insurance (a federal–state means-tested health insurance program), (b) have no health insurance, (c) Native American or Alaska Native children, or (d) not insured for recommended vaccines and are vaccinated at a Federally Qualified Health Center or Rural Health Clinic. The combination of VFC and the ACA's requirement that private health insurance cover ACIP-recommended vaccines ensures that all U.S. children have access to vaccine without out-of-pocket costs for the vaccine.

The VFC program has important characteristics that make it effective at assuring access to vaccine with a minimum of missed vaccination opportunities. First and foremost, VFC is an entitlement with mandatory federal funding that is not subject to the annual appropriations process. State and local VFC immunization programs determine the size of the VFC-eligible population in their jurisdiction, and the CDC uses this information to determine the vaccine purchase funding needed to meet the vaccination needs of all VFC-entitled children.

Second, the ACIP is the sole authority for the list of vaccines that are included in the VFC program. The ACIP indicates to the CDC which vaccines are included by passing a VFC resolution that specifies the number of doses and VFC age groups entitled to VFC vaccine. Unlike ACIP's vaccine recommendations, VFC resolutions are not subject to approval by the CDC director and become effective immediately after a passing vote. For a new vaccine to become available to VFC children, the CDC negotiates a contract with the manufacturers of the vaccine.

Enrolled VFC providers establish eligibility to the program at the point of service by asking parents whether their child meets any of the four eligibility categories. By VFC statute, independent verification is not required. Providers are required to indicate eligibility status in the child's medical record. Having point-of-service eligibility determination reduces missed immunization opportunities because parents are not required to sign their children up for VFC before visiting their child's healthcare provider. This provision is intended to prevent missed opportunities seen in the measles resurgence of 1989 to 1991 where mandatory referrals to public health department clinics were required.[26] VFC providers order and receive their vaccine without charge. The VFC program pays for the vaccine and its distribution to VFC providers, in contrast to the reimbursement model for private insurance where the provider has to pay for vaccine upfront at financial risk.[52]

The CDC also administers the Section 317 program to state and local immunization programs. Although smaller than VFC in total funding, immunization program grantees can use Section 317 vaccine to vaccinate populations that are not captured by private insurance or the VFC program (i.e., uninsured adults) and to vaccinate rapidly in response to a vaccine-preventable disease outbreak. The ACA authorized Section 317 permanently and also added the authority to allow states to purchase vaccine for adults using the CDC's vaccine contracts.

State and local immunization programs are responsible for enrolling providers into VFC. States also enroll non-VFC providers who can receive state or locally purchased vaccine or Section 317–purchased vaccine for the state/local priority populations. These networks of providers are vital to the success of government vaccine programs. The majority of VFC providers are private clinicians who use a combination of VFC vaccine and privately purchased vaccine to immunize children in their practices. VFC has more than 40,000 providers enrolled, and three quarters of these providers are private

providers. In total, VFC providers vaccinate approximately 90% of U.S. children.[53,54]

Maintaining the capacity and quality of their networks of providers is also a responsibility of state and local immunization programs. Federal funding is made available through VFC and Section 317 so that state and local programs are able to enroll new providers and conduct quality improvement activities among existing providers to help the providers practice in accordance with the standards of immunization practices. Section 317 grant funds are also available to provide direct service delivery in public health department clinics.

The community of immunization providers is large and growing in diversity. Many state and local immunization programs are expanding access to vaccines through pharmacists and community vaccinators who can vaccinate in schools and other settings.[55,56]

The governmental program role in assuring access to vaccines for adults has been more limited than the governmental role for assuring access to vaccines for children. Medicare Part B covers pneumococcal and influenza vaccination services for all persons 65 years of age or older enrolled in Medicare Part B (>95% of the older-than-65 population) and hepatitis B vaccine for people undergoing dialysis of any age. State Medicaid programs, supported by federal contributions, may cover recommended vaccines for younger adults enrolled in Medicaid, but there is not a requirement that Medicaid cover vaccines for adults. In 2005, Medicare part D was enacted to cover prescription drugs, including vaccines other than those included in Part B. Thus, all vaccines recommended for the Medicare population are covered by Medicare Part B or Medicare Part D, for persons who pay to participate. Provider billing for vaccines under Medicare Part D is more complicated than under Medicare Part B. The Centers for Medicare & Medicaid Services provides a comparison between Part B and Part D coverage for vaccines.[57]

The clinical work of vaccinating is supported with a fee-for-service payment mechanism in the private and public sectors. Private insurance and Medicaid pay vaccine administration fees with Medicaid paying the administration fee for Medicaid-enrolled VFC children and adults; reimbursement varies from state to state. VFC providers are allowed to charge parents of non-Medicaid VFC children a fee for the administration of VFC vaccine, although the VFC statute prohibits VFC providers from denying VFC vaccine to an eligible child solely because the parent cannot pay the administration fee. The importance of the vaccine administration fee is apparent from its prominence in the NVAC's vaccine financing recommendations. The NVAC made five recommendations to improve the vaccine administration fee, including that "the American Medical Association Relative Value Scale Update Committee should review its relative value unit coding to ensure that it reflects accurately the nonvaccine costs of vaccination, including the potential costs and savings with the use of combination vaccines."[29]

Control and Prevent Infectious Diseases

The desired outcome of immunization is reduction, elimination, or eradication of disease or disability and prevention or control of outbreaks and their associated disruption. The goals of an immunization program determine how intensively a vaccine-preventable disease is monitored (Table 73.2). When programs aim to achieve or sustain disease elimination, intensive efforts are needed surrounding each suspected case. Control programs may also require rapid identification and reporting of cases so that interventions can be offered promptly to reduce complications or limit transmission. Recognition of disease outbreaks is important to limit their scope. Outbreaks may also serve as sentinel events because they may provide the first indication of important program deficiencies or unanticipated limitations in vaccine performance. While some vaccine-preventable diseases manifest as relatively distinct clinical syndromes (e.g., paralytic poliomyelitis, measles, mumps, and congenital rubella syndrome), others may require laboratory testing to differentiate the illness from non–vaccine-preventable causes of the same syndrome (e.g., gastroenteritis or pneumonia). Vaccine-preventable causes of pneumonia (e.g., *Streptococcus pneumoniae* and *Haemophilus influenzae*) are difficult to diagnose even when optimal laboratory testing is available. Monitoring trends in the epidemiology of these diseases relies on targeted tracking of more specific manifestations of the disease, such as bacteremia and meningitis.

Reports of the occurrence of vaccine-preventable diseases have been the means of evaluating the impact of most of the immunization disease programs.[58] Information is obtained through state health departments, which have authority to mandate reporting of selected diseases to the state level by physicians and other healthcare providers.[59] The Council of State and Territorial Epidemiologists, in consultation with the CDC, establishes the list of nationally notifiable diseases. In the United States, most vaccine-preventable diseases of childhood are reported to the National Notifiable Diseases Surveillance System.

For all nationally notifiable diseases, data collected weekly include date of report and locating information (e.g., state and, when appropriate, county). For many of the vaccine-preventable diseases, supplemental information (e.g., date of onset, age, sex, race/ethnicity, vaccination status, whether the case was confirmed by a laboratory, and disease complications) is forwarded to the CDC. Reports by state of cases notified that week and the cumulative total for the year of many of the vaccine-preventable diseases are published in the *MMWR*. Case definitions have been established with the Council of State and Territorial Epidemiologists that detail criteria for confirmation of a given illness as a case of a vaccine-preventable disease.[60,61]

The National Notifiable Diseases Surveillance System is supplemented by other surveillance systems operated by the CDC. Diphtheria surveillance is enhanced through monitoring requests to the CDC for antitoxin, which the CDC has responsibility for distributing.[62] Efforts to collect data beyond the National Notifiable Diseases Surveillance System are made for several vaccine-preventable diseases. Some of these systems involve laboratory-based methods and others rely on death certificate data or other administrative data systems. Where data are not available nationally, special sentinel surveillance systems in selected states and communities may be established. Laboratory-confirmed, population-based surveillance systems in selected geographic areas are used to monitor causes of invasive bacterial disease, including *H. influenzae* type b, meningococcal disease, and pneumococcal disease.[63] The largest of these is the Active Bacterial Core surveillance within the Emerging Infections Program network, which tracks disease and assesses vaccine impact in parts or all of 10 states.[64]

The Emerging Infections Program has also been used to evaluate the incidence of hospitalization for laboratory-confirmed influenza, as well as vaccine effectiveness; the burden of invasive pneumococcal disease, and more recently the Emerging Infections Program network's HPV Impact has conducted active population-based surveillance of cervical intraepithelial neoplasia grades 2 and 3 and adenocarcinoma in situ, as well as associated HPV types in women 18 years of age and older.[65] The New Vaccine Surveillance Network, including population-based surveillance in three sites—Nashville, Tennessee; Rochester, New York; and Cincinnati,

TABLE 73.2 Objectives, Characteristics, and Limitations of Systems for Monitoring Vaccine-Preventable Diseases in the United States

Public Health Goal	Vaccine-Preventable Diseases	Surveillance Objectives	Key System Characteristics	Challenges
Elimination or eradication	Polio, measles, hepatitis B, rubella	Characterize circulating strains Maintain elimination or eradication (i.e., determine source of cases)	Active case-finding; high sensitivity and specificity; timely collection of specimens; verification of vaccination status of cases	Resource intensive; sustainability
Case management and/or intervention(s)	Diphtheria, meningococcal disease, hepatitis A, hepatitis B, invasive *Haemophilus influenzae* type b	Rapidly identify individual cases Trace contacts for prophylaxis	Population-based passive reporting with timely active follow-up; requirements for rapid local reporting	Speed of reporting to health department not always optimal; contact tracing may be incomplete; follow-up is resource intensive
Outbreak detection and control	Pertussis, influenza, hepatitis A, meningococcal disease, mumps, measles, varicella	Determine extent of outbreak Evaluate pathogen characteristics Verify effectiveness of control measures	Passive reporting (population- or facility-based) with rapid, active follow-up; laboratory confirmation of initial cases to confirm diagnosis; specimen collection	Speed of reporting to health department not always optimal; follow-up is resource intensive; specimens collected from limited number of cases; laboratory tests problematic for some vaccine-preventable diseases, especially in highly vaccinated population
Disease control	All	Monitor trends Identify gaps (pockets of need) Characterize populations at ongoing risk	Specific and consistent case definitions (e.g., laboratory confirmation); population-based (sentinel and/or national); adequate case information (demographics, vaccination status); longitudinal data; specimen collection to characterize strains[a] (sentinel laboratory-based reporting)	Routinely collected data may be of poor quality and incomplete; high-quality epidemiologic data and specimens primarily from sentinel active surveillance sites; high-quality systems do not exist in all jurisdictions—limited information to guide local programs

[a]Access to specimens to characterize infecting strain particularly is important when not all disease-causing serotypes/strains are included in the vaccine (e.g., pneumococcus, rotavirus, human papillomavirus, polio, influenza, meningococcus, *Haemophilus influenzae* type b).

From Schuchat A, Bell B. Monitoring the impact of vaccines postlicensure: new challenges, new opportunities. Expert Rev Vaccines. *2008;7:437–456.*

Ohio—provides data on the burden of influenza and rotavirus disease in children and the impact of various vaccines, and has now been expanded to include a total of seven sites.[66,67] As new vaccines are developed, licensed, and made available for use, surveillance and monitoring are critical to address their impact on communities and populations. New Vaccine Surveillance Network supports broad-based surveillance and research projects for acute gastroenteritis in areas with a population base of at least 500,000. A sentinel counties surveillance system was used for tracking hepatitis B infections, and varicella active surveillance has been conducted in three sites (Antelope Valley, California; Travis County, Texas; and Philadelphia, Pennsylvania).[68,69] Administrative data sources have provided information on varicella, rotavirus, and pneumococcal hospitalizations.[70–72] The National Health and Nutrition Examination Survey provides periodic reports on population immunity to various vaccine-preventable diseases, including antibody levels against pertussis, HPV, and other infectious agents.[73,74] Reporting completeness for each of the surveillance systems varies, and the active systems are substantially more sensitive than the National Notifiable Diseases Surveillance System. Completeness of reporting varies by source of report and type of disease, with more complete reporting from hospitals and laboratories than from physicians for diseases such as *H. influenzae* type b.[75]

Surveillance data are analyzed to determine whether reductions of disease occur with increasing vaccine coverage; greater-than-expected reductions and changes in incidence beyond the target age groups may signal important herd effects.[76,77] Surveillance data are also analyzed to evaluate potential changing epidemiology of disease, such as a shift to a predominance of adult cases where there had been a childhood focus or the emergence of disease caused by strains of the pathogen that are not targeted by the vaccine.[78] Surveillance can also determine whether cases are a result of failure of vaccine or of failure to vaccinate.[79,80]

Vaccine Effectiveness

When a substantial proportion of cases of vaccine-preventable disease occurs in persons with a history of vaccination, an investigation is often undertaken to determine whether the rates of vaccine failure are within expected ranges. *Vaccine effectiveness* is the term used for these observational studies, to contrast with *vaccine efficacy*, which is usually measured prospectively in randomized, double-blind, placebo-controlled

trials. Several methods are used to evaluate vaccine effectiveness in the postlicensure setting, including cohort, case-control, secondary attack rates in families, and other techniques.[76,81] Vaccine effectiveness is calculated as where ARV is the attack rate in vaccinated persons and ARU is the attack rate in unvaccinated persons. When case-control studies are used, the odds ratio is used to approximate the relative risk of disease in the vaccinated compared with the unvaccinated population (ARV/ARU).

Of particular note has been a relatively simple screening technique to help determine whether a more rigorous investigation of vaccine effectiveness is warranted. The screening analysis requires data on the vaccination status of cases and the vaccination status of the populations from which the cases are drawn. These data are often available from existing population-based estimates from surveys and other methods. Data must always be broken down into dichotomous variables, with unvaccinated persons compared with vaccinated individuals. For example, for a vaccine recommended in three doses, the population of cases vaccinated must be calculated excluding persons who received only one or two doses. Similar adjustments must be made for coverage assessment. Fig. 73.4 allows approximation of vaccine effectiveness using a nomogram.

Public health investigation of vaccine effectiveness can be facilitated in areas where comprehensive immunization information systems exist. One study of pentavalent rotavirus vaccine reported a vaccine effectiveness of 82% using data from an immunization information system (IIS) compared with 82% to 88% using data from providers.[82] Vaccine effectiveness studies may use population-based control subjects obtained through telephone surveys or household visits, as well as control subjects obtained through inpatient or outpatient healthcare facilities who have conditions different from the vaccine-preventable disease under investigation. For example, influenza vaccine effectiveness studies often use control subjects who have sought medical care for respiratory illness but have laboratory tests negative for influenza virus.[83] When vaccine effectiveness is within expected limits but disease transmission persists, new immunization strategies may be considered. For example, investigations showed that measles transmission could persist despite a vaccine effectiveness of greater than 90% and high levels of coverage with one dose of vaccine.[84] This information was critical in the decision to universally recommend a second dose of measles vaccine. When vaccine effectiveness is lower than expected, investigations also are triggered into potential causes such as failure to maintain vaccine at the proper temperature (i.e., deficiencies in the cold chain).

When most cases occur in unvaccinated persons, investigations can identify geographic and demographic characteristics to help guide future vaccination efforts. For example, a resurgence of measles in the United States during 1989 to 1991 was found to be caused by a failure to vaccinate young preschool children and led to a major national initiative to improve coverage.[26,32] In contrast, relatively small outbreaks of measles in 2008 and 2011 were focused in communities where personal beliefs led parents to exempt their children from vaccination required for school entry.[85,86] In 2013 and 2014, several measles outbreaks were linked to local religious and cultural communities where immunization rates were very low.[87–89]

Conduct Surveillance for Immunization Coverage

The U.S. immunization program uses a set of coverage surveys to monitor implementation of CDC/ACIP vaccination

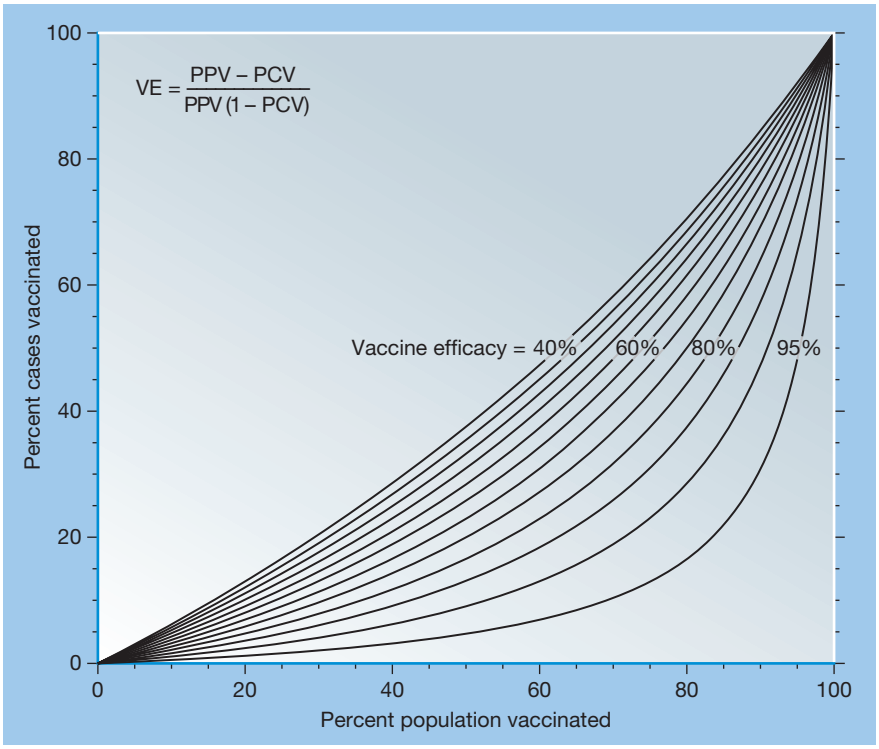

Figure 73.4. Percentage of cases vaccinated (PCV) per percentage of population vaccinated (PPV) for 12 values of vaccine efficacy (VE), varying from 40% through 95% at 5-percentage-point increments. Embedded formula uses proportions rather than percentages. *(From Orenstein WA, Bernier RH, Dondero TJ, et al. Field evaluation of vaccine efficacy.* Bull World Health Organ. *1985;63:1055–1068.)*

recommendations. These surveys provide an indirect measure of the population protection from vaccine-preventable diseases while assessing performance of the federal, state, and urban area immunization programs.

Coverage among young children has been comprehensively measured for the longest period. Measurement of childhood coverage has been measured since 1960, except for 1985 to 1991.[90,91] Beginning in 1994, immunization of preschool children has been assessed through the NIS, which consists of random-sample telephone surveys measuring immunization coverage of 19- to 35-month-old children (median age: 27 months). In 2006, the NIS was expanded to the NIS-teen to include children 13- through 17-years-old to assess coverage of vaccines recommended for 11- and 12-year-olds. Descriptions of this family of national immunization surveys is available at the CDC website.[92] The website provides information for the public and for healthcare professionals on the purpose, methods, instruments, and results of the surveys.[92]

The NIS and NIS-teen provide national estimates of coverage, usually with 95% confidence intervals of less than 3 percentage points, and comparable, statistically valid estimates for each of the 50 states, the six urban area Section 317 awardees, and the U.S. Virgin Islands, Guam, and Puerto Rico.[93,94] Although response rates vary by survey area, the methods are identical, allowing for comparison among the survey areas. In addition to the jurisdictions sampled annually, states are allowed to purchase from the CDC additional coverage surveys for geographic areas of interest within their jurisdictions.

Since parental recall of vaccination is known to have poor concordance with provider-verified vaccination status,[95] the NIS and NIS-teen surveys only report verified vaccinations by the immunization provider who administered the vaccine to the sampled child. Parents are interviewed about their demographics and access to vaccines, and they are asked permission to contact their child's providers to report the child's immunization history. Survey results are adjusted for telephone nonresponse. Because of the increasing use of cell phones and a concomitant decline in landline-only households, a cell phone sample frame was added in 2011 for adjustment of telephone access.[96] The NIS and NIS-teen results are reported annually in the CDC's *MMWR* and on the CDC's website. The CDC makes NIS and NIS-teen public-use data files available to researchers and others who request access to deidentified raw data. The CDC evaluates its immunization surveys for evidence of bias or nonrepresentativeness, and conducts research on methods to improve representativeness and value of the surveys.

The CDC estimates annual influenza vaccination coverage for the United States by using data from several nationally representative surveys: the Behavioral Risk Factor Surveillance System, the National Health Interview Survey, the NIS-flu survey, and Internet panel surveys of adults, healthcare personnel, and pregnant women. The CDC also provides ongoing vaccine effectiveness assessment during and after each influenza season through the Influenza vaccine effectiveness unit. The CDC's website provides reports, interactive figures, and data tables for these influenza coverage surveys at http://www.cdc.gov/flu/fluvaxview/index.htm. Coverage among adults for vaccines other than influenza is assessed using Behavioral Risk Factor Surveillance System and National Health Interview Survey. Vaccines include pneumococcal, HPV, zoster, and Tdap.[97]

Surveillance for vaccination coverage among new kindergarten students is conducted by the states and reported annually to the CDC. These data are published on the CDC's SchoolVaxView website and in the MMWR.[98,99] Managed care health plan performance on immunization is measured annually by the National Committee on Quality Assurance using the Health Plan Employer Data and Information Set (HEDIS). The HEDIS currently estimates immunization coverage for 2-year-old children, 13-year-old adolescents, and 50-year-old and older adults. Separate measures are made for commercial plans and Medicaid or Medicare plans. Results of HEDIS measures are published annually in a report called "The State of Healthcare Quality."[100]

Techniques for measuring immunization coverage at the provider level were developed during the 1990s and have been integrated into the VFC program since 2000. Additionally, immunization programs can use their IISs for determining provider-level coverage.[101] IISs are also an important way for immunization programs to assess coverage at the local level and target areas of undervaccination for outreach.

Sustain and Improve Immunization Coverage Levels

Sustaining and improving vaccination coverage levels requires a system that actively promotes vaccination of individuals targeted by recommendations. Simply making vaccines available will not result in coverage levels high enough to achieve immunization program goals and objectives. This section describes barriers to vaccination, key program activities to promote vaccination, and evidence-based strategies to improve coverage.

Barriers to Vaccination

In the United States, barriers to vaccination vary by vaccine and target population. For example, providers of vaccines recommended only for adults with behavioral or health risk factors must identify those for whom the vaccine is recommended; implementation of new vaccines must overcome the barrier of unfamiliarity; and seasonal vaccination against influenza must overcome time constraints associated with an annual seasonal vaccination schedule. However, common barriers to vaccination exist. These include lack of a provider recommendation to be vaccinated; missed opportunities to immunize during visits to immunization providers; lack of affordable access to vaccines; lack of knowledge that a vaccine is due or overdue to be given; lack of confidence in the safety or effectiveness of vaccines leading to hesitancy to vaccinate; and lack of belief in the necessity of vaccination.

For advice about vaccines and immunization, parents trust the advice of their children's healthcare providers more than any other source of information.[102] Thus, lack of a provider's recommendation to vaccinate can be a significant barrier to vaccine receipt as seen with HPV vaccination of adolescents.[103] Provider endorsement increases vaccine acceptance rates and lack of endorsement decreases acceptance.[104] Recommendations from providers serve not only as professional advice, but they also serve as reminders that a vaccination is due or overdue, thus helping parents and patients navigate a complicated vaccination schedule.

During a visit to a healthcare provider, failure to give all recommended vaccines constitutes a missed opportunity to immunize. Epidemiological investigation shows that missed opportunity to immunize was a prominent root cause of the 1989–91 measles resurgence in the United States.[105] Missed opportunities to immunize can be caused by use of false contraindications to vaccination, for example not administering influenza vaccine out of concern for mild illness at the time of vaccination; by deferring some vaccines to decrease the number of injections at a single visit; or by referring to another provider such as the public health clinics out of concern for

the costs to vaccinate. Supporting evidence that missed opportunities to immunize constitute barriers to achieving coverage goals is found in studies showing that if all opportunities were taken to vaccinate, coverage would improve. Fu and colleagues showed that 45% of undervaccinated children would have been up-to-date on their infant vaccinations had all age-appropriate immunization opportunities been taken,[105] and Stokley and colleagues showed that more than 90% of adolescent females could have been up-to-date with HPV vaccine had all vaccination opportunities been taken.[106]

Out-of-pocket costs for vaccination are a well-known barrier to vaccination. Indeed, many of the missed opportunities to immunize during the 1989–91 measles resurgence were caused by referral from a private provider to a free vaccine provider because of cost considerations, a finding that, in part, led to the creation of the VFC program. Currently, in the United States, government support and private health insurance largely cover the costs of vaccination of most children up to 18 years of age, and a combination of private and government insurance covers vaccination costs of adults older than 65 years of age and younger adults with health insurance coverage. Uninsured adults between 19 and 64 years of age comprise the largest group of individuals lacking coverage for vaccination services. Supportive evidence that out-of-pocket costs constitute a barrier to vaccination comes from studies demonstrating that provision of affordable access to vaccines increases coverage. In 2007, the Community Preventive Services Task Force (TFCPS) reviewed studies on the impact of reducing out-of-pocket costs on vaccination coverage levels. The TFCPS found that in 11 studies published between 1997 and 2009, the median increase in vaccination coverage by reducing cost barriers was 22 percentage points.[107]

Vaccination recommendations are updated at least annually as new vaccines are recommended or previous vaccine recommendations are changed with new evidence. The complexity and changing nature of the routine immunization schedule makes it unrealistic to assume that parents or patients track their child's or their own vaccination status. Supportive evidence that parents need reminders when vaccinations are due or past due comes from intervention studies showing the positive impact of reminder/recall systems on vaccine uptake. The TFCPS reviewed 62 qualified studies of reminder/recall systems that showed median increases in vaccination coverage of 12 percentage points among studies conducted in the 1980s and 1990s and 6 percentage points in studies conducted after 1997.[108] The TFCPS also reviewed evidence for impact of reminder systems for targeted adult vaccines. In nine studies, reminder systems increased coverage by a median of 18 percentage points.[109]

Parent or patient concern about the safety, effectiveness, or need for a vaccine can lead to hesitancy or outright refusal of vaccination. Vaccine hesitancy is a global phenomenon that has been studied by a working group of the World Health Organization's Strategic Advisory Group of Experts (SAGE) on immunization. In the definition of the World Health Organization's Strategic Advisory Group of Experts, vaccine hesitancy refers to "delay in acceptance or refusal of vaccination despite availability of vaccination services."[110,111]

In the United States, vaccine refusal among parents of young children is monitored indirectly through the NIS by assessing the number of young children with zero doses of vaccine, a figure that has remained below 1% nationwide since 2006. Evidence that vaccine hesitancy is a problem in the United States can be seen in surveys of parents and studies on exemptors from school vaccination requirements.[112] In a nationally representative survey of parents of children younger than 18 years of age conducted in 2009, Freed and colleagues found that more than half of parents had fears of serious adverse events from vaccines and that 12% of parents had refused to have their children vaccinated with at least one vaccine.[113] Objective measures of vaccine hesitancy show a relation between vaccine hesitancy and undervaccination of young children and adolescents.[114,115]

A 2015 NVAC report discusses the importance of vaccine confidence to maintain high immunization coverage levels in the United States. In this report, vaccine confidence refers to the trust that parents or healthcare providers have (a) in the recommended immunizations, (b) the provider(s) who administers vaccines, and (c) the process that leads to vaccine licensure and the recommended vaccination schedule. This report outlines current measures of vaccine confidence and recommends healthcare providers, immunization programs, and those involved in promoting recommended vaccinations actively reinforce that vaccination according to the ACIP recommended schedule is the social norm and not the exception.[116]

Key Program Activities

Reporting and Monitoring Adverse Events Following Vaccination. It is important to ensure that the vaccine recipient (or parent or guardian) is adequately aware of the risks and the benefits of vaccination and that the recipient has a record of all immunizations received. The National Childhood Vaccine Injury Act of 1986 and subsequent changes (section XXI of the Public Health Service Act) require that all vaccine providers formally notify patients and parents or guardians of the risks and benefits of vaccines covered by the National Childhood Vaccine Injury Act. Formal notification is accomplished through the use of standardized vaccine information statements.[117] Printable versions of these forms are available for downloading at the CDC website.[118]

The National Childhood Vaccine Injury Act also established a no-fault compensation mechanism for persons with injuries from the vaccines covered by the act. Persons wanting further information about this program should contact the National Childhood Vaccine Injury Compensation Program at 800–338–2382 or at the Program's website (see Chapter 83).[119] The National Childhood Vaccine Injury Act also requires providers to note in the patient's permanent medical record the date the vaccine was administered, the vaccine manufacturer, the vaccine lot number, and the name, address, and title of the person administering the vaccines, in addition to noting the provision of vaccine information materials. Finally, the Act requires that providers report selected adverse events occurring after vaccination and events that would contraindicate further doses of vaccines to the Vaccine Adverse Event Reporting System.[120] Providers are encouraged to report all serious adverse events following all vaccines, regardless of whether they believe that a vaccine caused the event. The Vaccine Adverse Event Reporting System forms can be obtained by calling 800–822–7967 or through the Internet.[121] (See Chapter 82 for further discussion of vaccine safety.)

Operating Immunization Information Systems. IISs have the potential to strengthen the system and raise and maintain immunization levels.[101] The IISs are confidential, computerized information systems that contain information about immunizations provided to individuals. The IISs are capable of monitoring the immunization status of individuals and population groups, generating reminder/recall notices, and generating official immunization records.[122] The Healthy People 2020 objectives call for 95% of children younger than 6 years of age to be enrolled in a fully operational population-based IIS.

Registries have demonstrated usefulness in sending reminder/recall notices, increasing coverage, monitoring

implementation of policy changes, generating official immunization records, assessing immunization levels for healthcare quality indices, reducing missed opportunities, preventing unnecessary immunization, vaccine inventory management, and public sector vaccine ordering. They have also been used to identify and recall children who did not receive vaccines during temporary, national shortages and to identify children in need of vaccination when new vaccines are introduced. The TFCPS recommends the use of IISs based on strong evidence of their effectiveness.

In 2015, all 50 states have active, functioning IISs. As of December 31, 2012, results from an IIS annual survey indicate that 86% (19.5 million) of U.S. children younger than 6 years of age had two or more vaccinations recorded in an IIS, and 25% (57.8 million) of U.S. adults had one or more vaccinations recorded in an IIS.[123] An important functional component of an IIS is that it receives information from an electronic health record. The percentage of IISs meeting Functional Standards 7 (i.e., meeting basic international standards for exchange of clinical data between systems) increased from 58% in 2011 to 77% in 2012, and 37% of IISs met more advanced functionality.[123] Thus, full interoperability between electronic health record systems and IISs is closer to reality. Another critical function of an IIS to improve accuracy of records and to reduce missed opportunities is for data to be exchanged between jurisdictions. A 2015 NVAC report promotes ongoing efforts to address the technical and legal barriers to cross-jurisdictional IIS data exchange.[117]

In 2012, the CDC launched a strategic plan to achieve the vision for the future of immunization information management that real time, consolidated immunization data and services for all ages would be available for authorized clinical, administrative, and public health users, and consumers, anytime and anywhere.[124] Table 73.3 summarizes the goals and challenges facing IISs. Strategic investments are being made at the federal level to support state and local IISs in meeting these challenges as a community.

Enforcing Laws and Regulations for Immunization. Laws requiring immunization in the United States date from the early 19th century.[125–127] Massachusetts enacted a law in 1809 that required smallpox vaccination of the general population, and other jurisdictions followed during the course of the century. In 1905, the Supreme Court affirmed the right of states to pass and enforce compulsory immunization statutes and in 1922 the Supreme Court also affirmed laws requiring vaccination before school entry. School entry laws were variably enforced, and the vaccines covered varied considerably. After measles vaccine was introduced in the mid-1960s, school entry requirements for measles vaccination became common because measles was a disease primarily of school-age children. It became apparent that states without laws were

TABLE 73.3 Immunization Information Systems Strategic Plan Focus Areas and Challenges, Centers for Disease Control and Prevention, 2012[a]

Focus Area	Long-Term Goal	Challenge
National Leadership	There is a national immunization and immunization information management program vision, strategy, policy and metrics.	Policies and standards to support immunization management are not coordinated nationwide across all immunization stakeholders. There is no overriding nationwide consent policy for interstate data exchange. There is no nationwide policy for interstate data exchange.
Sustainability	The national immunization information management program has sufficient funding and permanent informatics, epidemiology, economics, computer science, and information technology resources providing immunization-centric analytical services.	There is no IIS line item in VFC or section 317 funding programs; state-level support of IIS is variable and although CDC-provided Prevention and Public Health Fund awards have helped, these funds are short in duration and cannot be used to support ongoing operations to maintain the IIS technology and appropriately skilled staff to support it.
Provider Services	Providers transmit immunization event data automatically and receive consolidated patient history and clinical decision support within the same application.	Some IIS integration standards for providers and EHR-S vendors are applied in a variable way across jurisdictions due to local statutes and business rules. Immunization-centric data, functionality, usability, and interoperability standards are applied in a variable way for immunization data collection at the point of care.
Public Health Services	IIS collect and display real-time, accurate immunization coverage analytics for all ages and vaccine inventory status for the jurisdiction.	There is a lack of informatics, epidemiology, economics, computer science, and information technology knowledge, skills, and roles within some sectors of the immunization information management community. Some IIS functions are redundant while others are variable across jurisdictions due to local statutes and business rules. Some IIS interoperability standards for immunization programs and IIS vendors are implemented in a variable way across jurisdictions because of local statutes and business rules. Methods and standards for analyzing IIS data (e.g., developing coverage rates) vary from IIS to IIS, resulting in potential misinterpretation by public health officials and scientists.
Interoperability	Data exchange among immunization information management systems is automatic and transparent regardless of location.	Challenges remain to ensure immunization data in IIS are complete, accurate, and acquired in a timely manner.

experiencing a higher incidence of measles than those with laws and, with the Immunization Initiative of 1977, considerable emphasis was placed on enactment and enforcement of school entry laws.

Laws requiring immunization before entry in school or daycare are the safety net for the U.S. immunization program. All 50 states and the District of Columbia have laws in effect, although the precise vaccines, doses, and schedules vary. The impact of these laws on the decreased incidence of measles and mumps in states with laws versus states without laws was apparent. A major resurgence of mumps during 1986 was shown to occur almost exclusively in states without comprehensive laws requiring mumps vaccination.[128] A comprehensive review of the impact of school laws was done by Orenstein and Hinman.[126]

Although the vast majority of parents comply with school immunization requirements, a substantial—and possibly growing—number of parents exempt their children from school laws.[112] All states allow medical exemptions from school immunization requirements, and by July 2016, all but three states will allow religious or philosophical exemptions from school immunization requirements. The process of obtaining an exemption from school immunization requirements varies widely by state. Rota and colleagues showed that the difficulty of the exemption process was inversely related to the percentage of children obtaining exemptions, indicating that many exemptions are likely to be exemptions of convenience rather than deeply held convictions.[129]

Exemptions from school immunization requirements have consequences. Exemption was associated with a 35-fold higher risk of measles in a 1999 study.[130] Feikin and colleagues showed that exemption was associated with a sixfold higher risk of pertussis.[131] Omer and colleagues showed that the ease of obtaining exemptions was associated with a nearly threefold increase in pertussis outbreaks in Michigan, primarily owing to clustering of exemptors.[132] Parents who exempt their children from school immunization requirements hold measurably different beliefs about vaccines than parents complying with school immunization requirements. For example, Salmon and colleagues have shown that exempting parents are much more likely to believe that vaccines weaken the immune system and that immunization does more harm than good.[133] A recent review on exemption from school immunization laws summarizes much of the current literature.[134]

Using the Standards of Immunization Practices. In 1993, the NVAC recommended a set of 18 standards to improve the immunization performance of pediatric providers, and in 2002, these standards were updated to incorporate advances in knowledge of best immunization practices (Table 73.4).[27] Many of the standards specifically address improving immunization coverage in children, including removing barriers to immunization, taking advantage of all opportunities to vaccinate, simultaneously vaccinating and using only valid contraindications, establishing tracking systems to identify children who are underimmunized and to facilitate taking corrective actions, and semiannually auditing patients served by a given clinic or practice to evaluate performance and to determine whether improvements are needed. The Infectious Diseases Society of America has established 46 implementation standards that apply to adults, adolescents, and children.[122] These 46 standards are graded according to the quality of their supportive evidence.

In 2013, NVAC released revised Standards for Adult Immunization Practice, recognizing the importance of the healthcare provider recommendation for patients to receive needed adult vaccines, the current low vaccination rates among U.S. adults, and the changing environment within which adult vaccines are now given.[135] These standards are a call for all healthcare professionals to take the following steps to ensure that adult patients are fully immunized and have maximum protection from serious diseases:

- ASSESS immunization status of all patients in every clinical encounter.
- SHARE a strong recommendation for vaccines that patients need.
- ADMINISTER needed vaccines or REFER to a provider who can immunize.
- DOCUMENT vaccines administered or received by your patients.

The National Adult and Influenza Immunization Summit (NAIIS) is a partnership of more than 130 private and public

TABLE 73.4 Standards for Pediatric Immunization Practices

1. Immunization services are readily available.
2. There are no barriers or unnecessary prerequisites to the receipt of vaccines.
3. Immunization services are available free or for a minimal fee.
4. Providers utilize all clinical encounters to screen and, when indicated, vaccinate children.
5. Providers educate parents and guardians about immunization in general terms.
6. Providers question parents or guardians about contraindications and, before vaccinating a child, inform them in specific terms about the risks and benefits of the vaccinations their child is to receive.
7. Providers follow only true contraindications.
8. Providers administer simultaneously all vaccine doses for which a child is eligible at the time of each visit.
9. Providers use accurate and complete recording procedures.
10. Providers co-schedule immunization appointments in conjunction with appointments for other child health services.
11. Providers report adverse events following vaccination promptly, accurately, and completely.
12. Providers operate a tracking system.
13. Providers adhere to appropriate procedures for vaccine management.
14. Providers conduct semi-annual audits to assess immunization coverage levels and to review immunization records in the patient populations they serve.
15. Providers maintain up-to-date, easily retrievable medical protocols at all locations where vaccines are administered.
16. Providers practice patient-oriented and community-based approaches.
17. Vaccines are administered by properly trained persons.
18. Providers receive ongoing education and training regarding current immunization recommendations.

From Centers for Disease Control and Prevention. Standards for pediatric immunization practices. MMWR. *1993;42(RR-5):1-13.*

organizations that focuses on increasing adult and influenza immunization rates and on increasing implementation of the adult standards.[136] NAIIS has active workgroups on topics such as provider outreach, access and collaboration, patient education, policy and decision makers, and quality and performance measures. NAIIS has an annual meeting to bring together partners to discuss opportunities to improve adult immunization.

Educating and Updating the Immunization Workforce. The U.S. immunization schedule is complicated and changes at least once each year. Temporary changes in the schedule owing to vaccine supply disruptions can happen at any time. Specific vaccines can have safety concerns or issues that require temporary or permanent changes in vaccination practices. One example is the temporary halt in 2010 of the use of one of the licensed rotavirus vaccines because of the presence of porcine circovirus and the recommendation against using one of the licensed influenza vaccines owing to concerns about febrile seizures. This dynamic environment, coupled with the massive number of vaccinations given each year in the United States, require a means to educate and update the immunization workforce.

Continuously updated authoritative material is available at government sites listed later under "Sources of Additional Information." Professional organizations and other immunization education organizations also have continuously updated material, and several of these are listed in that section. Professional organizations, like the American Academy of Pediatrics, offer continuing medical education courses focused on immunization practices. The VFC program provides funding for state and local immunization programs to educate their VFC providers on all aspects of immunization practices, especially those required by law (use of the vaccine information statement and documenting immunizations properly), storage and handling of vaccines, and updates to the VFC program and immunization schedule.

State and local immunization programs communicate directly with their networks of immunization providers. To reduce the need to create multiple versions of immunization materials, the CDC now offers a new Web Content Syndication service that allows partners, including federal public health agencies, state and local public health departments, nonprofit organizations, academic institutions, and commercial organizations to syndicate CDC content directly to their sites. Public health partners can gain direct access to CDC Web content without having to monitor and copy updates, control which content from CDC.gov to use on their site, or integrate CDC content with localized content while keeping visitors on their sites. Information about content syndication is available at the CDC's Public Health Media Library.[137]

Communicating With the Public. Communicating with the public requires an understanding of the questions and concerns of the public and mechanisms to address them. With NVAC, the CDC developed a parental concerns module for the NIS that was administered in 2010. This module asked parents whether they have refused or delayed a vaccination, and, if so, which vaccine and why.[138] Using the NIS as the sample frame has the advantage of being able to link parent responses to immunization status of their child. The CDC also uses other survey and polling mechanisms to learn of parental concerns, and is currently conducting a prospective study looking at changes in vaccine attitudes among the same group of mothers over 5 years.[139]

Official communication with individual parents or guardians about vaccines and vaccine-preventable diseases is required on an individual basis for every vaccination with the vaccine information statement. These two-page information sheets are used by immunization providers to address questions and concerns and to bring important information to the attention of parents, guardians, and vaccinees. Broader communication with the public includes informational Internet sites as listed in this chapter and strategic communication with media channels. CDC launched an Internet site in 2011 dedicated to providing vaccine information to parents.[140]

Evidence-Based Strategies to Improve Coverage

The evidence of what works to raise and sustain immunization coverage levels has been systematically reviewed by the TFCPS[141] and other independent reviewers. The TFCPS is an independent body that reviews the evidence base of community preventive services and makes recommendations for interventions based on the quantity and quality of evidence regarding their effectiveness. The TFCPS has reviewed a number of interventions addressing approaches aimed at enhancing access to vaccination services, increasing community demand for vaccinations, and provider- or system-based interventions and updates these reviews regularly. Table 73.5 summarizes the Task Forces' recommendations.

Supporting Provider-Based Interventions. Physicians and nurses need to ensure that their patients are immunized. However, when queried, they tend to overestimate the coverage of the children they serve. Studies report that physicians overestimated coverage by 10% to more than 40%.[142] The purpose of assessment and feedback is to alert providers to the actual coverage in their patient populations and to help motivate them to improve that coverage. The VFC program funds state and local immunization programs to conduct assessment and feedback on providers enrolled in VFC using the AFIX method. The AFIX method includes four components:

- *A*ssessment of the immunization coverage of the preschool children served by a given clinic.
- *F*eedback of the results to persons in the clinic with the authority to make changes. Such feedback often includes potential problems identified during the review, such as failure to administer vaccines simultaneously.
- *I*ncentives for improved performance. In the public sector, this often involves community recognition, plaques, and/or dinners rather than financial incentives.
- e*X*change of information or comparing the performance of one clinic with that of others to stimulate competition to improve performance.

Assessment and feedback has been shown to increase immunization coverage for children in a provider's office and is a recommendation of the TFCPS. Many immunization programs are also implementing AFIX to provide assessment and feedback to providers on adolescent immunization coverage in their practice. While evidence supporting the impact of AFIX on adolescent coverage is limited, adolescent AFIX is an opportunity to engage providers and encourage a strong recommendation for HPV immunization in their practice.[143]

Many studies show that reminders for immunizations that are due or recall systems for immunization appointments that are missed can significantly improve immunization coverage in a variety of settings. In a health maintenance organization setting, computer-generated letters to families with children who had not received an measles-mumps-rubella (MMR) vaccine by 20 months of age improved coverage by 19 percentage points compared with similar children whose parents did not receive reminders (54% vs 35%), at a cost of US$4.04 per

TABLE 73.5 Effective Strategies to Improve Immunization Coverage

ENHANCING ACCESS TO VACCINATION SERVICES	
Home visits to increase vaccination rates	Recommended—March 2009
Reducing client out-of-pocket costs	Recommended—October 2008
Vaccination programs in schools and organized childcare centers	Recommended—June 2009
Vaccination programs in WIC settings	Recommended—March 2009
INCREASING COMMUNITY DEMAND FOR VACCINATIONS	
Client or family incentive rewards	Recommended—May 2015
Client reminder and recall systems	Recommended—May 2015
Client-held paper immunization records	Insufficient evidence—March 2010
Clinic-based education when used alone	Insufficient evidence—May 2015
Communitywide education when used alone	Insufficient evidence—March 2010
Community-based interventions implemented in combination	Recommended—October 2014
Monetary sanction policies	Insufficient evidence—April 2011
Vaccination requirements for child care, school, and college attendance	Recommended—June 2009
PROVIDER- OR SYSTEM-BASED INTERVENTIONS	
Healthcare system-based interventions implemented in combination[a]	Recommended—October 2014
Immunization information systems	Recommended—July 2010
Provider assessment and feedback	Recommended—February 2008
Provider education when used alone	Insufficient Evidence—May 2015
Provider reminders[b]	Recommended—June 2008
Standing orders	Recommended

[a]Combination refers to the situation in which an intervention is applied in concert with another intervention rather than as a standalone intervention. For example, combining client-based education with reducing out-of-pocket costs for vaccination.
[b]Provider reminders serve as prompts to vaccinate a patient being seen who is in need of vaccination.
From The Guide to Community Preventive Services. Increasing Appropriate Vaccination. Available at: https://www.thecommunityguide.org/topic/vaccination.

additional immunized child.[144] Provider-based recall systems have been shown to be effective at the community level in reducing racial and ethnic disparities in immunization coverage levels.[145] Provider reminders to inform those who administer vaccinations that individual clients are due for specific vaccinations are also effective. Immunization providers can use reminders and recalls in concert with other effective interventions to ensure the best protection possible for their patient population.

