Among patients with meningococcal disease, 10% to 20% have severe sepsis or meningococcemia. Meningitis may be absent, but the organism is widely disseminated in the bloodstream and in multiple organs. Spreading purpura heralds signs and symptoms of septicemia with rapid onset of hypotension and signs of multiple organ failure, although not all patients with shock or hypotension have purpura. White blood cell counts may be very high, normal, or low, and a prominence of immature band forms is often present. At the time of autopsy, acute adrenal hemorrhage may be present (Waterhouse-Friderichsen syndrome).

Up to 15% of patients with meningococcal disease have pneumonia, which is most commonly associated with capsular group Y strains.[10] In the absence of a characteristic rash and bacteremia, the cause of the pneumonia may go unrecognized because the clinical microbiology laboratory may not report isolation of *N. meningitidis* from oropharyngeal secretions as it is considered normal flora. Less-common manifestations of meningococcal disease include myocarditis, endocarditis, or pericarditis; arthritis; conjunctivitis; urethritis; pharyngitis; and cervicitis. Late in the course of treated disease, arthritis or pericarditis may occur as a result of immune complex formation. The case fatality rate from severe meningococcemia can be as high as 40%. More commonly, the course of meningococcal disease is less fulminant.

Complications of Meningococcal Disease

Approximately 10% to 20% of patients who survive meningococcal disease have permanent sequelae. In a multicenter study of 146 children surviving meningococcal infection, one required amputation of toes or all four extremities; 14 developed skin necrosis (four required skin grafting); 14 developed bilateral ($n = 8$) or unilateral ($n = 6$) deafness; four developed ataxia; and three developed hemiplegia.[6] Patients with certain genetic polymorphisms have an increased risk of dying or developing permanent sequelae (see subsequent text).[11] Patients with meningococcal meningitis who do not develop septic shock are less likely to die or have these sequelae (<10%), but they are at risk of developing neurosensory hearing loss, mild to moderate cognitive deficits, or seizure disorders.[12–17] In a study of UK children who survived group B meningococcal disease, approximately 9% had major disabling sequelae as compared with 2% of matched control children.[17] The risk of neurologic complications with meningococcal meningitis is generally lower than that of patients with meningitis caused by *Haemophilus influenzae* type b (Hib) or *Streptococcus pneumoniae*.[18–20]

Bacteriology and Molecular Epidemiology

Weichselbaum was the first to culture meningococcus from patients with meningitis in 1887.[21] The organism is a Gram-negative, encapsulated, oxidase-positive, aerobic diplococcus that naturally infects only humans.[22] Meningococci are usually grown on heated blood agar or Mueller-Hinton media in an

atmosphere containing 5% to 10% carbon dioxide. Catlin-6 medium[23] and Frantz medium[24] also have been used as defined and partially defined liquid culture media, respectively. Thirteen serologically distinct meningococcal capsular groups were reported on the basis of the immunochemistry of the polysaccharide.[25,26] However, what had been designated as group D was recently found to be an unencapsulated variant of group C; therefore, there are 12 known meningococcal capsular groups: A, B, C, E (formerly known as 29E), H, I, K, L, W (formerly known as W-135), X, Y, and Z.[27] Organisms with capsular groups A, B, C, W, X, or Y are responsible for almost all cases of disease.[28]

For epidemiologic purposes, meningococci have been further classified into serotypes and serosubtypes on the basis of the immunological reactivity of the PorB and PorA outer membrane proteins, respectively.[29–33] The accepted nomenclature lists the capsular group, PorB serotype, and PorA serosubtype, each separated by a colon (e.g., B:4:P1.7,4). The VR1 (loop 2) and VR2 (loop 4) encoded epitopes of PorA are given in order after the prefix P1.x, separated from one another by a comma.[34,35] Although phenotyping reagents for capsular group, type, and subtype are available,[36] these are not comprehensive. PorA subtypes are further classified into variants that cannot be classified serologically and can be defined by VR1 and VR2 gene sequence typing.[37] Another outer membrane protein, FetA, an enterobactin receptor, is also used for typing.[38–40] Sequencing of the meningococcal factor H (fH) binding protein gene has also been shown to provide additional evolutionary[41,42] and genomic epidemiologic information about meningococcal strains.[43] Meningococci also can be divided into immunotypes on the basis of variation in the lipooligosaccharide structure.[44]

The meningococcus is naturally competent for transformation with DNA, which provides a mechanism for horizontal exchange of DNA.[45,46] As a consequence, the organism has a highly panmictic population structure[47] and exchanges genes encoding key antigens that are used in the serologic characterization of isolates and as vaccine components.[40,48–50] The facility to exchange genes that encode for capsule and outer membrane proteins has implications for vaccine escape by virulent clones.[40,51,52]

For analysis of genetic lineage of isolates, multilocus sequence typing (MLST) is a commonly used method. MLST capitalizes on nucleotide sequence analysis to index variation based on sequence polymorphisms in housekeeping genes.[53,54] Despite the capacity of *N. meningitidis* to acquire DNA through horizontal gene transfer, a relatively small number of MLST-defined genetic lineages cause most invasive meningococcal disease (IMD).[28] This paradox may be explained by the presence of restriction modification systems that present a differential barrier to horizontal gene transfer and lead to the observed population structuring.[55]

Whole genome sequencing is replacing traditional molecular methods for meningococcal strain characterization. One of the most notable features of the meningococcal genome is the large number of repetitive elements, presumed to contribute to genome fluidity, and more than 100 putative phase-variable genes.[56] These features make an important contribution to the antigenic variability and phenotypic adaptability of the organism.

Risk Factors for Disease and Carriage

The meningococcus colonizes only the pharynx of humans and has no other known environmental niche. The organism is usually a harmless commensal, and there are major differences in carriage rates by age, geography, and time.[57–61] Carriage rates are usually highest among adolescents and young adults.[62–65] Aerosol droplets or direct contact leads to transmission of the meningococcus from person-to-person through respiratory secretions and requires close contact, such as kissing. Viral respiratory infections,[66–69] exposure to tobacco smoke[70–72] or indoor firewood stoves,[73] bar or discothèque patronage, and binge drinking[71,74–77] are all associated with increased rates of meningococcal carriage or disease. There are a variety of plausible mechanisms for the association between these environmental and behavioral factors and meningococcal infection. Respiratory viruses and tobacco smoking cause alterations in the mucosal surface that enhance bacterial binding or decrease the ability of the host to clear the organism from the nasopharynx. Bar patronage and binge drinking could increase transmission through crowding, coughing caused by exposure to tobacco smoke, and other close contact. In the United Kingdom, being a university student,[78] a freshman living in a university residence hall,[79] and intimate kissing with multiple partners were associated with an increased risk of acquiring meningococcal carriage or disease. These data suggest that behavior, not age or gender per se, is the main determinant of meningococcal carriage in this population. However, children with a history of preterm birth[78] and patients with HIV infection are at increased risk of developing meningococcal disease, which demonstrates that comorbidities can affect risk of disease as well.[80,81,81a]

Pathogenesis

As mentioned above, most IMD is caused by bacteria from a limited number of hypervirulent lineages.[28,51] Carriage isolates, in contrast, belong to a broader group of lineages, many of which have been rarely associated with disease.[60,82] These observations indicate that certain meningococci are genetically predisposed to cause disease. In addition, IMD is, with rare exception, caused by encapsulated strains, whereas colonizing strains often do not express capsule, which underscores the importance of the meningococcal capsule as a virulence factor.[83,84]

Following attachment to pharyngeal mucosal cells, the organism replicates and establishes a carrier state. Pili seem to be the most important adhesin, and two opacity-associated proteins (Opa and Opc), lipooligosaccharide, and interbacterial interactions (via PilX) facilitate subsequent tight attachment.[85–87] Attachment to epithelial cells is mediated by specific receptors such as CD46[87] and carcinoembryonic antigen receptors.[88] Attachment initiates loss of piliation by the bacteria as well as cytoskeletal rearrangements in the host cell that result in internalization of the bacteria within membrane-bound vesicles by endocytosis.[85,89] Once the organism has established the carrier state, the likelihood of acquiring IMD depends on the virulence of the particular isolate, host factors affecting innate susceptibility,[11] and the presence or absence of serum bactericidal antibodies.[90] Once the organism enters the bloodstream, the spleen is involved in bacterial clearance. Because of impaired clearance, patients with asplenia or hyposplenic function may be at increased risk of severe meningococcal disease.[91]

The complement cascade is activated by serum antibodies via the classical pathway, which results in opsonization and bacteriolysis of meningococci. In the absence of specific antimeningococcal antibodies, these complement-mediated functions also can be activated by the alternative pathway.[92] Given the central role of complement proteins in host defenses against invasive *N. meningitidis* disease, persons with underlying deficiencies of properdin, C3, or the late complement components (C5 through C9) are at greatly increased risk of acquiring meningococcal disease.[93–100]

fH is an important downregulatory molecule in the alternative complement pathway cascade. fH binds specifically to *N. meningitidis* and enhances resistance of the organism to serum bactericidal activity (SBA).[101,102] Binding of fH, therefore, is a mechanism by which the organism can evade complement-mediated killing. Polymorphisms within the complement fH and complement fH-related protein 3 have been found in genome-wide studies to be associated with a lower risk of meningococcal disease.[103] Two vaccines that were recently licensed for prevention of meningococcal group B disease target a ligand on meningococci that binds fH to the bacterial surface (referred to as fH binding protein).

Meningococcal disease causes rapidly progressive cutaneous hemorrhage and skin necrosis, disseminated intravascular coagulation, and shock. Many factors contribute to overwhelming meningococcal disease, but the most important are the rapid doubling time of the bacteria and their propensity to release endotoxin-rich outer membrane vesicles (blebbing), which results in very high levels of endotoxin in the circulation and porin proteins and DNA.[104] These trigger various pattern recognition receptors expressed on monocytes and macrophages (see subsequent discussion), which results in proinflammatory cytokine release and activation of fibrinolytic and complement pathways. Endotoxin (lipooligosaccharide) is the most potent toxic molecule,[105] and levels of lipooligosaccharide in the circulation correlate directly with severity of clinical manifestations and case fatality rate.[106]

Host Genetic Factors

Activation of the complement cascade and binding of complement components to the surface of *N. meningitidis* are critical host defenses against developing IMD. Deficiency of proteins in the complement cascade, particularly components of the membrane attack complex, such as C5, C6, or C7, has long been recognized as an important risk factor for IMD. Complement deficiency was recognized in 0.3% of 297 patients with meningococcal disease in the United Kingdom.[107] Other smaller studies have found no complement-deficient patients and in one population-based study, three (19%) of just 16 patients with meningococcal disease had a low complement 50 level (CH_{50}).[108–110] In another study, complement-deficient persons had a more than 1000-fold higher lifetime risk of developing IMD than the general population.[111] Complement deficiency is more common (30% or more) among individuals with disease caused by less-common capsular groups (X, Y, Z, W, 29E).[95,112] In addition, the complement-deficient patients frequently had recurrent episodes of IMD as teenagers or adults, and their disease was often caused by strains with capsular groups that rarely cause disease in the general population. Accordingly, complement deficiency should be considered in patients with recurrent meningococcal disease and patients with disease caused by strains with less-common capsular groups. Deficiencies in serum levels of C3 or C4, properdin, or alternative complement pathway activation from factor D deficiency are also associated with increased risk of IMD.[99,113] Mannose-binding lectin (MBL)[114–117] is a constituent of serum that binds to meningococci and activates the complement cascade.[111] Although there are conflicting data,[78] persons with low serum concentrations of MBL[113] or MBL polymorphisms associated with diminished function[115] are reported to be at increased risk of IMD.[118,119] Because the prevalence of polymorphisms of MBL is much greater in the general population than complement deficiencies, these structural variants of MBL may have an important role in overall susceptibility to meningococcal disease in the population, particularly in children and adolescents who have not yet acquired serum bactericidal antibodies.

Toll-like receptors (TLRs) are components of the innate immune system with specificity for different microbial molecules. TLR4 binds bacterial lipopolysaccharide and is responsible for innate host response to Gram-negative infections. Heterozygous missense mutations of TLR4 have been reported to be more frequent in patients with meningococcal disease than in the general population.[120]

A variety of other genetic polymorphisms are reported to increase the severity of meningococcal disease without affecting the risk of acquiring meningococcal disease.[11] These include a receptor on neutrophils for immunoglobulin (Ig) G_2 or IgG_3, termed Fcγ receptor IIA (FcγRIIA), which affects the ability of the phagocytic cell to clear opsonized bacteria from the bloodstream.[121–123] Several studies found an association between the FcγRIIA-R131 polymorphism, which binds IgG2 poorly, and an increased risk of severe forms of meningococcal disease.[121–125] Polymorphisms of the interleukin-1 gene family,[126] genotypes associated with high expression of interleukin-10[127] or with altered production of tumor necrosis factor-α,[127,128] and the presence of a specific allele of the angiotensin-converting enzyme are reported to increase the risk of severe meningococcal disease.[129] While most of these associations were identified in small sample sets and require independent confirmation, the accumulating data support a genetic component of altered host responses in otherwise healthy persons that underlies the disparities in clinical outcomes of persons exposed to meningococci. As mentioned above, mutations related to complement fH are associated with a lower risk of meningococcal disease.[103]

DIAGNOSIS

Confirmation of meningococcal disease is usually achieved through conventional cultures of blood, cerebrospinal fluid (CSF), or other infected sites. Gram staining to demonstrate the characteristic Gram-negative diplococcus also can be used for diagnosis. Latex agglutination testing for detection of meningococcal capsular polysaccharides in serum or CSF commonly leads to false-negative results.

A polymerase chain reaction (PCR) assay that detects meningococcal DNA in normally sterile body fluids can be used to establish the diagnosis and is particularly useful in the setting of negative cultures because of previous antibiotic use.[130] Capsular group-specific PCR assays are available to discriminate among capsular groups A, B, C, W, X, Y, Z, and 29E.[131–133]

In Europe, a substantial proportion of meningococcal cases are detected using PCR, as opposed to the United States where PCR is less commonly used. In the United Kingdom, for example, 55% of all cases were diagnosed based on positive PCR.[134,135] Using PCR for diagnosis of meningococcal disease has dual benefits: it provides a more accurate picture of disease burden and establishes the diagnosis in a greater proportion of cases.

TREATMENT AND PREVENTION

Antibiotics

Although many antimicrobial agents are effective for management of meningococcal disease, intravenous aqueous penicillin was traditionally considered the therapy of choice once meningococcal disease is confirmed. Although the clinical importance is unknown, some meningococcal isolates from the United States have intermediate susceptibility to penicillin (minimum inhibitory concentration: 0.1–1.0 μg/mL).[9,136]

In Belgium during 2011–2012, the frequency of clinical isolates with decreased susceptibility to penicillin increased; however, there was no resistance to expanded-spectrum cephalosporins, such as ceftriaxone.[137] Among 466 meningococcal isolates from the 10 Active Bacterial Core surveillance sites in the United States from 2004, 2008, 2010, and 2011, 10.3% had intermediate susceptibility to penicillin, 0.6% (three isolates) were resistant to penicillin, and all were susceptible to ceftriaxone.[138] The uncertainty about the clinical significance of intermediate susceptibility to penicillin, the more convenient dosing schedule, and the availability of generic ceftriaxone make it a reasonable option for therapy of meningococcal disease, even after the diagnosis has been established. In fact, pencillin is uncommonly used in the United States and ceftriaxone is the recommended antimicrobial agent for treatment of meningococcal disease in the United Kingdom.[138a] Early initiation of antibiotic therapy and attention to circulatory status in patients suspected of having meningococcal infection may help decrease morbidity and mortality.[139,140] Because the clinical features of meningococcal disease can overlap those of bacterial meningitis or sepsis caused by other bacterial pathogens, depending on the age of the patient, clinical manifestations, exposure history, the results of Gram stains of CSF or petechial hemorrhages, and the presence or absence of other epidemiologic risk factors, broader initial empirical therapy is standard before the diagnosis is confirmed.[9] Antibiotic treatment for 5 to 7 days is adequate therapy for most systemic meningococcal illnesses. In resource-poor settings, single-dose intramuscular chloramphenicol in oil or ceftriaxone has been effectively used.[141]

Other Therapies

Patients with purpura fulminans have the highest case fatality rates (as high as 50%). This syndrome is a result of a massive release of proinflammatory mediators[142] and development of shock and disseminated intravascular coagulation from a procoagulant state with local accumulation of thrombi in small and large arterial vessels.

One therapy for severe systemic meningococcal infection focused on activated protein C, an endogenous anticoagulant that suppresses excessive thrombosis and fibrin formation.[143,144] Although recombinant human activated protein C (drotrecogin alfa [activated]) was licensed based on a clinical trial, additional studies failed to show a survival benefit and the drug was withdrawn from the market.[144–147]

Dexamethasone therapy for 4 days, with the first dose given before the initiation of antibiotic therapy, is reported to decrease the rate of neurosensory deafness in patients with meningitis caused by Hib. In a randomized controlled trial in adults with bacterial meningitis, dexamethasone use also was associated with decreased mortality. A statistically significant benefit was seen only in patients with pneumococcal meningitis, but the study was not sufficiently powered to demonstrate efficacy for other pathogens.[148] High doses of corticosteroids have been demonstrated not to be beneficial in septic shock. Although low-dose corticosteroids are often administered,[149,150] a randomized, controlled study in patients with septic shock (Corticosteroid Therapy of Septic Shock [CORTICUS] trial) failed to demonstrate a benefit in overall 28-day mortality rate (33% for hydrocortisone recipients vs 31% for placebo recipients). Although the duration of shock was shorter in patients who received corticosteroids, adverse events, including new episodes of sepsis and septic shock, were more frequent in the hydrocortisone group. Sprung and colleagues concluded that for the majority of patients with septic shock, the potential advantages of corticosteroids do not outweigh the adverse risks.[151]

Chemoprophylaxis

Close contacts of a patient with meningococcal disease are at greatly increased risk of developing disease. The risk is greatest in household contacts and other close contacts exposed to oral secretions and in coattendees at child daycare. The risk of transmission to healthcare workers is low, but persons performing mouth-to-mouth resuscitation and unprotected healthcare workers exposed during management of endotracheal tubes are at increased risk.[152] Numerous cases of meningococcal disease among microbiology laboratory workers, primarily those who processed liquid cultures on an open bench, also have been reported.[153–155] In one report of 16 probable laboratory-acquired cases, 50% were fatal.[154] Rifampin, ceftriaxone, and ciprofloxacin eradicate nasopharyngeal *N. meningitidis* colonization, and these agents are recommended for chemoprophylaxis of close contacts.[5] Fluoroquinolone-resistant isolates were reported in 2008 in North Dakota and Minnesota, which prompted the Centers for Disease Control and Prevention (CDC) to recommend ceftriaxone, rifampin, or azithromycin for eradication of meningococcal carriage in areas where resistance has been identified.[156,157]

Chemoprophylaxis should be offered to household members and to other persons with a history of prolonged close contact. Prophylaxis of child daycare contacts and staff is recommended in the United States[5] but not in the United Kingdom.[158] Because the risk of disease in contacts is highest in the first week after onset of disease in the index patient, prophylaxis should be administered to contacts as soon as feasible, preferably within 24 hours of identification of the index patient.[267] Because penicillin therapy does not reliably eradicate nasopharyngeal colonization, additional antimicrobial treatment is recommended at the time of hospital discharge for eradication of colonization in patients treated exclusively with penicillin. Contacts who were previously immunized with meningococcal vaccines should still be considered for chemoprophylaxis because primary vaccine failure or lack of serum antibody persistence, or both, may render vaccinated persons susceptible to disease.

Chemoprophylaxis given to large populations in response to outbreaks of meningococcal disease may be of limited effectiveness in lowering the risk of disease, particularly as a standalone measure, and increases the likelihood of emergence of antimicrobial resistance. In small school-based outbreaks, chemoprophylaxis to all people within the population may be considered. Settings in which mass chemoprophylaxis may be of some benefit include relatively small populations that have limited mixing with outside populations and in which high antibiotic coverage can rapidly be achieved. If undertaken, the antbiotic should be administered to all persons at the same time.

EPIDEMIOLOGY

Incidence and Public Health Burden

Although meningococcal disease is a global problem that occurs in all countries,[28] the true burden of disease is unknown for many parts of the world because of inadequate surveillance.[159–161] The epidemiology is highly variable, dynamic, and fluid and is influenced by natural variation and immunization policy. In addition, the epidemiology varies substantially by capsular group. Group A meningococcus was historically remarkable for its ability to cause large epidemics.[3] Since World War II, epidemic meningococcal disease caused by group A organisms largely has been confined to developing countries, most often reported from the meningitis belt of sub-Saharan Africa. In this region, with recent widespread use

of a low-cost meningococcal A conjugate vaccine (see below), group A epidemics have largely been prevented.[162] Capsular group X and W strains now also cause substantial rates of disease in Africa. Group C disease, which in the past has rarely caused outbreaks in sub-Saharan Africa, has emerged in Nigeria and Niger.[163–166]

In the 1960s and 1970s, high rates of capsular group A disease were reported in China, Mongolia, and Nepal. As recently as 2005, group A epidemics were reported in India, and a meningococcal capsular group A outbreak occurred in the Philippines in 2004 and 2005, with 98 cases (33% mortality) reported to the World Health Organization (WHO).[167]

In Europe, most cases of meningococcal disease are sporadic and currently caused by capsular group B and C strains. However, some countries in Europe have experienced an increase in disease caused by group Y and W strains. During 2007–09, the proportion of invasive meningococcal cases caused by group Y strains in England and Wales increased from 3% to 6%, which was higher than in the previous three decades.[168] Nearly 40% of patients had underlying medical conditions. A high proportion of patients 65 years of age and older had pneumonia. Strains belonging to the ST-23 clonal complex were responsible for most of the increase. Other Eurpean countries have also reported increases in group Y disease.[169] The burden of endemic meningococcal disease varies substantially among countries and has declined dramatically in countries that introduced group C meningococcal conjugate vaccines. Using culture-confirmed cases, countries with the highest reported incidence rates per 100,000 population in 2012 were Lithuania (1.8), the United Kingdom (1.4 cases), and Ireland (1.3).[170] The capsular group distribution was group B (68% of cases), group C (17%), group Y (8%), and group W (4%).

Although a relatively small proportion of meningococcal disease in Europe is caused by group W, since 2009 the United Kingdom has experienced a rapid increase in group W disease, from 1.8% of cases in 2008–09 to 15% of cases 2013–14.[171,172] The increase was a result of clonal expansion of an ST-11 clonal complex strain. Analysis of whole-genome sequencing data indicated that the strain was not a descendent of the Hajj clone but more related to ST-11 group W strains that had been circulating pre-Hajj.[52,173] This observation is in contrast to a brief increase in group W disease that occurred in the early 2000s from the Hajj clone.[52] As a result of the increase and as discussed further below, a quadrivalent MenACWY immunization campaign for 14- to 18-year-olds was initiated in the United Kingdom in August 2015.[174]

Fig. 38.1 shows the annual incidence of meningococcal disease in the United States between 1984 and 2014.[175] The annual incidence of meningococcal disease since 2000 has been remarkably low, with an incidence in 2013 of 0.14 per 100,000.[176,177] The reasons for the decrease are not known but are likely multifactorial and include decreases in active and passive tobacco smoking, changing patterns of antibiotic use, increased use of influenza vaccines, declines in meningococcal carriage, and lack of novel antigenic variants among virulent strains to which the population does not have immunity.[178] A study from Maryland found that increases in capsular group C and Y disease incidence during the 1990s were associated with antigenic shifts involving key meningococcal outer membrane proteins.[40] Capsular switching from one meningococcal capsular group is also associated with emergence of meningococcal disease globally.[52] Meningococcal disease epidemiology is naturally cyclical; how the incidence will change in the future is unknown.

The age-specific incidence of meningococcal disease results from an interplay between the degree of immunity in the population and virulence of circulating strains. Disease

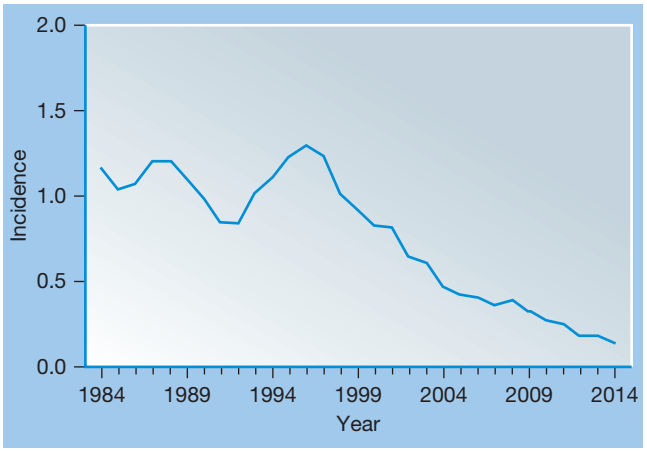

Figure 38.1. Incidence of meningococcal disease, 1982–2012. *(From Adams DA, Thomas KR, Jajosky RA, et al. Summary of notifiable diseases—United States, 2014.* MMWR Morb Mortal Wkly Rep. *2016;63:1–152.)*

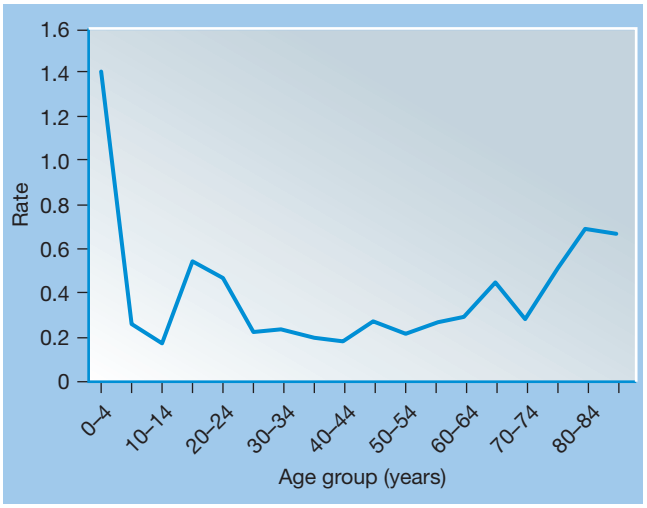

Figure 38.2. Rate per 100,000 of meningococcal disease, by age group, in the United States, 2002–2011. *(Cohn AC, MacNeil JR, Clark TA, et al, Centers for Disease Control and Prevention. Prevention and control of meningococcal disease: recommendations of the Advisory Committee on Immunization Practices [ACIP].* MMWR Recomm Rep. *2013;62:1–28.)*

incidence is highest among infants who have not yet acquired natural immunity. In the European Union, the reported rate of meningococcal disease (primarily group B) during 2012 among children younger than 1 year of age and between 1 and 4 years of age were 11.4 and 3.7 cases per 100,000 population, respectively.[170] During the same period, the incidence in the United States was much lower, 1.86, 0.41, and 0.20 among children younger than 1 year of age, children 1 year of age, and children 2 to 4 years of age per 100,000 population, respectively.[179] In the United States and Europe, there were peaks in incidence among adolescents and young adults, which have diminished over time (representative data for the United States is shown in Fig. 38.2).[5]

In temperate climates, rates of meningococcal infections are highest during the winter months. This association may be a result of closer personal contact during the winter months, lack of ventilation, or an increase in upper respiratory infections, all factors that facilitate transmission of or invasion by the organism, or both.

Meningococcal Capsular Group A Disease

Until recently, Group A strains of *N. meningitidis* were the major cause of epidemic and endemic meningococcal disease in the meningitis belt of sub-Saharan Africa, which extends from Senegal on the west coast to Eritrea on the east coast (Fig. 38.3).[28,180] These strains rarely cause disease in the United States[177,181] or in Europe.[170] A notable recent exception is Russia, where group A isolates were reported to account for the majority of isolates in Moscow as recently as 2010.[182–184]

The annual incidence of disease during group A epidemics in sub-Saharan Africa can exceed 1000 per 100,000 population, or 3000-fold higher than the current incidence of meningococcal disease in the United States. The case fatality rate during group A epidemics in Africa historically varied between 10% and 15%.[3] With the recent introduction of a monovalent group A conjugate vaccine, the incidence of group A disease in the meningitis belt has dramatically declined and substantial proportion of disease is now caused by groups W, X, and, more recently C.[163,164] Why disease caused by strains with these capsular groups has increased in the sub-Saharan region and why epidemics begin there with the dry season (generally November or December) and terminate abruptly with the onset of increased humidity and rain (generally June and July) is unknown. Most likely, environmental, host, and microbial factors in combination play a role.[185]

Meningococcal Capsular Group B Disease

See Chapter 39.

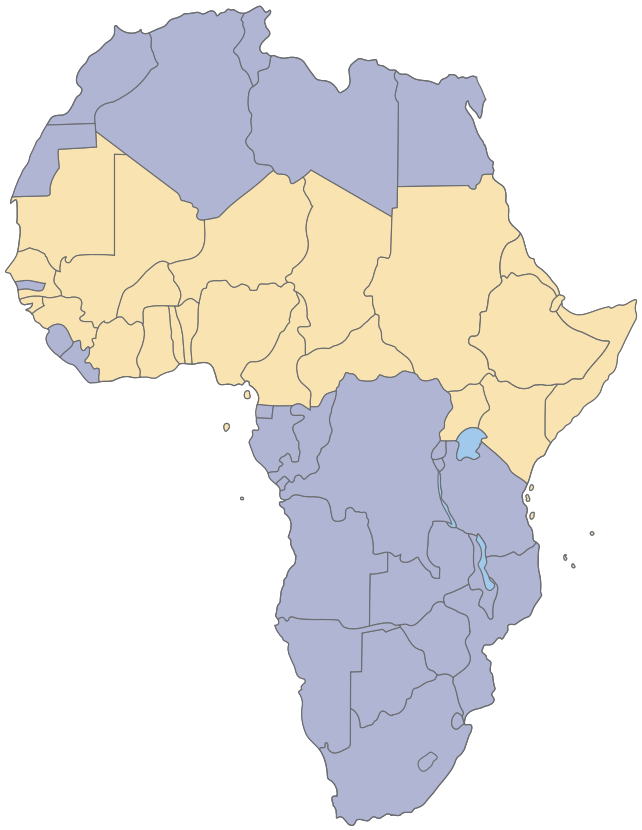

Figure 38.3. Sub-Saharan African meningitis belt. Countries shown in yellow experience explosive epidemics of meningococcal disease every 5 to 10 years that are usually caused by capsular group A strains. *(Courtesy the World Health Organization.)*

Meningococcal Capsular Group C Disease

Group C strains are a major cause of disease in many parts of the world, including North America, South America, Europe, and Australia, with the proportion of group C isolates varying by country. However, group C disease has declined substantially in countries that have introduced meningococcal conjugate vaccines into routine immunization schedules. For example, Canada, Australia, the United Kingdom, The Netherlands, and many other countries in Europe have experienced decreases in group C disease since the introduction of monovalent group C conjugate vaccines.[186–191] In 2012, 17% of disease in Europe was caused by group C strains, with 68% being caused by group B strains. More recently, group C conjugate vaccine was introduced into the routine pediatric immunization schedule in Brazil, with subsequent decreases in the incidence of group C disease.[192,193] In the United States, in part because of use of quadrivalent conjugate vaccines in adolescents, the incidence of disease in 2012–2013 caused by group C, in addition to groups W and Y, was only 0.05 per 100,000 population in persons 11 to 19 years old.[194] However, in 2013 group C strains still accounted for approximately 30% of all meningococcal disease in the United States.[195]

Group C meningococcus has periodically caused disease in the African meningitis belt but has not typically been a major cause of disease in this region. However, recent epidemics of group C disease have occurred in Niger and Nigeria.[163,164] Outbreaks of group C meningococcal disease have also been reported among men who have sex with men in the United States and Europe.[196–202a]

Meningococcal Capsular Group Y Disease

Group Y strains cause all the major meningococcal clinical syndromes, but patients with group Y disease are more likely to have pneumonia than patients with disease caused by strains with other capsular groups.[168,203,204] In the United States, the incidence of group Y disease increased substantially in the 1990s and by 1996 accounted for 33% of isolates.[205,206] In 2013, approximately 15% of IMD in the United States was caused by group Y strains.[195] Group Y strains have also been reported as a cause of a substantial proportion of disease in Colombia, parts of Canada,[207,208] South Africa,[209] Sweden,[210] and other European countries.[211] For reasons that remain unexplained, disease caused by group Y strains remains relatively rare in most other parts of the world despite observations that group Y strains are common causes of pharyngeal colonization.[59,64,212–214]

Meningococcal Capsular Group W Disease

In 2012, the nomenclature for what was previously referred to as group W135 was simplified to group W.[27] Until 2000, group W strains were a relatively uncommon cause of invasive disease worldwide and had not been known to cause outbreaks. That changed in 2000 and 2001, when outbreaks of group W disease occurred among Hajj pilgrims in Mecca, Saudia Arabia, where several million pilgrims from all the world gather each year in crowded conditions.[215–218] A group W clone belonging to the ST-11 complex caused the outbreak. ST-11 complex isolates typically expresss group C polysaccharide, which suggested that a group C to group W capsular switch had occurred at some point.[52,219] Group W strains belonging to the ST-11 complex were also isolated from patients with meningococcal disease in other African countries and globally.[220–223] In 2002, Burkina Faso reported more than 10,000 cases caused by group W isolates.[224,225] A study of a global collection of group W isolates dating from 1970 to 2013

using whole-genome sequencing suggested that the vast majority of ST-11 complex group W isolates arose from an ancestral strain that had undergone horizontal gene transfer events in the capsular operon.[219] By 2000, another series of horizontal gene transfer events involving, for example, fH binding protein, led to a strain that caused the Hajj outbreak and subsequent disease globally. W ST-11 strains unrelated to the Hajj outbreak contribute a significant proportion of W ST-11 cases globally.[52]

Group W strains now cause a substantial proportion of meningococcal disease in the African meningitis belt. For example, 81% of meningococcal cases in 2014 were caused by group W strains.[226] The recent emergence of non–group A strains in the meningitis belt comes in the face of the success of the monovalent group A meningococcal conjugate vaccine, which underscores the need for multivalent meningococcal vaccines for the meningitis belt.

An increase in disease caused by group W strains has also been reported from Argentina[227] and southern Brazil.[228] For example, the proportion of meningococcal cases caused by group W strains among children in Argentina increased from 7% in 2006 to 28% in 2008.[229] The proportion of cases caused by group W strains in the United Kingdom has increased, with 15% of cases being caused by group W during 2013–2014.[171]

Although an outbreak of 14 cases of group W meningococcal disease occurred in Florida between 2008 and 2009,[230] group W disease remains an infrequent cause of disease in the United States: for the period 2006–10, 3% of meningococcal infections in the United States were caused by group W strains.[181]

MENINGOCOCCAL IMMUNITY

Natural Acquisition of Humoral Immunity

Serum antibodies confer protection against meningococcal disease by activating complement-mediated bacteriolysis and, possibly, by enhancing phagocytosis (opsonic activity).[231] Naturally acquired serum antibodies are elicited by asymptomatic pharyngeal carriage of pathogenic and nonpathogenic meningococci,[232–234] or *Neisseria lactamica*.[62,235–237] Anticapsular antibodies stimulated by gastrointestinal colonization with *Escherichia coli* or *Bacillus pumilus* strains with cross-reacting polysaccharides also may contribute.[238–240]

Considerable data indicate that persons with SBA are protected from developing meningococcal disease (see below).[241]

Passive Immunization

Antibodies administered to infant rats passively conferred protection against meningococcal bacteremia.[242–252] However, studies of the ability of passive immunization to confer protection against bacteremia in infant rats likely overestimate protective activity because binding of certain complement downregulating proteins, such as fH, to *N. meningitidis* is specific for human fH (see below).

Immunity Following Active Immunization

Methods Used to Measure Vaccine Immunogenicity and Memory

Serum Antibody. Antigen-binding assays have been used to assess meningococcal vaccine immunogenicity.[253,254] Some investigations have suggested that an anticapsular antibody concentration of 2 µg/mL or greater is sufficient to confer protection against meningococcal disease.[255,256] The results, however, of antigen binding assays such as enzyme-linked immunosorbent assay do not consistently distinguish between bactericidal and nonbactericidal anticapsular antibodies.[243,244,254,257–259] Therefore, serologic assessments of meningococcal vaccine immunogenicity rely on measurements of complement-mediated SBA. In this assay, the test serum is heated to inactivate endogenous complement. Dilutions of the test serum are incubated for 60 minutes with the bacteria and a source of exogenous complement. The results are expressed as the dilution of serum giving 50% bacterial killing. The seminal study by Goldschneider and colleagues,[90] which demonstrated a correlation between naturally acquired SBA and protection against developing meningococcal disease, used endogenous complement (a fixed dilution of the human test serum that had been obtained to preserve endogenous complement and that had not been heated). For many years, infant rabbit serum was used as an exogenous source of complement for testing vaccine-induced bactericidal activity because of the difficulty of finding normal human serum without antibody that is suitable as a complement source for the assay.[258,260] Titers measured with rabbit complement are much higher than with human complement.[261] One reason is the presence of downregulatory complement proteins in human serum, such as fH, which demonstrate species specificity in binding to the bacteria.[101,102] In the absence of fH binding, the meningococcus is more susceptible to complement-mediated bactericidal activity.

Immunologic B-Cell Memory. Unconjugated polysaccharides elicit serum antibody responses largely without T-cell help (so-called T-cell–independent antigens).[262,263] Conjugation of a polysaccharide to a carrier protein confers T-cell–dependent properties to the polysaccharide. The immunologic hallmark of polysaccharide-protein conjugate vaccines is their ability to induce memory B cells capable of responding with a booster antibody response to a subsequent exposure to the polysaccharide. In practice, measuring serum antibody responses to an unconjugated polysaccharide vaccine "probe," following prior immunization with a conjugate, assesses induction of immunologic memory by the conjugate vaccine. Typically a reduced dose of the polysaccharide vaccine is used (as low as 1 µg),[264] based on the theory that a suboptimal immunogenic dose may be more useful for distinguishing memory antibody responses from antibody responses in subjects not primed by the conjugate vaccine.

The ability of a conjugate vaccine to prime for memory antibody responses on subsequently encountering meningococci was thought to be an important second mechanism of protection from developing disease in persons whose serum antibody concentrations had declined to subprotective levels.[265] However, persistence of functional antibody is now considered to be the most important determinant of MenC conjugate vaccine effectiveness, which casts doubt on the ability of memory antibody responses alone to protect against meningococcal group C disease.[266] The inability of memory antibody responses alone to confer protection is because it takes a minimum of 5 to 7 days to elicit a serum group C memory antibody response[264] and most IMD occurs within a few days after exposure to the organism.[90,267,268]

Induction of B-cell memory, therefore, has limited value as a potential mechanism of protection. In addition, the administration of test doses of unconjugated polysaccharide vaccine to assess memory antibody responses may be harmful by depleting antigen-specific memory B cells and impairing subsequent antibody responses.[269]

Induction of memory B cells is accompanied by avidity maturation, which reflects the effects of T cells on B-cell somatic mutation of antibody variable region genes. Memory

TABLE 38.1 Antibody Avidity in Relation to Age and Vaccine[a]

Vaccine	Age Group	Mean Avidity Constant (nM^{-1}) ± 2 SE		
		Pre	1 Mo Post	6 Mo Post
GROUP C ANTIBODY				
MPSV4	Adults	15 ± 3	26 ± 4	ND
MPSV4	3 y	ND	16 ± 2	17 ± 2
MCV4-DT	2 y	ND	22 ± 3	28 ± 3
GROUP W135 ANTIBODY				
MPSV4	3 y	ND	23 ± 2	21 ± 2
MCV4-DT	2 y	ND	27 ± 3	31 ± 4

[a]Vaccines: MPSV4, a quadrivalent meningococcal polysaccharide vaccine; MCV4-DT, a quadrivalent meningococcal conjugate vaccine with each of the four polysaccharides independently conjugated with diphtheria toxoid (see Table 38.3). At 1 and 6 months postvaccination, the mean antibody avidity is higher in the MCV4-DT group than in the MPSV4 group ($P = .002$ for capsular group C; $P < .02$ for capsular group W135). The increase in mean avidity between 1 and 6 months is statistically significant for the MCV4-DT group ($P < .001$ for group C, and $P < .05$ for W135) but not for the MPSV4 group.

ND, not done.

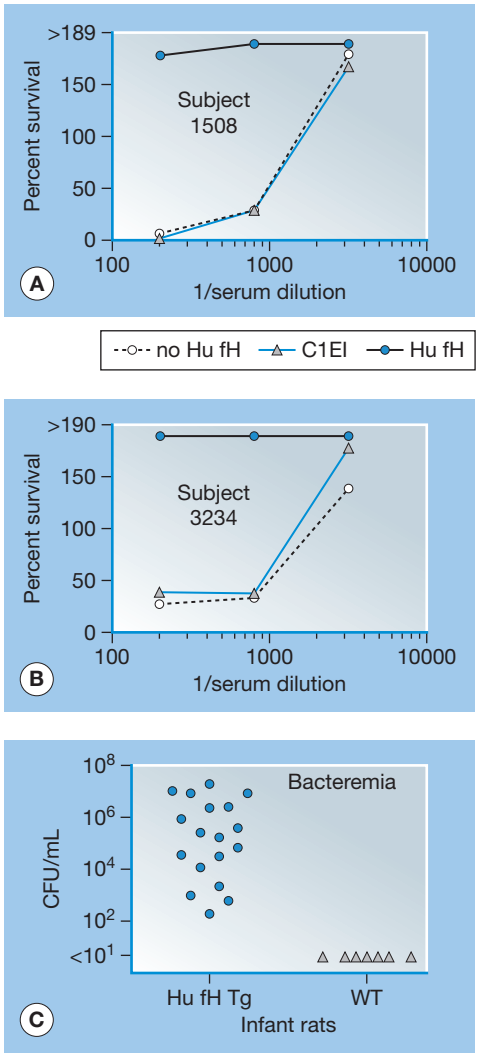

Figure 38.4. Effect of the addition of human factor H (fH) on survival of *Neisseria meningitidis*. A and **B,** Survival of group C strain 4242 when incubated with rabbit complement and dilutions of serum samples from children immunized with meningococcal polysaccharide vaccine. Open circles, no added human fH; triangles, addition of a negative control complement protein, C1 esterase inhibitor, 25 µg/mL; filled circles, addition of human fH (25 µg/mL).[277] **C,** Bacteremia 18 hours after intraperitoneal challenge of infant rats with group B strain H44/76 (≈1000 colony-forming units [CFU]/rat). Circles, human fH transgenic (Hu fH Tg) rats with serum human fH concentrations of 100–500 µg/mL; triangles, wild-type (WT) control littermates (human fH <12 µg/mL). *(Modified from Vu DM, Shaughnessy J, Lewis LA, et al. Enhanced bacteremia in human factor H transgenic rats infected by Neisseria meningitidis.* Infect Immun. *2012;80:643–650.)*

B-cell clones with mutated antibody combining sites have increased antibody avidity compared with antibodies elicited by primary immunization. Table 38.1 provides an example of avidity maturation of group C and W anticapsular antibodies in vaccinated children. During the 6 months of follow-up, a significant increase in avidity of the anticapsular antibodies was elicited by a dose of the meningococcal conjugate vaccine but not by a dose of the unconjugated polysaccharide vaccine. Thus, instead of administering a polysaccharide probe to assess induction of antigen-specific B-cell memory, it may be possible to use avidity as a correlate.[270–272] Other correlates include demonstration of booster antibody responses to a second injection of the conjugate vaccine (as demonstrated for groups C, Y, and W after quadrivalent meningococcal conjugate vaccination of adolescents; see later discussion)[273] and detection of antigen-specific peripheral blood memory B-cell responses after vaccination.[274,275] None of these approaches risks induction of antibody hyporesponsiveness or loss of immunologic memory that can accompany group C and, possibly, Y and W polysaccharide challenges.

Correlates of Protection. Since the first observations at the turn of the 20th century that some meningococci are serum sensitive while others are serum resistant, and that serum from some individuals has more bactericidal activity than serum from others,[276] it has become accepted that immunity to meningococci can be described by the titer of serum required to kill *N. meningitidis* in vitro. Epidemiological cohort studies[90] and vaccine evaluation studies[260] provide support for the routine use of a serum bactericidal assay as a correlate of protection. In the widely used assays, survival of meningococci following incubation in the presence of heat-inactivated test serum and an exogenous complement source (usually human or rabbit) is determined.

Fig. 38.4A and B show the percent survival of a group C strain incubated with rabbit complement and different dilutions of test serum obtained 1 month after immunization of two children with meningococcal polysaccharide vaccine. In the absence of added human fH, the bacteria were killed by rabbit complement and antibody at a serum dilution of approximately 1:800 (<50% survival after incubation for 1 hour compared with colony-forming units at time 0). The addition of 25 µg/mL of human fH eliminated the killing by binding to the bacteria and downregulating complement activation.[277] The addition of a negative control complement protein (C1 esterase inhibitor) had no effect on bacterial survival. Wild-type infant rats whose natural fH does not bind to

N. meningitidis are naturally relatively resistant to disease caused by many pathogenic group B *N. meningitidis* strains. After treatment with human fH, the rats became susceptible.[277] Human fH transgenic infant rats also are highly susceptible to meningococcal bacteremia, whereas control wild-type littermates whose rat fH does not bind to meningococci cleared the bacteremia (Fig. 38.4C). Collectively, these data illustrate one mechanism by which the meningococcus has uniquely adapted to cause disease in humans.

For meningococcal group B strains, there is consensus that only human complement bactericidal assays are reliable for predicting protection against disease.[241] As of 2012, rabbit complement assays were still used in Europe for licensure of new polysaccharide-protein conjugate vaccines against capsular group A, C, Y, or W strains[278,279] and were the basis of inferring efficacy for licensure in India of a new group A conjugate vaccine intended for Africa (see subsequent discussion). For group C strains, bactericidal titers as high as 1 : 128 using rabbit complement are needed to ensure that a titer of 1 : 4 is present if measured with human complement.[261] Using estimates of age-specific vaccine effectiveness from the United Kingdom, a titer of 1 : 8 or greater measured with rabbit complement has been suggested as the putative protective threshold following capsular group C conjugate vaccination.[265,280] A titer of 1 : 128 measured with rabbit complement was the basis of inferring efficacy for U.S. licensure of a quadrivalent meningococcal polysaccharide conjugate vaccine for adolescents (MCV4-DT; see subsequent discussion). Because meningococci cause disease only in humans and because of the exquisite human species specificity of binding complement–downregulating molecules by *N. meningitidis* and the corresponding uncertainty in inferring vaccine efficacy from bactericidal titers measured with rabbit complement, the U.S. Food and Drug Administration (FDA) requires bactericidal data from assays using human complement to support licensure of new meningococcal conjugate vaccines intended for infants and children.

History of Meningococcal Vaccine Development

Vaccines offering protection against meningococcal disease were first introduced into routine use in the military more than 40 years ago. Early attempts to develop meningococcal vaccines used killed whole bacterial cells.[281–283] Between 1900 and 1940, several trials were conducted, but the studies were poorly controlled, and, in most cases, it was impossible to tell whether the vaccines conferred protective immunity.[284] Pursuit of a whole-cell vaccine was curtailed by the excessive reactogenicity of such preparations. Following the successful development of tetanus and diphtheria toxoid vaccines in the 1930s, the protective potential of crude meningococcal culture filtrates containing inactivated exotoxin was explored.[285,286] These preparations were immunogenic, but they were certainly contaminated with capsular polysaccharide antigens, outer membranes, and endotoxin. Enthusiasm for development of meningococcal vaccines waned with the early successes with antibiotic treatment and prevention of secondary cases. By the early 1960s, sulfonamide-resistant isolates of *N. meningitidis* were widespread and represented an important problem among military recruits during the Vietnam War era, which promoted renewed interest in meningococcal vaccine development.[287,288]

During the early 1940s, Scherp and Rake demonstrated that serum from horses immunized with group-specific capsular polysaccharides protected mice against lethal challenge with *N. meningitidis*,[289] but purified preparations of capsular polysaccharide had failed to elicit antibody responses in humans.[290,291] The poor immunogenicity was subsequently attributed to the relatively low molecular size of the polysaccharide formulation tested, as studies showed that polysaccharide antigens of high molecular weight induced sufficient antibody responses in humans.[292,293] By the end of the 1960s, Gotschlich and colleagues had developed an alternative approach for the purification of high-molecular-weight meningococcal polysaccharides that was safe and immunogenic.[294,295] The principal limitation of polysaccharide vaccines is that they do not induce T-cell–dependent immunity. The lack of T-cell immunity has profound implications for the lack of immunogenicity of these vaccines in young children and the inability of polysaccharide vaccines to elicit long-term immunologic memory.[264,296,297] The chemical conjugation of polysaccharides to protein carrier molecules confers a T-cell–dependent immune response.[298] The success of this approach was first demonstrated in humans with Hib vaccines in the 1980s.[299–301] Subsequently, similar conjugate vaccines were investigated for the meningococcus for group A (*N*-acetyl mannosamine-1-phosphate) and group C (alpha 2–9 *N*-acetyl neuraminic acid [NANA]) polysaccharides,[302] group C polysaccharide,[303–306] and groups A, C, W (copolymer of NANA with galactose), and Y (copolymer of NANA with glucose).[246,259,307–310] These vaccines elicited high serum bactericidal antibody titers and boostable immune responses. As described, monovalent group C conjugate vaccines were introduced with great success in the United Kingdom in late 1999 and have been introduced into routine immunization shedules in Europe, Brazil, Canada, and Australia.