TABLE 73.6 Comparison of Prevaccine Era and 2016 Counts of Cases for U.S. Vaccine-Preventable Diseases, Excluding Invasive Meningococcal Disease and Human Papillomavirus–Related Diseases

Disease	20th Century Estimated Annual Cases[a]	2016 Reported Cases[b]	Percent Decrease
Smallpox	29,005	0	100%
Diphtheria	21,053	0	100%
Measles	530,217	69	>99%
Mumps	162,344	5311	97%
Pertussis	200,752	15,737	92%
Polio (paralytic)	16,316	0	100%
Rubella	47,745	5	>99%
Congenital rubella syndrome	152	1	99%
Tetanus	580	33	94%
Haemophilus influenzae	20,000	22[c]	>99%

[a]Data from Rousch SW, Murphy TV. Vaccine-preventable disease table working group. Historical comparisons of morbidity and mortality for vaccine-preventable diseases in the United States. *JAMA*. 2007;298(18):2155-2163.
[b]Data from Centers for Disease Control and Prevention. MMWR January 9,2015/63(53);ND-733-ND-746. (MMWR 2014 provisional week 53 data).
[c]*Haemophilus influenzae* type b (Hib) <5 years of age. An additional 12 cases of Hib are estimated to have occurred among the 226 reports of Hi (<5 years of age) with unknown serotype.

IMPACT OF IMMUNIZATION PROGRAMS

Occurrence of Disease

The occurrence of most vaccine-preventable diseases is at or near record low levels. Table 73.6 shows the representative annual levels of disease reported or estimated for selected vaccine-preventable diseases during the 20th century. Most often, these are the years immediately preceding vaccine licensure. Most diseases with mature vaccination programs have been reduced by 95% or more from representative 20th-century morbidity. In March 2000, a group of experts concluded that endemic transmission of measles in the United States had ceased,[146] and in 2003, rubella was declared to be eliminated from the United States.[147] Although measles outbreaks continue to occur around imported cases,[85] the elimination of indigenous transmission has been sustained. Maintaining elimination status is especially important in an era in which measles remains uncontrolled in many countries. Substantial reductions are also evident for several of the diseases for which vaccines have been introduced more recently, such as rotavirus and pneumococcal disease.[148–150] Vaccination in the United States has led to substantial reductions in hospitalizations attributed to pneumococcus, rotavirus, and varicella.[70,151,152]

Immunization Coverage

Preschool Immunization

The United States is currently experiencing record-high or near-record-high vaccination coverage levels among 2-year-old

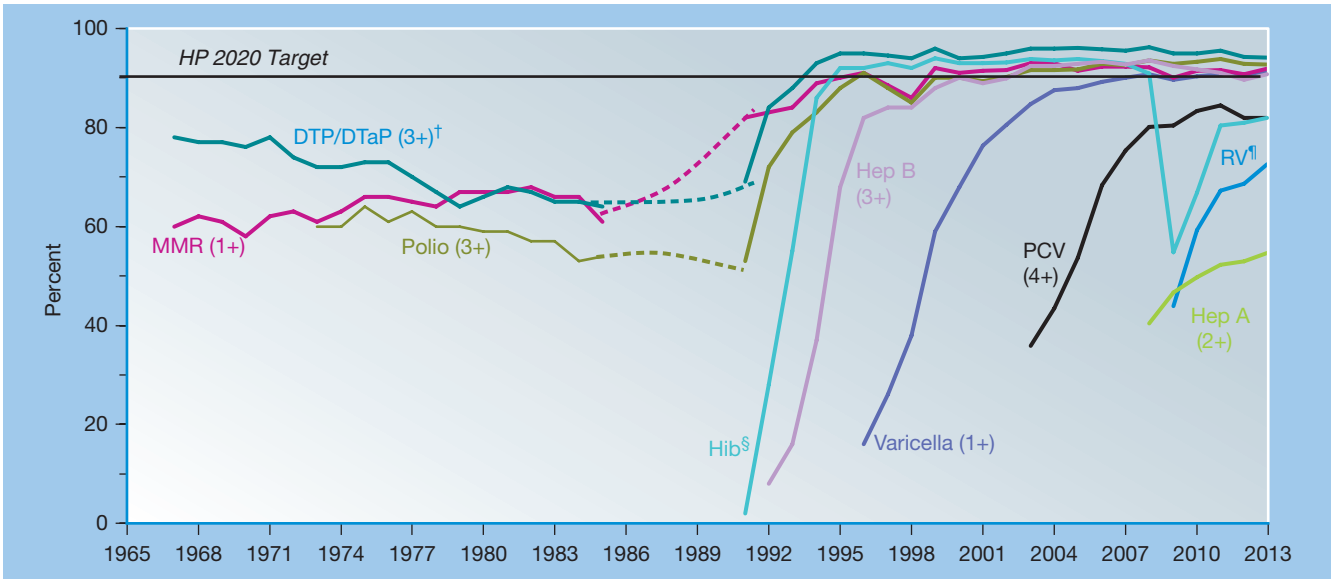

Figure 73.5. Vaccine-specific coverage among children 19 to 35 months of age, National Immunization Survey, 1994 to 2014. The *Healthy People 2020* (HP 2020) target for coverage is 90% for all these vaccines except rotavirus (80%) and HepA (85%). DTP/DTaP, diphtheria, tetanus toxoids, and pertussis vaccine/diphtheria, tetanus toxoids, and acellular pertussis vaccine; HepA, hepatitis A vaccine; HepB, hepatitis B vaccine; Hib, *Haemophilus influenzae* type b vaccine; MMR, measles, mumps, and rubella vaccine; PCV, pneumococcal conjugate vaccine. *(From CDC. For Immunization Managers. Figure Depicting Coverage with Individual Vaccines from the Inception of NIS, 1994 Through 2014. http://www.cdc.gov/vaccines/imz-managers/coverage/nis/child/figures/2014-map.html.)*

children, although there is moderate variation in coverage levels across states (Fig. 73.5). In 2014, the *Healthy People 2020* target of 90% was met for three or more doses of poliovirus vaccine (93.3%), one or more doses of MMR (91.5%), three or more doses of hepatitis B vaccine (91.6%), and one or more doses of varicella vaccine (91.0%). However, the targets were not met for four or more doses of diphtheria, tetanus, and pertussis vaccine (DTaP); the full series of Hib; four or more doses of pneumococcal conjugate vaccine; two or more doses of hepatitis A vaccine; the hepatitis B vaccine birth dose, and the full series of rotavirus vaccine.[1] The NIS monitors the number of young children who are completely unvaccinated—the "zero-dose" children. Since 2006, the number of zero-dose children has remained consistently below 1%. Coverage with vaccines scheduled to be given in the second year of life is lower than for vaccines given during the first year. Most recent immunization coverage tables for children by state, race, ethnicity, and poverty status can be found at the CDC's For Immunization Managers web page.[153]

The United States has made substantial progress in reducing vaccination coverage level disparities by race in the past three decades. Measles disease and measles immunization serve as an example. In the 1970s, the white–nonwhite disparity in MMR vaccine coverage was 18 percentage points, and attack rates for measles among children younger than 5 years of age were four to seven times higher in nonwhites than in whites. During the 1990s, the white–black coverage disparity was reduced to 2 percentage points, and the disease disparity was eliminated. Zhao and Luman analyzed series-complete data and found that during the time from 2000 to 2008, the series-complete coverage levels (four DTaP, three inactivated poliovirus vaccine, one MMR, three hepatitis B, three Hib, and one varicella vaccines) showed relatively little black–white coverage disparities. In 2000, the disparity was approximately 4 percentage points, and by 2008, it was reduced to approximately 2 percentage points.[154] Current disparities by race and ethnicity have remained relatively small, but disparities remain for doses given in the second year of life.

Teens

All U.S. adolescents are recommended to receive HPV, Tdap, and meningococcal conjugate vaccine-4 vaccines at 11 to 12 years of age. Coverage among 13- to 17-year-old teens has steadily climbed for Tdap and meningococcal conjugate vaccine-4 to over the Healthy People 2020 coverage goal of 80%, with 2014 coverage of 87.6% and 79.6% respectively.[2] However, coverage for HPV series initiation and completion continues to be low, with initiation rates of 60% among girls and 41.7% among boys in 2014 (Fig. 73.6). There is wide variation in coverage rates by state for all three vaccines, but disparities by race, ethnicity, and poverty status are small. The most recent coverage estimates for teens are available online at the CDC.[155]

Adult Immunization

Vaccination coverage levels among U.S. adults are substantially lower than coverage for young children.[97] Table 73.7 shows adult coverage for influenza, pneumococcal polysaccharide, and zoster vaccines, all three of which are recommended routinely for age-appropriate adults. Adult vaccination coverage levels reveal a much larger disparity by race and ethnicity than the disparity seen among young children and teens, with coverage for pneumococcal vaccine in adults 65 years of age and older, diphtheria and tetanus toxoids vaccine, and zoster vaccine lower among blacks and Hispanics compared to white non-Hispanics.[156,157] Influenza vaccination coverage varies by year and data from each influenza season can be found at the CDC's FluVaxView interactive website.[158]

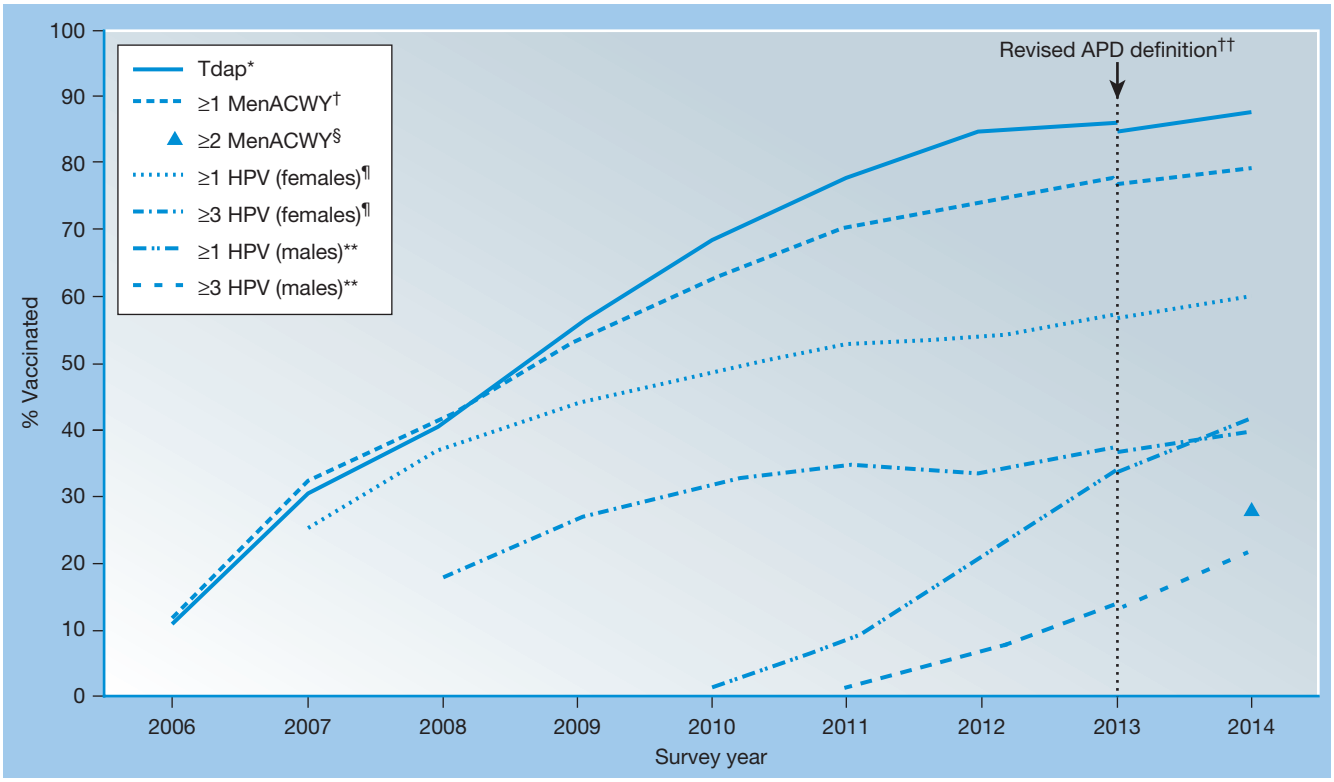

Figure 73.6. Vaccination coverage with selected vaccines and doses among adolescents age 13 to 17 years, by survey year—National Immunization Survey-Teen, United States, 2006 to 2014. HPV, human papillomavirus; MenACWY, quadrivalent meningococcal conjugate vaccine; Tdap, tetanus, diphtheria, and pertussis.

TABLE 73.7 Vaccination Coverage Levels of Adults, 2013

Vaccine and Age Group	National Average	White, Non-Hispanic	Black, Non-Hispanic	Hispanic
Pneumococcal polysaccharide, 19–64 y	21.2%	22.3%	21.2%	17.9%
Pneumococcal polysaccharide, >64 y	59.7%	63.6%	48.7%	39.2%
Td, 19–49 y	62.9%	69.0%	54.1%	52.5%
Td, 50–64 y	64.0%	67.3%	54.4%	55.0%
Td >64 y	56.4%	59.6%	40.3%	45.3%
Tdap, 19–64 y	18.4%	21.6%	13.6%	10.5%
Hepatitis A, 19–49 y	12.3%	12.6%	11.0%	10.6%
Hepatitis B, 19–49 y	32.6%	35.2%	30.5%	23.7%
Herpes zoster, >59 y	24.2%	27.4%	10.7%	9.5%
HPV, females 19–26 y	36.9%	41.7%	30.6%	30.3%

HPV, human papillomavirus; Td, tetanus and diphtheria vaccine.
From Williams WW, Lu PJ, O'Halloran A, et al; Centers for Disease Control and Prevention (CDC). Vaccination coverage among adults, excluding influenza vaccination—United States, 2013. MMWR Morb Mortal Wkly Rep. *2015:64;95–102.*

Impact of the U.S. Program

The immunization schedule, taken as a whole, saves lives, prevents suffering, and saves money for the healthcare system and for society. In 2014, a model was conducted to assess the impact of 20 years of the VFC Program (Table 73.8). This analysis was based on a modeling approach that assessed the economic impact of each of the recommended vaccines individually and combined into the routine program. Among 78.6 million children born during 1994 to 2013, routine childhood immunization estimated that 322 million illnesses (averaging 4.1 illnesses per child) and 21 million hospitalizations (0.27 per child) were prevented over the course of their lifetimes and 732,000 premature deaths from vaccine-preventable illnesses were averted. Vaccination will potentially save $402 billion in direct costs and $1.5 trillion in societal

TABLE 73.8 Estimated Number of Illnesses, Hospitalizations, and Deaths Prevented by Routine Childhood Immunization for Selected Vaccine-Preventable Diseases Among Children Born During the Vaccines for Children Era—United States, 1994–2013

Vaccine-Preventable Disease[a]	Cases Prevented (in Thousands)		
	Illnesses	Hospitalizations	Deaths
Diphtheria	5073	5073	507.3
Tetanus	3	3	0.5
Pertussis	54,406	2697	20.3
Haemophilus influenzae type b	361	334	13.7
Polio	1244	530	14.8
Measles	70,748	8877	57.3
Mumps	42,704	1361	0.2
Rubella	36,540	134	0.3
Congenital rubella syndrome	12	17	1.3
Hepatitis B	4007	623	59.7
Varicella	68,445	176	1.2
Pneumococcus-related diseases[b]	26,578	903	55.0
Rotavirus	11,968	327	0.1
Total	**322,089**	**21,055**	**731.7**

[a]Vaccines were considered as preventing disease for birth cohorts born in all years during 1994–2013 except for the following, which were only in use for part of the 20-year period: varicella, 1996–2013; 7-valent and 13-valent pneumococcal conjugate vaccines, 2001–13; and rotavirus, 2007–13.
[b]Includes invasive pneumococcal disease, otitis media, and pneumonia.

costs because of illnesses prevented in these birth cohorts. After accounting for $107 billion and $121 billion in direct and societal costs of routine childhood immunization, respectively, the net present values (net savings) of routine childhood immunization from the payers' and societal perspectives were US$295 billion and US$1.38 trillion, respectively.[159]

Immunization has consistently ranked as one of the most effective and cost-effective clinical preventive services available.[160]

CONCLUSION

Development and use of vaccines in the United States has had a profound effect on the occurrence of vaccine-preventable diseases. The success represents a blend of public-private and federal, state, and local partnerships. Measles, rubella, and polio remain eliminated as indigenous diseases in the United States, and large declines in other diseases for which routine vaccination is recommended have been seen. Childhood vaccination coverage levels have remained high for many years with small or no disparities by race and ethnicity. The number of children receiving no vaccines has remained less than 1% since 2006.

There are numerous challenges. During the past 20 years, the number of vaccine-preventable diseases of childhood has doubled, from eight to 16. Since 2004, vaccines against influenza, hepatitis A, meningococcal disease, rotavirus, and HPV have been routinely recommended for children and/or adolescents. In addition, an adolescent booster has become available for pertussis, a second dose of varicella vaccine has been recommended, and a new vaccine for zoster is recommended for all adults older than 60 years. Assuring financial barriers to access are removed, sustaining high coverage among children, and attaining high levels of coverage among adolescents and adults will be major challenges for the next several years as the U.S. immunization system works to achieve the Healthy People 2020 immunization objectives.

Sources of Additional Information

There are numerous sources of information about U.S. vaccines, immunization recommendations, and immunization systems, including the following:

- The CDC has a comprehensive website that includes information about ACIP, vaccines, vaccine-preventable diseases, immunization programs, communication and health education materials, and data and statistics about disease and coverage rates: https://www.cdc.gov/vaccines.
- Official package inserts. Manufacturers provide product-specific information with each vaccine; some of these circulars are reproduced in their entirety in the *Physicians' Desk Reference* (a new edition published annually can be obtained at http://www.PDRBookstore.com).
- *Morbidity and Mortality Weekly Report*. This report is published weekly by the CDC. ACIP statements are usually published in separate *Recommendations and Reports* supplements to the weekly publication. Current and back issues are available at https://www.cdc.gov/mmwr.
- *Red Book*: The Report of the Committee on Infectious Diseases of the American Academy of Pediatrics. The full report containing recommendations on all licensed vaccines is usually updated every 2 to 4 years, and updates are provided on the Red Book's Internet site: http://aapredbook.aappublications.org.
- *Health Information for International Travel* (the Yellow Book). This book is published every other year by the CDC as a guide to requirements and recommendations for specific immunizations and health practices for travel to various countries. It can be obtained by telephone at 800–545–2522 or from the publisher at http://www.us.elsevierhealth.com. A comprehensive and frequently updated resource for travel information is available at https://www.cdc.gov/travel. This site includes an online version of the Yellow Book. Advisory notices for international travel are also available at https://www.cdc.gov/travel.
- *Control of Communicable Diseases Manual*. This manual is published by the American Public Health Association at approximately 5-year intervals; the 19th edition (2008) is currently available. The manual contains valuable information concerning infectious diseases, their occurrence worldwide, immunization, diagnostic and therapeutic issues, and up-to-date recommendations on isolation and other control measures for each disease presented. It is available through Internet booksellers.
- State and local health departments, medical schools, and large hospitals. Many of these agencies or institutions provide routine immunizations, immunization cards, and schedules to patients. They may also send out routine reports of disease incidence. Internet sites for state and local immunization programs are available at https://www.cdc.gov/vaccines/partners.htm.
- The TFCPS (http://www.thecommunityguide.org) has published structured reviews of evidence for interventions to improve public health. These reviews cover universally recommended immunizations for children and adults and

targeted vaccination of children and adults at high risk of vaccine-preventable diseases or their complications.

- The CDC National Center for Immunization and Respiratory Diseases (NCIRD) has established toll-free numbers for answering questions from the general public and providers: 800–232–4636. Inquiries can also be addressed to the CDC by e-mail (nipinfo@cdc.gov).
- The Internet serves as a rich source of immunization information for providers, health officials, and the general public. The CDC maintains a list of immunization partner websites at https://www.cdc.gov/vaccines/partners.htm.
- The Department of Health and Human Services provides Internet resources for the public concerning vaccines and influenza at http://www.vaccines.gov and http://www.flu.gov, respectively.

74 Immunization in Europe

Kari Johansen, Dina Pfeifer, and David Salisbury

OVERVIEW

Europe is composed of a diverse group of countries and the extent of diversity depends on the definition of the boundaries of Europe. The European Union (EU) comprises 28 Member States of Austria, Belgium, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden, and the United Kingdom. The EU together with the three Member States of the European Economic Area (EEA) (Iceland, Lichtenstein, and Norway), has a population of approximately 500 million people (birth cohort ≈5 million and population under 15 years ≈75 million). The World Health Organization (WHO) European Region has a population of approximately 900 million (birth cohort ≈11 million and population under 15 years ≈160 million) and includes the EU/EEA countries and 23 others: Albania, Andorra, Armenia, Azerbaijan, Belarus, Bosnia and Herzegovina, Georgia, Israel, Kazakhstan, Kyrgyzstan, Monaco, Republic of Moldova, Montenegro, Russian Federation, San Marino, Serbia, Switzerland, Tajikistan, Former Yugoslav Republic of Macedonia, Turkey, Turkmenistan, Ukraine and Uzbekistan. While Lichtenstein is not a Member State of the WHO European Region, it along with other territories participates in elimination and eradication activities for vaccine-preventable diseases. The European Region covered in this chapter is defined by the countries from which the WHO collects annual data through the WHO and the United Nations Children's Fund (UNICEF) (WHO/UNICEF) Joint Reporting Form (JRF).[1]

The diversity of the European Region is reflected not only in the cultures and languages but also by economies and health systems. The countries of Europe have some of the highest per capita incomes in the world but in 2014 also include two lower-middle income countries with gross national income per capita of less than US$1500 (Kyrgyzstan (GNI US$1250) and Tajikistan (GNI US$1060).[2] This results in substantial diversity in the health systems among European Region countries and has contributed to the wide variation of immunization programs including which vaccines are offered and at what age. This makes it difficult to share experiences on best practices, but also imposes obstacles when individuals move between countries. Examples of variations in schedules are shown in the recommendations for when pertussis- or measles-containing vaccines are offered (Figs. 74.1 and 74.2).[3]

Vaccines for routine immunization in the European Region must have a Marketing Authorization prior to introduction into national immunization programs. Vaccines may be licensed nationally by respective national regulatory agencies or centrally by the European Medicines Agency (EMA) that was created in 1995 and serves the 31 EU/EEA countries. In the EU/EEA, most vaccines licensed since 1995 are authorized through the centralized procedure. Furthermore, batch testing of vaccines is controlled through EU legislation (for details, see Chapter 80).[4] Where the regulatory capacity for medicines is limited or when vaccines are procured through the UNICEF mechanism, countries are encouraged to engage in an assessment and accelerated national registration of WHO-prequalified pharmaceutical products and vaccines.[5]

All countries in the European Region have national mechanisms for setting immunization policy. However, in a number of countries, local and regional governments or health insurance providers have policies and programs that differ from those recommended at the national level.

To date, immunization policy or practice has not been subject to EU legislation for harmonization and EU/EEA countries do not have common immunization policies although there are agreed targets for influenza vaccination coverage of the elderly population.[6] Recommendations at the national level are supported by infectious disease surveillance and by the WHO Regional Office for Europe in collaboration with the European Centre for Disease Prevention and Control (ECDC), as well as with provision of scientific advice from the two organizations. Increased collaboration between the two organizations is being taken forward.

POLICYMAKING PROCESSES IN EUROPEAN COUNTRIES

In 2014, 26 Member States of the EU/EEA had National Immunization Technical Advisory Groups (NITAGs). Austria, Cyprus, Italy, Norway and Sweden did not. Of the non-EU/EEA countries in the Region, 17 countries had a NITAG. Monaco, Russian Federation, San Marino, Serbia, Tajikistan and Turkmenistan did not report having a NITAG in 2014. Efforts are underway to establish such independent recommendation-making entities in all countries in the region. The majority of the existing committees do have a legislative basis for making vaccine recommendations to the government. The effect of the recommendations varies according to how immunization programs are organized (centralized or decentralized) and the balance between public and private sector provision of services. The following examples demonstrate how immunization policy is made and implemented in selected countries with markedly different systems.

In Sweden, the national immunization schedule is recommended centrally by the government but local health authorities have the freedom to select among products having valid market authorization and may introduce vaccines before national recommendations are adopted. The cost of immunization services and vaccines are covered from regional public funds. Vaccines are offered through public well-baby clinics up to the age of 6 years, and thereafter through school-based preventive clinics.

In some countries, such as Germany and Spain, federal states (Germany) or the autonomous communities (Spain) are responsible for protecting public health. Although these countries have national advisory committees, their recommendations can be modified at the regional level and the vaccines actually provided depend on the choice of private practitioners and the reimbursement arrangements with governments and/or insurance companies.

The health system in Germany is decentralized with most responsibilities for public health resting with the sixteen federal states. Recommendations on vaccine use are made by the Standing Committee on Vaccination, which reports to the Ministry of Health through the Robert Koch Institute, a federal agency that oversees national surveillance and prevention

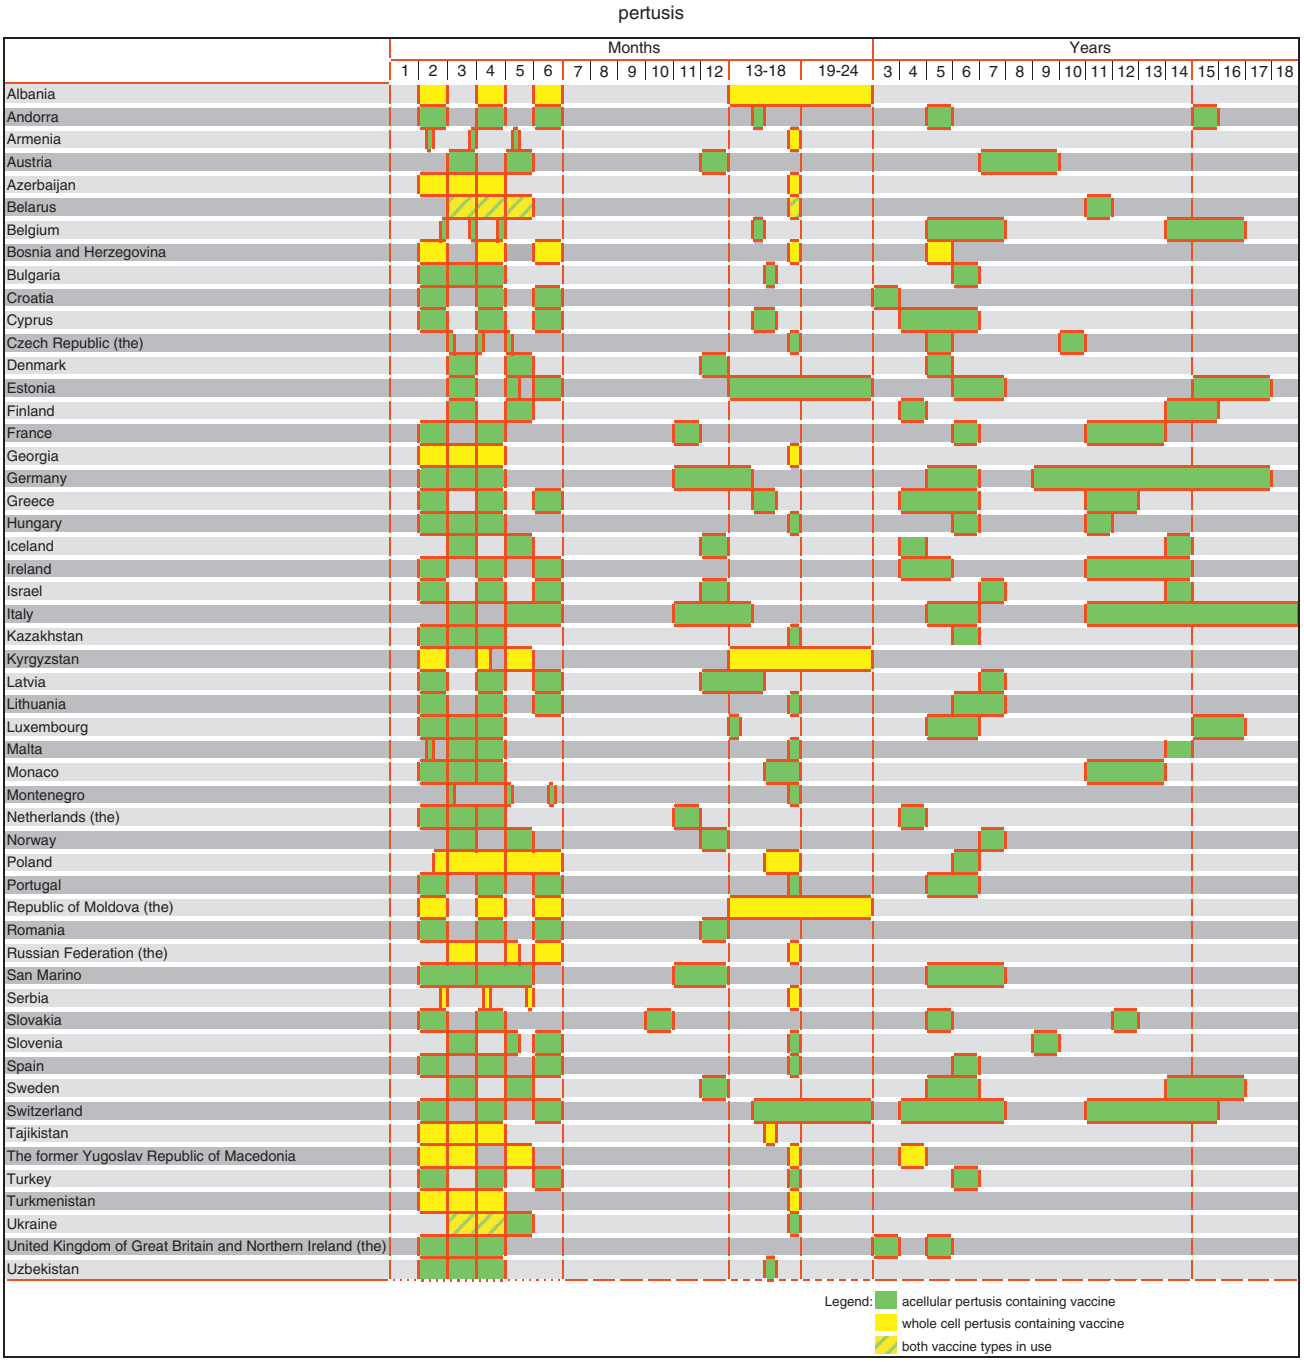

Figure 74.1. Pertussis-containing vaccine immunization schedules up to 18 years of age per country in region of Europe in 2014. *(From WHO vaccine-preventable diseases: monitoring system. 2016 Global summary. Available at: http://apps.who.int/immunization_monitoring/globalsummary/schedules.)*

activities for communicable diseases.[7] However, Standing Committee on Vaccination recommendations need to be approved by each federal state before being implemented.

Decisions regarding reimbursement for vaccination in Germany are made by each of the more than 400 insurance plans, almost all of which are statutory and predominantly financed through payroll taxes. Physicians bill the patient's insurance plan for services provided. Only 10% of vaccines are paid for by the federal states through special programs. The other 90% are primarily covered by the statutory insurance plans. The federal government sets requirements for which health services are mandatory, but vaccinations are not currently among these mandatory services.

France has a national level immunization technical advisory committee, Comité technique des vaccinations, set up by decree. It has voting and nonvoting members. This committee proposes the immunization schedule annually to the Directorate General for Health at the Ministry of Social Affairs, Health and Women's Rights that is responsible for management of the committee and implementation of its recommendations. Some vaccinations remain mandatory (polio, diphtheria, tetanus). Approximately 85% of childhood vaccinations are

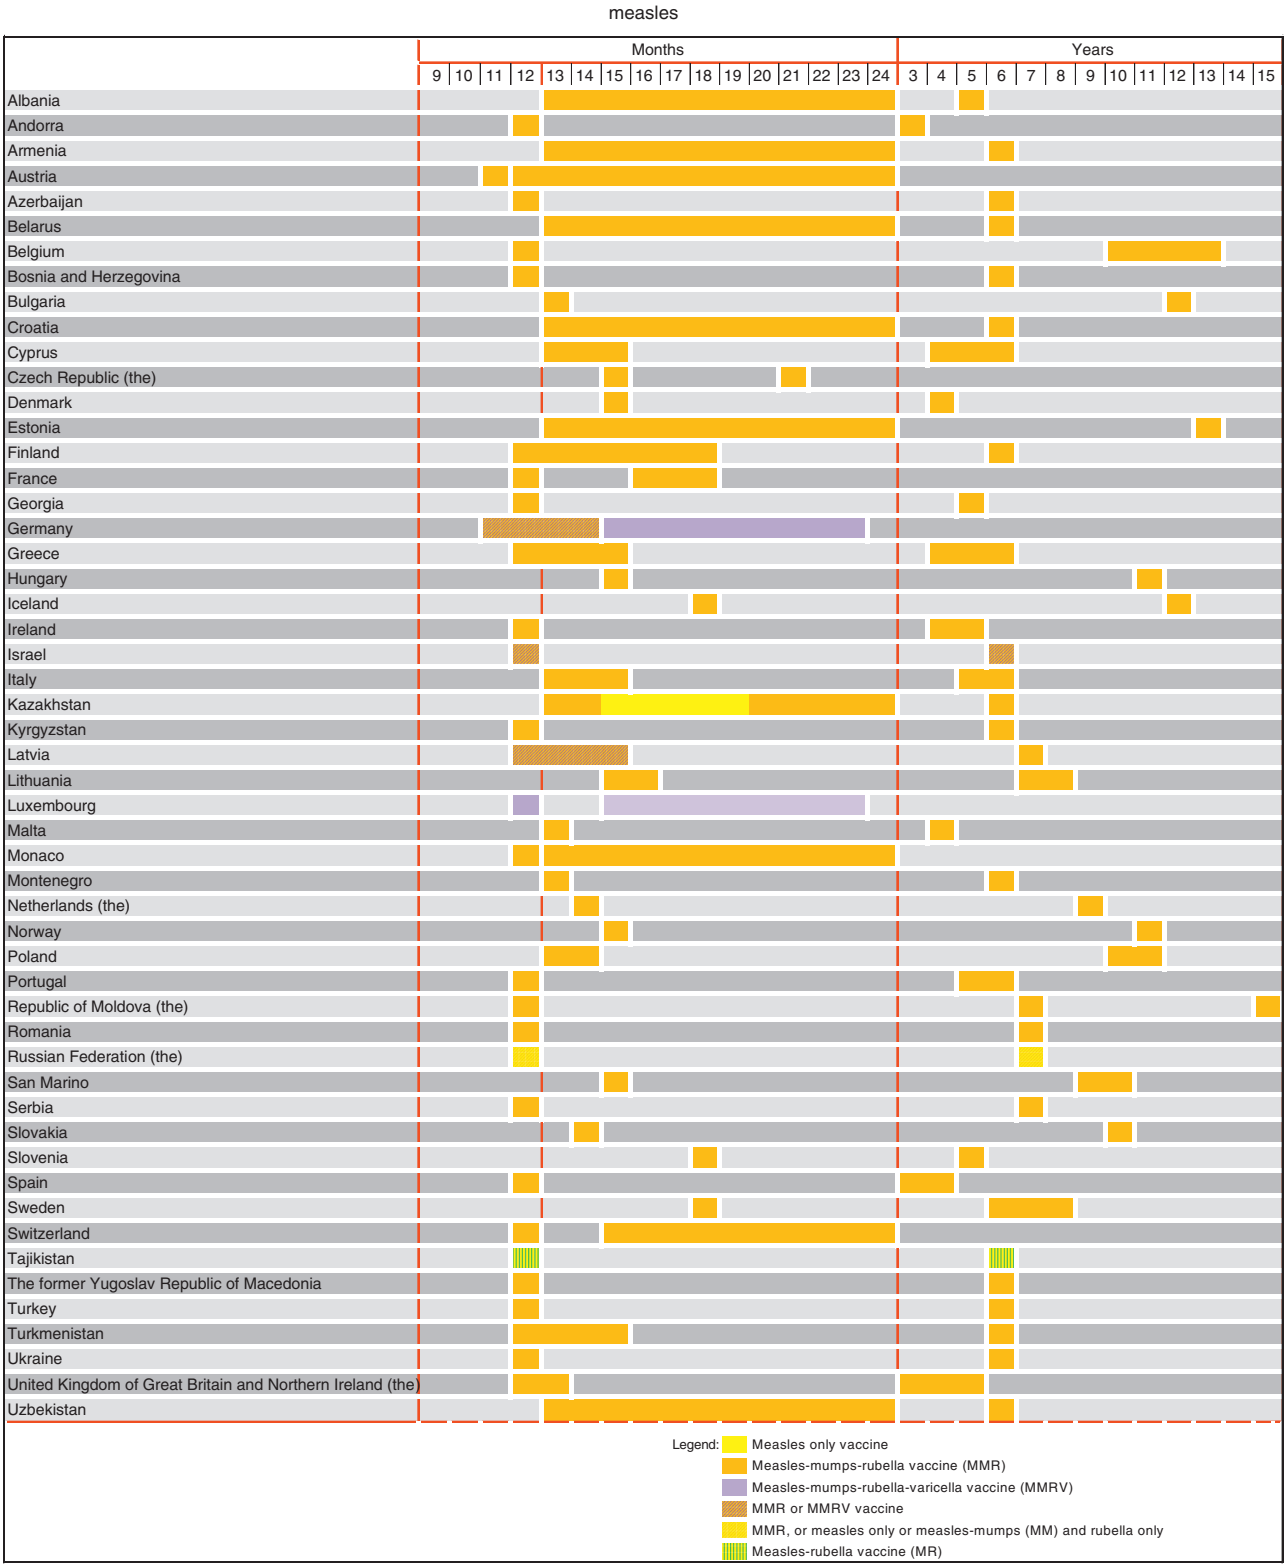

Figure 74.2. Measles-containing vaccine immunization schedules up to 15 years of age per country in region of Europe in 2014. *(From WHO vaccine-preventable diseases: monitoring system. 2016 Global summary. Available at: http://apps.who.int/immunization_monitoring/globalsummary/schedules.)*

performed by private sector pediatricians with the remainder provided by public maternal and child health clinics where most vaccinations are free. Parents claim reimbursement for paid-for vaccinations in the private sector either through their voluntary complimentary health insurance or through the Social Security Scheme. Measles-mumps-rubella (MMR) and influenza vaccinations for those in recommended groups are free, irrespective of where they are provided. Physicians in the private sector choose which products to offer to patients.[8] In 2012, the Directorate developed a national strategy to improve the immunization program in France over a 5-year period. The foci of the new policies are simplifying the immunization schedule, facilitating access to immunization services, and improving monitoring and evaluation of the program performance.[9]

The United Kingdom has a centralized health system in which the National Health Service (NHS) provides universal comprehensive health services, including immunization. The Chief Medical Officers within the health departments of England, Wales, Scotland, and Northern Ireland are responsible for coordinating and providing health-related advice to the government. Routine immunization services are provided by general practitioners in primary care or by nurses in school settings.

In the United Kingdom, the Joint Committee on Vaccination and Immunisation (JCVI), a statutory committee independent of the Department of Health, makes recommendations to the Secretary of State for Health for England and to the devolved administrations in Wales, Scotland, and Northern Ireland; thus policy is implemented similarly in each of these countries. There is a joint procurement process so that the same vaccines are provided in all of the United Kingdom. JCVI recommendations must have the approval of the Chief Medical Officers before they are submitted to the respective health minister and/or secretary of state for approval for implementation. In England, under the provisions of the Health Protection (Vaccination) Regulations 2009,[10] which implements the NHS Constitution in England, following a request for advice by the Secretary of State, the JCVI must make recommendations relating to new provision for vaccination (other than relating to travel or occupational health) under a national program. It also makes recommendation to change existing provisions under such a program, based on an assessment that demonstrates cost-effectiveness. The Secretary of State for Health is obliged to fund such recommendations. Once national funding has been agreed upon, implementation arrangements are taken forward, with all four countries implementing the new policy in the same way and almost always at the same time. Efforts are made to ensure that all localities make changes to their immunization programs simultaneously, facilitated by the existence of national conformity of immunization computing arrangements that call up children for their immunizations, chase defaulters, pay providers, and measure coverage. Local providers have very little discretion in whether to accept or modify national recommendations. Before implementation, consultation takes place with the representatives of the primary care providers because changes in policy can have consequences for the remuneration of physicians.

For many years, some vaccinations under national immunization schedules were considered mandatory under respective infection control legislations. These regulations are now being modified in a number of countries. In 2010, the Vaccine European New Integrated Collaboration Effort (VENICE) network conducted a survey in the EU/EEA to learn whether national vaccination programs were recommended or were mandatory.[11] Information was collected from all 29 EU/EEA Member States. Fifteen countries did not have any mandatory vaccinations; the remaining 14 had at least one mandatory vaccination included in their program. Vaccination against polio was mandatory for both children and adults in 12 countries; diphtheria and tetanus vaccinations were mandatory in 11 countries and hepatitis B vaccination in 10 countries. Some Member States consider mandatory vaccination to be a way of improving compliance with vaccination programs. However, compliance with recommendations is high in many programs in Europe without being mandatory. For countries with mandatory vaccination there is little evidence of any punitive action being taken against those who choose not to accept vaccination although the law may allow for it. Orders not to attend school during outbreaks are implemented in, for example, Germany, to contain spread of vaccine-preventable diseases, a strategy proven effective to increase uptake in some communities refraining from vaccination.[12]

There are fewer differences in the immunization policymaking processes in the non-EU/EEA countries of the region. Most countries have centralized policymaking processes, public sector programs and state procurement. In the eastern part of the region, in Albania and Armenia, for example, the national immunization schedule is also recommended centrally by the government, based on the recommendation of the NITAG and implemented through the immunization system managed by the government. Vaccines are centrally procured and paid from the national budget. In Georgia, the immunization policy is also set by the government but the services are delivered through privatized health insurance schemes.

In the absence of a national immunization technical advisory group, and if there are no identified experts in a country, the national immunization program's manager makes recommendations on vaccine introduction, primarily based on WHO recommendations, and the Ministry of Health makes the final decision. The WHO Regional Office for Europe is working with such member states to establish or enhance NITAGs to strengthen the policymaking process.

In addition, the European Region is experiencing an increasing involvement of the private sector in pediatric and adult immunization programs, for example, in Georgia, Greece, Spain and Turkey. The same is true for most European countries with regard to travel vaccines.

ORGANIZATIONS WORKING IN IMMUNIZATION IN THE EUROPEAN REGION

Box 74.1 lists the organizations and institutions working on immunization in the European Region.

WHO Regional Office for Europe

The WHO Regional Office for Europe (located in Copenhagen, Denmark) has overarching responsibility for developing immunization policies suitable for all 53 member states. The first WHO European Technical Conference on the control of infectious diseases through vaccination programs was held in Rabat, Morocco in 1959.[13] When the Expanded Programme on Immunization (EPI) was launched by WHO in 1974, most European Region countries had already successfully prevented outbreaks of serious childhood diseases such as poliomyelitis and diphtheria, through national immunization programs. Thus, the European Region considered participation in the EPI to be a low priority. This changed in the early 1980s when the member states were all signatories to the regional Health for All Strategy by the Year 2000.

In 1984, the second Conference on Immunization Policies in Europe was held in Karlovy Vary, Czechoslovakia. Participants reviewed the status of immunization programs,

BOX 74.1 Organizations and Institutions Working on Immunization in the European Region

WORLD HEALTH ORGANIZATION (WHO) REGIONAL OFFICE FOR EUROPE

The WHO Regional Office for Europe is responsible for developing immunization policies for 53 member states of the European Region. The WHO Vaccine-Preventable Diseases and Immunization Programme (VPI) coordinates regional immunization and vaccine-preventable diseases activities by providing normative guidance, policy advice, and technical support to the 53 member states ensuring that populations are protected from vaccine-preventable diseases, disability, and death through strong and sustainable immunization systems. European Technical Advisory Group of Experts on Immunization (ETAGE) serves as an advisory body to provide independent review and expert technical input to the WHO European Region's Vaccine-Preventable Diseases and Immunization Programme, with the objective of facilitating and accelerating achievements of the regional targets.

UNICEF REGIONAL OFFICE FOR CENTRAL AND EASTERN EUROPEAN AND COMMONWEALTH OF INDEPENDENT STATES (UNICEF CEE/CIS)

UNICEF CEE/CIS provides support to 22 countries and entities in Central and Eastern Europe, Caucasus, and Central Asia. It works with partner agencies to strengthen country health systems to achieve and sustain universal, high-quality, equitable, and sustainable immunization services. UNICEF advocates for the maintenance of immunization as a public health intervention available to all, particularly for the vulnerable and marginalized populations.

EUROPEAN UNION (EU)

European Commission (EC)

Directorate General for Health and Food Safety (DG SANTE). Directorate General for Health and Food Safety (DG SANTE) support EU countries in maintaining or increasing rates of vaccination against vaccine-preventable diseases and encouraging EU countries to ensure that as many children as possible receive the main childhood vaccines. According to article 168 of the treaty establishing the European Community, the EC may address proposals on measures to protect and improve human health to the council, which in turn may adopt the recommendations made by a qualified majority.[28]

Directorate General for Research and Innovation (DG RTD). The Directorate General for Research and Innovation coordinates European-funded health research. It has prioritized funding in the fields of infectious diseases: poverty-related diseases (HIV/AIDS, tuberculosis, malaria), neglected infectious diseases, antimicrobial drug resistance, and potentially new or re-emerging infectious diseases. Research on new vaccines and adjuvants has been funded under this group.

Joint Undertaking—Innovative Medicine Initiative (IMI). The Innovative Medicines Initiative (IMI) is working to improve health by speeding up the development of, and patient access to, innovative medicines, particularly in areas where there is an unmet medical or social need. It does this by facilitating collaboration between the key players involved in healthcare research, including universities, the pharmaceutical and other industries, small and medium-sized enterprises (SMEs), patient organizations, and medicines regulators. IMI is a partnership between the European Union (represented by the European Commission) and the European pharmaceutical industry (represented by EFPIA, the European Federation of Pharmaceutical Industries and Associations) co-funded through the Horizon 2020 program and the member manufacturers of the EFPIA.

EU Agencies

European Centre for Disease Prevention and Control (ECDC). ECDC identifies, assesses, and communicates current and emerging threats to human health posed by infectious diseases. To achieve this mission, ECDC works in close partnership with national public health bodies across the European Union to strengthen and develop disease surveillance and early warning systems and to produce authoritative scientific opinions about the risks posed by new and emerging infectious diseases. Through projects, with additional scientific advice panels, ECDC provides policy makers in the EU/EEA Member States with solid and scientifically sound evidence for Member States' decision-making processes.

European Medicines Agency (EMA). The European Medicines Agency is responsible for the scientific evaluation of medicines developed by pharmaceutical companies for use in the European Union. Under the European centralized procedure, companies submit a single marketing-authorization application to the European Medicines Agency (EMA). Once granted by the European Commission (EC), a centralized marketing authorization is valid in all EU/EEA Member States. All medicines for human and animal use derived from biotechnology and other high-tech processes, including vaccines, must be approved via the centralized procedure. The European Medicines Agency monitors vaccine safety through a pharmacovigilance network (Eudravigilance) and takes appropriate actions if adverse reaction reports suggest that the benefit-to-risk balance has changed since it was authorized. The Pharmacovigilance Risk Assessment Committee (PRAC) is responsible for assessing all aspects of the risk management of medicines, including vaccines, for human use. The Agency's Committee for Medicinal Products for Human Use (CHMP) prepares scientific guidelines in consultation with regulatory authorities in the EU/EEA Member States, to guide marketing-authorization applications as well as to provide harmonisation of quality, safety and efficacy requirements.

Consumers, Health, Agriculture and Food Executive Agency (CHAFEA). The CHAFEA implements the EU Health Programme, the Consumer Programme and the Better Training for Safer Food Initiative. The third Health Programme is the European Commission's main instrument for implementing the EU health strategy (http://ec.europa.eu/chafea/health/). The Health program funds projects and other actions (conferences, operating grants) aimed at improving the level of health and well-being of EU citizens and reducing health in equalities throughout the European Union including projects in the field of vaccine programs.

OTHER ORGANIZATIONS

Global Alliance for Vaccines and Immunization (GAVI)

Global alliance for Vaccines and Immunization supports GAVI-eligible countries in the European Region in the introduction of new vaccines, including *Haemophilus influenzae* type b, rotavirus, and pneumococcal vaccines. Funding has also been provided to GAVI-eligible countries for strengthening immunization services, conducting burden-of disease studies, strengthening injection safety, and developing comprehensive multiyear plans for immunization programs.

established immunization targets, determined necessary actions, and reinforced the commitment of member states to the goals and activities of the EPI. The conference became a turning point for strengthening region-wide coordinated immunization activities. The recommendations of the conference also strengthened the responsibility of the Regional Office.

The dramatic political and socioeconomic changes that occurred before, during, and after the dissolution of the Soviet Union compromised the ability of the newly independent states to produce or provide vaccines for disease-control and immunization programs through transforming health systems and hence WHO has prioritized the countries in the eastern part of the European Region for special attention. The reemergence of diphtheria in the 1990s, widespread measles outbreaks during the early 2000s, and an outbreak of wild poliovirus in 2010 are examples of the special needs in these countries.[14–17]

The European Advisory Group on the Expanded Programme on Immunization (EAG) was created in 1986 to facilitate the development of the regional immunization program. It effectively guided the program and facilitated and accelerated the achievements of the regional targets specified in the Health21 policy framework.[18] The EAG particularly provided direction for the revision of immunization policies in the newly independent states, reviewed diphtheria control strategies, and supported poliomyelitis elimination from the European Region. The EAG's terms of reference were revised to respond to major changes of member states' health systems as well as to the evolution of vaccine-preventable diseases epidemiology and the European Technical Advisory Group of Experts (ETAGE) was established in 2003. A further revision was made to ETAGE's operations in 2011 in order to better align them with that of the parent advisory committee at the global level, the Strategic Advisory Group of Experts on Immunization (SAGE), and with regional policies such as Health 2020.[19] Members of ETAGE are individuals acknowledged for their expertise in immunization and who are independent of WHO.[20] They are chosen from across the European Region through an appointment process similar to that used by SAGE. ETAGE meets at least once a year.

ETAGE serves as a forum for regular review of immunization services' performance in the Member States of the European Region, with special attention to the progress being made toward the vaccine-preventable disease control targets and objectives, especially identifying any constraints, obstacles, and threats. ETAGE engages in technical discussion and formulates recommendations on operational aspects of immunization policies and strategies, as well as incorporating new scientific developments. It provides technical support to NITAGs, and offers a forum for discussion on implementation of SAGE recommendations within the European Region context.[21]

The Regional Certification Commission for Poliomyelitis Eradication (RCC) is an independent panel of international experts established in 1996. Since the certification of the European Region as polio free in 2002,[22] the terms of reference of the Commission have been modified with a focus on sustaining the polio-free status, providing national risk assessments, and ensuring rapid action following any wild polio virus introduction or identified shortfalls of national polio programs. The RCC also monitors poliovirus containment and contributes to global polio elimination certification in line with objective 3 of the Global Polio Eradication and Endgame Strategic Plan 2013–2018.[23] The RCC meets annually or whenever necessary and its reports are publically accessible.[24]

The Regional Verification Commission for Measles and Rubella Elimination is also an independent panel of experts, established in 2012, tasked with determining whether endemic transmission of measles and rubella continues or has been interrupted in each Member State, based on annual updates submitted by national verification committees. Regional and national verification committees use a standardized review methodology and reporting requirements.[25] Annual assessments consider information about measles and rubella epidemiology, virological surveillance data, supported by molecular epidemiology, analyses of vaccinated population cohorts, the quality of surveillance and the sustainability of the relevant national immunization program.

WHO immunization-related activities in the European Region are encompassed in three strategic areas: strengthening of immunization systems, accelerated control of vaccine-preventable diseases, and associated laboratory-based surveillance. Crosscutting activities include performance monitoring, communications, data collection, and data management. The Vaccine-preventable Diseases and Immunization Programme publishes guidelines and technical documents, ensures routine interactions with national immunization program managers, and facilitates sharing of experiences, achievements, and constraints in attaining the regional targets. The Regional Office has developed surveillance guidelines for selected vaccine-preventable diseases. It collects information on acute flaccid paralysis cases (weekly, all member states); measles and rubella cases (monthly, all member states); diphtheria cases (monthly, 16 member states); rotavirus (quarterly, 8 member states); invasive bacterial diseases (quarterly, 5 member states); and influenza (weekly, 53 member states).

Since 1998, the WHO and UNICEF jointly collect annual disease surveillance and immunization data using a standardized questionnaire, the WHO/UNICEF JRF. National immunization programs complete the JRF and describe various aspects of their program, including vaccine schedules, vaccine financing, coverage rates achieved for each of the vaccines, reported vaccine-preventable disease incidence, and indicators of program performance. WHO and UNICEF jointly produce the best estimates of coverage from the data reported in the JRF as well as using other sources provided by the member states. All member states of the WHO European Region use this form to report annual vaccine coverage rates and incidence for vaccine-preventable diseases to the WHO Regional Office for Europe. Comparisons of immunization schedules by disease, antigen, and age for the WHO European Region countries are available from WHO/UNICEF JRF website.[1]

All the reported data are used for monitoring and evaluation and are disseminated through the region using the Centralized Information System for Infectious Diseases (CISID) and are aggregated for global reporting through WHO Headquarters. EU/EEA member states' data are submitted through the ECDC platform "European Surveillance System (TESSy)" and forwarded to the CISID platform to avoid double reporting. Feedback is provided monthly to member states on polio, measles, and rubella data, and quarterly reports are prepared for rotavirus and invasive bacterial diseases (meningitis/pneumonia/sepsis caused by infections caused by *Neisseria meningitidis*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*). A monthly publication, "WHO EpiData," and a quarterly bulletin, "WHO EpiBrief," provide feedback to all member states on trends and surveillance performance indicators toward elimination or maintenance of eradication status.[26] "Flu News Europe" is a weekly online publication on influenza surveillance jointly produced by ECDC and the Regional Office throughout the northern hemisphere winter season, from week 40 until week 20 of the following year.[27]

The Regional Office works closely with GAVI, the Global Alliance for Vaccines and Immunization, which has been an important partner for introducing new vaccines in GAVI-eligible countries in the European Region. Eleven countries

received support during the first 4 years of GAVI. In 2006, the number of GAVI-eligible countries decreased to eight (Armenia, Azerbaijan, Georgia, Kyrgyzstan, Republic of Moldova, Tajikistan, Ukraine, and Uzbekistan); in 2014 there are two GAVI-eligible countries (Kyrgyzstan and Tajikistan) and six graduated countries (Armenia, Azerbaijan, Georgia, Republic of Moldova, Ukraine, and Uzbekistan). WHO and GAVI provide technical support following graduation, with special focus on strategic planning, and strengthening national vaccine procurement and regulation systems to enable access to quality assured vaccines at affordable prices.

UNICEF Regional Office for Central and Eastern European and the Commonwealth of Independent States

The UNICEF Regional Office for Central and Eastern Europe and the Commonwealth of Independent States (UNICEF CEE/CIS) provides support to 21 countries and one territory in Central and Eastern Europe, the Caucasus, and Central Asia through its field offices. While working towards attaining regional immunization coverage and disease control targets, UNICEF's focus areas are generating evidence on immunization programs through field assessments toward ensuring adequate and reliable vaccine supplies and effective vaccine management while building capacity and strengthening country health communication systems to maintain and restore public trust in immunization.

European Union Institutions

Several EU institutions play a role in immunization. The European Commission, through the Directorate General for Health and Food Safety (DG SANTE, after the French denomination) can provide support to the implementation of national vaccine programs. DG SANTE is supported in this area by three European Agencies: the ECDC, the EMA, and the Consumers, Health, Agriculture and Food Executive Agency (CHAFEA).

According to Article 168 (ex art. 152) of the treaty establishing the EU,[28] the European Commission may address proposals on measures to protect and improve human health to the Council of the EU, which, in turn, may adopt the recommendations made by a qualified majority. The first example of such a legislative initiative in the area of human immunization is represented by the *Council Recommendation 2009/1019/EU of 22 December 2009 on seasonal influenza vaccination*.[6] In this recommendation, the EU Parliament and the EU Council have encouraged Member States to adopt and implement action plans or policies aimed at improving seasonal influenza vaccination coverage with the aim of reaching a vaccination coverage rate of 75% in elderly and other high-risk groups, and to improve vaccination coverage among healthcare workers. During the 2009 influenza pandemic, DG SANTE (at that time DG SANCO) played an active role in developing a common EU vaccination strategy and coordinating the overall public health response through the influenza subgroup of the Health Security Committee. This first Council recommendation was followed by a council conclusion on *Childhood immunisation: successes and challenges of European childhood immunisation and the way forward*.[29] Of importance going forward for all vaccination programs in the EU are the new *Council conclusions on vaccinations as an effective tool in public health* of 1 December 2014[30] addressing, among other things, the changes in the epidemiology of childhood diseases preventable by vaccination, and the observed shift towards older age groups, the importance of vaccination providing life-long protection, and not only vaccination for children. Furthermore, EU Member States are invited to conduct catch-up campaigns to improve the control of specific diseases. Finally, the Conclusions call upon the European Commission with ECDC and the EMA to (a) identify guidance and methodologies that might strengthen Member States' immunization programs, and (b) support the evaluation of risk communication and improving vaccine uptake strategies by Member States by putting forward appropriate research methods.

The ECDC, based in Stockholm, Sweden, became operational in 2005, with the aim of strengthening Europe's defences against infectious diseases, including vaccine-preventable diseases. The ECDC and the WHO Regional Office for Europe have established a close working relationship, with reciprocal participation on management and technical advisory committees.

To strengthen surveillance within the EU, a network for the epidemiologic surveillance and control of communicable diseases was established by Decision 2119/98/EC of the European Parliament and the Council of Europe in 1999.[31] This led to the creation of a number of surveillance networks funded by the European Commission to coordinate national data into an EU-wide system: the European Laboratory Working Group for Diphtheria, the EU Invasive Bacterial Infections Surveillance, which included *H. influenzae* and meningococcal infections; and the Surveillance Community Network for Vaccine Preventable Infectious Diseases, which included measles, rubella and pertussis. All the tasks previously conducted under these networks have since 2012 been transferred to the ECDC. Currently, 49 notifiable infectious diseases from 31 EU/EEA countries are reported to the ECDC TESSy database. Surveillance data are published in ECDC annual reports and increasingly on the website in almost real-time.[32,33] Eighteen of the communicable diseases are vaccine-preventable: cholera; diphtheria; *H. influenzae* type b causing invasive disease; hepatitis A; hepatitis B; *N. meningitidis* types A, B, C, W135, and Y causing invasive disease; influenza (seasonal, avian, and pandemic); measles; mumps; pertussis; poliomyelitis; rabies; rubella; smallpox; *S. pneumoniae* causing invasive disease; tetanus; tick-borne encephalitis; and tuberculosis. As of 2015, ECDC is not yet conducting surveillance for the following vaccine-preventable diseases: human papillomavirus (HPV), rotavirus, and varicella infections.

The ECDC has an established program on vaccine-preventable diseases running specific projects in partnership with European experts and national public health institutions. Priority areas and criteria for funding specific actions are set out in a work plan that is published every year and is followed by specific calls for proposals. The following network projects have been funded from 2008 and onwards.

The *VENICE II project* was launched in 2006 with the general aim of collecting and sharing information on national vaccination programs, initially through a network of professionals, and later through official nominations by EU/EEA countries. The VENICE network had been initiated earlier but was transferred in 2006 to ECDC. VENICE has for example provided vaccine coverage data by country in support of the above mentioned Council Recommendation 2009/1019/EU of 22 December 2009 on seasonal influenza vaccination, and timely updates on pandemic influenza vaccine coverage by country.[6,34] Another activity is documenting which countries have introduced new vaccines and, as mentioned earlier, to document which vaccines are mandatory and recommended in individual countries.[11] Their reports are available to the public and most data collected are published in the scientific literature.[11,35]

The *I-MOVE project* (Influenza—Monitoring Vaccine Effectiveness) was established to estimate seasonal and pandemic influenza vaccine effectiveness in 19 EU/EEA Member States

using test-negative design case-control and cohort studies. Vaccine effectiveness estimates have been provided since the 2008–09 season and presented to the annual WHO strain selection meeting and reported in the scientific literature.[36,37]

A further network, *SpiDNet*, was created for surveillance of invasive pneumococcal disease in the EU and to assess the impact of the conjugate vaccines on the incidence and severity of the disease among children younger than 5 years of age; it was initiated in 2012.[38] The project aims to measure pneumococcal vaccine effectiveness in Europe.

A small network for surveillance of rotavirus disease in the EU was created in 2011 to assess rotavirus vaccine effectiveness in Europe.[39]

The *VAESCO network* (Vaccine Adverse Events Surveillance and Communication) was initiated in 2009 with the aim of improving the quality of vaccine safety information in the EU by standardizing methods for association studies, facilitating data comparability, and building collaborative networks. The network has not received funding since 2013. The VAESCO network included nine EU/EEA countries that are able to conduct studies using large databases (e.g., hospital records, vaccine registries) that can be pooled and crosslinked. The ultimate goal of the project was to be able to provide background rates of adverse events of interest, such as Guillain-Barré syndrome, and to perform specific epidemiologic studies following detection of a vaccine safety signal using the VAESCO platform. Vaccine safety signals can either be raised by a Member State or through reports of national medicines regulatory agencies to the Eudravigilance database, a pharmacovigilance platform of EMA. The EMA Pharmacovigilance Risk Assessment Committee (PRAC) formally assesses any vaccine safety signal, and should pharmacoepidemiological studies be needed, the network may provide support. During and after the 2009 influenza pandemic, background rates for Guillain-Barré syndrome were developed and analyzed in a multicountry study[40] and after a safety signal of narcolepsy following vaccination with Pandemrix was detected, an incidence study using data linkage of the participating databases and a case-control study were conducted to assess the safety signal.[41,42] The future of such studies is currently under evaluation.

Through all of these projects, ECDC has built a large resource base that is complemented by additional scientific advice produced with internal and external expertise (ad-hoc scientific panels). Several guidance documents have been produced on influenza, HPV, varicella and diphtheria-tetanus-pertussis (DTP) vaccination.[43–46] In addition, risk assessments of threats to public health in the EU/EEA by vaccine-preventable diseases are conducted.[47] ECDC conducts risk assessments regularly and for vaccine-preventable diseases has published risk assessments on wild poliovirus when identified in environmental samples (2014), a pertussis-containing vaccine shortage (2015), as well as a shortage of diphtheria anti-toxin antibodies for treatment of toxigenic diphtheria (2015).[48–50]

ECDC hosts a website named *Vaccine Schedule*.[51] The Vaccine Schedule is an interactive platform of vaccination schedules of individual EU/EEA countries and is available for use by both health professionals and the general public.

ECDC publishes *Eurosurveillance*, a journal devoted to the epidemiology, surveillance, prevention, and control of communicable diseases.

An older EU network, the European Sero-Epidemiology Network (ESEN) established in 1996 through funding from the European Commission to coordinate and harmonize serologic surveillance of immunity to vaccine-preventable diseases, continued its work until 2014, eventually involving 18 Member States. Immunity to diphtheria, hepatitides A and B, measles, mumps, pertussis, rubella, tetanus, and varicella was assessed in selected populations.[52] This network showed significant immunity gaps in European populations against diseases such as diphtheria, measles, and rubella.[53–55]

The EMA is located in London, United Kingdom and became operational in 1995; it is responsible for the scientific evaluation of medicines including vaccines developed by pharmaceutical companies for use in the EU. The EMA works closely with national regulatory agencies; vaccine products can still be authorized nationally and can be recognized in other EU/EEA Member States through a mutual recognition procedure.[56]

The Agency's Committee for Medicinal Products for Human Use prepares scientific guidelines, in consultation with regulatory authorities in the EU/EEA Member States, to guide marketing-authorization applications as well as to provide harmonization of quality, safety, and efficacy requirements. Examples of particular importance are guidelines for dossier structure of influenza vaccines or vaccine adjuvants for human use.[57,58] More detail on the functions of the EMA can be found in Chapter 80.

The EMA monitors vaccine safety through a pharmacovigilance network (Eudravigilance database). The PRAC is responsible for assessing all aspects of the risk management of medicines, including vaccines, for human use. This includes the detection of signals, risk assessment, mitigation, and communication relating to the risk of adverse reactions, while taking the benefit-to-risk balance into account. It also has responsibility for the design and evaluation of post-authorization safety studies and pharmacovigilance audits. PRAC monitors effectiveness of risk-management systems that generate information for regulatory decision making. The PRAC also generally provides recommendations to the Committee for Medicinal Products for Human Use, the Co-ordination Group for Mutual Recognition and Decentralised Procedures-human (CMDh), the EMA secretariat, the Management Board, and the European Commission, as applicable.

The CHAFEA is located in Luxembourg and became operational in a smaller format in 2005. CHAFEA in its current form was created on January 1, 2015. CHAFEA implements the EU Health Programme, the Consumer Programme, and the Better Training for Safer Food initiative. The Third EU Health Programme is the European Commission's main instrument for implementing the EU health strategy and has four overarching objectives: (a) promote health, prevent diseases, and foster supportive environments for healthy lifestyles taking into account the "health in all policies" principle; (b) protect Union citizens from serious cross-border health threats; (c) contribute to innovative, efficient, and sustainable health systems; and (d) facilitate access to better and safer healthcare for Union citizens. The program has provided funding to support the development of prevention, vaccination, and immunization policies and to improve partnerships, networks, tools, and reporting systems for immunization status and adverse events monitoring.[59]

The EU supports research and development in health. European-funded health research is coordinated by the Directorate General for Research and Innovation. Horizon 2020 is an EU Research and Innovation program with nearly €80 billion of funding available over 7 years (2014 to 2020), in addition to the private investments that this money will attract. The goal is to support European research institutions reaching scientific breakthroughs, remove barriers to innovation, and make it easier for the public and private sectors to work together in delivering innovation. Research collaborations on new vaccines and adjuvants such as ADITEC, universal influenza vaccines, and Ebola vaccines have been funded under this stream.

Horizon 2020 contributes funding to the Innovative Medicine Initiative research program, a public and private partnership (joint undertaking) equally cofunded by the European Commission and the member manufacturers of the European Federation of Pharmaceutical Industries and Associations.[60] The main priority of the Innovative Medicine Initiative research agenda is to tackle the major challenges in drug development—including vaccines—with a specific focus on evaluating safety and efficacy. According to Vaccine Europe (earlier called the European Vaccine Manufacturers Association), 79% of their global production comes from the European Region, with a 47% growth in research and development investment over the past 8 years, and approximately 50% of current research and development projects based in the EU.[61,62] Five large vaccine-related projects have been funded in the last few years; PROTECT (Pharmacoepidemiological Research on Outcomes of Therapeutics funded in 2009), ADVANCE (vaccine benefit-risk assessments funded in 2013), Correlates of Protection for influenza funded in 2014, support to Ebola vaccine development funded in 2014, and pertussis vaccination research funded in 2015.

PROCUREMENT

Procurement of vaccines in EU/EEA countries may be undertaken by governments as public sector provision of vaccines—that are usually free to recipients; through private sector arrangements—where there may be full or partial reimbursements of costs; or through a mix of these arrangements. In non-EU countries, nearly all procurement of vaccines used under national immunization schedules is through government or public sector central arrangements. The role of the private sector in supporting immunization services is reportedly increasing in areas such as logistics and service delivery as countries move to decentralize public administration and health services, and phase out immunization as vertical standalone programs, anchoring it within general medical practice. The vaccine supply systems vary from very centralized public procurement and distribution systems to completely decentralized systems where each immunization site contracts with a private supplier for vaccines. Provision of paid private immunization services has significantly increased in central and eastern Europe and in the newly independent states since the turn of the present century, picking up an increasing role in meeting the demands of specific population groups.

National budget lines for routine immunization vaccine procurement exist in 42 of the European Region countries, most covering full costs of the recommended routine schedule.[3] Member states reporting less than 100% government funding for vaccines procurement reflect either financial or in kind contributions of GAVI or funding though insurance schemes. Immunization as per national schedule is available free of charge or against reimbursement through health insurance in all Member States of the Region, with some optional vaccines provided against copayment or full reimbursement by health insurance.

UNICEF plays a critical role in vaccine procurement in almost all GAVI-supported and GAVI-graduated countries (Armenia, Azerbaijan, Georgia, Kyrgyzstan, Republic of Moldova, Tajikistan, and Uzbekistan), as well as some other countries in the European Region that have specific considerations or difficulties in procuring vaccines. Some national legislation on public procurement allows contracting for the current calendar year only, which, in turn, may lead to difficulties securing stable vaccine supplies. The vaccines procured by UNICEF are not necessarily produced and registered in Europe, but all have been prequalified by the WHO.

There has been increasing conformity of the vaccines being used in European countries, diminishing the differences that used to occur between EU and former Soviet Union countries. However, there are considerable differences in the prices that are paid.[63] The EU countries tend to pay full industrialized country prices, subject to national procurement arrangements where centralized contracts might achieve better prices than private-sector purchasing. Countries with smaller to mid-range size of relevant cohorts frequently report problems negotiating prices and a lack of interest from suppliers to apply to vaccine procurement tenders, which often results in vaccine prices that exceed considerably the ones achieved by EU member states. Recently, the WHO Regional Office for Europe has been working closely with middle-income countries (those with a gross national income [GNI] per capita of more than US$1045 but less than US$12,736 in 2014) to ensure equitable access to vaccines at affordable prices. There is an ongoing review of different schemes, including tiered pricing and pooled procurement.

The 2009 influenza pandemic highlighted the differences in procurement arrangements for vaccines in Europe. Based on assessments of risks of H5N1 influenza viruses being the likely cause of the next pandemic, one half of the EU countries had made arrangements with vaccine-producing companies for access to pandemic vaccines through advance-purchase agreements. Under these arrangements, as soon as a pandemic was declared by WHO, production of seasonal vaccines would stop and production would switch to pandemic vaccine. Countries with advance-purchase agreements in place would then benefit from the first deliveries of production of the pandemic vaccine. Countries that had contracted for advance-purchase agreements paid monthly fees to vaccine companies; these fees were to cover ongoing research by the companies and to reserve production capacity when a pandemic occurred. When the 2009 H1N1 pandemic began, countries that did not have advance-purchase agreements were obliged either to wait for the second phase of pandemic vaccine production after the advance-purchase agreements had been fulfilled or to apply to WHO for access to its influenza A (H1N1)pdm09 vaccine supplies. Azerbaijan, Georgia, Republic of Moldova, and Tajikistan received vaccine through WHO donations.

There were considerable differences in the quantities of vaccine that were ordered through advance-purchase agreements. Austria, Sweden, Switzerland, and the United Kingdom committed to two vaccine doses per head of population and other countries had smaller orders. Poland chose not to have an advance-purchase agreement and not to seek supplies of influenza A (H1N1)pdm09 vaccine after the onset of the pandemic. Eastern European countries received their vaccine supplies much later than the western countries. Following the 2009 pandemic, EU member states asked the European Commission to investigate mechanisms that would permit a more equitable sharing of access to vaccine in a future pandemic so that less-affluent countries did not have to be as disadvantaged as they had been in 2009. The Commission investigated the opportunities ranging from central procurement for EU countries to joint contracting arrangements by like-minded countries and production of purchasing guidelines to help countries doing their own procurement. The European Commission issued an assessment report on EU-wide pandemic vaccine strategies in August 2010. The efforts have since continued and an EU/EEA-wide joint procurement mechanism for all countermeasures, including pandemic vaccines, is now in place, supported by legislation in the event of serious cross-border threats.[64] This should provide stronger negotiating power, lower costs, and equitable access, and would help to create a common understanding of liability issues. The triggering mechanisms of switching from seasonal influenza vaccine to

pandemic vaccine is currently being further defined by the WHO, and will include risk assessments of the severity of clinical cases, transmissibility in human populations, the epidemiological situation, and the characterization of the emerging influenza virus. Other issues to be addressed include dealing with excess doses, economic sanctions for delayed delivery of vaccines, liability should a safety concern arise, and conditions under which a contract becomes void.

SURVEILLANCE OF VACCINE-PREVENTABLE DISEASES IN THE EUROPEAN REGION

The responsibility for surveillance of vaccine-preventable diseases lies with individual countries. Within the countries, some vaccine-preventable diseases are statutorily reportable (measles in the United Kingdom, Germany, Kazakhstan), some are collected nationally on a voluntary basis (pneumococcal infection in the United Kingdom and the Netherlands), and others are kept under surveillance through sentinel systems (influenza in the United Kingdom and France, rotavirus in Ukraine, invasive bacterial diseases in Azerbaijan and Uzbekistan).

The ECDC and the WHO Regional Office for Europe have undertaken a review of diseases under epidemiologic surveillance and the case definitions used. This has resulted in strengthened surveillance systems for vaccine-preventable diseases within the European Region through the availability of information on a broader range of diseases, using mutually agreed upon case definitions and reducing the duplication of reporting by Member States.

For polio surveillance, 43 of 53 member states of the European Region, including 21 of 30 EU/EEA countries, conduct surveillance for acute flaccid paralysis (AFP) and report weekly to the Regional Office. The number of countries abolishing traditional AFP surveillance is increasing in an era of widespread use of advanced imaging techniques and molecular biology technologies that help establish a diagnosis in much shorter timeframe than is required for virus isolation. Thirty-nine countries conduct enhanced enterovirus surveillance and 22 conduct environmental surveillance through sewage collection (Fig. 74.3). A WHO polio laboratory network of 48 laboratories located in 37 countries undergo annual accreditation. In addition, four regional reference laboratories (Berlin, Bilthoven, Paris, and Rome) and three of the global polio reference laboratories (Bilthoven, London, Moscow) are located in the WHO European Region.[65]

Measles is notifiable in all 53 member states. Countries report clinically diagnosed measles cases to the WHO annually through the WHO/UNICEF JRF. In accordance with regional surveillance guidelines, 38 countries report case-based information to WHO monthly. The Regional measles and rubella laboratory network was established in 2002 and consists of 72 laboratories: one global (London), three regional (Luxembourg, Berlin, and Moscow), 48 national, and 20 subnational laboratories.

Fifty-one of the 53 member states, including all EU/EEA countries, conduct measles surveillance. All data are stored and disseminated using the CISID (the WHO European Region database).[66] National and regional reference laboratories provide a WHO measles and rubella regional laboratory network for genotyping viruses and sharing these data for identifying circulating viruses and monitoring progress toward elimination.[67]

Reporting of rubella cases at the national level is mandatory in 43 of the 53 Member States. Of these, 34 have case-based surveillance at the national level, and the reporting scheme is similar to the one described for measles. Belgium, Denmark, and France do not have mandatory notification systems covering the total population for reporting rubella cases. Germany introduced a national rubella notification system in 2013, which became operational in 2014. Intense efforts are under way to strengthen rubella surveillance in the region. Some countries face difficulties justifying the additional expense of comprehensive surveillance for measles and rubella given the current scarcity of funding for health and the nature of national health funding priorities.[68,69]

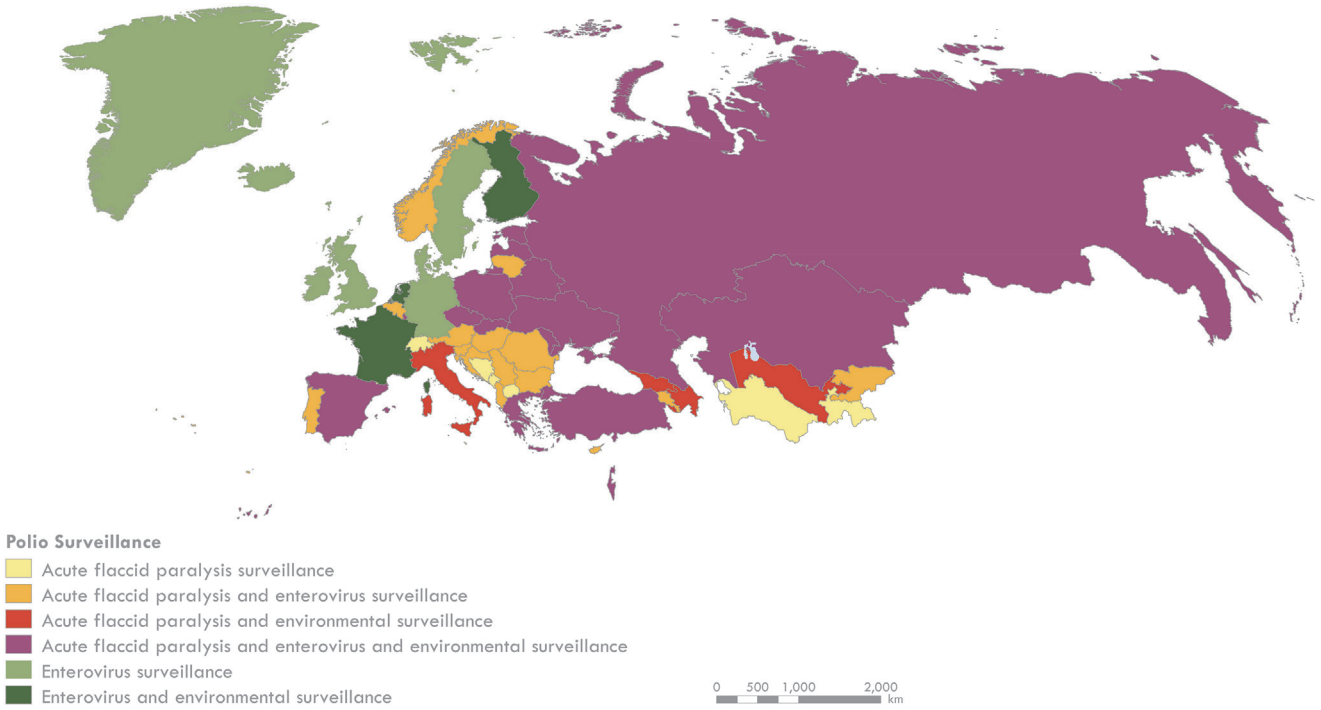

Figure 74.3. Types of polio virus surveillance in WHO Region of Europe in 2014.

All EU/EEA member states have surveillance for invasive bacterial diseases caused by *N. meningitidis, S. pneumoniae,* and *H. influenzae.* The WHO European Regional Office is working with eastern European countries and newly independent states to establish and strengthen the invasive bacterial diseases surveillance network, currently comprising laboratories in seven countries to monitor circulating serotypes.

The WHO European Regional Office has also established a rotavirus surveillance network for eastern European countries with a regional reference laboratory based in Minsk, Belarus. Surveillance for rotavirus in the western part of the region already exists through a regulatory requirement on the two manufacturers (Eurorotanet).[70,71] Rotavirus accounts for a substantial proportion of hospitalizations for diarrhea in the seven countries in the WHO network.

European member states had a target to eliminate indigenous diphtheria by 2000 (the absence of indigenous cases caused by toxigenic *Corynebacterium diphtheriae* strains). ECDC has since assumed diphtheria surveillance for the EU/EEA countries along with 16 non-EU/EEA countries, including Belarus, Republic of Moldova, Turkey, Ukraine; all eastern European countries report monthly to the Regional Office.

VACCINES USED AND IMMUNIZATION COVERAGE IN THE EUROPEAN REGION

The vaccines and immunization schedules used in the 53 countries of the European Region are undergoing continuous change with the introduction of new antigens and the increasing use of combined-antigen vaccines. Annual information is collected from WHO Member States on immunization programs and vaccine-preventable diseases using the WHO/UNICEF JRF as part of the global data collection jointly conducted with UNICEF.[1] The information for a given year is collected during the spring of the following year and usually is available by the autumn. The data referred to in this chapter are those available to the Regional Office on immunization programs for 2014.[3] For information on specific countries, the reader is encouraged to access the WHO website.[3] Table 74.1 provides summary information on childhood vaccines provided through routine national immunization systems. Other vaccines may be in selective use, either for specific risk groups, in selected geographical areas, by parental choice, for outbreak management or in relation to travel. Vaccines that have obtained NITAG recommendation but are pending introduction are not reflected in the overview.

The measurement of immunization coverage in the European Region is challenging because of the wide range of techniques employed for data collection in individual countries resulting in issues with data quality and comparability. ECDC, through the VENICE network, started the European Vaccine Coverage Project (EVACO) in 2011.[72] The main aim of this project is to provide reliable and standardized vaccine coverage data in the EU/EEA. A standard for data collection has been agreed on and a piloting phase has been concluded.

The methods for assessing coverage include collecting data manually or electronically by the administrative method (doses reported administered divided by estimates of the target population), conducting surveys at regular time intervals of selected populations, or use of electronic immunization registers. All three methods are used in the European Region and the number of countries with electronic immunization registries is increasing. In Denmark, Finland, Ireland, Israel, the Netherlands, Norway, and the United Kingdom, public health data are fully computerized and actively managed; thus coverage is calculated by comparing the number of children who have completed immunization by a specified age with the number of children of the same age residing in the particular community—coverage by birth cohort. Another 13 countries are known to have local registries: Belgium, Estonia, Germany, Hungary, Iceland, Italy, the Netherlands, Portugal, Romania, Spain, and Sweden.

In Austria, Belgium, France, Greece, and Spain, where the private-sector providers give many immunizations, coverage is calculated by comparing the number of doses of vaccine imported or distributed with the estimated target population. In these countries, allowances for wastage and inaccuracies in the target population make these coverage estimates unreliable.

In non-EU countries, administrative coverage is usually reported as the number of doses administered in each locality divided by the estimated target population. Inaccuracies can occur in the estimates of the numerators and denominators because of inaccurate census data and facilities incorrectly determining their catchment population. Many countries also routinely conduct household surveys, such as the Demographic Health Surveys or Multiple Indicator Cluster Surveys. These data are used in calculating the best estimate by WHO and UNICEF.

In most countries, coverage is measured at 2 years of age, but in Germany it is measured at school entry, usually at 5 years of age, through data held by insurance providers. Because countries use such different techniques for estimating coverage and with variable accuracy, comparisons among countries' coverage reports should be made with caution.

There are three schedule patterns for the primary immunizations in the region. The Netherlands and the United Kingdom use a three-dose early-onset schedule with vaccination at 2, 3, and 4 months of age, as do Azerbaijan, Bulgaria, Georgia, and Kazakhstan. Belgium, Ireland, and Switzerland used a three-dose middle-onset schedule at 3, 4, and 5 months of age or 2, 4, and 6 months of age. Most of these three-dose priming schedules offer a booster dose during the second year of life. France and Slovakia use a two-dose early schedule at 2 and 4 months of age with a third dose as booster administered at 10 to 11 months of age. Austria, Denmark, Finland, Norway, Sweden, Iceland, and Italy use a two-dose late schedule, whereby doses are recommended at 3 and 5 months of age and a third dose as a booster is given around the first birthday (see Fig. 74.1).

Diphtheria, Tetanus, and Pertussis Vaccines

Thirty-nine (74%) of the 53 countries in the European Region use acellular pertussis antigens in their DTP vaccines for primary childhood immunization; the remaining 14 countries use whole-cell pertussis vaccines (see Fig. 74.1).

The weighted WHO/UNICEF estimated vaccine coverage in 2014 for the third dose of DTP by 1 year of age was 95% among the 45 countries that reported. The eight countries not reporting coverage estimates in 2014 were Austria, Czech Republic, Finland, Germany, Israel, Monaco, Poland, and Ukraine.

Recognition of the increasing pertussis burden in young infants has prompted provision of acellular containing vaccines to pregnant women.[72,73] Routine maternal immunization against pertussis has been initiated in Ireland, Portugal, Spain, Switzerland, and the United Kingdom.[74]

Haemophilus influenzae Type B Vaccine

Fifty-two countries (98%) have national programs for *Haemophilus influenzae* type b (Hib) vaccine. Belarus has not introduced the vaccine into the routine schedule; however the vaccine is available as a monovalent product for risk groups.

TABLE 74.1 Vaccines Included in Routine National Immunization Schedules Up to 18 Years of Age in 2014[a]

[a]Risk group recommendations not included.
[b]Part of country.
aP, acellular pertussis vaccine; BCG, bacillus Calmette-Guérin; Hib, *Haemophilus influenzae* type b; HPV, human papilloma virus; IPV, inactivated polio vaccine; MenACWY, meningococcal ACWY vaccine; MenC conj, meningococcal C conjugated vaccine; OPV, oral polio vaccine; TBE, tick-borne encephalitis; wP, whole-cell pertussis vaccine.
From WHO vaccine-preventable diseases: monitoring system. 20165 global summary. Available at: http://apps.who.int/immunization_monitoring/globalsummary/schedules.

In the past, not all the countries using Hib vaccine had used a three-dose primary series followed by a booster in the second year of life. Both the United Kingdom and Ireland initially used only a three-dose primary series; both subsequently introduced a booster dose and undertook catch-up programs for children younger than 5 years of age following detection of an increase in cases of invasive Hib disease among children older than 1 year.[75,76]

In 2006, the United Kingdom augmented its routine schedule to include Hib and meningococcal type C (Hib/MenC) combination vaccine, offered at 13 months of age, at the same time as the first MMR immunization. This provided a booster for both Hib and MenC primary vaccinations. The introduction of the Hib/MenC booster allowed the reduction of the number of primary series MenC vaccine doses from three (2, 3, and 4 months of age) to two doses (3 and 4 months of age). The first two doses of pneumococcal conjugate vaccine (PCV) are given at 2 months and 4 months of age with a third dose at 12 to 13 months of age. From summer 2014, only a single dose of MenC vaccine is given in the primary series at 3 months of age.

In 2014, 30 countries had a three-dose Hib primary series with a booster in the second year of life. Of the remaining countries, 12 gave three doses of Hib containing vaccine by 6 months of age and no booster; nine gave the two-dose primary series and a booster at 12 months of age; and the Ukraine's schedule recommends Hib-containing vaccines at 3, 4, and 18 months of age.

Hepatitis B Vaccine

Among the 53 European Region countries, 48 have universal immunization programs for hepatitis B and 18 have universal administration of a birth dose. Malta provides a series of monovalent hepatitis B vaccinations in the second year of life; Slovenia provides hepatitis B vaccine as an option during infancy but the immunization is considered mandatory by school entry; Hungary and Switzerland immunize adolescents. The remaining countries (Denmark, Finland, Norway, Sweden, and the United Kingdom) recommend hepatitis B vaccine in programs for high-risk groups. As a consequence of a change of the multicomponent vaccine product used in the Danish national immunization program in 2014, hepatitis B vaccine was temporarily provided with the primary series in infancy. Iceland does not use hepatitis B vaccine.

Human Papillomavirus Vaccine

HPV vaccine is recommended for use in 31 European Region countries including 23 EU/EEA countries (Austria, Belgium, Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Luxembourg, Malta, the Netherlands, Norway, Portugal, Romania, Slovenia, Spain, Sweden, United Kingdom) and eight non-EU/EEA countries (Andorra, Israel, Kazakhstan, Monaco, Russian Federation [part of the territory], San Marino, Switzerland, and the former Yugoslav Republic of Macedonia) (Fig. 74.4).

There is no preference for type of vaccine: eight countries use both bivalent and quadrivalent vaccine. Only Austria recommends the inclusion of males for routine immunization. HPV vaccination is provided in schools in the United Kingdom, in nine of the 19 autonomous communities in Spain, Israel, Ireland, Kazakhstan, Sweden, and in the former Yugoslav Republic of Macedonia. The highest coverage rates are reported from countries using school-based immunization. Most countries have offered the vaccine in catch-up programs, although there are differences in the upper ages covered. Costs to vaccinees range from free for all female vaccinees through school-based programs in Denmark, to reimbursement through insurance in Germany, and with copayment in Belgium and France. Monitoring for impact on cervical cancer is being established in some countries.

The introduction of HPV vaccination into national schedules in Europe was reviewed in a VENICE II survey in 2010.[46,77]

Figure 74.4. Human papillomavirus vaccination in routine immunization program. *(Modified from WHO/UNICEF Vaccine-preventable Diseases Monitoring System Global Summary 2016. Available at: http://apps.who.int/immunization_monitoring/globalsummary/schedules.)*

Of the countries that reported coverage in 2009, two (Portugal and the United Kingdom) reported more than 80% for the third dose; Denmark, France, Italy, Luxembourg, and Norway reported coverage from 17% to 58%. France reported that 23% of the primary target group had received three doses of vaccine by December 2010. HPV vaccination was introduced in Spain in 2007 with immunization provided in schools or in health centers; higher coverage was reported from the schools and third-dose coverage was 77%. Health center–based immunization was implemented in the Netherlands, but only 53% of the 13- to 16-year-old girls of the 2009 cohort were vaccinated.