As of August 2015, two quadrivalent A, C, W, and Y meningococcal polysaccharide-protein conjugate vaccines were licensed in the United States and recommended for routine use in adolescents and young adults.[311] In addition, a meningococcal conjugate vaccine that contains capsular groups C and Y, as well as Hib, is licensed for use in infants and toddlers. Recently, two vaccines for prevention of capsular group B disease were licensed (see Chapter 39).

Polysaccharide Meningococcal Vaccines

Meningococcal polysaccharide vaccines are rapidly being replaced by conjugate vaccines because of the immunologic inferiority of the former. Although they have an acceptable safety profile and are immunogenic and effective in older children and adults, polysaccharide vaccines have substantial limitations relative to meningococcal polysaccharide-protein conjugate vaccines. They are poorly immunogenic in infants, do not provide a booster response, do not substantially decrease meningococcal pharyngeal colonization and therefore do not provide herd protection, and can induce the phenomenon of immunologic hyporesponsiveness. They are still used at times for outbreak control[312] and are still available in the United States and other countries. However, it is likely that their use will eventually be phased out. Table 38.2 shows currently licensed polysaccharide vaccines. For a comprensive review of this topic, refer to this chapter in the 6th edition.[313]

MENINGOCOCCAL POLYSACCHARIDE-PROTEIN CONJUGATE VACCINES

Meningococcal Capsular Group a Conjugate Vaccine for Africa

Until recently, the only meningococcal vaccines available in sub-Saharan Africa were a bivalent group A and C and a trivalent group A, C, and W polysaccharide vaccine (MPSV2 and MPSV3). These vaccines are poorly immunogenic in infants,

TABLE 38.2 Meningococcal Polysaccharide Vaccines[a]

Manufacturer	Vaccine	Active Constituents	Other Excipients	Diluent
Sanofi Pasteur	Mengivac	Group A polysaccharide Group C polysaccharide	Lactose (2 mg)	Phosphate-buffered saline solution
	Menomune	Group A polysaccharide Group C polysaccharide Group W135 polysaccharide Group Y polysaccharide	Lactose (2.5–5.0 mg) Sodium chloride (4.25–4.75 mg)	Pyrogen-free water
GlaxoSmithKline Biologicals	AC Vax	Group A polysaccharide Group C polysaccharide	Lactose (12.6 mg)	Saline solution
	ACWY Vax	Group A polysaccharide Group C polysaccharide Group W135 polysaccharide Group Y polysaccharide	Lactose (12.6 mg)	Saline solution

[a]Bivalent, trivalent, and quadrivalent meningococcal polysaccharide vaccines are referred to in the text as MPSV2, MPSV3, and MPSV4, respectively. All vaccines shown are licensed in European countries. Menomune is available in the United States and Canada and is sold in other countries under the trade name Menomune-A/C/Y/W135. All vaccines contain 50 μg of each of the capsular polysaccharides shown and are lyophilized, requiring reconstitution with preservative-free diluent. For multidose vials, the diluent used to reconstitute Menomune contains thimerosal (mercury derivative) 1:10,000 as a preservative. Note: although still licensed in Europe, the bivalent vaccines are generally no longer available.

the age group at greatest risk of acquiring disease, and have only a transient effect, if any, on colonization and spread of infection. For these reasons, meningococcal vaccination in Africa was largely done in response to epidemics, which was a logistically challenging and relatively ineffective strategy. Although an emergency response plan had been developed in collaboration with the WHO and the CDC,[314] implementation was often delayed because of limitations of surveillance or logistics. One study estimated that even under optimal circumstances, fewer than 60% of outbreak-related cases were prevented by implementing vaccination after an epidemic was recognized.[314] An improved meningococcal vaccine, therefore, was needed.

In sub-Saharan Africa, most meningococcal epidemics are caused by capsular group A strains. By the late 1990s, three vaccine manufacturers had developed capsular group C meningococcal conjugate vaccines for the United Kingdom, where there had been approximately 10,000 cases of disease caused by group C organisms and 1000 deaths during the previous decade.[315] There was little commercial interest in developing a group A meningococcal conjugate vaccine for sub-Saharan Africa, where there had been more than 700,000 cases and 100,000 deaths in the same decade.[3] The countries in this region remain some of the poorest in the world and could not afford to purchase the vaccine.

In 1999, the WHO funded a feasibility study to explore options to develop and manufacture a group A conjugate vaccine that could be sold in Africa for less than $0.50 a dose.[316,317] The results from this study formed the basis of a successful grant application to the Bill and Melinda Gates Foundation, which in 2001 awarded $70 million to the WHO and the Program for Appropriate Technology in Health to develop a meningococcal group A conjugate vaccine with the goal of eliminating group A epidemics in Africa.[316] Although there were concerns at the time about the potential for epidemics caused by capsular group W strains,[225,318–320] in the previous 100 years, more than 90% of epidemic meningococcal disease in sub-Saharan Africa had been caused by capsular group A strains. The dominance of group A disease and the greater technical challenges, higher cost, and extended timelines for developing a bivalent capsular group A and W conjugate vaccine made development of a monovalent group A vaccine more feasible as a first step.

A novel conjugation chemistry using reductive amination of group A polysaccharide aldehydes and tetanus toxoid hydrazides was developed by scientists at the FDA's Center for Biologics Evaluation and Research.[321] The process was transferred to the Serum Institute, a vaccine manufacturer in India.[322] Extensive testing of the vaccine in sub-Saharan Africa provided assurance of safety, immunogenicity, and manufacturing consistency.[323] In 2010, marketing authorization for MenAfriVac (MenA-TT conjugate vaccine) was granted by the Food and Drug Administration of India for the export of the vaccine to African countries. Mass vaccination of 1- to 29-year-olds was introduced in December 2010, as part of countrywide demonstration projects in Burkina Faso, Mali, and Niger.[324] More than 217 million people ages 1 through 29 years have received MenA-TT vaccine (containing 10 μg MenA polysaccharide) in 17 countries in the African meningitis belt by 2015.[325] It is hoped that high coverage in this age group will lead to herd protection of unvaccinated children younger than 1 year and elimination of epidemics of meningococcal A disease. In fact, MenA-TT led to a dramatic decline in group A carriage in African villages, suggesting that herd protection with this vaccine is substantial.[326,327] Once the mass vaccination campaigns are completed, the concern will be to protect subsequent birth cohorts throughout infancy. Two strategies are recommended: one for countries where MenA coverage is high and another where MenA coverage is low (<60%).[328] In high-coverage countries, vaccination should be administered as a single dose at 9 to 18 months of age. A lower-dose vaccine (5 μg of MenA polysaccharide) is available for children younger than 2 years of age. In low-coverage countries, periodic single-dose campaigns are recommended.

A major problem that has occurred since the widespread use of a capsular group A conjugate vaccine is the emergence of disease caused by strains with other capsular groups such as C, W, or X.[190,225,318,329–331] Currently there is no vaccine available for prevention of group X disease, which is extremely rare in North America and Europe.[332] For prevention of group W disease, quadrivalent (A, C, Y, and W) conjugate vaccines are available in industrialized countries (see earlier discussion), but these vaccines are expensive and not available in sub-Saharan Africa. A trivalent MPSV3 vaccine is available for Africa and kept in reserve by the WHO for response to capsular group C and W epidemics, but this vaccination strategy has

many limitations, as described. Work is currently underway to produce a low-cost pentavalent MenACWXY conjugate vaccine that could (potentially) replace the monovalent vaccine.

Monovalent Capsular Group C Conjugate Vaccines

Composition

Three group C conjugate vaccines (Table 38.3) are currently licensed in European countries, Australia, Brazil, and Canada; two are based on oligosaccharides derived from group C capsular polysaccharide that are conjugated to the nontoxic CRM_{197} derivative of diphtheria toxin; the third vaccine consists of de-O-acetylated group C polysaccharide conjugated to tetanus toxoid. Although these vaccines use different O-acetylated saccharides, all three vaccines are immunogenic in infants and elicit boostable serum meningococcal bactericidal antibody responses, whether or not the test organisms in the assay naturally express O-acetylated or de-O-acetylated group C capsules.

Meningitec (Pfizer, herein described as P-MenC-CRM) is prepared by the controlled treatment of group C polysaccharide with sodium periodate followed by the separation of the resulting oligosaccharides from high-molecular-weight saccharide and conjugation to CRM_{197} by reductive amination. Menjugate (GlaxoSmithKline Vaccines, recently acquired from Novartis Vaccines and Diagnostics, herein described as

TABLE 38.3 Meningococcal Conjugate Vaccines

Manufacturer	Vaccine	Other Designation	Active Constituents Per Dose	Adjuvant	Other Excipients	Presentation
Pfizer	Meningitec	P-MenC-CRM	10 μg *O*-acetylated group C oligosaccharide conjugated to 11–25 μg CRM_{197}	$AlPO_4$	Sodium chloride	Single-dose, liquid suspension vial
Pfizer (previously Baxter Bioscience)	NeisVac	MenC-TT	10 μg de-*O*-acetylated group C oligosaccharide conjugated to 10–20 μg tetanus toxoid	$Al(OH)_3$	Sodium chloride	Single-dose, prefilled syringe
GlaxoSmithKline vaccines (previously Novartis vaccines)	Menjugate	G-MenC-CRM	10 μg O-acetylated group C oligosaccharide conjugated to 11–25 μg CRM_{197}	$Al(OH)_3$	Mannitol, sodium phosphate buffer	Single-dose, freeze-dried, vial reconstituted with diluent
GlaxoSmithKline vaccines (previously Novartis vaccines)	Menveo	MCV4-CRM	5 μg each of groups C, Y, and W135 oligosaccharide and 10 μg of group A oligosaccharide conjugated to 33–64 μg CRM_{197}	None	Sucrose, potassium dihydrogen phosphate, sodium dihydrogen phosphate monohydrate, disodium phosphate dehydrate, sodium chloride	Single-dose vial with lyophilized group A component; single-dose vial with the three other components in liquid form
Sanofi Pasteur	Menactra	MCV4-DT	4 μg each of groups A, C, Y, and W135 polysaccharide conjugated to ≈48 μg of diphtheria toxoid	None	Sodium chloride	Single dose, prefilled syringe
Pfizer (previously GlaxoSmithKline)	Nimenrix	MCV4-TT	5 μg each of groups A, C, Y, and W polysaccharide conjugated to ≈44 μg of tetanus toxoid	None	Sucrose and trometamol	Liquid single dose
GlaxoSmithKline vaccines	Menitorix	Hib-MenC	5 μg Hib polysaccharide and 5 μg group C polysaccharide each conjugated to ≈17.5 μg of tetanus toxoid	None	Tris, sucrose, sodium chloride	Single-dose, freeze-dried vial reconstituted with prefilled syringe
GlaxoSmithKline vaccines	MenHibrix[a]	Hib-MenCY-TT	5 μg group C polysaccharide conjugated to 5 μg of tetanus toxoid, 5 μg group Y polysaccharide conjugated to 6.5 μg of tetanus toxoid, and 2.5 μg Hib polysaccharide conjugated to 6.25 μg of tetanus toxoid	None	Sucrose and trometamol	Single dose lyophilized with saline diluent

[a]GlaxoSmithKline announced that this vaccine would be discontinued as of February 28, 2017.

G-MenC-CRM) is manufactured from group C polysaccharide that has been partially hydrolyzed at low pH and size-fractionated before being conjugated to CRM_{197} through a bis *N*-hydroxysuccinimide ester of adipic acid.[302] In the manufacture of NeisVac-C (Pfizer, recently acquired from Baxter Bioscience, herein described as MenC-TT), the group C polysaccharide is first deacetylated with sodium hydroxide, but, because *N*-acetyl groups are part of the epitopes that elicit protective antibody, the amino groups are reacetylated with acetic anhydride.[333] Following limited depolymerization with sodium periodate and size fractionation, the de-O-acetylated oligosaccharide is conjugated directly to the tetanus toxoid by reductive amination. The single-dose formulations of all three vaccines do not contain preservatives.

Group C conjugate vaccines are stable at the recommended storage temperature (2°–8°C). Studies in which the conjugate vaccines have been stored at higher temperatures or subjected to repeated freeze–thaw cycles indicated that the structural stability of the oligosaccharide chains and of the protein carrier is related to the conjugation chemistry or formulation of the vaccine.[334] However, the immunogenicity of the vaccines in mice was affected only by incubation of the vaccines under more extreme conditions that resulted in the release of a substantial proportion of free saccharide.[335]

Immunogenicity

Prelicensure studies of monovalent meningococcal polysaccharide-protein group C conjugate vaccines demonstrated their safety and immunogenicity in all age groups. In infants and toddlers, the conjugate vaccines elicited higher antibody responses than did the polysaccharide vaccine, and the antibody elicited by the conjugate vaccine had greater bactericidal activity.[304,306,336,337]

Age-Related Immunogenicity

The hallmark of protection against meningococcal disease is SBA. Substantial evidence indicates that all three group C conjugate vaccines are highly immunogenic after two or three doses given in the first 6 months of life and elicit serum bactericidal antibody.[304,306,336,338] In most of these studies, the highest responses in infants or toddlers were with MenC-TT.[336,338,339] These early studies were performed with concomitant administration of combination vaccines containing diphtheria and tetanus toxoids and whole-cell pertussis (DTwP) vaccines. Since then, combination vaccines using acellular pertussis have largely replaced DTwP vaccines in most industrialized countries, and pneumococcal polysaccharide-protein conjugate vaccines have been introduced into the infant vaccination schedule. These changes have the potential to enhance or impair antibody responses to meningococcal conjugate vaccines.

A study in the United Kingdom compared serum antibody responses to the three MenC conjugate vaccines when administered at 2 and 3 months of age along with separate injections of a combination acellular pertussis vaccine ($DTaP_5$/IPV/Hib-TT, Pediacel, Sanofi Pasteur) and pneumococcal conjugate vaccine 7 (PCV7) (Prevnar, Pfizer).[340] At 2 months, a single dose of MenC-TT vaccine elicited higher serum bactericidal antibody responses than either of the MenC-CRM diphtheria toxoid vaccines (compare respective hatched bars in Fig. 38.5A). One month after the second dose (Fig. 38.5A, *bars without hatching*), the highest serum bactericidal geometric mean titer (GMT) was in the group given the G-MenC-CRM vaccine (1:682) followed by the MenC-TT (1:437) and P-MenC-CRM (1:229; $P < .02$) vaccines. In an earlier study with coadministration with $DTaP_5$/IPV/Hib-TT, the MenC-TT conjugate vaccine also elicited higher serum bactericidal antibody responses after one dose given at 2 months of age, but after two additional doses at 3 and 4 months of age, the responses were significantly higher to the G-MenC-CRM vaccine.[341]

The reasons for the higher group C antibody responses to one dose of the MenC-TT conjugate vaccine at 2 months and the higher responses to the G-MenC-CRM vaccine after a second or third dose are unknown. Epitopic or nonepitopic suppression to the tetanus toxoid carrier protein may have been induced by the first dose of the MenC-TT vaccine when coadministered with the DTaP vaccine, which dampened the anticapsular antibody responses to the second injection of the tetanus toxoid conjugate vaccine. This mechanism may explain the lower serum bactericidal antibody responses to the MenC-TT vaccine in preschoolers or adolescents, or both,

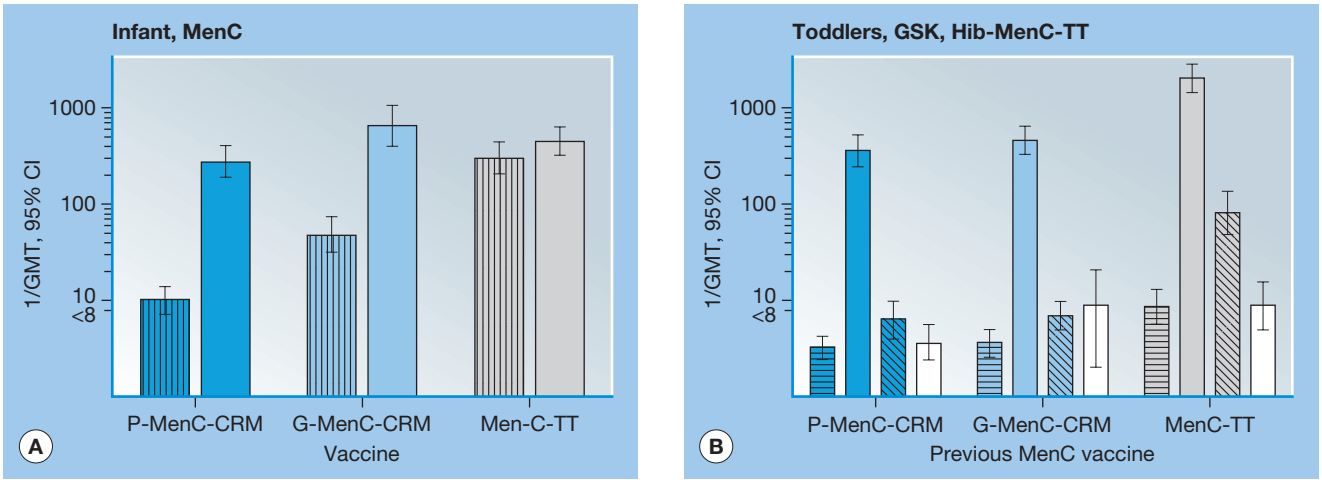

Figure 38.5. Serum bactericidal antibody responses of infants immunized with MenC conjugate vaccines (rabbit complement). A, Titers 1 month after a dose of vaccine given at 2 months *(hatched bars)* or after a second dose given at 3 months *(solid bars)*.[339] **B,** Serum bactericidal titers before *(horizontal hatched bars)* and after a booster dose of Hib-MenC-TT vaccine given at 12 to 15 months of age in relation to previous MenC vaccination at 2 to 4 months of age. Titers 1 month after the booster *(solid bars)*, at 24 months of age *(diagonal hatched bars)*, and at 36 months of age *(open bars)*.[352] CI, confidence interval; GMT, geometric mean titer; GSK, GlaxoSmithKline; Hib, *Haemophilus influenzae* type b.

given DT or Td at the same visit or at 1 month before the conjugate vaccine.[342–344] The clinical relevance of these lower responses is unclear because most subjects achieved putative protective titers (albeit measured with rabbit complement; see earlier discussion). Two studies also suggested interference might occur between coadministration of a combination of meningococcal and pneumococcal conjugate vaccines when CRM_{197} is the carrier protein of both vaccines.[345,346] In infants given P-MenC-CRM at 2, 3, and 4 months of age along with an investigational nine-valent pneumococcal conjugate vaccine that also used CRM_{197}, the meningococcal bactericidal GMT was 1:291 (95% confidence interval [CI], 208–407).[345] This response is substantially lower than the GMTs previously reported in children who received P-MenC-CRM alone. In another study, decreased meningococcal bactericidal antibody responses were observed in infants given an investigational combination pneumococcal-meningococcal CRM_{197}-based conjugate vaccine prepared by Pfizer, when compared with the responses of control infants given P-MenC-CRM (GMT, 1:179 vs 1:808, respectively).[346]

Anticapsular Antibody Kinetics and Persistence

Most adults immunized with group C conjugate vaccines develop protective serum bactericidal antibody levels within 7 to 10 days.[347] Serum bactericidal titers peak at approximately 2 to 4 weeks after immunization and persist for longer than a year.[348] Most teenagers immunized with the G-MenC-CRM conjugate vaccine had protective serum bactericidal titers at 3.7 years[268] or 5 years of follow-up.[349] Serum antibody persistence seems to be inversely correlated with age[262] as waning immunity was detected in the majority of 6- to 12-year-old children immunized an average of 6.8 years earlier as part of the United Kingdom national MenC catch-up campaign.[350] Similarly, only 44% of Australian children immunized at 2 to 8 years of age with a MenC vaccine had adequate serologic protection an average of 8.2 years following immunization.[351] As described subsequently, protective serum antibody levels decline even more rapidly after immunization of infants or toddlers.

At the end of the United Kingdom catch-up campaign, routine MenC conjugate vaccination was introduced for infants (three monthly doses beginning at 2 or 3 months of age). With this schedule, serum bactericidal titers declined to subprotective levels by 1 year (see Fig. 38.5B, *horizontal hatched bars*) and there was evidence of lower effectiveness in the second year of life.[266] To extend the duration of protective titers, a booster dose of a combined group C meningococcal-Hib tetanus toxoid conjugate vaccine (Menitorix, GlaxoSmith-Kline; see Table 38.2) was introduced in the United Kingdom for the 12- to 14-month age group. At 1 month after a booster dose, high serum bactericidal antibody titers were present in toddlers previously vaccinated with any of the three MenC conjugate vaccines (see Fig. 38.5B, *solid bars*).[352] By age 24 months *(diagonal hatched bars)* or 36 months *(open bars)*, however, the serum titers in the majority of the children had declined to less than the titers thought to be required for protection. In another study, infants were immunized at 2, 3, and 4 months of age with the G-MenC-CRM conjugate vaccine and boosted with MCV4-CRM at 12 months. At 40 to 60 months of age, 59% had protective titers of serum bactericidal antibody against capsular group C meningococci.[353]

Recent data assessing the impact of different conjugates (G-MenC-CRM or MenC-TT) or the numbers of doses (0, 1, or 2 doses) for primary immunization in the United Kingdom, on the persistence of protective titers after a Hib-MenC booster, again found that MenC-TT priming resulted in improved antibody persistence when compared with MenC-CRM priming. Of particular note, one priming dose of MenC-CRM resulted in superior booster responses to Hib-MenC when compared with two priming doses of MenC-CRM (Fig. 38.6).[354] Interestingly, antibody persistence to 2 years of age after the toddler Hib-MenC dose was the same with one or two priming doses as it was without any priming doses of MenC-CRM.[354]

Immunologic Memory

MenC conjugate vaccines prime for the ability to mount memory anticapsular antibody responses on subsequent exposure to a polysaccharide challenge (infants,[304,306,338] toddlers,[303] and adults[355]). In other studies, infants given lower doses of conjugated meningococcal A and C polysaccharide antigens[356,357] or fewer numbers of doses,[269,338] or both, mounted higher memory antibody responses to subsequent challenges with unconjugated polysaccharide vaccine than did infants who previously received higher doses or more injections of the conjugated antigen. Similarly, immunization with one dose of MenC-CRM resulted in higher memory responses than did two doses of MenC-CRM following a toddler dose of Hib-MenC-TT.[354] The immunization with the higher quantities of polysaccharide antigen per dose of conjugate vaccine or multiple injections, or both, resulted in higher serum bactericidal titers at 1 month after vaccination and greater serum antibody persistence, but lower memory responses.[356] Thus, the choice of the optimal dose of antigen and number of injections of a conjugate vaccine needs to consider the greater importance of having higher serum antibody concentrations for protection against meningococcal disease than the robustness of the memory antibody response. Underscoring this point are the UK data on decreasing vaccine effectiveness between 1 and 4 years after immunization of infants and toddlers,[266] at a time when the vaccinated children could mount robust memory antibody responses[271] but lacked protective levels of SBA.

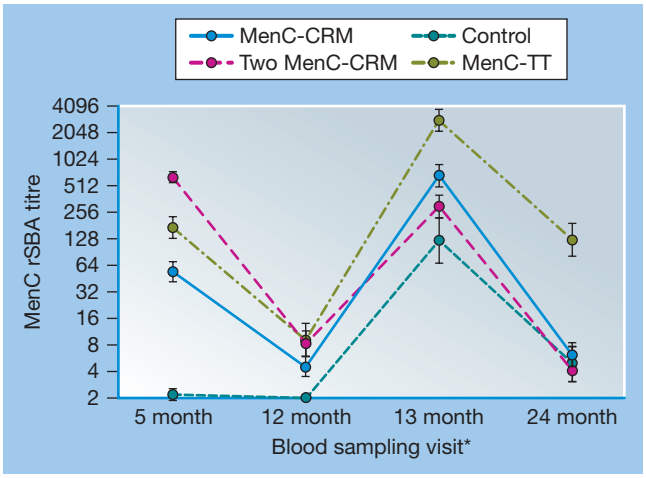

Figure 38.6. Geometric mean titers (and 95% confidence interval) for capsular group C meningococcal (MenC) rabbit serum bactericidal antibody (rSBA) at visits performed at ages 5, 12, 13, and 24 months according to type of MenC priming (G-MenC-CRM or MenC-TT) schedule and Hib-MenC boosting at 12 months of age (intention-to-treat population). Immunogenicity of reduced dose priming schedules of serogroup C meningococcal conjugate vaccine followed by booster at 12 months in infants: open label randomised controlled trial.* BMJ. *2015;350:h1554.)*

Effect of Prior Polysaccharide Vaccination Responses to MenC Conjugate Vaccine

Adults and toddlers previously vaccinated with one or more doses of meningococcal polysaccharide vaccine have lower serum antibody responses to a group C conjugate vaccine than do individuals immunized for the first time.[303,347,355,358] These lower responses to the conjugate vaccine probably are a result of depletion of memory B cells by exposure to the unconjugated polysaccharide. However, this phenomenon is not considered further here because conjugate vaccines have largely replaced unconjugated polysaccharides.

MenC Conjugate Vaccine Effectiveness

In England and Wales, the incidence of group C meningococcal disease rose substantially from 1994 to 1998.[359] Enhanced meningococcal surveillance was initiated, and the total number of group C cases for the 1998–1999 epidemiologic year (July 1 to June 30) was estimated at 1500 (Fig. 38.7, *left panel*), with at least 150 deaths. From November 1999, group C conjugate vaccination was introduced in the United Kingdom for all individuals younger than 19 years of age (later extended to younger than 24 years of age) in a catch-up program that took 12 months to complete. Individuals 1 to 18 years of age were given one dose, infants were given three doses at 2, 3, and 4 months of age along with their routine primary immunizations, with two doses for those 5 to 11 months of age.

Within 12 to 18 months after introduction of group C vaccination, a marked decline in the number of cases and deaths caused by group C disease occurred in the age groups targeted for immunization.[266,315,360,361] Ten years after vaccine introduction, group C meningococcal disease had been virtually eliminated in the UK population, including in the groups older than 24 years of age who were not vaccinated (see Fig. 38.7, *right panel*).

Formal estimates of age-specific vaccine effectiveness during the first year after vaccination were approximately 90% or more for all vaccinated age groups. Between 1 and 4 years after vaccination, however, effectiveness declined in all age groups.[266] The decline was most marked in infants vaccinated at 2, 3, and 4 months of age for whom there was no demonstrable effectiveness, –81% (95% CI, –7430% to 71%), and least in adolescents given one dose of vaccine, 90% (95% CI, 77% to 96%). In toddlers given one dose of vaccine, effectiveness between 1 and 4 years declined to 61% (95% CI, –327% to 94%).[266] In response to the decline in effectiveness in vaccinated infants, in September 2006, the ages of the routine infant UK MenC vaccination schedule were changed to 3, 4, and 12 months, with the final dose administered as a combination Hib-MenC vaccine.[266] Based on data inclusive from 2000 through the middle of 2009, vaccine effectiveness within 1 year of infant immunization was estimated to be 97% (95% CI, 91% to 99%) and was 68% (95% CI, –63% to 90%) at 12 or more months of follow-up.[188]

Between 2000 and 2003, 53 reported cases of group C conjugate vaccine failure occurred in persons from England or Wales.[361] There was no evidence of immunodeficiency in these immunized persons and the case fatality rate was 7.5%, which was similar to that of cases in unvaccinated persons in the same birth cohorts: 10.4%. Serum bactericidal titers in convalescent serum and avidity indices in acute serum were significantly higher in vaccine failures than in unvaccinated cases (5.7-fold higher for SBA titers, $P = .03$; 2.9-fold higher for avidity indices, $P = .01$), which are consistent with an anamnestic antibody response in the vaccine failures. These observations suggest that group C disease had occurred in vaccinated persons despite induction of immunologic priming (memory) by the group C conjugate.[361]

Additional effectiveness data are available from other countries that have introduced meningococcal group C conjugate vaccines using a catch-up campaign at the time of introduction, including Spain, The Netherlands, and Canada. These countries reported high vaccine effectiveness using various different schedules, but with some waning of effectiveness over time.[362–364] The decline in vaccine effectiveness in immunized infants and young children was consistent with the rapid decline in serum bactericidal antibody titers after vaccination (see Fig. 38.5). Booster doses for toddlers were widely introduced with the expectation that antibody, and thus protection, would persist better during early childhood after the 12-month dose. However, accumulating evidence indicates that persistence of serum antibody after this booster is poor,[354] more so with the MenC-CRM vaccines than the MenC-TT, and the observed protection against disease in the population was

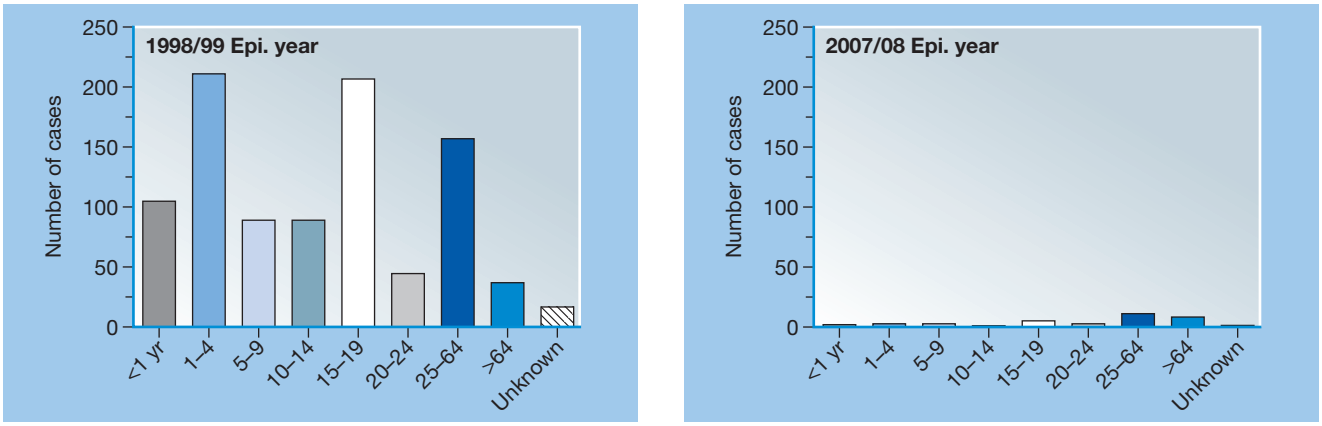

Figure 38.7. Group C meningococcal disease in the United Kingdom by age group, as determined by enhanced surveillance. *Left*, Cases for July 1998 to June 1999 before introduction of group C meningococcal conjugate vaccine. *Right*, Cases for July 2007 to June 2008 after vaccine had been used in the United Kingdom for 10 years. Epi. year, epidemiologic year. *(Data from Helen Campell, UK Health Protection Agency, Centre for Infections. From Campbell H, Andrews N, Borrow R, et al. Updated postlicensure surveillance of the meningococcal C conjugate vaccine in England and Wales: effectiveness, validation of serological correlates of protection, and modeling predictions of the duration of herd immunity.* Clin Vaccine Immunol. *2010;17:840–847.)*

likely maintained chiefly through herd protection from decreased group C meningococcal carriage. Thus, the focus of the UK program has now switched to maintaining herd protection rather than optimizing antibody levels in the first few years of life. Accodingly, in 2013 the UK infant schedule was changed to 3 and 12 months, with a second MenC booster offered in early adolescence.[365] In 2015 the teenage MenC dose was replaced with MCV4 in response to an increase in MenW cases. In 2016 the 3-month dose of MenC was dropped once the majority of teenagers had been immunized and herd protection had been secured.[366] Similarly, many other countries and regions with established infant/toddler immunization programs have either introduced an adolescent booster dose of MenC or MenACWY vaccine or plan to do so.

Effect of MenC Conjugate Vaccine on Carriage and Herd Protection

To measure the effectiveness of group C conjugate vaccines on decreasing carriage of meningococci,[367] oropharyngeal swabs were obtained in 1999 from 15,106 UK students 15 to 19 years of age before introduction of group C conjugate vaccines. After vaccine introduction (single dose for this age group), swabs were obtained from 18,095 students in 2000, and 19,710 students in 2001. After 1 year of vaccine use, there was a 66% decrease in carriage of encapsulated group C meningococci, which reached 75% by 2 years.[59] In contrast, there was no evidence of decreases or increases in carriage by isolates with other capsular groups.[59] Consistent with these data, there also was a 66% decrease in the attack rate of group C meningococcal disease in unvaccinated persons.[368] Thus, the near eradication of group C meningococcal disease from the United Kingdom during the past 15 years (see Fig. 38.7) occurred despite relatively limited vaccine efficacy beyond 1 year after vaccination in the youngest age groups.[188] It is likely that direct protection of the vaccinated indivduals was important in the rapid control of disease but, as antibody levels waned rapidly in the younger age groups, sustained control has been driven by decreased colonization and thus decreased circulation of hypervirulent group C strains as a result of vaccine-induced herd protection. Recent data show that the current carriage rates of capsular group C meningococci remain very low, even 15 years after introduction of the vaccine.[369,370] Herd protection with group C conjugate vaccines has been documented in other countries as well.[371,372]

Although the incidence of group C disease in the United Kingdom and the rates of group B carriage remain very low, serum group C anticapsular antibody levels in the childhood population have waned.[262,373] Thus, there is a large susceptible population potentially at risk of disease should a virulent group C clone be introduced. However, as discussed above, the addition of MenC adolescent boosters from 2013 and a MenACWY catch-up campaign among 14- to 18-year-olds from 2015, should boost immunity among teenagers and maintain herd protection, as sustained persistence of antbody has been observed in this age group.

Before introduction of group C conjugate vaccination in the United Kingdom, concerns were raised that immune pressure induced by vaccination might select for capsular switching from group C to group B strains.[374] Capsular switching between group B and group C strains had been observed in the United States.[51,181,375] Switching from group C ST-11 complex isolates to group B ST-11 complex isolates also has been reported in France, together with conservation of virulence.[376] To date, there is no evidence of increased rates of group B disease in the United Kingdom by strains that have undergone capsular switching; indeed rates of capsular group B disease have actually declined over the past decade.[377] There also is no evidence of capsular group switching or replacement observed among UK carriage isolates.[59] In contrast, since introduction of group C conjugate vaccine immunization in Spain, an increase in ST-11 capsular group B disease has occurred in Navarra, which suggests that group C–to–group B capsular switching and subsequent clonal expansion of the group B clone had occurred, but there is no clear evidence that this was driven by vaccination.[378] Similarly, an ST-11 W clone emerged in the United Kingdom in 2009, which appears to have originated in Latin America and is apparently unrelated to the MenC vaccine program.[174]

Safety of MenC Conjugate Vaccines

From prelicensure safety studies in the United Kingdom, transient headache of mild to moderate severity was the most commonly reported adverse event, with the highest rate (12%) in the first 3 days after vaccination. Headache was reported more frequently in secondary school than in primary school children, and more frequently in girls than in boys. Local reactions at the injection site consisted mostly of pain, tenderness, and occasional redness. These reactions tended to be of mild to moderate severity, were maximal on the third postvaccination day, and typically resolved within 1 day. Local reactions were more common after diphtheria toxoid or diphtheria toxoid–tetanus toxoid booster vaccination than after group C conjugate vaccination. Preexisting allergies did not seem to affect reactogenicity.[379] Postlicensure passive surveillance through reports of adverse vaccine events from health professionals to the UK Medicines Control Agency/Committee on Safety of Medicines indicated a rate of one adverse event per 2875 doses of meningococcal group C vaccine distributed in the first 10 months of the UK campaign.[380] Nearly all these adverse events consisted of transient headache, pyrexia, or dizziness, or local reactions. Anaphylaxis was reported at a rate of one per 500,000 doses distributed. Although some new reactions to group C conjugate vaccine were identified (e.g., headache, nausea, vomiting, abdominal pain, and malaise in all age groups), these were generally not serious, and the balance of risks and benefits for group C conjugate vaccines was considered overwhelmingly in favor of immunization.

Five cases of Guillain-Barré syndrome (GBS) were reported in persons immunized with monovalent group C conjugate vaccines during the UK catch-up campaign when millions of doses were administered. This number of cases was considered by the UK Health Protection Agency to be lower than the expected background rate.

MULTIVALENT MENINGOCOCCAL CONJUGATE VACCINES

Composition

As of September 2015, three meningococcal conjugate vaccines are licensed in the United States (see Table 38.3). One is a combination Hib-meningococcal C and Y conjugate (MenHibrix, GlaxoSmithKline, referred to herein as Hib-MenCY),[381–383] and the other two are quadrivalent conjugate vaccines: Menactra (Sanofi Pasteur; referred to as MCV4-DT), and Menveo (GlaxoSmithKline Vaccines, referred to as MCV4-CRM).[384–386] However, GlaxoSmithKline recently announced that Hib-MenCY will no longer be available. One or both of the quadrivalent vaccines also are licensed in Canada, Europe, and some countries in Latin America, the Middle East, and Asia. A third quadrivalent conjugate vaccine called Nimenrix (recently acquired by Pfizer Vaccines from GlaxoSmithKline, referred to herein as MCV4-TT) is licensed in Europe, Canada, and Australia and is under review or licensed in various other countries.

A combination Hib conjugate vaccine and group C meningococcal conjugate vaccine (without Y) (Menitorix, GlaxoSmithKline, referred to herein as Hib-MenC) is available in Europe and Australia. None of these vaccines contains an adjuvant or preservative.

MCV4-DT is prepared by performing controlled, limited depolymerization of capsular groups A, C, Y, and W polysaccharides, which are then derivatized with a dihydrazide-containing linker molecule. The derivatized polysaccharides are independently conjugated to the carboxylic acid groups on diphtheria toxoid. One dose of the quadrivalent vaccine contains 4 μg of each of the four polysaccharides and a total dose of approximately 48 μg of diphtheria toxoid in 0.5 mL of phosphate-buffered physiologic saline (see Table 38.2).[309] The vaccine is currently available in 0.5-mL single-dose vials and single-dose, prefilled syringes; the single-dose vials contain dry natural latex rubber stoppers.

For manufacturing MCV4-CRM, the oligosaccharide from each polysaccharide is prepared by the processes of hydrolysis, sizing, and reductive amination, and linked covalently to CRM_{197}. One dose contains 5 μg of oligosaccharide for each capsular group C, Y, and W, 10 μg of capsular group A oligosaccharide, and a total dose of 33 to 64 μg of CRM_{197}. The vaccine is presented as a single-dose vial containing the group A conjugate component in lyophilized form and another single-dose vial containing the three other components in liquid form. The group A component is reconstituted with the groups C, Y, and W liquid conjugate vaccine component immediately before administration.

For manufacturing MCV4-TT, the conjugate is made by sizing, cyanate ester formation, and derivatisation of the oligosaccharide with a spacer prior to conjugation to TT by carboxylic group activation (MenA and MenC) or sizing, and conjugation via a cyanate ester group (MenY and MenW). One dose contains 5 μg of each oligosaccharide conjugated to a total dose of 44 μg of tetanus toxoid.[387] MCV4-TT is presented as a freeze-dried powder in a single-dose vial for constitution with saline.

For manufacturing Hib-MenC or Hib-MenCY, the Hib polysaccharide is derivatized with a dihydrazide-containing linker molecule and conjugated to the tetanus toxoid carrier protein via carbodiimide condensation. The meningococcal polysaccharide(s) is activated by cyanylation and directly linked to tetanus toxoid through its amino group. One dose of the Hib-MenC vaccine contains 5 μg of Hib polysaccharide, 5 μg of meningococcal C polysaccharide, and a total dose of approximately 17.5 μg of tetanus toxoid.[388] The presentation is a single-dose vial containing the vaccine as a powder, which is reconstituted with 0.5 mL of saline solution that is provided in a prefilled syringe. One dose of the Hib-MenCY contains 2.5 μg of Hib polysaccharide, 5 μg each of C and Y polysaccharides, and a total dose of approximately 18 μg of tetanus toxoid, and is presented as a lyopholised product for reconstitution with saline.[389]

Immunogenicity

MCV4-DT

In adolescents, MCV4-DT elicited noninferior serum bactericidal antibody responses as compared with a U.S.-licensed meningococcal quadrivalent polysaccharide vaccine (MPSV4).[310] In children 2- to 11-years-old, the conjugate vaccine elicited superior serum bactericidal antibody responses.[309] In infants given three doses of MCV4-DT at 2, 4, and 6 months of age, serum bactericidal antibody responses 1 month after the third dose were approximately 50-fold lower than those obtained after three doses of monovalent group C conjugate vaccines.[390] MCV4-DT, therefore, was considered insufficiently immunogenic in infants using this schedule. On the other hand, toddlers 12 to 23 months old given two doses of MCV4-DT, separated by 2 months, developed geometric mean serum bactericidal antibody responses of 1 : 300 to 1 : 400 against test strains with capsular groups C, Y, or W and about 1 : 3000 to a group A strain.[391] In other studies, a two-dose schedule of MCV4-DT given at 9 and 12 months of age was investigated in 1128 children.[392] The first dose was given alone, and the second dose was given alone; with measles, mumps, rubella, and varicella vaccine; or with pneumococcal 7-valent conjugate vaccine (PCV7). The proportions of children with SBA titers (using human complement) of 1 : 8 or more were 90.5% to 95.6% for group A, 97.8% to 100% for group C, 95.1% to 96.4% for group Y, and 81.2% to 86.4% for group W. Although there was overlap in the 95% CIs, meningococcal antibody titers were lower in children who received MCV4-DT concomitantly with PCV7 than in children who received MCV4-DT alone. In addition, in the children who received concomitant PCV7, noninferiority criteria were not met for the pneumococcal IgG GMTs for serotypes 4, 6B, and 18C. No data have been reported for concomitant use of MCV4-DT and pneumococcal conjugate vaccine (PCV13), which replaced PCV7 in the infant immunization schedule in the United States in 2010.

There is also evidence for immunologic interference between MV4-DT and Daptacel (diphtheria and tetanus toxoids and cellular pertussis vaccine, DTaP, Sanofi Pasteur). Among children 4 to 6 years old, antibody responses to each of the four meningococcal capsular groups did not meet noninferiority criteria among children to whom MCV-DT was given 30 days after DTaP. This phenomenon was not observed when MCV4-DT and DTaP were given concomitantly.[392a]

These immunogenicity and safety results formed the basis of licensure of MCV4-DT in Canada and the United States.

MCV4-CRM

For licensure of the new MCV4-CRM conjugate vaccine, its immunogenicity was compared with that of the licensed MCV4-DT conjugate vaccine. In a randomized trial of 2907 children 2 to 10 years old, the respective serum geometric mean reciprocal titers (human complement) 1 month after a dose of MCV4-DT or MCV4-CRM vaccine were similar for capsular groups A and C, and approximately twofold higher in the MCV-CRM group for capsular groups W and Y.[393] Fig. 38.8A (2- to 5-year-olds) and B (6- to 10-year-olds) show the proportions of children with protective titers 1 month after vaccination. In both age groups, the MCV4-CRM conjugate vaccine met preestablished noninferiority criteria against capsular groups C, Y, and W, whereas the responses to group A did not satisfy noninferiority criteria.[394] In a second study, the immunogenicity of MCV4-CRM and MCV4-DT was evaluated in 11- to 18-year-old children; noninferior criteria were met for all four capsular groups (Fig. 38.8C).[370] At 28 days after vaccination, clear differences in favor of MCV4-CRM were observed in the reverse cumulative distribution curves of the serum bactericidal titers against capsular groups A, W, and Y, while noninferiority criteria were met for capsular group C (Fig. 38.9).

MCV4-CRM also is highly immunogenic in infants given a variety of schedules starting at 2 months of age.[396] Fig. 38.10A summarizes the serum bactericidal antibody responses (using human complement) after immunization at 2, 4, and 6 months. Titers peaked 1 month after the third dose and declined nearly 10-fold by 6 months after vaccination (age 12 months). A booster dose at 12 months elicited high serum bactericidal titers against strains from each of the four capsular groups (Fig. 38.10B).

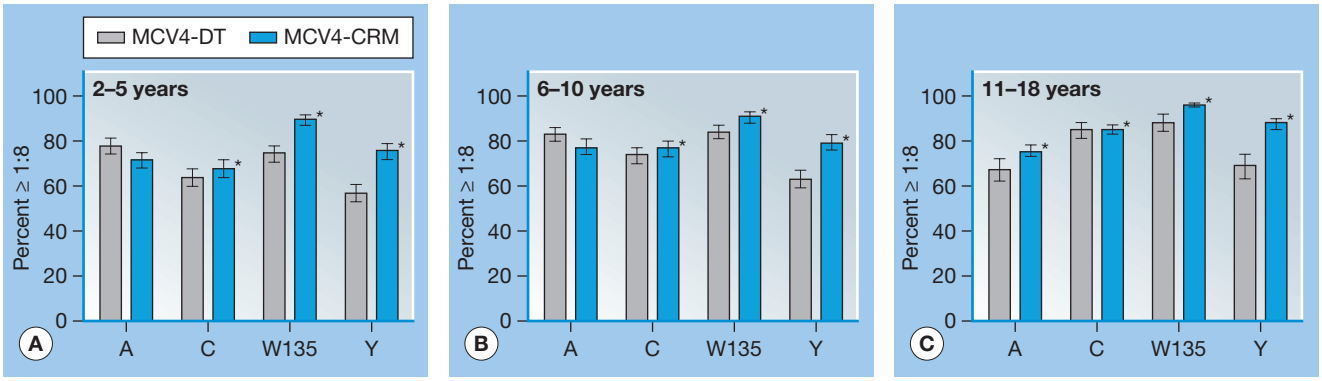

Figure 38.8. Serum bactericidal antibody responses 28 days after a dose of quadrivalent meningococcal conjugate vaccine. A and **B,** Data from a randomized study in children 2 to 10 years old.[393] **C,** Data from a randomized study in adolescents aged 11 to 18 years.[395] Bars represent the percentage of subjects with protective titers (defined as 1:8 measured with human complement). Error bars represent 95% confidence intervals. Asterisks indicate that the response to the new MCV4-CRM vaccine met preestablished noninferiority criteria compared with the licensed MCV4-DT vaccine. These criteria were not satisfied for group A in the age groups 2 to 5 and 6 to 10 years. For capsular groups W135 and Y, the new vaccine elicited superior bactericidal responses in all three age groups ($P < .05$).

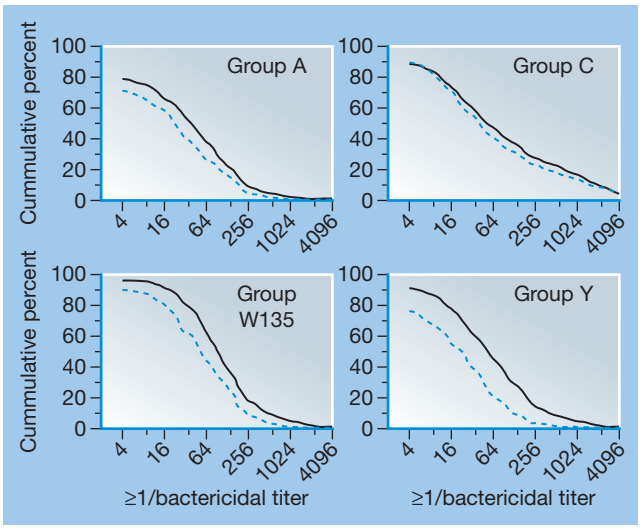

Figure 38.9. Reverse cumulative distribution of bactericidal titers (human complement) in serum samples obtained 28 days after vaccination of teenagers with MCV4-DT or MCV4-CRM. The responses were higher for the MCV4-CRM vaccine group against strains with capsular group A, W135, or Y. *(Data from Jackson LA, Baxter R, Reisinger K, et al, V59P13 Study Group. Phase III comparison of an investigational quadrivalent meningococcal conjugate vaccine with the licensed meningococcal ACWY conjugate vaccine in adolescents.* Clin Infect Dis. *2009;49:e1–e10.)*

MCV4-CRM also is highly immunogenic in toddlers.[397] After two doses given at 12 and 18 months, the percentages of subjects with protective bactericidal titers of 1:8 or more were 100% for capsular group C, W, and Y, and 84% for capsular group A.[397] The titers to group C after the second dose were more than 10-fold higher than after one dose at 12 months.

MCV4-TT

As of December 2016, this vaccine was not yet approved in the United States. A recent systematic review assessed the immunogenicity of MCV4-TT and found the vaccine to be not inferior to licensed quadrivalent meningococcal polysaccharide vaccines. When compared with MCV4-CRM, there were no differences in the proportions of individuals achieving responses over the putative protective threshold but GMTs were generally higher for MCV4-TT for A, W and Y, especially in younger children.[398]

The immunogenicity of MCV4-TT was compared with MCV4-DT in only one study, where it was found to be noninferior with 51.0% to 82.5% of adolescents and young adults mounting vaccine responses (defined as human SBA [hSBA] titer of at least 1:8 for those seronegative at baseline and a fourfold rise in titer for those seropositive at baseline) to strains with each of the four capsular polysaccharides.[399] A study in Korea also documented responses to MCV4-TT among adolescents with 79% to 99% of adolescents with hSBA responses 1:4 or greater.[400]

In a study conducted in the United Kingdom, an adolescent booster dose of MCV4-TT was compared with MCV4-CRM among teenagers who had been primed during childhood with one of the three monovalent C conjugates. Both booster vaccines induced strong MenC rabbit serum bactericidal antibody (rSBA) responses with 100% above the putative protective threshold at 1 month and 96% 9 months later. Overall the highest responses occurred after a MCV4-CRM booster dose with any MenC vaccine prime, but the strongest postbooster resposes were among those primed with MenC-TT and boosted with MCV4-TT.[401]

In younger children (9–12 months of age), 50% to 94% after one dose and 88% to 100% after two doses of MCV4-TT of infants made an hSBA response 1:8 or greater. Antibody responses waned and were substantially lower in both one- and two-dose groups for capsular group A (20.6% and 25.9%, respectively).[402]

Hib-MenC and Hib-MenCY

Hib-MenC is used as a toddler booster following infant priming with monovalent MenC in several countries, including the United Kingdom, and is highly immunogenic. Hib-MenCY is approved in the United States for primary and booster immunization beginning at 6 to 8 weeks of age, although the manufacturer recently announced that this vaccine will be discontinued. In one study of Hib-MenC, 95.6% of MenC-CRM–primed toddlers achieved postbooster Hib-MenC rSBA 1:8 or greater.[403] Interestingly, responses were greater among a group who were primed with Hib-MenCY (99% rSBA ≥1:8).

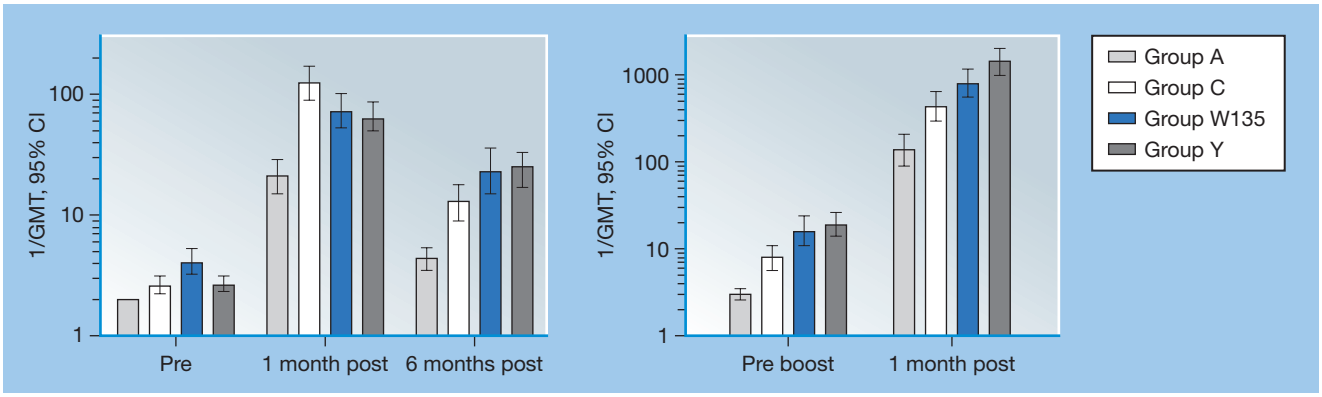

Figure 38.10. Serum bactericidal antibody responses (human complement) of infants immunized with MCV4-CRM vaccine at 2, 4, and 6 months and boosted at 12 months of age. *Left,* Reciprocal geometric mean titers (GMTs) of serum were obtained before immunization *(pre-)* and 1 and 6 months after *(post)* the third dose. *Right,* Reciprocal titers before and 1 month postbooster dose given at 12 months of age. Note that the respective preboost bars in the right panel are the same as those for the bars shown at 6 months after in the left panel, except that the *y*-axis is expanded on the right panel. CI, confidence interval. *(Data from Snape MD, Perrett KP, Ford KJ, et al. Immunogenicity of a tetravalent meningococcal glycoconjugate vaccine in infants: a randomized controlled trial.* JAMA*. 2008;299:173–184.)*

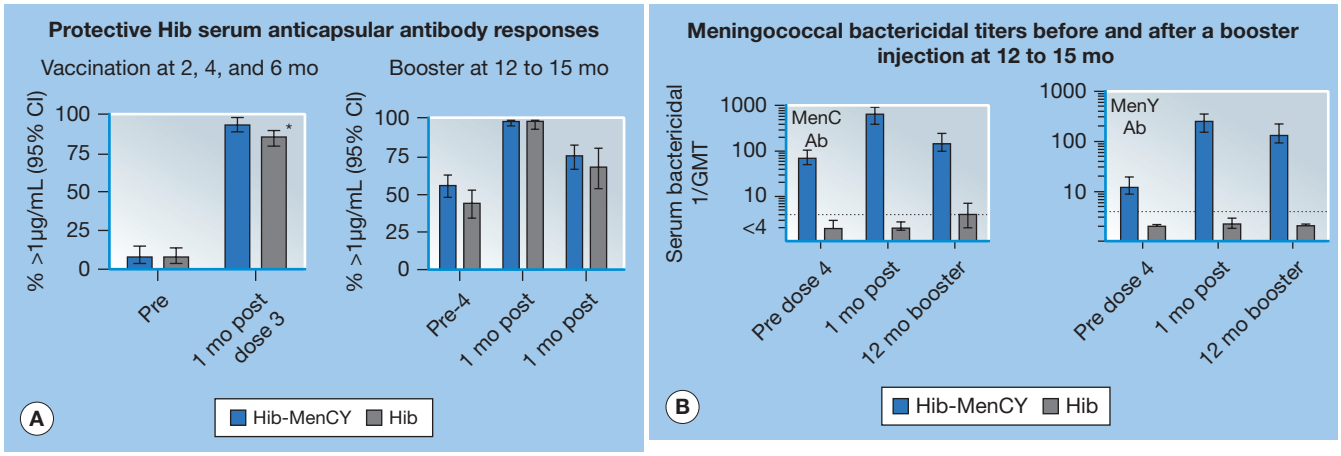

Figure 38.11. Meningococcal serum bactericidal antibody titers before (**A**) and after (**B**) a toddler booster (fourth dose) of Hib-MenCY at 12–15 months of age. Ab, antibody; GMT, geometric mean titer *(Modified from Marshall GS, Marchant CD, Blatter M, et al. Immune response and one-year antibody persistence after a fourth dose of a novel Haemophilus influenzae type b and Neisseria meningitidis serogroups C and Y-tetanus toxoid conjugate vaccine (HibMenCY) at 12 to 15 months of age.* Pediatr Infect Dis J*. 2010;29:469–471.)*

Hib-MenCY is highly immunogenic in infants and toddlers. For example, in a schedule at 2, 4, and 6 months of age with a booster between 12 and 18 months, Hib responses were higher with Hib-MenCY than with Hib-TT and more than 95% of toddlers had antibody titers above the seroprotective threshold. The vaccine was also studied in a 2-, 3-, 4-, and 12-month schedule and was found to induce strong antibody responses against the three vaccine components.[404] Antibody persistence has been studied up to 1 year after the toddler booster with anti–polyribosylribitol phosphate concentrations ≥0.15 µg/mL and MenC and Y hSBA greater than 1:8 at 100%, 96.6%, and 83.8%, respectively (Fig. 38.11).[382]

Serum Antibody Persistence After Quadrivalent Meningococcal Conjugate Vaccines

Serum samples were obtained from a group of teenagers immunized 3 years earlier with MCV4-DT.[310] Although bactericidal titers had declined compared with peak titers at 1 month, the proportions of subjects at 3 years with titers of 1:128 (rabbit complement) or greater were 95% (group A), 71% (group C), 83% (group W), and 96% (group Y). A subset of the 3-year postvaccination serum samples was reassayed with human complement using a bactericidal titer of 1:4 or greater as a measure of protection (Fig. 38.12, *right panel*).[246] As expected from previous studies, the absolute percentages of serum samples with "protective" titers with human complement were lower than with rabbit complement; with human complement, the majority of subjects lacked protective titers to capsular groups C and W and 42% lacked protective titers to group Y (titers to group A were not measured). In another study of 108 children who received MCV4-DT 5 years earlier at the age of 2 to 10 years, 55% and 94% had SBA titers (using rabbit complement) more than 1:128 for capsular groups C and Y, respectively.[405]

A third study compared serum antibody persistence 22 months after immunization of adolescents with MCV4-CRM or MCV4-DT (Fig. 38.12, *left panel*).[406] The proportions of subjects with protective serum bactericidal titers (defined as ≥1:8 with human complement) were 36% vs 25% in favor of MCV4-CRM for group A, 62% vs 58% for group C, 84% vs 74% for group W, and 67% vs 54% for group Y. These differences for capsular groups A, Y or W were statistically significant ($P < .05$ for each capsular group). Although the clinical and

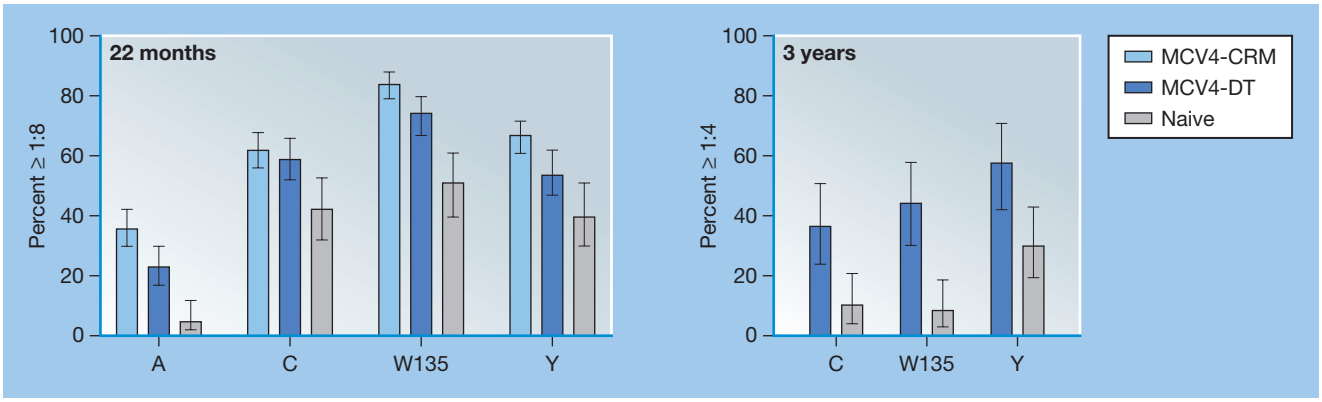

Figure 38.12. Persistence of serum bactericidal antibody (human complement) after vaccination of teenagers with quadrivalent meningococcal conjugate vaccines. Results from 22 months of follow-up of subjects immunized with MCV4-CRM or MCV4-DT *(left)*[406] or from 3 years of follow-up with MCV4-DT *(right)*.[246] At 22 months, the MCV4-CRM–vaccinated group had greater antibody persistence than the MCV4-DT group ($P < .05$ for all four capsular groups). In each study, groups of vaccine-naïve subjects were bled at the time of the respective follow-up of the vaccinated subjects.

TABLE 38.4 Recommendations for Use of Meningococcal Conjugate Vaccines Available in the United States[a]

Risk Group	Primary Series	Booster Dose
Routine immunization of healthy persons aged 11–18 y who are not at increased risk for meningococcal disease	1 dose of MCV4-CRM or MCV4-DT, preferably at age 11–12 y	At age 16 y if primary series at age 11 or 12 y At age 16–18 y if primary dose at age 13–15 y No booster needed if primary dose on or after age 16 y
Persons aged 2–23 mo with complement component deficiency,[b] human immunodeficiency virus infection, functional or anatomic asplenia, or increased risk of exposure[c]	MCV4-CRM at 2, 4, 6, 12–15 months or (only if age >9 mo) MCV4-DT at 9 and 12 mo of age (in this age group, MCV4-DT contraindicated in asplenia and human immunodeficiency virus infection[d,e])	In persons immunized at age <7 y, after 3 y In persons immunized at ≥7 y, after 5 y If continued risk, additional boosters every 5 y
Persons aged ≥24 mo with complement component deficiency,[b] human immunodeficiency virus infection, or functional or anatomic asplenia	2 doses of MCV4-CRM or MCV4-DT 8–12 weeks apart[e,f]	In persons immunized at <7 y, after 3 y In all persons immunized at ≥7 y, after 5 y If continued risk, additional boosters every 5 y
Persons aged 24 mo to 55 y with increased risk of exposure[c]	2 doses of MCV4-CRM or MCV4-DT 8–12 weeks apart 1 dose of MCV4-CRM or MCV4-DT[e,f]	In persons immunized at age 9 mo to 6 y and who remain at increased risk of exposure, after 3 y In all persons immunized at 7 y or older, after 5 y In persons immunized at age <7 y and who remain at increased risk of exposure, after 3 y In all persons immunized at ≥7 y, after 5 y If continued risk, additional boosters every 5 y

[a]See http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6202a1.htm, http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6324a2.htm, and http://www.cdc.gov/mmwr/volumes/65/wr/mm6543a3.htm for current ACIP recommendations.
[b]Such as C3, C5-C9, properdin, factor D, factor H, or eculizumab administration.
[c]For example, microbiologists routinely working with *Neisseria meningitidis* at risk because of a community outbreak caused by a vaccine capsular group, and travelers to or residents of countries where meningococcal disease is hyperendemic or epidemic.
[d]MCV4-DT contraindicated in this scenario because of interference with pneumococcal conjugate vaccine.
[e]MCV4-DT is used, it should be given either before or at the same time as DTaP. This recommendation is based on new evidence indicating that hSBA responses to all four meningococcal capsular groups did not meet noninferiority criteria when MCV4-DT was given 30 days after DTaP.
[f]If MCV4-DT is used, it should be administered at least 4 weeks after administration of all pneumococcal conjugate vaccine doses.
Modified from recommendations of the Advisory Committee on Immunization Practices.

public health importance of these differences is unknown, the greater persistence of group Y SBA in the MCV4-CRM group would be expected to translate into greater protection against capsular group Y strains, which account overall for nearly one-third of cases of meningococcal disease in the United States. Collectively, the antibody persistence data also indicate that for both vaccines, protective serum titers wane in immunized adolescents. Taken together with evidence of declining MCV4-DT vaccine efficacy over time in adolescents immunized in the United States with MCV4-DT, in 2010, the Advisory Committee on Immunization Practices (ACIP) recommended the addition of a booster dose of MCV4-DT or MCV4-CRM (Table 38.4; also see "Recommendations for the Use of Meningococcal Vaccines in the United States" below).[311] Similar findings have been reported among military personnel.[407]

Most MCV4-CRM use in the United States is currently targeted at adolescents and more recent data address persistence after a booster dose in adolescents immunized initially with either MCV4-DT or MCV-CRM. Two years after an MCV4-CRM booster, 77% to 100% of individuals had an hSBA of 1 : 8 or

greater.[408] Similarly, in a study conducted 3.5 years after a dose of MenACYW-TT (not yet FDA approved) all volunteers among a small group of adolescents maintained an rSBA of 1:8 or greater.[409]

Limited data are available on serum antibody persistence in younger children immunized with MCV4-DT. In one study, children 2 to 11 years old were given one dose of MCV4-DT or MPSV4 and were followed up for 6 months. Between 1 and 6 months, serum bactericidal titers declined in both vaccine groups, but titers waned more rapidly in the MPSV4 group.[309] When the 6-month follow-up serum samples were retested with human complement,[243] the results confirmed more rapid waning of immunity in the MPSV4 group. In a second study, serum samples were obtained at a mean interval of 2.4 years after MCV4-DT vaccination of 2-year-old children.[307] The proportions of MCV4-DT–vaccinated children with titers of 1:4 or greater (using human complement) were 15% (group A), 33% (group Y), and 45% (group W). The respective percentages for unvaccinated children were lower (2.5%, 15%, and 17.5%). In a separate analysis, serum group C antibody concentrations, which were measured by a binding assay, remained elevated for 2 to 3 years after MCV4-DT vaccination compared with unvaccinated children, but serum group C bactericidal titers of 1:4 or greater were infrequent in both groups (14.6% and 6.4%, respectively; $P = 0.3$).[259] In vaccinated children, some serum samples with bactericidal titers less than 1:4 conferred passive protective activity against group C bacteremia in the infant rat model. These results are difficult to interpret in the light of more recent studies showing that complement activation on *N. meningitidis* is not downregulated by rat fH because the molecule does not bind to meningococci.[277] Therefore, the bacteria are more easily cleared by antibodies interacting with rat complement than they would be with human complement and, therefore, the passive protection results in the rat bacteremia model in the absence of human fH are likely to overestimate protection compared with protection in humans.

At 5 years of age antibody had waned after three- or four-dose infant schedules with MCV4-CRM such that 9% to 69% had an hSBA of 1:8 or greater after three doses against the different stains, and 11% to 85% had an hSBA of 1:8 or greater after four doses, with the best responses being against W.[353] Antibody persistence was evaluated 5 years after immunization of 2- to 10-year-old children with MCV4-CRM, and about half were found to have maintained "protective" antibody levels for C, Y, and W, but persistence was poor for A.[410]

Among toddlers 12 to 23 months of age, MCV4-TT was highly immunogenic and noninferior to MenC-CRM with at least 90% of toddlers maintaining rSBA titers of 1:8 or greater 3 years after vaccination. However, in this study hSBA was also measured and shown to have waned markedly for capsular group A (only 21% maintained an hSBA of 1:4 or greater at 3 years of age).[411]

Persistence of antibody after Hib-MenC vaccine is discussed above under "Hib-MenC and Hib-MenCY."

Immunologic Memory Elicited by MCV4 Vaccines and Effect of Previous Administration of MPSV4 Vaccine

A booster dose of MCV4-DT given to adolescents 3 years after a primary MCV4-DT vaccination elicited higher groups C, Y, and W anticapsular antibody responses than in control subjects immunized with MCV4-DT for the first time (Fig. 38.13). In contrast, a dose of MCV4-DT vaccine given to adolescents who had previously been given a dose of MPSV4 vaccine elicited lower serum bactericidal antibody responses than in control adolescents immunized with MCV4-DT for the first time (Fig. 38.13). Although the impaired serum antibody response to group C was the most affected, polysaccharide-induced antibody hyporesponsiveness also was present to capsular groups A, Y, and W. Nevertheless, 100% of the subjects previously immunized with the polysaccharide vaccine who were immunized with MCV4-DT developed bactericidal titers of 1:128 or greater (using rabbit complement) to all four capsular groups, which should be sufficient for protection.

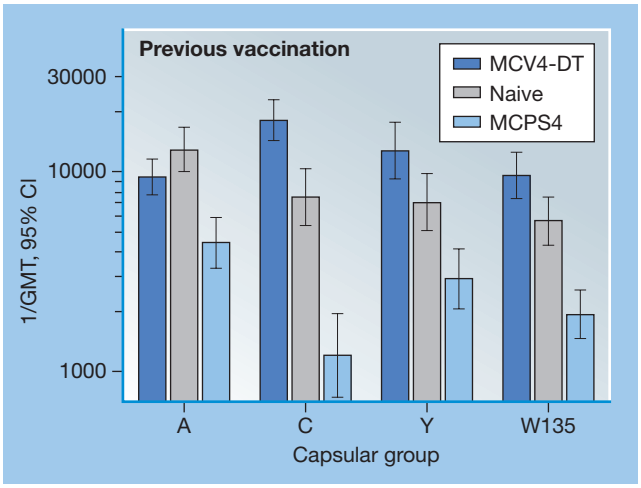

Figure 38.13. Serum bactericidal antibody titers of adolescents 8 days after a dose of quadrivalent meningococcal conjugate (MCV4-DT) vaccine in relation to previous vaccination. Three years earlier, the subjects had received a dose of MCV4-DT vaccine or quadrivalent meningococcal polysaccharide (MPSV4) vaccine as part of a randomized vaccine trial. A newly recruited control group of vaccine-naïve adolescents was given a dose of MCV4 vaccine. For capsular groups C, Y, and W135, the reciprocal serum geometric mean titers (GMTs) to the second dose of MCV4-DT were higher than those to a first dose given to the naïve subjects ($P < .05$; evidence of immunologic priming by the first injection). For all four capsular groups (A, C, Y, and W), the reciprocal serum GMTs to the dose of MCV4-DT vaccine in subjects previously vaccinated with MPSV4 were lower than those to a first dose of MCV4-DT given to the naïve subjects ($P < .05$; evidence of antibody hyporesponsiveness induced by the polysaccharide vaccine). CI, confidence interval. *(Data from Keyserling H, Papa T, Koranyi K, et al. Safety, immunogenicity, and immune memory of a novel meningococcal [groups A, C, Y, and W-135] polysaccharide diphtheria toxoid conjugate vaccine [MCV-4] in healthy adolescents.* Arch Pediatr Adolesc Med. *2005;159:907–913.)*

Adolescents previously immunized with MCV4-CRM mounted stronger responses to a booster of MCV4-CRM than was observed in both naïve individuals and those previously immunized with a quadrivalent polysaccaharide vaccine, which indicated an anamnestic response.[412]

Immunologic memory was assessed in infants immunized with MCV4-CRM vaccine by administration of a decreased dose of MPSV4 at 12 months of age. The infants had been immunized at 2 and 4 months or at 2, 4, and 6 months.[396] The percentages of the children responding with fourfold increases in human complement serum bactericidal titers to the polysaccharide probe at 12 months ranged from 65% (group C) to 95% (groups W and Y). These response rates are substantially higher than those of immunologically naïve historical control subjects who showed minimal or no detectable bactericidal responses when immunized with a dose of polysaccharide vaccine at 1 to 2 years of age.

Rationale for Two-Dose Primary Series in Certain High-Risk Groups

In the United States, a single dose of MCV4-DT or MCV4-CRM was considered sufficient for eliciting protective antibody responses in persons 2 years or older. Recently, for certain patient populations with increased risk of meningococcal disease, a two-dose primary schedule was recommended (see "Recommendations for the Use of Meningococcal Conjugate Vaccines in the United States" below). The rationale for this recommendation is that (1) persons with certain underlying medical conditions respond suboptimally to meningococcal vaccines and (2) there is evidence that a two-dose primary vaccination series given 2 months apart increases the antibody response. Also, although persons with deficiency of late complement components are reported to respond as well to MPSV4 as persons without such deficiencies, serum antibody titers wane more rapidly in complement-deficient patients.[413,414]

In one study of asplenic patients, approximately 20% did not achieve putative protective bactericidal antibody responses following a single dose of one of three group C meningococcal conjugate vaccines, and their GMTs were nearly 10-fold lower than in control subjects without asplenia (158 vs 1448).[415] Patients with a congenital or functional reason for asplenia had lower antibody responses than did patients with asplenia as a result of trauma. Among 23 persons who did not achieve a bactericidal antibody titer of 1:16 (using rabbit complement) or greater after the first dose, 61% achieved a titer of 1:16 or more after a second dose. These data suggest that a two-dose series would provide protection superior to a one-dose series.

In a study of meningococcal conjugate vaccination in adolescents with HIV infection, 86%, 55%, 73%, and 72% of patients had serum bactericidal titers of 1:128 or greater (using rabbit complement), respectively, for capsular groups A, C, Y, and W after one dose of MCV4-DT.[416] Lower $CD4^+$ lymphocyte percentages and higher HIV viral loads were independently associated with a poorer response to immunization.[417]

Postlicensure MCV4-DT Effectiveness

In 2014, MCV4-DT vaccine coverage among U.S. 13- to 17-year-olds was estimated to be 79%, although with a great deal of regional variation.[418] The small numbers of cases from the historically low rates of meningococcal disease in the United States have made it challenging to establish the effectiveness of MCV4-DT. However, several recent studies using different approaches have provided a picture of the effectiveness of this vaccine. In one study, surveillance for MCV4-DT vaccine failures was conducted and vaccine effectiveness was modeled based on the expected number of vaccine failures and estimates of MCV4-DT coverage.[419] This analysis suggested a vaccine effectiveness of 80% to 85% within 3 to 4 years after vaccination, which is similar to that expected for meningococcal polysaccharide vaccine. In a case-control vaccine effectiveness study, overall vaccine effectiveness (all capsular groups) for 0 to 8 years postvaccination was estimated to be 69% (95% CI, 51–80%). Over time, there was evidence for waning of effectiveness with estimates of 79% (49–91%) during the first year after vaccination, 69% (44–83%) at 1 to less than 3 years, and 61% (25–79%) at 3 to less than 8 years.[419a] These results are consistent with waning serum bactericidal titers and supported the addition of a booster dose (see earlier discussion and Fig. 38.12).

Based on active surveillance of meningococcal disease in regions of the United States with 13% of the overall population (ABCs[420]), the incidence of IMD among 11- to 17-year-olds caused by capsular group C, Y, or W strains fell from 0.37 per 100,000 population during 2006 to rates of less than 0.1 cases per 100,000 population in 2013. Rates have changed little in other age groups (Fig. 38.14).

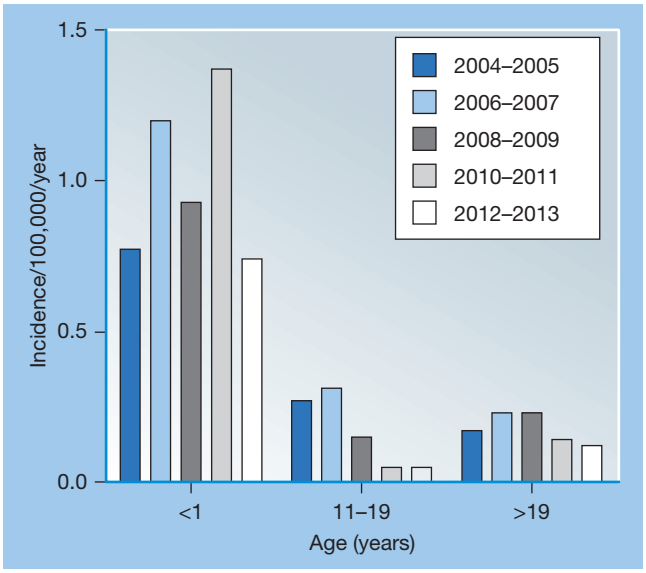

Figure 38.14. Incidence of capsular groups C, Y, and W meningococcal disease in the United States, from 2004–2013 by age group.

Although attribution of causality is not possible in this ecological analysis, these data, in combination with the vaccine effectiveness data, suggest a selective effect of MCV4-DT on the immunized population and a lack of substantial herd protection in the unvaccinated population, although this may be because the coverage was low initially. In addition, there are no data on the impact of MCV4-DT on pharyngeal carriage of vaccine capsular groups. No postlicensure effectiveness data are available for MCV4-CRM because it was licensed in the United States in 2010 and follow-up has been too brief. However, use of quadrivalent conjugate vaccines in Latin America and the United Kingdom to control recent outbreaks of ST-11 capsular group W disease will likely provide evidence in due course.

MCV4-DT and MCV4-CRM provide capsular group–specific coverage, which does not include capsular group B strains. One concern about widespread use of vaccines that do not cover all disease-causing strains is the possibility of capsular switching and subsequent clonal expansion from a virulent vaccine-capsular group strain (i.e., group C, Y, or W) to a nonvaccine capsular group strain (i.e., group B). To assess the meningococcal population structure in the United States before licensure of MCV4-DT in 2005, a study was performed on isolates from 2000 to 2005 from Active Bacterial Core surveillance (ABCs) sites throughout the United States.[51] Of 1160 isolates included in the study, 1.5% of group B, 12.9% of group C, and 0.9% of group Y isolates showed evidence of capsular switching. For example, there were one and four isolates, respectively, that expressed capsular group B polysaccharide and belonged to sequence type 11 or 103, which are both hypervirulent meningococcal lineages that typically express group C capsules.[51] An update to this study in 2015 found no new evidence of vaccine driven changes in the population.[181] It is noteworthy that although a group B vaccine was not introduced in the United States until 2015, the incidence of capsular group B disease in the United States has fallen dramatically since the 1990s.

Safety of MCV4 Vaccines

In prelicensure studies, MCV4-DT was administered to approximately 7000 persons. Vaccination was safe and well tolerated.[310,384] In randomized studies, fever (temperature, ≥38°C) was more common after MCV4-DT than MPSV4 (5.1% vs 3.0%, respectively, in immunized adolescents; and 1.5% vs 0.5% in adults). Fewer than 5% of subjects vaccinated with MCV4-DT or MPSV4 experienced serious systemic reactions (defined as high fever; headache, fatigue, malaise, chills, or arthralgia requiring bed rest; or anorexia [missing three meals]; three or more episodes of vomiting; five or more episodes of diarrhea; or the presence of rash or seizures). The respective rates of serious reactions in the MCV4-DT group met predetermined noninferiority criteria as compared with the respective rates observed in the MPSV4 vaccine group.

The prelicensure MCV4-DT studies also showed that local reactions were more common than with MPSV4, which likely reflected the presence of diphtheria toxoid as the carrier protein in the conjugate vaccine. Thus, 16.7% of adolescents given MCV4-DT and 3.9% of the MPSV4 group reported moderate pain at the injection site,[310] and 2.5% and 0.7%, respectively, reported moderate swelling. Severe pain (unable to move arm) occurred in 0.7% of the MCV4-DT group and 0% of the MPSV4 group, while severe swelling at the injection site (>2 inches) was reported by 0.7% and 0%, respectively. These local reactions generally resolved within 48 to 72 hours. The frequencies of local reactions in MCV4-DT–vaccinated adolescents were similar to those observed in this age group after Td (diphtheria and tetanus toxoids–adult) vaccination. The respective rates of local reactions in MCV4-DT–immunized adults were lower than in adolescents and similar to those observed after typhoid vaccination of adults.

In prelicensure studies, the safety and tolerability of MCV4-CRM were compared with those of MCV4-DT. In 2- to 5-year-olds, the respective rates of local reactions were similar for the two vaccines (e.g., 27% vs 25% for erythema and 33% vs 35% for pain, respectively).[393] Rates of systemic reactions were also similar (e.g., 21% vs 22%, respectively, for irritability). In the same study, there were also no substantial differences for the two vaccines in adverse reactions for 6- to 10-year-olds. In a separate study, tolerability in 11- to 18-year-olds was similar for MCV4-DT and MCV4-CRM, with, for example, 70% and 64% of subjects, respectively, reporting mild to moderate solicited reactions.[395] Tolerability of a single dose of MCV4-CRM or MPSV4 also was similar, with reported local reactions, respectively, in 63% to 71% vs 60% to 62%, and systemic in 44% to 56% vs 46% to 59%.[421]

Soon after MCV4-DT licensure in 2005, cases of GBS with onset 2 to 4 weeks after MCV4-DT vaccination were reported to the Vaccine Adverse Event Reporting System (VAERS).[422] An increased rate of GBS was not observed after vaccination with MPSV4 or diphtheria toxoids, the two principal components of MCV4-DT nor with other conjugate vaccines. Several studies conducted to clarify the association between MCV4-DT vaccination and GBS were done. A review of Vaccine Safety Datalink data revealed no GBS cases following 889,684 MCV4-DT doses. The statistical power, however, of this study alone to measure increased risk, if any, was limited. Another study was conducted to estimate the risk of GBS during the 6 weeks following MCV4-DT vaccination as compared with vaccinees at other times and in persons who had not received MCV4-DT.[423] Five health plans with a total membership of approximately 50 million persons participated. GBS cases were identified through claims data and confirmed through a review of medical records. There were 99 GBS cases confirmed and more than 1.4 million MCV4-DT immunizations observed, but no GBS cases occurred within 6 weeks following MCV4-DT immunization. The 95% upper confidence limit was 1.5 cases per million MCV4-DT doses. Taken together, these studies do not support an increased risk of GBS from MCV4-DT immunization. Based on these data, on June 23, 2010, the ACIP removed the precautionary language about the risk of GBS and this vaccine and no new safety concerns have arisen since.

Safety data have been developed during the licensure of MCV4-CRM and do not identify any unexpected adverse events signals from the trials. One study involving more than 7700 infants found that safety of MCV4-CRM is noninferior to routine vaccines after adjusting for study center.[424]

RECOMMENDATIONS FOR THE USE OF MENINGOCOCCAL CONJUGATE VACCINES IN THE UNITED STATES

The ACIP has published its recommendations on the use of meningococcal conjugate vaccines.[425–427a] Conjugate vaccines are preferred over unconjugated polysaccharide vaccines because conjugate vaccines are at least equivalent or more immunogenic than polysaccharide vaccines, can be used from early infancy, and prime for booster antibody responses. In addition, although not documented for meningococcal conjugate vaccines licensed in the United States, conjugate vaccines in general and capsular groups C and A meningococcal conjugate vaccines specifically induce herd protection through decreased pharyngeal carriage. In contrast, the meningococcal polysaccharide vaccines have minimal effect on carriage and induce antibody hyporesponsiveness to a subsequent injection. The reason conjugate vaccines, but not polysaccharide vaccines, have a substantial effect in decreasing meningococcal carriage is that the T-cell help associated with conjugate vaccines leads to higher levels of antibody that have higher avidity than those associated with polysaccharide vaccines. Therefore, except for certain circumstances, such as for those age 55 years or older for whom there are insufficient data on the use of meningococcal conjugate vaccines, a conjugate vaccine is preferred over an unconjugated polysaccharide vaccine. That said, off-label use of meningococcal conjugate vaccines could be considered for persons 55 years of age and older.

Routine Immunization

ACIP recommends routine immunization for all persons 11- to 18-years-old with MCV4-DT or MCV4-CRM, with a preference for beginning immunization at 11 to 12 years of age (see Table 38.4). For children immunized at 11 to 12 years of age, a booster dose is recommended at age 16 years (at least 3 years later). Only a single dose is recommended for those older than 16 years of age and routine vaccination is not recommended for those older than 19 years of age. This recommendation is based on an increased risk of meningococcal disease in adolescence and, as described, evidence for waning serum antibody levels and vaccine effectiveness over time.[427] Routine vaccination is not recommended for other ages in the United States.

MCV4-CRM and Hib-MenCY are approved by the FDA for use in infants as young as 6 to 8 weeks of age. However, as of September 2015, these vaccines were not recommended by the ACIP for routine immunization before age 11 years although the incidence of disease in children younger than age 1 year is more than sevenfold higher than in adolescents (Fig. 38.15).

The reasons the ACIP does not recommend routine vaccination with MCV4 beginning at 2 months of age include low

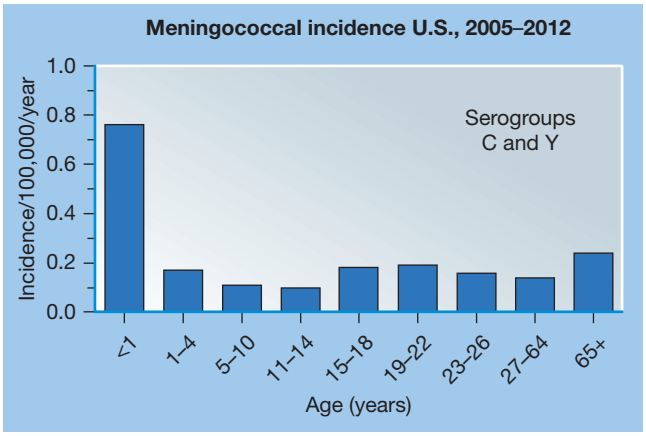

Figure 38.15. Incidence of meningococcal disease in the United States, from 2005 to 2012 by age group. *(From Centers for Disease Control and Prevention. Advisory Committee on Immunization Practices Meeting, October 2014.)*

disease burden, the majority of infant disease is caused by capsular group B strains, the high price of the vaccine, and concerns that additional injections would be unacceptable in an already overcrowded and complex infant and toddler vaccination schedule.[428]

Groups at Increased Risk of Disease, Ages 2 Months to 55 Years

Ages 2 Months to 23 Months

A four-dose course of MCV4-CRM is recommended at 2, 4, 6, and 12 months of age for infants known to be at increased risk of meningococcal disease.[426] MCV4-CRM is the only quadrivalent vaccine licensed for infants younger than 9 months of age and so infants who fall into a risk group at ages 7 to 23 months should have a two-dose course of MCV4-CRM (second dose given when infant is older than 12 months of age and at least 3 months after the first dose). MCV4-DT also can be used as an alternative for infants older than 9 months of age.

If MCV4-DT or MCV4-CRM or Hib-MenCY have been used to initiate immunization at 2 to 13 months of age, the first booster should be given 3 years later with a quadrivalent vaccine and subsequent boosters every 5 years.

Infants and toddlers with functional or anatomic asplenia should receive MCV4-CRM or wait until 2 years of age and receive MCV4-DT as MCV4-DT may interfere with PCV13-CRM responses.

Ages 24 Months to 55 Years

A two-dose primary course of MC4-DT or MCV4-CRM (8 weeks apart) is recommended for individuals with complement deficiency, or functional or anatomic asplenia, and for individuals with HIV infection who have one of the other indications for immunization (i.e., not routinely recommended in HIV infection). A single dose of MCV4 is recommended for travelers to regions with epidemic or hyperendemic meningococcal disease, college freshmen living in dormitories (younger than 22 years of age), microbiologists with routine exposure to *N. meningitidis,* and during an outbreak. For those at ongoing risk of disease, initial booster doses are recommended after 3 years of age among those younger than 7 years of age and at 5 years for children aged 7 and older and adults. Further boosters are recommended every 5 years.

Persons Age 55 Years or Older

There are no data available on the use of quadrivalent meningococcal conjugate vaccines in the 55-years-or-older age group. When meningococcal vaccination is indicated for persons 55 years of age or older, the ACIP recommends MPSV4, although the immunological advantages of MCV4 make this advice appear rather conservative. If the polysaccharide vaccine is not available or repeated vaccine doses are likely to be required as a result of ongoing risk, ACIP agrees that off-label use of one of the conjugate vaccines could be considered.

Mass Vaccination Programs to Control Outbreaks

Outbreaks of meningococcal disease can occur in institutions and communities. An outbreak has been defined by the CDC as the occurrence of three or more cases in less than 3 months resulting in a primary disease attack rate of at least 10 cases per 100,000 population in persons who have a common affiliation or who live in the same area but have no close contact.[5] Either of the quadrivalent meningococcal vaccines (MCV4-DT, from age 9 months, or MCV4-CRM, ages 2 months to 55 years) can be used for control of outbreaks caused by a strain with a vaccine-preventable capsular group.[384] For the aforementioned reasons, one of the conjugate vaccines is preferred.

Precautions and Contraindications

No clinically important adverse effects have been documented among women vaccinated with MCV4 during pregnancy or their newborns. Therefore, MCV4 can be administered during pregnancy, if indicated.[427,433–435] Meningococcal vaccines can be administered during a minor acute illness, including in the presence of low-grade fever but deferred in those with a moderate to severe illness. Meningococcal conjugate vaccines can be safely admininistered to the immunocompromised. All vaccines are contraindicated in persons with known hypersensitivity to any vaccine component.

The use of meningococcal conjugate vaccines in adolescents has occurred in the context of the addition of other vaccines in this population, including acellular pertussis, human papillomavirus, and influenza vaccines.[416,436,437] Coadministration of MCV4-DT vaccine with diphtheria combined with tetanus toxoid (dT) in adolescents and with typhoid vaccine (Vi polysaccharide) in adults is safe and immunogenic. Coadministration of MCV4-CRM with human papillomavirus vaccine and tetanus, diphtheria, and pertussis (Tdap) in adolescents also is safe and immunogenic, as is coadministration with measles-mumps-rubella-varicella (MMRV) in toddlers.[394,438,439] Studies in infants have also shown that MCV4-CRM is safe and immunogenic when given with routinely administered vaccines in Europe. In general, polysaccharide-protein vaccines can be safely and effectively coadministered with live attenuated viral vaccines or purified subcomponent vaccines. Given the risk of syncope after immunization, particularly in adolescents,[440] the ACIP recommends observation of patients for 15 minutes after vaccine administration.[441]

Hib-MenCY has been studied concomitantly with routine infant immunizations including DTaP-HepB-IPV and pneumococcal conjugate vaccine in infants and with measles, mumps, rubella (MMR), and pneumococcal conjugate vaccine among toddlers and has an acceptable profile.[442,443]

MENINGOCOCCAL VACCINES IN CANADA

There are currently two meningococcal polysaccharide vaccines (MPSV4 and MPSV2 [capsular groups A and C], both

called Menomune) licensed in Canada, and five meningococcal conjugate vaccines[444]: the conjugate products are MCV4-DT and MCV4-CRM, and three monovalent group C conjugate vaccines (P-MenC-CRM, G-MenC-CRM, and MenC-TT; see earlier section). In 2001, the Canadian National Advisory Committee on Immunization (NACI) recommended routine group C meningococcal conjugate vaccine for infants, children through 4 years of age, and adolescents and young adults.[159,445] In 2010, the NACI recommended the use of quadrivalent conjugate vaccine in place of monovalent group C conjugate vaccines in early adolescence. In addition, the NACI recommends the use of quadrivalent conjugate vaccine for persons 2 to 55 years of age who are at high risk. The NACI is an advisory organization, and immunization policy in Canada is made at the provincial level. For example, as of June 2011, Alberta recommended routine vaccination with three doses of a monovalent MenC conjugate vaccine at 2, 4, and 12 months; British Columbia recommended two doses at 2 and 12 months; and Ontario, Saskatchewan, and Quebec recommended one dose at 12 months. The diverse group of schedules used in Canada is available online.[444]

All provinces recommend a booster dose of C conjugate vaccine in adolescence but in some provinces this is administered as MCV4 and in others as a monovalent vaccine; the age of administration varies also.

MENINGOCOCCAL CONJUGATE VACCINE POLICY IN EUROPE

Between 1999 and 2006, in response to relatively high endemic rates of meningococcal C disease, multiple European countries (Belgium, Iceland, Ireland, The Netherlands, Spain, and the United Kingdom) introduced meningococcal C conjugate vaccines as part of national immunization programs. The initial regimen in the United Kingdom included immunization of infants beginning at 2, 3, and 4 months of age. Because vaccine effectiveness fell substantially after 1 year among infants immunized with this regimen, the UK vaccination schedule was changed in 2006 to include a booster dose at 12 months of age (3, 4, and 12 months of age). The 4-month dose was dropped in 2013 and replaced by a booster of MenC for adolescents to sustain herd immunity. The latter was changed to MCV4 in 2015 and the 3-month dose of MenC was dropped in 2016 so that the final schedule starts at 12 months of age (as Hib-MenC-TT) followed by MCV4 in adolescence (see below).

In several European countries where the incidence of meningococcal disease remained low and stable during the 1999 to 2006 period (≈0.2 per 100,000 population),[446] routine vaccination with meningococcal C conjugate was not initially implemented but has now become routine (Germany, Portugal, and Switzerland in 2006, and France in 2009; Table 38.5). Although waning serum bactericidal antibody titers have been observed after immunization,[349,352,373] vaccine effectiveness remains high,[188,314] although, as in the United Kingdom, an adolescent booster to maintain vaccine effectiveness is being considered or has been introduced in a number of countries either as the monovalent C conjugate or the quadrivalent product.

MCV4-CRM and MCV4-TT are both licensed in Europe but because of the low incidence of meningococcal disease in the region attributable to strains with capsular group A, W, or Y, recommendations for use of the quadrivalent conjugate vaccine in Europe are limited. In response to a marked increase in the number of cases of group W disease in the United Kingdom, a routine one-dose adolescent program of MCV4 was introduced in 2015 with catch-up for adolescents 14 to 18 years of age.

A MENINGOCOCCAL CAPSULAR GROUP A CONJUGATE VACCINE FOR AFRICA

Up to 2010, the only meningococcal vaccines available in sub-Saharan Africa were a bivalent groups A and C and a trivalent groups A, C, and W polysaccharide vaccine (MPSV2 and MPSV3). These vaccines are poorly immunogenic in infants, the age group at greatest risk of acquiring disease, and have only a transient effect, if any, on colonization and spread of

TABLE 38.5 Meningococcal Vaccine Policy in Selected European Countries[a]

Country	Current Vaccination Schedule	Initial MenC Catch-Up
Austria	MenC at 12–14 mo and MCV4 at 12 y	
Belgium	MenC at 15 mo	1–5 y/1–18 y; regional variation
Czech Republic	MenB vaccine in 3 doses at 2–5 mo with a booster at 12 mo. Two doses of MenB at 13–15 y. One dose of MCV4 at 1–2 y and at 13–15 y	
France	MenC at 12–24 mo	Catch-up to 24 y
Germany	MenC at between 12 and 24 mo	Recommended for unvaccinated through age 17 y
Greece	MenC at 2, 4, and 15–18 mo and MCV4 at 11 y	
Iceland	MenC at 6 and 8 mo	Through 20 y
Italy	MenC at 12–15 mo	
Ireland	MenC at 4 and 12 mo and 12–13 y	Through 23 y
Netherlands	MenC at 14 mo	1 through 19 y
Portugal	MenC at 12 mo	Through 18 y
Spain	MenC at 2 and 12 mo and 12 y	<6 y; regional variation
United Kingdom	MenC at 12 mo and MCV4 at 13/14 y. MenB at 2, 4, and 12 mo	In 1999 MenC <18 y; expanded to 24 y. MCV4 catch up 14–18 y initiated in 2015

[a]MenC conjugate vaccines are recommended for routine use in various countries in Europe and Hib-MenC is used at 12 months of age in the United Kingdom. MenB and MCV4 is now recommended in the United Kingdom and is under consideration elsewhere. See http://vaccine-schedule.ecdc.europa.eu/Pages/Scheduler.aspx and http://www.szu.cz/uploads/IMO/Recommendation_for_vaccination_IMD.pdf

infection. For these reasons, meningococcal vaccination in Africa was largely done in response to epidemics, which was a logistically challenging and relatively ineffective strategy. Although an emergency response plan had been developed in collaboration with the WHO and the CDC,[314] implementation was often delayed because of limitations of surveillance or logistics. One study estimated that even under optimal circumstances, fewer than 60% of outbreak-related cases were prevented by implementing vaccination after an epidemic was recognized.[314] An improved meningococcal vaccine, therefore, was needed.

In sub-Saharan Africa, most meningococcal epidemics are caused by capsular group A strains. By the late 1990s, three vaccine manufacturers had developed capsular group C meningococcal conjugate vaccines for the United Kingdom, where there had been approximately 10,000 cases of disease caused by group C organisms and 1000 deaths during the previous decade.[315] There was little commercial interest in developing a group A meningococcal conjugate vaccine for sub-Saharan Africa, where there had been more than 700,000 cases and 100,000 deaths in the same decade.[3] The countries in this region remain some of the poorest in the world and could not afford to purchase the vaccine.

In 1999, the WHO funded a feasibility study to explore options to develop and manufacture a group A conjugate vaccine that could be sold in Africa for less than US$0.50 a dose.[316,317] The results from this study formed the basis of a successful grant application to the Bill and Melinda Gates Foundation, which in 2001 awarded $70 million to the WHO and the Program for Appropriate Technology in Health to develop a meningococcal group A conjugate vaccine with the goal of eliminating group A epidemics in Africa.[316] While there were concerns at the time about the potential for epidemics caused by capsular group W strains,[225,318–320] in the previous 100 years, more than 90% of epidemic meningococcal disease in sub-Saharan Africa had been caused by capsular group A strains. The dominance of group A disease and the greater technical challenges, higher cost, and extended timelines for developing a bivalent capsular groups A and W conjugate vaccine made development of a monovalent group A vaccine more feasible as a first step.