Over the period of 6 years starting from introduction of HPV vaccine in 2008, the annual coverage in the United Kingdom for the third dose ranged from 77.5% to 85.9%; the Netherlands reported coverage of 60.7% with three doses in 2014 and Germany estimates coverage with three doses to be just below 40% with higher uptake in older teenage cohorts.[78–80] Conversely, Ireland had higher uptake in first-level secondary schools age 12 to 16 years of age (84.9%) compared to sixth grade 16 to 18/19 years of age (44.6%) in 2013–14.[81] While public health authorities are addressing obstacles to achieving higher uptake, early surveillance data from Denmark and Sweden are noting substantial reduction of cervical lesions and genital warts respectively at the currently achieved coverage levels.[82,83]

Influenza Vaccine

The WHO Regional Office for Europe, in partnership with the VENICE Collaboration and the ECDC, conducted a comprehensive survey on seasonal influenza vaccine policies and vaccination uptake (2008–09 and 2009–10 seasons) among all 53 Member States of the Region.[84] Forty-seven countries (89%) responded to the survey. Of these, 37 countries (79%) had influenza vaccine recommendations for the elderly and eight countries recommended vaccination for all adults without specific reference to elderly populations. Of the 37 countries that recommended vaccination of the elderly, 29 (78%) had mechanisms in place to monitor uptake for this specific population group.[84] Of the 47 countries responding to the survey, 18 countries recommended vaccination for children, 41 recommended influenza vaccination for all or some healthcare workers, and 29 recommended vaccination of pregnant women.[84] In an updated survey conducted following the 2012–13 season, no significant changes were observed in EU/EEA countries.[85]

Vaccination coverage for elderly populations for the seasons 2008–09 and 2009–10 ranged from 0.2% to 83%, with only one country reaching a 75% coverage target for the elderly.[84] A more recent report by ECDC for the 2012–13 season showed vaccination coverage rates between EU/EEA varied from 1% to 77.4%, with only the Netherlands having reached the 75% target, followed closely by the United Kingdom.[85] Finally, the VENICE III study outcomes on influenza vaccination provided for 2013–14 and 2014–15 show little change in coverage.

Most countries used either administrative coverage measurement or surveys to determine coverage rates; however, coverage by the different target groups is not available in all countries. The coverage among healthcare workers was known in 13 countries, ranging from 9.5% in Poland to 45.6% in England with a median of 28%.[85] The coverage for clinical risk groups was reported by nine countries ranging from 28% in Portugal to 80.2% in Northern Ireland, with a median of 50%.[85] The coverage for pregnant women in a subset of 10 countries ranged from 0.2% in Lithuania to 64.6% for all pregnant women in Northern Ireland (median: 16%).[85] The coverage for residents of long-stay care facilities was available in three countries: 71.1% in Slovakia, 73% in Ireland, and 89% in Portugal. In England, two-thirds of primary care physicians (general practitioners) report influenza vaccination coverage weekly using automated reporting systems that provide near real-time data by risk group. One hundred percent of general practitioners provide monthly data. National coverage data are also available by vaccination of type of healthcare worker and by locality.[86]

The United Kingdom introduced routine influenza vaccination of all children using live attenuated influenza vaccine in 2013. The program started with 2- and 3-year-old children and was extended to 4-year-old children the following year. Pilot programs of vaccination of school-age children have been implemented in a variety of settings (inner city, outer city, urban, and rural). Early results suggest that there have been reductions in influenza-like illnesses and respiratory infections in nonvaccinated groups in pilot localities.[87]

Measles, Mumps, and Rubella Vaccines

All countries in the European Region have routine two-dose measles vaccination programs.[3,88] By the end of 2014,47 countries (89%) used combined MMR vaccine; four used MMRV; the Russian Federation used MMR or measles only/measles-mumps with monovalent rubella vaccine; and Tajikistan used measles-rubella vaccine (see Fig. 74.2). Austria, France, Germany, Monaco, and Switzerland provide a second dose of measles-containing vaccine by 24 months of age. For 2014, the WHO/UNICEF estimated vaccine coverage for the first dose of measles-containing vaccine was 94% and 84% for the second dose in the European Region. Despite this high estimate of first-dose measles-containing vaccine coverage, there remain considerable local variations with pockets of low coverage in a number of countries. These coverage variations and consequent cohorts of susceptible individuals account for the continuing reports of measles outbreak, and to some extent rubella and mumps from European countries.

Meningococcal Vaccines

Sixteen Member States use meningococcal group C conjugate vaccines in their universal childhood immunization programs. Austria and Greece provide polysaccharide meningococcal ACYW vaccine to their adolescent populations. Cyprus, Finland, Israel, Kazakhstan, Latvia, Russian Federation, Serbia, Slovenia, the United Kingdom, and Uzbekistan use these vaccines for high-risk groups. The United Kingdom offers conjugate ACYW vaccine to teenagers and university students following a rise in group W135 infections.[89] The Czech Republic and United Kingdom introduced meningococcal B vaccine in 2015. Three doses are given in the United Kingdom at 2, 4 and 12 months of age. No catch-up campaign was implemented at the time of the launch of the program.

Pneumococcal Conjugate Vaccines

Thirty-six countries (68%) include PCVs in the national immunization schedule (Fig. 74.5). Those countries have been switching progressively from seven-valent vaccine to 10- or 13-valent vaccines. Some countries such as Denmark, Italy, and the United Kingdom use a three-dose schedule with doses at 2 to 3 and 3 to 6 months of age and a booster at 1 year of age; Bulgaria, Germany, Greece, and Turkey use a four-dose schedule. There does not appear to have been any difference in reported impact from the reduced dose schedules. The United Kingdom has reported high impact against strains of pneumococci contained in the seven-valent conjugate vaccine using a two-plus-one schedule, but has also reported

Figure 74.5. Pneumococcal conjugate vaccine (PCV) vaccination in routine immunization program. *(Modified from WHO/UNICEF Vaccine-preventable Diseases Monitoring System Global Summary 2016. Available at: http://apps.who.int/immunization_monitoring/globalsummary/schedules.)*

considerable increases in nonvaccine strains coincident with the immunization program. The United Kingdom switched to 13-valent conjugate vaccine in 2010 following a rise of the nonvaccine strains that emerged after the introduction of seven-valent vaccine. Eight years of PCV use in England and Wales has reduced the overall incidence of invasive pneumococcal disease by more than 50%. The herd protection induced by the seven-valent conjugate vaccine is continuing, and similar indirect protection is occurring from the additional serotypes covered by the 13-valent conjugate vaccine. There is, however, evidence of increasing invasive pneumococcal disease resulting from non–13-valent conjugate vaccine serotypes, particularly in children younger than 5 years of age in 2014.[90,91] Belarus, Croatia, Czech Republic, Iceland, Malta, Serbia, Slovenia, and Spain have recommendations only for vaccination of risk groups. Hungary introduced 13-valent vaccine in 2014 and Spain plans to introduce it in 2016.[51]

Polio Vaccine

The WHO/UNICEF estimated vaccine coverage for the third dose of polio vaccine (inactivated polio vaccine [IPV]/oral polio vaccine [OPV]) by 1 year of age was 95% for the European Region. Nine countries (17%) used OPVs for routine immunization of infants in 2014, compared to 16 in 2011. Eleven countries (21%) have a sequential IPV-then-OPV strategy and 33 (62%) use only IPV.[3,92] Following silent circulation of wild polio virus type 1 in Israel in 2013, the national immunization schedule that previously included IPV-containing vaccines at 2, 4, 6, and 12 months of age was amended with two additional doses of bivalent OPV (bOPV) at 6 and 18 months of age.[93] Countries that were using trivalent oral polio vaccine (tOPV) switched to inactivated polio vaccine (IPV) alone (Poland and Belarus) or bivalent oral polio vaccine (bOPV) in April 2016 and destroyed any residual tOPV stocks. Countries that had been using only tOPV were encouraged to introduce at least one dose of IPV into their schedules. Due to supply shortages, IPV introduction has been delayed in Moldova, Kyrgyzstan, Tajikistan, Uzbekistan, and Turkmenistan.[93a]

Rotavirus Vaccine

Rotavirus vaccine is recommended for routine use in Austria, Armenia, Belgium, Estonia, Finland, Georgia, Germany, Greece, Israel, Italy, Luxemburg, Norway, Republic of Moldova, the United Kingdom, and Uzbekistan (Fig. 74.6). Sweden has introduced the vaccine in two of 21 counties. Albania, Latvia, and Tajikistan introduced the vaccine in 2015. Impact data from Austria, Belgium, Finland, Spain and the United Kingdom all confirm high effectiveness as observed in non-European countries.[94,95]

Varicella Vaccine

Cyprus, Germany, Greece, Latvia, Luxemburg, Spain, Switzerland, and Turkey have recommendations for the use of varicella vaccine in their universal childhood immunization programs.[3,96] Iceland, France, Slovenia, and the United Kingdom use it among specific groups. To date, reliable data on coverage are not available.

Zoster vaccines for older individuals have been introduced in Austria, France, and the United Kingdom. Coverage in the first vaccinated cohorts of 70- and 79-year-old individuals in England are approximately 52%.[97]

CHALLENGES TO IMMUNIZATION IN THE EUROPEAN REGION

Vulnerable Groups

All countries in the European Region have persons and groups who are difficult to vaccinate because they are isolated from routine health services for reasons of culture, language, ethnicity, or frequent change of place of residence. These groups

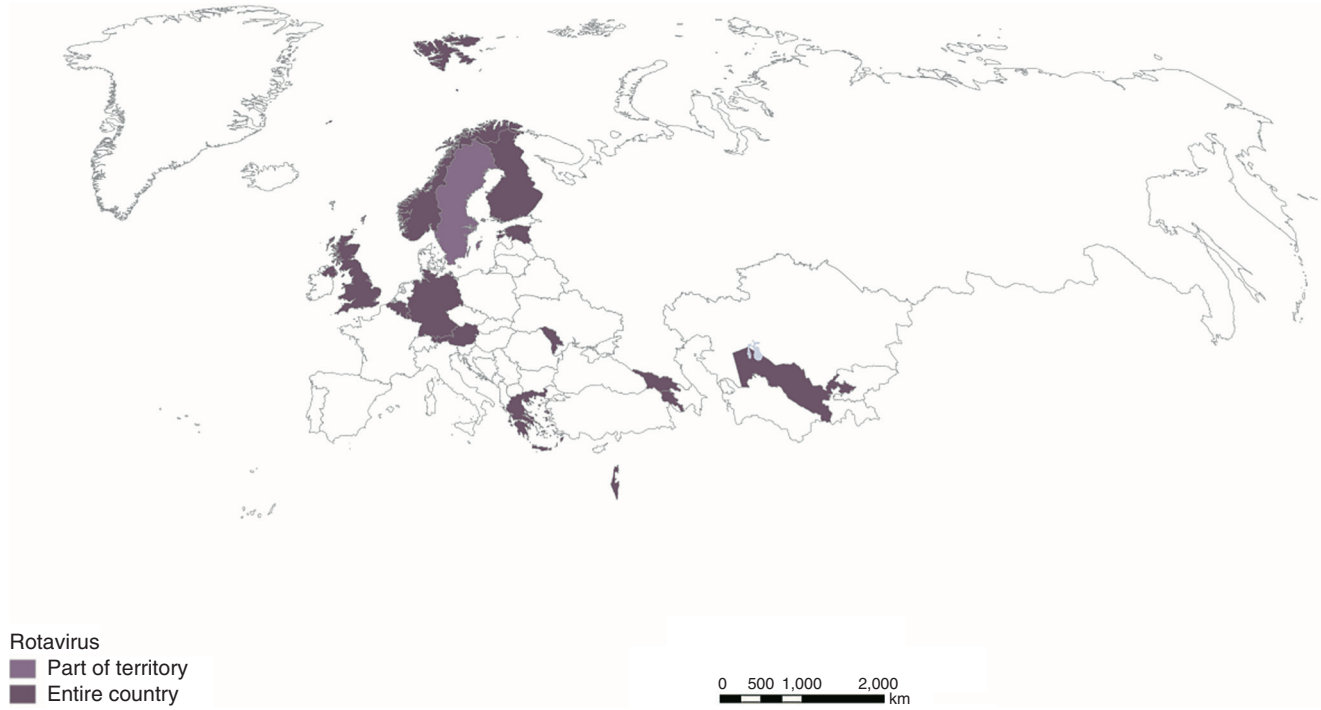

Figure 74.6. Rotavirus vaccination in routine immunization program. *(Adapted from WHO/UNICEF Vaccine-preventable Diseases Monitoring System Global Summary 2016. Available at: http://apps.who.int/immunization_monitoring/globalsummary/schedules.)*

include immigrants, asylum seekers, refugees, persons characterized as Irish Travelers, Roma, or gypsies, as well as migrant workers and their family members.[98] Outbreaks of measles and rubella have occurred among these groups in Greece, Germany, United Kingdom, Serbia, Spain, and a number of other countries in the European Region.[99–102]

It has been estimated that 6.8 to 8.9 million of the 12 to 15 million Roma living around the world live in Europe.[19] Most of the Roma are thought to live in Central and Eastern Europe but some Western and Northern European countries also have sizable populations. It is thought that many of these Roma might not have adequate access to or appropriately use health services available within the countries in which they live for a number of reasons, including personal knowledge and understanding, cultural practices, geographic isolation, and more systemic barriers within the health system.[19]

In 2009–11, the measles virus Hamburg D4 spread primarily within the Roma populations in a number of countries in the Region, including Bulgaria, Romania, Spain, and Turkey.[103] The ensuing nationwide outbreak in Bulgaria resulted in more than 24,000 cases and 24 deaths from measles-related complications.[104,105] This outbreak underscores the need to strengthen access to services among vulnerable populations, bringing vaccine to these populations through extended routine immunization or specifically targeted services. It is of concern that these groups also might not be adequately immunized against polio, tetanus, and diphtheria.

Vaccine Hesitancy

Clear trends are emerging related to vaccination coverage in Member States of the whole Region. After the creation of national immunization programs in the 1980s and 1990s, there was high acceptance of immunization as evidenced by the high immunization coverage rates reached (>90%) for most vaccines. However, in recent years the trend has been affected by fears over vaccine safety, public acceptance of mandatory immunizations, as well as other behavioral factors and determinants. The United Kingdom has had to deal with a long legacy of claims, not supported by scientific evidence, that MMR vaccine induced autism, resulting in over a decade of suboptimal MMR uptake.[106] In 2006, four deaths in Israel in temporal association with seasonal influenza vaccination led to a 25% decrease of vaccination coverage in the elderly compared to previous years and a marked increase of pneumonia deaths during the 2006–07 influenza season.[107] Anecdotal reports of multiple sclerosis occurrences following hepatitis B vaccination in France resulted in very slow uptake of the vaccine from 51% in 2009 at its introduction to 83% in 2014.[3] Suspicions of an association between HPV immunization and sudden death (Austria, Germany, Kazakhstan, and Spain) or infant vaccines and sudden death (Bosnia and Herzegovina, Germany) were never confirmed, but have threatened to disrupt vaccination programs.

As a consequence of the perceived absence of vaccine-preventable diseases in Europe and shifts to a more safety-oriented and risk-averse public, antivaccination sentiment has been growing in many European countries. However, in the United Kingdom, where there has been a long experience of tracking of parental attitudes to vaccination there has been a progressive and encouraging shift of parental opinion away from weighing up the pros and cons to automatically vaccinating when the immunization was due.[108–110] Studies show the importance of accurate information being available for parents and healthcare workers whose influences play a major role in determining immunization coverage.[108,111–113]

Vaccine Resistance Because of Religious Beliefs

Anthroposophic Communities in German-Speaking Countries and Elsewhere

Between 2001 and 2014, Germany reported 21,498 cases of measles, of which the highest incidence over the last 2 years was reported from the states of Berlin, Bayern, and

Brandenburg.[114] In spite of reported immunization coverage of greater than 90% by the age of school entry, numerous pockets of low vaccination coverage remain, some of which were linked to the anthroposophic beliefs of parents and some physicians. In November 2001, an outbreak in Coburg, Bavaria, which started in an anthroposophic school opposed to vaccination, infected 1100 people, of whom 398 developed complications such as pneumonia and 21 were hospitalized.[115] Further outbreaks occurred in 2005 and 2008 where there were concentrations of unvaccinated children in some communities, certain schools, and childcare facilities (most of which had connections with the anthroposophic teachings of Rudolf Steiner).[115,116] Outbreaks from similar settings have been repeatedly reported from Austria and Switzerland.[117–120] People of these communities are selective about the medical services they use and often refuse vaccination, especially for measles. Outbreak assessments in 2013 of measles outbreaks in Waldorf schools of Bremen, Erftstadt, and Landsberg indicated that less than half of students attending the schools had been vaccinated against measles. In 2014, upon return of a student with measles from abroad, half of school children attending an anthroposophic school in Finland were placed under quarantine because they were unvaccinated against measles.[120] The German Gesellshaft Antroposophischer Ärtze in Deutschland e.V. has regularly published the leaflet "Merkblatt Masern." In the issue published August 2015 a change in the view of measles can be noted; measles is no longer regarded a childhood disease only because it may cause severe disease in older children and pregnant women.[121] Among other consequences of nonvaccination mentioned are risks to exposed infants when older siblings are ill, the obligation to avoid exposure of others, and the willingness to accept an extended absence from kindergarten or school. It should be noted that the "Merkblatt Masern" cannot be compared to issued guidelines in conventional medicine and it is unknown if this change in views will have an impact on immunization coverage long term among the anthroposophic communities in Germany and elsewhere.

Religious Groups in the Netherlands Rejecting Vaccination

In 1992, the *New Scientist* reported "Dutch Panic over Polio Outbreak."[122] At the time of the report, only one case of polio—in a 14-year-old boy—had occurred. However, this child came from a community that rejected immunization and outbreaks of polio had occurred previously in the same community, notably in 1978. The *New Scientist* report noted that "the affected boy and his family were members of a strict Calvinist church (Dutch Orthodox Reformed Church) that rejects vaccination on the grounds that acquiring disease is an 'act of God.'"

The outbreak in the end affected 71 individuals (age range: 10 days to 61 years of age; median: 18 years), of whom two died and 59 developed paralysis. None of the patients had been vaccinated and all but one belonged to a socially and geographically clustered group of people who refuse vaccination. Despite the cases occurring in the group that rejected immunization and the widespread transmission in that community, no cases were detected in the remainder of the Dutch population.[123] Although there was no evidence for ongoing transmission within the Dutch population, there was evidence that the poliovirus responsible for the Netherlands outbreak had been exported into Canada with circulation among a community that shared the beliefs of the Netherlands group.[124]

Measles and rubella outbreaks are also repeatedly recorded among individuals of the Orthodox Dutch Reformed Church denomination, including measles related deaths or cases of congenital rubella syndrome.[125–127] The Netherlands is making efforts to work with the religious groups to prevent such vaccine-preventable outbreaks and to ensure that cases do not spread outside of the identified communities.[128]

Availability of Vaccines

Vaccine procurement by member states or through UNICEF Supply Division has ensured stable access to vaccine supplies. However, a total of 16 products have been reported to be in short supply in 2014, the most frequently being bacille Calmette-Guérin (BCG), and acellular and whole-cell pertussis–containing vaccines.[3,49,129] Bosnia and Herzegovina, Bulgaria, Croatia, Montenegro, Romania, and Slovakia reported "stock-outs" leading to interruptions of immunization programs,[3] and Serbia reported a delay with IPV introduction in 2014 because of selection of a combination product that is in short supply. Similarly, difficulties with BCG vaccine availability have been reported because of a reduction of number of vaccine manufacturers producing the vaccine. In 2015, a large number of EU/EEA Member States reported stock-outs of acellular-containing vaccines and vaccine shortage was the subject of the European Commission's Health Security Committee meetings under the new serious cross-border threats legislation.[31,130]

Low Vaccine Uptake Leads to Outbreaks

A number of countries have faced periods of low vaccine uptake as a result of economic, political, or safety-related concerns. During the war in Bosnia and Herzegovina in the 1990s, a switch from MMR to measles-rubella (MR) and difficulties with access to immunization services rendered cohorts of children unimmunized or underimmunized. Coverage in later catch-up campaigns in the post-conflict period left the population susceptible to measles and mumps outbreaks.[131] The situation was further aggravated by significant antivaccination sentiments following media coverage of infant deaths in temporal association with routine immunization and reports of increased rates of reactions to the mumps component of MMR vaccine administered to older children and adolescents. A nationwide outbreak of measles in Bosnia and Herzegovina with more than 6,800 cases reported from January 2014 through December 2015, largely involving cohorts born during the conflict years and the immediate postwar period (1990–2000).[132,133] Most cases are among unimmunized persons or those with unknown immunization status.

During 2000–11, more than 65 million persons received measles-containing vaccines through supplemental immunization activities (SIAs) in 21 of 53 member states of the European Region.[3,134] Azerbaijan (2001, 2002) and Kyrgyzstan (2004, 2006) immunized more than 5 million persons 7 to 23 and 7 to 25 years of age, respectively, in addition to women of childbearing age up to 35 years of age. Lot quality assurance coverage surveys confirmed high coverage.[134] Georgia planned a nationwide SIA in 2008 targeting 980,136 individuals 6 to 27 years of age. Vaccination safety concerns raised during Ukraine SIAs interfered with vaccination uptake in Georgia, resulting in coverage of 50.3% in 2008.[134] Despite the SIAs, Georgia, Kyrgyzstan, and Ukraine reported more than 21,000 cases of measles from January 2014 until April 2015, prompting further SIAs.[135] Likely causes of these recent outbreaks are the gradual accumulation of susceptible individuals born after earlier measles and rubella supplementary immunizations activities were undertaken, presence of suboptimally performing immunization

programs, migration, changes of immunization systems, and instances of nosocomial transmission. The three countries organized a variety of SIAs between 2013 and 2014 and administered more than 2.5 million doses of measles-containing vaccine. Coverage in Azerbaijan and Kyrgyzstan was greater than 95%, while Georgia achieved only 14% of the targeted population 2 to 29 years of age.

Ukraine experienced a return of epidemic diphtheria in 1991 affecting all oblasts by 1995. It has been hypothesized that the diphtheria epidemic in Ukraine started among children, who had been left vulnerable as a result of inadequate childhood immunizations, and then quickly spread to inadequately protected adults.[136] At the peak of the epidemic, more than 5000 cases and more than 200 deaths were reported.[136] Selective target-group immunization was ineffective in controlling the outbreak, requiring a change of strategy. Campaigns conducted in all of the 27 oblasts and administrative regions of the country over an 18-month period led to a decrease of reported cases of diphtheria by 1996. The campaigns were affected by inadequate logistic and strategic preparation, unanticipated resistance from healthcare workers, and expression of distrust by a small, but significant, proportion of the population.[136] Between September 2005 and mid-June 2006, more than 50,000 measles cases were reported in Ukraine. Outcomes of a case-control study in undertaken in the Dnepropetrovsk region suggested vaccine effectiveness with one dose of measles vaccine of 63.0% (95% confidence interval [CI], –92.3% to 93.9%) and two doses of 92.0% (95% CI, 79.4% to 97.2%) when matched by school or university.[137] The level of population immunity achieved with two doses of vaccine still permitted sufficient numbers of susceptibles to accumulate over time and was estimated to be approximately equal to 440,000 in 2008.[137] A national MR campaign targeting the population 15 to 29 years of age, regardless of prior vaccination status, was planned for May 2008 but encountered obstacles similar to those experienced during the diphtheria campaign a decade earlier.[134,136,138] Within days of the campaign start, a 17-year old boy died within 13 hours of vaccination of an unrelated cause.[139] This event led to widespread concerns, a wave of hospitalizations among vaccinees, cancellation of the campaign, and extremely intense widespread antivaccination sentiments which persist. Since 2008, Ukraine has faced further major measles outbreaks and a significant decline of public trust in the routine immunization program, with major concerns about vaccine safety in particular. Vaccine procurement problems, major vaccine stock-outs, and erosion of the public health system are further reasons for the steep decline of vaccination coverage and accumulation of a significant cohort of children susceptible to vaccine-preventable diseases. In 2014, only 50% of children in Ukraine were immunized against polio (three doses of polio containing vaccine by 12 months of age) compared to 99% in 2004.[3] In 2015, Ukraine reported two cases of circulating vaccine-derived poliovirus type 1, both from the Zakarpatskaya oblast, in southwestern Ukraine, bordering Romania, Hungary, Slovakia, and Poland.[140]

Failure to maintain high coverage through routine immunization services over long periods present a serious challenge to maintaining polio-free status.[17,141] In 2010, importation of wild-type 1 polio virus resulted in a large-scale outbreak of poliomyelitis in Tajikistan with 460 laboratory-confirmed cases of poliomyelitis, including 29 deaths. The virus also spread to neighboring countries and in 2010 the Russian Federation reported 14 laboratory-confirmed cases of poliomyelitis and one death, Turkmenistan reported three cases, and Kazakhstan reported one case, all resulting from wild poliovirus type 1 from Tajikistan.

Silent Wild Poliovirus Circulation in Israel

Environmental surveillance for enteroviruses was established following the 1988 polio outbreak in Israel. Composite sewage samples have been collected monthly from sentinel sites covering 30% to 40% of the Israeli population using computerized automatic inline samplers located at the mouth of sewage treatment facilities.[142] In April 2013, wild poliovirus type 1 of the South Asia (SOAS) lineage was recovered from sewage in southern Israel.[143] The virus was detected in sewage only; no case of paralytic polio has been reported for the duration of the outbreak. The Israeli routine immunization schedule had recommended three doses of IPV by the age of 6 months and two boosters at 12 months and 7 years of age. The use of OPV had stopped in 2005. IPV3 coverage has been maintained at between 94% and 96% over the last decade. A stool sample study in 2013 indicated that majority of shedders belonged to a cohort of children immunized with IPV vaccine only.[143] The outbreak response included intensification of environmental, enterovirus, and AFP surveillance; a catch-up campaign using IPV vaccine at the epicenter of the outbreak was followed by a national vaccination campaign using bOPV vaccine. The first bOPV round achieved coverage of 79% (range by district: 65% to 92%); a second round was conducted only in the Southern district and reached coverage of 52%.[93] Public health authorities faced several challenges communicating the need for a mass campaign in the context of asymptomatic wild polio virus transmission.[144] Based on a review by the Israeli NITAG and the National Polio Certification Commission, the Israeli routine immunization schedule has been modified by reintroducing OPV (bOPV) vaccine into the routine schedule for infants born after July 2013; the schedule is now IPV at 2, 4, 6, 12 months, and 7 years of age, in addition to bOPV at 6 and 18 months of age. The last wild poliovirus type 1 isolation from an environmental source in Israel was in March 2014.

Vaccine Safety Issues

Autism and Measles-Mumps-Rubella Vaccine

Starting in 1993, a number of scientific articles were published reporting studies of the relationship of measles or measles-containing vaccines and chronic inflammatory bowel disease and autism. Most of the studies originated from one group working in the United Kingdom. The studies attempted to show that Crohn disease and, variably, ulcerative colitis was associated with either early measles infection or measles immunization. The studies were based on either epidemiologic or virologic data.[93,142–150] These claims for infection or vaccine-linked causes of inflammatory bowel disease received much media attention. As each new claim appeared, work was subsequently published that failed to confirm the earlier findings.[151–167]

The publication of each report that failed to confirm the earlier claims attracted less media interest than the original claims, leaving the impression that the putative associations with vaccination were robust.[168] In 1998, new claims were made of an association between MMR immunization and bowel disease and autism.[169] Although the authors were careful to say that their findings did not confirm a causal association, the media reported the findings as if the study had implicated the vaccine. At a press conference timed to coincide with the publication, one of the paper's authors stated that he believed that autism and bowel disease might be preventable by separating MMR and giving its ingredient vaccines singly with year-long intervals between doses. There remains no published epidemiologic evidence that confirms a causal association between MMR vaccine and autism. Numerous studies using different populations and different analytic techniques

have failed to confirm any increased risk of autism or bowel disease in association with MMR.[170–181]

Virology studies had reported as showing evidence for the presence of measles virus genetic material in bowel tissue, blood, and cerebrospinal fluid. These reports have come from one group, or workers associated with that group, and there has been no fully independent confirmation of these claims.[182] Three separate other groups have studied peripheral blood lymphocytes from autistic children and failed to find evidence of persistence of measles infection.

After 1997, there often was high media interest in MMR, culminating in early 2002, when the public and political focus became intense, with calls for either withdrawal of the vaccine or replacement with single-component vaccines for MMR. Vaccine coverage and public confidence in the safety of MMR had both been adversely affected, with coverage falling from 92% to 93% in the late 1990s to 83% in 2002.[183,184] During 2001 and 2002, it became clear that those opposed to the use of MMR vaccine were adopting a new strategy: The results of studies that challenged the safety of MMR were released to the media before exposure to the scientific community, exacerbating the public perception of risk from the vaccine without any opportunity to evaluate the quality of the work. More recently, and closely linked to the disappearance of media support for the MMR–autism story, coverage has risen, with matching returns in assessments of parents' confidence in the safety of MMR. The loss of media support for the proponents of the MMR–autism story followed newspaper and television investigations into the events surrounding the research of those proposing the link.[185] Additionally, two detailed studies, undertaken by journalists, revealed the impact of unbalanced reporting on a major public health issue.[186,187]

In 2010, following a protracted investigation by the General Medical Council, the body responsible for the registration of physicians in the United Kingdom, the names of two of the authors of the 1998 *Lancet* paper were removed from the UK Medical Register, preventing them from practicing medicine in the United Kingdom. In 2011, the *British Medical Journal* published a series of linked articles by an investigative journalist that demonstrated that in addition to the charges found proved by the General Medical Council, there had been extensive research fraud.[188–190]

Despite the decline in coverage, cases of measles remained rare until 2006, with fewer than 100 confirmed cases in 2005.[191] However, from 2006, confirmed cases started to rise, with many cases being part of a linked series of outbreaks across the United Kingdom. Many of the cases occurred in the Travelers community, often originally Irish, non-Roma gypsy, mobile groups.[192,193] Current small outbreaks have been linked to travel to Europe.

The Department of Health in London adopted a clear strategy to respond to the threats to the MMR immunization program. New information materials were disseminated widely to health professionals, and matching materials were prepared for parents. Immunization coordinators with local responsibility for implementing immunization services were briefed with all new materials as they became available. Newspaper and radio advertisements were used to direct parents to sources for these information materials. In addition to making information available on existing Department of Health and allied Web sites, a site dedicated to MMR was set up, with a facility for parents to send in their MMR-based questions.[194] Despite pressure from the media and parents for single vaccines to be made available to allow parents to choose whether their children would have MMR or single vaccines, single vaccines remained available only outside of the National Childhood Immunization Programme, and many of the products were unlicensed. Throughout the time of the campaign against MMR, there was strong political support for the vaccine, despite intense media-driven pressure.

The results from repeated media stories linking MMR vaccine with autism and other adverse outcomes led to progressive loss of confidence in the safety of MMR vaccine among health professionals and parents.[109,183,184] As a consequence, MMR vaccine coverage fell from greater than 90% in 1994 to approximately 80% nationally in 2003–04, but with much lower figures in some parts of the country, especially in London and South Wales.[195,196] Since 2005, however, MMR coverage has progressively increased as anti-MMR stories faded from the media, and as local campaigns improved vaccination uptake.[197]

As a result of these activities, coverage started to rise in 2005, with consistent increases in coverage at 16 months of age and with commensurate increases in 2-year coverage (Fig. 74.7). In 2015, MMR coverage in the United Kingdom exceeded

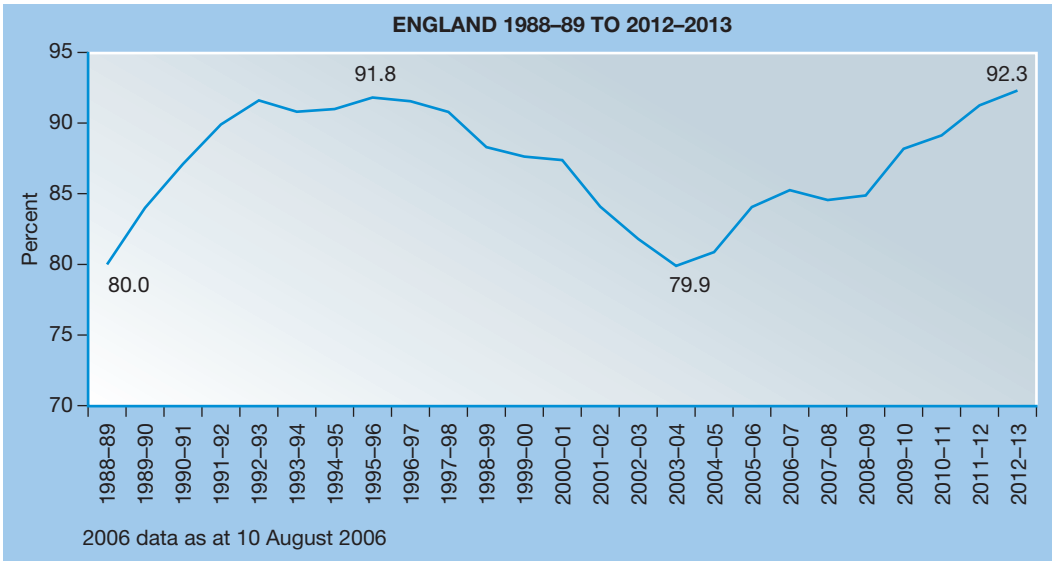

Figure 74.7. Measles-mumps-rubella (MMR) coverage at 24 months of age. *(From Mason BW, Donnelly PD. Impact of a local newspaper campaign on the uptake of the measles mumps and rubella vaccine.* J Epidemiol Community Health. *2000;54:473–474.)*

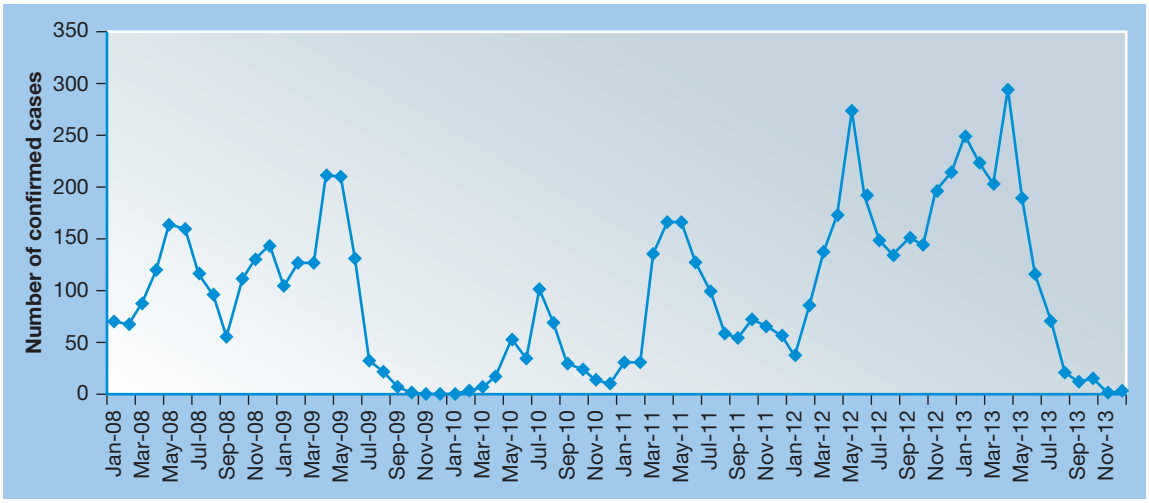

Figure 74.8. Number of confirmed measles cases by month of onset, England 2008–2013. *(From Ramsay ME, Jin L, White J, et al. The elimination of indigenous measles transmission in England and Wales.* J Infect Dis. *2013;187 Suppl 1:S198–S207.)*

90% by the third birthday and reached that level by the second birthday.

Measles had been virtually eliminated from England and Wales between 1994 and 2001, but by 2006 there were resurgences of localized measles outbreaks (although no national level outbreaks occurred).[198] Despite the apparently reassuring increases in MMR coverage, exceeding 90% by 2011, there was still a high risk of measles resurgences, owing to the cohorts of undervaccinated children born during the years when MMR coverage was lowest. As these cohorts began to attend school, they started to come into contact with many more children, raising the risk of measles transmission. In 2012, measles cases rose to levels that had not been seen in England and Wales since 1989, reaching a peak of 1912 confirmed cases (Fig. 74.8).[199] Multiple outbreaks were detected, especially in the North East, the North West and in South Wales. Cases continued to rise up to the first quarter of 2013.

The highest numbers of cases were in children and young people who had been born during the years of lowest MMR vaccine coverage, when anti-MMR rhetoric was at its height. A national MMR vaccine catch-up campaign was therefore rolled out, targeted at those who had had no MMR vaccine (those 10 to 16 years of age were the highest priority), followed by those who had only had a single dose of MMR. By the midpoint of the 2013 campaign, coverage in the 10- to 16-year-old group was estimated to have reached more than 95%. Since the completion of the campaign, measles cases have reverted to extremely low levels.

Narcolepsy Associated With Use of an AS03-Adjuvanted Influenza A (H1N1)PDM09 Vaccine Produced and Used in Europe

The AS03-adjuvanted influenza A (H1N1)pdm09 vaccine (Pandemrix) was the most used vaccine in Europe for protection against the 2009 influenza A pandemic. It has been estimated that more than 30.5 million Europeans received Pandemrix.[200] Although at least 20 EU/EEA countries are known to have administered Pandemrix to their population in vaccination campaigns conducted in 2009–10, the amount of vaccine used per unit population was highly variable and there were also important differences in the age groups that received the vaccine. The highest overall vaccine coverage was obtained in Finland, Ireland, Norway, and Sweden, where school-based immunization targeting children and adolescents were common.

Pandemrix contained the WHO-recommended flu strain A/California/7/2009 (H1N1) v-like strain (X-179A), an immunostimulating adjuvant (AS03) that included α-tocopherol (vitamin E) and squalene, and the often-used preservative thiomersal. Pandemrix was produced in Dresden, Germany. A very similar AS03-adjuvanted influenza A (H1N1)pdm09 vaccine (Arepanrix) was produced in Quebec, Canada by the same manufacturer. This vaccine was used extensively in Canada, including in children and adolescents.

Spontaneous adverse drug reaction reports of narcolepsy in children and adolescents previously vaccinated with Pandemrix started to appear in August 2010,[201] after vaccination campaigns had long ceased. Subsequent formal epidemiological studies confirmed an epidemiological association. The first study came from Finland in 2012 and showed a 12.7-fold increased risk for development of narcolepsy in children and adolescents between 4 and 19 years of age observed within 8 months after vaccination when compared with unvaccinated individuals in the same age group.[202,203] A series of further studies conducted in France, Ireland, Norway, Sweden, and the United Kingdom confirmed the epidemiological association. Similar studies conducted in Canada suggest a significantly smaller increased risk.[42,204–208] By January 2015, a total of 1379 reports of narcolepsy following vaccination with the Pandemrix vaccine had been received in the EMA Eudravigilance database.

Narcolepsy is a chronic disorder presenting with excessive daytime sleepiness often combined in young individuals with cataplexy (a transient loss of muscle tone triggered by strong emotional stimuli such as laughter or sadness) and is linked to the HLA-DQB1*0602 haplotype and a dysregulation of the hypocretin ligand-hypocretin receptor pathway. Investigations of narcolepsy patients have shown that loss of hypothalamic cells results in deficiency of the neuropeptide hypocretin in the cerebrospinal fluid. However, the mechanism leading to this loss of hypothalamic cells is unknown.

Recently, a possible biological mechanism for development of narcolepsy following Pandemrix vaccination was proposed.[209] The study compared antibody reactions to the influenza nucleoprotein and the hypocretin receptor 2 protein. It showed that a significant proportion of sera from HLA-DQB1*0602 haplotype-positive narcoleptic patients with a

history of Pandemrix vaccination and antibodies to nucleoprotein contained cross-reactive antibodies to the hypocretin receptor 2 protein when compared to sera from nonnarcoleptic individuals with a history of either a 2009 influenza A (H1N1) infection or MF-59 adjuvanted influenza A (H1N1) pdm09 (Focetria) vaccination. Although this study provides a first hypothesis for a possible biological mechanism, further studies are urgently needed.

An earlier study noted higher levels of antibodies to nucleoprotein in children with DQB1*06:02 risk allele and in DQB1*06:02 transgenic mice immunized with Pandemrix when compared to controls.[210]

Adolescent and Adult Immunization Programs

School-based programs providing vaccines to adolescent populations are reported by 25 of 53 member states[3] providing mainly tetanus toxin, diphtheria and tetanus toxoids or tetanus, diphtheria, and pertussis boosters, HPV, and to a lesser extent meningococcal vaccine, primary series of hepatitis B, MMR or BCG following purified protein derivative testing. Twenty-three Member States report schedules involving adolescents; however vaccination services continue to be provided by pediatricians, general practitioners, or other means. Adult immunization programs are often organized for special groups; for example, occupational groups, pregnant women, those older than 65 years of age, and individuals with specific conditions. There are extensive data to show that some adult groups are underimmunized. Measles nosocomial outbreaks provide testimony of unimmunized or underimmunized healthcare workers.[211] In 2014, a 47-year-old index case with a history of travel to India during the incubation period was diagnosed with measles in Masaryk Hospital in the Czech Republic. Subsequently, over a period of 4 months, 305 suspected measles cases were reported, of which 186 cases were laboratory-confirmed. Of the laboratory-confirmed cases, 88 were healthcare workers: 54 were nurses, 12 medical doctors, and 22 other hospital workers in emergency, infectious disease, and dermatology departments.[212] Also in 2014, nosocomial infections were reported in three Latvian hospitals involving 13 healthcare workers, while Spain reported an outbreak in Catalonia of which 24% of cases were healthcare workers, most of whom were unimmunized or had received only one dose of measles-containing vaccine.[211]

Reaching adults for immunization is challenging, but recommendations for adult immunization differ widely across the region.[213,214] Accurate data on uptake are not readily available.

Vaccinology Training

There are few data available on the amount of training on vaccines and vaccination throughout European countries. One EU project, VACSATC (Vaccine Safety, Attitudes, Training and Communication), performed a benchmarking study on undergraduate training in vaccinology in Europe.[215,216] Results showed that training on vaccines and immunization is disseminated over a wide range of courses over several academic years during medical education and in nursing and midwifery schools. Topics such as immunology and vaccine-preventable diseases were well covered during the training, but major gaps in knowledge and competencies were identified in understanding vaccine safety, communication with parents, addressing antivaccine arguments, and performing practical skills. This survey underlined the rationale for adequate training, identified opportunities for improving training, and indicated that the medical and nurse undergraduate training in Europe is not sufficiently equipped to ensure that all future healthcare workers are able to deliver such responsibilities. Undergraduate immunization training should not replace specialization courses or postgraduate training, but it should ensure that every healthcare worker, after basic training, can and will effectively communicate about vaccination, based on knowledge, competence, and skills.

In the United Kingdom, an advisory group hosted by the then Health Protection Agency produced National Minimum Standards for Immunization Training to offer consistency in the training provided across the country and to aid in those areas where training is not yet established.[217] The authors observed that undergraduate courses rarely include much training about immunization and that the provision of (postgraduate) immunization courses for healthcare workers varied considerably between localities. Mid-level and higher-level training courses on vaccinology are increasingly available in different localities. Students were accepted from a wide range of related disciplines on a global basis.[218]

The WHO Regional Office for Europe in collaboration with the European Society for Paediatric Infectious Diseases (ESPID) has developed vaccinology training materials under a continuous medical education scheme.[218a]

The World Wide Web is a widely used source of information on various topics; however, some of the information provided is of dubious credibility and is at times misleading. This is particularly true in the area of vaccine safety, where many websites have been developed that provide unbalanced and misleading information. Often these websites are linked and thus can create undue concerns among health professionals and the general public.

In response, the WHO has supported the development of a network of websites that meet criteria of good information practices as approved by the Global Advisory Committee on Vaccine Safety.[219,220] Launched in 2004 by the WHO Geneva and the WHO Regional Office for Europe, the vaccine safety network now includes 53 WHO-approved websites globally, including 26 websites in 12 languages within the European Region. The listed sites are reevaluated for their adherence to credibility and content every 2 years. Further work is under way within the European Region to increase the number of approved websites as well as those available in major European languages, particularly Russian.

EUROPEAN REGION STRATEGY FOR STRENGTHENING NATIONAL IMMUNIZATION SYSTEMS

European Vaccine Action Plan

The European Vaccine Action Plan 2015–2020 (EVAP) is a regional interpretation of the Global Vaccine Action Plan developed to address the specific needs and challenges related to immunization in the WHO European Region. Aligned with Health 2020 and other key regional health strategies and policies, EVAP was formulated through a consultative process, reviewed by Member States and endorsed by the ETAGE on Immunization before submission to the 64th session of the Regional Committee for Europe in September 2014.[18,19,221] EVAP's aim is to guide European Member States towards a Region free of vaccine-preventable diseases. It establishes six goals (sustain polio-free status, eliminate measles and rubella, control hepatitis B infection, meet regional vaccination coverage targets at all administrative levels throughout the Region, make evidence-based decisions on introduction of new vaccines, and achieve financial sustainability of national immunization programs) and outlines a path to achieve them through defined objectives, priority action areas, proposed

actions, and an evaluation and monitoring framework. Relevant elements of EVAP progress are addressed in the following sections.

Measles and Rubella Elimination Goal

In 2005, the WHO Regional Committee for Europe recommended rubella elimination as part of a resolution on strengthening national immunization systems.[222] A revised strategic plan was published in 2005 and included five key strategies[88]:

- Achieve and sustain very high coverage (>95%) with two doses of measles vaccine and at least one dose of rubella vaccine through high-quality routine immunization services.
- Provide a second opportunity for measles immunization through SIAs to populations susceptible to measles.
- Provide rubella vaccination opportunities, including SIAs, to all rubella-susceptible children, adolescents, and women of childbearing age.
- Strengthen surveillance systems by rigorous investigation of cases and laboratory confirmation of suspected cases.
- Improve the availability of high-quality, valued information for health professionals and the public on the benefits and risks associated with immunization against measles and rubella.