A novel conjugation chemistry using reductive amination of group A polysaccharide aldehydes and tetanus toxoid hydrazides was developed by scientists at the FDA's Center for Biologics Evaluation and Research.[321] The process was transferred to the Serum Institute, a vaccine manufacturer in India.[322] Extensive testing of the vaccine in sub-Saharan Africa provided assurance of safety, immunogenicity, and manufacturing consistency.[323] In 2010, marketing authorization for MenAfriVac (MenA-TT conjugate vaccine) was granted by the Food and Drug Administration of India for the export of the vaccine to African countries. Mass vaccination of 1- to 29-year-olds was introduced in December 2010, as part of countrywide demonstration projects in Burkina Faso, Mali, and Niger.[324] More than 217 million people ages 1 through 29 years had received MenA-TT vaccine (containing 10 μg MenA polysaccharide) in 17 countries in the African meningitis belt by 2015.[325] It is hoped that high coverage in this age group will lead to herd protection of unvaccinated children younger than 1 year of age and elimination of epidemics of meningococcal A disease. MenA-TT led to a dramatic decline in group A carriage in African villages, suggesting that herd protection with this vaccine will be substantial.[326] Once the mass vaccination campaigns are completed, the concern will be to protect subsequent birth cohorts throughout infancy. Two strategies are recommended, one for countries where MenA coverage is high and another where MenA coverage is low (<60%).[328] In high-coverage countries, vaccination should be administered as a single dose at 9 to 18 months of age. A lower dose vaccine (5 μg of MenA polysaccharide) is available for children younger than 2 years of age. In low-coverage countries, periodic single-dose campaigns are recommended.

A major problem that has occurred since the widespread use of a capsular group A conjugate vaccine is the emergence of disease caused by strains with other capsular groups such as C, W, or X.[225,318,329–331] Currently there is no vaccine available for prevention of group X disease, which is extremely rare in North America and Europe.[332] For prevention of group C and W disease, tetravalent (A, C, Y, and W) conjugate vaccines are available in industrialized countries (see earlier discussion), but these vaccines are expensive and not available in sub-Saharan Africa. A trivalent MPSV3 vaccine is available for Africa and kept in reserve by the WHO for response to capsular groups C and W epidemics, but this vaccination strategy has many limitations, as described. Work is currently underway to produce a low-cost pentavalent MenACWXY conjugate vaccine that could (potentially) replace the monovalent vaccine.

Acknowledgments

This chapter incorporates some material written by Martha Lepow, Bradly Perkins, Patricia Hughes, and Jan Poolman, authors of the chapter on meningococcal vaccines that appeared in the third edition of *Vaccines;* Ian Feavers, an author of the chapter that appeared in the fourth edition; Ray Borrow, an author of the chapter that appeared in the fifth edition; and Steve Pelton, an author of the chapter that appeared in the sixth edition.

The work was supported in part by grants R01 AI046464 and R01 AI114701 (D.M.G.) from the National Institute of Allergy and Infectious Diseases, National Institutes of Health (NIH).

39 Meningococcal Capsular Group B Vaccines

Dan M. Granoff, Andrew J. Pollard, and Lee H. Harrison

The modes of transmission, bacteriology, pathogenesis, diagnosis, and treatment of capsular group B meningococcal disease are indistinguishable from meningococcal disease caused by other capsular groups and are discussed in Chapter 38. As described below, the conjugate vaccine approach proved problematic against capsular group B strains because the capsular polysaccharide is an auto-antigen and poorly immunogenic. The protein antigens used in the new capsular group B vaccines are novel and have immunogenic properties and underlying mechanisms that are different from those associated with polysaccharide antigens. Therefore, the vaccines targeting capsular group B strains are described separately in this chapter.

The different capsular polysaccharides expressed by meningococci have traditionally been defined serologically and referred to as "serogroups." More recently, DNA sequencing of specific genes involved in capsular synthesis is replacing serologic methods to define an isolate's capsular polysaccharide.[1–3] Therefore the term "serogroup" no longer seems apt for describing an isolate's polysaccharide capsule. This chapter replaces the term "serogroup B" with "capsular group B" or, simply "group B."

CAPSULAR B DISEASE BURDEN

Capsular B disease accounts for up to 90% of sporadic meningococcal cases in certain European countries that have successful capsular group C vaccine programs in place, and approximately a third of cases in the United States in 2013.[4] Compared with group A epidemics, capsular group B epidemics generally begin more slowly, are associated with lower rates of disease, and are more prolonged, at times lasting a decade or longer. Group B epidemic disease also is associated with the emergence of hypervirulent strains.

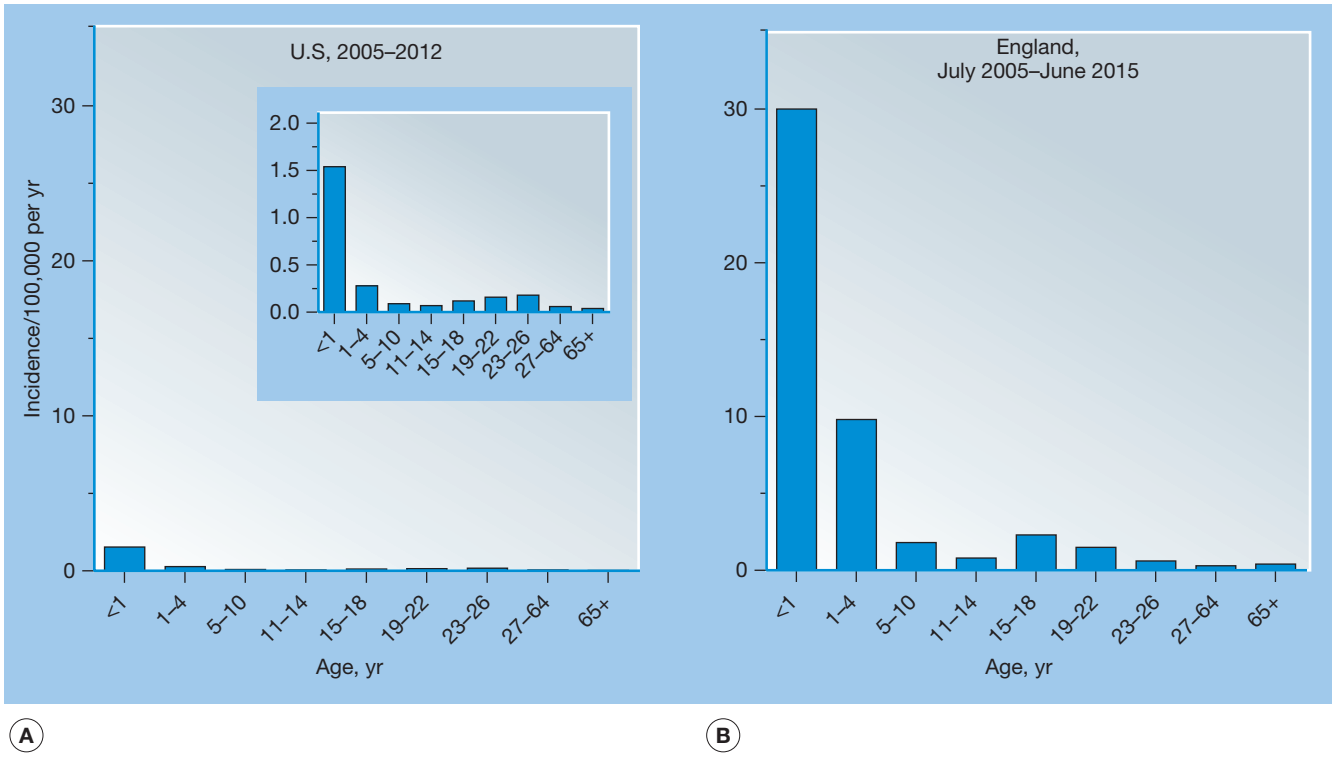
As described in Chapter 38, meningococci are classified by multilocus sequence types (ST) and capsular group, serotype (PorB), and serosubtype (PorA). The nomenclature lists the capsular group, PorB serotype, and PorA serosubtype, each separated by a colon (e.g., B:4:P1.7,4). The VR1 (loop 2) and VR2 (loop 4) encoded epitopes of PorA are given in order after the prefix P1.x, separated from one another by a comma. For example, in the 1970s, an increase in the incidence of disease caused by ST-32 group B strains was noted in Norway (B:15:P1.7,16) and in Spain (B:4:P1.19,15).[5] In the 1980s, a severe epidemic in Cuba was also caused by ST-32 group B strains (B:4:P1.19,15), which spread to São Paulo, Brazil, in the late 1980s.[5] Group B meningococci strains from this genetic complex became established in Canada in the 1990s, and substantial increases in incidence also were noted in the United States in Oregon and Washington State (B:15:P1.7,16).[6] The incidence of disease in Oregon caused by this outbreak peaked in the 1994–96 period, but the clone of meningococcus responsible has remained an important cause of disease.[7,8] Interestingly, the Oregon clone caused disease across the United States, but only Oregon was associated with a substantial increase in disease rates.[9]

New Zealand experienced an epidemic of group B meningococcal disease that started in 1991.[10] The epidemic was caused by a strain identified as B:4:P1.7-2,4, ST-41/44 complex.[11] A strain-specific outer membrane vesicle (OMV) vaccine, described below, was developed and introduced in July 2004 for mass immunization in New Zealand,[12–15] which ultimately contributed to control of the epidemic.[16]

Over the past few years, the epidemiology of college-associated outbreaks has changed in the United States. Before the routine use of quadrivalent meningococcal vaccines in adolescents, most outbreaks in institutions of higher learning were caused by capsular group C strains, but are now predominantly caused by a diverse assortment of group B strains (Table 39.1). From 2008–16, there were at least 10 group B outbreaks on college campuses, ranging in size from two to 13 cases.[17–22] Immunization campaigns with one or both of the recently licensed group B vaccines were conducted in response to the recent outbreaks.

One of the most important epidemiologic features of group B meningococcal disease is that it is the predominant cause of disease in infants.[23] A second important feature is that for reasons that are not known, incidence rates of endemic group B disease in different countries can vary; for example, they are approximately 20-fold higher in infants in England than in the United States (Fig. 39.1). The recent licensure in Europe and elsewhere of a capsular group B vaccine for infants means that disease in infants is now potentially vaccine preventable. In the United States, however, the two licensed group B vaccines are only approved for the age group 10 to 25 years.[19] Currently, the only infant vaccine under development for prevention of infant group B disease in the United States is a pentavalent vaccine for capsular groups A, B, C, W, and Y,[24–26] which is unlikely to be available for several years.

HISTORY OF GROUP B VACCINE DEVELOPMENT



The group B polysaccharide capsule cross-reacts with sialylated proteins present on human tissues.[27] The polysaccharide also is a poor immunogen, even when conjugated to a protein carrier.[28] Also, there are potential safety concerns for a vaccine that elicits high serum titers of autoreactive antibodies to the group B polysaccharide. These concerns prompted investigators to investigate the potential of noncapsular antigens, particularly outer membrane proteins.[29,30] The idea that noncapsular antigens could be sufficiently exposed on the surface of encapsulated meningococci to be accessible to protective antibodies was at first controversial.

Compelling data showing that protein antigens could elicit protective antibodies came from pioneering studies with OMV vaccines, which were developed by several groups more than 25 years ago.[31–33] The OMVs were treated with detergents to extract lipooligosaccharide and decrease endotoxin activity. The OMV vaccines appeared to be safe and efficacious.[34] The initial OMV studies used two doses of vaccine, which were sufficient to elicit serum bactericidal antibody antibodies and protect older children and adults.[31] However, a case-control study done in Brazil in the early 1990s found no efficacy in infants younger than 24 months,[35] which for nearly a decade dampened enthusiasm for the OMV vaccine approach. A seminal finding was the publication by Tappero and colleagues in 1999 demonstrating that three doses of OMV vaccines elicited serum bactericidal antibody responses in infants

Age incidence of meningococcal capsular group B disease in the (A) United States, 2005–12, and (B) England, July 2005 to June 2016. *(U.S. data are from the Centers for Disease Control and Prevention, adapted from a presentation at the U.S. Advisory Committee on Immunization Practice (J. MacNeill), October 30, 2014. Data from England are from Public Health, England.)*

younger than 1 year.[36] This finding set the stage for developing protein antigen vaccines for the age group with the highest incidence of disease.

One limitation of OMV vaccines, however, is that serum bactericidal antibody responses of infants are largely directed against the porin protein, PorA,[36] which is antigenically variable.[37] OMV vaccines, therefore, were tailor made and mainly used to control group B epidemics caused by a predominant strain. Subsequent efforts to broaden protection used OMV vaccines prepared from more than one strain[38] or from mutants expressing more than one PorA type.[39–41] While these vaccines elicited serum bactericidal antibody responses in human infants, certain PorA types were poorly immunogenic.[42] Furthermore, in the United States endemic meningococcal disease is caused by genetically diverse strains with more than 20 PorA variable region types. These factors and the discovery of more promising recombinant protein antigen approaches beginning in 2000[29] eventually led to

discontinuation of most efforts to license detergent-treated OMV vaccines as standalone meningococcal capsular group B vaccines for prevention of endemic disease. However, as described below, an OMV is one component of one of the recently licensed group B vaccines. A key lesson from the OMV vaccine trials was that a vaccine based on protein antigens could prevent disease caused by encapsulated meningococci and that a correlate of group B vaccine efficacy was serum bactericidal activity.[43,44]

The 1990s witnessed the discovery of several promising recombinant meningococcal protein vaccines capable of eliciting broad serum bactericidal antibody responses in mice.[34] These included Neisserial surface protein A (NspA)[30,45,46] and a transferrin-binding protein (TbpB).[47–49] However, in Phase I clinical trials these recombinant protein vaccines failed to elicit serum bactericidal antibody responses in humans.[50,51] NspA was subsequently shown to specifically bind human complement factor H (FH),[52] and TbpB was known to bind specifically to human transferrin.[53] The lack of serum bactericidal antibody responses to these vaccines in humans may have resulted in part from binding of the vaccine antigens to host proteins. For example, human FH transgenic mice immunized with NspA vaccines that bound human FH had lower serum bactericidal antibody responses than wild-type mice whose mouse FH did not bind to NspA.[54] Also, pigs immunized with a mutant *Haemophilus parasuis* TbpB vaccine with decreased binding to porcine transferrin elicited higher T- and B-cell responses and provided greater protection from infection than a native TbpB vaccine that bound porcine transferrin.[55] As described below, there also are data from human FH transgenic mice[56–60] and infant primate models[61–63] that show binding of human FH to Factor H binding protein (FHbp, an antigen in both licensed group B vaccines; see below) impairs protective antibody responses. Collectively the data indicate that binding of a host protein to a vaccine antigen can decrease protective antibody responses.

In 2000, the first full DNA sequence of a meningococcal genome was described[64] and was used to identify a large number of new meningococcal protein antigen vaccine candidates.[29] In the subsequent decade, Novartis Vaccines (now GSK) used three of the antigens in combination with an OMV derived from the New Zealand outbreak strain to develop a group B vaccine (Bexsero). Because the vaccine contains four components capable of eliciting serum bactericidal activity, the vaccine is referred to as MenB-4C (4C-MenB in Europe). In the United States, a second group B vaccine that contains two FHbp sequence variants was developed by Pfizer Vaccines (Trumenba; referred to herein as MenB-FHbp).

These group B vaccines provide coverage against some strains with other capsular groups such as A, C, Y, W, or X, since the protein antigens are shared by strains from all capsular serogroups.[8,65–67] However, because the capsular polysaccharide contains multiple repeating epitopes and is more abundant and accessible on the bacterial surface than most protein antigens, serum anticapsular antibodies have greater complement-mediated bactericidal activity (i.e., require lower antibody concentrations to elicit bactericidal activity than antibodies that target protein antigens). Not all meningococcal strains are susceptible to antibodies elicited by the protein vaccine antigens because of amino acid sequence diversity of the antigen, low antigen expression in some strains,[68–70] or absence or truncation of a functional gene encoding the antigens.[71–74] Also, because group B vaccines appear to have less effect on decreasing carriage of the organism than conjugate vaccines,[75] the group B vaccine probably will not provide the same degree of herd protection found with the conjugate vaccines.[76] Therefore, while the group B protein vaccines may supplement protection against some strains with other capsular groups, it is unlikely that the protein vaccines will replace polysaccharide conjugate vaccines for prevention of disease caused by non–group B strains.

VACCINE COMPOSITION

MenB-4C

The MenB-4C vaccine contains three recombinant proteins: FHbp subfamily B (as a fusion protein with GNA 2019), Neisseria Heparin binding antigen (NHba, as a fusion protein with GNA 1030), and Neisseria adhesin A (NadA), which are combined with OMV from strain NZ98/254 (Fig. 39.2). A 0.5-mL dose contains 50 µg of each the three recombinant proteins and 25 µg of OMV. The antigens are adsorbed with 0.519 mg of Al^{3+} (as aluminum hydroxide) (Table 39.2). MenB-4C was licensed in Europe in 2013 and approved for the age group 2 months to 55 years.[77,78] The vaccine was subsequently approved in Canada, Australia, and more than 34 other countries, including the United States. In the United States, MenB-4C is approved for use in the age group 10 to 25 years.

MenB-FHbp

MenB-FHbp contains two lipidated recombinant FHbp sequence variants, one from each subfamily.[79,80] The 0.5-mL dose contains 60 µg of each FHbp variant (total of 120 µg of protein) (see Table 39.2). The antigens are adsorbed with 0.25 mg of Al^{+3} (as aluminum phosphate). In the United States, the MenB-FHbp vaccine is approved for the age group 10 to 25 years.

DISCOVERY AND CHARACTERIZATION OF GROUP B VACCINE ANTIGENS

The licensed group B vaccines contain a novel antigen called FHbp, which is a lipoprotein present on the surface of nearly

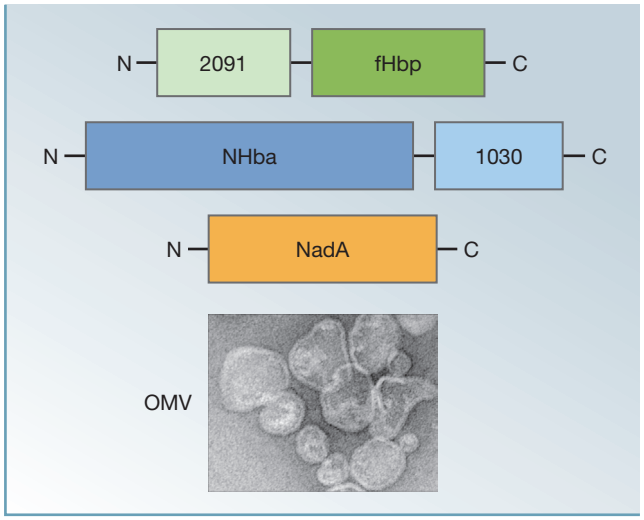

Figure 39.2. Schematic representation of the three recombinant proteins and outer membrane vesicles (OMVs) contained in the meningococcal MenB-4C vaccine. Two of the components are fusion protein (GNA2091 fused with FHbp and NHba fused with GNA 1030). The third component is recombinant NadA. N and C refer to the amino and carboxy terminal portions, respectively, of the proteins. The three recombinant proteins are combined with detergent-extracted OMV vaccine from group B strain NZ98/254 with PorA P1.4. *(Modified from Granoff DM. Review of meningococcal group B vaccines.* Clin Infect Dis. *2010;50[Suppl 2]:S54-S65.)*

TABLE 39.2 Composition of Licensed Group B Vaccines

MenB-4C Vaccine (Bexsero, GSK)	Quantity Per 0.5-mL Dose	MenB-FHbp Vaccine (Trumenba, Pfizer)	Quantity Per 0.5-mL Dose
Antigens		Antigens	
Recombinant GNA2091-FHbp (Subfamily B) fusion protein[a]	50 µg	Recombinant FHbp (Subfamily A)[b]	60 µg
Recombinant NHba-GNA130 fusion protein	50 µg	Recombinant FHbp (Subfamily B)[c]	60 µg
Recombinant NadA	50 µg		
OMV (strain NZ98/254, PorA P1.4)	25 µg		
Other		Other

pH	6.4-6.7	pH	6.0

[a]FHbp peptide ID 1, as described in the public database http://pubmlst.org/neisseria/fHbp/. This sequence variant is assigned to variant group 1 in an alternative classification system.[81]
[b]FHbp ID 45 (called A05 by Pfizer using an alternative classification of amino acid sequence variants (98).
[c]FHbp ID 55 (called B01 by Pfizer; see above).

all meningococcal strains. There are, however, notable differences in the antigenic composition between the two vaccines. The Pfizer vaccine contains two recombinant FHbp lipoprotein molecules, one from each subfamily (see below), and is referred to as MenB-FHbp. In contrast, the GSK vaccine contains a subfamily B FHbp sequence variant and three additional antigens capable of eliciting serum bactericidal activity (i.e., four components: FHbp, NadA, NHba, and OMVs containing PorA serosubtype P1.4, described in detail below).

FHbp

First discovered by scientists at the former Chiron Vaccines in Siena, Italy, using genome mining,[81] the protein was designated "genome-derived Neisseria antigen 1870" or "GNA1870." Investigators at Wyeth Vaccines (now Pfizer) in New York independently discovered the same antigen using biochemical and immunologic approaches and called it "lipoprotein 2086" or "LP2086."[82] The protein was subsequently found by Sanjay Ram and colleagues to bind a human protein, called Factor H, which downregulates complement activation (particularly the alternative pathway).[83] The binding was shown to be specific for human and some nonhuman primate FH[84–86] and enabled meningococci to survive in nonimmune serum (Fig. 39.3). Rat FH does not bind to meningococci, and the organism is killed by 20% nonimmune infant rat serum after incubation of the bacteria for 60 minutes.[87] The addition, however, of as little as 3 µg/mL of human FH was sufficient to downregulate the rat alternative pathway and "rescue" the bacteria (typical concentrations of FH in human serum range from 200 to 600 µg/mL).[88] These data provide one reason why meningococci naturally infect only humans; in humans, binding of FH to the bacteria allows the organism to evade host defenses. A human genomewide association study identified variants in the FH region associated with host susceptibility to meningococcal disease.[89] Because of the importance of binding of FH to GNA1870/LP2086 in enabling the organism to evade complement, the various names of the antigen were changed to FHbp.[83]

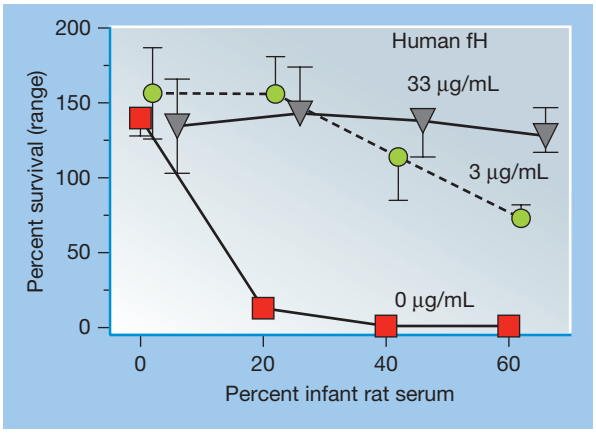

Figure 39.3. Effect of human Factor H (FH) on survival of *N. meningitidis* group B strain H44/76 in infant rat serum. *(Data from Granoff DM, Welsch JA, Ram S. Binding of complement factor H (fH) to* Neisseria meningitidis *is specific for human fH and inhibits complement activation by rat and rabbit sera.* Infect Immun. *2009;77: 764-9.)*

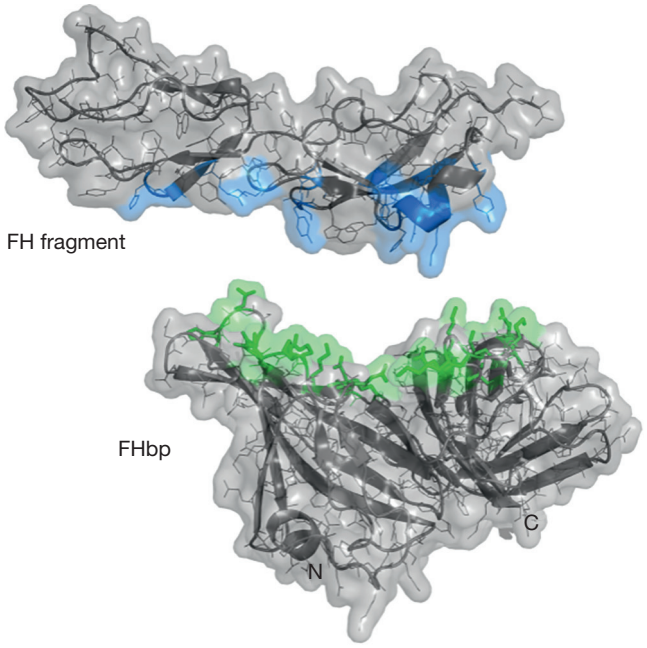
The FH molecule contains 20 domains.[88,90] Each domain contains approximately 60 amino acids and can be thought of as a series of individual beads on a string. Domains 1 to 4 are responsible for downregulating complement activation, and domains 6 and 7 contain the amino acid residues that interact with FHbp.[91–93] The structure of FHbp in a complex with FH domains 6 and 7 is shown in Fig. 39.4. The FHbp molecule contains two antiparallel β-barrel domains.[94] The amino acid residues in FHbp that interact with FH are located on both the N-terminal and C-terminal portions of the molecule and appear to be the most important epitopes for eliciting bactericidal anti-FHbp antibodies.[61,95] In immunized mice whose mouse FH does not bind to the vaccine antigen, serum anti-FHbp antibodies are directed at epitopes located in the FH binding site, and the antibodies block FH binding.[60] With



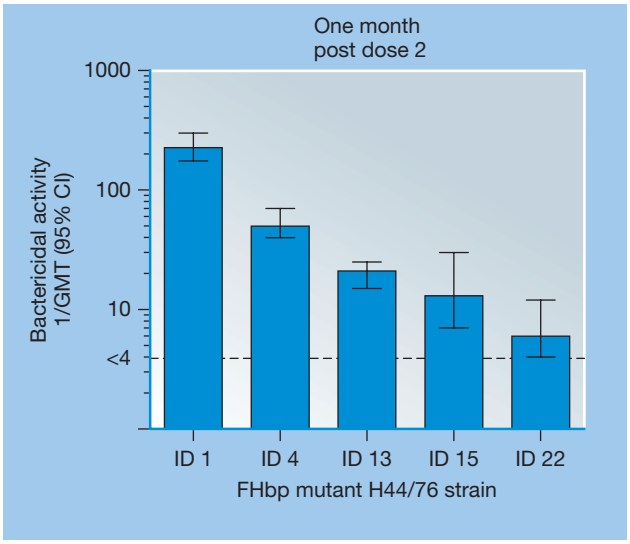


Figure 39.4. Structure of Factor H (FH) binding protein (FHbp) in a complex with a human FH fragment (domains 6 and 7). *(Data and coordinates from Schneider MC, Prosser BE, Caesar JJ, et al.* Neisseria meningitidis *recruits factor H using protein mimicry of host carbohydrates.* Nature. *2009;458:890-893.)*

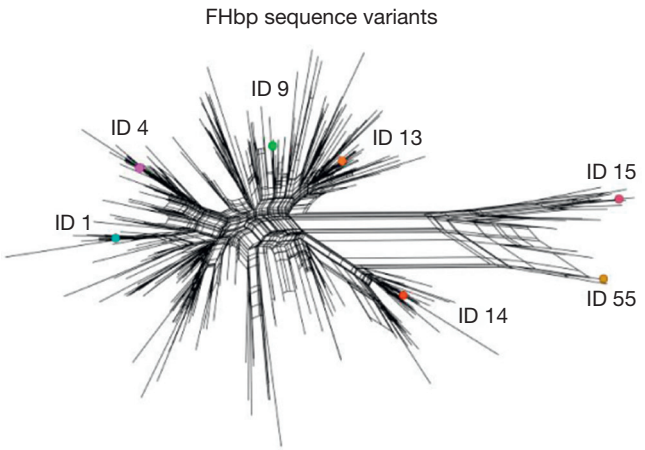

less bound FH, there is less complement downregulation and the bacteria become more susceptible to complement-mediated bactericidal activity.[96,97] In immunized humans and nonhuman primates, binding of FH to the FHbp vaccine antigen appears to mask these epitopes, and the resulting anti-FHbp antibodies are largely directed to epitopes outside of the FH binding area. As a result, the antibodies do not block FH binding.[61,62,98]

As of October 2016, more than 970 distinct FHbp amino acid sequence variants (peptide alleles) had been identified in a public database[99] and assigned individual FHbp peptide identification (ID) numbers. Based on amino acid sequence similarity, these variants can be subclassified into three variant groups (1, 2, or 3)[81] or two subfamilies (A and B).[100] Variant group 1 corresponds to subfamily B, and variant groups 2 and 3 correspond to subfamily A. Within a subfamily, FHbp amino acid sequence identity ranges from 88% to 99%. Between subfamilies, sequence identity is approximately 60%. While exceptions have been noted,[101] in general, antibodies directed at FHbp in subfamily A have greater bactericidal activity against strains expressing subfamily A FHbp, and vice versa for strains expressing FHbp in subfamily B.[81,82,102] Because of amino acid relatedness and extensive cross-reactivity between FHbp sequence variants in variant groups 2 and 3 (subfamily A),[72,102] this chapter uses the subfamily classification system.

MenB-FHbp contains two lipidated recombinant FHbp sequence variants, one from each subfamily. The lipidation is thought to act as an adjuvant and increase immunogenicity.[82,103] The subfamily A FHbp sequence variant in this vaccine is ID 45 (called A05 by Pfizer), and the subfamily B variant is ID 55 (also called B01) (Fig. 39.5). MenB-4C contains a subfamily B FHbp variant (ID 1) that is not lipidated, and three other antigens capable of eliciting serum bactericidal activity (see Fig. 39.2). The FHbp antigen in MenB-4C is a fusion

The MenB-4C FHbp vaccine antigen is subfamily B ID 1 (far left). The MenB-FHbp subfamily B antigen is ID 55 (far right). *(A, Graph prepared from published data from macaques with high binding of FH to FHbp. Data from Granoff DM, Costa I, Konar M, et al. Binding of complement Factor H (FH) decreases protective anti-FH binding protein antibody responses of infant rhesus macaques immunized with a meningococcal serogroup B vaccine.* J Infect Dis. *2015;212:784-92.)*

protein with a second antigen called GNA 2091.[104] GNA 2091 was initially thought to contribute to vaccine protection and was combined with FHbp to facilitate vaccine production. The antigen was subsequently found to be localized on the periplasmic side of the outer membrane[105] and did not elicit serum bactericidal activity. The manufacturer considers GNA 2091 an "accessory protein" in the MenB-4C vaccine, and the presence of GNA 2091 in the FHbp fusion protein may increase FHbp stability and immunogenicity.[106]

FHbp vaccines elicit broad serum bactericidal antibody responses in mouse, rabbit, and nonhuman primate models.[62,69,81,82,102,107] Both manufacturers have proposed that if there is a match between the FHbp subfamily (or variant group) of the vaccine and the strain, and if strain antigen expression is above a certain threshold, then the isolate can be considered covered by the vaccine.[69,70] However, the story actually may be more nuanced.[68,107,108] For example, within a subfamily there can be 10-fold or greater differences in susceptibility against mutants with different FHbp amino acid sequence variants (compare, for example, titers of rhesus macaques immunized with MenB-4C measured against a strain with FHbp ID 1 [an exact match with the vaccine antigen], to titers against the mutants of the strain with FHbp ID 4, 13 or 15; see Fig. 39.5).[62] There also was some unexpected cross-reactive bactericidal activity against the mutant with ID 22 in subfamily A, which is mismatched with the FHbp subfamily B antigen in MenB-4C. Fig. 39.6 shows the effect of decreasing strain antigen expression on lowering serum bactericidal activity of mice immunized with a recombinant FHbp vaccine ID 1 that matched the FHbp in the test strains.[66] Note that many wild-type meningococcal strains causing disease have similar FHbp expression to the mutant used in this study with 50% decreased FHbp expression.[66,66,69,70,98,109] Intrinsic strain resistance to anti-FHbp bactericidal activity also may be mediated by binding of FH to two other meningococcal FH ligands, NspA and a porin protein called PorB, which can downregulate complement.[110]

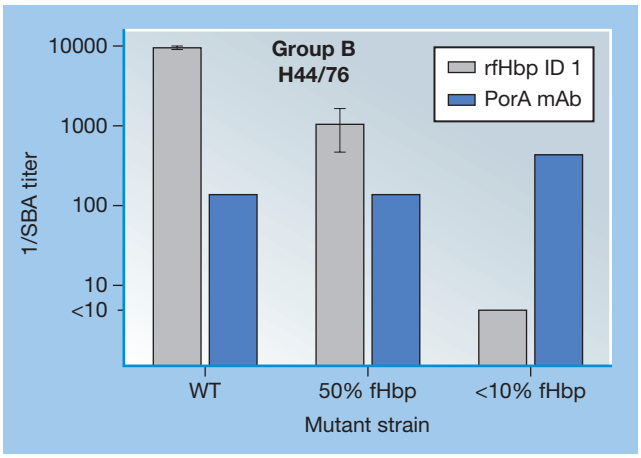

Figure 39.6. Effect of strain expression of FHbp on susceptibility of complement-mediated anti-FHbp bactericidal activity of sera from mice immunized with recombinant FHbp (ID 1). Wild-type (WT) strain H44/76 is a naturally high expresser of FHbp. Isogenic mutants of H44/76 with decreased FHbp expression exhibited increasing resistance to killing by the serum anti-FHbp antibodies (gray bars) but not by an anti-PorA monoclonal antibody (mAb) (blue bars). Titers were measured with human complement. *(From Pajon R, Fergus AM, Koeberling O, et al. Meningococcal factor H binding proteins in epidemic strains from Africa: implications for vaccine development.* PLoS Negl Trop Dis. *2011;5:e1302.)*

These experimental observations underscore the challenges for predicting strain coverage by antibodies elicited by FHbp vaccines.

Rarely (~1 : 1000), invasive meningococcal isolates with absent FHbp genes or frameshift mutations have been identified that do not express a functional FHbp.[71] These isolates express other FH ligands, such as NspA or PorB, and are completely resistant to anti-FHbp bactericidal activity.[111] Whether widespread vaccination with FHbp vaccines will select for emergence of FHbp-null strains is not known.

Effect of Factor H Binding to FHbp Vaccines on Immunogenicity

Clinical trials with meningococcal FHbp vaccines had begun before the protein was discovered to bind specifically to human and some nonhuman primate FH.[83] As noted above, FH is present in high concentrations in human serum (300–600 μg/mL). The effect of binding of FH to the vaccine antigen on immunogenicity had not been assessed by the earlier experimental animal studies because mouse or rabbit FH does not bind to FHbp. The effect of binding of FH to FHbp vaccines on immunogenicity was investigated in a human FH transgenic mouse model.[56,57,58,59,62] FHbp vaccines that bound human FH elicited 4- to 8-fold lower serum bactericidal antibody responses than in control mice whose mouse FH did not bind to the vaccines.[59,60] These findings prompted investigation of the effect of FH binding on FHbp immunogenicity in a nonhuman primate model, which may be more relevant to human immunity than mouse models. Because of a FH polymorphism (two amino acids), some rhesus macaques have FH that binds weakly with FHbp, while other animals have high avidity FH binding to FHbp.[86] The macaques with the high FH binding phenotype had lower anti-FHbp serum bactericidal titers to MenB-4C than the animals whose FH bound with low avidity to the FHbp vaccine antigen.[62] In contrast, the respective serum bactericidal antibody responses of the two groups to two other antigens tested in the MenB-4C vaccine that did not bind FH (NadA and PorA P1.4) were similar.[62] More recently, a mutant recombinant FHbp vaccine with two amino acid substitutions that decreased FH binding elicited up 15-fold higher serum bactericidal antibody responses in infant macaques than the control wild-type recombinant FHbp vaccine that bound macaque FH.[61] There also was evidence that the mutant FHbp vaccine elicited an anti-FHbp antibody repertoire directed at FHbp epitopes within the FH binding site, which resulted in greater protective activity than the antibodies elicited by the control vaccine, which targeted FHbp epitopes outside the FH combining site.

Neisseria Adhesin A

MenB-4C contains a subfamily B FHbp antigen. Vaccine coverage against meningococcal strains with subfamily A FHbp is largely dependent on protective antibodies elicited by the three other vaccine antigens. One of these is NadA, which is a surface-exposed lipoprotein discovered by genome mining and designated GNA1994.[73] Present in the outer membrane as a homotrimer, NadA has structural similarities to a family of autotransporter adhesins and may promote *Neisseria* adhesion to epithelial cells (hence the name NadA).[112] In experimental animals and humans, recombinant NadA vaccines elicited serum bactericidal antibodies.[73,113–115]

As of October 2016, there were 78 NadA amino acid sequence variants in the public database.[116] In a classification system updated in 2014, NadA was subdivided into three variant groups based on amino acid similarity (NadA-1, NadA-2/3, and NadA-4/5).[117] MenB-4C contains a variant from

group 2/3, which elicits cross-reactive antibodies to NadA-1 but not NadA-4/5.

An important limitation of NadA as a vaccine antigen is that, overall, only about 30% to 40% of serogroup B strains have genes coding for the protein (primarily strains from clonal complexes STs 8, 11, and 32).[8,118] Furthermore, the isolates for which anti-NadA antibodies might be most important for protection after MenB-4C vaccination (isolates with FHbp subfamily A, which is not present in the vaccine) infrequently have *nadA* genes (6–19%).[8,72] NadA expression levels also are largely controlled by a transcriptional regulator NadR (Neisseria adhesin A regulator).[119] Expression of NadA is repressed in many strains by NadR, which can result in resistance to anti-NadA serum bactericidal activity.[120] Experimentally, NadA expression can be induced by certain small molecules in saliva that inhibit NadR repression. In an ex vivo model of human whole blood infection, meningococci did not activate genes encoding for NadA.[121] Nevertheless, expression of NadA during human disease was sufficient to induce anti-NadA antibodies in convalescent serum.[122] In short, MenB-4C can induce anti-NadA bactericidal activity against some NadA-positive meningococcal strains (such as strain 5/99, which has naturally high NadA expression and is used by the manufacturer to assess anti-NadA serum bactericidal responses).[113–115] However, for many NadA gene-positive strains, expression of the protein is low under in vitro growth conditions used to measure bactericidal activity, and some NadA-positive strains are relatively resistant to serum bactericidal activity elicited by MenB-4C in adults (see below).[21,123] Defining the actual contribution of anti-NadA antibodies to MenB-4C vaccine coverage therefore remains challenging.

Neisseria Heparin Binding Antigen

NHba is a surface-exposed lipoprotein that also was discovered by genome mining and designated GNA 2132.[124] Subsequently the protein was found to bind heparin in vitro, which correlated with increased survival of unencapsulated meningococci in human serum.[125] While the role of heparin binding as a surrogate for interactions of *N. meningitidis* with host polyanions and pathogenesis remains uncertain, the name of the protein was changed to NHba to reflect its heparin-binding function. As of October 2016, there were 677 NHba amino acid sequence variants in the public database.[126] To date, these variants have not been classified into related families because of the lack of clear relationships between the respective amino acid sequence variants to antigenic cross-reactivity. For classification, each NHba sequence variant is designated with a specific peptide ID. MenB-4C contains NHba peptide 2, which is part of a fusion protein with a second antigen, GNA 1030 (see Fig. 39.2). GNA1030 was initially thought to contribute to vaccine-induced protection and was combined with NHba to facilitate vaccine production. However, GNA1030 was subsequently found to be a ubiquinone-8 binding protein[127] and not to elicit serum bactericidal activity. As is the case for GNA 2091 (the second antigen in the FHbp fusion protein), the manufacturer considers GNA 1030 an "accessory protein" in the NHba antigen. The NHba fusion protein expresses the expected epitopes found in the native NHba and appears to be stable.[128]

Defining the role of NHba in MenB-4C coverage has been challenging. In some strains, an endogeonous protease, NalP, cleaves NHba, which releases a C-terminal 22-kDa fragment that may contain epitopes recognized by anti-NHba antibody.[125] NHba also was found to be cleaved by protease activity of human lactoferrin. Although the investigators concluded that proteolytic cleavage of NHba did not affect anti-NHba bactericidal response, the activity was measured with rabbit complement.[125] Because rabbit FH does not bind to meningococci, the anti-NHba activation of complement was not downregulated, which would have falsely increased bactericidal activity measured with human complement.[84] Early studies of mice immunized with a recombinant NHba vaccine given with Freund's adjuvant showed that serum anti-NHba antibodies were bactericidal primarily with rabbit complement (only two selected strains were killed with human complement).[124] The vaccine manufacturer also has had difficulty finding a suitable meningococcal strain for measuring anti-NHba–specific serum bactericidal activity after MenB-4C vaccination. As a result, anti-NHba bactericidal activity was not measured in the early studies of the immunogenicity of the MenB-4C vaccine in humans.[113–115,129–132] Also, anti-NHba bactericidal activity was not included in the human immunogenicity dataset for U.S. licensure of the MenB-4C vaccine.[133]

In a recent study, Rossi et al.[123] investigated serum bactericidal activity elicited by MenB-4C against different serogroup B strains responsible for two outbreaks on U.S. college campuses. Both outbreak strains were susceptible to bactericidal activity of sera from rhesus macaques or a human immunized with MenB-4C. This result was predicted based on high expression of two of the vaccine antigens in both strains, subfamily B FHbp and NHba, and moderate expression of a third vaccine antigen, NadA, in one of the strains. Depletion of anti-FHbp antibodies from the postimmunization sera, however, resulted in loss of all of the vaccine-induced bactericidal activity. Thus, despite strain NHbp expression and high titers of anti-NHba antibody in the FHbp-adsorbed sera, there was no detectable anti-NHba bactericidal activity measured with human complement. The basis for this resistance is unknown and requires further investigation. These data, together with recent data on limited serum bactericidal responses of MenB-4C-vaccinated adults against some strains expressing NHba but mismatched for the other three MenB-4C antigens,[21] underscore the difficulty of predicting the contribution of anti-NHba antibodies to protection elicited by MenB-4C.

Outer Membrane Vesicles

OMV vaccines have been used for many years to control capsular group B outbreaks and appear to be safe[134–136] and effective.[16,31,137,138] Their major limitation is that serum bactericidal antibody responses of infants and children are largely directed at a porin protein, PorA,[36] which is antigenically variable.[139] The variability of PorA limits the utility of OMV vaccines for prevention of endemic group B meningococcal disease caused by antigenically diverse strains with multiple PorA variable region STs. The OMV in MenB-4C is prepared from strain NZ98/254, which contains a PorA serosubtype P1.4 (defined serologically) or by the variable region (VR2) ST, 1.4. This OMV component was used in New Zealand as a stand-alone vaccine (MeNZB, Chiron Vaccines) for the age group 6 weeks to 20 years to control a longstanding capsular group B epidemic.[138] Initially, three doses of the OMV vaccine were administered, with each dose separated by 2 months. A booster dose in the second year of life was added for infants vaccinated beginning at 6 to 8 weeks of age to achieve more persistent serum bactericidal responses. The vaccine was safe and immunogenic, with the strongest bactericidal activity against meningococci sharing the same P1.4 PorA antigen as in the vaccine.[140] Overall vaccine effectiveness was estimated to be between 68% and 73%.[137,138] By June 2008, routine OMV vaccination had been halted in New Zealand because of declining incidence of disease, controversies about the contribution of vaccination to decreasing disease incidence,[141,142] and the cost of the program. The OMV vaccine used in New Zealand was added to the three recombinant protein antigens

in MenB-4C to provide some anti-PorA coverage and, perhaps more importantly, as an adjuvant to enhance immunogenicity of the recombinant protein antigens.[143]

IMMUNOGENICITY

The low global incidence of meningococcal group B disease precluded performing randomized controlled efficacy trials to determine whether vaccination with the new group B vaccines decreased the incidence of meningococcal disease. Instead, efficacy was inferred from serum bactericidal antibody responses. For technical reasons (small volumes of serum, limited amounts of human complement, and strain differences in assay performance), both manufacturers tested serum bactericidal activity against a panel of three or four selected strains. Interpreting the published data also is challenging because the endpoints use in the different studies were not consistent (i.e., postimmunization reciprocal titers ≥4, ≥5, ≥8, ≥1 : 16; or 4-fold or greater increases in titer compared with the respective preimmunization titer), or a composite endpoint (i.e., how many individuals have antibodies to all strains or antigens tested).

MenB-4C

To assess antigen-specific serum bactericidal antibody responses, the manufacturer selected reference (indicator) strains that were each mismatched for three of the four antigens in MenB-4C that elicit bactericidal antibody responses. These strains also had high expression of the antigen of interest, with susceptibility to bactericidal activity by antibody to the target antigen, and resistance to antibodies directed at the other three mismatched vaccine antigens. As described below, these reference strains are more susceptible to serum bactericidal antibody elicited by MenB-4C than many wild-type, disease-causing strains.[21] Nevertheless, when the data from the reference strains are combined with data on expression and cross-reactivity of antigens expressed by isolates causing disease in the population (see below), and serum bactericidal activity measured against additional disease causing isolates, the results collectively provide important information on vaccine immunogenicity and potential strain coverage.

Immunogenicity in Infants

The immunogenicity of the three recombinant antigens in MenB-4C when administered with OMV (MenB-4C) or without OMV (MenB-3C) was investigated in two studies in infants.[114,115] In one study, two doses of the vaccines, separated by 2 months, were given beginning at age 6 to 8 months with a booster dose at 12 months.[114] In a second study, three doses were given at 2, 4, and 6 months with a booster dose at 12 months.[115] Three test strains were used to measure antigen-specific bactericidal responses to NZ98/254 (PorA), 5/99 (NadA) and H44/76 (FHbp). At the time the studies were performed, a suitable test strain for the fourth antigen, NHba, was not available (see NHba antigen section, above). Serum bactericidal responses also were measured against four disease-causing strains from the United Kingdom. Only MenB-4C, but not MenB-3C, elicited serum bactericidal antibody responses against the majority of the strain panel. Vaccine coverage therefore benefited from the addition of PorA-specific serum bactericidal antibodies elicited by the OMV component (and perhaps other antibodies elicited by minor OMV antigens) and an adjuvant effect of the OMV on enhancing antibody responses to the recombinant proteins, which was also observed in a subsequent study.[143]

Serum bactericidal antibody responses of infants immunized with three doses of MenB-4C at 2, 4 and 6 months, and boosted with a fourth dose at 12 months, are shown in Figs. 39.7 and 39.8. More than 90% of the infants developed protective titers ≥1 : 4 against the three indicator reference strains (H44/76, NZ98/254 and 5/99; see Fig. 39.7). After the 12-month booster, the majority of the infants also developed protective titers against three of the four disease-causing test isolates (MO1-1, MO1-2, and MO1-3), although the respective geometric mean titers were lower than the reference strains (see Fig. 39.8). In larger Phase IIb or III studies, the vast

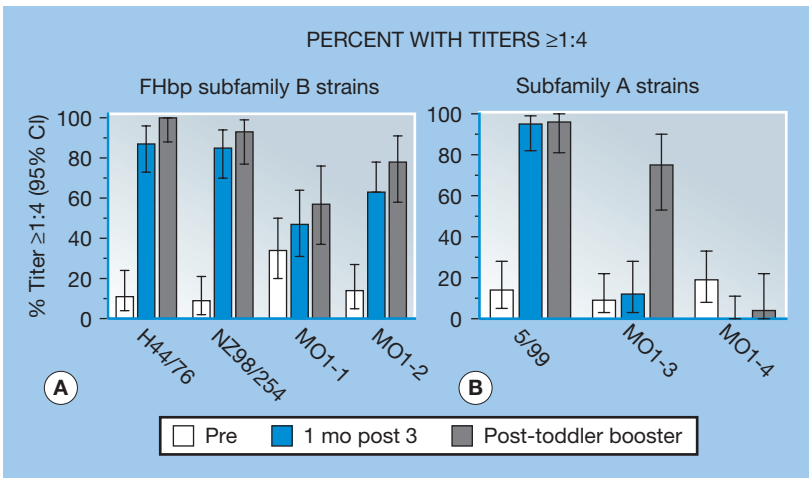

Figure 39.7. Serum bactericidal antibody responses of infants immunized with MenB-4C at 2, 4, and 6 months and boosted at age 12 months: Titers ≥1 : 4. Bactericidal antibody titers were measured with human complement in serum obtained 1 month after vaccination. **A,** Group B strains with factor H binding protein (FHbp) in subfamily B. H44/76 had FHbp ID 1, which matched the FHbp in the vaccine. The other strains had FHbp subvariants. NZ98/254 was the strain used to prepare the vaccine outer membrane vesicle (OMV) and expressed PorA 1.7-2,4. Strains designated MO1-1 and MO1-2 refer to MO1 240101 and MOO 242922, respectively (MO1-2 also had PorA 1.7-2,4, which matched the vaccine OMV). **B,** Group B strains with FHbp from subfamily A, which were not part of the vaccine. Strain 5/99 was selected to measure responses to NadA. Strains designated MO1-3 and MO1-4 refer to strains MO1 240364 and MO1 240355, respectively. Figure 39.9. Serum bactericidal antibody persistence at age 40 months in children previously vaccinated with MenB-4C at 2, 4, 6, and 12 months. Data are shown for four indicator strains, 5/99 (NadA), M10713 (NHba), H44/76 (PorA), and NZ98/254 (PorA) and four disease-causing strains in the United Kingdom. Titers were measured with human complement. Strain MO1-7 refers to M01-240355, MO-8 refers to MO1-240364, MOO-5 refers to MOO-242922, and MO1-6 refers to MO1-24101. Strain MO1-07 is mismatched to all four antigens in the MenB-4C vaccine considered to elicit bactericidal responses. *(Data from Snape MD, Saroey P, John TM, et al. Persistence of bactericidal antibodies following early infant vaccination with a serogroup B meningococcal vaccine and immunogenicity of a preschool booster dose.* CMAJ. *2013;185:E715-24.)*

majority of infants and toddlers given two or three doses of MenB-4C also developed protective responses against the three reference antigen-specific strains.[113,144] These larger studies, however, did not include additional disease-causing strains, which are often more resistant to MenB-4C bactericidal antibody than the reference indicator strains (see Fig. 39.10).

A recent study administered a booster dose of MenB-4C in children at 12, 18, or 24 months. The children had been previously immunized with three doses at 2, 3, and 4 months, or 2, 4, and 6 months.[145] After a 12-month booster dose, 95% of the children developed titers ≥1:5 against all three indicator strains for FHbp, NadA, and PorA P1.4.

Persistence of serum bactericidal activity in infants vaccinated with MenB-4C at 2, 4, 6, and 12 months was measured at age 40 months in another study.[146] The results were compared with serum titers of control children of the same age who had not been vaccinated with MenB-4C (Fig. 39.9). For two of the indicator strains, 5/99 (NadA) and NZ98/254 (PorA P1.4), and one disease-causing strain (MOO-5), the respective proportions of children with bactericidal titers ≥1:4 at 40 months were higher in the MenB-4C-vaccinated

than in the MenB-4C-naïve children. For the remaining five test strains, the respective proportions of children with protective titers were similar in the vaccinated and unvaccinated groups.

To prolong protection, two studies administered booster MenB-4C in children at age 40 months who either had been immunized at 2, 4, 6, and 12 months ($n = 16$)[147] or at 6, 8, and 12 months ($n = 11$ to 12).[148] The percentages of subjects at 60 months with serum titers ≥1 : 4 ranged from 44% to 100% against the three group B indicator strains for FHbp, NadA, or NHba. For the PorA indicator strain, the percentages were 69% for the children vaccinated beginning at 2 months of age[147] and 17% for children vaccinated with four doses beginning at 6 months of age.[148] The reason for the discordant anti-PorA results is not known. Also, for these studies the manufacturer had recently selected strain M10713 to measure anti-NHba–specific bactericidal responses. However, interpretation of antibody persistence to NHba in the vaccinated children (45% and 88% with titers ≥1 : 4 in the two studies) was confounded by the presence of naturally acquired bactericidal activity in the majority of the 60-month-old MenB-4C-naïve control children (67% and 83%). This strain also was killed by naturally acquired serum antibactericidal antibodies in two other studies (titers ≥1 : 4 in 18% of MenB-4C-naïve infants at 12 months[144] and in 68% of children at 40 months of age[146]; see Fig. 39.9). The naturally acquired bactericidal antibodies to this strain are likely directed at antigens other than NHba, since by enzyme-linked immunosorbent assay relatively few MenB-4C-naive adults have serum immunoglobulin G antibodies to this NHba. In conclusion, additional studies are needed to determine whether infants vaccinated in the first year of life and boosted in the second year will require additional booster doses of MenB-4C to maintain protection and, if needed, the optimal age of booster dose (e.g., at adolescence).[149]

Supporting data for concomitant administration of MenB-4C with vaccines routinely administered to infants were provided for antigens in DTaP-HBV-IPV/Hib and heptavalent pneumococcal conjugate vaccine (PCV7).[113] The only immune responses that appeared to show evidence of interference by MenB-4C were the *Bordetella pertussis* protein pertactin and the pneumococcal serotype 6B antigen in PCV7, in which there were minor decreases in responses that failed to meet the prespecified 95% cutoff level. In another study,[144] supporting data for concomitant administration of MenB-4C and DTaP-HBV-IPV/Hib were provided for responses to diphtheria and tetanus toxoids, Hib polysaccharide, hepatitis B virus, pertussis toxin, filamentous hemagglutinin antigen, pertactin, and poliovirus types 1 and 3. For poliovirus type 2, there was a small decrease in the proportion of children developing neutralization titers of ≥1 : 8, which failed to meet the prespecified 95% cutoff level (MenB-4C and routine vaccines 88%, 95% confidence interval [CI] 84–92; vs routine vaccines only 94%, 95% CI 90–97). It seems unlikely that these minor decreases in immune responses are clinically important.

Immunogenicity in Adolescents and Adults

In one study conducted in Chile, 92% to 97% of 1631 adolescents immunized with one dose of MenB-4C developed serum bactericidal titers of ≥1 : 4 against the three indicator strains for NadA, PorA, and FHbp, and 99% to 100% had protective titers after two or three doses.[130] For licensure in the United States, the U.S. Food and Drug Administration (FDA) reviewed additional immunogenicity data from two studies of adolescents and young adults immunized with two doses of MenB-4C separated by 1 month. Study 1 was conducted in adolescents ages 11 to 17 years in Canada and Australia.[131] Study 2 was conducted in U.K. university students ages 18 to 24 years. The package insert summarized the results using 4-fold or greater increases in serum bactericidal titer against three indicator strains.

At 1 month after dose 2, nearly all of the adolescents in Study 1 developed responses to the indicator strains for FHbp or NadA (98% and 99%), but the response to the PorA strain was lower (39%). The respective percentages of responders in Study 2 were 78%, 94%, and 67%. Fig. 39.10A compares data from Studies 1 and 2 with a third study (Study 3) of 20 adults ages 21 to 44 years immunized with MenB-4C in the United Kingdom or Northern California.[21] Against the three indicator strains, the respective results of the three studies are similar. Study 3 also included genetically diverse clinical isolates, which were more resistant than the reference strain; only 25% to 45% of the subjects had ≥4-fold increases in serum bactericidal titers against six test strains with FHbp subfamily A sequence variants (Fig. 39.10C) or three test strains with FHbp subfamily B variants (all from U.S. college outbreaks or hyperendemic disease in Quebec[150]; Fig. 39.10D). Collectively, the data indicated that the clinical isolates with FHbp amino acid sequence variants divergent from ID 1 in the vaccine (Fig. 39.10B) were generally more resistant to MenB-4C-induced bactericidal activity than the reference strains.

A ≥4-fold bactericidal response requires a minimum postimmunization serum titer of 1 : 16. Thus, immunized persons who do not achieve ≥4-fold titer increases at 1 month can have protective serum titers of ≥1 : 4 (see Fig. 39.10E, showing post–dose 2 titers of 12 individual subjects tested against a strain from Quebec [2013]). By 4 to 6 months postimmunization, however, serum titers declined to less than 1 : 4 in the majority of subjects with available follow-up sera. A working model, therefore, is that the percentage of subjects with titers ≥1 : 4 at 1 month postimmunization may correlate with short-term protection, particularly if the titers at 1 month are relatively low, whereas the percentage with ≥4-fold titer increases represent more robust responses to vaccination, which may predict longer-term protection.

Persistence of bactericidal activity was investigated in sera obtained 18 to 24 months after MenB-4C immunization of adolescents in Chile.[129] In subjects given one dose of vaccine, the proportion with serum bactericidal titers ≥1 : 4 at 18 to 24 months against the three indicator strains ranged from 62% to 73%. For subjects immunized with two or three doses, the proportions ranged from 75% to 93%, and for the control MenB-4C-vaccine-naïve adolescents, proportions ranged from 25% to 50%. This study only evaluated indicator reference strains; if more diverse clinical isolates had been tested, the proportions of protected subjects at the different follow-up time points likely would have been lower. Also, the antibody responses of the MenB-4C vaccinated adolescents in Chile appear to be higher than those of immunized adolescents from the United States or Europe, which may reflect greater immunologic priming in Chile from natural exposure to *Neisseria meningitidis* or cross-reacting organisms.

As of October 2016, supporting data from randomized controlled studies supporting concomitant administration of MenB-4C with vaccines routinely administered to U.S. adolescents were not available.[19] In one small study, laboratory workers aged 18 to 65 years were immunized concomitantly with a quadrivalent meningococcal conjugate vaccine (MCV4-CRM) and MenB-4C at visit 1, followed by two additional doses of MenB-4C at 3 and 6 months.[151] Protective serum bactericidal antibody levels were elicited by both vaccines. The main tolerability concern was severe pain and injection site tenderness after MenB-4C (in at least 16% of subjects after each dose).

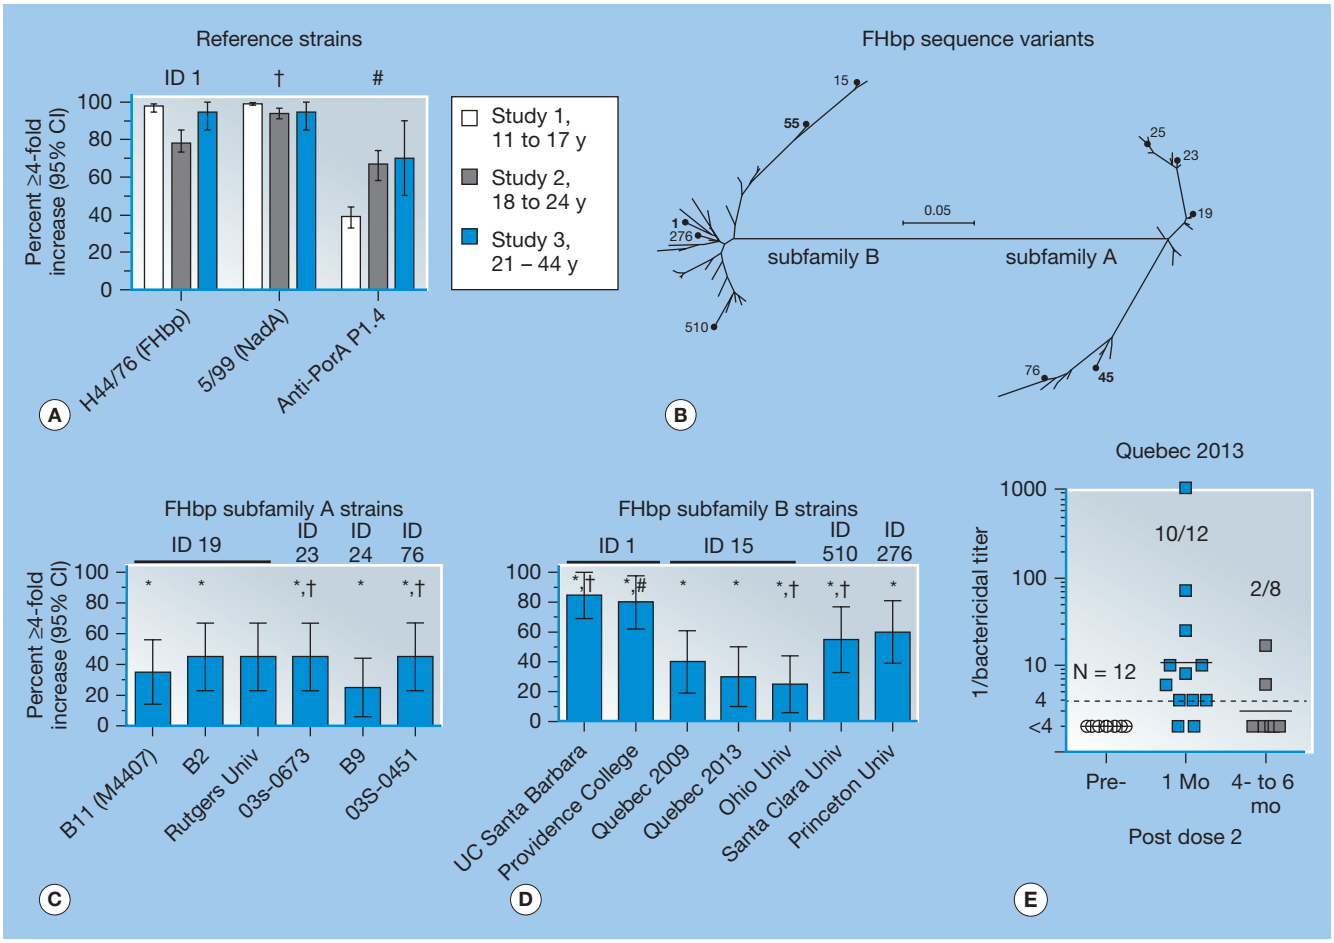

Figure 39.10. Serum bactericidal responses of adolescents and adults immunized with MenB-4C vaccine. The subjects received two doses of MenB-4C separated by 1 to 2 months. **A, C–D,** Percent of subjects with fourfold or greater increases in bactericidal titer in sera obtained 1 month after dose 2, compared with respective preimmunization titers. **A,** Reference indicator strains used to infer antigen-specific bactericidal activity (i.e., each strain is mismatched for three of four MenB-4C antigens reported to elicit bactericidal activity). Studies 1 and 2, data from U.S. Food and Drug Administration MenB-4C package insert (October 2015); Study 3 from published data.[21] Strain expression MenB-4C antigens are designated by *(NHba), †(NadA) or #(PorA P1.4). **B,** FHbp sequence variants. Vaccine Effectiveness

In September 2015, the United Kingdom introduced routine MenB-4C vaccination for infants using a two-dose infant priming schedule beginning at 2 months of age. When the vaccine was introduced there was a limited catch-up for those born before May 2015. In October 2016, short-term effectiveness data became available from a national observational cohort study.[152] Vaccine uptake was high, with 95.5% of the birth cohort receiving one dose by 6 months of age and 88.6% receiving two doses. During the 10 months of follow-up, 37 cases of meningococcal serogroup B disease were identified by intense public health surveillance in the age cohort eligible for vaccination. Of these cases, 29 (78%) had been vaccinated 14 days or more before disease onset with at least one dose, with 8 (21.6%) receiving two doses. Using the screening method, which takes into consideration the proportion of the general U.K. infant cohort vaccinated, the two-dose vaccine effectiveness against all meningococcal B cases was 82.9% (95% CI, 24.1–95.2). Also, the number of cases in the vaccine-eligible cohort was 50% lower than the average number of cases in that age cohort during the 4 years before the vaccine was introduced. Collectively, these results provide clear evidence of short term-protection by two doses of vaccine.

As is the case with all observational study designs, the possibility of residual confounding cannot be excluded. Also, the small number of cases included in the U.K. study resulted in large 95% CIs about the point estimate of vaccine effectiveness. Further, the study did not address duration of protection, which is important because antibody titers can decline rapidly. The authors also did not provide strain data on the vaccine antigens (in part because most of the cases were confirmed

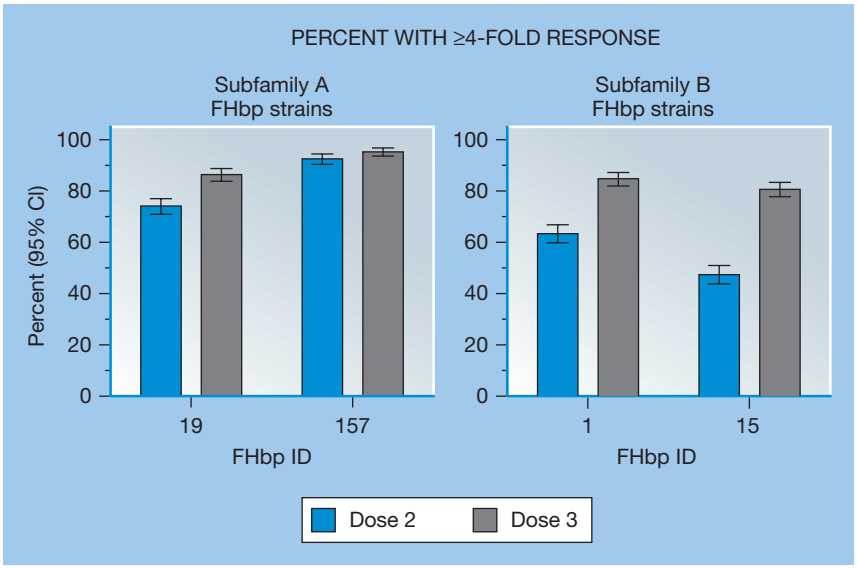

Figure 39.11. Serum bactericidal responses of adolescents immunized with MenB-FHbp vaccine. Adolescents aged 11 to 17 years received three doses of MenB-FHbp at 0, 2, and 6 months. The data shown are from the 788 subjects given MenB-FHbp in one arm and saline in the other and are expressed as percent of subjects with fourfold or greater increases in bactericidal titer in sera obtained 1 month after doses 2 or 3, compared with the respective preimmunization titers. The four serogroup B reference test strains had different FHbp amino acid sequence variants (ID). The subfamily A strains had ID 19 or 187 (referred to by Pfizer as A22 and A56, respectively) and the subfamily B strains had FHbp ID 1 (B24) or ID15 (B44; see Fig. 39.10B). *(Data from group 2 [MenB-FHbp/saline] from the Trumenba U.S package insert [October 2015].)*

only by polymerase chain reaction). Therefore, it is not possible to know whether the antigens expressed by the strains causing disease in the case patients matched those in the vaccine.

In 2013–14, two epidemiologically unrelated outbreaks of group B meningococcal disease occurred among students at Princeton University and the University of California Santa Barbara (UCSB).[18,153] At the time there was no licensed group B meningococcal vaccine in the United States, and the FDA authorized use of the European-licensed MenB-4C vaccine to control the outbreaks. Approximately 8000 students at Princeton University, and more than 10,000 students at UCSB, received at least one dose of vaccine. No further cases occurred in vaccinated persons, but two cases subsequently occurred in close contacts of students (one from each campus). In a subsequent study, serum bactericidal responses were measured in a subset of the Princeton students vaccinated with MenB-4C. Although by antigen typing the Princeton outbreak strain expressed two MenB-4C antigens and was predicted to be susceptible to serum bactericidal antibody elicited by the vaccine,[123] only 66% of the students developed protective titers ≥1 : 4.[22]

MenB-FHbp

MenB-FHbp was licensed in the United States in October 2015. For licensure the manufacturer provided immunogenicity data from a randomized trial in U.S. adolescents aged 11 to 17 years vaccinated at 0, 2, and 6 months with either MenB-FHbp + HPV4 vaccine (given as separate injections; $n = 792$), or MenB-FHbp + saline ($n = 788$).[154] Subsequently, the manufacturer provided additional data supporting a three-dose schedule at 0, 1 to 2, and 6 months, or a two-dose schedule at 0 and 6 months.[155,156] In these studies, serum bactericidal activity was measured against four capsular group B test strains with FHbp amino acid sequences representative of disease-causing isolates. Two of the strains had FHbp subfamily A sequence variants (ID 19 and ID187, referred to by Pfizer as A22 and A56, respectively), and two had subfamily B sequence variants (ID 1 [B24] and ID 15 [B44]; Fig. 39.11). After two doses of MenB-FHbp, fourfold or greater increases in bactericidal titers developed in 74% and 93% of subjects against the two subfamily A FHbp isolates and in 47% and 63% of subjects against the two FHbp subfamily B isolates (see Fig. 39.11). The corresponding percentages of responders after three doses were 86% and 95% for subfamily A and 81% and 85% for subfamily B. Similar respective response rates were observed in subjects given MenB-FHbp with a separate injection of saline or with HPV4 vaccine.

In another study, 1713 healthy adolescents aged 11 to 18 years from the Czech Republic, Denmark, Finland, Germany, Poland, Spain, and Sweden were randomized to receive one of five different MenB-FHbp vaccination schedules (0, 1, and 6 months; 0, 2, and 6 months; 0 and 2 months; 0 and 4 months; and 0 and 6 months).[157] Serum bactericidal responses were measured against four reference strains. One month after dose 3, the respective percentages of subjects with bactericidal titers ≥1 : 8 (the threshold used to define protection) immunized at the 0, 1, and 6 months or 0, 2, and 6 months schedules were not significantly different: 92% to 95% (ID 19), 99% (ID 187), 88% to 89% (ID 1), and 86% to 89% (ID 15). The respective geometric mean titers for each strain also were not significantly different. For the two-dose schedules, the longer the interval between the injections, the greater the response rate. The three-dose schedules resulted in the highest response rates, particularly against the subfamily B strains, and higher geometric mean titers. However, two doses of MenB-FHbp, separated by at least 5 months, also conferred a high level of immunity, which was similar to that after three doses at 0, 1 to 2, and 6 months. These results formed the basis of the FDA approval in October 2016 of both three-dose and two-dose schedules as long as the interval between the two-dose schedule was at least 5 months.

One recent study investigated serum bactericidal antibody responses of teenagers and young adults immunized with MenB-FHbp against a panel of 27 genetically diverse strains.[171a] One month after 2 doses of vaccine, depending on the strain,

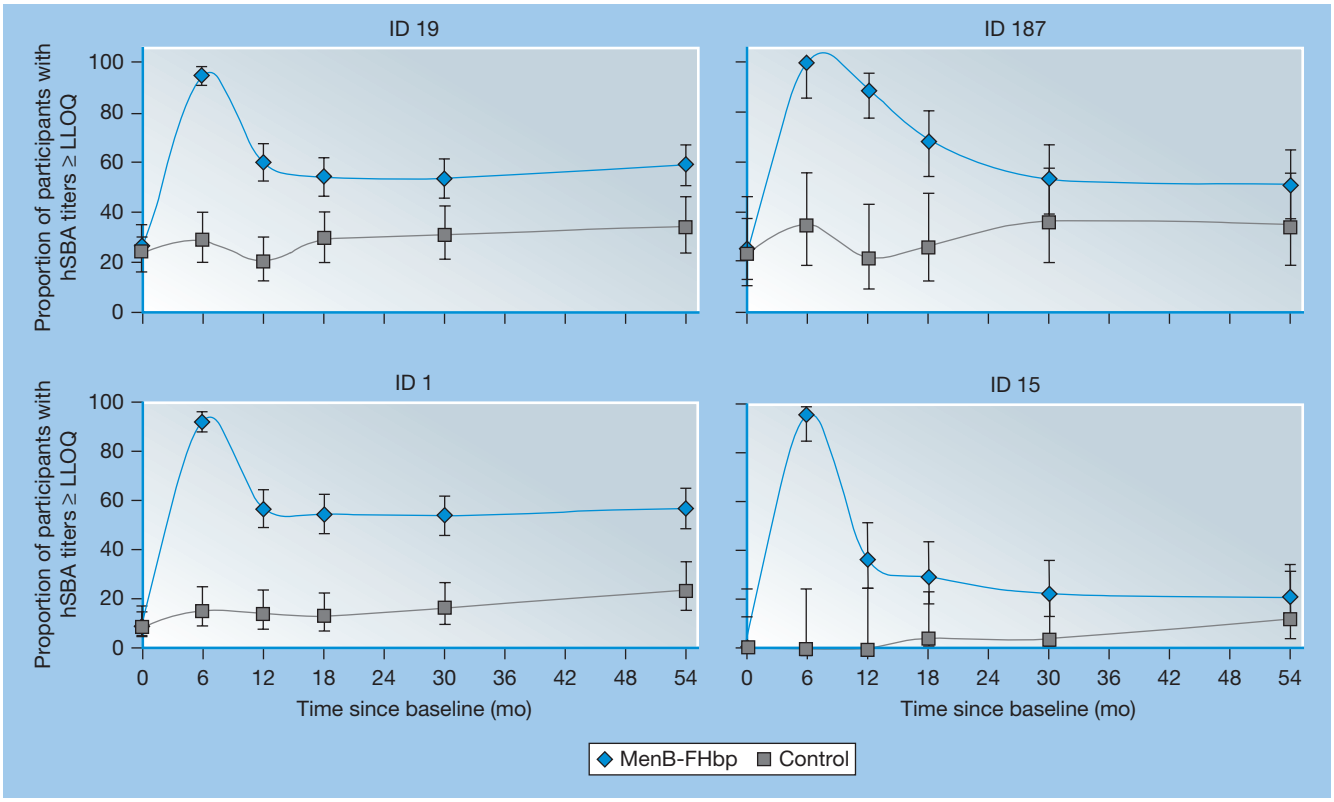

Figure 39.12. Serum bactericidal antibody persistence in teenagers immunized with MenB-FHbp. Subjects were immunized with three doses of MenB-FHbp at 0, 2 and 6 months, or a control vaccine, hepatitis A. Serum samples were obtained before and 1 month post dose 3 (7 months post baseline), and at 12, 18, 30, and 56 months post baseline. Error bars, 95% confidence interval. LLOQ, lower limit of quantification, which was 1:16 for the strain with FHbp ID 19 (A22 according to the Pfizer classification) and 1:8 for strains with ID 187 (A56), ID 1 (B24), or ID 15 (B44). hSBA, serum bactericidal activity measured with human complement. *(From Marshall HS, Richmond PC, Beeslaar J, et al. Meningococcal serogroup B-specific responses after vaccination with bivalent rLP2086: 4 year follow-up of a randomised, single-blind, placebo-controlled, phase 2 trial. Lancet Infect Dis. 2017;17:58-67.)*

32% to 96% of the subjects had titers considered to be protective; the corresponding percentages after three doses were 56% to 100%.

Published data also became available in October 2016 on serum antibody persistence in adolescents immunized with three doses of MenB-FHbp at 0, 2 and 6 months.[158] The proportion of subjects protected by vaccination was defined by serum bactericidal titers greater than or equal to the lower limit of quantification (LLOQ), which was 1:16 for the strain with FHbp ID 19 (A22) and 1:8 for the other three test strains. One month after three doses of MenB-FHbp (7 months from baseline), 93% to 100% of the subjects had titers above the LLOQ, which by 6 months (12 months from baseline; Fig. 39.12) had decreased to 57% to 89% for three of the test strains (ID 19, ID 187, and ID 1), and to approximately 40% for the fourth test strain (ID 15). By 12 months from baseline the titers appeared to be stable through 54 months of follow-up. These data suggest that a fourth booster vaccination may be required to maintain immunity in adolescents.

Supporting data for concomitant administration of MenB-FHbp with vaccines routinely administered to U.S. adolescents are available for 4vHPV (Gardasil, Merck),[159] MCV-4-DT (Menactra, Sanofi Pasteur),[160] Tdap (Adacel, Sanofi Pasteur),[160] or dTaP/IPV (Repevax, Sanofi Pasteur)[161] vaccines.[19] With one exception, there was no interference in meningococcal antibody responses or responses to the concomitant vaccine antigens. The exception was the HPV type 18 antigen in the 4vHPV vaccine, which failed noninferiority criteria after the third dose.

Vaccine Effectiveness

There are no available data on effectiveness of MenB-FHbp for preventing disease or decreasing oropharyngeal colonization.

SURROGATES FOR PREDICTING VACCINE COVERAGE OF DISEASE-CAUSING STRAINS

The serum bactericidal data from testing three or four "indicator" strains provide useful information on functional activity of antibodies elicited by the different vaccine antigens. However, the vaccine antigens present in strains causing disease can vary in different geographic regions and over time within one region.[162] Furthermore, the isolates responsible for disease often have lower antigen expression and/or greater sequence divergence from the vaccine antigens than present in the indicator strains. Even modest FHbp amino acid sequence divergence (see Fig. 39.5)[62,68] or decreased strain FHbp expression (see Fig. 39.6)[66,67,163] can increase resistance to anti-FHbp bactericidal activity (confirmed in human adults immunized with MenB-4C; see Fig. 39.10C–D).

To estimate MenB-4C strain coverage, the manufacturer developed the meningococcal antigen typing system (MATS) that uses polymerase chain reaction to determine the strain PorA VR ST and an enzyme-linked immunosorbent assay to measure strain expression and cross-reactivity of the other three MenB-4C antigens (NHba, NadA, and FHbp).[70] Initial studies suggested that strains with the P1.4 PorA VR ST, which is present in the vaccine, or strains with a certain threshold

expression of any of the three other vaccine antigens, had 80% or greater probability of being susceptible to anti-MenB-4C bactericidal activity.[70] Since the initial study, many investigators have applied MATS to collections of disease-causing capsular group B strains from different populations.[164–170] In one study, the results of MATS predicted that 78% of 1052 group B strains collected from cases in 2007–08 from England and Wales, France, Germany, Italy, or Norway would be killed.[168] To experimentally validate this prediction, investigators compared MATS results to bactericidal activity of pooled sera from immunized infants and adolescents. The MATS results were reported to have 78% accuracy and 96% positive predictive value.[171] Other studies concluded that MATS was a "conservative" predictor of vaccine coverage.[165,171] However, these studies used pooled serum from vaccinated subjects, which may not reliably reflect activity of antibodies present in sera from individual subjects because antibodies in an individual serum that lack bactericidal activity may have cooperative bactericidal activity when combined.[95,101,163] While data supporting the use of pooled sera have been reported[172] and additional data may confirm that MATS results predict vaccine coverage, the bactericidal contribution of antibodies to individual MenB-4C antigens may be more complicated than suggested by the overall MATS analysis. This is particularly true for antibody to NHba or NadA, where strains with high antigen expression can be resistant to anti-NHba bactericidal activity[21,101,123] (see Fig. 39.10D). Thus, not all antigens in MenB-4C are necessarily equal with respect to their ability to elicit serum bactericidal antibody; additional studies are needed to confirm the hypothesis that antigen-specific thresholds measured by MATS to any one of the three antigens indicate a high probability of the strain being covered by MenB-4C.

For predicting coverage by MenB-FHbp, the manufacturer provided data that human immune sera killed 36 of 45 (80%) group B isolates tested, with the best predictor being the level of FHbp expression as measured by a flow cytometric assay that used broadly reactive anti-FHbp mAbs.[69] Unlike MATS, which uses polyclonal rabbit antisera with greater avidity for the respective vaccine antigens than for antigens with amino acid sequence divergence, the flow assay only measures strain expression (since the anti-FHbp mAbs used are reported to be broadly cross-reactive). Additional studies are therefore needed to determine whether measurement of strain FHbp expression alone without taking into account cross-reactivity with the vaccine antigen will be an accurate guide to predicting strain coverage by the MenB-FHbp vaccine.

In summary, assays such as MATS or flow cytometric detection of strain FHbp expression ultimately may prove useful for estimating vaccine coverage in different geographic areas. However, the assays remain surrogates of bactericidal activity, which is a correlate of protection. While it is true that the available volumes of serum from infants restrict the number of strains that can be tested for bactericidal activity, with adolescent and adult vaccination it should be feasible to include assays of both antigen-specific indicator strains and representative disease-causing strains to inform public health recommendations. In the United States, as part of an accelerated approval process that was used to license the vaccines, both manufacturers committed to performing studies after vaccine licensure to confirm that the group B vaccines elicit serum bactericidal antibody against diverse epidemiologically relevant meningococcal group B strains. Ultimately, however, the true impact of these two new vaccines can only be determined by carefully performed postlicensure vaccine effectiveness studies as well as other observational studies, such as was recently reported from the United Kingdom on the effectiveness of two doses of MenB-4C given to infants in preventing disease.[152]

EFFECT OF VACCINATION ON COLONIZATION

Licensed meningococcal vaccines elicit serum bactericidal activity, which protects individuals against developing invasive disease. Vaccines that also protect against acquisition of asymptomatic pharyngeal carriage confer herd protection, which decreases exposure to the organism and therefore decreases the incidence of disease in unvaccinated individuals.[76,173] Little is known about the effect of immunization with vaccines that target protein antigens on carriage. Read and colleagues investigated the effect of MenB-4C vaccination on oropharyngeal colonization in adults in the United Kingdom aged 18 to 24 years.[75] 2954 subjects were randomized to receive two doses of MenB-4C, 1 month apart, or two doses of a Japanese encephalitis vaccine (negative control), or one dose of MCV4-CRM followed by one dose of a placebo. Oropharyngeal cultures were obtained before vaccination and at five time points over 1 year. One month after dose 2 (primary endpoint), there were no significant differences in meningococcal carriage rates among the three groups. However, during the period from 3 months after dose 2 to 11 months, the authors reported a significant effect of MenB-4C vaccination on lowering carriage for any meningococcal strain (18% carriage reduction, 95% CI, 3 to 31). In general, vaccination is not expected to decrease carriage in those already colonized; the most important effect of vaccination on carriage should be on new acquisition of strains. During the period from 3 months after dose 2 to 11 months, there was a trend for lower rates of acquisition of new group B strains in the MenB-4C vaccinated group (34 of 628 [5%]), compared with the control group (50 of 674 [7%]). However, this trend was counterbalanced by a higher rate of new acquisition of group B strains in the MenB-4C vaccinated group during the 1- to 2-month period after dose 2 when vaccine-induced immunity should have been greatest (21 of 659 [3%] compared with 13 of 699 [2%] in the control group). Taking into consideration all of the data on new acquisition of group B carriage from 2 months to 11 months of follow-up after dose 2, MenB-4C vaccination did not appear to have a beneficial effect on decreasing group B colonization. However, the jury is out on this question since several factors in the study design may have limited the ability of the authors to detect an effect of vaccination on carriage, if it was present. These included high baseline meningococcal carriage rates (30%), enrollment of the students after they had arrived on campus during a period when there were relatively high rates of acquisition of meningococcal carriage (which could have resulted in acquisition of natural immunity by the control group), and progressively lower acquisition rates in both those vaccinated and controls during the 11 months of follow-up. One or more of these factors may have led to the relatively low effect of the control conjugate vaccine in this study on decreasing carriage of group C, Y, or W strains (36% reduction; 95% CI, 16–52). Whether MenB-4C provides any herd protection and the potential impact on vaccination on strain variation and carriage will need to be determined in postimplementation surveillance studies.[174]

VACCINE SAFETY AND TOLERABILITY

MenB-4C Vaccine

MenB-4C contains OMV from group B strain NZ98/254, which was used as a stand-alone vaccine in New Zealand. While more than 3 million doses of the OMV vaccine were safely administered in New Zealand to individuals younger than 20 years,[134–136] vaccination was associated with high rates of local reactions and systemic reactions such as fever, irritability, and lethargy.[140] However, not all of the reactions to

MenB-4C can be attributed to the OMV component because administration of the recombinant proteins alone without the OMV to infants also elicited high rates of local and systemic reactions (albeit less than to MenB-4c).[115]

For the European Union, the safety of MenB-4C vaccination of infants and toddlers was investigated in controlled trials involving 4843 subjects. In one study, 1885 infants were randomized to receive the MenB-4C vaccine at 2, 4, and 6 months given with routine vaccines; MenB-4C at 2, 4, and 6 months and routine vaccines at 3, 5, and 7 months; or routine vaccines alone at 2, 3, and 4 months.[113] Fever 39 °C or greater, severe irritability, and unusually severe crying occurred more frequently when MenB-4C was administered with other routine vaccines such as DTaP, Hib, hepatitis B, and pneumococcal conjugate vaccine (Fig. 39.13). The severity or frequency of reactions did not increase with subsequent doses of MenB-4C. In this study, two cases of Kawasaki disease were reported, one of which was thought by an independent panel of experts to be possibly related to MenB-4C vaccination.

Data on adverse events temporally related to MenB-4C vaccination are also available from a second large Phase III study of infants immunized at 2, 4, and 6 months with MenB-4C given concomitantly with routine vaccines (n = 2481), or routine vaccines and a control meningococcal group C conjugate vaccine (MCV-CRM; n = 659), or routine vaccines alone (n = 659).[144] For the tolerability analyses, the data for the three primary injections were pooled for each group. Relatively high rates of common local reactions at the MenB-4C injection site were observed during the 7 days of observation, such as any tenderness (87%) or erythema (93%), compared with 54% and 53%, respectively, at the MCV-CRM injection site in the control group. Severe tenderness at the MenB-4C injection site occurred in 29% compared with 5% for the MVC-CRM vaccine. The most common systemic reaction to the MenB-4C vaccine given with routine vaccines was fever, which was most prevalent on day 1 and usually had resolved by day 3 (Fig. 39.14). The higher rates of fever in the MenB-4C group resulted

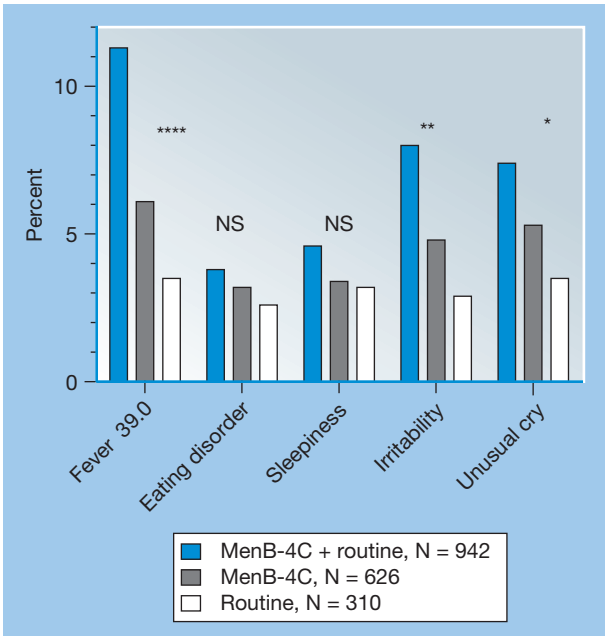

Figure 39.13. Severe systemic reactions observed in infants within 7 days of a dose of MenB-4C vaccine given at 2 months of age. "Severe" defined as follows: eating disorder (child missed more than two feedings), sleepiness (child slept most of the time and was hard to arouse), irritability (child was unable to be consoled), and unusual crying (high-pitched screaming, unlike the child's normal crying, which persisted for ≥3 hr). *P < .05; **P < .01; ***P < .001. *(Data from Gossger N, Snape MD, Yu LM, et al. Immunogenicity and tolerability of recombinant serogroup B meningococcal vaccine administered with or without routine infant vaccinations according to different immunization schedules: a randomized controlled trial.* JAMA. *2012; 307:573-582.)*

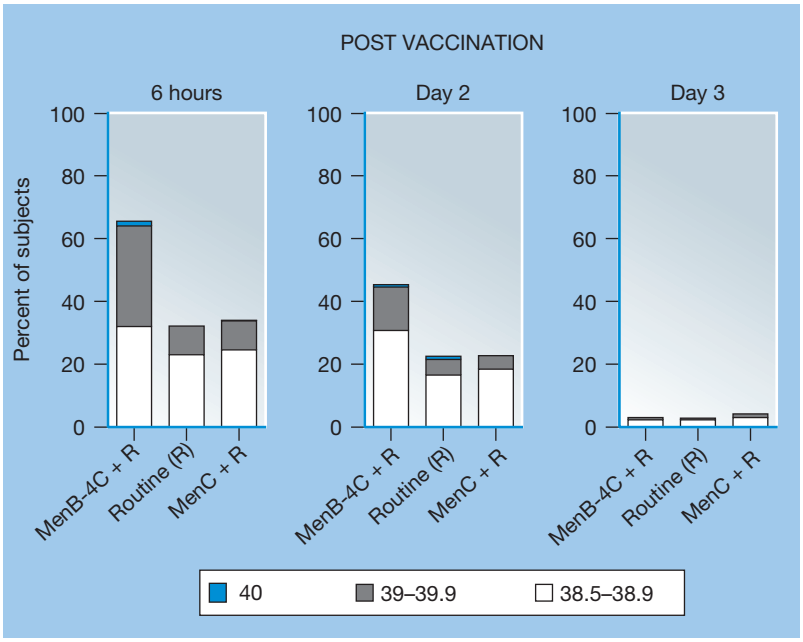

Figure 39.14. Fever observed within 3 days of MenB-4C vaccination in infants immunized at 2, 4, and 6 months of age. Pooled data for three injections. *(Data from Vesikari T, et al, and Group EUMBIVS. Immunogenicity and safety of an investigational multicomponent, recombinant, meningococcal serogroup B vaccine [4CMenB] administered concomitantly with routine infant and child vaccinations: results of two randomised trials.* Lancet. *2013;381:825-835.)*

in greater use of antipyretics (93% for the MenB-4C plus routine vaccination group, 71% for routine vaccines alone, and 66% for routine vaccines plus MVC-CRM vaccine). Other systemic reactions in the MenB-4C group such as any irritability (93%), excessive sleeping (87%), or poor appetite (72%) occurred at slightly higher frequencies than in the control groups.

In this study, two confirmed cases of Kawasaki disease and one unconfirmed case occurred 3, 7, and 14 weeks after vaccination in the 2480 infants in the MenB-4C vaccine + routine vaccines group. One confirmed case occurred at 23 weeks in 1149 control infants who received routine vaccines given with or without MCV-CRM (respective attack rates of 0.12% and 0.08%). The cases of Kawasaki disease in the MenB-4C group, and the one case in the earlier Gossger et al.[113] study considered possibly related to MenB-4C vaccination, and a subsequent case in Quebec[175] are too few to establish a relationship between MenB-4C vaccination and the risk of Kawasaki disease. However, the cases underscore the need to investigate the risk of Kawasaki disease during postlicensure surveillance.

For U.S. licensure, the safety of MenB-4C vaccination was investigated in controlled trials involving 3058 teenagers and adults aged 10 to 26 years.[133] As observed in immunized infants, there were high rates of local reactions such as injection site pain and erythema, but the rates of systemic side effects in the teenagers and young adults appeared to be less than those described for the immunized infants.

Among the 3058 teenagers and young adults in these studies, there were five serious adverse events (SAE) considered related or possibly related to MenB-4C vaccination: tremor ($n = 1$), dyspnea ($n = 1$), acute thyroiditis ($n = 1$), and juvenile arthritis ($n = 2$).[19] The overall rates of SAEs were similar in the control subjects. Information on SAEs occurring within 30 days of MenB-4C vaccination also was collected on more than 59,000 individuals who were immunized with MenB-4C as part of efforts to control group B outbreaks at two U.S. college campuses[18] and a group B outbreak in Quebec.[19] Three SAEs were considered related or possibly related to vaccination: rhabdomyolysis ($n = 1$), anaphylaxis within 30 minutes of vaccination ($n = 1$), and fever ($n = 1$), all of which resolved.

In a third study, data on adverse events were collected by a survey of 2967 students immunized with MenB-4C in response to an outbreak on a college campus in Canada.[176] About 30% of the vaccinated students responded to the survey, and the adverse events reported were consistent with those previously observed in young vaccinated adults. There were no reports of hospitalizations related to vaccination.

MenB-FHbp

A study of MenB-FHbp in infants was terminated early because of a high rate of fever.[177] The manufacturer subsequently discontinued efforts to license the vaccine for infants and toddlers. Both recombinant FHbp antigens in MenB-FHbp are lipidated, which may contribute to the vaccine's reactogenicity.

For teenagers and young adults the safety of MenB-FHbp vaccination was investigated in controlled trials involving more 4282 subjects aged 10 to 26 years.[178] The most common side effects were "any" pain at the injection site (93%), any fatigue (64%), any headache (57%), any muscle pain (41%), any chills (30%), and any joint pain (22%). Most of these reactions were mild to moderate in severity and transient, and the rates were only slightly higher than those of individuals getting similar FDA-approved vaccines such as HPV. Infrequently, the reactions to the MenB-FHbp vaccine were "severe," as defined by preventing daily activity. For adolescents given the first dose of MenB-FHbp vaccine, the rates of severe pain at the injection site (8.2%) or redness in an area greater than 10 cm (2.2%) were higher than those in controls injected with saline (0.2% and 0%, respectively). The occurrence of severe systemic reactions such as headache (1.4%), fatigue (4.3%), chills (1.3%), generalized myalgia (3.1%), or joint pain (0.9%) were uncommon but also exceeded rates of severe systemic reactions in subjects vaccinated with a control HPV vaccine (Fig. 39.15). There were trends for lower frequencies of these reactions in the MenB-FHbp group with subsequent doses.

There were no SAEs considered related or possibly related to MenB-FHbp vaccination among the 2557 subjects in the four controlled clinical trials summarized above (one published[179]). In a Phase III controlled study, 5712 healthy adolescents and young adults aged 10 to 25 years were randomized (2:1) to receive MenB-FHbp at 0, 2, and 6 months or a control vaccine (hepatitis A/saline).[180] The rate of medically attended adverse events did not differ between the two vaccines (5% to 7.0% of subjects after each dose). SAEs occurred in 1.6% of MenB-FHbp vaccinated subjects compared with 2.5% of subjects given the control vaccine. Two subjects in the MenB-FHbp group had SAEs considered to be related to the MenB-FHbp vaccine: neutropenia and an anaphylactic reaction.

In summary, vaccination with MenB-4C or MenB-FHbp is associated with higher rates of local and systemic reactions than with other commonly administered vaccines. The prelicensure and postlicensure studies did not detect an excess of SAEs related to either vaccine. One exception in infants may be Kawasaki syndrome, and one exception in adolescents and young adults may be anaphylaxis.

A theoretical safety risk of immunizing with an antigen that binds to a host protein is exposing the host to neoantigens in immune complexes that form after the antigen is injected, which can potentially elicit autoantibodies. In both human FH transgenic mice and rhesus macaques immunized with MenB-4C, a few animals developed serum autoantibodies to FH.[60,61] In the mice the antibodies were limited to immunoglobulin M, and in rhesus macaques the antibodies appeared to be transient (detected after dose 2 but not after dose 3).

Serum anti-FH antibodies are found in approximately 4% to 5% of healthy adults.[181] However, anti-FH antibodies appear to be implicated directly in the pathogenesis of atypical

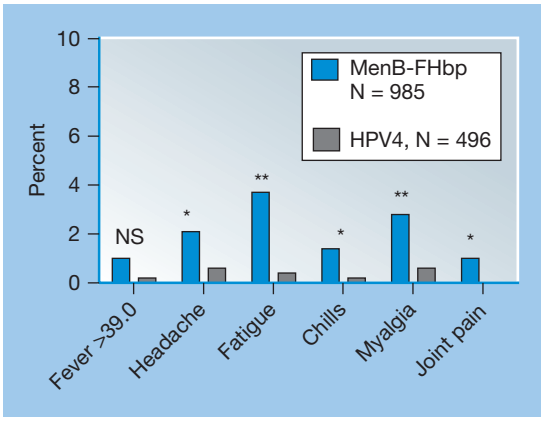

Figure 39.15. Severe systemic reactions within 7 days of dose 1 of MenB-FHbp in teenagers aged 11 to 17 years. Data shown for subjects randomized to receive MenB-FHbp or a control human papilloma vaccine (HPV4). "Severe" reaction was defined as "prevents daily activity." *$P < .05$ by Fisher exact test; **$P < .01$. *(Data from the Trumenba U.S package insert [October 2015].)*

hemolytic syndrome[182–188] and are also found in increased frequency and higher titers in patients with C3 glomerulopathies and in lupus and antiphospholipid syndromes.[182–185,188–190] The study design and sample sizes of the prelicensure and postlicensure studies of MenB-4C or MenB-FHbp and the limited postlicensure use of these vaccines are insufficient to detect rare adverse events, including autoimmune diseases. The experimental "signals" of anti-FH autoantibody in two animals models indicate the need to investigate the presence and clinical significance, if any, of these antibodies in immunized humans.

COST EFFECTIVENESS

A cost-effectiveness analysis for The Netherlands concluded that at the currently low level of disease, routine infant MenB-4C vaccination with four doses at 2, 3, 4, and 11 months was unlikely to be cost effective unless the group B disease incidence increased or the vaccine price was substantially lower than 40 euros.[191] In Germany,[192] France,[193] and Italy,[194] similar analyses concluded that with the current low incidences of serogroup B disease, universal vaccination would prevent only a small number of cases at very high overall costs. This conclusion was particularly true if vaccination did not also lower meningococcal carriage. Two cost-effectiveness analyses in the United Kingdom used modeling to investigate the potential effect of introducing MenB-4C vaccination and concluded that vaccination could decrease the disease burden and be cost effective if the vaccine were priced competitively and, in the case of adolescents, if vaccination protected against carriage.[195,196]

Given the higher disease burden in infants, the U.K. Joint Committee on Vaccination and Immunisation (JCVI) recommended introduction of routine infant vaccination if a low price could be obtained from the vaccine company, since a program for prevention of a rare disease would only be cost effective at a low vaccine cost.[197,198] To improve cost effectiveness, JCVI suggested using a three-dose schedule at 2, 4, and 12 months, which, based on some limited published post–dose 2 data and unpublished data, they believed would be sufficiently immunogenic instead of the four dose EU-approved schedule for this age group.[197] To decrease cost further the JCVI recommended eliminating one of the meningococcal C conjugate vaccine doses at age 3 months, reasoning that with the low group C disease incidence in the United Kingdom and group C herd immunity, eliminating this dose of the conjugate vaccine would have a minimal, if any, effect on the incidence of serogroup C disease (see Chapter 38).[197]

For the United States, a preliminary cost-effectiveness analysis was published as part of the Advisory Committee on Immunization Practices (ACIP) recommendations for meningococcal B vaccination for teenagers and young adults.[199] Because of the low disease incidence, even with the use of optimistic assumptions such as a decline in protective efficacy extending over 15 years, routine vaccination at ages 16 or 18 years was not cost effective (i.e., $3.7 to $4.1 million per quality-adjusted life-year).