With the widespread use of measles- and rubella-containing vaccines across the Region, reported measles and rubella cases have dramatically declined. During 2007 to 2009, measles incidence in the region declined to historically low levels of less than 10 cases per million. The decline in cases was a result of high immunization coverage with two doses of measles- and rubella-containing vaccines and implementation of SIAs. The latter were implemented in more than 10 countries targeting remaining susceptible age cohorts and reached more than 55 million persons during 2003 to 2009.[223] Most countries that implemented SIAs conducted them in less than 1 month; some countries, such as the Russian Federation, implemented them using a phased approach. Rubella-susceptible women who have immigrated into the European Region have been identified as an important target group and programs to immunize them will be necessary even after the elimination target for rubella has been met.[224]

Along with the decline of incidence and the reduction of outbreaks in the eastern part of the Region, the proportion of reported cases has increased in the western part of the region. In 2009, outbreaks in five countries in Western Europe accounted for 89.6% of reported cases. The major challenges to achieving the regional measles and rubella elimination goal by 2010 included ongoing outbreaks caused by a failure to vaccinate, rather than the failure of measles vaccine: nearly 90% of the reported measles patients eligible for vaccination had not received two doses of a measles-containing vaccine.[225] Although national measles immunization coverage estimates remain high, coverage at the subnational level and among vulnerable populations in many countries reveal coverage to be much lower than the recommended 95% or higher for two doses. In some instances, the outbreaks led to reestablished endemicity (Switzerland and the United Kingdom). Marginalized and vulnerable populations with limited access to immunization services and decreased demand for vaccines because of an increased focus on measles vaccine safety by parents have also been major challenges to achieving the elimination goal.

The existence of geographic areas with coverage less than 95% has resulted in pockets of susceptible individuals, sufficient to support transmission and lead to explosive outbreaks, as has been seen with the recent resurgence of measles cases in western and central European countries.[226,227] In 2009, the likelihood of eliminating measles by 2010 was assessed for all 53 member states. Although the regional elimination goal had been thought to be attainable, it was determined that it would not be met by the target date of 2010.[225] Therefore, in September 2010, the European Regional Committee revised the target date for elimination to 2015.[228]

Despite substantial progress made by many Member States since 2010, the regional target of measles and rubella elimination remains under threat. In 2012, there were 27,134 measles cases and 29,601 rubella cases reported in the Region.[229,230] In 2013, these figures were 31,520 and 39,367 respectively. Most measles cases in 2013 (96%; $n = 30,178$) were reported by nine countries: Georgia (7830), Germany (1773), Italy (2216), the Netherlands (2499), Romania (1074), Russian Federation (2174), Turkey (7404), Ukraine (3308), and the United Kingdom (1900). Most cases were among unvaccinated persons and more than one in three patients were 20 years of age and older. Gaps in population immunity were reconfirmed by reports of 16,156 measles cases in 2014, of which greater than 41% of cases were adults 20 years of age or older.[135] That year, more than 75% of European measles cases were reported from Bosnia and Herzegovina, Georgia, Italy, Russian Federation, and Ukraine. The highest incidence rates per 1 million population were in Bosnia and Herzegovina and Georgia at 5762 and 7379, respectively.[231] The number of cases for 2014 appears to have dropped to the lowest level since 2010 ($n = 30,604$).[135] However, measles transmission continued in 2015 with large-scale outbreaks reported in Bosnia and Herzegovina, Germany, Kyrgyzstan, and Serbia.

In 2013 and 2014, most Europe-wide rubella cases were reported by Poland ($n = 38,585$; 98% in 2013; $n = 6516$; 91% in 2014). In 2013, the incidence of rubella in boys and men was significantly higher than the incidence in girls and women (181.4 vs 23.9), as a result of the immunization policies (1987 to 2003) that provided single doses of rubella vaccine to 13-year-old girls only, and where no catch-up campaigns were implemented where two-dose MMR schedules were introduced.[232]

The Regional Verification Commission for Measles and Rubella Elimination, based on annual reports provided by national verification commissions, concluded that as of the end of 2013, there were 22 countries in which endemic measles transmission had been interrupted, and 23 countries in which endemic rubella transmission was interrupted. Of those, nine countries were at high risk of reestablishing endemic transmission of one or both diseases, mainly because of significant immunity gaps in the population. Thirteen Member States were considered to have endemic measles transmission, and of these, nine were considered to also have endemic rubella transmission.[233]

To stop both endemic and imported measles virus circulation, all efforts continue to be directed toward reaching very high immunization coverage and population immunity for these diseases in all countries. The "Package for Accelerated Action" for measles and rubella elimination identifies priority areas in which the Regional Office provides technical support to Member States as they seek to eliminate these vaccine-preventable diseases, and sets indicators and milestones by which progress resulting from the efforts of all stakeholders can be measured.[234] Political commitment and accelerated action by Member States and partners remain the most crucial factors in achieving elimination of measles and rubella in the WHO European Region.

Polio Eradication Goal

In 2002, the Regional Certification Commission for Polio Eradication reviewed evidence from all countries in the European Region and announced that transmission of wild polio viruses had been interrupted, based on the evidence presented.[22] The continuing priorities were maintenance of certification level surveillance, laboratory containment, and sustainability of polio immunization programs.

Each country has its own method for implementing polio surveillance (see paragraph on surveillance of vaccine-preventable diseases above). Nine countries in the Region reported AFP surveillance as their only polio surveillance system in 2014, and an additional nine reported exclusive use of other types of surveillance in the absence of AFP surveillance. The remaining 34 countries (except San Marino) reported using AFP surveillance together with a variety of supplementary surveillance systems or activities. For those countries continuing to report AFP surveillance, the AFP index of surveillance quality remains high in Member States from the eastern part of the Region and poor in those in the southwestern part of the Region. Five countries claiming to maintain AFP surveillance failed to detect any AFP cases in 2014.[235]

Sustained indigenous transmission has not recurred since polio elimination was certified in 2002. However, the risk of importation of wild polioviruses into the European Region became a reality in 2010 when type 1 wild poliovirus genetically related to virus from Uttar Pradesh, India, was imported into Tajikistan, and in 2013 when silent transmission of wild polio virus type 1 of South Asian genotype was confirmed in Israel through environmental surveillance. In 2010, Tajikistan conducted six rounds of national SIAs with two rounds in children younger than 6 years of age and four rounds in children younger than 16 years of age. Uzbekistan conducted four national SIAs and one round of subnational immunization days. SIAs were conducted also in Turkmenistan (three national SIAs), Kyrgyzstan (two national SIAs), Kazakhstan (one national SIA and one subnational immunization day), and the Russian Federation (two subnational immunization days). The effective response measures ensured that wild poliovirus transmission was interrupted within 6 months after detection of the first case. In 2011, the five Central Asian republics, the Russian Federation and Azerbaijan conducted coordinated SIAs to close any immunity gaps. In total more than 45 million doses of monovalent OPV1 and trivalent OPV were used for outbreak response immunization activities in the Region. Israel public health authorities conducted two immunization rounds in 2013 using bOPV vaccine.[144] Given special consideration because of the outbreak of polio in Syria in 2013 and significant cross-border movements of refugees, Turkey implemented four rounds of subnational SIAs targeting resident, refugee and "hard-to-reach" populations[236] in 2014.

Although high routine poliovirus immunization coverage has been maintained in most countries and good performance indicators for polio surveillance are reported by many member states, data suggest that the quality of AFP surveillance has been slowly declining since 2002. Vulnerable subpopulations and underserved areas remain.

To ensure an adequate level of preparedness for responding to introduction of wild polio viruses, the WHO Regional office for Europe regularly organizes polio simulation exercises with a focus on member-states considered to be at high risk of a polio outbreak following introduction of polio virus.[237–240] To date, 14 countries have participated in the exercises.

The global strategy for minimizing risks associated with laboratories and healthcare facilities includes destruction of poliovirus-containing materials in all but a few essential facilities and strict adherence to required safeguards by such facilities. Each country must establish a national poliovirus policy prohibiting retention of poliovirus materials in all nonessential facilities, including promulgating enforceable legislation or regulations. Twenty-three member states of the European Region reported in 2014 that 69 facilities are storing wild poliovirus infectious materials. This represents a decrease from 25 countries with 111 laboratories in 2006. Of the vaccine production facilities that handle wild-type and vaccine polioviruses in the world, 85% are located in 10 countries, eight of which are Member States of the WHO European Region. Early in 2015, the Regional Office informed all affected Member States that they should update and finalize an inventory of facilities holding wild and Sabin (vaccine and vaccine-derived) polioviruses and prepare for the destruction or containment of all type 2 strains and/or samples. Essential poliovirus type 2 materials will be contained in or transferred to designated facilities that have obtained national certification in compliance with Global Action Plan (GAP) III.[241]

Diphtheria Elimination Goal

Operational targets for diphtheria immunity and surveillance were established toward achieving the 2000 elimination goal of less than one case per 1,000,000 population. Since 1995 these included 95% coverage of the primary vaccination course (DTP3) by 2 years of age and include a booster dose/doses of diphtheria-containing vaccine in school-age children in all countries in the region. Every country in the region should have achieved either 95% coverage for this dose or an immunity rate of 90% for children and 75% for adults.[242] By 1997, no district in any country should have reported less than 90% coverage for the primary course at 2 years of age. Operational targets for surveillance included effective diphtheria surveillance to ensure that every case is identified, as well as access to laboratories to differentiate toxigenic from nontoxigenic strains by 1994 in all countries. By 1995 all reported cases of diphtheria were to be classified as indigenous or imported.

Significant progress has been made in reducing diphtheria in the European Region. Indigenous transmission has been interrupted in much of the region. The regional decrease in reported cases since 2005 has been dramatic: from more than 200 cases and carriers in 2005 to fewer than 40 in 2015.[3] There have been sporadic cases (less than one per 1 million population) in a number of countries over the last decade with Georgia, Latvia, Russian Federation, and Ukraine reporting sporadic cases most frequently. To ensure elimination, high coverage must be sustained, surveillance and laboratory capacity must be maintained, the coverage rates for adult booster doses must be increased, and research needs to be conducted to better understand the remaining risk groups.

Immunization Registries

For the vision of a European Region free of vaccine-preventable diseases established in the EVAP, where all countries provide equitable access to high-quality, safe, affordable vaccines and immunization services throughout the life course tools such as immunization registries or immunization information systems could be useful. Such systems could among many tasks monitor the agreed EVAP targets such as: all countries should obtain high-quality immunization coverage data, all 53 countries should have less than a 5% dropout rate between first and third doses of DTP-containing vaccine, and all countries should have sustained coverage with DTP-containing vaccines of greater than 90% for 3 or more consecutive years. The number of countries with electronic immunization registries/

immunization information systems is increasing in the region. ECDC and WHO EURO are collaborating to support countries wishing to establish or expand their capacity to monitor all vaccination, including travel and occupational vaccines, in immunization information systems building upon best practices in countries that have functioning and advanced registries.

Tailoring Immunization Programs

The WHO Regional Office for Europe has developed a framework "Tailoring Immunization Programmes (TIP)" that helps to identify and prioritize vaccine hesitant populations and subgroups, allows diagnosis of the demand and supply-side barriers to vaccination in these populations, and designs evidence-informed responses to vaccine hesitancy appropriate to the setting, context, and hesitant population.[112] The framework was tested in in Bulgaria (to profile and target Roma populations and healthcare providers working within these underserved communities) and Sweden (to improve vaccination coverage among immigrants, the anthroposophic community, and undocumented migrants).[243,244] It was also used in Montenegro to better understand seasonal influenza vaccine uptake by healthcare workers.[245] Subsequently, TIP is being rolled out in several countries across the Region. A TIP project in the United Kingdom will determine demand- and supply-side barriers to vaccination among the Haredi Jewish population of North London. Facing recurrent outbreaks of vaccine-preventable diseases in sections of the population, immunization programs of Belgium, Israel, and the United States are also considering using the European TIP framework to address the barriers to immunization. Kazakhstan, Germany, and Switzerland are preparing TIP projects to be implemented in 2015.

European Immunization Week

European Immunization Week (EIW) is a regional initiative, led and coordinated by WHO Europe and implemented by Member States to address their particular immunization-related issues and to share common immunization themes. Partner organizations, including UNICEF and the ECDC, contribute at regional and national levels. EIW aims to help member states advance plans to ensure universal immunization by using the power of advocacy and targeted communication to boost awareness and increase the success of immunization programs. These efforts aim to reach people who have not been immunized or did not receive all recommended vaccinations and to contribute to building confidence in immunization among those who have participated in EIW. The effort began in 2005 as a small pilot initiative designed to spotlight promulgation of the regional goals for measles and rubella elimination by 2010. Since its beginnings with only a handful of participating countries, the initiative has spread across the region and has become an effective tool for sharing and reinforcing its central message: "Prevent. Protect. Immunize." In 2011, 52 of the 53 Member States participated in EIW with the theme "Shared solutions to common threats." In 2014 the focus of the initiative was "Are you up to date?," looking at immunization across the life course from infancy to old age. Celebrating its tenth anniversary in 2015, the campaign focused on closing immunization gaps and reaching equity in immunization.

EIW brings awareness to immunization strategies and efforts implemented by member states, WHO and its partners. Activities during the week in 2015 have included information and media outreach campaigns using traditional communication methods, but they have also branched out into more innovative tools such as online tests and smartphone apps to track immunization status.[246] Several countries conducted immunization campaigns that provided access to vaccines for more than 10 million people during the month of April. Other countries focused their efforts on organizing meetings, conferences, and training.

CONCLUSIONS

Although the European Region is composed of a diverse group of countries with different immunization policies, the immunization programs offered to different age groups have successfully reduced the burden of vaccine-preventable diseases. However, there are vaccines that are not available in countries that have, so far, decided not to recommend them; there are also countries with hesitant subpopulations that reject recommended vaccines when they are available. Some remaining gaps can be identified with tools such as the newly developed TIP tool that could help identify and respond to vaccine hesitant populations and subgroups, as well as identifying other barriers to vaccination decision making or access to immunization services. Using the outcome of such assessments can facilitate targeted training of the general public and healthcare workers. Increasing numbers of countries are putting registries in place to obtain the benefits that such data systems offer. Meanwhile, reaching and sustaining Regional elimination goals remain challenging, especially for measles and rubella.

75 Immunization in the Asia-Pacific Region

Theodore F. Tsai, Raman D.S.V. Rao, and Zhi Yi Xu

The Asia-Pacific region, spanning one-third of the globe's circumference and containing more than half of the world's population, is highly diverse culturally, politically, economically, and in other dimensions that impact vaccine development and implementation. The region includes China and Japan, the second and third largest national economies globally but, at the same time, also encompasses nine Gavi (The Vaccine Alliance)–eligible countries, as well as others that meet Gavi low-income, but not other, eligibility criteria.[1] In a region this diverse and experiencing breakneck economic development, all stages of vaccine innovation, production, and consumption are represented, along with paradoxical overlaps of reliance on aid for global vaccination programs by countries that also are vaccine exporters. While China, India, Indonesia, and Vietnam are Gavi-graduate or Gavi-eligible countries, eight manufacturers located there and in Korea are among the 12 Developing Country Vaccine Manufacturers Network (DCVMN) suppliers that produce 75% of United Nations (UN) agency-procured vaccine doses.[2] Asian manufacturers have evolved from providers of downstream vaccine processing, to developers of lower-cost production solutions for previously licensed vaccines, such as hepatitis B (HepB), oral polio, diphtheria-tetanus-pertussis (DTP) combination vaccines incorporating *Haemophilus influenzae* type b (Hib) antigen, measles-containing vaccines, and more recently, group A meningococcal glycoconjugate vaccine. At the same time, they have become innovators of novel products such as an oral cholera vaccine, virus-like particle hepatitis E and live-attenuated hepatitis A vaccines, typhoid glycoconjugate vaccine, rotavirus vaccines, and inactivated enterovirus A71 (EV-A71) vaccine—representing, in fact, a continuation of local innovation to meet public health needs to control regionally important diseases such as Japanese encephalitis (JE), hemorrhagic fever with renal syndrome (HFRS), and Kyasanur Forest disease (KFD; see "Kyasanur Forest Disease Vaccine" later).

While investment in biomedical research and development (R&D) from 2007 to 2012 declined in the United States, Canada, and Europe, expenditures by countries in Asia-Oceania increased from 18.2% of the global share to 23.8%, led by China.[3] Interestingly, inflation-adjusted R&D spending by the U.S. public sector remained flat in this interval, while expenditures of U.S. industry declined by US$12.9 billion even as Asia-Oceania regional industry expenditures increased by US$15.1 billion, enlarging its global share from 19.0% to 26.5%. The trend may reflect industry recognition of the greater growth potential of vaccine opportunities in Asia, which as a component of other emerging-country markets, has been projected to exceed that of developed countries by 2020.[2,3] The trends in R&D expenditure also are reflected in growth rates of scientific publications and patents from Asian institutions that now exceed those from the United States and Europe.[4]

Manufacturers are entering the global network of vaccine production and supply, not only by providing basic Expanded Programme on Immunization (EPI) vaccines but also by commercially exporting products to Africa, Latin America, and within the region (e.g., meningococcal polysaccharide vaccine from China to Latin America and Africa; live attenuated and inactivated Vero cell–derived JE vaccines from China, Japan, and Korea, regionally; live attenuated hepatitis A vaccine from China, regionally; live attenuated and inactivated pandemic and seasonal influenza vaccines from India and China, internationally; and oral cholera vaccine from Vietnam, internationally). Previously, Asian manufacturers did not themselves market novel vaccines in Europe or the United States, choosing to distribute their innovative products, such as acellular pertussis and live attenuated varicella vaccines, through multinational companies. However, an increasing global integration is taking place, as multinational companies acquire Asian manufacturers (e.g., Sanofi-Aventis, France, acquired Shantha Biotechnics, India); Asian companies acquire or obtain technologies and distribution rights from European countries (e.g., inactivated polio vaccine by Serum Institute of India Ltd. acquiring Bilthoven Biologicals, Netherlands; Astellas, Japan, acquiring recombinant influenza hemagglutinin from Protein Sciences, U.S.; Thai Government Pharmaceutical Organization acquiring chimeric JE vaccine from Sanofi-Pasteur, France; and Biological Evans, India, acquiring JE vaccine from Intercell AG, Austria); and vaccine codevelopment is agreed between entities in developed and Asian countries (e.g., genetically modified, inactivated HIV vaccine codeveloped by Sumagen, Korea, and the University of Western Ontario, Canada; mycobacterial proteinAg85A candidate tuberculosis vaccine codeveloped by Tianjin CanSino Biotechnology, China, and McMaster University, Canada; universal influenza vaccine codeveloped by Xiamen Wantai and Sanofi-Pasteur, France; and novel pneumococcal conjugate vaccine codeveloped by SK Chemicals, Korea and Sanofi-Pasteur, France).[2,4,5]

The role of Asian companies as developers and providers of neglected and improved vaccines for the region and, for developing countries more generally, is an emerging trend as illustrated by the joint research activity agreement between the National Research Council, Canada, and the Chinese National Biotec Group that covers development of *H. influenzae* type a and Hib bivalent conjugate vaccine, novel mucosal adjuvants and therapeutic vaccines against *Helicobacter pylori* infection, and cell culture manufacturing platforms for viral and vectored vaccines. A Korean-manufactured biosimilar (generic) biological, infliximab, now is licensed in Europe, a step toward commercial expansion of Asian region-manufactured biologicals to developed countries. The emergence of Asia as the base of new multinational vaccine companies with broad development, production, and distribution capabilities is on the horizon, even as consolidation of existing companies occurs elsewhere.[6–8]

The broad income range within countries in the region results in large population segments that have sufficient means to pay for vaccines out-of-pocket. Even among countries that otherwise qualify economically for Gavi funding (e.g., India), substantial numbers of families can avail themselves of vaccines not covered by the national EPI, resulting in a two-tiered system of vaccination, paralleling the public–private dichotomy of healthcare delivery in general. Practitioners serving these and expatriate families generally follow current U.S., European, or Australian vaccine recommendations, or some modification of those schedules.

Perceptions of the value of vaccines and their risks also range widely, regionally and within individual countries, from largely enthusiastic acceptance and even demand for additional routine vaccinations (e.g., for JE vaccine in southern and Southeast Asia) to a degree of skepticism equal to, if not more deeply and widely held, than vaccine hesitancy in Europe and the United States. Within the last 20 years, Japan discontinued routine childhood vaccine programs for combination measles-mumps-rubella, influenza, and JE, and withdrew recommendations for the human papillomavirus (HPV) vaccine for adolescents, owing in several of instances, to incorrectly thinking that coincidental adverse events were causally related. The requirement for subcutaneous, as opposed to IM administration for all vaccines, exemplifies the misattribution of adverse reactions, arising in this case from an extrapolation of muscle contractures resulting from repeated IM administration of antibiotics, to other intramuscularly administered products, including vaccines.[9,10] The extrapolation has had unintended consequences of impeding the licensure of vaccines with newer adjuvants with mechanisms of action that require IM administration. With the global spread of information, concerns over the thimerosal content of childhood vaccines and vaccine-associated autism have been as active a parental concern among middle-class families in developing countries as elsewhere. Parental refusal of routine JE vaccination in Korea and significant declines in vaccine coverage occurred in a different context after seven cases of temporally related cases of anaphylactic shock and neurological disease, including five deaths, occurred in 1994. The cases could not be excluded as causally related to administration of the mouse-brain–derived vaccine, prompting a national debate and establishment of a vaccine adverse events reporting scheme, a national vaccine injury compensation system, and introduction of a live attenuated JE vaccine derived from a nonneural tissue substrate.[11]

From this mosaic, we describe some common themes, highlighting representative approaches and unique issues that hold a wider interest. Because they are covered elsewhere in this volume, we have not reviewed specific vaccines of regional concern (e.g., pandemic influenza and JE vaccines) or vaccination topics common to developing countries (e.g., initiatives surrounding injection safety, measles and neonatal tetanus elimination, and polio eradication, nor financing mechanisms). We concentrate, instead, on other aspects of vaccine development and implementation, organized by the steps of vaccine development, approval, production, recommendation, and delivery. We also focus on childhood vaccines and vaccination and on selected countries in the region.

VACCINES DEVELOPED IN AND FOR THE ASIA-PACIFIC REGION

Japan is acknowledged as the innovator of several vaccines now used internationally, including acellular pertussis and live attenuated varicella vaccines, but other novel vaccines have been developed by Japan, China, India, Australia, and Vietnam for region-specific needs (Table 75.1). These include vaccines for JE, Hantaan (HTN)- and Seoul (SEO) virus-related HFRS, Russian spring–summer encephalitis, KFD, cholera, severe acute respiratory syndrome, and Q fever. In addition, novel attenuated strains of measles, mumps, hepatitis A, rotavirus, and intranasally delivered pandemic H1N1 virus have been derived for products distributed principally within the region. Additional novel vaccines for hepatitis E and EV-A71 have potential for broader use internationally, an indicator of the region's transition from a provider of fill-finish and manufacturing capacity to a full-fledged participant in biotechnology research and clinical development.

Japanese Encephalitis Vaccines

Five JE vaccines have been developed and licensed in Asian countries. The widely used first-generation inactivated suckling mouse brain (SMB)–derived vaccine is being replaced rapidly in economically disadvantaged countries by the Chinese developed and manufactured live attenuated or inactivated vaccine (SA14-14-2 strain) grown in primary baby hamster kidney (PHK) cells and in higher-income countries with Vero cell–derived inactivated vaccines (licensed in the United States, Australia, Canada, and Europe, as well as several Asian countries) or a replicating chimeric yellow fever–JE virus recombinant vaccine (manufactured in Thailand). Details are provided in Chapter 33.

Tickborne Encephalitis Vaccine

To control cases and occasional outbreaks of the Far Eastern subtype of tickborne encephalitis virus in northeastern China, the Changchun Biologicals Institute developed a formalin-inactivated vaccine, derived from a human isolate, Senzhang strain, and grown in PHK cell cultures. Related vaccines prepared from Central European strains and distributed in Europe are described in Chapter 59.

Kyasanur Forest Disease Vaccine

The Kyasanur Forest disease virus (KFDV) is a highly pathogenic member of the family Flaviviridae causing a zoonosis, KFD, that is transmitted by the bite of infective ticks (*Haemaphysalis spinigera*) primarily in its nymphal stage, and characterized by acute febrile illness with severe hemorrhagic manifestations.[12] It was first described from outbreaks centered in Karnataka State, India, among herders and villagers with forest exposure and was considered to be localized in the Shimoga district area of the state. However, since first being reported in 1957, the virus has been found in other areas of India including the Kutch and Saurashtra parts of Gujarat state, Andaman Islands and West Bengal. It is estimated that close to 500 cases of KFD occur in India every year and, from 2003 to 2012, among 823 confirmed cases, 28 were fatal.

Following the outbreak in India various vaccines including a formalin inactivated Russian Spring Summer Encephalitis virus, a Russian Spring-Summer Encephalitis virus–based mouse-brain vaccine, and a live attenuated vaccine that was serially passaged in tissue culture were tried but with limited success.[13] Finally, a formalin inactivated vaccine with the KFD virus grown in chicken embryo fibroblasts was tested in a large field trial from 1990 to 1992 among inhabitants of 72 affected villages. The disease attack rates reported were 0.15% (14/9072) among persons receiving one dose and 0.047% (10/21,083) among recipients of two doses, respectively, compared to an attack rate of 0.870% (325/37,373) in unvaccinated persons, for vaccine efficacies of 82.4% and 94.8%, respectively.[14] The vaccine was subsequently commercialized and is produced by the state Institute of Animal Health and Veterinary Biologicals, Hebbal, Bangalore, and has been central to KFD prevention efforts in the state of Karnataka. Annual vaccinations have been done since 1990 in the Shimoga and adjacent districts wherein two doses of the vaccine were administered in individuals 7 to 65 years of age at an interval of 1 month. Periodic boosters were also administered after 6 to 9 months.

However, recent observations suggest a lower field effectiveness than had been reported previously, especially following a single dose, while overall coverage has also been low. Between 2005 and 2010, effectiveness among individuals

who received two primary vaccine doses was 62.4% (95% confidence interval [CI], 26.1 to 80.8), and 82.9% (95% CI, 71.3 to 89.8) among those who received two doses followed by a booster.[9] Moreover, vaccination during the months of April and May 2011 did not confer protection in an outbreak in Shimoga during the months of December 2011 to March 2012.[15] The reasons for low vaccine efficacy and coverage rates need to be investigated and the appropriate vaccine regimen for effective control requires further definition. Newer vaccine approaches (e.g.., chimeric or virus protein subunit vaccines) are being investigated to potentially replace the current vaccine.

Elsewhere, a nearly identical strain to the KFDV was isolated from a patient suffering from acute febrile illness from Yunnan province, China in 1985. Seroprevalence studies indicate that KFDV (or the Nanjianyin virus or a related tickborne flavivirus) may be present in various parts of southwestern China.[16] In 1995 a virus similar to KFDV called Alkhurma hemorrhagic fever virus was isolated from patients with febrile illness in Saudi Arabia.[17] Overall, 10 cases with two deaths occurred in sheep and camel handlers exposed to a tick *Ornithodoros savignyi*. The disease has now been confirmed to be more widespread in the country than previously considered.[12]

As tickborne diseases are "diseases of place," KFD virus itself, if it spreads, is likely to disseminate locally. Nevertheless, the discovery of antigenically related viruses elsewhere, such as Alkhurma hemorrhagic fever virus, suggests a potential for more widespread use of KFD vaccine, depending on public health needs.

Hantavirus Vaccines

HFRS, a widespread rodent-borne bunyaviral zoonosis in Asia, is a pantropic infection with prominent capillary hemorrhages, interstitial nephritis, and a 3% to 10% case-fatality ratio that, until the last decade, caused more than 1000 annual cases in the Republic of Korea and more than 100,000 cases in China.[18] Although the disease had been well known in parts of Russia and Asia as a sporadic and occasionally epidemic disease among farmers, soldiers, and others exposed to campestral and sylvatic habitats, it was largely unknown in the West until thousands of military cases and deaths occurred during the Korean war, when the disease was described as Korean hemorrhagic fever. The etiologic agent eluded investigators until 1976, when a novel bunyavirus, HTN virus was isolated from the striped field mouse, *Apodemus agrarius*, which proved to be the principal viral reservoir in most areas of Asia. Later, antigenically related SEO virus was isolated from *Rattus rattus* and *Rattus norvegicus*, explaining the occurrence of sporadic HFRS cases and outbreaks in urban areas. Subsequently, Sin Nombre and related hantaviruses were discovered in the Western hemisphere, where rare encounters with infected rodents lead to small numbers of cases that feature prominent pulmonary involvement. A multitude of hantaviruses now have been described globally.

The widespread impact of HFRS in China led public health authorities in the 1980s and 1990s to pronounce the disease second only to HepB as a public health menace, and, beginning in 1991, several Chinese vaccine manufacturers used SMB, primary baby gerbil kidney cells (GKCs) or PHK cells to produce inactivated, monovalent vaccines against HTN or SEO viruses. The GKC vaccine was inactivated by β-propiolactone and the other two by formalin. Subsequently, Vero cell line-derived vaccines have been developed. These vaccines were evaluated in nine Chinese provinces hyperendemic for HFRS during 1994 to 2000.

The GKC-derived vaccine against HTN virus produced seroconversions to putatively protective titers of neutralizing antibody in 70.0% of subjects after three primary doses at 0, 7, and 28 days, the proportion rising to 91.2% after a booster at 1 year, and declining to 59.0% at 2 years and 38.9% at 3 years.[1] Similar immunogenicity results were reported for the PHK-derived vaccine and the purified SMB vaccine.[19]

In a randomized, controlled, three-arm trial of GKC vaccine in which vaccinated subjects received three primary doses and a booster at 1 year, 18 HFRS cases were observed in the 7866 age-, sex-, and residence- matched controls, and 23 cases in the 10,196 unvaccinated subjects of similar age (16 to 60 years), compared with none in 7866 vaccinees during 76 months of follow-up, for a protective efficacy of 100% (95% lower confidence limit of 81.94%, $P = .00003$, cumulative binomial probability).[20] Efficacy of the three primary doses alone was shown in the year between administration of the three primary dose series and the booster dose: with zero cases in the vaccinated, and nine and 10 cases in the unvaccinated and control groups respectively. Among 41 cases in the control and unvaccinated groups, 24 were caused by HTN virus, 13 were caused by SEO virus, and four by a virus of indeterminate serotype. Thus, the monovalent GKC-derived HTN virus vaccine was protective not only against the homologous virus, but also cross-protective against SEO virus. No vaccine-related serious adverse event was reported during the trial, and mild local and systematic reactions were reported in 3.78% of vaccinees.

The efficacies of the PHK vaccine and the purified SMB vaccine were similar: in nonrandomized trials, one HFRS case was found in 40,757 recipients of PHK vaccine, compared with 53 in 47,313 unvaccinated subjects, a reduction of 97.81%; for the purified SMB vaccine, the rates were 3.71 per 100,000 (1/26,942) versus 97.98 per 100,000 (34/34,699) for vaccinees and unvaccinated subjects, respectively, a reduction of 88.45%. The observed reductions were maintained through 6 years of follow-up. Nonsevere reactions were found in 1.57% of PHK vaccine recipients and in 3.26% of SMB vaccine recipients.[21,22]

Bivalent HTN and SEO GKC- and PHK-derived vaccines were developed and improved by purification procedures through gradient density ultracentrifugation or chromatography to be more immunogenic and less reactogenic. The purified bivalent GKC vaccine induced neutralizing antibody seroconversion against HTN virus and SEO viruses in 95.4% (83/87) and 93.1% (81/87) of volunteers, respectively, after two doses with an interval of 14 days, and 96.3% (78/81) and 95.1% (77/81), respectively, after a booster dose at 6 months. Only mild reactions were observed; local reactions in 1.72% (14/812) and systemic reactions in 2.83% (23/812) of the vaccinees.[23] The purified bivalent PHK vaccine induced neutralizing antibody seroconversion against HTN virus and SEO virus in 87.4% (90/103) and 89.3% (92/103) of subjects, respectively, after two doses separated by 14 days, and 93.3% (84/90) and 92.2% (83/90), respectively, after a booster dose at 6 months. No systemic reaction was found among 396 vaccinees and mild local reactions were observed in two (0.5%).[24]

The purified, bivalent GKC vaccine was tested for protective efficacy in a nonrandomized trial among 225,576 subjects, 16 to 60 years of age; 112,143 persons received the two primary doses with an interval of 14 days and a booster dose at 6 months; 113,433 persons were unvaccinated. The two groups were similar in age distribution. During 3 years of follow-up, 22 HFRS cases were found in 337,812 person-years among the unvaccinated, a rate of 6.51 per 100,000, compared with none in the vaccinated 334,086 person-years, a reduction of 100%.[25]

Several manufacturers have adapted their processes from primary gerbil or hamster cells to continuous Vero cells. The purified, bivalent Vero cell–derived vaccine administered in two doses separated by 14 days, induced neutralizing antibody against HTN virus and SEO viruses in 90.12% (73/81) and

91.35% (74/81) adult volunteers, respectively.[7] Mild systemic reactions were observed in 3.66% (12/328) and mild local reactions in 1.83% (6/328) of vaccine recipients.[26] The immunogenicity and safety profiles of the Vero cell–derived, purified bivalent vaccine were similar in children and older adults.[27]

Based on the above data, a schedule of two primary doses with an interval of 14 days, plus a booster at 6 months, has been recommended for the purified bivalent GKC-, PHK-, and Vero-cell–derived vaccines.

A postlicensure, retrospective study was conducted to measure the long-term effectiveness of the GKC vaccine among 24,556 adults 16 to 60 years of age, in 21 villages located in a hyperendemic area of Shaanxi Province.[28] HFRS incidence rates were compared between the vaccinated and the unvaccinated adults: 0.06% (4/6828) versus 3.09% (27/875), respectively, for the first 5 years after vaccination; 0.18% (10/5707) versus 1.53% (28/1827) in years 6 to 10; 0.11% (5/4673) versus 0.96% (26/2719) for years 11 to 14; and 0.29% (5/1713) versus 2.80% (6/214) at 15 to 17 years. The vaccine's effectiveness was thus estimated at 98.06%, 88.24%, 88.54%, and 89.64%, respectively, for the four study periods. The effectiveness was underestimated because the year of onset of HFRS was unknown for 36 cases, all of whom belonged to the unvaccinated group and were not included for analysis.[10] The overall HFRS attack rate was 0.13% (24/18921) in the vaccinees and 2.18% (123/5635) in the unvaccinated subjects, a reduction of 94.04%.[28]

A long-term study of the monovalent PHK-derived SEO virus vaccine also was conducted among adults 15 to 60 years old in a SEO virus-predominating area, from 1995 through 2005.[11] Only three primary doses were given at 0, 7, and 28 days without a booster. Seven HFRS cases were found in 1,467,188 subjects in the vaccine group, a rate of 0.48 per 100,000, and 412 cases were found in 6,379,278 controls, a rate of 6.46 per 100,000, with an overall reduction of 92.61% (95% CI, 87.09% to 98.13%) during the 11 years of the study. The vaccine's effectiveness was estimated at 100% for the first year, 95.56% for the second year, and 92.61% for the 11th year. The rate reductions in other years were approximately 92%.[29]

A SMB-derived HTN virus vaccine also was developed in the Republic of Korea and is available for at-risk individuals. The incidence of HFRS in China and Korea has declined in the last 10 years with the introduction of vaccination and probably, more importantly, because of urbanization, rural economic development leading to improved (cement) houses, and grain harvesting and storage practices, resulting in reduced exposures to the rodent reservoir. This trend has been most evident in rapidly developing areas of southeastern China and likely will continue in other regions, leading to a diminution of disease incidence and, potentially, discontinuation of routine vaccination in endemic provinces.

Other Novel Vaccines Developed in the Asia-Pacific Region

See Table 75.2.

Two similar live attenuated hepatitis A vaccines, based on the H2 and LA-1 strains, and measles vaccines, based on the Shanghai S-191 and Changchun-47 strains, have been licensed in China and are used domestically and exported. The National Institute of Hygiene and Epidemiology in Vietnam developed an oral bivalent O1-O139 killed whole-cell cholera vaccine that now is produced and distributed by VABIOTECH, Company for Vaccine and Biological Production No.1, in Hanoi; another oral bivalent O1-O139 vaccine based on the VABIOTEC vaccine but with improved production design is produced in India by Shantha (Sanofi, France). Both vaccines are used domestically and also exported. Similarly, live rotavirus vaccines based on local strains have been developed in India and China for local use. EV-A71 and related enteroviruses have emerged in major seasonal epidemics in Asia and Australia, leading to millions of cases and extensive social disruption as daycares and schools are closed. The extent and impact of seasonal outbreaks stimulated vaccine development in China, Taiwan, Malaysia, Singapore, and Japan, with government prioritization and support in some countries, analogous to mechanisms that facilitated pandemic influenza vaccine development. An *Escherichia coli*–expressed capsid peptide virus-like particle hepatitis E vaccine, approved by the China Food and Drug Administration, is the first novel recombinant vaccine developed and licensed in Asia. Its potential use in Africa, South Asia and, possibly, even in developed countries in immunocompromised or other risk groups could be envisioned.

CLINICAL DEVELOPMENT AND REGULATORY APPROVAL

Implicit in the region's progress toward novel vaccine development is a maturing capacity to conduct clinical trials and improvements toward more robust regulatory processes and capacity, including pharmacovigilance systems. In addition, multinational companies increasingly have turned to countries in Asia to conduct clinical trials because of lower costs and more streamlined regulatory approvals of clinical trial applications. International contract research organizations operate in many countries, and a growing local infrastructure to conduct clinical trials in compliance with the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use and good clinical practices standards will improve clinical research conducted in the region.

Unlike Europe, Asian countries are not unified in a central regulatory approval process. Nor is there a regional public health presence as in Latin America, where the Pan American Health Organization (PAHO) leads regional vaccination programs and also provides central purchasing of certain qualified vaccines. However, the 10-nation Association of Southeast Asian Nations (ASEAN; includes Brunei-Darussalam, Cambodia, Indonesia, Lao PDR, Malaysia, Myanmar, Philippines, Singapore, Thailand, and Vietnam) in 1992 initiated efforts for a subregional regulatory harmonization scheme to reduce differences in technical requirements and regulatory procedures for pharmaceuticals.[30] A 1999 harmonization initiative, under auspices of a Pharmaceutical Product Working Group, aimed to remove barriers to regional commerce and to eliminate technical barriers to trade without compromising product quality, efficacy, and safety. Eventually, a subregional central or mutual-recognition procedure similar to that of the European Union could be envisioned. Importantly, local clinical trials are not required for registration under abbreviated pathways specified by the ASEAN Common Technical Dossier if the vaccine was approved and licensed by a benchmark regulatory agency, resulting in a certificate of pharmaceutical product. By contrast, the national regulatory authorities of China, India, Japan, Korea, and Taiwan have required local clinical trials before or after registration, and in other countries, while data in local populations may not be required for registration, those data are important in deliberations on a vaccine's inclusion in the national schedule. For dengue, a disease of special public health urgency regionally, the global debut of candidate vaccines in the region is being considered, with individual country vaccine registrations ahead of approval by a benchmark agency and provision of a certificate of pharmaceutical product. The

[a]Information obtained through surveys of local governments and manufacturers, through April 2015.
[b]Major investment/partnership with multinational company.

initiative is a collaboration among the nongovernmental organizations, the Dengue Vaccine Initiative, and the World Health Organization (WHO) Developing Countries Vaccine Regulatory Network (DCVRN). The WHO through the DCVRN has been actively working toward harmonizing procedures in affiliated countries, including China, India, and Indonesia, to bring those regulators under the WHO prequalification umbrella and to facilitate approval and supply of their products for Gavi and United Nations Children's Fund (UNICEF).[31]

The requirement of some national regulatory authorities for clinical data in local populations is based on a concern that racial, ethnic, or environmental differences could affect responses of the local population, both immunologically and in their risk for adverse events. Genetically based differences in drug pharmacokinetics and pharmacodynamics, as well as disease risk, increasingly have been recognized, including immune responses to vaccines. Studies of antibody responses to pneumococcal conjugate vaccines in Asia, for example, have found higher prevaccination and postvaccination antibody titers among Philippine and Taiwanese infants compared with European or historical control subjects, and in Korea, a considerably higher proportion of subjects were seropositive to meningococcal serogroup W135 polysaccharide at baseline than in the United States.[32–34] While the basis for these differences may be an earlier exposure in life to cognate or cross-reacting antigens (e.g., because of regional differences in host microbiomes), genetically restricted responses, as have been observed with HepB, measles, vaccinia, rubella, Hib, and other antigens, or, in the case of oral rotavirus vaccine, in genetically determined viral attachment or receptor binding molecules, have been described.[35–38] From the perspective of adverse events following immunization, the example of narcolepsy occurring in some recipients of an adjuvanted pandemic H1N1 vaccine illustrates the role of genetic background as a cofactor in risk.

In many examples, regulatory systems and processes in the region have had the effect of markedly slowing or effectively blocking the introduction of novel vaccines developed externally. In China, the introduction of an internationally registered and otherwise widely used product nevertheless necessitates recapitulating the entire clinical development program in China, including Phase I studies, despite an abundance of previously scrutinized evidence. This requirement introduces a delay of a decade or more for registration of internationally developed, as opposed to domestically developed, vaccines. Specifications in national pharmacopeias that deviate from established compendia, for example, exclusion of well-accepted excipients or methods, also have seriously impeded or prevented registration of foreign products or, when imposed with a revision of the pharmacopeia, have led to withdrawal of a previously registered product. Clinical trial processes also have hindered local introduction of established or novel products (e.g., a 2013 Indian Supreme Court ordered suspension of ongoing clinical trials and reexamination of previously approved trials was followed by a wholesale revision of clinical trial guidelines, leading to a temporary cessation of all industry-sponsored clinical trial activity). The potential inclusion of video recording of the informed consent process, newer insurance requirements and further proposed but unclear amendments to the Drug and Cosmetics Act that could impose criminal penalties against trial investigators for poorly defined violations may further limit trial activity.[39] China and Indonesia place severe restrictions on the exportation of clinical samples from study subjects, thereby requiring that validated laboratories and procedures are established locally, adding a barrier that has led to delays of or avoidance of clinical studies in those countries. Whether resulting from inexperience, a dearth of trained personnel, trade protection, or other reasons, administrative mechanisms in various countries in the region have had the effect of delaying the registration of proven vaccines that otherwise could have prevented significant morbidity and mortality with more timely introductions.

Descriptions of individual regulatory requirements for clinical trial applications and new product approvals are beyond the scope of this chapter; see the previous edition for a more detailed introduction.

VACCINE PRODUCTION

Governments have had a greater role in vaccine manufacturing in the region than elsewhere, although devolution toward privatized or state-owned enterprises (i.e., government-owned corporations) has occurred (e.g., Commonwealth Serum Laboratories in Australia was privatized, and the six major government vaccine institutes in China now operate as a state-owned enterprise, China National Biotech Group; see Table 75.2). Although a growing number of private manufacturers have emerged, especially in China and India, in other countries, national and local government manufacturers continue to be important sources of certain vaccines and biologicals for domestic needs (e.g., the Government Pharmaceutical Office in Thailand, Research Institute for Tropical Medicine in the Philippines, Biofarma in Indonesia, the National Institute of Hygiene and Epidemiology in Vietnam, and the Central Research Institute and local government institutes in India). These and other facilities also fill and distribute bulk vaccines supplied by international manufacturers. Several private and state-owned enterprise manufacturers in the region are members of the DCVMN, a consortium that seeks to identify and develop solutions to common challenges faced by manufacturers in developing countries.[2,4,8,40]

A number of manufacturers (including 12 in five Asia-Pacific countries) operate under practices and procedures that have prequalified them to produce certain vaccines for UNICEF, PAHO, and Gavi purchases (e.g., pentavalent DTP combinations, oral polio vaccine, inactivated polio vaccine, HepB, rabies, influenza, oral cholera, and measles-containing vaccines) or that allow them to export vaccine to other countries in the region. A reliable supply of inexpensive diphtheria and tetanus toxoids combined with whole-cell pertussis (DTwP)-Hib-HepB combination vaccines, made possible largely by Indian and Korean manufacturers, has facilitated the introduction of Hib antigen into schedules of economically disadvantaged countries that otherwise would not have adopted the monovalent vaccine. Similarly, provision of measles and measles containing vaccine by Indian manufacturers was key to the elimination of that disease in Latin America and the current state of polio elimination could not have been achieved without supplies from Asian regional manufacturers. The provision of oral cholera vaccine for outbreak control in Haiti, Pakistan and other countries is an important example of the increasing ability of and global dependence on these manufacturers.

WHO prequalification requires that the manufacturers and plants not only must satisfy WHO good manufacturing practices inspections, but, in addition, that national notifications of adverse events following immunization are captured and analyzed satisfactorily. This last requirement has been the principal impediment to prequalification of products from some countries and prequalification aided by WHO Blueprint and other vaccine safety-related guidelines have facilitated the improvement of vaccine-related pharmacovigilance in the region.

In China, the state-owned China National Biotec Group is the dominant supplier of vaccines in the country, providing 82% of doses used in the public program and 28% taken up

privately. The Group comprises 12 manufacturing sites, which produce some 40 products, including the first WHO prequalified vaccine produced in China (SA14-14-2 JE vaccine). Other private companies compete principally to provide vaccines for out-of-pocket sales at local centers for disease control and prevention and hospitals.

Within the ASEAN community, comprised principally of low- and middle-income countries, regional vaccine security has been a focus of discussion, reflected in the establishment of the ASEAN-Network for Drug, Diagnostics and Vaccines Innovation that focuses on a broad agenda of health technology development and collaborations on vaccine manufacturing and plans for regional vaccine purchasing—similar to PAHO's revolving fund. Similarly, the eight-nation South Asian Association for Regional Cooperation includes biotechnology in its agenda for cooperative research. A goal to achieve self-reliance in vaccine supply also has been articulated in Korea, in its 2020 horizon-setting.

To a growing extent, multinational companies are acquiring or partnering with local companies in the region, with the result that manufacturing standards and their regulation should improve toward meeting international specifications.[29]

Table 75.2 lists the region's principal vaccine manufacturers and their licensed products. The list is not intended to be comprehensive, as the sometimes rapid emergence or disappearance of pharmaceutical and vaccine companies in China and elsewhere is difficult to track. Vaccines that are manufactured elsewhere and refilled and distributed by local manufacturers are not listed.

VACCINE POLICY AND SCHEDULES

Countries in the region can be divided broadly into countries with a single national schedule and countries in which a basic schedule of free EPI vaccines is supplemented by recommendations of a professional organization (such as the national pediatric society) for additional antigens that are paid for out-of-pocket. Countries in the first group include, on the one hand, mainly developing countries offering a basic EPI schedule and, on the other, countries like Australia, New Zealand, and Taiwan that provide a universal vaccination program that includes an array of antigens or combination vaccines paralleling those of European and U.S. schedules.

The continued introduction of new and frequently expensive vaccines is an ongoing tension for vaccine recommending and funding entities that must weigh the relative value of such innovations against other preventive and therapeutic health expenditures. Even for low-middle-income countries in the region, the total per capita expenditure for all healthcare may be less than the cost of a full course of a novel vaccine! On the other hand, national schedules in the region can be as comprehensive as to include the HPV vaccine (Australia) and influenza and varicella vaccines (e.g., Korea, Taiwan). At the same time, Hib vaccine still is not recommended in some jurisdictions with high per capita income (Hong Kong, Singapore). To some degree, the seemingly paradoxical recommendations of relatively high-income countries in the region reflect different social expectations of personal responsibility in healthcare purchases (see subsequent text). As shown in Table 75.1, some national schedules provide optional recommendations for some antigens; in many countries where government tenders choose specific manufacturer products, specific combinations are recommended in the national schedule. In addition, for some antigens, provincial-specific recommendations address regional differences in risk (e.g., for routine group AC meningococcal vaccine in China; for JE vaccine in Sarawak, Malaysia, and for the Torres Straits, Australia; and for rabies vaccine [preexposure] in areas of the Philippines).

In most countries in the region, public health authorities now draw on external advisors to help formulate national vaccine recommendations in National Immunization Technical Advisory Groups (NITAG), resulting, in part, from activities of the Supporting Independent Immunization and Vaccine Advisory Committees Initiative (at the Agence de Médecine Préventive).[41–44] The Advisory Committee on Immunization Practices (ACIP) in Taiwan and Korea, Expert Committee on Immunization in Singapore, Chinese Expert Committee on EPI, Hong Kong Scientific Committee on Vaccine Preventable Diseases, Immunization Committee of the Indonesian Pediatric Society, National Technical Advisory Group for Immunization in India, and the Australian Technical Advisory Group on Immunization are examples of such medical advisory groups. In China, vaccine recommendations are made through the National Centers for Disease Control based on recommendations of the Chinese Expert Committee on EPI under the Ministry of Health and Family Welfare; however, provincial or local Centers for Disease Control may issue independent recommendations for specific vaccines or modify the national recommendation for routine vaccines (see Tables 75.1 and 75.3).

The issues considered by Asian NITAGs in formulating vaccine recommendations parallel those of other NITAGs, focusing on medical need, vaccine safety and efficacy, national resources, as well as implementation issues, including supply, cold-chain, fit within the national schedule, vaccine presentation, etc. Health economic analyses are considered in the deliberation of some committees or are provided by an independent body (e.g., the Health Intervention and Technology Assessment Program in Thailand); although, in general, the use of health technology assessments in the region lag behind the United States and United Kingdom. In some cases, industry sponsors, in providing such analyses to NITAGs in their justifications to include new vaccines into national programs, have played a role in introducing cost-to-benefit analyses to the recommendation process. In Indonesia and Malaysia, the halal status of vaccines is an important factor in public acceptance of a product and also is a consideration in the vaccine recommendation process, although there is movement to remove this consideration from debate.

In certain Asian countries, as well as in Latin America, the approval process to include a new vaccine into the national program is used to leverage multinational companies to foster local manufacturing expertise. In Brazil, technology transfer of the vaccine production process is required in turn for the vaccine's inclusion into the national schedule while, in Indonesia, all EPI vaccines are locally produced by BioFarma, and no new vaccine has been introduced into the national schedule unless it was produced locally. Technology transfer of some element of the manufacturing process also is a factor in introduction of new vaccines to Thailand and Malaysia. Such requirements may be tested as costly vaccines manufactured by more complex technologies are introduced to the region.

The recommendation process in Japan illustrates how, even after registration, organizational and administrative processes can result in a lengthy interval before a new vaccine is introduced to the national schedule.[44] Although, since 2009, Japan has recovered from a "vaccine gap"—the self-acknowledged interval during which antigens such as Hib and pneumococcal conjugate, rotavirus, HPV, inactivated polio and various combination vaccines were not introduced into Japan despite their widespread use in other developed countries—adoption of new vaccines into the National Immunization Program after their registration still lags several years. A number of sequential approvals lengthens the process: the Immunization Policy and Vaccination Committee provides an initial recommendation whether the newly registered vaccine should

TABLE 75.3 Adult Immunization Recommendations by Antigen and Jurisdiction, Asia-Pacific Region[a]

Jurisdiction	Tdap Variations[b]	Seasonal Influenza	Pneumococcal	MMR
Australia	DT 45, 54 y	65 y+, pregnant women, *>15 y+*	PPS 65 y+, *50 y+,* 15–49 y high-risk	
Brunei Darusalaam		Chronic illness, pregnancy, HCW, Hajj travelers

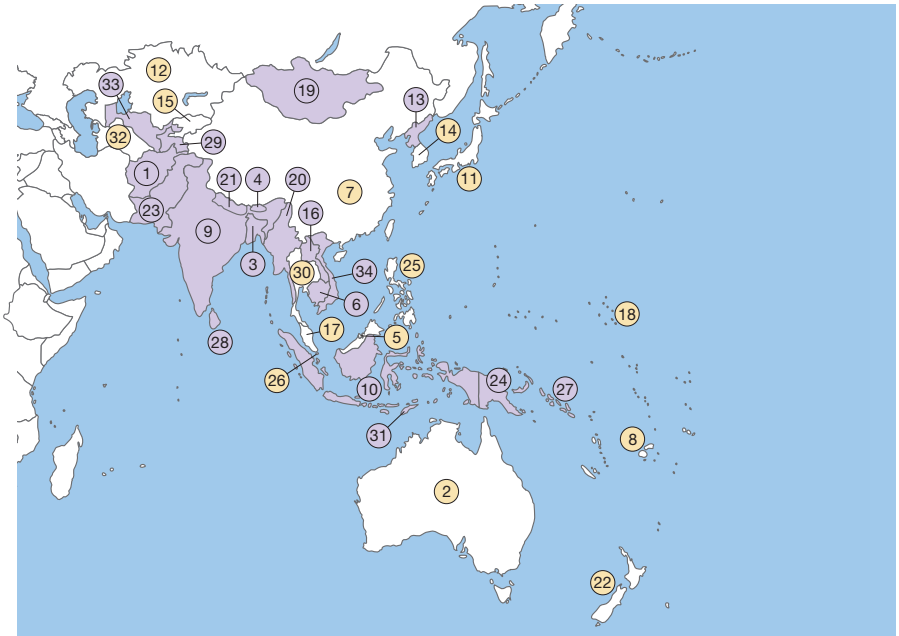
						Food handlers	

be classified as either "routine" or "voluntary," based on available data; the technical recommendation is considered by the Tuberculosis & Infectious Diseases Control Division which makes the administrative decision for the vaccine's inclusion in the national schedule; however, that decision requires additional legislative approval whether the disease (category A or B) qualifies for full or partial vaccine funding (up to circa 70%), respectively. The recommendation process is even lengthier than appearances suggest, as the Immunization Policy and Vaccination Committee does not convene a deliberative vaccine working group until after the product is registered, unlike the parallel activities of the U.S. ACIP and Food and Drug Administration. Only then does the committee assemble a dossier (Fact Sheet) that establishes the epidemiology of the disease and its local burden; if insufficient data are available, de novo studies might be required to establish need. The overall interval between vaccine approval and issuance of a recommendation typically is 3 years.

Other Asian countries have similar or even lengthier intervals between vaccine registration and full EPI implementation. In Thailand, for example, after a preliminary NITAG recommendation, a new vaccine is implemented in a pilot program to establish effectiveness and to collect additional safety experience. Such a program may be gradually extended to other localities over a period of as long as a decade before the antigen is provided nationally. For diseases with regional differences in disease burden, high-risk provinces may be covered first (e.g., JE vaccine initially was introduced in Thailand to eight high-incidence provinces and progressively, from 1990 to 2000, to all 76 provinces, while local production was established and expanded). For new, often costly vaccines, phased introduction provides a mechanism to accommodate their full EPI coverage costs over time. In the interim, local governments of wealthier provinces or municipalities have issued their own recommendations for vaccines to be reimbursed (e.g., Shanghai provides pneumococcal polysaccharide vaccine free of cost to older adults and Bangkok established a school-based HPV vaccination program, while neither vaccine is included in respective national schedules).

Innovative financing mechanisms have played an important role in the introduction of vaccines to low-income countries, and their extension to graduating Gavi will enable more rapid adoption of new vaccines in those countries. At the same time, tiered pricing, negotiated between sponsors, local government and other entities will aid middle income countries to accelerate vaccine adoption, as exemplified by introductions of PCV and rotavirus vaccines.

During the interval between a vaccine's registration and its inclusion in the national schedule, after which it is available without cost, out-of-pocket sales still may result in considerable uptake. While rotavirus vaccine is still considered a voluntary vaccine in Japan, coverage among infants is estimated to be approximately 50%. In Korea, although almost all pediatric vaccines are self-paid by parents, vaccine coverage for antigens such as Hib and pneumococcal conjugate vaccine rapidly reached coverage rates of approximately 90% that, with herd effects, led to disappearance of the respective diseases as quickly as in other countries. Although in Japan, the "voluntary" vaccine recommendation emanates from a government committee, in other countries, academic societies play the principal role in recommending vaccines that are not included in the EPI schedule. The Malaysian Pediatric Association, The Pediatric Society of Thailand, and The Philippines Foundation for Vaccination not only advise their respective ministries and NITAGs in formulating national recommendations, but also promulgate recommended schedules of administration for other approved but not EPI-covered antigens, emulating in large part or entirely from U.S., Australian, or European schedules. Table 75.1 distinguishes schedules of such bodies from respective national EPI schedules.



VACCINE DELIVERY AND COVERAGE

Vaccines are delivered in varying proportions through public or private channels, depending mainly on local income levels and accessibility to private practitioners. In general, vaccines on national schedules are available at no cost in primary health centers or their equivalent (e.g., puskesmas in Indonesia; polyclinics or government hospital clinics in Singapore, Malaysia, and Thailand; village and county level Centers for Disease Control in China; village communes in Vietnam; public health centers and clinics in India and Japan; and at general practitioner offices in Japan, and Australia). As vaccines generally are available free in public clinics, even in affluent countries, families may obtain them in government clinics or hospitals (e.g., in Singapore, ≈60% of families obtain vaccines through the government system of polyclinics and hospitals). However, to avoid long waiting times and rotating staff at public clinics, many families opt to obtain these otherwise free vaccines privately and to pay out-of-pocket at pediatric, general practitioner, or other private clinics. In addition, as newer vaccines may be delayed in their introduction to the national reimbursement scheme, it is common for parents to pay voluntarily for these vaccines (see earlier). As might be expected from the distribution of income, the proportion of children vaccinated in government primary health centers is higher in rural areas. Overall, approximately 90% of children in Thailand and 70% in Malaysia are vaccinated through public channels. In China, all vaccinations are under control of centers for disease control and prevention; therefore, nearly all Chinese children receive free EPI vaccines, as well as payable optional vaccines (e.g., Hib, pneumococcal conjugate vaccines, varicella, rotavirus, and others) at public clinics. Fig. 75.1 summarizes the coverage for EPI vaccines for selected countries.[45]

Supplementary immunization activities have played a critical role in the elimination of polio from the WHO Southeast Asian Region that was achieved in 2014, and in ongoing efforts to eliminate measles and congenital rubella syndrome. Routine and supplementary immunization activities tetanus vaccinations have eliminated maternal and neonatal tetanus in all but four countries in the region: Cambodia, Indonesia, Papua New Guinea, and Pakistan.

FUTURE TRENDS AND CHALLENGES

Economic growth and development in Asia and secular trends in population structure and the evolution of healthcare systems are forces that inevitably will change various aspects of immunization in the region, if in as-yet unforeseeable ways.[31,32] The population of Asia, as in other regions, is aging and shifting toward a structure with a larger proportion of adults and elderly persons. Between 2005 and 2025, the birth cohort of Asia will decrease slightly from 76.1 to 72.2 million, and the population of children 0 to 4 years old will hold nearly constant while the number and proportion of adults from 15 to 64 years will increase dramatically, and the number of people older than 65 years of age will nearly double, from 250.6 to 480.6 million. A demographic crossover point with more adults 60+ years of age than children younger than 15 years of age was reached in Europe in the 1990s, and will occur within another generation in Asia (Fig. 75.2).[46] With the exception of almost universal EPI programs of tetanus toxoid vaccination of pregnant women, adult vaccination has been viewed mainly in the context of travel, as in group A meningococcal vaccine for the Hajj, and in tropical Asia, influenza vaccine

*Estimates may not include coverage achieved through private channels

Figure 75.1. Estimated coverage of basic childhood vaccines by country, 2015. DPT3, at least 3 doses of DPT vaccine; Hep3, at least 3 doses of hepatitis B vaccine; Pol3, at least 3 doses of polio vaccine; Hib3, at least three doses of *Haemophilus influenzae* type b-containing vaccine; MCV, at least one dose of a measles-containing vaccine; MCV2, second dose of a measles-containing vaccine. Many Global Alliance for Vaccines and Immunization–eligible countries (shaded) have similar coverage rates of basic vaccines as countries at higher levels of economic development, illustrating the success of Expanded Programme on Immunization.

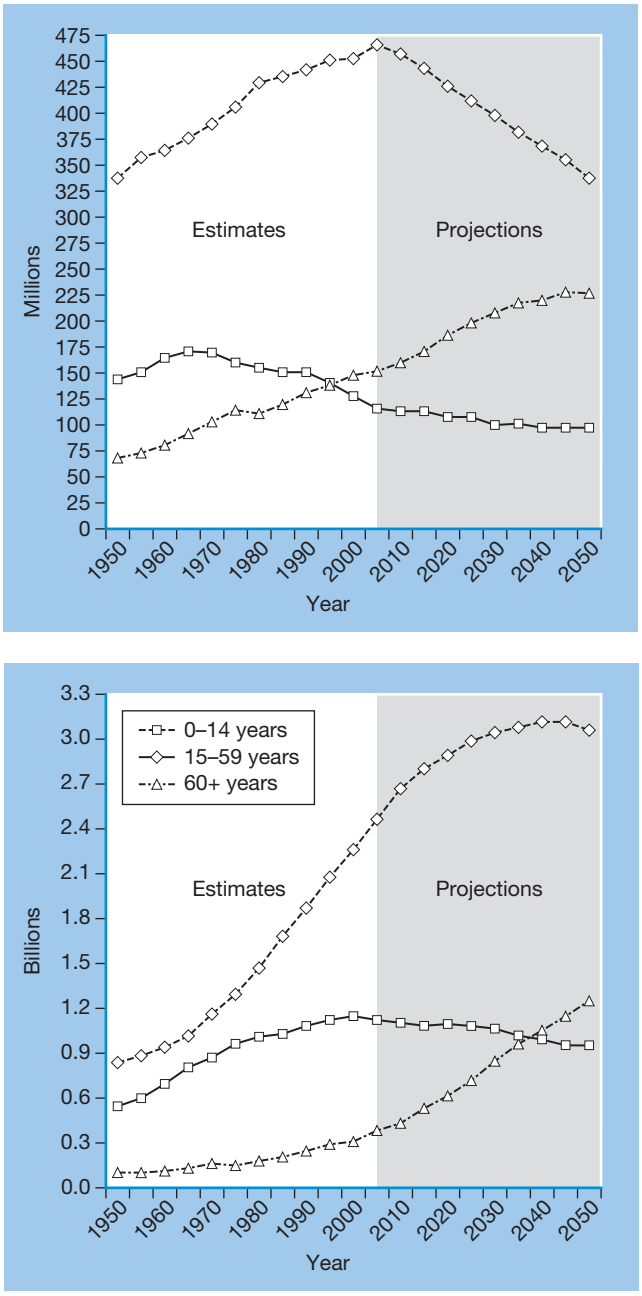

Figure 75.2. Population strata by age in Europe (top) and Asia (bottom), 1950 to 2050 (projected). The crossover point when the population of adults older than 60 years of age exceeded the population of children younger than 14 years of age was crossed in Europe around 1995; that crossover is projected to occur in Asia around 2037, within a generation from now.

for travelers to temperate locations. However, the severe acute respiratory syndrome and pandemic H1N1 outbreaks and the regional threat of H5N1 influenza have focused attention on routine seasonal influenza vaccination for the first time in many countries, beginning with elderly populations, and the role of children in influenza transmission is being recognized while it is rediscovered in Japan. As a result of high pediatric vaccination coverage in developed countries in the region, JE has become almost exclusively a disease of adults older than 45 years of age, reflecting the intrinsic biological susceptibility of older adults to neurotropic flaviviruses and suggesting a future need for adult vaccination.[47] Hepatitis A, interestingly, is now principally a risk in the cohort of young adults who were raised in an era of economic development and improved sanitation and who therefore lack natural immunity but were born before routine childhood vaccination was implemented.[48] A catch-up program to address this epidemiological shift has been recognized by adult vaccination recommendations in some countries (see Table 75.3). In China, adult measles vaccination is under discussion, as more than 100,000 cases have occurred annually in recent years, in equal proportion in adults older than 20 years and in infants who had not received their first vaccine dose. Growing awareness of adult vaccination is reflected in an increasing number of countries with adult vaccination recommendations (see Table 75.3).

Two other population trends that will influence the demand for vaccines and channels for their delivery are urbanization and income disparity.[37] The urban-dwelling population in Asia is projected to increase by almost a billion persons between 2005 and 2025, from 1.5 billion to 2.4 billion, while the rural population will decline only slightly. Urban crowding is likely to affect the transmission patterns of certain person-to-person transmitted diseases and even of infections acquired from environmental sources. Dengue, for example, is transmitted by mosquito vectors that are more prevalent in urban environments; the already great need for a dengue vaccine will almost certainly increase with the growth of urban centers.[49] While the growing size and number of large cities may increase transmission of certain infections, delivery of vaccine and of healthcare in general is better organized in cities than in rural areas. Specific interventions are needed to ensure that the existing disparity in access to healthcare between urban and rural dwellers does not widen.

Associated with urbanization is the increasing income gap in many countries that, in the health arena, has translated into a two-tiered system of healthcare, including preventive medicine. While vaccines are regarded by many as a public good to be provided as a government service, as mentioned, access to the increasing number of new vaccines is likely to be stratified by income level and ability to pay, as governments must choose among increasingly costly vaccines and other health interventions. As shown in Table 75.1, pediatric societies in a number of countries promulgate recommendations emulating those of the U.S. ACIP, and these schedules, aimed at practitioners serving private-paying families, may diverge increasingly from the national EPI schedules benefiting the majority of children in those countries. How the public and governments will respond to an increasing disparity of what has been perceived as a basic medical service remains to be seen.

In coming years, more novel vaccines are likely to be developed in Asia or licensed first in Asia for a regional, developing world, or international market. Governments and ASEAN have expressed increased interest in providing for national and regional vaccine security. The collaboration of industry sponsors with nongovernmental organizations and government in public private partnerships for new product development has been highlighted by the successful introduction of vaccines and drugs for several neglected diseases, for which the DCVMN view a responsibility. For example, the Japan International Cooperation Agency and Kitasato Daiichi Sankyo provided technical assistance to establish domestic measles-rubella vaccine production in Vietnam's public corporation, Center for Research and Production of Vaccines and Biologicals, POLYVAC. At the same time, the entry of nongovernmental organizations as actual sponsors of novel vaccine development for certain target diseases introduces competition with DCVMN manufacturers and multinational companies that might also consider similar development programs. Asian academic institutions and companies possess elements

of the scientific and technical expertise needed to develop vaccines for current and emergent needs and, seemingly, the will to establish themselves on the global stage and contribute to their development. Regional institutions responded rapidly to threats of Middle East Respiratory Syndrome virus and Ebola virus with candidate vaccine development even when transmission was geographically remote. Further participation of regional institutions in global responses in the future is likely.

Trends toward increasing local development and manufacturing in the region and the accompanying need to strengthen respective regulatory agencies have been recognized by the WHO and local national regulatory authorities. Revising and harmonizing guidelines and procedures to international standards and enforcing procedures in a consistent and predictable manner will improve the timely regional introduction of vaccines developed internationally. As important, compliance with international standards will be required of regional manufacturers hoping to license locally developed vaccines more broadly. Indian and Chinese manufacturers currently export a limited number of vaccines, mainly regionally and to African and Latin American countries, but their horizons undoubtedly will expand.

In the six-component framework of product development capability—manufacturing; national and international distribution systems; private and public R&D capabilities; intellectual property system; and drug and vaccine regulation—regional manufacturers are at different stages of maturation.[50] In its ascendance to an advanced country producing complex biologicals as well as other high technology products, Korea followed a path that might be emulated by others in the region, highlighted by its arrival at a stage with a national system of innovation in science and technology, linking government, universities and industry, a strong regulatory system and observation of intellectual property rights, including adherence to Trade-Related Aspects of Intellectual Property Rights (TRIPS agreement).

A specific area of regulatory control needing particular attention is the strengthening of national control laboratories. Many countries lack the laboratory capacity to test samples for lot release, and because manufacturing and testing technologies change rapidly, keeping up with new procedures and purchasing needed equipment are ongoing challenges. Continuous support also is needed to produce working quantities of reference standards, validation of new assays, staff training, and proficiency testing. As resources are unavailable in many countries to establish and maintain a fully functioning national control laboratory, a regional network has been proposed as an approach to share expertise and to divide workload, while at the same time standardizing methods and criteria. Field surveillance of adverse events following immunization is another area requiring strengthening. Investigations of adjuvanted H1N1 and H5N1 pandemic and prepandemic vaccines administered in Korea and Taiwan, respectively, illustrated the interest in and epidemiological capacity of local investigators but also the limitations of existing systems and databases. Japan is establishing a database of clinical encounters that if linked to immunization records could be used as a future adverse events surveillance system.

Regulatory oversight of clinical trials and human subjects protection are other areas that are under growing pressure for improvement. Multinational companies have increased the number of clinical trials in Asian countries to reduce costs and to obtain local registration of products. Their activities serve an important role in strengthening local compliance with Good Clinical Practices, as many groups conducting trials in the region have limited experience with these precepts and procedures. Countries in the region have an interest to establish and enforce clear guidelines, not only as hosts to an increasing number of trials but also because their manufacturers, as future sponsors of new products, will be accountable internationally to uphold recognized standards.

76 Immunization in Developing Countries

Thomas Cherian, Felicity Cutts, Rudolf Eggers, Patrick Lydon, Samir V. Sodha, and Jean-Marie Okwo-Bele

Since the late 1970s, childhood immunization has been one of the most effective and cost-effective public health preventive measures in developing and developed countries.[1–4] Immunization is estimated to prevent 2 to 3 million deaths annually across all age groups.[5]

The history of immunization in low-income countries can be traced back to the birth of the Expanded Programme on Immunization (EPI) in 1974. At that time less than 5% of the infants in low-income countries were receiving basic immunization. The success of the smallpox eradication program, the recognition of the enormous potential of vaccination to control communicable diseases even in the most resource-poor settings, and the fact that in many regions and countries children had almost no access to this lifesaving intervention, led the World Health Assembly to pass a resolution (WHA27.57) establishing EPI in May 1974. Thus, EPI was created as the legacy of the smallpox eradication program for the purpose of expanding large-scale delivery of vaccines from a single antigen (i.e., smallpox) to include vaccines against an additional six life-threatening or disabling diseases, namely, tuberculosis, diphtheria, tetanus, pertussis, poliomyelitis, and measles. The principles and lessons learned from the smallpox eradication program were key to the successful implementation of EPI.[6]

Global policies for immunization, with a goal for providing universal access to immunization to all children by 1990, were established in 1977, through a World Health Assembly resolution (WHA30.53). Concern about the slow progress in increasing coverage led to the establishment of the Universal Childhood Immunization initiative led by United Nations Children's Fund (UNICEF) in collaboration with the World Health Organization (WHO) in 1984, with the aim of increasing coverage with three doses of diphtheria-tetanus-pertussis (DTP)-containing vaccines (DTP3) to 80% globally by 1990.[7] This initiative was extremely successful in rapidly increasing immunization coverage. Estimated DTP3 global coverage rose from approximately 20% in 1980 to close to 80% in 1990; coverage in low-income countries rose from less than 10% in 1980 to 51% in 1990 (Fig. 76.1).

This early success with increasing immunization coverage and its consequent impact on the diseases targeted, led to the establishment of ambitious disease eradication (poliomyelitis), elimination (measles, rubella, and maternal and neonatal tetanus), and control (hepatitis B and Japanese encephalitis) goals. Surveillance capacity to document progress with eradication and elimination goals provided a platform for communicable disease surveillance that has served to detect and respond to a range of diseases, including those that are not vaccine-preventable.

However, despite these early successes, immunization coverage stagnated in the 1990s. In addition, none of the new lifesaving vaccines that were becoming available were reaching children in the poorest countries. Gavi, the Vaccine Alliance, was established in 2000 to improve the access to new and underused vaccines for children living in the world's poorest countries and to reduce the historical time lag between the time when such innovations became available to rich but not to poor countries.[8] In its initial phases, available new and underused vaccines—hepatitis B, *Haemophilus influenzae* type b (Hib), yellow fever, pneumococcal, and rotavirus vaccines—were selected on the basis of the estimated burden of disease in Gavi-eligible countries and a WHO recommendation for use. In subsequent years, as the number of new and underused vaccines increased, selection of vaccines for support was determined through a Vaccine Investment Strategy, an evidence-informed and consultative process that is undertaken every 5 years.[9]

Eligibility for Gavi support is based on the Gross National Income (GNI) per capita. Countries with GNI of US$1580 or less (according to the World Bank data for the latest available year) are eligible to seek support for the introduction of new or underused vaccines, or for strengthening of health systems. Countries enter into a "graduation" process and start phasing out of Gavi support once their per capita GNI exceeds the prescribed threshold. Countries entering graduation have an additional year to apply for new vaccine support and can access time-limited catalytic investments to support their graduation plans. Table 76.1 lists the countries were eligible for new vaccine support in 2015.

Support from Gavi catalyzed the introduction of new and underused vaccines in low- and low-middle income countries. As a result, most countries, including the low- and middle-income countries have nine or more vaccines in their national schedules, compared to the six when EPI was established (Fig. 76.2). With the addition of vaccines targeted to preadolescents and adolescents (e.g., human papillomavirus vaccines), pregnant women and the elderly (e.g., seasonal influenza vaccines), as well as additional doses of existing vaccines in the second year of life or later to enhance disease control, EPI evolved from being a program primarily targeting infants to one targeting individuals across the life span.

With newer, more expensive, vaccines rapidly becoming available, guidance is required to enable developing countries to make informed choices on the introduction and use of these vaccines in their national programs. Most developing countries, as well as their development partners, including Gavi, look to the WHO to provide such guidance. The WHO Strategic Advisory Group of Experts (SAGE) for immunization was established in 1999 to advise the WHO on vaccine policy. In 2005, the SAGE was restructured and its working mechanism adjusted to meet the emerging needs of the program.[10] The group functions in an open and transparent manner and provides policy and strategy recommendations on the use of vaccines in national programs, which form the basis of the WHO position papers published in the *Weekly Epidemiological Record*.[11] The latest addition is the publication of tables that assess and grade the quality of the evidence underlying the recommendations using the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) approach.[12]

Despite the remarkable success of the global immunization program, the full potential of immunization is still to be realized. Increasing immunization coverage above 80% to reach the "fifth child" with the required doses of vaccines has proved to be difficult for many developing countries (Fig. 76.3). As a result, an estimated 19.4 million children still fail to receive all three of the required doses of DTP-containing vaccines[13] and an estimated 1.5 million children still die each year from vaccine-preventable diseases, most of them in low- and

middle-income countries (Fig. 76.4). The increasing number of vaccines in national programmes has exposed the fragility of the immunization systems and stretched the immunization budgets in many low- and middle-income countries, leading to concerns about their long-term sustainability. Even though the quantum of immunization data being collected and reported has increased exponentially, the quality and use of the data has remained suboptimal and has not resulted in timely action. Armed conflict, insecurity, and other humanitarian disasters, including disease outbreaks, have led to sharp declines in immunization coverage in countries that had well-performing immunization programs.[14]

GLOBAL VISION FOR VACCINES AND IMMUNIZATION

Recognition of the substantial achievements of EPI since its inception, coupled with the realization that the full potential of immunization was yet to be tapped and the unprecedented opportunities to make a greater impact on the health of populations through the use of the new array of lifesaving vaccines led to the call for a Decade of Vaccines in 2010.[15] In response to this call, the Global Vaccine Action Plan (GVAP) was developed through a broad consultative process that involved more than 1100 individuals from 140 countries, representing more than 290 different organizations, to provide a framework for achieving a common vision of a world in which all individuals and communities enjoy lives free from vaccine-preventable diseases.[16]

The GVAP, which was endorsed by the World Health Assembly in May 2012, replaced the existing Global Immunization Vision and Strategy. While the GVAP reiterated several of the goals and principles of the Global Immunization Vision and Strategy, it also included some shifts in emphasis, namely: (a) country ownership and the need for better governance of the program; (b) equal emphasis on community demand and service delivery; (c) the need to make immunization programs an integral part of the broader health systems and the need for better coordination and synergy with other primary healthcare programs; (d) moving beyond equity in coverage at the district level to include other parameters of equity and to reach every community with immunization services; and (e) greater focus on research, not just for development of new vaccines, but also for development of delivery technologies and for the social science research to enhance access to and delivery of immunization. Beyond these changes in content, in what is considered a game changer, the GVAP is accompanied by a monitoring and accountability framework and an independent assessment of progress that is presented annually to the WHO governing bodies. The first three assessments of progress were presented to the WHO Executive Board and the World Health Assembly in 2014, 2015, and 2016.[17,18]

PROGRESS WITH ACHIEVING GLOBAL GOALS

The GVAP includes the following five global goals for immunization: (1) achieve a world free of poliomyelitis; (2) meet global and regional elimination targets for measles, rubella, and neonatal tetanus; (3) meet vaccination coverage targets in every region, country, and community; (4) develop and introduce new vaccines and technologies; and (5) exceed the Millennium Development Goal 4 target for reducing child mortality. In 2016, the WHO SAGE for immunization, the body charged with making an independent assessment of progress as per the monitoring and accountability framework, reviewed progress against these goals. Based on a review of data from 2015, the SAGE concluded that at the mid-point of the Decade of Vaccines, the implementation of the GVAP has been patchy and slow.[14] The assessment report noted that there were six immunization targets for 2014 or 2015, of which only one, the target for the introduction of new vaccines in low- and middle-income countries, appeared to be on track; the remaining were missed. While the targets related to different diseases and vaccines, two common threads ran throughout: failure to extend vaccination services to those who cannot access them at all, and failure to strengthen the healthcare systems so that all the required doses are reliably provided. In a sense, the fundamental changes that the GVAP aimed to bring about are not being realized. The progress against the goals are briefly summarized below.

Polio Eradication

The interim goal for polio eradication was the interruption in transmission of wild virus by 2014. This goal was missed. Although there was substantial progress in 2011–12 with India and the Southeast Asia region being declared wild virus–free, the situation deteriorated in other regions, with an increasing number of cases in Pakistan and the subsequent spread of the virus to the conflict-affected countries in the Middle East and the horn of Africa. Despite the failure to achieve the 2014

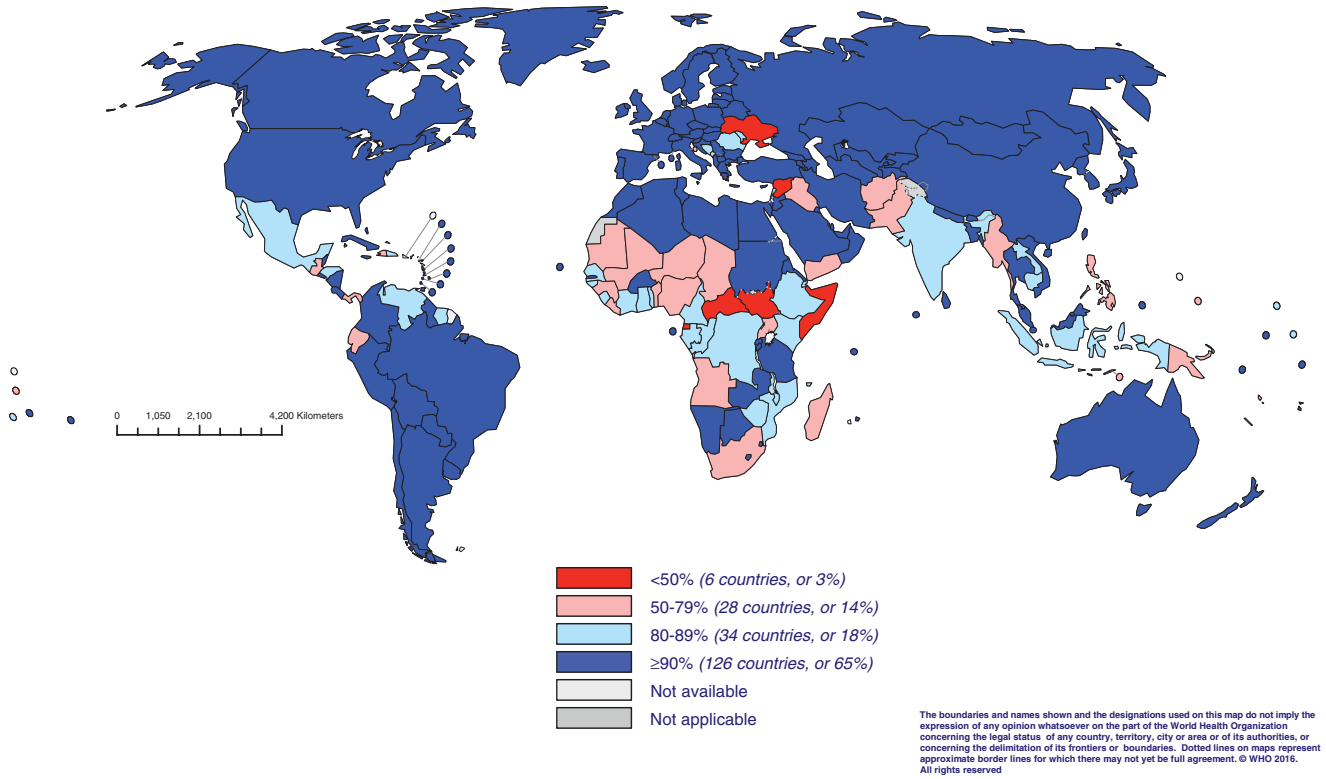

Figure 76.3. Immunization coverage with three doses of diphtheria, tetanus and pertussis (DTP)-containing vaccines in infants in 2015. *(From WHO/UNICEF coverage estimates 2015 revision, July 2016. Map production: Immunization Vaccines and Biologicals [IVB], World Health Organization.)*

target, there was progress. In 2013, for the first time in history, all cases of wild poliovirus disease were caused by a single serotype, type 1.[19] For 2016 (as of October 19), 27 cases of wild poliovirus disease had been reported in three countries (Pakistan, Afghanistan, and Nigeria). In 2015, only two countries—Pakistan and Afghanistan—reported wild poliovirus; progress in these two countries is impeded by insecurity, including the killing of health workers.

Measles and Rubella Elimination

Worldwide, the estimated mortality from measles has been reduced by 79% since the year 2000 (Fig. 76.5). In 2015, 85% of children globally were estimated to have received their first dose of measles-containing vaccines (MCV1), 61% received a second routine dose of measles containing vaccines and more than 100 million children were reported to have received additional doses each year through supplementary immunization activities. However, elimination of measles is thought to require coverage exceeding 95% with two doses of measles-containing vaccines. The interim global milestone for 2015 to achieve greater than 90% coverage with MCV1 and reducing measles incidence to less than five per 1 million population was not met. By 2014, all six WHO regions had established goals for eliminating measles by 2020 or earlier. The region of the Americas was declared to have eliminated measles in 2016, but remains under constant threat of spread of disease following importation from other regions, highlighting the challenges of maintaining elimination in the face of ongoing transmission in other regions and competing health priorities. The remaining three regions that had established goals to eliminate measles by 2015, namely the Eastern Mediterranean, European, and Western Pacific regions, did not achieve their target. The African and South-East Asian regions have adopted goals to eliminate measles by 2020 but face significant challenges to achieving their goals. Despite sustaining high routine coverage, some countries have experienced large outbreaks that pick out pockets of susceptible individuals. The experience in the Americas shows that elimination is possible, but requires strong political commitment, financial resources, and sustained efforts to achieve and sustain elimination.

Elimination of rubella and congenital rubella syndrome (CRS) from at least five regions by 2020 is one of the goals in the GVAP. This ambitious goal was based on the assumption that if all countries used measles- and rubella-containing vaccines for achieving and sustaining measles elimination, rubella and CRS elimination would follow. However, only three regions, namely the American, European, and Western Pacific regions, have established regional elimination goals; the South-East Asia region has established a control goal, while the African and Eastern Mediterranean regions have not yet established goals. By December 2015, 47 countries, mainly those in regions without elimination goals, had not introduced rubella containing vaccines in their national immunization programs. These include 40 countries who are eligible for and could receive Gavi support for introduction of rubella-containing vaccines; some of these countries have partially introduced the vaccine or have plans to introduce the vaccine. Rubella and CRS surveillance systems are weak and cases remain underreported, particularly in countries that have not yet introduced rubella-containing vaccines and/or do not have rubella control or elimination goals. Hence, global rubella and CRS surveillance data do not reflect the true burden of these diseases. Failure to fully integrate prevention of rubella and CRS with measles elimination activities represents a major missed opportunity for immunization.

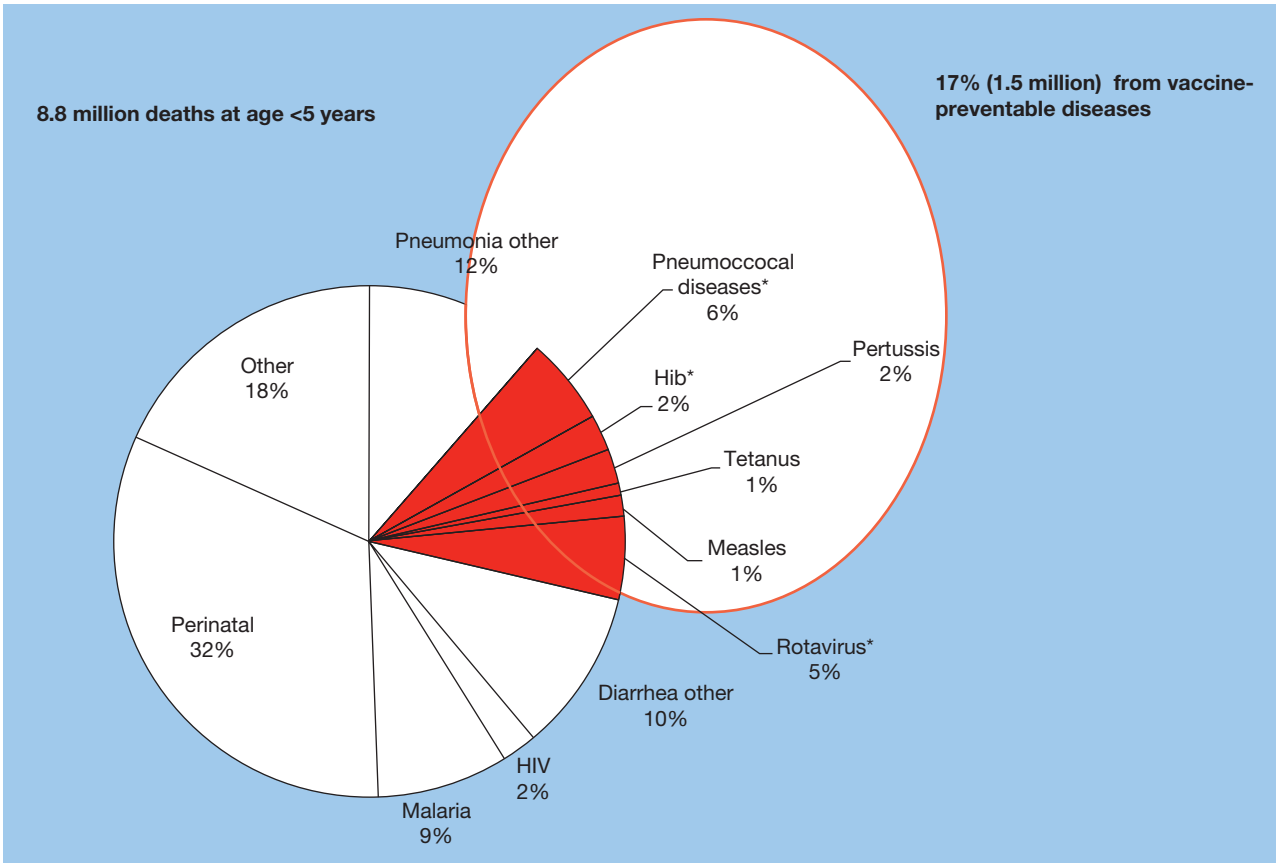

Figure 76.4. Global mortality of children age <5 years: role of vaccine preventable diseases (estimates for the year 2008). *(From World Health Organization estimates; and Black RE, Cousens S, Johnson HL, et al; Child Health Epidemiology Reference Group of WHO and UNICEF. Global, regional, and national causes of child mortality in 2008: a systematic analysis.* Lancet. *2010;375[9730]:1969–1987.)*

Maternal and Neonatal Tetanus Elimination

In 1988, the WHO estimated that 787,000 newborn infants died of neonatal tetanus each year, which led to the adoption of a goal to eliminate neonatal tetanus (defined as <1 death/1000 live births) by 1995. This goal was later shifted to 2005 and then to 2015, as each target was missed. Elimination efforts were focused on 59 countries that carried almost all the burden of disease. In 2015, the estimated deaths from neonatal tetanus were 34,019, representing a 96% reduction compared to 1988. However, by December 2015 only 38 of 59 priority countries had been validated as having achieved elimination (Fig. 76.6), leaving 21 countries yet to achieve elimination. Thus, the target to achieve elimination of maternal and neonatal tetanus by 2015 was missed yet again.

Neonatal tetanus represents an important consequence of health inequity. The disease occurs mainly in communities that lack access to basic health services, including immunization, antenatal care, and safe and clean deliveries. Bridging this equity gap remains a challenge. The GVAP assessment report noted that maternal and neonatal tetanus elimination was "embarrassingly underfunded."[14] Success in many countries indicate that the existing strategies work and what is required is the political will, the required finances, and the provision of the vaccine in compact, prefilled, autodisable devices that will make it easier to deliver vaccine to pregnant women and women of childbearing age living in remote areas, inaccessible to routine health services.

Immunization Coverage and Equity

DTP3 coverage is often used as a proxy measure for the overall performance of an immunization program and has sometimes been used as an indicator of the performance of the broader health system. In 2005, a goal for achieving 90% or greater DTP3 coverage nationally and 80% or greater in every district or equivalent administrative unit in the country by the end of 2015 was established. Sadly, the estimated global DTP3 coverage has remained stagnant for the past 5 years. In 2015, only 126 (65%) of countries had achieved national coverage of 90% or greater, although the number of countries achieving and sustaining DTP3 of 90% or greater for 3 or more years has been steadily increasing (Fig. 76.7). In 2015, DTP3 was below 50% in six countries; some of these countries, such as the Central African Republic, Somalia, South Sudan, and the Syrian Arab Republic have been affected by conflicts.