VACCINE RECOMMENDATIONS

In the European Union, three doses of MenB-4C, each separated by 2 months of age, are approved for infants beginning immunization at ages 6 weeks to 5 months, with a fourth (booster) dose given in the second year of life. For infants aged 6 to 11 months, two doses are approved, with a third booster dose given in the second year. For adolescents and adults up to age 55 years, two doses are approved, separated by at least 1 month. As of January 1, 2017, MenB-FHbp was not licensed in the European Union. In the United Kingdom, to improve cost effectiveness, JCVI recommended using a three-dose MenB-4C infant schedule at 2, 4, and 12 months, which was implemented in October 2015. As described above, preliminary data indicate that the two-dose priming schedule provided a high level of short-term protection.[152]

As of January 1, 2017, MenB-4C vaccination was recommended in the United Kingdom and some regions of Germany, Ireland, Italy, Poland, and the Czech Republic.[200] However, with the exception of the United Kingdom, this has not been implemented in the European Union (except on the private market), partly because of recent decreases in the incidence of group B disease, lack of evidence of herd immunity from vaccination, and concerns about the high cost of a vaccination program.[191,195,196,198] In England, the annual incidence of capsular group B disease in infants in the first year of life (30 per 100,000; see Fig. 39.1) is approximately 13-fold higher than in adolescents aged 15 to 18 years (2.3 per 100,000). Because doubts remain about whether MenB-4C vaccination confers herd protection, and disease rates remain low in adolescents, MenB-4C is not recommended for routine immunization of adolescents because the economic model indicated that the vaccine could not be cost effective without the additional benefits of herd immunity.

In the United States, two group B vaccines are approved by the FDA for the age group 10 to 25 years. To date, there are no studies directly comparing the immunogenicity or tolerability of MenB-4C and MenB-FHbp. In separate studies, the reported rates of local and systemic reactions appear to be similar. For MenB-4C, two doses are recommended separated by at least 1 month. For MenB-FHbp, three doses are recommended at 0, 2, and 6 months or 2 doses at 0 and 6 months. Given the major differences in vaccine composition, the vaccines are not considered to be interchangeable; thus, the same vaccine product should be used for all the doses. The group B vaccine recommendations of ACIP are the same for both vaccines except for the different vaccine schedules.

ACIP recommends vaccination of persons who are at increased risk of acquiring group B meningococcal disease.[19] These individuals should receive two doses of MenB-4, separated by a minimum of 1 to 2 months, or three doses of MenB-FHbp at a 0, 1 to 2, and 6 months schedule. High-risk persons include those with occupational exposure (such as microbiologists exposed to *N. meningitidis*) or exposure to meningococcal group B outbreaks, or patients with functional or anatomic asplenia or complement deficiency. The latter group includes persons being treated with eculizumab (Soliris) for atypical hemolytic uremic syndrome or paroxysmal nocturnal hemoglobinuria because the drug inhibits the terminal complement pathway and increases risk of neisserial infection, including invasive meningococcal disease.[201–204] Because there are no theoretical differences in the safety of group B vaccines for persons older than 25 years, ACIP recommends off-label vaccination of persons who are at increased risk of acquiring group B meningococcal disease to include persons older than 25 years.[19] The ACIP recommendation for group B immunization of high-risk groups is Category A (i.e., intended for all persons without contraindications in these risk groups).

Certain risk groups included in the meningococcal polysaccharide-protein conjugate vaccine recommendations are not included in the group B vaccine recommendation, such as persons traveling or residing in countries where meningococcal disease is hyperendemic or epidemic (unless the strain is known to be group B), or first-year college students living in residence halls, military recruits, all adolescents, or children younger than 10 years even if they have underlying complement deficiencies or impaired splenic function (e.g., sickle cell disease). However, given the high risk of

developing invasive meningococcal disease in children younger than 10 years with complement deficiencies or impaired splenic function, physicians may consider off-label immunization with MenB-4C vaccine, which is licensed in Europe, Canada, and Australia for infants as young as 6 weeks of age. In these children the potential benefits of vaccination would appear to outweigh any theoretical risks.

The ACIP also recommends that group B vaccine be administered to adolescents and adults aged 16 to 23 years in the general population to provide short-term protection against most strains causing serogroup B disease.[199] The preferred age is 16 to 18 years because the majority of cases in adolescents and young adults occur after age 15 years (see Fig. 39.1B). For immunization of low-risk individuals in this age group, two doses of either vaccine, separated by 6 months, can be used. The interval can be as short as 1 month for MenB-4C and 5 months for MenB-FHbp. For persons immunized with two doses of MenB-FHbp at an interval of 1 to 4 months, a third dose should be given at least 4 months after the second dose. The recommendation for group B immunization of adolescents and young adults in the general population is Category B (requiring individual clinical decision by the healthcare provider).[199]

PRECAUTIONS AND CONTRAINDICATIONS

MenB-4C and MenB-FHbp are contraindicated in persons with known hypersensitivity to any of the components of the vaccine or a history of a severe reaction to a previous dose. There are no data on safety of either vaccine in pregnant women. Therefore the vaccine should be used in pregnancy with caution and only if clearly needed. There also are no data on whether the vaccines are excreted in human breast milk. While not contraindicated, the possibility that the vaccines may be present in human breast milk should be considered when immunizing nursing mothers. For MenB-FHbp, the caps of the prefilled syringes contain latex, which may cause allergic reactions in sensitive persons.

PUBLIC HEALTH PERSPECTIVE

The United Kingdom has targeted routine MenB-4C vaccination of infants younger than 1 year for group B vaccination, which is the age group at greatest risk of acquiring disease (see Fig. 39.1). Although it is not known whether a booster immunization will be required during later childhood to maintain protection in the population,[149] vaccination of infants is more cost effective than adolescents, particularly for a vaccine that is not proved to provide herd immunity.

In the United States, overall rates of group B disease are much lower than in England, and the group B vaccines in the United States are only licensed for the age group 10 to 25 years, a group with an incidence rate 10-fold lower than in the younger than 1 year age group. Thus, between 2009 and 2013, there were 36 cases and five deaths in the United States in the age group 18 to 23 years with an annual incidence is this age group of 0.14 per 100,000 population.[205] Assuming the group B vaccines have 75% or higher efficacy, about one case of disease will be prevented in the first year per 1 million persons vaccinated. The number of cases potentially prevented by vaccination will be greater if vaccination offers herd protection and/or the duration of protection is substantially longer than 1 year (e.g., declining over 15 years).[199]

The cost in the United States of immunizing a cohort of 1 million was estimated to be approximately $402 million, which included vaccine purchase, administration, and wastage.[205] To these costs must be added the cost of adverse events from vaccination. Based on observed rates of "severe" reactions reported in teenagers within 7 days of a dose of MenB-FHbp (see Fig. 39.15), in a cohort of 1 million teenagers given three doses, 31,000 would be expected to develop severe headache, 51,000 to experience severe fatigue, 38,000 to have severe myalgia, and 12,000 to have severe joint pain in excess of the number of these reactions observed in persons immunized with a HPV4 vaccine (severe defined as preventing daily activity). In short, given the currently very low group B disease burden in adolescents and young adults in the United States, the cost of prevention of one case or one death in the first year by vaccination with a group B vaccine is high and vaccine reactinogenicity is considerable. However, the major factors that appeared to influence the ACIP to decide on a category B recommendation for group B vaccination, rather than category A, were the low disease burden in the general population, unresolved scientific questions about the vaccines (including duration of protection), and the high cost of a vaccination program.[199,206] ACIP will revisit the current recommendations as additional data about these vaccines and meningococcal disease epidemiology in the United States become available.

NEXT GENERATION MENINGOCOCCAL B VACCINES

MenB-4C Combined With MCV4-CRM

MenB-4C is unlikely to become available in the United States for infants. Instead the manufacturer announced plans to combine the group B protein vaccine antigens with MCV4-CRM as a "universal" meningococcal vaccine, eventually targeting infants.[207] Results of studies defining an optimal formulation of the combination vaccine, based on immunogenicity and safety in adolescents, are promising.[24–26] Serum bactericidal antibody responses against serogroups A, C, W, and Y were higher for all of the combination MenB/MCV4-CRM formulations tested compared with MCV4-CRM alone. Two of the vaccine formulations containing OMV appeared to elicit the greatest serum bactericidal antibody responses without any identified safety concerns. Extending these studies to infants will be challenging; it will therefore be a number of years before a vaccine that prevents capsular group B disease will be available for infants in the United States.

Improving FHbp Immunogenicity

As described in the section on FHbp, after injection of FHbp, the antigen can form a complex with human FH. Data from both human FH transgenic mouse and nonhuman infant primate models indicate that binding of FH to FHbp decreases serum bactericidal antibody responses,[59,60,62] possibly by covering important epitopes. Furthermore, mutant FHbp antigens with one or two amino acid substitutions that decreased FH binding elicited higher serum bactericidal antibody responses in human FH transgenic mice,[56,58,59,208,209] or an infant macaque model[61] than control FHbp vaccines that bound human FH. In theory, the mutant FHbp antigens also may be safer by having less risk of eliciting autoantibodies to human FH.[219]

Native Outer Membrane Vesicle Vaccines

Conventional OMV vaccines such as the OMV component in the MenB-4C vaccine are treated with detergents to extract endotoxin and increase vaccine tolerability. This treatment also extracts desirable antigens such as FHbp or NHba, which are lipoproteins. To increase anti-FHbp antibody responses, native OMV (NOMV) vaccines (not treated with detergents)

have been prepared from mutant meningococcal strains engineered to overexpress FHbp.[210] A second mutation (LpxL1 knock-out) in lipopolysaccharide biosynthesis is introduced to attenuate endotoxin activity,[211,212] which avoids the need for treatment of the OMV with detergent. In mice, native (non–detergent-treated) OMV vaccines from LpxL1 KO mutants with overexpressed FHbp elicited broader serum bactericidal antibody responses than control recombinant FHbp vaccines or detergent-treated OMV vaccines prepared from wild-type strains.[212–214] By absorption studies, the principal serum bactericidal antibodies elicited by the mutant native OMV vaccines were directed against PorA and FHbp. A native OMV vaccine from an LpxL1 knock-out mutant with overexpressed FHbp also elicited broadly protective serum antibodies in a nonhuman infant primate model, which is likely to be more relevant for predicting human antibody responses than mouse models.[215] The NOMV vaccine approach can incorporate mutant FHbp antigens with low FH binding. In human FH transgenic mice, an NOMV vaccine with overexpressed mutant FHbp elicited higher serum anti-FHbp bactericidal antibody responses than a control NOMV vaccine with overexpressed FHbp that bound human FH.[58] In human FH transgenic mice, the NOMV vaccine also elicited higher and broader serum bactericidal responses than MenB-4C,[216] and in human CEACAM1 transgenic mice conferred protection against nasopharyngeal meningococcal colonization.[217]

40 Mumps Vaccines

Steven A. Rubin

HISTORY OF THE DISEASE

The clinical picture of mumps was first described by Hippocrates in the 5th century BC in his first book of *Epidemics*, in which he described outbreaks among young males characterized by swelling about one or both ears, occasionally accompanied by painful swelling of one or both testes, referring to parotitis and orchitis, the hallmarks of this infectious disease. Recognition of neurovirulence as part of the clinical picture was made by Hamilton in his 1790 report to the Royal Society of Edinburgh[1] which included descriptions of involvement of the central nervous system (CNS). The origin of the word *mumps* is obscure, but may be related to the old English verb, which means "grimace, grin, or mumble." Mumps has since been recognized as a ubiquitous disease of childhood and continues to be so in countries that do not include mumps vaccine in their national immunization program. Where mumps vaccines are widely used, the disease has been nearly eliminated, although sporadic, and sometimes large, outbreaks still occur despite vaccination.

WHY THE DISEASE IS IMPORTANT

Mumps is generally an acute, relatively benign communicable disease. Common presentations, however, such as orchitis and parotitis, can be debilitating, and more serious complications can occur. Prior to the vaccine era, mumps was the leading cause of viral encephalitis and sudden onset deafness in the United States.[2,3] The disease is highly contagious, with nearly all persons having evidence of prior infection by age 15 years in the prevaccine era.[4–6]

Although historically a disease of childhood, mumps gained notoriety as an illness of armies during times of mobilization. During World War I, mumps was a leading cause of days lost from active duty in the U.S. army in France, with an average annual rate of hospitalization of 55.8 per 1000 for a total of 230,356 cases.[7] Gordon noted in 1949 that to the military "mumps is no passing indisposition of benign course but ranks with many of the more formidable diseases."[8] Mumps was also a major cause of morbidity among Confederate soldiers during the American Civil War[9] and during World War II,[10] and continues to occur in military settings[11–13] in addition to the general population.

Based on an analysis of data from 2009, Zhou and colleagues estimated a savings of more than $2.37 billion in societal costs in the United States through mumps vaccination.[14]

BACKGROUND

Clinical Description and Complications

Table 40.1 summarizes the clinical manifestations of mumps. Symptoms and duration vary widely among studies and are dependent on age group, sex, vaccination status, and the basis for defining a case. Complications are more frequent in adults than children; by factoring out sex-specific manifestations (e.g., orchitis, oophoritis, mastitis), rates of complications are similar in males and females, except for neurological manifestations, which have a 3:1 or greater male-to-female ratio.[15–17] The most common manifestation is salivary gland swelling, usually the parotid, which serves as the basis for the clinical case definition. Parotitis may be unilateral (Fig. 40.1) or, more commonly, bilateral. Parotitis develops an average of 16 to 18 days after exposure[18,19] and may be preceded by several days of nonspecific symptoms, including fever, headache, malaise, myalgias, and anorexia. Fever usually lasts 1 to 6 days, but enlargement of the parotid gland may persist 10 days or longer.

If viruria is used as an indication of kidney infection, then kidney involvement is common in mumps, although clinical nephritis is rarely diagnosed. Utz and colleagues found asymptomatic excretion of mumps virus in the urine of 72% of mumps cases evaluated.[20] A similar frequency of viruria was identified among military personnel with mumps admitted to a medical center.[21] Abnormal renal function can be measured in more than a third of cases; however, kidney-specific manifestations are rare.[21,22]

Orchitis, typically unilateral, occurs in up to a third of cases in postpubertal men.[5,23,24] In cases of bilateral orchitis, hypofertility and testicular atrophy have been reported; however, these are uncommon and sterility is exceedingly rare.[25] An increased risk of testicular cancer has been reported in association with mumps orchitis but remains unproved.[26–28]

In females, oophoritis and mastitis can occur, with rates ranging from 5% to 30% of cases.[5,29,30] Infertility subsequent to oophoritis has been suggested but not confirmed.[31]

Involvement of the CNS occurs in fewer than 1% to up to 62% of clinical cases, depending on the stringency of assessment. If lumbar punctures are performed routinely, greater than half of persons with mumps may show evidence of meningitis based on pleocytosis of the cerebrospinal fluid (CSF),[32,33] whereas clinical evidence of meningitis is only seen in approximately 5% of cases. Encephalitis is much more serious, occurs in approximately 0.5% of clinically apparent mumps infections, and is responsible for the majority of fatal cases.[15,16,34] Neurological manifestations are generally preceded by parotitis by 4 to 5 days but can occur before or in the absence of detectable salivary gland swelling.

Pancreatitis, usually mild, is seen in approximately 4% of cases.[29,35] Significantly higher rates have been reported in some outbreaks, although these are likely overestimates given that the diagnosis is often based on elevated serum amylase levels irrespective of clinical symptoms.[36]

Other infrequent complications include endocardial fibroelastosis[37,38] cerebellar ataxia,[39,40] transverse myelitis,[41,42] hydrocephalus,[43,44] arthropathy,[45,46] autoimmune hemolytic anemia,[47,48] thyroiditis,[49,50] thrombocytopenia,[51,52] and hearing loss. Hearing loss is typically unilateral and transient,[53–55] but sudden onset permanent deafness occurs in approximately 1 in 20,000 cases.[56,57]

Nonspecific respiratory symptoms have been ascribed to mumps, but it is not clear if such symptoms are caused by the virus or are coincidental.[58,59]

Based on assessments of seroconversion in longitudinal studies or outbreak studies, asymptomatic infections occur in approximately 20% to 40% of infected persons.[5,58,60] The high rate of subclinical mumps infections was experimentally

TABLE 40.1 Major Clinical Manifestations of Mumps[a]

Manifestation	Frequency (%)			No. of Studies
	Mean	Range	90% CI	
GLANDULAR				
Parotitis	97	83–100	96–99	40
Submaxillary and/or sublingual glands	20	1–53	8–32	8
Epididymoorchitis[b]	13	1–31	10–15	40
Oophoritis	4	<1–17	1–7	9
Mastitis[c]	10	<1–31	2–18	6

demonstrated in a small study by Henle and colleagues in 1947. Of 15 initially seronegative children orally inoculated with high doses of live mumps virus, all seroconverted, yet seven (47%) showed no evidence of mumps-specific symptoms.[19]

Virology

Granata was the first to suggest a viral etiology for the disease in 1908 based on experiments in rabbits,[61] work that was replicated in monkeys by Nicolle and Conseil in 1913[62] and by Gordon in 1914.[63] A viral etiology was finally proven in 1935 by Johnson and Goodpasture in a remarkable study, although perhaps not for its time, wherein Koch's postulates were fulfilled using children residing in the neighborhood of one of the investigators.[64]

The virus is an enveloped, negative-strand RNA virus in the Paramyxoviridae family, genus *Rubulavirus*. The genome consists of 15,384 nucleotides encoding seven genes: the nucleoprotein (N), V, matrix (M), fusion (F), small hydrophobic (SH), hemagglutinin-neuraminidase (HN), and the large (L) protein genes. Each gene encodes a single protein, except the V gene, which additionally encodes the phosphoprotein (P) and I protein via cotranscriptional insertion of nontemplated guanine residues.[65,66]

The role of the N protein is to coat the viral RNA to form the ribonucleoprotein, which is the template for RNA synthesis, performed by the RNA-dependent RNA polymerase, a complex consisting of the P and L proteins.[67] The viral envelope is a host-cell–derived lipid bilayer membrane containing the M protein on its internal surface and the HN and F proteins on its outer surface. The M protein appears to be involved in the assembly of viral proteins by forming a bridge between the N proteins of the ribonucleoprotein and the cytoplasmic tails of the HN and F proteins followed by budding from the cell.[68,69] The HN protein is responsible for adsorption of the virion to its cellular receptor, sialic acid, and release of nascent virions from the cell surface.[70,71] The HN and F proteins work cooperatively to induce fusion of the virion membrane with the host cell membrane and to induce cell-to-cell fusion.[72,73] The nonstructural V protein is involved in circumventing the interferon (IFN)-mediated antiviral responses by blocking its signaling and limiting its production.[74,75] The SH protein, like the V protein, also appears to aid in evasion of the host antiviral response, but by blocking the tumor necrosis factor-α–mediated apoptotic signaling pathway.[76] Neither of these proteins are essential to virus replication, as demonstrated by the rescue of recombinant viruses engineered to not express these proteins.[77,78] The role of the putative I protein in virus replication and infection is not known.

Only antibodies directed to the F and HN proteins definitively have been shown to neutralize the infectivity of the virus in vitro and confer protection in vivo.[79–82]

Mumps virus is considered serologically monotypic; however, there is some evidence that antigenic differences between strains may allow for breakthrough infection by heterologous strains[83–89] in persons with low levels of neutralizing antibodies (see "Risk Factors for Vaccine Failure and Recent Outbreaks" below).

Pathogenesis as It Relates to Prevention

Based on knowledge of the pathogenesis of related respiratory viruses, it is presumed that mumps virus initially infects and multiplies in the upper respiratory tract before spreading to draining lymph nodes and disseminating via plasma viremia. Given the wide array of acute inflammatory reactions, there is little doubt that viremia ensues; however, primary sites of virus replication following exposure have not been demonstrated and virus has been detected in blood only rarely.[90–92]

Reported symptoms and laboratory findings indicate glandular tissues (parotid glands, testes, breasts, and pancreas) and the CNS as the most common sites of mumps virus dissemination. If viruria is used as an indication of kidney infection, then kidney involvement is also common.

Virus is shed in saliva as early as 11 days after exposure, which is about a week before symptom onset (i.e., parotitis).[19,93]

Viruria can be detected during the first 5 days of illness, and can last up to 14 days.[21,22,94] The period of virus shedding in saliva does not seem to be influenced by vaccination status[95] or symptom severity, including in those asymptomatically infected.[19] Termination of viral shedding in saliva correlates with the local appearance of virus-specific salivary immunoglobulin (Ig) A and IgM, usually appearing within a few days of symptom onset.[96,97] Fewer than 15% of patients continue to shed virus in saliva beyond day 5 of symptom onset.[95]

The pathogenesis of specific complications, such as nephritis and orchitis is uncertain. Nephritis may be the result of direct viral infection of the kidney or immune complex glomerulonephritis. Although a limited number of pathologic specimens have been examined, there is evidence to suggest that immune complex deposition may have a role in some cases.[22] In the rare cases in which renal biopsies or necropsies were performed, findings included adherent renal capsule, epithelial debris in the renal capsule lumen, interstitial mononuclear cell infiltration, edema, and focal tubular epithelial cell damage.[98,99]

Orchitis is thought to be a result of direct viral invasion, based on the recovery of virus from the semen and testis,[100,101] but some cases have been hypothesized to be caused by an immune-mediated adverse reaction.[102]

The pathogenesis of mumps infection of the CNS is almost wholly based on studies in hamsters using hamster-adapted strains of the virus.[103–105] Based on these studies, it appears that virus enters the CNS through the venous vasculature of the choroidal and ependymal epithelial cells. Once infected, these cells become a reservoir for continued production and release of virus, which can penetrate deeper into the brain parenchyma causing encephalitis and numerous neurological complications (see "Clinical Description and Complications" above).

Mumps virus–induced deafness likely involves retrograde penetration by the virus into the perilymphatic fluid following viremia via the cervical lymph nodes, leading to infection of the cochlea.[109] Although the perilymph communicates with the cerebrospinal fluid, deafness does not occur more frequently in persons with CNS complications, suggesting that mumps deafness is not a complication of CNS infection. Damage to the organ of Corti is a common finding, with degeneration of the stria vascularis and tectorial membrane being reported in some, but not other, studies.[106,107,110,113] Hearing loss caused by indirect effects of virus infection (e.g., immune-mediated damage) also has been suggested.[111]

Modes of Transmission

The demonstration by Johnson and Goodpasture[64] and by Henle and colleagues[19] that the virus can be transmitted to humans by nasal or buccal mucosal inoculation suggests that natural infection is initiated by droplet spread. Mumps virus appears to be capable of being transmitted transplacentally and infect the fetus, but this has been reported only rarely.[114,115]

The incubation period is typically 16 to 18 days after exposure, but considering that virus is shed in saliva as early as 1 week before symptom onset it is perhaps not surprising that outbreak investigations performed during the prevaccine era indicate that most transmissions occur before symptom appearance or during the first few days of symptom onset,[6] highlighting the difficulty in preventing virus transmission by case isolation.

DIAGNOSIS

A diagnosis of mumps is usually made clinically, based on the presence of parotitis; however, when disease incidence is low, laboratory testing is essential for case confirmation because other viruses, including influenza A virus, Coxsackieviruses, parainfluenza viruses 1, 2, and 3, Epstein-Barr virus, and adenovirus, can cause parotitis.[116,117,117a]

Prior to widespread vaccine use, laboratory case confirmation was relatively straightforward by demonstrating the presence of IgM or a significant rise in IgG levels between paired acute (or preexposure) and convalescent serum samples. However, in regions of high vaccine coverage, most cases may occur in vaccinees, in whom an IgM response may not be detectable as it is not a major component of the anamnestic immune response. Whereas IgM is readily detectable in unvaccinated persons, rates of IgM detection are 15% or less in two-dose vaccine recipients.[118–120] Furthermore, IgG levels in vaccinees may already be high, precluding the demonstration of a significant increase in IgG titer. In studies where a large proportion of notified cases were laboratory tested, fewer than 10% could be serologically confirmed.[116,121,122]

Considering caveats of serologic testing, reverse-transcription polymerase chain reaction (RT-PCR)–based methods are becoming more widely used for case confirmation. Viral culture is no longer commonly practiced because of its lack of specificity if not combined with laborious immunofluorescence techniques. Furthermore, a number of studies have found RT-PCR methods to be as sensitive as viral culture techniques in detecting mumps virus, obviating the need for the latter.[85,118,123,124]

Virus can be readily detected by RT-PCR and culture using oral fluid specimens (buccal swabs, throat swabs, or saliva). Virus can also be detected in the CSF, and to a lesser extent, urine. Virus rarely has been detected in blood. The relative success of virus detection by RT-PCR can depend on the timing of sample collection, sample handling, the genome target, and possibly vaccination status. Using oropharyngeal swabs obtained on the day of parotitis onset from presumably unvaccinated children, Cusi and colleagues identified mumps virus RNA in 85% of the clinical specimens.[125] Similar results were reported by others using oral specimens from one-dose vaccinees,[85,126] but success rates on samples from two-dose vaccinees were in the range of only 30%.[118,127] Rates of RT-PCR positivity were shown to be substantially greater if swabs are obtained soon after symptom onset, particularly among cases in persons with a history of vaccination. Among persons with a one- or two-dose history of mumps-containing vaccine, Rota and colleagues reported RT-PCR positivity in six of 28 (21%) samples collected 3 or more days after symptom onset compared to 103 of 152 (68%) samples obtained within 2 days of symptom onset.[128] This difference was not apparent among unvaccinated persons (50% of samples testing positive by RT-PCR when collected 3 or more days after symptom onset vs 55% of samples collected within 2 days of symptom onset), possibly suggesting that the duration of virus shedding is shorter in vaccinees, although a recent study found no difference in either the duration of virus shedding in saliva or the concentration of virus in saliva between vaccinated and unvaccinated persons.[128a]

TREATMENT

Mumps is generally a self-resolving illness. Therapy is symptom based and supportive, such as use of analgesics and the application of cold compresses to affected areas (e.g., the parotid and testes). Subcutaneous administration of IFN-α2B helps attenuate the course of mumps orchitis and preserves the organ and its function in some studies,[129,130] but other studies have questioned its safety and effectiveness.[131,132] Standard immunoglobulin or γ-globulin preparations do not appear to be effective treatment options.[60,133]

EPIDEMIOLOGY

Incidence and Prevalence

In the years before the introduction of mumps vaccine in the United States, mumps was most commonly reported among young school-age children. In a study conducted by the U.S. Public Health Service of cases reported between 1960 and 1964 in selected U.S. regions, children younger than 15 years of age accounted for 92% of cases.[134] In this and other studies conducted around this time, more than half of cases were in the age group 5 to 9 years and about a quarter in the age group 0 to 4 years.[135,136] These data are consistent with prevaccine era serosurveys from around the world. A seroepidemiologic study in St. Lucia demonstrated that 70% of children were seropositive for mumps at 4 years of age.[137] In The Netherlands, peak acquisition occurred between ages 4 and 6 years[3] and in the United Kingdom and Spain between ages 5 and 7 years.[138,139]

Table 40.2 shows annual incidences in various countries, averaging approximately 300 per 100,000 population based on passive reporting during the prevaccine era. The actual annual incidence in the general population is likely much higher, as indicated in limited prospective studies.[59,135,140] It has been estimated that less than a third of mumps cases are reported.[58]

In most countries seropositivity is high in unvaccinated populations by adolescence, indicating high infection rates in school-age children. A retrospective analysis of mumps in six European countries (Denmark, England, France, Germany, Italy, and The Netherlands) showed, in general, an inverse relationship between incidence and vaccine coverage, except in France, when at the time of analysis vaccine coverage was elevated in young children, but low in adolescents and the result was a considerable incidence of mumps.[141]

Hope-Simpson demonstrated in household contact studies that mumps is less infectious than measles or varicella.[18] Secondary attack rates among susceptible household contacts younger than 15 years were 76% for measles, 61% for varicella, and 31% for mumps. Some of the observed differences were undoubtedly a result of a higher rate of subclinical infection with mumps, but the higher average age at infection observed for mumps also supports the less-efficient transmission of mumps virus.[142]

Most epidemiologic reports suggest an interepidemic period for mumps of approximately 3 years,[138,143,144] as portrayed by Barskey and colleagues who summarized the number of reported cases of mumps in the United States in the prevaccine era (Fig. 40.2). In temperate zones, mumps exhibits seasonality, with peak incidence during the winter and spring and a nadir in the summer. Seasonality of mumps has not been noted in tropical areas.

In 1989, the Advisory Committee on Immunization Practices (ACIP) recommended all children receive two doses of measles vaccine.[145] Because measles vaccine is generally given in the United States as MMR (measles, mumps, and rubella trivalent vaccine), implementation of this recommendation has meant that most children receive two doses of mumps vaccine. Fig. 40.3 shows the effect of implementation of a two-dose vaccination schedule on disease incidence in the United States. Despite this dramatic reduction in disease incidence, large mumps outbreaks still occur even in fully vaccinated populations, indicating that complete protection against mumps using current vaccines and vaccination schedules may not be feasible (see "Effectiveness in Field Use and Duration of Immunity" below).

Surveillance

For molecular epidemiological purposes and to monitor the global distribution of mumps viruses, the genotype of an isolate is determined and is based on the viral SH gene sequence, which is the most variable in the genome. Twelve such genotypes have been assigned to date, designated A to N, excluding the erroneously designated genotypes E and M.[146] Intergenotypic nucleotide variation ranges from 3.8%

TABLE 40.2 Average Annual Reported Mumps Incidence in Several Countries in the World Health Organization European Region Before and After Introduction of Mumps Vaccine and in Two Countries With No Mumps Vaccination

Country	Years	Prevaccine Average Annual Incidence (Per 100,000 Population)	Years	Postvaccine Average Annual Incidence (Per 100,000 Population)	Reduction

to 19%.[146–148] Certain genotypes predominate in certain geographic regions, but the clinical significance of such trends is unknown and cocirculation of multiple genotypes within a region is not uncommon.[149,150] As of the time of writing this chapter, members of the genotype G group of mumps viruses are responsible for the overwhelming majority of outbreaks. Historically, this genotype was mostly identified in the Western hemisphere, but its distribution is now global. Although some have suggested that certain genotypes are more virulent than others,[151–153] this remains controversial.[154–156]

High-Risk Groups

High-risk groups include international travelers, college and other post–high school students, military personnel, and healthcare personnel born during or after 1957.

Reservoirs of Infection

Although numerous mammalian species can be experimentally infected with mumps virus, humans are the only natural reservoir and only source of transmission. A virus with very

high (>90%) sequence identity to mumps virus has been identified in bats and has been determined to be conspecific to human mumps virus, but it is unclear if this virus can be transmitted to humans.[156a]

Significance as a Public Health Problem

Prior to widespread use of mump-containing vaccines, annual incidences ranged from 100 to 1000 per 100,000 population, and by adolescence, nearly everyone had serological markers of prior infection. Mumps is particularly a problem in large groups of people in close, frequent contact, such as the schools and the military. In a 1968 editorial surrounding discussion on whether a mumps vaccine is warranted, the Georgia Department of Public Health Chief Epidemiologist stated "As a cause of continuing school absenteeism and year-long disruption of teaching schedules, mumps has no equal."[157] The problem for the military was discussed earlier (see "Why the Disease Is Important"). The burden of disease in the absence of vaccination is staggering when considering direct costs for outpatient and inpatient visits, costs of outbreak control, and productivity losses incurred by days of missed work, including for provision of care for sick children and family member. Zhou and colleagues estimated that more than 2.3 million cases of mumps were prevented in the United States by vaccination in 2009, equating to a savings of greater than $1.4 billion in direct costs and more than $2.3 billion in societal costs.[14] Interestingly, whether or not to routinely vaccinate against mumps was a subject of great debate in the late 1960s, with some citing the general benignity of mumps, hazards of occult contaminating agents that might be present in vaccine, sensitization and oncogenicity that might result from use of live virus vaccine, and concerns over use in young children.[157–159] In retrospect, these concerns were for naught.

PASSIVE IMMUNIZATION

Standard immunoglobulin or γ-globulin preparations are not effective for postexposure prophylaxis against mumps or for the prevention of complications.[60,133] Mumps virus–specific immunoglobulin preparations are somewhat effective in conferring protection, but only when used early after the start of the outbreak[133] or soon after symptom development.[160] Nonetheless, the value of mumps-specific immunoglobulin to public health was considered insufficiently high to warrant routine use. The product has not been licensed for use in the United States since the 1980s.[161]

The relative success with use of specific mumps immunoglobulin is consistent with observations of the protective efficacy of maternally transferred antibody which seems to protect infants from developing mumps during infancy.[6,162] Based on the presence of antibodies, the protective effect of maternal antibody would be expected to be most effective during the first 3 months of life; beyond this time, only a small percentage of infants still possess maternal antibody.[163–165] Consistent with the measles literature, vaccine-induced maternal antibody wanes more quickly than antibody derived from maternal natural infection; however, the effect does not appear to be as significant as that for measles. The median time to loss of mumps antibodies in children of naturally immune women was 3.8 months in one study, compared to 2.4 months for children of vaccinated women ($P = .025$).[150]

ACTIVE IMMUNIZATION

History of Vaccine Development

Following his 1945 discovery that mumps virus can be cultivated in embryonated hens' eggs, (also reported by Levens and Enders the same year[166]), Karl Habel of the U.S. Public Health Service produced the first experimental vaccine (inactivated) and tested its effectiveness in 1946 among 2825 West Indian workers on a sugarcane plantation in the Everglades region of Florida.[167] Forty cases developed among 1344 vaccinees between weeks 3 and 16 postvaccination compared to 106 cases among 1481 unvaccinated controls, for a vaccine efficacy over that time period of 58%. Although inactivated vaccines were somewhat effective, the duration of immunity was short, and their use was abandoned in the United States and elsewhere in the 1950s[168,169] in favor of live attenuated vaccines, which were being developed at about that time.

The first live attenuated mumps virus vaccines for routine use were developed in the 1950s in the former Soviet Union[170,171] and in the 1960s in the United States.[172] Live vaccines have been adopted into public health practice in most developed countries, typically as part of a trivalent vaccine with measles and rubella viruses (i.e., MMR). Systematically applied, they have exerted excellent control over the disease, although not as successfully as against measles and rubella. Safety problems also have impinged on the use of some strains of mumps vaccines.

All mumps vaccines in recent use are live viruses (Table 40.3). Some strains are produced by multiple manufacturers, which may result in slight differences in their safety and effectiveness. Strains have been adapted to embryonated hens' eggs and numerous cell types as indicated in Fig. 40.4, which gives the history of passage during the attenuation of some of the more prominent strains listed in the table.

The first widely used live mumps vaccine, Leningrad-3, was produced in the former Soviet Union in 1956. The vaccine was derived from five wild-type isolates obtained from saliva and CSF specimens from children with mumps.[173] Each virus isolate was passaged in embryonated hens' eggs before being pooled for further passage in eggs to produce vaccine. In 1961, the vaccine was further passaged in guinea pig kidney cells and quail embryo fibroblast cells, with final product produced in guinea pig kidney cells.[171,174]

In 1965 the Jeryl Lynn (JL) vaccine strain of mumps virus was produced, derived from virus isolated from the throat of Jeryl Lynn Hilleman, daughter of Maurice Hilleman who developed the product at Merck & Co. The isolate was attenuated by passage in embryonated hens' eggs and whole chick embryo cell culture.[175] The vaccine was licensed in 1967 and is the only mumps vaccine approved for use in the United States; it is used widely throughout the world. The vaccine has been demonstrated to contain two distinct but genetically related viruses identified as JL-major (sometimes referred to in the literature as JL-1 or JL-5) and JL-minor (sometimes referred to in the literature as JL-2), existing in an approximate 5:1 ratio, respectively.[176] These two viruses differ from each other at 414 nucleotide sites (3%), leading to 87 amino acid substitutions.[177] GlaxoSmithKline (SmithKline Beecham Biologicals, at the time) clonally isolated JL-major from a vial of Merck's JL vaccine and passaged it two times in chick embryo fibroblast cells to obtain a preparation designated RIT-4385, which was used as the virus seed for production of their mumps-containing MMR vaccine, Priorix.[178] Based on prelicensure and postlicensure experience, both vaccines have similar safety and immunogenicity profiles.[179–185] Other JL-based vaccines have also been produced and are in more limited use (see "Description of Vaccines and Producers").

The Urabe Am9, Leningrad-Zagreb, and Leningrad-3 also have been shown to contain variant virus populations, but the level of variation is not as great as with JL, and they do not represent distinct virus strains, but are rather part of the quasispecies formed by negative-strand RNA viruses.[186] The Urabe Am9 vaccine from two manufacturers has been demonstrated to contain at least two major variant virus populations existing in a 1:3 ratio.[161,187] At least two major variants were also identified in the Leningrad-Zagreb vaccine[188] and in the Leningrad-3 mumps vaccine.[189,190] The clinical significance of variants is not known.

The Urabe Am9 strain was developed by the Biken Institute in Japan from an isolate obtained from the saliva of a child named Urabe.[191] The virus was isolated in primary human embryonic kidney cells and passaged in primary green monkey kidney cells followed by passages in the amniotic cavity of developing chick embryos. Virus was then plaque purified in quail embryo fibroblast cultures and one of the purified clones, clone 9, was selected and passaged in the amniotic cavity of developing chick embryos to produce Urabe Am9 vaccine.[192]

The Leningrad-Zagreb vaccine strain was produced by limited passage of the Leningrad-3 strain in chicken embryo fibroblast culture.[174]

The Rubini mumps vaccine virus was derived from a mumps isolate obtained from the urine of Carlo Rubini in Switzerland in 1974.[193] The isolate was passaged in WI-38 human diploid cell culture, followed by passages in embryonated hens' eggs before adaptation to the human diploid cell line MRC-5, which was also the substrate for vaccine production.[193] Interestingly, sequence analysis of the SH gene demonstrated that the Rubini vaccine strain is 99% identical at the nucleotide level to the tissue culture-adapted Enders strain prepared in the United States in 1945,[88,194] and is also closely related to wild-type strains isolated in Germany from 1987 to 1992.[195] As described later, this vaccine was found to offer virtually no protective efficacy. In 2001, the World Health Organization (WHO) recommended against its use.[80] The product is no longer manufactured.

Because of the high neurotropism of wild-type mumps viruses, preclinical neurological safety testing of candidate mumps vaccines is required by national regulatory authorities. Historically, such testing has been performed in old world monkeys (Cercopithecidae) and is based on an evaluation of mumps virus–specific neuropathology (periventricular inflammation and neuronal necrosis) following intracerebral inoculation. However, two independent studies conducted in 1999 indicated monkey neurovirulence safety test results do

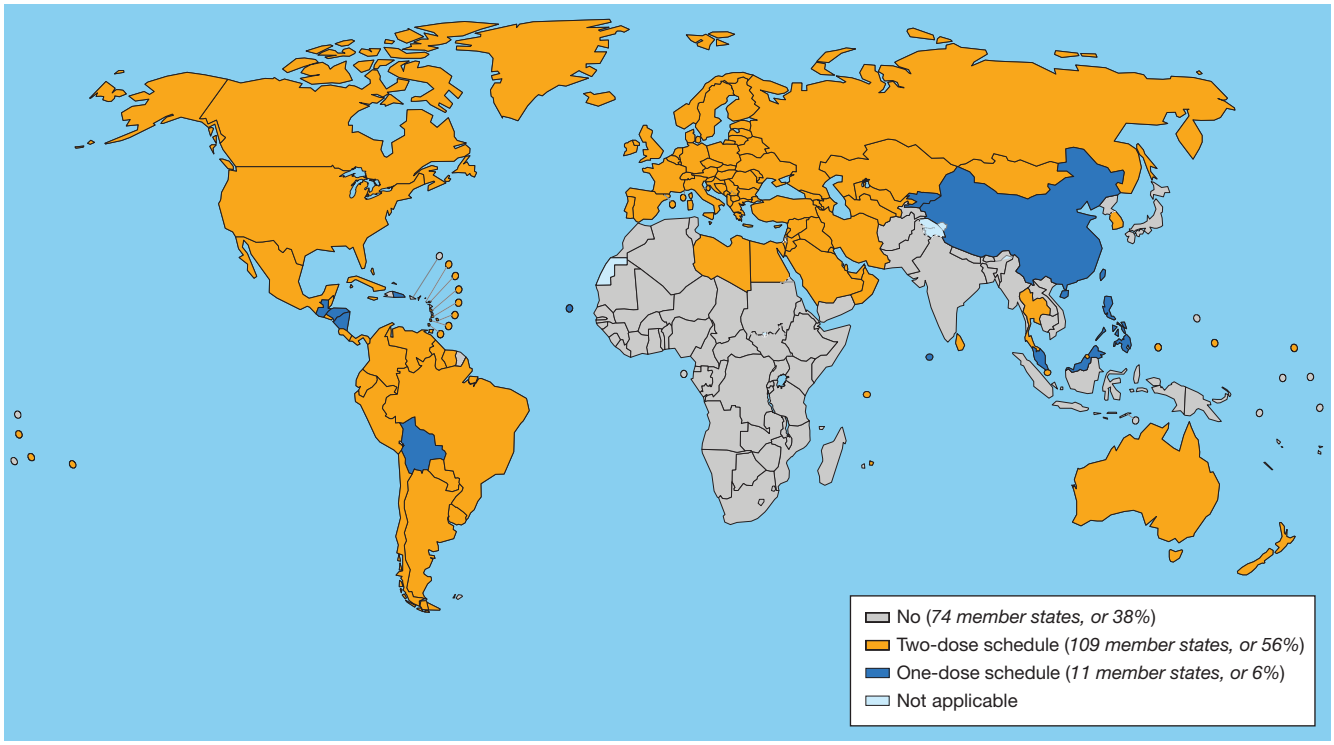

Figure 40.5. Distribution of countries using 0, 1, and 2 doses of mumps-containing vaccine. *(From data reported to World Health Organization [WHO] by 193 WHO Member States as of February 2015.)*

not correlate well with the risk of vaccine virus neurovirulence for humans.[142,196] It is therefore perhaps not entirely surprising that certain mumps vaccines presumably passing the monkey neurovirulence safety test have produced aseptic meningitis in vaccinees (see "Rare Reactions"). On the other hand, the incidence of vaccine-associated aseptic meningitis is but a small fraction of the incidence of aseptic meningitis following natural infection, and compared to natural disease with a known risk of encephalitis, postvaccine aseptic meningitis is relatively mild, suggesting that vaccine strains passing the monkey neurovirulence safety test are considerably neuroattenuated. While efforts have been made to identify specific molecular correlates of mumps virus neurovirulence, none have been identified that broadly distinguish virulent from attenuated mumps virus strains. Several groups have identified numerous genetic differences between attenuated and virulent variants of the Urabe Am9 vaccine strain, but which of these and in what combination are responsible for the observed attenuation cannot be discerned and whether any might influence attenuation of other mumps virus strains appears doubtful.[197–200] Similar conclusions have come from studies of other mumps virus strains.[154,155,201] Rather than attempting to identify point mutations that might impact virus attenuation, others have engineered mumps viruses to preclude transcription of specific genes, for example, the V gene,[78] or viruses that lack specific gene open reading frames, for example, the SH gene.[77] In both cases attenuation of these investigational recombinant viruses was achieved based on animal studies while preserving the ability of the virus to productively replicate in vitro. Whether this is a valid approach to rational vaccine design requires further study of additional wild-type clinical isolates.

Vaccine Use

In the United States, mumps vaccine was first licensed in 1967 and has been administered as MMR since 1971.[202] The ACIP first recommended inclusion of MMR in the national immunization schedule as a single dose in 1971, and then as a two-dose regimen in 1989.[145] As of February 2015, 120 of the 194 (61.9%) WHO member states were using at least one dose of mumps-containing vaccine. Of these 120 countries, 109 use a two-dose regimen. The distribution of countries is shown in Fig. 40.5 and vaccine use in select countries is given in Table 40.4.

In the United States the two-dose MMR series is administered at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose. For international travel, the ACIP recommends vaccinating infants 6 through 11 months of age before departure from the United States, followed by doses at 12 through 15 months of age and at least 4 weeks later.[203] For older children who will travel internationally, the first dose is recommended on or after age 12 months before departure and the second dose at least 4 weeks later.

In other countries, with few exceptions, the first dose is administered at 12 to 18 months of age, but the age at which a second dose is administered varies, from as soon as 1 month after the first dose, to 10 to 12 years after the first dose. The impact of the timing of the second dose is unclear. LeBaron and colleagues found similar levels of neutralizing antibody in 17-year-old children 12 years after receiving their second dose of MMR II at 4 years of age versus antibody levels in 17-year-old children 7 years after receiving their second dose of vaccine at 10 years of age, suggesting no advantage to delaying the age at which a second dose is administered.[204]

In most countries, MMR vaccination is not compulsory; thus, mumps virus seroprevalence varies widely between countries. In the United States, where vaccine use is a requirement for school entry (see "Public Health Considerations" below), vaccine coverage is relatively high. For the 2015–16 school year (the most recent available data), median two-dose MMR vaccination coverage among children in kindergarten was

From World Health Organization. WHO Vaccine-Preventable Diseases: Monitoring System. 2016 Global Summary. For a complete list of vaccination schedules by country, see http://apps.who.int/immunization_monitoring/globalsummary/schedules.

estimated at 94.6%,[205] and among adolescents 13 to 17 years of age it was estimated at 90.7%.[206] Vaccine use is also relatively high in a number of other countries, including Finland, Sweden, The Netherlands, Denmark, and Belgium.[141,207–209] In some countries with purportedly high vaccine coverage, seroprevalence is lower than expected, suggesting noncompliance with vaccine use recommendations.[141,210–212]

Description of Vaccines and Producers

Dosage, Route of Administration, and Composition

All current mumps vaccines are supplied as lyophilized powders and are administered subcutaneously following reconstitution with sterile water. The JL mumps virus vaccine produced by Merck & Co. is available in trivalent MMR formulation "MMR II" (or MMR-Vax in some countries) and in tetravalent measles-mumps-rubella-varicella (MMRV) formulation "ProQuad," both of which are preservative free. Production of monovalent Merck JL mumps vaccine (Mumpsvax) and bivalent measles-mumps vaccine (M-M-Vax) was discontinued in 2009. Each 0.5 mL dose of MMR II and ProQuad contains at least 12,500 and at least 20,000 times the median tissue culture infective dose ($TCID_{50}$) of mumps virus, respectively. Both vaccines contain sucrose phosphate, glutamate, gelatin, and albumin as stabilizers, and less than 25 μg of neomycin per dose.

Merck's JL vaccine virus has been used by other companies to produce their own vaccines. GlaxoSmithKline (then SmithKline Beecham Biologicals) clonally isolated the major component of the vaccine by limit dilution and passaged it an unstated number of times in chick embryo cultures to obtain a seed virus to produce a "new" vaccine strain in 1998 called RIT-4385,[179] which since has been incorporated with measles and rubella vaccine strains to produce the MMR vaccine Priorix or additionally with varicella to produce the tetravalent MMRV vaccine Priorix-Tetra. The Shanghai, Beijing, and Lanzhou Institutes of Biological Products in China obtained JL vaccine and passaged it three times in chicken embryo cells in 1979 to produce the S79 strain, which is used as a monovalent product, or as a bivalent vaccine with measles, or as MMR.[213] The Czech firm Sevapharma obtained the JL vaccine strain and passaged it in primary canine kidney cells to produce Pavivac. Neither S79 nor Pavivac are widely used outside the region of manufacture.

Each 0.5-mL dose of GSK's Priorix and Priorix-Tetra contains not less than 5000 $TCID_{50}$ and 25,000 $TCID_{50}$, respectively, of mumps virus. The vaccines contain sorbitol and mannitol as stabilizers and neomycin, but not gelatin. Priorix and Priorix-Tetra replace the company's discontinued Urabe

Am9 containing products Priorix (monovalent), Trivirix (MMR), and Pluserix (MMR) due to reports of Urabe Am9–associated aseptic meningitis (see "Rare Reactions"). Urabe Am9–containing vaccines produced by the Biken Institute and Novartis also have been discontinued. Vaccine containing the Urabe Am9 strain is now produced only by Sanofi Pasteur. Each 0.5-mL dose contains not less than 5000 $TCID_{50}$ of mumps virus. The trade names of these products differ by manufacturer (see Table 40.3).