In many countries that are failing to achieve national DTP3 coverage of 90% or greater, high dropout rates between the first and third doses of DTP-containing vaccines have remained a persistent problem. Large countries like India, Nigeria, Pakistan, Indonesia, and Ethiopia have substantial dropout rates and reducing this rate could have a large impact on the global DTP3 coverage (Fig. 76.8). Addressing the causes of undervaccination, including missed opportunities for vaccination, could have a large impact in reducing the number of such children.

Assessment of equity in coverage is affected by the lack of valid data. Only 112 (58%) of the 194 WHO Member States

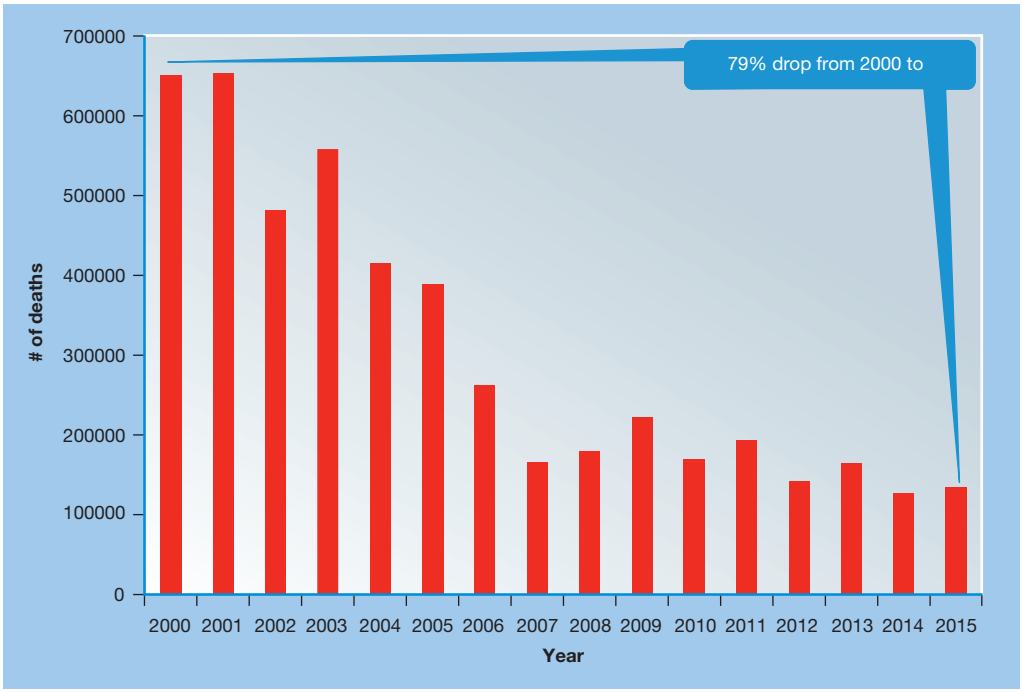

Figure 76.5. Reduction in estimated measles deaths, 2000–2015. *(From Weekly Epidemiological Record No. 45, 2016:525–536.)*

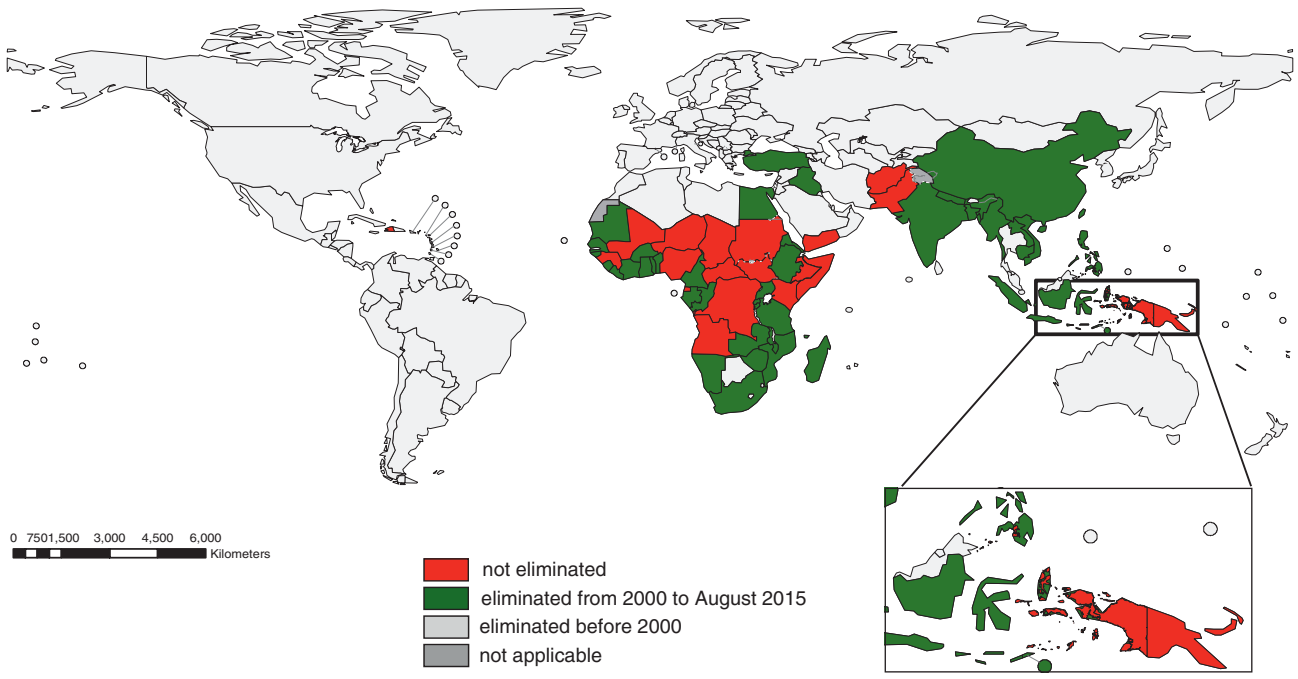

Figure 76.6. Status of maternal and neonatal tetanus elimination. *(Data from WHO-UNICEF database, July 2016. Map production: Immunization Vaccines and Biologicals [IVB], World Health Organization.)*

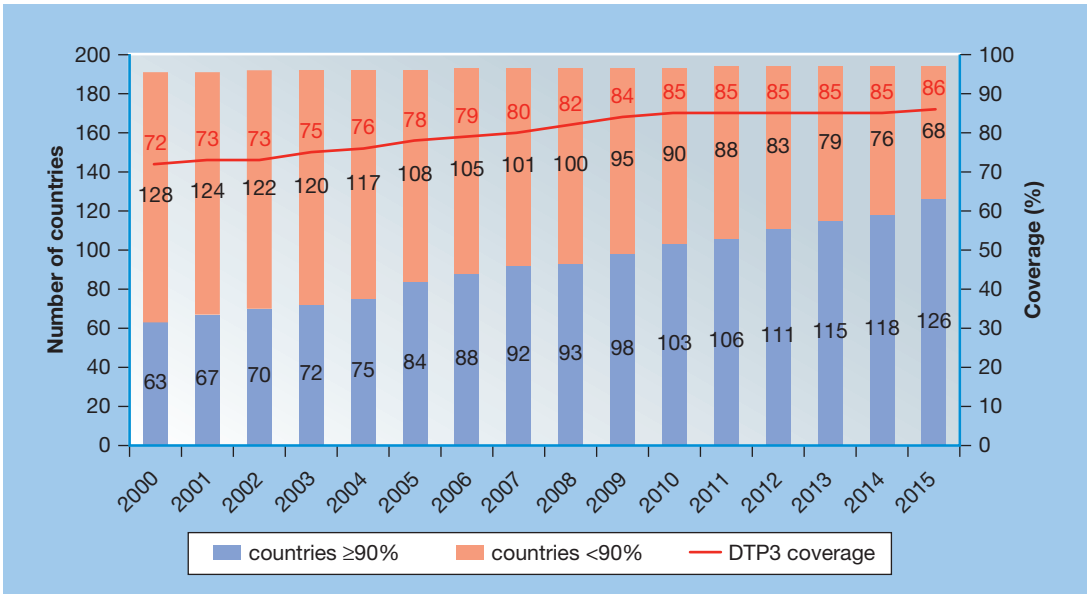

Figure 76.7. Number of countries that reached and sustained 90% or greater coverage with three doses of diphtheria, tetanus, and pertussis (DTP)-containing vaccines and global DTP3 coverage from 2000–15. *(From WHO/UNICEF coverage estimates, 2015 revision. July 2016. Map production: Immunization Vaccines and Biologicals [IVB], World Health Organization.)*

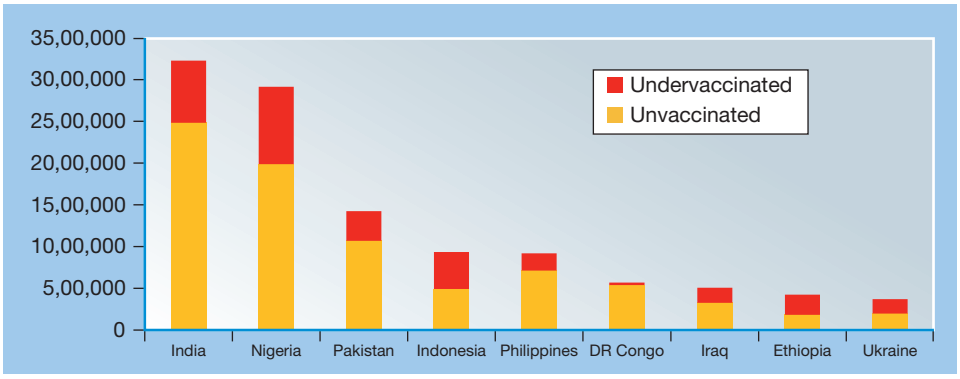

Figure 76.8. Ten countries with the most undervaccinated and unvaccinated children (based on coverage with the first and third doses of diphtheria, tetanus, pertussis [DTP]-containing vaccines), 2015. *Unvaccinated*, those who have not received any dose of DTP-containing vaccines; *undervaccinated*, those who have received one but not all three doses of DTP-containing vaccines. *(From WHO/UNICEF coverage estimates, 2015 revision. July 2016.)*

provided valid district-level coverage data in 2015, with only 52 (27%) having DTP3 coverage of 90% or greater nationally and of 80% or greater in all districts. Only 64 countries had coverage data from recent surveys, of which 31 had a difference of 10% or more in coverage between the richest and poorest wealth quintiles; the difference was 20% or more in 20 of these 31 countries. Thus, even though two-thirds of countries are estimated to be achieving high national coverage (i.e., ≥90%), inequity in coverage is prevalent.

Introduction of New Vaccines in Low- and Middle-Income Countries

There has been significant progress in recent years in the introduction of new vaccines in national immunization programs. A total of 160 new vaccine introductions took place in 99 low- and middle-income countries in the period 2010 to 2015.[20] The vaccines introduced include vaccines against Hib, *Streptococcus pneumoniae*, human papillomavirus, rubella, and Japanese encephalitis. Among these 99 countries, 64 benefited from support from Gavi. Among 62 middle-income countries not eligible for Gavi support, 35 (56%) have introduced a vaccine during the period 2010 to 2015, compared to 64 of 73 (88%) of Gavi-eligible countries, indicating a lag in countries that do not benefit from Gavi support.

Innovation and Research

Beyond the full use of the vaccines available today, it must be recognized that vaccine science has enormous future potential, including vaccines and technologies that would specifically address the needs of developing countries. The assessment of progress with the GVAP implementation included an assessment of progress with research and innovation.[14]

The assessment concluded that there is a robust pipeline of new or improved vaccines under development, including candidate vaccines against tuberculosis (13 candidates), malaria

(30 candidates), and HIV (40 candidates), all of which potentially address a large burden of disease in developing countries. However, the report also noted that there were a number of bottlenecks that needed to be addressed, including the following: (1) lengthy and expensive clinical evaluation processes; (2) failure or delays in reporting clinical trial results that could potentially lead to biased decision making; (3) complex development pathways and regulatory processes, with inadequate capacity in many developing countries to deal with these complexities; and (4) lack of coordination between different agencies and research groups conducting vaccine research.

While vaccine research is conducted in all regions in the world, the quantum of research is very unevenly distributed. Of the 624 vaccine clinical trials registered in different clinical trial registries during the period May 2015 to April 2016, only 37 were in the African region and 10 in the Eastern Mediterranean region.[20] This suggests the need for strengthening capacity in developing countries to conduct the relevant research to serve their needs.

With the increasing costs of vaccines and the vaccination programs, and with ever-increasing and competing health and development priorities, national decision makers and ministries of finance are likely to demand more evidence in support of the increased budgetary requests. This will include proper documentation of the impact of vaccination. Even though some of the data may be generated through improved disease surveillance, as described later in this chapter, some of the information required will need specifically designed and well-implemented research studies. This further underlines the urgent need to strengthen epidemiology and research capacities in developing countries. Failure to do so may result in inadequate investments and continued dependency on support from development partners and international agencies.

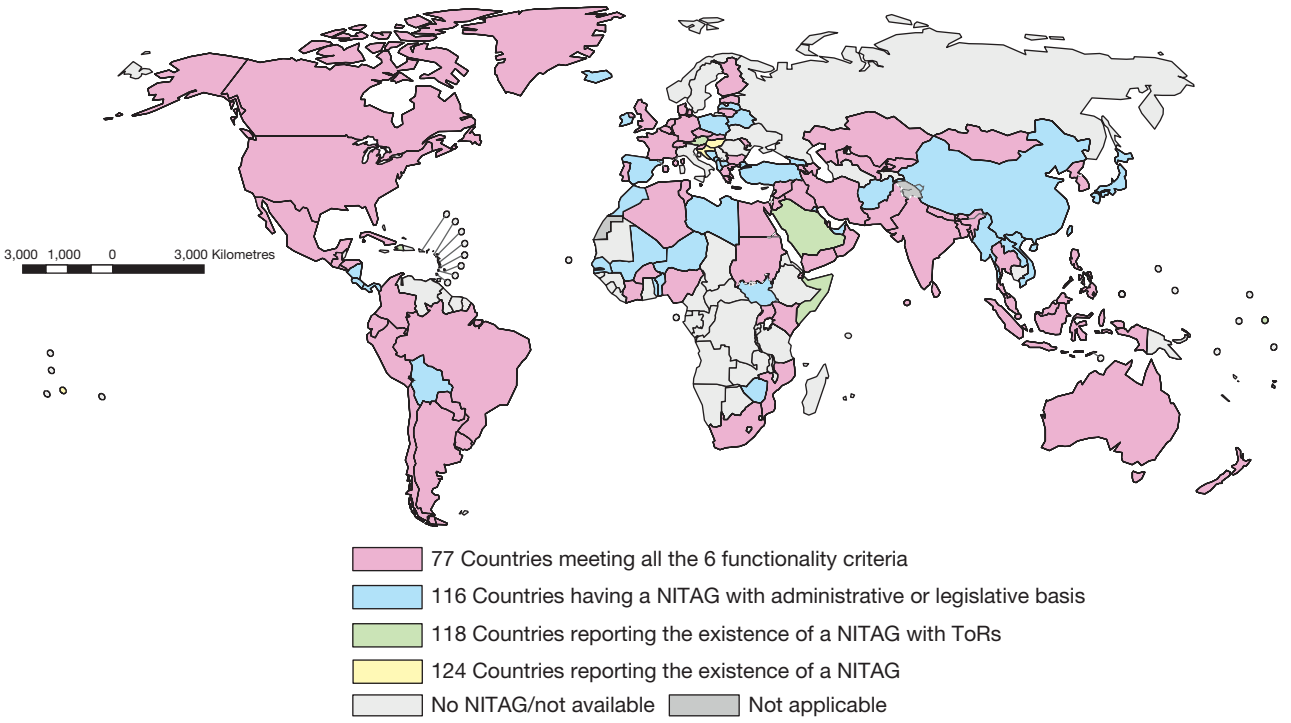
As vaccines are added to the national programs in developing countries, their immunization schedules are likely to become more crowded, straining the immunization systems and requiring additional human resources with appropriate training to properly deliver the vaccines. A number of new technologies are available that could simplify delivery and address some of these bottlenecks. However, these products have cost implications, making the demand uncertain and, thus, not providing incentives for investing in the development and commercialization of vaccines to be delivered using these technologies in developing country markets. This calls for a better assessment of the trade-off between the increased costs of the product, the cost savings from the method of vaccine delivery, and the increased impact through expanded coverage to inform decisions, stimulate demand, and lead to greater investments in further developing and using these technologies.

Developing countries face a number of managerial, health systems, sociobehavioral, and communications challenges for achieving and sustaining high immunization coverage and introducing new vaccines. Implementation research can generate information to support evidence-informed solutions. Once again, many developing countries may lack the capacity to identify research needs and to design and implement the required research. The WHO is developing a prioritized implementation research agenda in consultation with key stakeholders and offers to provide technical support to enhance country capacity to design and conduct such research and provide a platform for researchers to share their results.[21]

OVERCOMING THE CHALLENGES

The assessment of progress clearly indicates that we are not on track to achieving the goals established for the Decade of Vaccines. The shortfalls are mainly in developing countries, which also stand to gain the most from the use of vaccines. To overcome some of the challenges that these countries face, several broad areas need to be addressed particularly these: (a) enhancing country ownership and governance; (b) strengthening health systems, including human resource capacity, access to sustained supply of vaccines at affordable prices, vaccine supply chains, and information systems; and (c) strategies to improve the quality and coverage of service delivery.

Country Ownership, Management, and Financing of Immunization Programs



Lack of ownership and good governance of the immunization program constitutes an important barrier to its successful implementation in several countries, particularly those with the largest numbers of unimmunized children. In these settings, weak capacity for developing evidence-based national policies and insufficient or poor quality of data required for planning have often led to poor management of national immunization programs.

Ensuring effective immunization programs requires collaboration among multiple stakeholders, including policymakers, and is facilitated through comprehensive national multiyear plans (cMYPs) for immunization.[22,23] Annual work plans should be generated from and aligned with cMYPs to ensure that programs are working toward established longer-term goals. Evidence-based decisions must be made about the goals of the vaccination program, including the introduction of additional vaccines and technologies and the integration or improved coordination with other programs.

The WHO and its partners encourage countries to develop national immunization technical advisory groups,[24] which serve a key role in supporting government decision making. The existence and functionality of these groups is being used as an indicator of country ownership in the GVAP monitoring and accountability framework.[16] An increasing number of countries are now reporting the existence of a National Immunization Technical Advisory Group (NITAG). In 2015, 124 of 194 (64%) countries reported the existence of a NITAG, of which 77, including 49 developing countries, reported a NITAG that met the six indicators for functionality (legislative or administrative basis for the advisory group; formal written terms of reference; at least five different areas of expertise represented among core members; at least one meeting per year; circulation of the agenda and background documents at least 1 week prior to meetings; mandatory disclosure of any conflict of interest) established by the WHO (Fig. 76.9). The number of NITAGs meeting the six process indicators for assessing functionality increased from 43 in 2010 to 77 in 2015.

Technical guidelines and standard operating procedures must be established regarding vaccine delivery, including selection of the optimal schedule and recommendations regarding contraindications to vaccines. National interagency coordinating committees or equivalent structures, which should include all key government ministries (e.g., health, education, and finance), international partners, civil society organizations, and the private sector, can provide a key mechanism to facilitate coordinated planning, financing, advocacy, capacity strengthening, and community mobilization, as well as to promote a cohesive effort to enhance and sustain the performance of the national immunization programs.[23]

Immunization programs in developing countries traditionally have been organized under a centralized system, with services delivered predominantly through the public sector. Ministries of Health are responsible for setting policies and norms and for managing programs. Donor support is given

through the ministries of health that control the budget for immunization.

This structure is evolving, however, with several cross currents of change creating great diversity among countries and regions. Under health sector reforms implemented in some countries, there is an increasing trend toward decentralization of health services and a burgeoning private sector.[25–27] The growing private sector is often disconnected from the public sector with an unclear role in achieving national goals.[28] At the same time, international support has increased substantially for specific disease-control initiatives (e.g., Global Polio Eradication Initiative) as well as for the health sector as a whole (e.g., sector-wide approaches and the International Health Partnership). Countries vary in the degree to which health services have been decentralized and in the proportion of funding provided for specific programs and under the broader health umbrella. With decentralization, health services are under local government control, budgets are often managed at the district level, while the central ministries of health focus on policy making, procurement of vaccines and injection supplies, and surveillance and monitoring of program impact. There is also a trend toward greater involvement of private and civil society organizations in health services delivery, including national and international not-for-profit agencies and private for-profit practitioners.[28–30] These changes have increased the need for effective national leadership and coordination of the different service providers and international funders and for the dissemination of clear and practical policies.

The costs of immunization programs in developing countries vary widely according to the vaccines used, source of vaccine and its price, immunization coverage, the level of a country's economic development, and, importantly, the delivery strategies used to reach more children. The costs of a national routine immunization program typically include vaccines, human resources (salaries of the immunization team, support staff, and supervisors), cold chain equipment and maintenance, vehicles and transportation, diseases surveillance, health worker training, and social mobilization. The growth of EPI and the addition of several new more-expensive vaccines has led to a severalfold increase in the price of a full vaccination course for a child.

Before 2000, human resources accounted for the greatest share of a national immunization program. Since 2000 and with the increased availability and use of a wider range of newer vaccines, vaccines are now the single largest cost driver of routine immunization programs in developing countries. In Africa from 2006 to 2012, government spending on vaccines increased from $35 million to $65 million, but during this same time period, there was a decrease in percentage of

governments spending on vaccines from 54% to 36%.[31] In general, the cost to fully immunize a child decreases as the number of children immunized increases,[32,33] although there may be a U-shaped curve as the marginal costs of reaching the last 10% of the population may be higher. However, the cost-effectiveness of different strategies varied widely in different geographic locations, and the number of high-quality studies is limited.[34,35] The cost per child immunized needs to be balanced against the effectiveness of the strategy in accessing all children in need of vaccination.

Access to sufficient and predictable financing is essential to the ability of an immunization program to improve the health of children through vaccination, with continuous increases in coverage, quality, and access to traditional and newer vaccines.[16] In developing and developed countries, the management and financing of immunization services are considered core functions of the state and need to be considered in the overall context of a country's health sector financing, planning, and budgeting.[23,36,37]

After many years of being almost entirely reliant on external financing for their immunization programs in the 1970s and 1980s, developing country national governments are increasing the allocations of domestic resources for their immunization programs, although there is considerable variation from region to region and country to country. The poorest countries are still largely dependent on external support for their immunization programs and are projected to continue to remain financially dependent in the coming years.[38–40] Government financing for immunization seems to be related to national income, so as a country's economic development improves, so does its allocation to immunization.[23] With the advent of more expensive, lifesaving vaccines and efforts to increase coverage and meet disease control and eradication goals, ensuring sustainable immunization financing for all countries has become an important challenge for national and donor governments.[16]

In the 1970s and 1980s, external donors made major investments to help countries attain the 1990 goal of universal childhood immunization. However, in the 1990s, donor funding for routine immunization programs declined, with funding for vaccines and immunization targeted to disease control and eradication initiatives.[7,41] Unfortunately, the withdrawal of external funding for immunization was not matched by a commensurate increase in national financing, and immunization coverage slipped in the 1990s.[41] Since the mid-1990s, the Global Polio Eradication Initiative, accelerated disease-control programs such as the measles mortality reduction initiative and neonatal tetanus elimination, and Gavi have contributed significant resources to immunization programs. Gavi has emerged as a pivotal and important financier of immunization programs for the world's poorest countries. In 2006, it was estimated that Gavi contributed 37% of immunization program expenditures in poor countries, the majority toward the procurement of new vaccines. While it was previously estimated that, on average, donors finance 21% of immunization programs in low-income countries,[23] there is still a 57% projected funding gap of low and middle income countries through 2020.[38]

There are three widely used indicators of national financing capacity: the presence of a national budget line item for vaccines and for immunization operational costs; the percentage of government funding of expenditures on vaccines used in routine immunization; and the percentage of government funding of overall expenditures on routine immunization. Globally, the proportion of countries that have a line item in the national budget for routine immunization increased from 82% in 2006 to 89% in 2012; among low-income countries, the proportion increased from 71% in 2006 to 94% in 2012. The proportion of expenditures on vaccines used in the routine program financed by national governments decreased from 80% in 2006 to 71% in 2012; in low-income countries this proportion decreased from 30% in 2006 to 18% in 2012. However, in absolute amounts, government expenditures on immunization has increased in low- and middle-income countries, although not as rapidly as donor contributions, largely Gavi support for new vaccine introduction, have increased. There was also wide variation in routine immunization financing by governments in the different regions of the world in 2012, ranging from 50% in the African region to 92% in the Americas.[31] Countries in the African region are still heavily dependent on external financing to support their immunization programs.

With the increasing attention to financial sustainability of health and immunization programs, a number of new tools have been developed to help countries evaluate the cost, cost-effectiveness, financing, and sustainability of their immunization programs. To support financial planning, the WHO in collaboration with other Gavi alliance partners developed a cMYP costing tool and maintains an immunization financing resource database complete with analyses of cMYPs and financial sustainability, which are required as part of the country applications for Gavi support.[42] National financial sustainability planning is increasing, with governments taking the lead in working with partners to identify long-term resources for immunization through multiyear planning; in some developing countries, this has resulted in increased national financing for purchase of new vaccines and autodisable syringes. In 2005, the Pan American Health Organization (PAHO) initiated the ProVac Initiative (Promoting Economic Analysis for Vaccine Introduction in the Americas) to strengthen national capacity to make evidence-based, informed decisions on new vaccines, including conducting and using cost-effectiveness analyses.[43] With help from the Sabin Vaccine Institute, this initiative is now being rolled out to other regions through the formation of the ProVac International Working Group.

Strengthening Health and Immunization Systems

To realize the full potential of vaccines, health and immunization programs in all countries need the systems and people in place to reach all populations, including the hard-to-reach populations. This section explores some of the critical deficiencies in the health systems in developing countries that need to be addressed to reach the goals for the Decade of Vaccines.

Human Resources

The role of trained health workers in the strengthening of health systems is well recognized.[44] The relationship between healthcare worker density and immunization coverage has been well documented in studies from several developing countries[45–48]; one of these studies in Turkey also found that the relationship between healthcare worker density and immunization coverage is stronger in rural provinces.[47] Despite the recognition of the problem, there has been little progress in addressing the human resource crisis. However, it is recognized that the solutions are not straightforward and considerable investments in time, effort, and money are required to train and retain health workers. In the World Health Report 2006, 57 countries, 36 of which are in Africa, were identified as having a health-worker-to-population ratio below the threshold of 2.3 per 1000 population, which is considered to be necessary for meeting the health-related Millennium Development Goals.[47] This implies that below this critical level countries would be unable to increase their immunization coverage to greater than 80%, among other health indicators.

A review of progress published in 2011, 5 years after the publication of the World Health Report, indicates that progress has been patchy, with a diverse picture of country efforts, challenges, and successes, and suggests that success in meeting the goal set by the World Health Assembly in 2008 to reduce the number of crisis countries by 25% by 2015 will be determined by the level of investments made in this area in the interim.[49]

As immunization programs in developing countries increase in complexity as a result of adding new vaccines and the need to extend coverage to reach 90% or more of their target populations, both the number of health workers and their skill levels will need to be addressed. Specialized skills will be required for managing the different components of the health systems, such as supply chains, information, and regulatory systems. Addressing the human resource constraints remains an area where appropriate guidance for countries is either not available or is not being fully implemented. No benchmarks exist for the number of healthcare workers required to deliver immunization services and there is no guidance on what increments may need to be made when countries add new vaccines to their national programs. As a result national programs demand more from their health workers without providing the commensurate training or resources. While training materials and tools exist, program reviews and evaluations reveal gaps in health worker knowledge and practice. Supportive supervision has been shown to improve program performance, but there is still a lack of recognition of the need for and the knowledge and tools to implement supportive supervision in many developing countries.[50] As is the case with health systems in general, human resource development for immunization remains an underinvested area. Failure to address this critical bottleneck is likely to be a barrier to achieving national goals in developing countries and global goals as a consequence.

Sustainable Supply of Vaccines at Affordable Prices

Another key challenge is to ensure a reliable, sufficient, and affordable global vaccine supply. Ensuring an adequate supply of safe and effective vaccines for developing countries, as well as to each vaccination session in these countries, continues to be a global priority in a world that is seeing unprecedented changes in the vaccine industry and market.[51–53] In the 1980s, the vaccine market was in serious decline, with many companies in developed and developing countries exiting the market, viewing vaccines as high-volume, low-margin products.[54] The exit of vaccine producers led to shortages in key products and reliance on a small pool of source suppliers for key vaccine products.[55]

Beginning in 2000 and intensifying since 2005, the vaccine industry is experiencing a major turnaround, driven in part by blockbuster sales of pneumococcal conjugate and human papillomavirus vaccines in developed countries and the prospects for growth in lower- and middle-income country markets. Developing country manufacturers are now fulfilling an increasing role in vaccine supply, and their entrance into the market is stimulating price declines of key vaccines.[56] More than 60% of traditional EPI vaccines are supplied by developing-country manufacturers.[57] The Serum Institute of India in Pune, India, supplies more than 80% of measles vaccine to developing countries. Developing-country manufacturers are increasingly entering into joint development agreements with developed-country vaccine manufacturers to produce new vaccines, and many now participate in a developing country vaccine manufacturers' network.[58]

The WHO continues to focus on strengthening national regulatory authorities (NRAs) in vaccine-producing countries as weak NRAs have been consistently identified as a major barrier to entry for new suppliers. Multiple criteria in seven basic functions have been developed to determine whether each NRA is able to guarantee that a vaccine is of "assured quality" (national regulatory system; market authorization and licensing; NRA lot release; laboratory access; postmarketing surveillance, including adverse events following immunization [AEFIs] surveillance; regular inspections; and authorization/approval of clinical trials). In June 2016, 43 countries were documented to be producing vaccines for human use, of which 37 had a functional NRA. Twenty-two of these countries were producing one or more vaccines prequalified by WHO for procurement by United Nations agencies, the Russian Federation being the latest addition to the list of countries producing prequalified vaccines.[20]

To sustain the national, regional, and even global supply of EPI vaccines, the most important areas of technology transfer for developing countries are those relevant to achieving and maintaining good manufacturing practices standards in vaccine production, establishing independent and credible national quality-control laboratories, and instituting national (or regional) regulatory capability. Facilitating successful and sustainable technology transfers is a challenge facing the international organizations that support the global EPI.

Affordability of the newer vaccines, especially for middle-income countries who are not eligible for or will soon lose Gavi support, is becoming an increasing concern.[59] Available information suggests that there is a wide variation in the prices paid by middle-income countries for the same products. However, the solutions are not simple and issues beyond just access to affordable prices need to be considered to support the introduction of new vaccines in middle-income countries not eligible for Gavi support. These issues include strengthened decision-making processes, increased political and financial commitment from national governments, and enhanced public demand for vaccines. These issues have been considered in earlier sections of the chapter. This section specifically deals with the issues to be considered to secure a sustained supply of vaccines at optimal prices, including the following: (1) efficient procurement processes; (2) efficient regulatory and product registration processes; (3) access to price and contract information; (4) access to revolving funds; and (5) pooled procurement and access to external procurement services.

Previous studies have identified inefficient procurement as a barrier to obtaining competitive prices for vaccines.[60] The support provided to countries in improving their procurement practices has been patchy and remains an area where more needs to be done to secure access to affordable prices.

Inefficient and lengthy processes for the registration of vaccines can drive up the cost for suppliers and consequently the price of vaccines. The barrier that the onerous and lengthy processes pose are likely to have a greater effect on lower cost manufacturers who may not have in-country representatives and fewer resources, thus limiting the choice of products for the countries concerned and resulting in higher prices from a lack of competition. At least 30 middle-income countries not eligible for Gavi support could benefit from more streamlined and efficient regulatory processes.[61]

Available data suggests that increasing price transparency can result in more favorable outcomes from contract negotiations and better prices.[62] While international agencies such as UNICEF and the PAHO have started publishing the prices of vaccine procured by them, data on prices paid by self-procuring countries is sparse. The WHO has established the Vaccine Product, Price and Procurement (V3P) web-based platform with a goal of increasing vaccine price transparency to inform contract negotiations and decisions on vaccine procurement.[63]

Lack of assurance that suppliers will be paid on time adds to their risk and hence to higher prices. Many middle-income

countries face uncertainties about allocation and release of funds for procurement. Others may have legal restrictions about prepayment for goods or face barriers related to currency fluctuation. Revolving funds, such as the PAHO revolving fund and the UNICEF Vaccine Independence Initiative,[64–66] provide solutions to some, but not all, of these problems by providing a line of credit for countries not able to produce the funds at the time when they are needed. However, the existing funds are available only to a limited number of countries in the regions they serve. Expanding the access of other middle-income countries to revolving funds may contribute to their being able to access lower prices.

The use of external procurement services, such as through UNICEF, could benefit a number of middle-income countries, especially those with small populations and limited bargaining power. When coupled with a revolving fund, such pooled procurement through external agencies has been shown to lead to lower prices.[64] However, many countries have legal barriers to using external procurement services.

Immunization Supply Chains

Situation After Years of Neglect. The success of immunization systems in developing countries over the past decades can be attributed to a large extent to its backbone—the supply chain and logistics systems that strive to ensure the uninterrupted availability of vaccines up to service delivery levels as efficiently as possible. These supply chains have fairly successfully supported the flow of vaccines through a quality cold chain system that safeguard their potency from heat or freeze damage from the moment they arrive in a country until vaccination.

Unfortunately, during the past 2 decades these supply chain systems have been largely neglected and taken for granted. With few exceptions, immunization supply chains in developing countries continue to face chronic difficulties in providing uninterrupted availability of potent vaccines up to service delivery levels, and many government-managed systems remain crippled by inefficiencies in vaccine storage, distribution, vaccine management, and stock control.[67–69] An increasing number of new vaccines with different characteristics and immunization schedules, using a variety of service delivery strategies to cover an expanding target population are just a few of the new realities that immunization supply chain systems are being confronted with today.[70] The existing systems in many developing countries were designed to manage fewer, less-expensive, and less-bulky vaccines and related supplies.

Faced with the mounting concerns, the WHO and UNICEF have been supporting developing countries in the implementation of the Effective Vaccine Management (EVM) initiative that allows for an end-to-end, in-depth diagnosis of the strengths, weaknesses, and bottlenecks of an in-country immunization supply chain and to develop comprehensive plans for improvements based on the outcomes of the assessment.[71] Since 2010, more than 80 developing countries have conducted EVM assessments reviewing nine critical dimensions of an effective system in terms of vaccine arrival procedures; cold chain storage adequacy; efficiency in temperature control throughout the cold chain; compliance with vaccine management policies; vaccine distribution and handling best practices; information systems for forecasting, stock management, and stock control; and adequate infrastructure and maintenance services for the supply chain. The EVM assessment sets a minimum standard to reach for each of these dimensions, based on WHO norms and guidance. The available evidence from the 80 countries indicate that none reached the minimum standard on each dimension at each level of the supply chain, from the national to the service delivery point (Fig. 76.10).

Key findings from these assessments include the following: (1) adequate temperature control for vaccines is achieved in only 40% of countries, which suggests that vaccine potency is

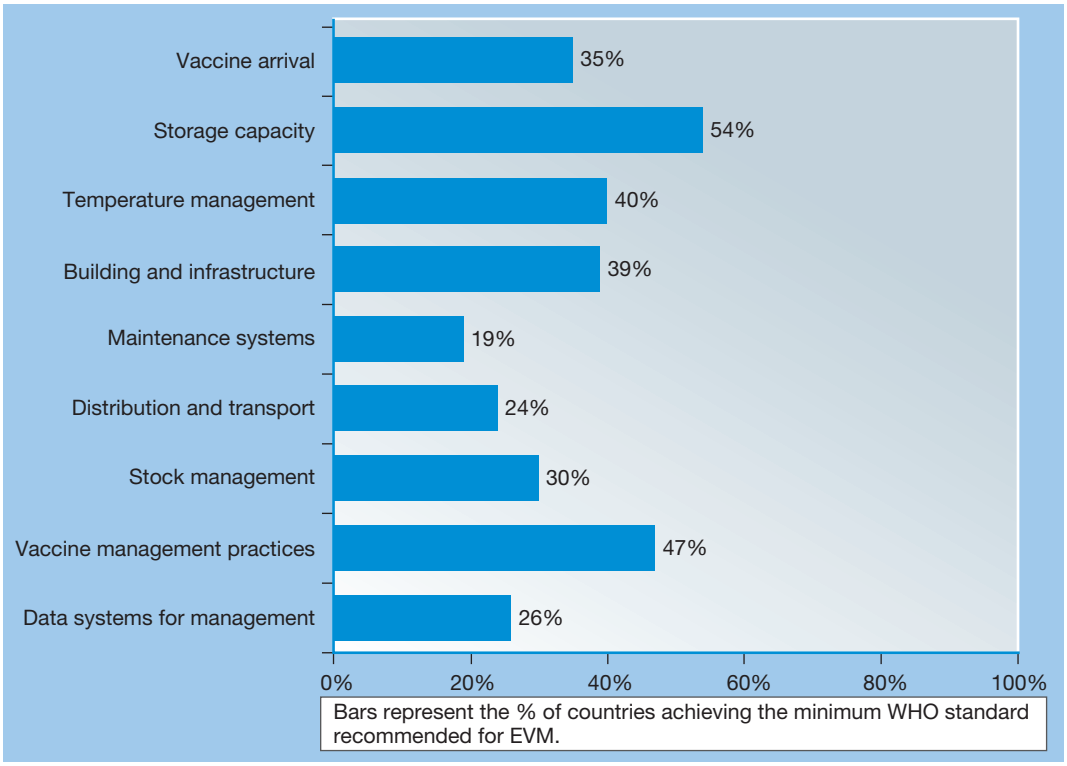

Figure 76.10. Supply chain performance in 80 developing countries that have conducted Effective Vaccine Management (EVM) assessments, 2010–15. *(Source: WHO EPI.)*

at risk in the cold chain systems of many countries; (2) sufficient storage capacity for existing vaccines and related supplies is available in only 54% of countries, which suggests that infrastructure is generally insufficient for existing vaccines, let alone for introducing new vaccines; (3) functional vaccine stock management is attained in only 30% of countries with the resultant increased risk of vaccine stock out or unopened vial wastage; (4) effective distribution of vaccines is compliant with the established standards in only 24% of countries, compromising the timely availability of vaccines at relevant subnational levels; and (5) adherence to vaccine management policies and practices are reached in only 47% of countries, which leads to inefficiencies and poor vaccine handling practices.

More recent evidence has brought to light that many countries report regular shortages of vaccines at the national level; consequently, 38% of developing countries in 2015 experienced at least one stockout incident for one vaccine for 1 month (Table 76.2). The extent to which this has led to interruptions of services at lower levels remains an open question, but this additional evidence points to the chronic difficulty of securing an uninterrupted flow of vaccines—one of the key goals of an effective immunization supply chain system. A root-cause analysis of national level vaccine stockouts conducted between 2010 and 2015 identified poor forecasting, stock management, or procurement issues being the cause of 41% of national-level stockouts and confirms country weaknesses in basic vaccine management practices.[72]

Coupled with these persistent challenges of ensuring that fundamentals are in place like EVM, good forecasting, and stock control for vaccines, new challenges resulting from the rapid evolution and growth of national immunization programs add to the pressure on currently fragile and strained systems. Compared to a decade ago, many immunization programs in developing countries now manage six times as many doses of vaccines in the supply chain; store and transport four times more vaccine volume per fully immunized child; safeguard the potency of vaccines when the value of supplies at risk in the cold chain has increased fivefold; and have doubled inventory levels and buffer stocks that have implication on the cold chain infrastructure.

New challenges include the growing number of vaccines, along with their formulation, thermostability, and packaging. These add more layers of complexity that have a tremendous impact on in-country supply systems. In the initial years of EPI, most of the basic six antigens used in national immunization programs had more standardized multidose presentations (usually 10 to 20 doses per vial). The vaccine management rules were much simpler, especially with the introduction of the Vaccine Vial Monitor more than 2 decades ago. The Vaccine Vial Monitor is a temperature indicator that measures the cumulative exposure to damaging heat. Not only did this help healthcare workers identify if vaccine potency had been compromised by excessive exposures to heat, the Vaccine Vial Monitor was instrumental in the implementation of the open vial or multidose vial policy—an approach to reduce vaccine wastage and reduce the overall impact on cold chain capacity requirements.

Today, however, many of the new vaccines ready to be introduced in developing countries come in liquid formulations that are sensitive to freezing. Yet, there is no equivalent of a Vaccine Vial Monitor to indicate if a vaccine has lost its potency from being exposed to undetected but damaging freezing temperatures. With the knowledge that at least 35% of vaccines are exposed to extended periods of freezing in the cold chain of developing countries,[73] safeguarding the potency of the newer, more expensive, vaccines will require measures for much stricter temperature control in the cold chain to let health workers know if the vaccine has been exposed to freezing temperatures (see "Game-Changing Solutions to Renew Systems" for technological solutions). In the coming years, wastage of vaccines because of freezing can have substantial financial consequences and will no longer be acceptable. Moreover, some of these new vaccines lack preservatives and, therefore, come in single- or two-dose vials to reduce wastage, which lead to markedly increased cold chain storage and shipping volumes.

The combination of a lack of attention and funding has meant that immunization supply chains have failed to evolve and adapt, resulting in delays to introduce new vaccines, stockout of existing vaccines, avoidable wastage, or loss of vaccine potency from storage in weak cold-chain systems unable to protect vaccines from excessive heat or freeze damage—all of which have implications in terms of increased costs and lower immunization coverage. These inefficiencies not only hinder the ability to meet desired immunization targets, they lower the return on health outcomes for those investing in improving immunization programs in developing countries.[70]

TABLE 76.2 Summary Statistics for Developing Countries[a] Reporting National Vaccine Stockout[b]

	2015	2014	2013	2012	2011	2010
Number of developing countries reporting stockouts	31	25	36	33	34	38
% Developing countries reporting stockouts	38%	31%	44%	41%	42%	47%
Number of stockout events[c–e]	57%	55%	79%	71%	72%	99%
BCG vaccine	42%	38%	39%	42%	38%	35%
DTP-containing vaccines	37%	29%	33%	32%	33%	48%
Measles-containing vaccines	5%	16%	13%	8%	15%	6%
OPV/IPV vaccines	16	16	15	17	14	10
Average number of stockout events[d,e]	1.84	2.20	2.19	2.15	2.12	2.61
Average duration of a stockout event (days)[d]	47	62	49	40	36	70

[a]Developing countries are defined as the 81 low- and lower-middle income countries based on the 2015 World Bank classification.
[b]For BCG, DTP-, measles-, and polio-containing vaccines.
[c]Some countries reported multiple stockouts in a given year, resulting in stockout events being greater than number of countries reporting stockout.
[d]Number of stockout events/number of countries reporting stockouts.
[e]For 81 developing countries reporting stockout events.
From WHO Expanded Programme on Immunization (2016).

Game-Changing Solutions to Renew Systems. Fortunately, a range of technological and supply systems solutions exist that hold the promise of addressing the majority of the current and new challenges faced by immunization supply chains in developing countries. There are several promising and transformational solutions ready for wider scale adoption in countries by 2020.

Leveraging the True Thermostability of Vaccines. Several vaccines commercialized for use in developing countries are, in fact, quite heat stable. Unfortunately, irrespective of the actual thermostability of a vaccine, almost all vaccines used today are

licensed for storage at 2°C to 8°C at all points in the immunization supply chains. In November 2012, a meningococcal A conjugate vaccine, MenAfriVac (Serum Institute of India, Pune, India), became the first product to be relicensed for use up to 40°C for up to 4 days in campaign settings. As there is no associated loss of safety, potency, or efficacy, this regulatory approval opened the possibility of keeping doses of this vaccine in a relatively simple controlled temperature chain for a few days rather than in a standard cold chain system. Several other vaccines are equally heat resistant and have the potential to be used in a controlled temperature chain. This comes with important benefits since reaching hard to reach areas and people is no longer bound by the reach of the cold chain if vaccines can be kept in a controlled temperature chain even for relatively short periods. In addition, the incidence of freeze damage for freeze sensitive vaccines like hepatitis-B could be drastically reduced if this heat stable vaccine could be used in a controlled temperature chain. Moreover, this approach has the potential to alleviate the burden on the traditional 2°C to 8°C cold chain storage space, and has been documented to reduce by up to 50% the overall cold chain and logistics cost of conducting immunization campaigns.[74–76]

Extending the Reach of Vaccines With New Cold Chain Technologies. Large areas of many developing countries cannot make vaccines available to the communities in need because energy requirements to run the cold chain are nonexistent, either because areas do not have electricity or cannot reliably provide fossil fuels for the main alternatives to electrically powered cold chain (kerosene- and gas-driven refrigerators). Even when the supply of fossil fuels is within reach, these types of equipment are plagued by problems with gas supply interruptions, low efficiency, high cost, poor temperature control, and frequent/expensive maintenance needs. Since 2010, important technological breakthroughs in cold chain equipment have occurred. The first is the availability of battery-free solar cold chain equipment whose performance, reliability and life-cycle costs are significantly better than nonelectrical models available (kerosene or gas).[77,78] The second is the availability of long-lasting passive cooling containers for health centers and "last mile" usage. These superinsulated containers can store vaccines for more than 30 days using regular ice. Whether it's the new generation of battery-free solar refrigerators or long-lasting passive cooling containers, these new technologies allow vaccine storage in areas where cold chain infrastructure was previously impossible to have. Extending the reach of the cold chain much further down the supply chain not only increases the availability of vaccines at the point of delivery, it can respond to and decongest the storage capacity constraints further up the chain.