The Rubini mumps vaccine strain was produced by the Swiss Serum and Vaccine Institute, Berne, Switzerland (subsequently Berna Biotech, and now Crucell) and was used to formulate the MMR vaccine Triviraten. Because of poor efficacy, this vaccine strain is no longer in use. Each 0.5-mL dose contained not less than 5000 $TCID_{50}$ of mumps virus.

The Leningrad-Zagreb strain is produced by the Institute of Immunology of Zagreb and the Serum Institute of India and is formulated with measles and rubella to produce the vaccine Tresivac. Each 0.5-mL dose contains not less than 5000 $TCID_{50}$ of the Leningrad-Zagreb mumps virus strain.

Many of the other strains listed in Table 40.3 have had limited use, often sold in only one country[214] and are not further described here.

Although the route of administration for mumps vaccine is subcutaneous, most other pediatric vaccines (which are invariably inactivated) are typically given by the less-challenging intramuscular route, making it likely that in practice, mumps-containing vaccines are occasionally given intramuscularly. However, studies found that the intramuscular and subcutaneous routes induce similar levels of antibody.[215,216]

Aerosol administration of mumps-containing vaccines has yet to be approved by regulatory bodies. Studies in mice demonstrated that this route leads to induction of neutralizing antibodies[217] and investigational studies in humans have found postaerosol vaccination enzyme-linked immunosorbent assay (ELISA) IgG titers to be comparable or superior to those measured in control groups receiving vaccine subcutaneously.[218,219] Further studies in seronegative children are awaited.

AVAILABILITY IN COMBINATIONS

Nearly all the combination MMR vaccines listed in Table 40.3 contain the RA 27/3 rubella strain, but differ in the measles and mumps strains. MMR II contains the Moraten measles strain and the Merck JL mumps strain. Trimovax, Priorix, and Trivac contain the Schwarz measles strain, but differ with respect to the mumps virus components. Trimovax contains the Urabe Am9 mumps virus vaccine strain, whereas Priorix and Trivivac contain the RIT-4385 and Sevapharma JL-based strains, respectively. Tresivac contains the Edmonston–Zagreb measles and Leningrad-Zagreb mumps virus strains. The quadrivalent vaccines ProQuad and Priorix-Tetra contain the same strains as their trivalent counterparts (MMR II and Priorix, respectively), but additionally contain the OKA varicella vaccine strain. The Shanghai, Beijing, and Lanzhou Institutes of Biological Products JL-based S79 strain is also used as a bivalent vaccine with the domestically produced Shanghai-191 (S191) or the Leningrad-4–derived Changchun-47 (C47) measles vaccine strain,[220] or as MMR additionally using either the domestically produced BRD-II rubella strain or the RA27/3 rubella vaccine strain.[221]

In general, administration of combination vaccines results in immune responses similar to those produced by the administration of individual measles, mumps, rubella, and varicella vaccines at different sites or at different times; however, there is evidence that seroconversion to mumps is somewhat higher in children receiving MMR and varicella vaccines given concomitantly at separate injection sites compared with administration of quadrivalent vaccine (ProQuad or Priorix-Tetra). In an open, randomized, controlled study among 9-month-old mumps-seronegative children, Goh and colleagues reported 92% of 118 participants seroconverted to mumps virus after concomitant receipt of Priorix and varicella vaccines, compared with 85% of 133 participants receiving Priorix-Tetra. However, seroconversion was 100% in both groups following a second dose administered 2 months later.[222] In other studies, while slightly lower responses following MMRV versus concomitant administration were apparent, differences were not statistically significant.[223–225]

The safety of combination vaccines is similar to that of individual vaccines administered at different sites or at different times, except for the occurrence of fever and febrile seizures, which have been found to occur more frequently in children 12 to 23 months old receiving ProQuad versus concomitant administration of MMR II and varicella vaccine as a first dose.[226] Consequently, administration of MMR and varicella vaccine separately is recommended for the first dose in children 12 to 47 months of age, with ProQuad given as a second dose at 4 to 6 years of age.[227,228]

SIMULTANEOUS ADMINISTRATION WITH OTHER VACCINES

MMR can be administered simultaneously with diphtheria and tetanus toxoids and acellular or whole-cell pertussis vaccine (DTP/DTaP), with oral or inactivated poliovirus vaccine, with *Haemophilus influenzae* type b conjugate vaccine, hepatitis B vaccine, varicella vaccine, or live attenuated influenza vaccine without impairing antibody responses or increasing rates of serious adverse events.[84,229–232] MMR should be given 1 month before or after administration of other live viral vaccines.

STABILITY OF VACCINE

Most lyophilized mumps virus–containing vaccines are stable for 18 to 24 months when stored and handled per the manufacturer's instructions. Exceeding the recommended storage temperature or dating period may result in accelerated potency loss to levels below those known to be efficacious. MMR II vaccine must be stored at −50°C to +8°C and be protected from light. When reconstituted to a liquid state, the vaccine should be kept at 2°C to 8°C and used within 8 hours. ProQuad is available in two formulations, one that must be stored at −50°C to −15°C, but can be kept at 2°C to 8°C for up to 72 hours prior to reconstitution and a refrigerator-stable formulation. Reconstituted vaccine may be stored at room temperature, protected from light, for up to 30 minutes, after which it should be discarded.

IMMUNOGENICITY OF VACCINES

Antibody Responses

IgM is detectable within a few days of vaccination, followed by IgG and neutralizing antibody 2 weeks later, both peaking between 1 and 3 months postvaccination.[233,234] IgM levels decline to minimal levels by 6 weeks postvaccination,[235] whereas IgG levels persist for decades, although complete loss of mumps virus-specific IgG has been reported within a few years of vaccination (see "Persistence of Antibodies" below). IgM may not be detectable in previously vaccinated or naturally infected persons who have a new infection with wild mumps virus (see "Diagnosis" above).

Virus-specific IgM and IgG antibody are typically measured by direct or indirect ELISA, rather than the more labor-intensive virus neutralization test. However, because both virus-neutralizing and nonneutralizing antibodies yield positive results in the ELISA, the ELISA can provide false-positive results in the context of assessing immunity, presuming that immunity is mediated by virus-neutralizing antibodies and not nonneutralizing antibodies.[236–238] For example, seroconversion has been demonstrated by ELISA even in the absence of demonstrable neutralizing antibody.[239] On the other hand, results of the virus neutralization assay are difficult to interpret due to the absence of an established neutralizing antibody titer that can be used as a surrogate maker of protection (see "Correlates of Protection" below). Older methods of antibody quantitation, such as complement fixation or hemagglutination inhibition, are no longer practiced.

Immunization results in lower levels of neutralizing antibody than is found following natural infection.[172,240–243] In one of the first prelicensure immunogenicity studies of the JL strain, conducted in Philadelphia in 1965, the mean neutralization antibody titers in children 6 to 8 weeks after vaccination was 1 : 9, compared with 1 : 60 after natural disease, based on hemadsorption as an end point.[172] Impressively, however, the seroconversion rate following vaccination of children who initially tested seronegative for mumps neutralizing antibody was 98.1% (355 of 362).[172] Similar results have been reported from other studies.[233,244–246] The total prelicensure experience in U.S. children showed that 97% of 6283 initially seronegative children developed neutralizing antibody after vaccination.[172] Similar seroconversion rates against mumps virus are observed following administration of trivalent formulations containing the JL vaccine strain (MMR II) or the JL-derived RIT-483 strain (Priorix),[247] as well as vaccines containing most other mumps virus strains, such as the Urabe Am9 strain,[248,249] the Leningrad-Zagreb strain,[174] the Leningrad-3 strain,[174] and the Hoshino strain.[214]

However, in contrast to the very good immunogenicity of these vaccines, significantly lower seroconversion rates have been observed with other mumps vaccines. For example, in a comparative study between MMR II (JL), Pluserix (Urabe Am9), and Triviraten (Rubini) trivalent vaccines, ELISA-based seroconversion rates were 96.5%, 100%, and 38%, respectively.[250] These data are reflected in a prospective study in Cadiz, Spain involving children within 18 months of MMR II or Triviraten vaccination. Whereas 97% of those given MMR II were mumps seropositive, only 39% of those with a history of Triviraten vaccination were seropositive.[181] Poor effectiveness of the Rubini mumps virus strain has been reported in numerous studies, ultimately leading to discontinued use of the product (see "Effectiveness in Field Use and Duration of Immunity" below). Interestingly, although the ELISA-based seroconversion rate measured for the Rubini vaccine was very low (38%), the authors stated that upon additional testing by immunofluorescence assay and plaque neutralization assay, the seroconversion rate increased to 93.4%.[250] As to how much of this increase was attributable to plaque neutralization testing was not stated, but based on data presented for a subset analysis, the geometric mean titer (GMT) of neutralizing antibody was only 2.6, which approximates the limit of assay detection. Another example is the Pavivac JL vaccine strain produced in primary canine kidney cells. In contrast to the consistently high seroconversion rates (>95%) to the JL strains produced by Merck or GSK, seroconversion after Pavivac has been found to be much lower, ranging from 75% to 82% based on limited studies.[240,250a]

Compared to measles and rubella antibody, mumps antibodies generated in response to vaccination are of relatively low avidity,[251] which might be related to the fact that of the three MMR vaccine components, mumps is the least effective. However, studies examining the relationship between IgG avidity index and protection are lacking.

Factors Influencing Seroconversion

Mild illnesses do not affect seroconversion or the magnitude of the antibody response to mumps vaccine.[252] Administration of mumps vaccine to children 6 months of age or younger is associated with vaccine failure, irrespective of the presence of maternal antibody, suggesting an intrinsic deficiency in humoral responses in this younger age group. In a study involving infants seronegative at vaccination, Buynak and colleagues reported seroconversion in 50% of infants younger than 6 months of age compared with 95% of infants 6 to 11 months old.[253] In a separate study of infants lacking maternal antibody, Gans and colleagues reported seroconversion in 91% and 93% of children vaccinated at 9 and 12 months of age, respectively, compared to 74% of children vaccinated at 6 months of age.[254] The difference in seroconversion rate at 6 versus 12 months was statistically significant, as were the GMTs of neutralizing antibody at these ages (GMT of 18 vs 51). Although this and other studies found no significant differences in rates of seroconversion between children receiving mumps-containing vaccine at 9, 12, or 15 months of age, GMTs were almost always higher in the 12- and 15-month-old age groups.[254–257] In aggregate, these studies indicate better antibody responses in children 12 months of age or older compared with responses in younger children.

Seroconversion rates among adults are similar to those observed among children, although data vary among studies. A prelicensure immunogenicity study demonstrated neutralizing antibody responses after vaccination in 95% of 20 initially seronegative adults.[258] The total prelicensure experience in adults vaccinated with the JL strain (monovalent) showed a seroconversion rate of 93% among 163 initially susceptible adults (132 men; 31 women).[246] However, Christenson and Böttiger found only 80% of seronegative 12-year-olds to seroconvert following MMR II administration compared with 92% of seronegative 18-month-olds.[259]

Primary vaccine failure occurs in approximately 5% of mumps vaccinations[260]; however, many persons not responding to the first dose of vaccine seroconvert following a second dose.[261,262] In the rare cases of inability to respond to mumps vaccination, certain human leukocyte antigen (HLA) haplotypes and cytokine/cytokine-receptor single nucleotide polymorphisms may be involved.[263–265] Genetic nonresponsiveness to measles vaccination seems to be more prevalent than genetic nonresponsiveness to mumps vaccination, as suggested by fewer HLA supertypes associated with nonresponsiveness to mumps vaccine[265] and lower heritability of these "responsiveness factors" for mumps (38.8%) than for measles (88.5%).[263]

Cellular Responses

Cell-mediated immune responses following vaccination are similar in scope and magnitude to those measured following natural infection and persist for decades. Jokinen and colleagues found mumps antigen-specific lymphoproliferative responses in 49 of 50 persons assessed 21 years after receipt of a second dose of MMR II, 14 (28%) of whom lacked detectable levels of mumps antibody.[266] The levels of IFN-γ and interleukin-10 produced in the lymphoproliferative responses were as high as those detected in a control group consisting of naturally immune persons. This was also suggested in an observational, nonrandomized cohort of 10 adults with a history of natural infection and 10 adults who received a

second dose of MMR II at least 10 years earlier. In that study, virus-specific T-cell responses were identified in 80% of naturally immune and 70% of vaccinated persons with similar amounts of IFN-γ produced by stimulated T cells in both groups.[267] Vandermeulen and colleagues reported similar results, but only for persons with relatively high antibody titers.[268] Whereas lymphoproliferation was demonstrated in 19 (79%) of 24 subjects with high antibody titer, only 13 (54%) of 24 subjects with low antibody titers demonstrated lymphoproliferative responses. The mean stimulation index for subjects with low antibody titers was approximately half that measured for subjects with high antibody titers, suggesting some correlation between antibody and cell-mediated immune responses to mumps vaccination.

In contrast with humoral immune responses to vaccination, which may be age-dependent (see "Factors Influencing Seroconversion" above) and wane with time (see "Persistence of Antibodies" below), the magnitude of cellular immune responses seems to be independent of these factors.[254,266]

As with natural infection, the role of vaccine-induced cell-mediated immune responses in protection against reinfection or attenuating the course of disease has not been established (see "Correlates of Protection"). That levels of lymphoproliferative responses induced following one and two doses of MMR II were similar to those induced following one and two doses of Triviraten,[269] a vaccine that confers virtually no protection (see "Effectiveness in Field Use and Duration of Immunity" below), suggests that the mumps virus–specific cell-mediated response following vaccination is not predictive of vaccine effectiveness, and, by extension, protection.

Studies of B-cell responses to infection are limited and deserve more attention, particularly in light of data from Latner and colleagues indicating that MMR vaccination results in substantially lower numbers of mumps virus–specific memory B cells as compared to numbers of measles- and rubella-specific memory B cells,[270] and data from Kontio and colleagues indicating that mumps antibodies (vaccine or wild-type virus–induced) are of lower avidity than measles and rubella antibodies.[251] Both of these observations might suggest some deficiency in the process of mumps virus–specific B-cell affinity maturation, which could be a factor in vaccine efficacy (see "Risk Factors for Vaccine Failure and Recent Outbreaks" below).

CORRELATES OF PROTECTION

The presence of neutralizing antibody is linked to protection; however, numerous attempts to define a level of antibody that correlates with protection have failed. For example, prevaccine era studies consistently found neutralizing antibody titers in the range of 1:4 to 1:8 to be associated with protection[237,271–273]; however, many persons with much higher titers succumbed to mumps. In a study of MMR-II vaccinees involved in an outbreak in the United States in 2006, neutralizing antibody titers of approximately 1:30 or higher were associated with protection, but titers in cases and exposed noncases overlapped and no cutoff points clearly separated these two groups.[275] In a 2014 retrospective study comparing mumps-specific IgG antibody concentrations in preoutbreak samples from cases and exposed noncases among students in two Dutch university cities, preoutbreak IgG concentrations were found to be lower among cases than noncases ($P = .005$), but no serological cutoff for protection could be established.[276]

More recently, in a retrospective study of preoutbreak sera from students in The Netherlands who were later exposed during an outbreak, mean neutralizing antibody titers against the vaccine virus strain (JL) and two wild-type strains (including an isolate from the outbreak) were lower among virus-infected individuals compared with uninfected individuals. However, there was near complete overlap in the range of antibody titers measured in the virus infected versus uninfected groups.[276a] In this and other studies, no association has been found between mumps virus–specific IgG concentrations and protection or between any of the numerous investigated cell-mediated immune responses and protection.[266,268,277–279] These data suggest that immune responses other than those measured in routinely performed in vitro assays likely play an important role in protection. Such immune mediators may include antibodies involved in antibody-dependent cellular cytotoxicity (ADCC), complement-dependent lysis, and Fc-mediated phagocytosis. Unfortunately, these antibodies are challenging to identify and quantify in vitro, and such assessments are rarely performed.[278a,278b]

IMMUNOCOMPROMISED PERSONS

The immunogenicity of mumps-containing vaccine in immunocompromised persons varies by study, but overall, there does appear to be a benefit to vaccination in this group. In studies of mumps virus seronegative pediatric patients revaccinated with MMR II 2 to 3 years after bone marrow transplantation, rates of seroconversion ranged from 37% to 80%.[280–282] In a study of children with end-stage renal disease undergoing maintenance hemodialysis, five of 10 children seroconverted after receiving MMR II.[283] On revaccination of mumps virus seronegative liver transplant recipients, all seroconverted, but titers declined to very low levels during a 7-month follow-up period.[284] No vaccine-related adverse events were reported in any of the aforementioned studies; nonetheless, MMR is contraindicated in persons with evidence of severe immunosuppression or persons actively receiving chemotherapy or long-term immunosuppressive therapy (defined as ≥2 weeks of daily receipt of ≥20 mg of prednisone or equivalent).[285]

MMR vaccination should be considered for asymptomatic HIV-infected persons and for symptomatic persons without evidence of severe immunosuppression.[285,286] The vaccination schedule in children infected with HIV is accelerated, with two doses of MMR vaccine given 1 month apart.

The majority of children receiving highly active antiretroviral therapy (HAART) seroconvert in response to mumps vaccination, although the response may be transient. Of 29 mumps virus seronegative HIV-infected children undergoing HAART, 69% seroconverted following MMR vaccination when assessed 4 weeks later, but when assessed 24 weeks postvaccination, approximately half of children who had seroconverted had either very low levels of antibody or lacked antibody. Seroconversion to measles and rubella viruses in this study were much higher, ranging from 90% to 100% when assessed at 4 weeks to approximately 80% 24 weeks postvaccination.[287] No serious adverse reactions were attributed to revaccination. These data indicate that revaccination with MMR vaccine in HIV-infected children receiving immune recovery therapy should be considered.

Safety data are not available for formulations including varicella vaccine (e.g., ProQuad, Priorix-Tetra) in HIV-infected children, and, thus, these vaccines are currently not recommended for them.[285]

EFFICACY AND EFFECTIVENESS

Protective Efficacy in Controlled Clinical Trials

Prelicensure studies of the JL vaccine strain in two clinical trials demonstrated that a single dose was 95% or more effective in preventing mumps disease. The first clinical trial was conducted in Philadelphia from 1965 to 1967 among children

and their siblings attending nursery school or kindergarten.[172,288] Of 867 children enrolled, 398 (174 vaccinees; 224 control subjects) had documented exposure to mumps during the 20-month follow-up. Five cases of mumps occurred in the vaccinated group, compared with 133 cases among the control children for an overall protective efficacy of 95.2% (95% confidence interval [CI], 88–98%). Point estimates of efficacy varied from 91.7% to 95.9% by subgroups of exposed persons (families vs classrooms) and by interval from vaccination to exposure (0–10 vs 11–20 months).

The second clinical trial was a double-blind, placebo-controlled study conducted from 1966 to 1967 of children attending 44 schools in Forsyth County, North Carolina.[245] During follow-up from 30 to 180 days after vaccination, five cases of mumps occurred among the 2965 children who received mumps vaccine, compared with 13 cases among the 316 control children, giving a vaccine efficacy of 96% (95% CI, 88–99%).

Smorodintsev and coworkers reported a small clinical trial of the Leningrad-3 strain among children 3.5 to 6 years old.[171] Of the 85 vaccinated children, two developed mumps, compared with 42 of 108 children in the control group, giving a vaccine efficacy of 94% (95% CI, 76–98%). Subsequent studies of efficacy gave protection rates from 91% to 99%, but it was not clear whether the unvaccinated control subjects were randomly chosen.[289]

Information on the protective efficacy in controlled clinical trials of other mumps vaccine strains is absent from the literature.

Effectiveness in Field Use and Duration of Immunity

The effectiveness of a single dose of the JL mumps vaccine as determined in field studies is approximately 77% and that of two doses is approximately 85%, but estimates range widely across studies (Table 40.5). These estimates are significantly lower than the efficacy determined in clinical trials, where issues such as differing case definition, incomplete surveillance with limited case ascertainment, and inaccurate determination

of vaccination status may come in to play. Furthermore, the controlled clinical trials involved mostly young children vaccinated within a few years of observation, whereas field studies often involve persons with long intervals since vaccination, setting up the possibility of waning immunity as a variable.

Although the intent of a two-dose MMR vaccination schedule was to capture the small percentage of individuals who either missed the opportunity for receipt of a first dose, or who may have failed to respond to the first dose, it is clear that two doses of vaccine are more effective than one ($P = .018$, Mann-Whitney rank sum test, Table 40.5, JL data only). Nonetheless, this level of effectiveness does not appear to be adequate to prevent outbreaks, most clearly indicated by outbreaks in the United States where, 96% to 100% of cases were found to have occurred in persons with a history of two doses of MMR II.[118,290,291,291a] Mumps outbreaks among high two-dose vaccinated populations have also been reported in other countries.[35,292–296] However, this should not be misconstrued to imply that the vaccine provided no benefit. Data from many of these outbreaks indicate that mumps vaccination was effective to a large degree and likely responsible for limiting outbreak size. In the one study in which it was possible to calculate, vaccine effectiveness was estimated at 80%,[291] demonstrating a great benefit to vaccination. Notably, attack rates in these outbreaks were low, ranging from 2% to 8%, compared with 25% to 49% calculated in unvaccinated persons before mumps vaccination became widespread.[6,18,297] One example comes from a retrospective cohort study conducted among children attending a summer camp in New York. Of the study participants, 96% had a history of at least one dose of vaccine, 91% of whom had a two-dose MMR vaccine history.[298] The mumps attack rates among two-dose, one-dose, and zero-dose vaccine recipients were 3.6%, 8.7%, and 42.9%, respectively.

Comparisons of the effectiveness of different mumps vaccines show varying results, but overall, except with the Rubini vaccine which has virtually no efficacy, the results are similar. Based on the data provided in Table 40.5, compared to a one-dose JL efficacy of 77%, that of a single dose of Urabe-containing vaccines is 76%. Demicheli and colleagues estimated the effectiveness of at least one dose of MMR to be between 69% and 81% for JL-containing vaccines and between 70% and 75% for Urabe Am9–containing vaccines.[299] The effectiveness of other mumps vaccine strains is difficult to determine owing to more limited use and fewer studies.

Influence on Symptomatology

Numerous studies indicate that mumps vaccination attenuates the course of disease, complications, and complication severity. Data from a large mumps outbreak in the New York area during 2009–2010 found that among male case patients 12 years of age or older, the frequency of orchitis was 4% in patients with a two-dose MMR history compared to 11%

TABLE 40.6 Association Between Receipt of Vaccination and Mumps Complications, Adjusted for Age and Sex, England and Wales, April 1, 2002–March 31, 2006

among unvaccinated case patients ($P = .04$).[300] Similar observations were made in epidemiological studies of mumps outbreaks in The Netherlands and Taiwan, which also found an association between vaccination and reduced risk for overall complications and hospitalizations.[295,301]

There is also ample evidence of fewer and less-severe complications in two- versus one-dose vaccinees. Based on a study of nearly 6000 mumps cases reported in the Czech Republic during the first 6 months of 2005, compared with two-dose vaccinees, the odds ratios for complications were 6.6 in one-dose vaccinees and 7.9 in unvaccinated persons.[35] In an analysis of mumps cases in the Czech Republic reported during 2007–12, adjusted vaccine effectiveness against specific complications was significantly higher among persons with a history of two doses of vaccine versus one dose.[301a] In an investigation of a series of outbreaks in England and Wales between 2002 and 2006, compared to unvaccinated patients, the odds of hospitalization, orchitis, and meningitis were reduced by 50%, 56%, and 69%, respectively, for one dose of vaccine, and by 64%, 83%, and 78% for two doses.[302]

Yung and colleagues analyzed data from mumps cases reported between 2002 and 2006 in England and Wales.[302] These data show significantly lower odds ratios for hospitalizations, orchitis, meningitis, and pancreatitis among one- and two-dose vaccinees than among unvaccinated persons, with a greater impact of two doses compared to one dose (Table 40.6). However, some studies have not found vaccination status to be significantly associated with complication prevalence or severity.[29,303]

HERD IMMUNITY (COMMUNITY PROTECTION)

Mathematical models of the potential impact of mass vaccination on the incidence of mumps disease predict that an 85% to 90% level of vaccination coverage by 2 years of age would be required to eliminate transmission of the virus in the Western hemisphere.[138,304] Indeed, high levels of two-dose MMR vaccine coverage in many countries resulted in dramatic reductions in disease incidence to the point of near elimination (see Table 40.2), but not elimination. In the United States, by 1996, 91% of 19- to 35-month-old children had received at least one dose of MMR II.[305] This figure has remained relatively unchanged over the past 2 decades, rising only slightly to 91.9% by 2015.[305a] Vaccine coverage among kindergardeners is higher, with a median two-dose MMR vaccine coverage of 94.6% based on data from the 2015–16 school year, a figure unchanged from the prior year.[205] Based on the 2015 National Immunization Survey–Teen (NIS-Teen), the estimated two-dose MMR vaccine coverage among adolescents aged 13 to 17 years was 90.7%, also unchanged from the prior year.[206] Despite achieving the mathematically predicted threshold for eliminating virus transmission, large outbreaks continue to occur, including in environments where vaccine coverage is at, or close to, 100%.[118,290,291a] These data suggest that herd immunity, while reducing the risk of an outbreak, can be overcome under certain conditions, such as environments where the force of infection may be high and immunity waning (see "Risk Factors for Vaccine Failure and Recent Outbreaks" below). Data from numerous studies strongly indicate that circulating wild-type mumps viruses can be spread from vaccinated individuals to close contacts who are also vaccinated.[118,290,306] Based on a serology study, Dittrich and colleagues estimated that for every case of clinical mumps in a vaccinated person, there are at least three asymptomatic cases among vaccinees.[307] Consequently, in an outbreak setting, the role of asymptomatic infections to disease spread may be substantial.

It is important to recognize that vaccination does not result in sterilizing immunity. This is evident from data on mumps reinfections[307a,307b] and the significant boosting effect revaccination has on antibody levels, indicating some ability of the vaccine virus to replicate in previously vaccinated individuals. Importantly, although viral loads in the saliva of children who contracted mumps within a few years of vaccination were found to be lower than in unvaccinated children,[306] no such difference was observed among persons with longer time intervals since vaccination.[128a] These data further raise concern as to the long-term effectiveness of the vaccine in preventing mumps virus transmission.

EXCRETION OF VACCINE VIRUS

In the Philadelphia prelicensure immunogenicity study of the JL vaccine, none of the 365 children who were classroom or household contacts of the vaccinated children seroconverted, suggesting that vaccine virus is either not shed or is not infectious under such circumstances if shed.[172] Subsequent studies failed to identify evidence of vaccine virus spread to susceptible contacts, including no evidence of virus in blood, urine, or saliva of vaccinees.[233,308] However, given that the JL vaccine

strain can cause parotitis in a small fraction of vaccinees,[248,309–311] it is reasonable to speculate that the JL strain can be excreted in saliva.

For other vaccines, evidence of vaccine virus shedding and transmission is more clear. The RNA genomes of Urabe Am9, Miyahara, Hoshino, Leningrad-3, and Leningrad-Zagreb vaccine strains have been detected by RT-PCR in throat swabs in children with parotitis 2 to 3 weeks postvaccination, and horizontal transmission of the Urabe Am9, Leningrad-3, and Leningrad-Zagreb vaccine strains has been demonstrated.[312–318] In cases of horizontal transmission of the Leningrad Zagreb vaccine, mumps symptoms appeared within 4 to 6 weeks of vaccination of close contacts, consistent with vaccine virus shedding 2 to 4 weeks postvaccination, followed by a 2- to 4-week incubation period. Nevertheless, these seem to be rare events, and compared with complications following natural infection, the course of symptoms were mild and short-lived.

DURATION OF IMMUNITY AND PROTECTION

Persistence of Antibodies

Studies of antibody persistence yield wide ranging results; however, it is clear that levels of antibody wane with time postvaccination, in some cases to undetectable levels. Whether waning of antibody levels equates to waning immunity is a subject of debate, but seems likely.

Serologic studies of children enrolled in the first clinical efficacy trials of the monovalent JL vaccine strain demonstrated that mumps virus-neutralizing antibody titers persisted for at least 12 years after vaccination, but GMTs decreased by 27% during this time, despite evidence of asymptomatic boosting of antibody levels during the follow-up period as a result of reinfection.[319–321] These longitudinal studies also demonstrated that with the passage of time antibody levels after vaccination remain consistently lower than those after natural infection (Table 40.7). In a longitudinal serologic study of 87 children who provided a serum sample 2 to 5 years after administration of the first dose of MMR II and another sample 10 years after the second dose of the vaccine, all 87 children were found to have virus-neutralizing antibody at the first time point, and all but one at the second time point, but by the latter time point, the GMT of neutralizing antibody had declined by approximately 50%.[322] Date and colleagues[323] and LeBaron and colleagues[204] also observed a 50% decline in neutralizing antibody GMTs over a similar time interval among kindergarteners, middle schoolers, and university students. In all three studies, the proportion of study subjects with low levels of neutralizing antibody progressively rose with time postvaccination.

TABLE 40.7 Persistence of Mumps-Neutralizing Antibody in Seropositive Children After Clinical Mumps or Vaccination With Jeryl Lynn Strain of Mumps Vaccine

	Mumps-Neutralizing Antibody Geometric Mean Titers	
Time	Vaccine (34 Children)	Clinical Mumps (36 Children)
1 mo	10.1	62.8
1 y	12.8	27.6
2 y	11.9	42.1
4 y	11.8	34.5
7 y	10.3	18.6
9.5 y	12.5	24.4

Waning of antibody titers to undetectable levels also has been suggested. In one study, 19% of MMR II and 13% to 16% of MMR–Urabe Am9 recipients lacked mumps virus-neutralizing antibody when assessed 4 years after receipt of a single dose of vaccine at 12 to 18 months of age.[324] Similar results were reported by Broulianne and colleagues.[325] With longer time intervals, much higher rates of mumps seronegativity were measured. Broliden and colleagues reported the lack of anti–mumps virus-neutralizing antibodies in 27% of recipients of a single dose of MMR II when assessed 10 years later.[326] Nearly the same rate of seronegativity (26% by ELISA) was reported in a different study of MMR II vaccinees tested 15 years after the second dose.[327] However, in the aforementioned studies, baseline serostatus postvaccination was not determined, and, thus, it is not known what portion of seronegative persons were indeed seropositive at an earlier time. In a study where sequential bleeds were obtained from children postvaccination, Davidkin and colleagues found the proportion of ELISA-seropositive persons to have declined from 86% at 3 months after MMR II vaccination to 73% at 1 year postvaccination.[262] Upon revaccination 4 years after dose 1, the seroconversion rate increased to 95% but then declined to 86% 4 years later. A similar pattern was observed in children receiving their first dose of vaccine at 6 years of age followed by a second dose 4 to 5 years later.[262]

RISK FACTORS FOR VACCINE FAILURE AND RECENT OUTBREAKS

Primary vaccine failure is not likely, given data from clinical trials demonstrating seroconversion in greater than 95% of vaccinees following one dose and nearly 100% after two doses.[260] Furthermore, if primary vaccine failure were responsible for outbreaks, outbreaks would likely affect younger school-aged groups, which is contrary to the currently observed epidemiology of mumps outbreaks in vaccinated populations where cases predominantly involve persons 18 to 25 years of age.[295] Failure to vaccinate or use of only one of the two recommended doses of MMR is also not a likely factor given that recent outbreaks are characterized by very high two-dose coverage.

Numerous studies identified time since last vaccination as a risk factor.[36,290,328–331] A retrospective assessment of mumps outbreaks in Belgium among recipients of a least one dose of MMR vaccine indicated that after the first year postvaccination the odds of developing mumps increased by 27% annually (Fig. 40.6).[332] A smaller odds ratio was calculated in an assessment of multiple mumps outbreaks in France in 2013. For persons with a history of at least one dose of MMR, the odds of developing mumps increased by 7% for every additional year since last vaccination. In a subset analysis of persons with a two-dose MMR history, the odds of developing mumps was found to increase by 10% per year.[332a] While factors to explain these odds ratio differences have not been explored, the preponderance of data indicate that time since vaccination is a risk factor for disease acquisition, a phenomenon also seen in vaccine effectiveness studies. An analysis of a large mumps outbreak in the United Kingdom revealed that one-dose vaccine effectiveness declined from 96% in the immediate postvaccination period to only 66% 10 years later.[330] A similar finding was reported from a matched case-control study involving 469 persons in each group wherein one-dose vaccine effectiveness steadily declined from 98.5% (95% CI, 95–100%) 1 year postvaccination to 53.0% (95% CI, 32–66%) 12 years later (Fig. 40.7). There are numerous other examples of declining vaccine effectiveness as a function of time since

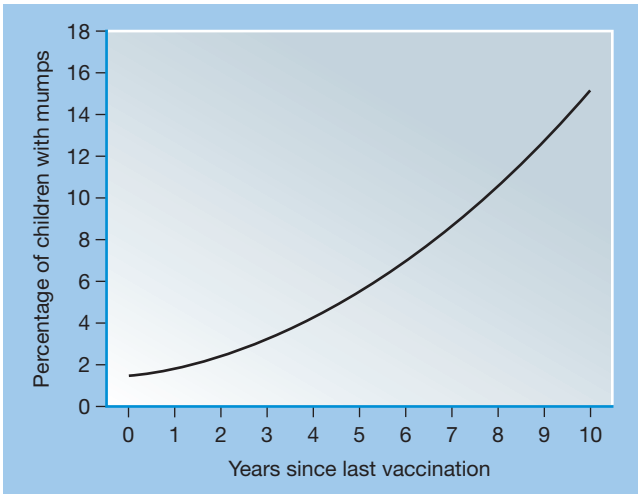

Figure 40.6. Logistic regression analysis of the percentage of children with mumps as a function of time since vaccination. *(Modified from Vandermeulen C, Roelants M, Vermoere M, et al. Outbreak of mumps in a vaccinated child population: a question of vaccine failure?* Vaccine. *2004;22:2713–2716.)*

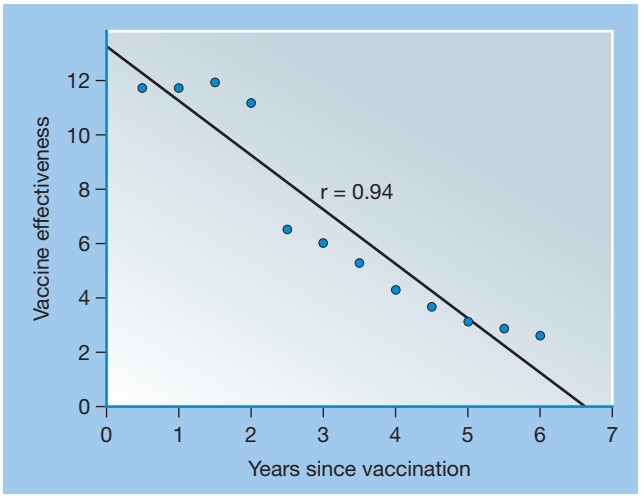

Figure 40.7. Decline in single-dose vaccine effectiveness (JL-derived S79 strain) measured during a 12-year period postvaccination. *(Modified from Fu C, Liang J, Wang M. Matched case-control study of effectiveness of live, attenuated S79 mumps virus vaccine against clinical mumps.* Clin Vaccine Immunol. *2008;15:1425–1428.)*

vaccination,[36,330,331] which dovetails well with observed declines in anti–mumps virus antibody levels as a function of time postvaccination (see "Persistence of Antibodies" above), making it tempting to link the two phenomenon. However, not all studies have found evidence of time since vaccination to be a risk factor[120,243,298,333–336] and it bears mentioning that waning immunity itself is insufficient to trigger an outbreak; otherwise mumps outbreaks would occur continually, not sporadically.

The cause of waning mumps immunity is unclear. One possibility could be, ironically, the success of the vaccine itself; that is, decreased opportunities for periodic natural boosting. However, this raises the question as to why this is not a general phenomenon across all vaccines. For example, measles outbreaks appear to almost exclusively affect isolated pockets of unvaccinated individuals within the larger vaccinated population,[337] which is quite different from the mumps experience where a high proportion of cases have occurred in vaccinees. Perhaps one clue is from a study by Latner and colleagues demonstrating very low levels of mumps virus–specific memory B cells compared to levels of measles- and rubella-specific memory B cells based on testing peripheral blood mononuclear cells isolated from persons previously vaccinated with MMR.[270] Levels of antibody-secreting cells induced following natural infection are also much greater than those induced following vaccination, suggesting that the poor B-cell responses observed in vaccinees may be an issue with the vaccine strain of the virus, not mumps virus in general; however, this difference may simply be a consequence of different routes of infection (subcutaneously in the case of vaccination and oronasally in the case of natural infection). A related finding is the in silico observation that certain amino acids at certain positions of the JL HN protein, which are unique to this virus, are predicted to impact B-cell epitopes and the ability of CD4 T-helper cells to recall antibody responses upon wild-type virus challenge.[338] Both of these observations require further study.

Another factor that is frequently cited as a possible cause of mumps in vaccinated individuals is antigenic differences between the vaccine strain and the wild-type strain, possibly permitting immune escape. This notion arose with the observation of a mismatch between the genotype of current circulating viruses (mostly genotype G of late) versus that of vaccine virus strains (genotype A: JL and JL-derived; genotype B: Urabe Am9; and vaccines of undesignated genotype, e.g., Leningrad-Zagreb)[35,36,84,292,339–343] and is supported by laboratory data demonstrating virus strain–specific differences in antigenicity.[84,85,88,89,152,344] However, these antigenic differences seem only to affect the relative potency of antibody against heterologous virus strains within a certain range as opposed to resulting in a complete inability to neutralize the virus.[322,345,345a] From a historical perspective, despite ongoing sporadic and sometime large mumps outbreaks, the disease has been nearly eliminated in countries where vaccine coverage has been consistently high.[346–349] That this could be achieved in the face of persistent circulation and importation of numerous wild-type mumps viruses of varying genotype suggests that any antigenic mismatch between circulating strains and vaccine strains is not, and has not been, a major issue.

Whatever the underlying immunologic failure, an exacerbating factor appears to be environments where the force of infection is high, such as college and university campuses where students are in prolonged, intense contact. Recent investigations of a series of mumps outbreaks in Jewish orthodox schools in New York and New Jersey revealed the number of hours spent per day in close contact with study partners and the number of study partners to be associated ($P < .05$) with classroom mumps attack rates in univariate analysis.[350] Attack rates were as high as 42% in some of the classes investigated despite two-dose MMR vaccine coverage that often exceeded 90%. Prolonged, intense contact between students was also indicated as a risk factor in a different study of the same series of outbreaks.[300] The authors of both studies postulated that in such environments inoculum exposures were sufficiently high so as to overcome vaccine-induced protection. Notably, disease transmission to non–Orthodox persons in the affected communities where contact is not as intense was rare, and when it did occur, was not sustained.

It is noteworthy that even in outbreaks in populations with high vaccine coverage, vaccine efficacy has been found to be high (see, "Effectiveness in Field Use and Duration of Immunity" above). When outbreaks occur in highly vaccinated populations, and vaccine efficacy is less the 100% (as almost

always is the case), most of the cases can be expected in vaccinees. This point is often missed by the lay media who often fail to consider the percentage of vaccinated and unvaccinated individuals within the affected population who develop disease.

POSTEXPOSURE PROPHYLAXIS

Vaccines have been used as postexposure prophylaxis (PEP) for mumps, but their effectiveness as such is unclear. During an outbreak in a Tennessee high school in 1986, MMR was given to 53 of 178 presumably unvaccinated, exposed students. Of the 53 students receiving PEP, 15 (28.3%) developed mumps compared to 51 (40.8%) of the 125 students not receiving PEP.[334] In a second study conducted during an outbreak in a New York community in 2009, MMR vaccine was given to household contacts within 5 days of the household's index case. Mumps attack rates were compared between 28 persons who received MMR as a third dose and 77 persons who had a history of two doses of MMR, but did not receive PEP. No cases occurred among the PEP recipients, compared to four cases (5.2%) among the untreated group.[351] Statistical significance could not be established in either study.

Although not specifically employed as a PEP measure, MMR was used as a control measure in school-based outbreaks in Guam,[352] New York,[353] and Illinois.[291a] In these outbreaks, MMR was used as a third dose. The mumps attack rate in students receiving the intervention in the Guam study declined by 62.5% compared to the attack rate in students not receiving the intervention, but statistical significance could not be established because of the small number of cases recorded. In the New York study, the mumps attack rate declined by as much as 97.4% after the intervention, but the intervention was initiated after the outbreak started to decline, making it difficult to evaluate the effectiveness of the intervention. Attack rates also declined precipitously following administration of a third dose of vaccine during the mumps outbreak in Illinois, but as with the prior examples, it was not clear if the reduction in cases was the result of the intervention. While there is a lack of data that clearly support use of mumps-containing vaccine to limit the scope of an outbreak, available data do not argue against such vaccine use. Based on the U.S. experience of use of a third dose of MMR vaccine as an experimental outbreak control measure, in 2013 the French health authority (Haut Conseil de la Santé Publique) recommended administration of a third dose of MMR in an outbreak setting involving schools and other semiclosed populations for individuals last vaccinated more than 10 years earlier.[345a]

SAFETY

Common Reactions

Safety data for monovalent mumps vaccines are limited. Among 402 initially seronegative subjects in the two controlled prelicensure studies of the JL vaccine strain, fever or other clinical signs or symptoms did not occur more frequently than in control groups.[354] In a different study, among 49 initially seronegative subjects, no evidence of fever or other clinical reactions referable to the JL vaccine were observed.[246] Based on diary cards completed by parents over a 3-week period postmonovalent JL vaccination, Vesikari and colleagues reported a number of mild adverse events among 58 children 14 to 20 months of age (Table 40.8), but an unvaccinated control group was not included making it difficult to determine if the reported reactions are likely attributable to the vaccine.[355]

Most other safety data for the JL vaccine strain come from studies using bivalent or trivalent formulations with measles and rubella, complicating the assessment of mumps vaccine–associated adverse reactions. However, the very low rate of vaccine-associated adverse events reported with these products attests to their excellent safety profile. A review by Lievano and colleagues of postmarketing surveillance safety data for MMR-II accumulated between 1978 and 2010, representing a time period when more than 575 million doses were distributed, identified an overall rate of 30.5 adverse events per 1,000,000 doses.[356] The most frequently reported events per million doses of vaccine distributed were pyrexia (5.49), rash (4.63), injection site reaction (2.19), febrile convulsions (1.34), syncope (0.85), and arthritis (0.67). No differences were found in comparing the safety of MMR-II

TABLE 40.8 Rates of Solicited Reactions Occurring Within 3 Weeks of Receipt of Different Vaccines in Two Different Studies Among Children Age 14–20 Months

	STUDY A: Monovalent Vaccine		STUDY B: Bivalent Vaccine With Measles	
Reported Event	Jeryl Lynn (n = 58)	Urabe Am9 (n = 58)	Jeryl Lynn- Moraten (n = 85)	Urabe Am9- Schwarz (n = 108)
Fever (>37.5°C)	13 (22.4%)	12 (20.7%)	47 (55.3%)	72 (66.7%)
Restlessness	18 (31.0%)	8 (13.8%)[a]	46 (54.1%)	74 (68.5%)[a]
Rash	4 (6.9%)	2 (3.4%)	23 (27.1%)	33 (30.6%)
Cough	8 (13.8%)	4 (6.9%)	25 (29.4%)	37 (34.3%)
Vomiting	3 (5.2%)	6 (10.3%)	4 (4.7%)	19 (17.6%)[a]
Diarrhea	5 (8.6%)	4 (6.9%)	16 (18.8%)	19 (17.6%)

Rev Panam Salud Publica. *2002;12:240–246; and Vesikari T, Andre FE, Simoen E, et al: Comparison of the Urabe Am 9-Schwarz and Jeryl Lynn-Moraten combinations of mumps-measles vaccines in young children.* Acta Paediatr Scand. *1983;72:41–46.*

to Priorix (containing the JL-derived RIT-4385 strain), except local symptoms of injection site pain, redness, and swelling, which tended to occur less frequently in Priorix vaccinees.[179,357–359]

Data on the reactogenicity of other vaccines are more limited. In a comparative trial of monovalent JL and Urabe Am9 vaccines among 116 children 14 to 20 months of age randomized to receive either of the monovalent vaccines,[311] no significant differences among reported events were observed (see Table 40.8). Table 40.8 also shows the results of a similarly designed study of bivalent formulations with either the Moraten or Schwarz strains of measles vaccine virus.[360] In this study, statistically higher rates of restlessness, vomiting, lymphadenopathy, and local reactions were identified in recipients of the Urabe Am9–containing product. Whether these differences were caused by the mumps virus strains or the different measles virus strains used in the bivalent formulations cannot be discerned. Popow-Kraupp and colleagues conducted a prospective, randomized clinical trial wherein the safety of these same bivalent vaccines was compared in 400 children ages 9 months to 4.5 years, but found no differences in reactogenicity.[248]

Dos Santos and colleagues conducted a randomized, double-blind, placebo-controlled trial comparing MMR formulations containing the JL, Urabe Am9, and Leningrad–Zagreb mumps virus strains among 10,142 children 6 to 12 years of age.[311] These data are summarized in Table 40.9. The incidence of fever was significantly higher among Leningrad-Zagreb vaccinees than among Urabe Am9 or JL vaccinees, with no significant difference between the Urabe Am9 and JL vaccinees. Compared to JL vaccinees, the incidence of nausea, cough, lymphadenopathy, and parotitis were also statistically greater in Leningrad-Zagreb vaccinees. Local reactogenicity was similar across all three products, except for injection site redness, which was greater in Leningrad-Zagreb vaccinees (1.0%) compared to JL (0.5%) and Urabe Am9 (0.5%) vaccinees.

Comparative information on local and systemic common reactions associated with other mumps virus strains is lacking.