Improving the Quality of the Cold Chain With Continuous Temperature Monitoring Technologies. As an increasing proportion of the value of vaccines now being procured is comprised by vaccines that are freeze-sensitive,[79] accidental freezing of vaccines is a growing threat. Today, an increasing number of inexpensive devices exist for continuous temperature monitoring. The use of these devices can mitigate the risks of potency loss of vaccines from damaging temperature excursions in the cold chain during both storage and transport. Studies have shown that the use of electronic continuous temperature monitoring and freeze prevention technologies can help reduce the incidence of inadvertent freezing of vaccine by 55%.[80] Continuous temperature monitoring has the additional advantage of helping improve vaccine handling quality, detecting malfunctioning cold chain equipment, and mitigate damaging temperature fluctuations and freeze events even when health workers are not present.

Moving Away From a Paper-Based Data Management System. Supply chain managers in countries seldom have information on vaccine stock balances beyond the central stores; do not have knowledge of avoidable vaccine wastage in the system from breakage, leakage, or expiration; have incomplete understanding of current cold chain capacity or what equipment is not functioning; and can never be sure if vaccine stockouts are occurring at the lower levels of the supply chain. The lack of reliable and timely data for accurate vaccine forecasting, immunization supply chain planning and to adequately respond to vaccine orders within a country is often cited as a key bottleneck. The lack of visibility of vaccine stocks and flows within an immunization supply chain is a detriment to ensure timely availability of vaccines and lead to inefficiencies in the supply chain (e.g., need to have idle buffer stocks throughout the chain; not delivering enough vaccines leading to stock out; delivering too much vaccine leading to expired vaccines that need to be discarded).

One root of the problem is that many developing countries continue to manage their supply chain with a "paper-based" logistics management information systems that do not permit real-time tracking and tracing of vaccines and visibility of stock levels throughout the supply chain. Yet, the rate of innovation in the field of information and communications technology to respond to this has been staggering in recent years. Many cost-effective information and communications technology solutions are available to developing countries. These range from mobile phone networks and devices that can now connect even the most remote locations to the Internet and cloud-based server hosting, making it possible to operate networked systems between the central vaccine store and subnational stores. In addition, barcode systems are more widespread allowing their printing onto vaccine packaging to enable tracing of vaccine lots down to the district level and beyond. The widespread availability of mobile and cloud-based information and communications technology enable the establishment of networked systems for ordering vaccines, managing stocks and equipment, monitoring consumption and vaccine use, and help vaccine supply managers make sure that vaccines are being kept in the right conditions and made available when and where they are needed.[81,82] These technologies could be expanded to other low- and middle-income countries to improve stock management and to ensure reliable and constant supplies of vaccines at the service delivery points.

Optimizing the Supply Chain Network Design. Many developing country immunization supply chains were designed more than 35 years ago and few have adapted their distribution network to the needs of today's national immunization programs. Most government-run vaccine supply chain networks replicate the administrative structure of the health system rather than being designed with the objectives of ensuring availability of vaccines, making rational use of the cold chain infrastructure, or optimizing distribution circuits for more efficient vaccine deliveries. With the surge in the volume of vaccines, some of the storage capacity constraints and bottlenecks can be overcome by redesigning the supply chain network. This is particularly true in countries where vaccine supplies have to transit through an inordinate number of levels from the point of entry at the national level to the service delivery points. Each storage point and distribution route along the way poses a risk to the vaccines (from mishandling to breaks in the cold chain). In addition, each point continuously requires infrastructure expansion of the cold chain capacity. Improved distribution methods and "level-skipping" could alleviate some of the cold chain capacity constraints in the system by reducing handling touch-points in the supply chain.

In recent years, there is increasing evidence that redesigning supply chain networks have the potential to improve vaccine availability, reduce stockouts, speed up delivery time, increase

storage capacity downstream, and reduce costs. One study indicates that without any change to the network design, timely vaccine availability at lower levels of the system, following the introduction of new vaccines, could drop by 71% because of bottlenecks in storage capacity.[83] Network redesign has also been shown to reduce the logistics cost of delivering a dose of vaccines to the service delivery point by up to 60%.[83–85]

Synergies With Other Health Commodity Supply Chains. Since 2010, there has been a rising trend in developing countries where central medical stores and health supply chains are government-managed to explore how to rationalize the use of both dry and cold storage infrastructure, and how to leverage economies of scale from supply chain integration. Historically, vaccines were among the handful of essential commodities that required their own specific supply chain—most vaccines needing to be kept in a strict 2°C to 8°C cold chain, unlike other essential medicines. Today, this is no longer the case. There are a growing number of pharmaceutical products needed at the more peripheral healthcare facilities that require strictly controlled temperature storage, particularly at the last mile. One example is oxytocin, an injectable drug to prevent postpartum hemorrhaging in women, the efficacy and shelf life of which deteriorate when exposed to heat. As immunization supply chains struggle to meet current and upcoming challenges, and with other temperature-sensitive lifesaving health commodities competing for cold chain space, opportunities for supply chain integration of time and temperature-sensitive health products is an emerging solution. When implemented correctly, it has the potential to address storage constraint and to reduce redundancies, complexities, and costs to the health system as compared to operating parallel and vertical supply chains.[86]

Private Sector Engagement in Immunization Supply Chains. Many developing country immunization programs are recognizing that government-managed logistics functions that were once ancillary now require important investments and tie up significant resources should they be scaled up appropriately to meet service delivery targets and to introduce new vaccines. Many developing countries have seen the emergence of private sector logistics providers who have made significant advances with the use of technology and information management, and capable of providing better and more efficient services than what is possible in the public sector. Rather than attempt to keep pace with these advances, more and more countries are recognizing the benefits of engaging the private sector in supply chain and logistics functions by outsourcing the physical storage and handling of vaccines to specialized private sector operators when the right expertise is available in country. In many instances, the private sector can complement governments' efforts in improving health logistics in specific aspects such as procurement, storage and in-country distribution. Outsourcing supply chain function to the private sector can enhance operating performance and leverage managerial efficiencies, allowing governments to focus on core expertise. Although outsourcing can help improve the performance of the vaccine supply chain, it has the potential to do the reverse if done incorrectly.[87]

Strengthening Human Resources for Effective Vaccine Management. Immunization supply chain systems critically depend on the skills and commitment of a strong and sufficient supply chain and logistics health workforce. The availability of skilled cold chain logisticians has eroded over the past decade as part of the overall neglect and inattention given to immunization supply chains in developing countries. With more valuable inventories of vaccines to handle, store, and distribute, this has put increased pressure on country supply-chain managers to ensure that EVM best-practices are implemented, and that vaccine management policies are strictly followed. As the evidence shows, there are important shortcomings in this regard (see Fig. 76.10).

The EVM initiative has established management standards for the vaccine supply chain and logistics system and benchmark these against best-practice standards.[71] The EVM is first and foremost a continuous quality improvement process to stimulate supply chain managers to strive toward the highest quality management practices for their vaccine supply chain. With the acceleration of new vaccine introduction, greater cold storage capacity is now required at every level of the supply chain, and countries must strive to maintain lower stock levels, reduce closed vial wastage, improve their logistics management information systems to accurately forecast vaccine requirements, and prevent cold chain equipment failures so that vaccines are not damaged by heat or freezing. Today, vaccine logisticians in countries need to be trained and imparted with the right skills to handle new vaccine products, use and monitor new cold chain equipment and cooling technologies, and learn how to establish and use new data and information management systems to forecast needs, allocate stock, act rapidly where cold chain equipment becomes dysfunctional, and recommend policy changes in support of network optimization, supply chain integration, or engagement with the private sector. The EVM initiative builds on the well-established principles of quality management to ensure the skills of supply-chain managers and vaccine logisticians are raised and that a holistic process to assess, plan and implement change is built as part of a continuous quality improvement process for reaching recommend standards for EVM.[71]

Future Prospects and Opportunities. While these systems have shown extreme resilience to deal with the growing challenges, they have done so by resorting to ad hoc solutions and unsustainable coping strategies. The limits of these approaches have now been reached, to the point where in-country immunization supply chains have become a bottleneck to achieving future immunization goals and aspirations in developing countries. In the absence of systematic, coherent, and planned improvements for both current and future challenges, and without significant investments to upgrade immunization supply and logistics systems through the wide-scale adoption of known game-changing solutions, the aspirations to strengthen routine immunization as a whole by 2020 will remain quixotic at best.

The level of investment required is substantial. However, compared to the investments being made in vaccine products themselves, these investments are relatively marginal.[38] Estimates suggest that investing annually up to 10% of the value of vaccines being procured will be sufficient to upgrade in-country immunization supply chain systems in developing countries by 2020 and ensure EVM best practices.[88] While investments for strengthening developing country supply chains are desperately needed, these investments need to be directed toward the right strategies and implementing frameworks. In response to this, recent global initiatives have begun to revitalize immunization supply chain efforts beginning with the development of a 2020 Vision and action plans[89]; moving toward securing international resources to invest in country systems as part of the Gavi Alliance Immunization Supply Chain strategy[90]; and establishing a global mechanism for supporting developing countries to implement change and to adopt game-changing solutions through the recently established WHO-UNICEF immunization supply chain hub. These opportunities hold the promise to facilitate the equitable access and availability of effective vaccines at service delivery points over the next decades and ultimately support immunization programs to reach the estimated 19.4 million children who remain unimmunized or underimmunized.

Information Systems: Monitoring and Evaluation of Immunization Programs

The availability of *good quality* data is fundamental to achieving the goals and objectives of the GVAP. The term *good quality* when applied to immunization data can be interpreted in many different ways, depending on the intended use of the data. In 2013, the WHO SAGE on immunization highlighted the importance of the need and use of high-quality data both to improve performance and to monitor the results. Data may be considered to be of *good quality* if it contributes to a **complete, unambiguous, meaningful,** and **correct** inference of the status of an immunization system. Data should also be available, analyzed, and interpreted in a **timely** way, to allow managers to take actions to optimize the performance and impact of the program.

Data required to monitor the performance and impact of immunization programs include the following:

- *Data to monitor indicators of program activities and inputs*—to detect potential problems with the availability and quality of vaccination services and to identify appropriate solutions;
- *Data to monitor indicators of program outputs*—coverage of each dose of each vaccine in the national schedule and related indicators of dropout and missed opportunities; these are intermediate indicators that are more easily measured than the measurement of disease impact through surveillance and allow monitoring of progress toward GVAP and country goals;
- *Data on the burden and trends of vaccine-preventable diseases (VPDs)*—reduced disease incidence and mortality are the ultimate indicators of program success[91];
- *Data on AEFIs*—must be monitored to ensure that any such events are detected and investigated, and that an appropriate response is mounted.

The WHO and UNICEF collect and compile information annually for all countries on key program indicators through the joint reporting form.[92] The WHO also collects information through reports from the various program assessments as well as reports of household surveys. However, beyond reporting to WHO and UNICEF, it is more important that these data and indicators be monitored and used both nationally and at the district (or other appropriate) administrative level at which the program is managed. Provision of regular feedback to health workers at all levels of the health system is a powerful way to motivate health workers to improve.[93–95] In addition to the above groups of indicators, vaccine effectiveness can be monitored through a number of methods described in Chapter 73.

Monitoring Program Inputs and Activities. It is important to ensure that the program is adequately resourced and that activities are conducted as planned, both in terms of their quantity and their quality. Routine reports provide data on the availability of micro plans and on vaccine supply. These should be supplemented by periodic assessments of vaccination activities, for which a number of tools and opportunities exist. The immunization system as a whole is reviewed periodically either by comprehensive program reviews often involving external assessors,[96,97] or during a "postintroduction evaluation," which is a systematic method for evaluating the impact of the introduction of a vaccine on the existing immunization system in a country.[98] In both of these, onsite observation and interviews are performed at national, regional, district, health center, and community levels in selected areas, using a series of questionnaires and checklists produced by the WHO. Following data analysis, a list of major issues is prepared. For each issue, achievements and problems are listed and an action plan is formulated. At the local level, district managers are encouraged to conduct health facility–based assessments of missed immunization opportunities,[99,100] data quality self-assessments,[101] and cold chain performance.[102] These provide quick information at the local level on program performance that should lead to timely remedial action.

Monitoring Vaccination Coverage. At the global level, vaccination coverage is a tracer condition for results-based financing,[103] an indicator of eligibility for Millennium Challenge Account assistance,[104] and a criterion for support from the Gavi for the introduction of new vaccines.[105] At national and subnational levels, monitoring coverage of different vaccines can provide insight not only into the overall program success in providing all vaccines to the target population (percentage of children vaccinated with each vaccine and fully vaccinated with all vaccines in the national program), but also into areas of program weakness. High coverage with DTP1 and the first dose of polio-containing vaccine (POL1) indicates high access to primary healthcare facilities. If DTP1/POL1 coverage is high by age 2 months but coverage for the respective third doses or for the MCV1 is low, further investigation to determine the cause of the dropout is required. High coverage of one vaccine (e.g., DTP) but lower coverage of another scheduled concurrently (e.g., pneumococcal conjugate vaccine) may show missed opportunities to administer vaccines when the child attends a vaccination session, because of vaccine stockouts, real (rare) or perceived (more common) contraindications, or reluctance to administer multiple vaccines at the same visit.

Coverage and the related indicators of dropout, missed opportunities, and timeliness of vaccination are monitored through several methods, each having advantages and disadvantages (Table 76.3).[106,107]

Register-Based Coverage Estimates. Ideally, vaccination coverage should be monitored continuously using registries or administrative reports.[107] Electronic immunization registries aim to document all vaccinations of each individual in each birth cohort.[108–110] Denominators may derive from the same registry or from a separate vital statistics system. When well implemented, electronic immunization registries can provide data for coverage measurement and for program-management activities such as monitoring vaccine supply and requisitions and sending vaccination reminders. Challenges facing such registries include accounting for migration within and between countries, ensuring complete and timely birth registration and vaccination reporting, avoiding record duplication,[111] and ensuring continuity after organizational changes.[112] As access to information and communications technology expands, the use of electronic registries is increasing and lessons learned from pilot studies as well as national experiences are being exchanged among countries and regions to improve their use.[110] However, substantial time and resources are required to conceptualize, design, pilot, and scale-up the use of these registries countrywide.

Administrative Reports. So-called administrative coverage is calculated using aggregate reported data on the number of doses of each vaccine administered to children in the target age group in a given time period and target population estimates and projections from censuses or, in some cases, from the number of registered births. All countries have such systems in place for vaccination of infants (national coverage data are reported annually to the WHO and UNICEF), and an increasing number also monitor booster doses and vaccination of

TABLE 76.3 Advantages and Disadvantages of Methods to Measure Vaccination Coverage

Method	Advantages	Disadvantages
Register-based (electronic)	• Can give complete and accurate information on cumulative vaccination status of individual persons and populations • Can be used to set appointments and issue reminders and recalls • Use of electronic systems could reduce time spent on paper registers that are widespread in low-income countries and often not used	• Need good computer access • Need complete birth registry for true denominator • Need unique ID number throughout life • If held locally, difficult to track vaccination of migrants • If held nationally, feedback/use at local level may be slow • Requires adequate funding and human resources • Need secure procedures to maintain confidentiality
Routine reports of vaccinations delivered	• Simple in conception • Continuous information allows monitoring of cumulative coverage through the year and by district/health facility • Can be used at local level to track coverage and dropout rates	• Population denominators often inaccurate • Private sector often does not report • Exaggeration of doses administered common (e.g., double counting of same child if home-based record mislaid, inclusion of children outside target age group, or purposeful exaggeration) • Transcription errors at each health system level when paper-based systems used
Surveys	• If well-conducted, can provide accurate information • Other indicators (e.g., missed opportunities, caretaker knowledge) can be assessed • Involvement of health workers can be training opportunity • Large-scale surveys for multiple programs can reduce costs • Lot quality sample surveys can be used to identify health facilities and low coverage population subunits	• Accuracy of data depends on adequate survey design, training, supervision, and quality control • Sampling frame often based on outdated census information • High-risk subgroups (e.g., migrants, street children) may be missed • Home-based records may be missing or incomplete, and accuracy of verbal history of vaccination varies • Participation rate affects reliability of results • Often long delays until results are known • Small samples give imprecise results; large samples are expensive and more time-consuming

other age groups, such as human papillomavirus vaccine to school-age girls.

The administrative method has the advantages of providing continuous information at the local and district levels and being relatively inexpensive. Each facility and district can track achievement of coverage goals and dropout using standard immunization monitoring charts and take immediate action to correct any problems identified. This approach is central to the district approach recommended in the Reach Every District strategy. From routine reports, the doses administered to children also can be compared with total doses distributed to estimate wastage rates.[113]

Despite these advantages, "administrative coverage" is often unreliable as a result of incomplete, inaccurate, or delayed reporting of numerator data and out-of-date information on population denominators.[106] There are often additional difficulties in accounting for vaccinations of individuals from outside the catchment area or from other countries.

Community Surveys. Household surveys are complementary ways to determine coverage.[106] The most common surveys have been the EPI cluster survey[114–117] and the larger UNICEF Multiple Indicators Cluster Survey (MIC) and Demographic and Health Surveys (DHS).[118,119] In the past, the EPI cluster survey method typically did not use a probability sample (one in which each individual has a known and nonzero probability of being included in the survey) and did not always implement or document strict quality control measures.[106] The WHO updated the EPI survey guidelines so that surveys now use probability sampling and excellent quality control is required.[120]

Data from surveys are often considered to be more reliable (closer to the "true" vaccination coverage) than those from administrative reports, but this is not necessarily the case. The accuracy of survey data is affected by factors such as selection bias and information bias, which cannot be solved by increasing the sample size.[106] Common causes of selection bias are exclusion of certain population groups from the sampling frame (e.g., for security reasons or homeless populations); poor field practices such as substituting a sampled household with one that is easier to reach or not revisiting households where respondents were absent on the first visit. These factors most often inflate coverage estimates. Information bias occurs when a child's vaccination status is misclassified because of mistakes on the vaccination record, transcription of data from the record, or the guardian's recall for children without a written record, and may lead to over- or underestimation of coverage in surveys.

When well conducted and of adequate size, surveys may provide more accurate and nuanced information than other sources. If designed appropriately, coverage at subnational level can be measured or classified and clusters in the survey that had extremely low numbers of vaccinated children can be highlighted, pointing to the need for further investigation in those geographic areas. Analyses can assess whether vaccines are received as close to the scheduled ages as possible—not too early or with too short an interval between doses ("invalid doses"), which might reduce vaccine effectiveness, but as early as recommended to shorten the period that a child remains at risk of contracting the relevant disease.[106,121] Missed immunization opportunities through the failure to administer vaccines simultaneously can also be measured. Questionnaires can also assess reasons for failure to vaccinate [122–124] and the occurrence of adverse events, such as abscesses after vaccination.[125] Coverage surveys can be extended to include indicators of other programs, especially if home-based records include dates of visits to healthcare facilities for curative care or growth monitoring.[94,126]

Lot Quality Sample Surveys. Originating from the manufacturing industry, lot quality assessment sampling (LQAS) methods classify results found in a survey as acceptable or unacceptable, based on predefined upper and lower cutoffs. In its classical form, LQAS uses simple random samples. In many instances, however, this is not feasible for field surveys even with small overall sample sizes, and a clustered LQAS

design has been developed whereby within each lot (e.g., district), a certain number of clusters are selected with probability proportional to estimated size (e.g., from a list of all villages with their respective populations).[126,127] In each cluster, a sample of the required number of children is selected, most often using nonprobability sampling methods. For evaluation of polio campaigns, commonly six clusters of 10 children each are sampled per lot,[128,129] but ideally a larger number of clusters would be included and children would be selected by random sampling within each cluster.[130]

It is important to recognize that LQAS surveys inevitably have a central range of coverage (the "gray area") that is not excluded by either the "adequate" or the "inadequate" classification.[131] That is, neither classification excludes the medium category. As a consequence of small sample sizes, quantitative estimates for each subunit are not available, although under certain circumstances, results from multiple subunits can be pooled to derive an overall estimate. LQAS has been used to identify health service units, neighborhoods or villages, that are not meeting predefined standards, such as coverage in an immunization campaign,[132–134] immunization coverage among clinic attendees, cold chain maintenance, safe injection techniques, and use of all opportunities to vaccinate.

Sero-Surveys. Although biomarkers are under consideration for estimating coverage, they have several limitations for this purpose[106,135] and are not currently included routinely in surveys measuring childhood vaccination coverage. For most vaccines, the presence of antibody following vaccination cannot be distinguished from that following "natural" infection. Exceptions are the presence of tetanus antibody (infection does not generate lasting immunity) and the presence of antibodies to antigens included in subunit vaccines such as hepatitis B (anti-HBs [anti-surface antibody]) but not to other antigens found in the whole organism (anti-HBc [anti-core antibody]), which are considered to be an indication of vaccine-induced immunity. Even for these vaccines, detection of antibodies does not indicate reliably how many doses have been received.[136] Furthermore, absence of antibody means either that the child is unvaccinated, that vaccines have lost their potency, or that antibody levels have waned if a long period has elapsed since vaccination. Biomarkers are therefore potentially useful to estimate population-level protection,[137] but not necessarily to validate coverage measurements or vaccination program performance. The development of antibody assays on oral fluid samples for tetanus[136] and measles[138] may make surveys with repeated sample collection more acceptable and may facilitate evaluation of vaccination campaigns.[139,140]

Triangulating Coverage Data From Different Sources: WHO-UNICEF Estimates of National Immunization Coverage. Since June 2000, the WHO and UNICEF have done annual reviews of routine immunization coverage worldwide.[92] Administrative coverage and any available national coverage survey data are reviewed and survey data ranked in terms of perceived quality. Draft estimates are determined and sent to national authorities, modified in light of comments received, and published as the WHO-UNICEF estimates of national immunization coverage in July or August of the year following the end of the reporting period.[141] Country-specific estimates are updated annually. If a new survey becomes available that contains information for previous years, retrospective adjustment of coverage estimates is made for relevant years. This process has helped improve the quality of administrative reports from many countries. There are, however, several constraints,[141] including the quality and availability of empirical data from routine reports or surveys, and delays before obtaining results from surveys which mean that major retrospective changes in WHO-UNICEF estimates of national immunization coverage may occur. To account for the availability and limitations of empiric data, an indicator of the WHO's confidence in the estimates is shown for each country on the individual report.

To improve coverage data quality, the following merit consideration:

- Prioritizing the improvement of the quality and availability of administrative data as the most effective, representative, and penetrative source of information on program performance;
- Promoting the regular use of data to inform policies, strategies, and corrective actions to enhance program performance at all administrative levels (because if data are not used, there will be no incentive to improve quality);
- Promoting a systematic approach to data quality assessments and corrective actions (reviews of data quality can be useful training tools);
- Promoting the strategic and cost-effective use of household surveys to provide supplementary data, through clear definitions of survey objectives and designing survey methods to meet the objectives;
- Strengthening the human resource capacities for improving data quality and meeting program needs; and
- Advocating for investments in sustainable solutions to improve the availability and quality of data.

Acting on Coverage Data. Improving the quality of coverage data is only useful if the results lead to action. Program managers should investigate reasons for low immunization coverage at national or subnational levels, by addressing the following questions[142]:

- Is the present vaccination delivery system inadequate?
- Are there characteristics of incompletely vaccinated children and their families that can help identify them?
- Do parents lack accurate information about the "where, when, and why" of vaccination?
- Do unfavorable attitudes (including rumors about perceived adverse events) among communities and families outweigh even a good vaccination system and good information?

Available information should be collected from secondary data sources (such as reports of previous program reviews, analysis of coverage data by health center) and by direct observation of vaccination practices and clinic organization during supervisory visits. Program inputs and activities should be compared between areas having high and those with low coverage, together with data on the catchment populations (size, demographics, socioeconomic and educational status, migration patterns, security issues, etc) to look for reasons for the differences in coverage and identify solutions. Program managers need to develop strategies to reduce barriers at health services and to reach the families and populations who have characteristics that make them harder to reach—for example, one of the most consistent findings is the association of low coverage of vaccination and other health interventions with low levels of education, particularly female education.[143] Discussions with experienced healthcare workers and community discussions will help identify programmatic barriers to immunization and/or vaccine hesitancy at the community or individual levels.[144–147] Often these practical investigations and sharing of experience will generate ideas for action to improve coverage.

Occasionally, supplementary studies may be needed to answer specific questions that remain after the above

investigations. A number of methods are useful for studies of reasons for incomplete vaccination, including any combination of the following:

- Health facility–based surveys (e.g., "health-facility assessments"), which include a mixture of observation of practices, interviews with providers to assess their knowledge and practices, and exit interviews with mothers.[94,148] These inexpensive studies can easily be coupled with home visits to adjacent neighborhoods to investigate reasons for undervaccination in households with easy access to health services.[148,149]
- Qualitative methods such as key informant interviews and focus groups to evaluate healthcare professional knowledge and attitudes relating to vaccination and family and community demand for vaccination.[150–152] These methods may be used alone,[152] as preliminary work to develop a quantitative data collection instrument,[153] or after quantitative surveys to examine how risk factors operate and to develop interventions.[154]
- Interviews of mothers of incompletely vaccinated or of fully vaccinated children to describe their characteristics (case studies or case series).[155]
- Cross-sectional studies with interviews of a random sample of participants to assess attitudes to vaccination and describe vaccine confidence and vaccine hesitancy.[147]
- Quantitative studies of factors associated with incomplete vaccination which compare characteristics of "vaccinated" with "unvaccinated" groups in cross-sectional "knowledge, attitudes, and practice" surveys,[122,125,156] case-control studies,[157] or cohort studies.[158]
- Intervention studies, in which communities are randomized to the intervention compared with a control group[124] or in which a whole population receives the intervention and "before and after" comparisons of coverage are made.[35,150,159–161]

Disease Surveillance. Surveillance is fundamental to measure the impact of immunization programs on reducing VPDs and to generate information to inform policy decisions and support sustained financing for the immunization program. It is also important to identify changes in disease epidemiology which may require modifications of vaccination schedules (e.g., addition of booster doses) and/or adaptation of program strategies (e.g., implementation of supplementary immunization activities of different age ranges). Early identification of outbreaks allows rapid response to avert as much morbidity and mortality as possible.

Different methods of surveillance are used at different stages of immunization programs and for varying objectives. No single approach may be sufficient to meet the epidemiological information needs for planning or for the comprehensive documentation of the impact of immunization. Hence, a variety of approaches are used to monitor the epidemiology of diseases targeted by vaccines. One or more approaches are used for any particular disease. These include the following:

- Passive countrywide aggregate reporting of VPDs and outbreak investigation;
- Active countrywide surveillance (usually case-based) with laboratory confirmation;
- Sentinel site surveillance; and
- Special studies and sero-surveys (e.g., for estimating hepatitis B vaccine impact).

For all disease surveillance, standard case definitions and minimum data elements should be used.[162,163] Surveillance systems should be monitored through the use of quality indicators, the main three being the timeliness and completeness of reporting, the proportion of reported cases and outbreaks that are investigated in a timely manner (including laboratory confirmation of diagnosis, where appropriate), and the proportion of investigated cases and outbreaks that are followed by an appropriate response.[164]

Passive Countrywide Reporting of Vaccine-Preventable Diseases and Outbreak Investigation. Since its inception, the EPI has promoted the reporting of aggregate numbers of cases of selected VPDs. The WHO has also published surveillance standards and case definitions for reporting cases.[162] Currently, almost all Member States report aggregate numbers of cases of these diseases through the WHO/UNICEF joint reporting form. However, the quality of these reports is highly variable and the disease trends in some countries, especially the low- and middle-income countries, are often difficult to interpret.[163] While most countries report clinically suspected or confirmed cases, others may also report laboratory confirmed cases and a few only report laboratory confirmed cases. Currently, most countries do not have mechanisms for data verification and the WHO does not have a way to assess the quality of the reported data.

Active Countrywide Surveillance, With Laboratory Confirmation. This surveillance platform builds on the acute flaccid paralysis and poliomyelitis surveillance network. The platform has been used to establish or strengthen case-based surveillance, with laboratory confirmation of cases, for measles and rubella. The resources available through this platform, along with the associated laboratory networks, have also been used to investigate outbreaks of other diseases, both vaccine-preventable as well as those that are currently not vaccine preventable.

Critical elements of case-based reporting include active case-finding (a systematic approach to identify and report every eligible case, e.g., as used for acute flaccid paralysis surveillance in the polio eradication initiative), negative (or "zero") reporting (i.e., submitting a report of zero cases if there are no cases during a specified reporting period), prompt investigation of each reported case of disease to collect relevant risk-factor and program information, laboratory confirmation, and program response. Case-based reporting requires substantially more human resources than routine reporting and should be initiated only in programs with high vaccine coverage and disease reduction and/or elimination initiatives.

Most countries now report case-based data for polio and measles to the WHO weekly and detailed guidance on surveillance and laboratory methods is available.[165] An increasing number of countries are now using the same platform to also report rubella cases.

Although active countrywide surveillance is likely to provide more useful information than passive aggregate reporting, there are still many challenges with interpreting data. Measles, for example, remains grossly underreported.[166] Globally, in 2013 there were 194,139 reported cases, compared to 122,000 estimated measles deaths in 2012—this would imply an implausible case fatality rate of 62%.[167] Insensitive surveillance may be used to evaluate trends if sensitivity remains constant but it is more difficult to assess trends when reporting completeness changes over time, and insensitive surveillance is inadequate for planning actions to sustain measles elimination. Surveillance of rubella and CRS is even more limited, even in some industrialized countries in Europe; Belgium, France, and Germany do not have rubella surveillance systems covering the total population.[166]

Sentinel Site Surveillance. Sentinel site surveillance (a system where surveillance is conducted in a limited number of reporting units, usually health facilities, as opposed to conducting countrywide surveillance), as a platform to generate information to support the introduction of Hib, pneumococcal conjugate, and rotavirus vaccines, was established in a few regions through the Paediatric Bacterial Meningitis and Rotavirus Diarrhoea surveillance networks. With the establishment of the PneumoADIP (Pneumococcal vaccines Accelerated Development and Introduction Plan), Rotavirus Vaccine Program, and the Hib Initiative, these networks were expanded to include all regions. In 2008, these networks transitioned to WHO coordination.[168] Recognizing technical, financial and human resource limitations, the WHO and partners proposed a layered approach for surveillance for invasive bacterial diseases, whereby the intensity of surveillance and number of disease syndromes reported varied by country. In addition, centers of excellence were identified to conduct specialized epidemiologic studies to complement surveillance. Following an external strategic review by an expert panel,[169,170] the surveillance objectives are being refined and the performance management framework has been updated.

This surveillance platform lends itself for the inclusion of other potentially VPDs, including acute encephalitis, typhoid fever, and CRS.

Special Studies. Special surveys have been used to determine disease burden in areas where access to healthcare facilities is low, particularly in the early years of immunization programs, and more recently for certification of neonatal tetanus elimination.[133,171,172] For some diseases, serologic surveys may be suitable to determine disease burden and measure impact on disease (e.g., hepatitis B).[173] Serological surveillance is a potentially important tool for elimination programs, especially once disease incidence is very low, as serology can potentially indicate problem areas where population susceptibility is increasing and there is the potential for an outbreak. Serological surveys may help identify which age groups should be included in campaigns, and evaluate the contribution of campaigns to reducing population susceptibility.[106,166]

Use of Mathematical Models to Estimate Burden of Vaccine-Preventable Diseases and Impact of Vaccination. The choice of vaccination strategy requires an understanding of the dynamic effects of vaccination on disease transmission and knowledge of age-related changes in severity of disease, vaccine complications, and the probability of transmission of the infection.[174,175] Mathematical modeling is useful to estimate the burden of disease for which surveillance data are insufficient (e.g., rubella and hepatitis B). Mathematical models can assist with comparing the merits of different strategies and improving our understanding of the observed impact of vaccination programs.[176–179]

Dynamic simulation models attempt to describe the dynamics of infections in populations and to predict their behavior under the conditions of vaccination programs.[174,176,180,181] Modeling has been used to explore thresholds for elimination or eradication of infections from populations[174,182–184] and to examine the immunologic response to vaccines and the minimum number of vaccine doses necessary to induce long-term protective immunity.[185]

The potential to combine economic with dynamic modeling to predict the effects and cost-effectiveness of different vaccination strategies has increasingly been recognized,[186,187] particularly to take into account herd-immunity externalities when assessing the cost-effectiveness of vaccines that prevent infection. With the growing complexity of the vaccine schedule, vaccine presentation (e.g., single-dose or multidose vials; prefilled syringes), and vaccine procurement and distribution, modeling is now being used to investigate how to optimize the supply chain in different settings.[83,188] Multiple factors are assessed, including vial size and type, storage patterns (degree of decentralization), transport patterns, methods for determining the frequency and size of vaccine shipments to peripheral levels (e.g., based on estimated or actual consumption), and integration or not of vaccine distribution with that of other commodities. With the availability of global positioning system maps, models can assess a variety of supply chain dynamics according to the actual geography and demography of a country or district.

Monitoring Adverse Events Following Immunization. Although modern vaccines are well tolerated and efficacious, no vaccine is totally safe. The more successful vaccination programs are in controlling disease, the higher the attention attracted by adverse events, often reported in the media. An inadequate response to such events can erode public trust, lead to the reduction in vaccination coverage, with the resultant risk of reemergence of VPDs. Developing countries are increasingly facing such situations and many have had to interrupt vaccination temporarily in response to AEFIs. When disease has been eliminated, the acceptance of even very rare adverse events may become politically untenable. The WHO and individual countries have greatly strengthened immunization safety activities, convening a Global Advisory Committee on Vaccine Safety,[189] which has issued reports on controversial vaccine safety issues; supported the Brighton Collaboration in the development of common definitions for adverse events; established the Vaccines Safety Net project; and required enhanced AEFI reporting as a critical function of national vaccine regulatory authorities.[190,191]

Reported adverse events can either be true adverse events (i.e., resulting from the vaccine or immunization process) or coincidental events that are not caused by the vaccine or the immunization process but are temporally associated with immunization. In 2012, the existing classification regarding cause-specific categorization of AEFIs was revised by the Council for International Organizations of Medical Sciences and the WHO, and a new categorization was introduced (Table 76.4).

All countries should establish immunization safety monitoring activities.[191] The WHO has published guidance on the investigation of AEFI, how to analyze surveillance data, causality assessment and how to respond to serious AEFI, including communication.[192] The guidance document also includes a description of the causes and classification of vaccine reactions, the most common reactions, and updated references in vaccine pharmacovigilance.

National surveillance for AEFIs should emphasize reporting and follow-up of cases caused by program error. Such errors include reconstitution with the wrong diluent; administration of dangerous drugs mistaken for vaccines; contamination of multiple-use vials, leading to abscesses or sepsis; and use of contaminated needles or syringes, which may transmit bloodborne viral pathogens such as HIV and hepatitides B and C.[193–195] Single serious events or clusters of unusual events should be appropriately investigated and an independent review committee should review serious cases and assess causality. Surveillance should also monitor and investigate any serious events perceived to be potentially caused by vaccines. Training on adverse events surveillance is critical to remind healthcare workers of the potential for adverse events and the need for constant vigilance when biologic preparations are administered. The WHO has developed an e-learning course on vaccine safety, which is available online.[196]

TABLE 76.4 Cause-Specific Categorization of Adverse Events Following Immunization

Cause-Specific Type of AEFI	Definitions
Vaccine product-related reaction	An AEFI that is caused or precipitated by a vaccine owing to one or more inherent properties of the vaccine product
Vaccine quality defect-related reaction	An AEFI that is caused or precipitated by a vaccine that is owing to one or more quality defects of the vaccine product, including its administration device as provided by the manufacturer
Immunization error-related reaction (formerly "programmatic error")	An AEFI that is caused by inappropriate vaccine handling, prescribing, or administration and thus by its nature is preventable
Immunization[a] anxiety-related reaction	An AEFI arising from anxiety about the immunization
Coincidental event	An AEFI that is caused by something other than the vaccine product, immunization error, or immunization anxiety, but a temporal association with immunization exists

[a]"Immunization" is used in these definitions to mean the use of a vaccine for the purpose of immunizing individuals. "Use" includes all processes that occur after the vaccine product has left the manufacturing/packaging site (e.g., prescribing and administration of the vaccine).
AEFI, adverse events following immunization.
From Council for International Organizations of Medical Sciences and the World Health Organization, 2012.

Enhancing Service Delivery

Overview of Vaccines, Schedules, and Delivery Strategies. As discussed earlier, during the past decade most developing countries have added new vaccines to their national immunization schedules and extended immunization activities to also include older age groups. In particular, many developing countries have added or scaled up the use of vaccines in the second year of life (for second routine measles doses and other booster doses of vaccines administered in infancy) and during school age. With the recent introduction of human papillomavirus vaccine, several developing countries have also included vaccination of the preteen and adolescent age groups in their national immunization schedules. As a result, the fairly simple table with the recommended immunization schedule developed at the inception of the EPI have now been transformed into fairly complex tables that reflect the WHO recommendations for vaccination as stated in the WHO vaccine position papers (Table 76.5).[197] The recommendations in the tables provide countries with the flexibility to tailor national schedules to suit their needs based on the local disease epidemiology and their program characteristics.[198]

The tables are designed for use by national immunization managers and key decision makers, chairs and members of national advisory committees on immunization to guide the development of the respective national schedules, and for the information of partner organizations, including the vaccine industry. They were not intended for direct use by health workers.

As developing countries increased their immunization coverage from the historically very low levels to reach close to the 80% mark, they found coverage levels stagnating as the programs found it difficult to identify and deliver services to the remaining smaller segment of their target populations. Thus, many developing countries are faced with the dual challenge of dealing with the increasing complexity of the program, with several new vaccines and additional doses being added to the immunization schedule, as well as with tracking and delivering services to the so-called fifth child. Strengthening immunization and health systems (referred to in the previous section of this chapter) is one part of the solution. However, this needs to be coupled with strategies to reach those who are consistently missed by the system.

In developing countries administration of vaccine is most often done in a fixed site such as a health post, a clinic, or a health center. Birth doses tend to be given in the postnatal care clinic or ward. However, as health facilities in some countries are not accessible by populations living further away, across difficult terrain or are on the move because of the seasons or other influences, many countries augment their fixed site routine vaccination delivery services with various mobile and outreach services; in some countries mobile and outreach services have become the primary mode of delivering immunization. Community-level service delivery may be accomplished in several different ways:

- *Outreach services*: These are generally held regularly at the same site but are manned only when the outreach team arrives. They may be held at a formal health site or be held in community gathering places such as schools, places of worship, or markets. Generally, the outreach sessions are held regularly at least every month, and the attendant health workers would normally return to their home base on the same day of the service. In some countries, such as Bangladesh, approximately 80% of immunizations are delivered through outreach services.
- *Multiday outreach services*: In this case, the health worker would not return to their home base between outreach sessions, but would continue to the next outreach sites before returning home. This is clearly logistically more challenging, requiring lodging for the health worker and ability to maintain the vaccines in the cold chain throughout the outreach period.
- *Mobile teams*: These services would be provided in very sparsely populated areas, where the team would provide services in many places during the course of a day, moving from one vaccination post to the next.
- *Pulse vaccinations*: In this case, services are provided to far-flung areas requiring extensive and complicated logistical support (e.g., boats, helicopters, multiday walking excursions). Normally these would be done quarterly, half-yearly, or annually, as the resources required for this approach can be considerable.
- *Periodic intensification of routine immunizations)*: These are held on an ad hoc basis to catch-up routine vaccinations that have been missed, and are frequently combined with other appropriate preventive interventions, and may be promulgated as "Child Health Days" or the like.[199]

In addition to scheduled, routine vaccination doses, national immunization programs may try to reach the children left susceptible by inadequate routine vaccination services through supplementary immunization activities or vaccination campaigns. Whereas routine vaccination doses depend on the health worker making a decision to vaccinate each individual child that is seen by reviewing the previous vaccination history and eligibility for a dose, the doses given to children during supplementary immunization activities are given to every age-eligible child without contraindications

TABLE 76.5 Recommended Vaccination Schedule for All Immunization Programs Based on the World Health Organization's Vaccines Position Papers

Antigen	Type	Age of 1st Dose	Doses in Primary Series	Interval Between Doses			Booster Dose	Considerations (see footnotes for details)
				1st to 2nd	2nd to 3rd	3rd to 4th		
RECOMMENDATIONS FOR ALL CHILDREN								
BCG[1]		As soon as possible after birth	1					Exception: HIV
Hepatitis B[2]	Option 1	As soon as possible after birth (<24 h)	3	4 wk (min) with DTP1	4 wk (min) with DTP3			Premature and low birth weight; coadministration and combination vaccine; high-risk groups
	Option 2	As soon as possible after birth (<24 h)	4	4 wk (min) with DTP1	4 wk (min) with DTP2	4 wk (min),with DTP3		
Polio[3]	OPV + IPV	6 wk (see footnote for birth dose)	4 (IPV dose to be given with OPV dose from 14 wk)	4 wk (min) with DTP2	4 wk (min) with DTP3			OPV birth dose; transmission and importation risk criteria
	IPV/OPV Sequential	8 wk (IPV 1st)	1–2 IPV, 2 OPV	4–8 wk	4–8 wk	4–8 wk		
	IPV	8 wk	3	4–8 wk	4–8 wk		See WHO website footnote	IPV booster needed for early schedule (i.e., first dose given <8 wk)
DTP[4]		6 wk (min)	3	4 wk (min)-8 wk	4 wk (min)-8 wk		1–6 y of age (see WHO website footnote)	Delayed/interrupted schedule; combination vaccine
Haemophilus influenzae type b[5]	Option 1	6 wk (min)	3	4 wk (min) with DTP2	4 wk (min) with DTP3		See WHO website footnote	Single dose if >12 mo of age; not recommended for children >5 y; delayed/interrupted schedule; coadministration and combination vaccine
	Option 2	59 mo (max)	2–3	8 wk (min) if only 2 doses 4 wk (min) if 3 doses	4 wk (min) if 3 doses		At least 6 mo (min) after last dose	
Pneumococcal (conjugate)[6]	Option 1	6 wk (min)	3	4 wk (min)	4 wk		See WHO website footnote	Initiate before 6 mo of age; coadministration; HIV+ and preterm neonates booster
	Option 2	6 wk (min)	2	8 wk (min)			9–15 mo	
Rotavirus[7]	Rotarix	6 wk (min) with DTP1	2	4 wk (min) with DTP2				Not recommended if >24 mo old
	Rota Teq	6 wk (min) with DTP1	3	4 wk (min)–10 wk with DTP2	4 wk (min) with DTP3			
Measles[8]		9 or 12 mo (6 mo min, see WHO website footnote)	2	4 wk (min) (see footnote)				Combination vaccine; HIV early vaccination; pregnancy

Continued on following page

TABLE 76.5 Recommended Vaccination Schedule for All Immunization Programs Based on the World Health Organization's Vaccines Position Papers *(Continued)*

Antigen	Type	Age of 1st Dose	Doses in Primary Series	Interval Between Doses			Booster Dose	Considerations (see footnotes for details)
				1st to 2nd	2nd to 3rd	3rd to 4th		
Rubella[9]		9 or 12 mo with measles-containing vaccine	1					Achieve and sustain 80% coverage; combination vaccine and coadministration; pregnancy
HPV[10]		As soon as possible from 9 y of age (females only)	2	6 mo (min 5 mo)				Target girls age 9–13y ; pregnancy; older age ≥15 y = 3 doses; HIV and immunocompromised
RECOMMENDATIONS FOR CHILDREN RESIDING IN CERTAIN REGIONS								
Japanese encephalitis[11]	Inactivated Vero cell-derived vaccine	6 month	2 generally	4 wk (generally)				
	Live attenuated	8 mo	1					Vaccine options and manufacturer's recommendations; pregnancy; immunocompromised
	Live recombinant vaccine	9 mo	1					
Yellow fever[12]		9–12 mo with measles-containing vaccine	1					
Tickborne encephalitis[13]		≥1 y FSME-IMMUN and Encepur ≥3 y TBE-Moscow and EnceVir	3	1–3 mo FSME-IMMUN and Encepur 1–7 mo TBE-Moscow and EnceVir	5–12 mo FSME-IMMUN and Encepur 12 mo TBE-Moscow and EnceVir		At least 1 every 3 y (See WHO website footnote)	Definition of high-risk; vaccine options; timing of booster
RECOMMENDATIONS FOR CHILDREN IN SOME HIGH-RISK POPULATIONS								
Typhoid[14]	Vi PS	2 y (min)	1				Every 3 y	Definition of high risk
	Ty21a	Capsules 5 y (min) (see WHO website footnote)	3 or 4 (see footnote)	1 day	1 day	1 day	Every 3–7 y	Definition of high risk