Rare Reactions

Less-common reactions include parotitis, aseptic meningitis, orchitis, and pancreatitis. Of these, aseptic meningitis has received the most attention and has been responsible for the discontinuation of some mumps virus vaccines. Rates of vaccine-associated aseptic meningitis vary widely, even between different studies of the same vaccine strain, likely the result of methodological differences influencing rates of detection of vaccine-associated meningitis and coincidental meningitis after vaccination due to wild-type mumps and other viruses. The most widely reported incidences of aseptic meningitis are in association with Urabe Am9–containing vaccines. Reported rates have ranged from 1 case per 336 doses to 1 case per 295,000 doses, as summarized in Table 40.10. There is some evidence that these rates may be manufacturer-related,[187] but this could be a function of differences in adverse event reporting by country, study size, method of surveillance (active vs passive), inclusion/exclusion criteria (particularly in regard to one- vs two-dose vaccine recipients), definition of vaccine-associated aseptic meningitis, and differences in background rates of aseptic meningitis. Owing to the potential of the Urabe Am9 vaccine strain to produce meningitis, MMR vaccines containing this strain were withdrawn from use in several countries in the early 1990s and mostly replaced with MMR containing the JL strain (MMR II) or the JL-derived RIT-4385 (Priorix). In Japan, mumps vaccination as part of the national immunization program was halted and has yet to resume; mumps vaccination in Japan is currently voluntary, even though the relative risk of aseptic meningitis

TABLE 40.9 Data From a Randomized, Double-Blind, Placebo-Controlled Trial Comparing Different MMR Formulations Among Children Age 6–12 Years

	MMR-II (n = 2216)	Trimovax (n = 2179)	Tresivac (n = 2226)	Controls (n = 3521)
Mumps component	Jeryl Lynn	Urabe Am9	Len.-Zagreb	Unvaccinated
Measles component	Moraten	Schwarz	Edm.-Zagreb	Unvaccinated
Rubella component	Wister RA 27/3	Wister RA 27/3	Wister RA 27/3	Unvaccinated
Headache	8.4%	8.9%	9.1%	2.2%

TABLE 40.10 Incidence of Postvaccine Aseptic Meningitis Following Vaccination With MMR Vaccines Containing the Urabe Am9 Mumps Virus Strain

Manufacturer	Country (Dates Covered by Study)	Rate (N)	Type of Study and Surveillance
SANOFI PASTEUR			
Rebiere et al[468]	France (1991–93)	1/28,400 (1/65,750)[a]	Retrospective: capture-recapture method
Joinville-Bera et al[469]	France (1989–92)	1/121,951	Retrospective: passive surveillance; 4 of 54 cases with laboratory confirmation of mumps virus in CSF
Dos Santos et al[311]	Brazil (1996)	0/2179	Randomized double-blind clinical trial in children 6 to 12 years old
GLAXOSMITHKLINE			
Furesz et al[470]	Canada (1986–90)	1/62,000	Retrospective: passive surveillance; 8 cases with virologic confirmation
Dourado et al[471]	Brazil (1997)	1/14,000 (452,344)	Prospective: passive surveillance of hospital admissions for meningitis; 32 cases identified
Miller et al[180]	UK (1991–92)	1/12,400 (49,585)	Retrospective: computerized hospital records for children ages 12–23 months with meningitis; 4 cases identified
SANOFI PASTEUR OR GLAXOSMITHKLINE[b]			
Miller et al[472]	UK (1990–91)	1/11,000 (78,300)	Retrospective: CSF evaluation in children discharged with diagnosis of meningitis within 15 to 35 days after MMR vaccination; 4 of 13 cases virus positive
Farrington et al[473]	UK (1988–93)	1/15,000 (77,200)	Retrospective: linkage of vaccination records and hospital discharge for meningitis; 5 cases identified
JAPAN MINISTRY OF HEALTH AND WELFARE OR BIKEN			
Fujinaga et al[474]	Japan (1989)	1/336 (11,750)	Retrospective: passive surveillance; 35 cases identified
Sugiura et al[475]	Japan (1989)	1/6,564 (630,157)	Retrospective: surveillance by physicians; 96 cases with viral confirmation
Ueda et al[367]	Japan (1990–93)	1/905 (5430)	Prospective: active surveillance by parents; 6 cases identified
Ueda et al[367]	Japan (1990–93)	0/566 (566)	Prospective: active surveillance by parents; physician confirmed
MANUFACTURER NOT SPECIFIED			
Maguire et al[476]	UK (1990–91)	1/61,000 (est. 1,650,000)	Prospective: passive surveillance by physicians with active follow up by laboratory or clinical confirmation; 7 definite cases, 17 probable cases
Colville et al[477]	UK (1988–91)	1/3,800 doses	Retrospective: 6 virologically confirmed cases in a small population
Al Mazrou et al[478]	Saudi Arabia (2000)	1/295,000 (est. 2,000,000)	Prospective: active surveillance following booster vaccination in a "catch-up" campaign; 6 cases confirmed

[a]Rate of 1/28,400 is based on an estimate of 116 cases of postvaccine aseptic meningitis by the capture-recapture method. The actual number of observed cases was 46, and no virus isolation was carried out. The rate calculation using the number of observed cases is 1:65,750.
[b]At the time of the study, Urabe Am9 vaccines manufactured by both Sanofi Pasteur (then Aventis Pasteur) and GlaxoSmithKline were licensed, and it is not possible to relate occurrence of postvaccine aseptic meningitis to a specific vaccine.
CSF, cerebrospinal fluid; MMR, measles, mumps, rubella; UK, United Kingdom.

after natural mumps is approximately 25 times greater than after vaccination with the Japanese product.[361] Based on an assessment in 2005, fewer than 25% of children 3 to 5 years old are vaccinated against mumps in Japan and it has been estimated that more than 1 million cases of mumps occur annually.[361,362]

Aseptic meningitis also has been reported in association with vaccines containing the Leningrad-Zagreb,[363,364] Hoshino,[365–367] Torrii,[365,367] Miyahara,[361] NK-M46,[368] Leningrad-3[369,370] and Sofia-6[371] strains. The rate of aseptic meningitis following MMR–Leningrad-Zagreb vaccination in Brazil and Croatia was estimated to be one case per 3390 doses and one case per 2020 doses, respectively,[363,364] but very different estimates were obtained in association with a vaccination campaign in the Bahamas where less than one case per 100,000 doses were reported.[372] In a prospective, postmarketing safety study conducted in Egypt, no cases were identified among 453,119 recipients of the Leningrad-Zagreb vaccine.[373] However, as discussed earlier (see "Excretion of Vaccine Virus"), the Leningrad-Zagreb vaccine virus RNA was isolated from Leningrad-Zagreb vaccinees presenting with meningitis, raising little doubt that this vaccine can cause meningitis.

In contrast, aseptic meningitis after vaccination with the JL strain rarely has been reported and is estimated to occur after only 1 in 1.8 million doses administered, a rate not significantly different from background.[309,374,375] In a nested case-control study, receipt of MMR II was not demonstrated to be a risk factor for hospitalization for aseptic meningitis.[376] In no case has a causal association been confirmed between the JL vaccine strain and aseptic meningitis. Similarly, aseptic meningitis has not been reported in association with the RIT-4385 strain.

In evaluating the importance of this complication, one should consider the incidence of clinical meningitis that would occur in natural mumps, conservatively estimated between 1% and 10%.[377] Assuming a conservative rate of

vaccine-associated meningitis of 1 in 10,000 and an incidence of mumps greater than 1% per year, vaccination is clearly better than not vaccinating, a conclusion also reached after evaluation of safety and effectiveness data from 64 different MMR vaccine studies involving more than 14 million children.[299]

Like aseptic meningitis, parotitis is a common complication of wild-type mumps virus infection, and therefore, it should be of little surprise that parotitis can occur after vaccination with some mumps virus strains. Parotitis following JL vaccination has been reported, although the frequency of this complication varies widely from one per 90,000 doses based on spontaneous reports from physicians[309] to 1.6% in a prospective, randomized clinical trial involving children 9 months to 4.5 years of age.[248] In this same prospective, randomized clinical trial, the incidence of Urabe Am9–associated parotitis was 2.0%, which was not statistically different from JL-associated parotitis. However, these trials lacked an unvaccinated control group; thus one cannot rule out that some of these cases of parotitis could have been caused by coincidental wild type infection in the population studied, or infection by other viruses that can cause parotitis, particularly influenza A virus (see "Diagnosis"). In the Dos Santos study (see Table 40.9), which included an unvaccinated control group, parotitis occurred in 3.1% of MMR–Leningrad-Zagreb vaccinees, 1.3% in MMR–Urabe Am9 vaccinees, and in 0.5% of MMR-JL vaccinees. The incidence in the unvaccinated control group was 0.2%.

Other infrequent mumps vaccine–associated complications include orchitis,[102,378,379] pancreatitis,[380,381] and possibly deafness,[382] although the latter is exceedingly rare. Encephalitis following vaccination does not occur more frequently than the background rate in the normal population; only 0.4 cases of encephalitis have been reported in the United States per million doses of live virus mumps vaccine distributed.

Despite the use of chicken embryo as the substrate for many mumps vaccines, few serious allergic reactions have been attributed to egg protein. Allergy to the gelatin included in some mumps virus–containing vaccines is more frequently associated with acute reactions.[383]

Immunosuppressed

Precautions regarding the safety of mumps virus–containing vaccines in immunosuppressed persons are based on very limited data or anecdotal evidence and theoretical risks based on the known biology of the live viral components. MMR and MMRV vaccines are not recommended in persons with primary or acquired immunodeficiencies (including AIDS or severe immunosuppression associated with HIV infection) or in persons with leukemia, lymphomas, or other malignant neoplasms affecting the bone marrow or lymphatic system. These vaccines should also not be used in persons receiving systemic immunosuppressive therapy, including corticosteroids equal to or greater than 2 mg/kg of body weight or equal to or greater than 20 mg/day of prednisone or equivalent for persons who weigh more than 10 kg, when administered for 2 weeks or longer.[384] Use of MMR, but not MMRV, is recommended in asymptomatic HIV-infected persons without evidence of severe immunosuppression.

In Pregnancy

Because of a theoretical risk to the fetus, MMR vaccines should not be administered to pregnant women or women attempting to become pregnant. If vaccine is administered to a woman who is attempting to become pregnant, she should be advised to avoid becoming pregnant for 28 days after vaccination. Inadvertent vaccination with MMR during pregnancy should not be considered an indication for termination of pregnancy. The vaccine can be given to eligible persons who have pregnant household contacts.

Spread to Contacts

There are no reports of transmission of mumps vaccine virus from recipients of JL-containing vaccines to susceptible contacts. Horizontal transmission of the Urabe Am9, Leningrad-3, and Leningrad-Zagreb vaccine strains, although rare, has been demonstrated.[313,315–318] In such cases, mumps symptoms appeared within 4 to 6 weeks of vaccination of close contacts, consistent with vaccine virus shedding 2 to 4 weeks postvaccination, followed by a 2- to 4-week incubation period (see "Excretion of Vaccine Virus").

INDICATIONS FOR VACCINATION

In the United States, the ACIP recommends two doses of MMR II vaccine for all children and for certain high-risk groups of adolescents and adults, including international travelers, people attending universities and other higher educational institutions, and people who work at healthcare facilities.[349] ProQuad may be given instead of MMR II, with some limitations (see "Vaccine Use" above and "Contraindications and Precautions" below).

In general, people can be considered immune to mumps who have documentation of vaccination with live mumps virus vaccine on or after their first birthday, have laboratory evidence of mumps immunity, have documentation of physician-diagnosed mumps, or were born before 1957 (although during mumps outbreaks, vaccination with mumps-containing vaccine should be considered for people born before 1957).

On June 24, 2009, the ACIP revised its recommendations for evidence of mumps immunity for healthcare personnel to include documented administration of two doses of vaccine, or laboratory evidence of immunity or laboratory confirmation of disease. For unvaccinated personnel born before 1957 who lack laboratory evidence of mumps immunity or laboratory confirmation of mumps, healthcare facilities should consider vaccinating with two doses of mumps-containing vaccine at the appropriate interval.[385]

Laboratory testing for mumps susceptibility before vaccination is unnecessary.[349] There is no increased risk of adverse reactions to vaccination of people who are already immune. In certain situations, MMR II has been given as a third dose (see, "Postexposure Prophylaxis" and "Treatment" above). Very few adverse events, all nonserious, were reported and did not differ substantially from rates seen following one or two doses.[352,386] Seronegative persons who had a history of receipt of two doses of MMR II rapidly seroconverted in response to the third dose.[323]

CONTRAINDICATIONS AND PRECAUTIONS

Most mumps vaccines are produced in chick embryo cell culture and contain small quantities of ovalbumin; however, the risk for serious allergic reactions in people allergic to eggs is extremely low and therefore egg allergy is not a contraindication for vaccination. Cutaneous testing for identifying egg-allergic children is of limited value.[387–389]

Caution should be exercised when administering MMR II or ProQuad to people who have a history of an anaphylactic reaction to gelatin. Skin testing for gelatin sensitivity could be considered, but no specific protocols for this purpose have been published.[349] Persons with a history of anaphylactic

reactions to neomycin should not receive the vaccine; a history of contact dermatitis to neomycin is not a contraindication to vaccination. Mumps-containing vaccines used in the United States and most other countries do not contain penicillin.

Mumps-containing vaccine should be given at least 2 weeks before the administration of immunoglobulin or deferred until 3 months after such administration because of the concern that passively acquired antibody may interfere with response to the vaccine, although data from coadministration studies have found no evidence of such interference.[253]

Mumps-containing vaccine should not be given to pregnant women because of the theoretical risk of fetal damage. Likewise, vaccinated women should avoid pregnancy for 1 month after vaccination.[285]

People with severe febrile illnesses should in general not be vaccinated until they have recovered. Vaccination should not be postponed because of minor illness.

The measles virus component in mumps-containing vaccines may temporarily suppress tuberculin reactivity,[285] and therefore tuberculin testing should be done before vaccination, or 4 to 6 weeks afterward.

Untreated active tuberculosis and a history of thrombocytopenia/thrombocytopenic purpura are contraindications for MMR II or ProQuad vaccination. The benefits of immunity to MMR are thought to outweigh the risk of recurrence or exacerbation of thrombocytopenia after vaccination. However, if a prior episode of thrombocytopenia occurred shortly after vaccination, avoidance of a subsequent dose of MMR II or ProQuad should be considered.[285]

MMR II or ProQuad vaccine should not be given to people with acquired immunodeficiency or suppressed immunity (e.g., leukemia, lymphoma, generalized malignancy, or therapy with corticosteroids, alkylating drugs, antimetabolites, or radiation). An exception is children infected with HIV. MMR II vaccination is recommended for all HIV-infected people who do not have evidence of severe immunosuppression and for whom measles vaccination would otherwise be indicated. Because the immunologic response to vaccines may decrease as HIV disease progresses, HIV-infected infants without severe immunosuppression should be given MMR II at age 12 months and a second dose as soon as 1 month later.[349] Data are not available on safety, immunogenicity, or efficacy of ProQuad vaccine in HIV-infected children; consequently, this vaccine should not be used in this population.[285]

Patients with leukemia in remission who have not received chemotherapy in at least 3 months may receive mumps-containing vaccine, as may people who have received short-term (i.e., <2 weeks' duration) steroid therapy.[349] There are limited data on the safety and efficacy of MMR II or ProQuad vaccine in transplant recipients receiving immunosuppressive therapy. Because the diseases prevented by MMR II or ProQuad do not result in significant morbidity (mumps, varicella) or are of a low contraction risk owing to population immunity (measles, rubella), vaccination should be avoided. However, during an outbreak, immunization may be advisable.[390] MMR II or ProQuad vaccination is recommended for persons completing immunosuppressive therapy who are determined to be immunocompetent.[285]

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Effects of Vaccination

United States

In the United States, reported cases of mumps decreased from more than 185,000 in the prevaccine era to fewer than 5000 cases within 5 years of the 1977 ACIP recommendation for inclusion of MMR in the national immunization schedule. In the years following implementation of a two-dose schedule in 1989, further declines were achieved (see Fig. 40.3). The dramatic reduction in reported cases of mumps in the United States since 1991 reflects increasing implementation of school immunization laws requiring two doses of MMR II. Between 1999 and 2005 fewer than 400 cases were being reported annually, a time period coinciding with the 1998 ACIP recommendation that all states take immediate steps to implement the two-dose MMR II schedule so that by the year 2001, all children in kindergarten through grade 12 received two doses of the vaccine.[349] Based on data from the 2015–16 school year, (the latest data available at the time of writing this chapter) median two-dose MMR vaccine coverage among kindergardeners in the United States was 94.6% and among adolescents aged 13 to 17 years was 90.7% (see "Vaccine Use").

Before widespread use of mumps vaccine, cases mostly occurred in children 5 to 9 years old. Following wider vaccine use, the average age of reported cases gradually increased, resulting in an increasing proportion of cases reported among people 15 years of age and older. From 1967 to 1971, only 8% of reported cases were among this older group, compared with more than 33% from 1987 to 1992.[392,393] This shift was an expected result of the implementation of immunization programs, which were directed at preschool-age children and led to widespread interruption of mumps virus transmission; a similar shift was previously observed for measles and rubella. National U.S. immunization policy was slow to endorse mumps vaccine as a routine immunization of childhood. Thus, a decade elapsed between licensure of the monovalent vaccine in 1967 and the recommendation at the end of 1977 that it be given routinely to all children (as part of MMR). Consequently, a cohort of children born between 1967 and 1977 (i.e., people 10 to 20 years old in 1987) grew up when the chance of exposure to wild mumps virus for a preschool-age or young school-age child was markedly declining while the opportunity to receive mumps vaccine was uncertain. The greater mobility of older children and adolescents increased the potential for contact among susceptible people in these age groups. This may explain the 1986–87 resurgence of mumps, with 7790 cases and 12,848 cases reported, respectively (see Fig. 40.3). Many of these outbreaks occurred in high schools,[334] colleges,[394,395] and the workplace.[396] Since 1989, reported cases of mumps again decreased. By 1992, the highest age-specific incidence shifted back to the 5- to 9-year-old group, but even in this group cases declined, a likely result of increasing implementation of school immunization requirements for two doses of MMR vaccine. The peak age of mumps acquisition remained in this age group in the United States until the multistate mumps outbreak in 2006 when the age-specific incidence shifted again to the older age group (Fig. 40.8).[397,398] However, unlike the 1986–1987 mumps resurgence, the mumps epidemic in 2006 was not caused by an unvaccinated cohort, as nearly all cases in many outbreaks occurred in persons with a history of two doses of vaccine and in highly vaccinated populations. In the years following the 2006 mumps outbreak, the highest age-specific incidence returned to the younger age group,[399,400] until the 2009–2010 outbreaks in New York and New Jersey, where, again, most cases occurred in young adults, many of whom had a history of receipt of two doses of vaccine.[391] The occurrence of mumps predominantly in young adults during outbreaks in highly vaccinated populations is now a common feature globally (see "Risk Factors for Vaccine Failure and Recent Outbreaks" above). Nonetheless, compared to the prevaccine era, mumps outbreaks are relatively uncommon; thus, whatever the cause of vaccine breakthroughs, the impact is small, highlighting the continued effectiveness of mumps vaccines.

From 1975 to 1984, there was approximately one death from mumps per 5000 reported cases and one case of mumps encephalitis per 500 reported cases (Fig. 40.9). Since 1984, these proportions have been more variable owing to smaller numbers of reported events, and since 1995, mumps encephalitis has not been a reportable disease in the United States.[401] Because of underreporting of mumps and mumps encephalitis, these figures probably overestimate the risk of mortality and underestimate the rate of mumps encephalitis. Indeed, before the introduction of mumps vaccination, mumps was the most commonly diagnosed cause of viral encephalitis in childhood in developed countries; introduction of routine vaccination has resulted in the virtual elimination of mumps encephalitis.[15,402] During the 2006 multistate mumps outbreak in the United States, of 1327 patients for whom clinical data were available, only four cases of encephalitis were reported, an incidence of 0.3%, which is similar to the incidence of mumps encephalitis reported before 1984.[403]

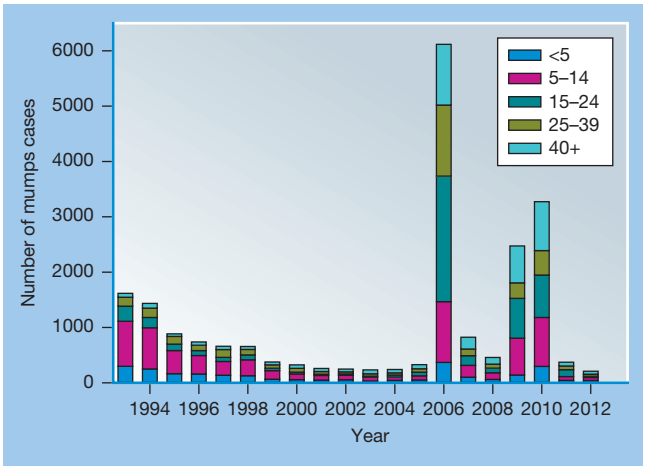

Figure 40.8. Reported cases of mumps by age group, United States, 1993–2012. In each year, the age distribution of cases of known age has been applied to the cases of unknown age. *(From the National Notifiable Diseases Surveillance System, Centers for Disease Control and Prevention.)*

Countries Other Than the United States

Although nearly all developed countries use mumps-containing vaccines, in many mumps is not a notifiable disease and vaccination is often voluntary. Nevertheless, mumps vaccination has had a tremendous impact where used, with reductions in incidence and morbidity exceeding 90%.[174,209,336,404–408] However, mumps has made a comeback in nearly all countries where the disease once had been under control. This disease, which was historically one of childhood, now predominantly occurs in young adults.[35,36,292,348,409–413] In many of these outbreaks, waning immunity has been postulated to be a major factor. However, unlike the U.S. outbreaks where it was clear that cases were occurring in fully vaccinated populations, in other countries, other factors may have had a role.

For example, at about the time of an outbreak in the Czech Republic, data reported by the public health authority indicated MMR vaccine coverage exceeded 97%; however, this did not correspond to data from a seroprevalence survey indicating that only 70% to 86% of persons 1 to 15 years old had mumps virus antibodies.[35,414] Similarly, in Austria, despite a one-dose national immunization schedule since 1974, and a two-dose schedule since 1994, nearly half of cases identified in a recent outbreak had not been previously vaccinated,[410] suggesting a lack of compliance with the recommended vaccine schedule. In Denmark, disease incidence increased 10-fold, from less than 0.1 case per 100,000 population in 2003 to nearly one case per 100,000 population in 2013, and was mostly attributed to low immunity in older age groups who grew up during a period when MMR vaccination was not routinely offered.[415] In China, mumps vaccine was introduced into the national routine immunization program in 2007, and has been used since in a one-dose regimen in infants 18 to 24 months of age; however, according to a recent publication, there is no clear evidence that disease incidence has declined.[416]

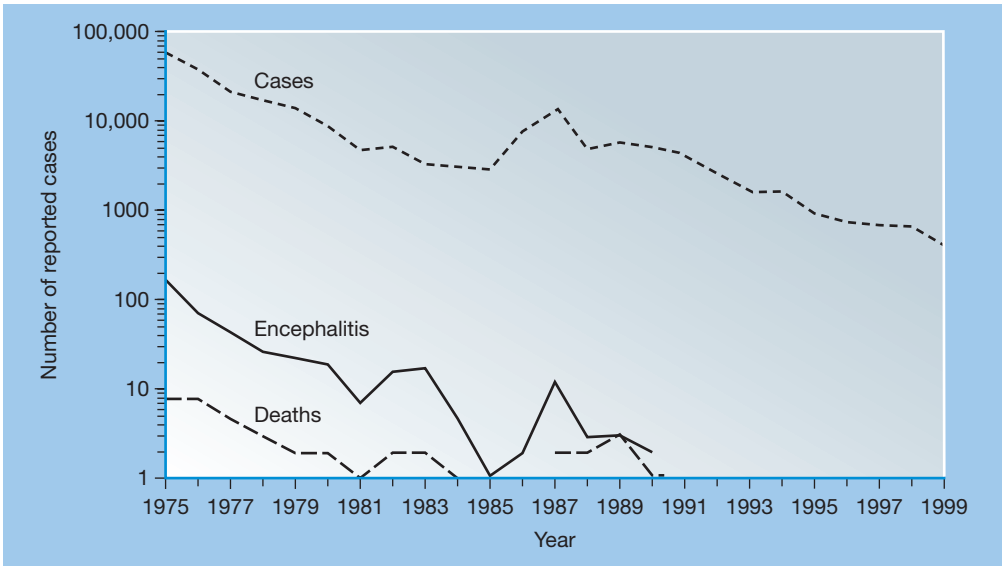

Figure 40.9. Reported cases of mumps, mumps encephalitis, and mumps deaths, United States, 1975–1999. Since 1990, two or fewer deaths reported annually, most are not likely mumps related. Data on mumps encephalitis not available after 1990. *(From the National Notifiable Diseases Surveillance System, Centers for Disease Control and Prevention.)*

In Israel and Spain, data suggest changes in population demographics may be responsible for the changing epidemiology of mumps. An assessment of mumps antibodies among Israeli military recruits conducted in 1987 revealed a seroprevalence of 94%; however, seroprevalence declined to 83% by 1999.[417] Immigration was identified as a contributing factor to the decrease in population seroprevalence over time. Similarly in the Catalonia region of Spain, a rise in the incidence of mumps in 2006–07 was thought to be partly from lower vaccine coverage in the immigrant population, which increased sixfold relative to the increase of the highly vaccinated indigenous population.[336]

In the former Yugoslav republics of Macedonia and Moldova, recent mumps outbreaks were attributed to missed opportunities for vaccination as a result of the timing of the vaccine schedule[36,412] resulting in unvaccinated or incompletely vaccinated cohorts, much as was the case in the U.S. outbreaks in 1986 and 1987. Missed opportunities for vaccination were also believed to be the primary cause of the resurgence of mumps in the United Kingdom, where routine vaccination with MMR at 12 to 15 months of age was introduced in 1988 and a second dose in 1996 at 3.5 to 5 years of age. The impact of vaccination on disease incidence was prompt, as reflected in notified cases in England and Wales, which decreased by more than 85% from 1989 to 1991, remaining at this level through 2002 (Fig. 40.10). Based on reports from sentinel surveillance, the most dramatic decrease occurred among children 0 to 14 years old. One-dose vaccine coverage reached 91% of 24-month-old children by 1996.[418] This trend of relatively low mumps incidence abruptly changed in 2004–2005, with more than 70,000 reported cases, mostly in persons 15 to 24 years old.[413,419–421] This outbreak was attributed in part to a shortage of MMR in 1994 when a measles vaccine catch-up campaign for 5- to 16-year-olds was initiated. Instead of using MMR, the bivalent measles-rubella vaccine was used.[421] Thus a large population of children born in the years 1978 to 1989 missed an opportunity for mumps vaccination. Indeed, the highest attack rate occurred in persons born between 1983 and 1986.[419] Notably, it was estimated that only 2.4% of confirmed cases in 2004 occurred in persons who would have been age-appropriate to participate in the routine two-dose MMR program.[413] This was confirmed by the data; only 3.3% of cases occurring in 2004 were reported as having received two doses of mumps-containing vaccine, and another 30% had received only one dose.[413] The number of confirmed mumps cases has declined, but still remains high with an average of 8600 cases reported annually between 2010 and 2014, a likely reflection of declining MMR coverage, which began in 1998, possibly in association with popularization of a published report linking MMR vaccination with autism.[422] The report was retracted in 2010 owing to scientific and ethical misconduct[423] and subsequent research found no evidence of such a link,[424–428] but the damage was done. By 2004, one-dose MMR coverage was down to 86% in most of England and less than 80% in London.[429] These percentages have improved since. As of the second quarter of 2016, one-dose MMR vaccine coverage among persons 2 years old in England was estimated at 91.4%, and 84.4% for London, and by 5 years of age, two-dose coverage was estimated at 87.5% and 80.2%, respectively.[430]

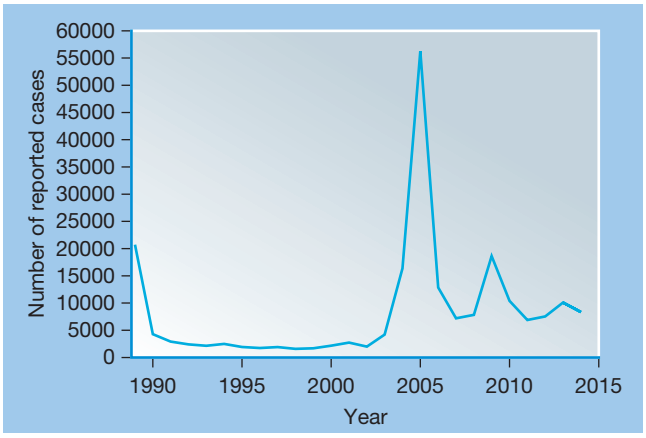

Figure 40.10. Number of mumps cases reported in England and Wales, 1989–2014. *(From Public Health England. Research and analysis: Notifiable diseases: historic annual totals. 2016. Available at: https://www.gov.uk/government/publications/notifiable-diseases-historic-annual-totals.)*

This situation contrasts sharply with that of Finland, where by 1986, more than 95% of eligible children had been vaccinated.[431] By 1994 there were fewer than 30 reported cases of laboratory-confirmed mumps and data indicate that these were probably imported.[432] By 1997, indigenous mumps disappeared from Finland, with only rare imported cases remaining.[347] Between 1997 and 2010, only 37 mumps cases had been diagnosed in Finland, despite an average of 5 million travelers to the country annually.[207] Based on data published by the WHO, no cases of mumps were reported in Finland in 2014 or 2015. In 2013, only one case was reported.[432a] The success of the Finnish program, achieved by the routine two-dose schedule of MMR vaccination, serves as a model for other countries that want to eliminate measles, rubella, and mumps.[433]

In other countries, the resurgence of mumps was found to be the cause, indirectly, of the vaccine itself. In Portugal, where routine vaccination was introduced in 1987, reports of unusually large numbers of cases began in 1994. During the first 8 months of 1996, 7620 cases were reported. Although incidence increased among all age groups, rates were highest among children 1 to 4 years old. This finding was unexpected because reported MMR vaccination coverage among children 12 to 23 months old had exceeded 90% since 1991. Three mumps vaccines—Urabe Am9, Rubini, and JL strains—were initially available in Portugal as MMR. Following recognition of aseptic meningitis after vaccination with Urabe Am9 mumps vaccine, the sale of Urabe Am9–containing vaccine was suspended in Portugal in October 1992, and subsequently only Rubini-containing MMR was used.[434] Use of the poorly efficacious Rubini strain as a substitute for the Urabe Am9 strain was followed by a mumps epidemic.[434] Similarly, despite vaccine coverage of 96% in Spain, protection against mumps was estimated to be 79% overall and was lowest in regions where the Rubini strain was used exclusively.[435]

The JL strain mumps vaccine (given as MMR II) first became available in Switzerland in 1971, and MMR vaccine including the Urabe Am9 strain was introduced in 1983. Routine vaccination of children was recommended by Swiss public health authorities in 1985. MMR containing the Rubini mumps vaccine strain (Triviraten) became available in 1986 and subsequently accounted for more than half the doses of MMR vaccine used in the country. Reports from a sentinel network of physicians demonstrated an increase in reported cases of mumps beginning in 1991. Increases in mumps cases were seen among all age groups but were most striking among children 5 to 9 years old. By 1993–94, 59% of reported cases were noted to occur in children previously vaccinated, compared with only 9% in 1986–87.[436] A 1991–92 seroprevalence survey found mumps immunity in young children to lag behind that for measles and rubella, perhaps reflecting the relatively poor immunogenicity of the Rubini strain.[437]

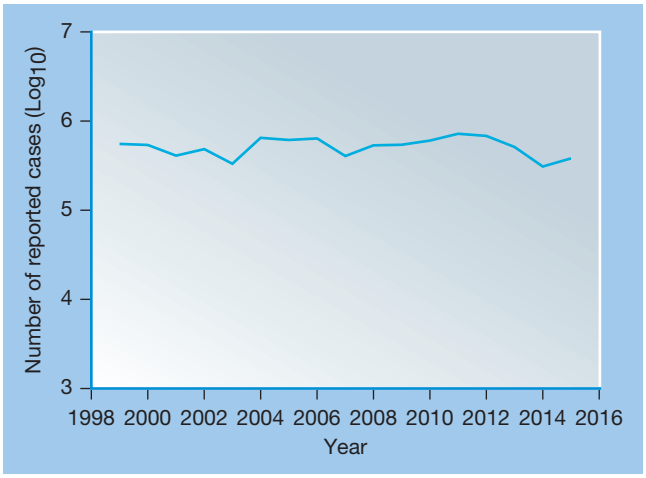

Figure 40.11. Mumps cases reported to the World Health Organization from its member states between 1999 and 2015. *(From World Health Organization. WHO vaccine-preventable diseases: monitoring system 2016 global summary. Available from: http://apps.who.int/immunization_monitoring/globalsummary/timeseries/tsincidencemumps.html.)*

The WHO received reports of 384,195 mumps cases during 2015 from its member states, which is a 24% decline from 2 years earlier, but not a significant deviation from case numbers on whole over the past 15 years (Fig. 40.11). The numbers are gross underestimates as many of the member states do not immunize against mumps and report no cases.[438]

Cost-to-Benefit Information

Cost-to-benefit analyses show that US$7 to US$14 are saved for every dollar spent on a program of vaccination with monovalent mumps vaccine or MMR vaccine.[439,440] Unpublished data from the Centers for Disease Control and Prevention (CDC) found similar cost-to-benefit ratios: 6.1 for direct costs and 13.0 for direct and indirect costs for use of monovalent mumps vaccine, and for MMR vaccine 16.3 for direct costs and 21.3 for direct and indirect costs. Zhou and colleagues estimated that more than US$1.5 billion in costs are averted annually by vaccinating against mumps, with a saving of US$3614 per case prevented per year.[441]

DISEASE CONTROL STRATEGIES AND POSSIBLE ERADICATION

To control the spread of disease, the CDC and the American Academy of Pediatrics recommend that persons with mumps be maintained in isolation with standard precautions and droplet precautions for 5 days after onset of parotitis.[442] In schools and colleges experiencing an outbreak, the CDC recommends that unvaccinated students be excluded and readmitted only after they have been vaccinated. Students with a history of one dose of vaccine should receive their second dose and be allowed to remain in school. Students who have been exempted from mumps vaccination for medical, religious, or other reasons should be excluded from school until the 26th day after the onset of parotitis in the last person with mumps in the affected school.[349]

A critical issue for further study concerns the extent and duration of protection conferred by two doses of mumps vaccine per the current administration schedule. Widespread use of the live virus mumps vaccine since U.S. licensure in 1967 has resulted in an exceptional decrease in the incidence of mumps, but continuing outbreaks in highly vaccinated populations worldwide illustrate the potential for continued epidemics regardless of vaccine coverage. A review of the literature shows that close to 95% of children respond to their first dose of mumps vaccine with virus-neutralizing antibodies, and nearly all those who do not will seroconvert following a second dose.[260] However, as reviewed in this chapter, a substantial proportion of vaccinees become seronegative or demonstrate significant declines in antibody titers over time (see "Persistence of Antibodies" above). In parallel, the effectiveness of mumps vaccines seems to decline with time postvaccination as well (see "Risk Factors for Vaccine Failure and Recent Outbreaks" above). These observations are suggestive of waning immunity. In the context of low levels of virus-neutralizing antibody, antigenic differences between vaccine strains and contemporary circulating viruses may be of more significance than previously appreciated. Together, these concerns indicate possible utility of an additional dose of vaccine during adolescence or later. The potential effectiveness of an additional dose later in life was suggested in studies where the MMR vaccine was used as a control measure in school-based outbreaks (see "Postexposure Prophylaxis" above). Although the mumps attack rates in students receiving the intervention declined substantially in these studies, conclusions could not be drawn because of study power as well as the caveat of the intervention being initiated after the outbreak started to decline. Nonetheless, use of an additional dose of vaccine during an outbreak would seem prudent. This notion is supported by data on the immunogenicity of a third dose of MMR among 685 young adults in a non-outbreak setting as reported by Fiebelkorn and colleagues.[443] In that study, the GMT of virus-neutralizing antibody titers was observed to significantly increase in response to the third dose when measured 1 month after vaccination. However, at 1 year postvaccination, the GMT retreated close to baseline, suggesting only a transient benefit of a third dose of vaccine, making it difficult to justify a change to the current MMR vaccine schedule for routine vaccine use. Unfortunately, other biological indicators of improved immunity, such as more robust B-cell memory or higher antibody avidity, were not examined.

FUTURE VACCINES

As a consequence of the resurgence of mumps over the past decade despite high vaccine coverage, changes to the current vaccination schedule or development of new, more effective vaccines have been suggested. As described in "Disease Control Strategies and Possible Eradication" above, changing from a two-dose to a three-dose MMR schedule was evaluated, but the results raised doubt whether this or any other change to the vaccination schedule would improve the long-term effectiveness of the vaccine. This leaves development of new vaccines as the only practical approach to improving vaccine performance; however, prospectively designing improved vaccines is predicated on knowing what is responsible for the less-than-desirable performance of existing vaccines, as well as knowledge of reliable markers of vaccine efficacy, neither of which are known. In the absence of a clear understanding of factors that influence the kinetics, robustness, and duration of meaningful immune responses to mumps vaccination, and how these parameters can be reliably measured, there is little promise of new vaccines performing any better than existing vaccines.

Some have suggested that the problem is one of a mismatch between vaccine genotype and circulating virus genotype; however, genotype-matching of the vaccine to circulating

strains is impractical, given the time required to conduct clinical trials supportive of vaccine safety and efficacy and the changing molecular epidemiology of the virus. Furthermore, as discussed in "Risk Factors for Vaccine Failure and Recent Outbreaks" above, data linking a difference between vaccine virus and circulating virus genotypes to vaccine failure are unconvincing, particularly in light of data to the contrary, including laboratory data[322,345] and empirical data, such as the fact that disease incidence in the United States and other countries has declined by well over 90% in association with the wide use of the genotype A JL vaccine, in the face of wild-type circulating mumps virus strains belonging to many different genotypes.[444]

Perhaps the best leads toward improved vaccines come from studies on B-cell responses to vaccination. Not only are levels of mumps virus–specific antibody-secreting cells following vaccination significantly lower than levels induced by natural infection, but among the viral components of the MMR vaccine, far fewer mumps virus–specific memory B cells are generated than measles- and rubella-specific memory B cells.[270] Furthermore, the avidity of MMR vaccine-induced mumps antibodies are much lower than the avidity of the measles and rubella antibodies measured in the same subjects.[251] Whether these issues are peculiar to responses to mumps viruses in general, or if they are vaccine virus strain specific, is not known. However, data from a recent study of antibody avidity among persons developing antibody in response to vaccination versus natural infection, low antibody avidity was characteristic of both groups, suggesting that mumps virus, regardless of strain (wild type vs vaccine), does not engender high avidity antibody upon initial exposure.[444a] On the other hand, an immunoinformatics study using software to predict B-cell linear epitopes and major histocompatibility complex binding affinities suggested that low antibody avidity and B-cell memory might be specific to the JL mumps virus vaccine.[338] These data come from single small studies and require further investigation, but do provide some direction for future work in this area.

Overall, however, despite less-than-ideal performance by mumps vaccines, it must be kept in mind that the preponderance of data demonstrate these products to be highly effective and solely responsible for the near elimination of this once ubiquitous disease in all countries where mumps-containing vaccine is rigorously used.

41 Noninfectious Disease Vaccines

Aadil El-Turabi and Martin F. Bachmann

OVERVIEW

This chapter provides an overview of the challenges and latest advances in vaccine development for chronic and noncommunicable diseases. Because of space limitations it is not possible to provide an exhaustive representation of the field; consequently, we address a few major themes with examples of challenges and vaccine-based solutions. There also is a vast literature on T-cell–based cancer vaccines, which are discussed more comprehensively in Chapter 13.

The incidence of many chronic conditions increases with age and with more individuals living longer, this places operational and financial pressures on healthcare systems. More than 90% of all medications administered to patients during their lifetimes are administered in the last 10 years of life. Some estimates suggest that a staggering one-third of all healthcare costs will be expended in the final year of life.[1–3]

INTRODUCTION

Sizeable global demographic changes are leading to significant challenges for professionals charged with preserving the health and well-being of the population in the first century of the new millennium. There have been many successes in combating once prevalent global infectious diseases through vaccines and antimicrobials, leading to an estimated net increase in life expectancy of nearly 30 years in industrialized countries over the past decade.[4,5] Indeed, the "maturing" of global societies is a major achievement, with people today living longer and healthier lives than previous generations (with the World Health Organization quoting a global figure of an average life-expectancy increase of 20 years compared to 50 years ago[6]). This demographic change offers enormous social and economic benefits in opportunities to harness the experience, expertise, and creativity of a large number of older people. However, it also brings difficulties caring for an aging population, given that healthcare costs associated with treating and caring for the elderly are considerable and are likely to increase. In addition the prevalence of chronic diseases, long overlooked in the global context, has swiftly emerged as a major problem accounting for 48% of all global mortality.[7] Although much of this can be addressed by existing knowledge and cost-effective solutions, there are many as yet unmet medical challenges that require novel therapies.

One important objective must be to preserve health, prevent disease by encouraging "good" habits (e.g., exercise and nutrition), and intervene early in disease processes before they become debilitating. Of course this presumes that we have the means to detect diseases early, effective tools for medical interventions, and accessibility to the population at risk (both in terms of compliance and costs). Vaccines are highly successful in preventing infectious and communicable diseases; thus there is precedent for the goal of repeating such feats in the combating of noncommunicable diseases.

Monoclonal antibodies targeting self-proteins have provided much needed relief and life-altering therapies for several chronic diseases.[8–12] Current examples include anti–tumor necrosis factor (TNF) drugs such as adalimumab (Humira), certolizumab pegol (Cimzia), etanercept (Enbrel), golimumab (Simponi), and infliximab (Remicade) for rheumatoid arthritis, ankylosing spondylitis, and Crohn disease. These products have been extensively evaluated in preclinical and clinical efficacy trials prior to their widespread use in clinical practice.[9–12] These treatments provide rapid therapeutic effects with a high degree of specificity inherent in antibody-target interactions, but are expensive, require fairly large doses, and must be given frequently. In addition, the potential for secondary treatment failures, when recipients mount an immune response against the therapeutic agent,[8,13,14] necessitates the development of alternative therapies.

The possibility to replace the passive immunization approaches with active immunization is an attractive proposition and presents opportunities for improved compliance (fewer injections), reduced risk of secondary failure (as the immune system is encouraged to produce an antibody response), and lower cost (smaller doses and cost-effective manufacture of vaccines).[15,16] However, this entails the not insignificant task of inducing a safe and efficient immune response against self-antigens.

OVERCOMING THE IMMUNE SYSTEM'S SAFETY MECHANISMS—UNRESPONSIVENESS AND TOLERANCE

In general, humans do not generate antibody responses against self-antigens even if they are given with adjuvants, because the immune system has evolved a set of checkpoints to avoid autoreactive responses. Antiself immune responses are inhibited by several different mechanisms, including deletion of self-reactive lymphocytes (elimination of cells), anergy (functional silencing), and lack of stimulation (immune-competent lymphocytes are present in the periphery but are not stimulated, because they do not encounter the self-antigen in an immunogenic context).[17,18] This unresponsiveness toward self, also referred to as tolerance, occurs at the T- and/or B-cell level. Whereas autoreactive T cells are efficiently deleted or silenced in the thymus, B-cell tolerance is mainly induced in the bone marrow. Both B- and T-cell tolerance also occurs in the periphery. A key feature of deletion of B cells in the periphery is the crosslinking of the B-cell receptor (BCR). Hence, B cells specific for highly expressed membrane proteins are eliminated particularly efficiently, whereas B cells specific for soluble antigens typically escape negative selection and remain in circulation.[19] In contrast, because of the expression of most antigens in the thymus and the transport of soluble antigens to the thymus, T-cell tolerance, in particular T-helper (Th) cell tolerance, is a much more efficient process. Thus, while most autoreactive T cells are eliminated, a largely normal B-cell repertoire exists for secreted and soluble self-antigens. Importantly, because naïve B cells critically depend on T-cell help to proliferate, undergo isotype switching, and differentiate into long-lived plasma cells, deletion or silencing of autoreactive T cells avoids self-specific B-cell responses and maintains B-cell unresponsiveness. Nevertheless, low-affinity autoreactive T cells can escape the thymic and peripheral tolerance processes and may be activated by administration of the antigen in the presence of strong adjuvants such as complete

Freund adjuvant.[20] Bypassing or circumventing T-cell tolerance appears to be the method of choice for the induction of antibodies against self-antigens. This is best achieved by fusing a strong foreign T-cell epitope to the self-antigen or by conjugating the self-antigen to a foreign carrier protein.

INDUCTION OF B-CELL RESPONSES

For a B cell to generate a long-term response, two signals are needed: activation of the BCR and stimulation by antigen-specific Th cells. Through covalent linkage of an antigen to a carrier molecule, B cells expressing a BCR specific for the antigen will acquire carrier-specific T-help (Fig. 41.1).[21] Carrier molecules successfully used for licensed glycoconjugate vaccines are pathogen-derived proteins like diphtheria toxoid, tetanus toxoid, meningococcus B outer membrane protein C, or *Haemophilus influenzae* protein D. Other clinically tested carriers include toxin B, *Pseudomonas aeruginosa* exoprotein A, and keyhole limpet hemocyanin (KLH). Well established virus-like particle (VLP) systems (such as hepatitis B vaccine and human papillomavirus vaccine) induce excellent immune responses with increased attention to finding ways to generate responses to heterologous antigens. VLPs share many of the features of whole viruses but are not infectious. Their particulate nature, their highly ordered repetitive structure, and their Th cell epitopes are the source of their remarkable immunogenicity.[22–24]

For this reason, VLPs have gained interest as platforms for vaccines against noninfectious diseases.[25–29] Bacteriophage Qβ-derived VLPs, which are readily produced in large quantities under good manufacturing practices in *E. coli*, have been extensively tested as immunological carriers in animals and humans.[21–29] Using chemical heterobifunctional crosslinkers,[30,31] antigens can be directionally conjugated to their surface and presented in a highly ordered fashion to B cells. As a result BCRs are efficiently crosslinked, inducing potent immune responses.[32] Moreover, during self assembly in *Escherichia coli*, host RNA, a potent TLR7/8 agonist, is packaged into the VLPs acting as an adjuvant, thereby enhancing B-cell response and inducing class switching.[33] In light of these virtues, bacteriophage VLPs have been successfully used as carriers to induce potent immune responses against self-antigens and haptens in various preclinical[34–42] and clinical studies.[25–27,43] These targets include examples such as tumor necrosis factor, interleukin-1β, angiotensin II, and amyloid beta (discussed later).

LONGEVITY OF THE RESPONSE AND GENERAL SAFETY CONSIDERATIONS

High antibody titers against a given target could be maintained by yearly boosting. In contrast, the memory responses to classical vaccines are boosted with subsequent exposure to the pathogen. Patients suffering from a chronic disease or drug addiction are not naturally exposed to the antigen in an immunogenic form, because self-antigens are seen by B cells in the absence of specific Th (which had been delivered by the carrier during vaccination).[18,20] Hence, regular booster

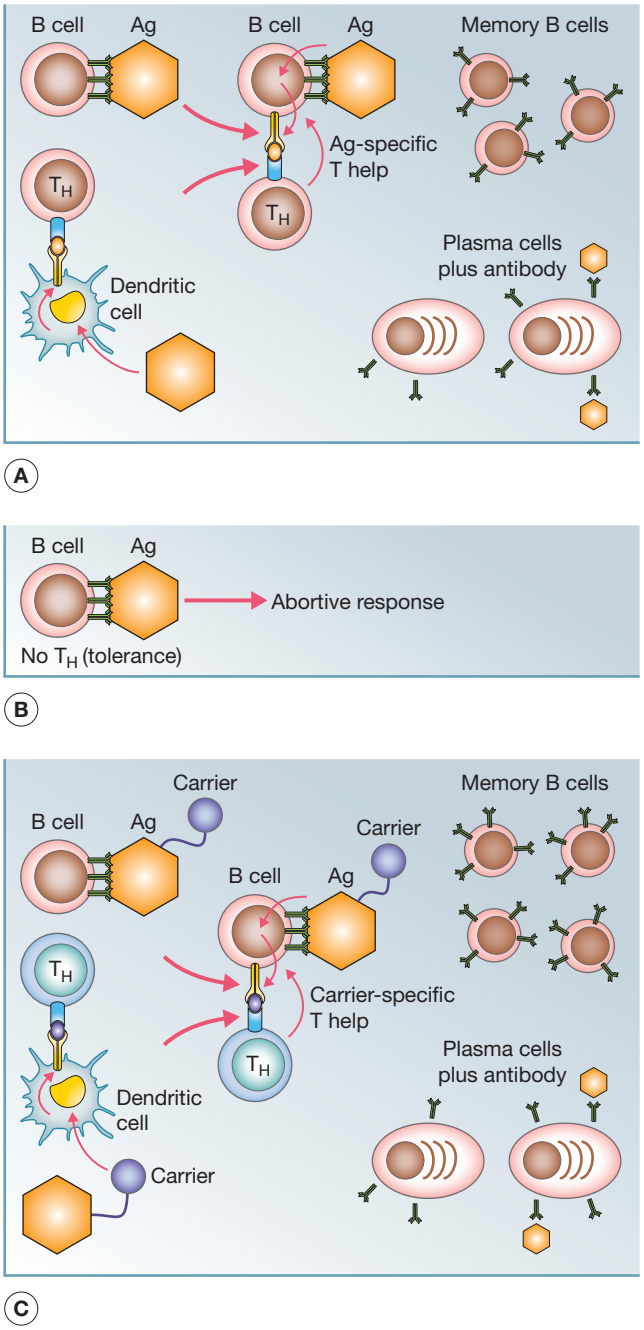

Figure 41.1. How B cells and T_H cells collaborate to circumvent T_H cell tolerance. A, After immunization with a foreign antigen, specific B cells bind the antigen (Ag), inducing an initial activation signal. In addition, B cells endocytose the antigen and display antigen-derived peptides on their major histocompatibility complex (MHC) class II molecules. B cells are not usually able to activate naïve T_H cells, and dendritic cells are an essential intermediate in the activation of T cells. Dendritic cells also take up the antigen and process it for presentation in association with MHC class II molecules. In contrast to B cells, dendritic cells are able to trigger the activation of naïve T_H cells. These activated T_H cells recognize antigen-derived peptides on B cells, leading to successful T- and B-cell collaboration: B cells proliferate, produce antibody, and undergo isotype switching. **B,** In the absence of T_H cells resulting from tolerance, antibody responses remain abortive. **C,** It is possible to circumvent T_H-cell tolerance by coupling the self-antigen to a foreign protein or peptide carrier. B cells specific for the self-antigen are able to take up the antigen plus the linked carrier and present carrier-derived peptides on their MHC class II molecules. As there is no T_H-cell tolerance to the carrier protein, a regular antibody response against the self-molecule will now be mounted. *(From Bachmann MF, Dyer MR: Therapeutic vaccination for chronic diseases: a new class of drugs in sight.* Nat Rev Drug Discov. *2004;3:81–88.)*

immunization may be required to maintain antibody titers at therapeutic levels.[44] The waning of the antibody response in the absence of continued boosting may be advantageous from a safety perspective, particularly if the vaccine targets self-antigens. In this case, lifelong immune responses may not be desired or required, and therapy could be stopped after improvement in health or if antibody-mediated adverse events occur.

For B-cell vaccines different adverse events may be seen and must be carefully assessed; toxic effects may arise and need to be addressed in detail in preclinical models and early phase clinical trials in a target-specific manner.[44] Such adverse effects include generation of immune complexes with soluble target molecules or binding to self-antigens expressed on tissue with the subsequent induction of local inflammation by activation of antibody-dependent effector cells. Consequently, not all antigens make appropriate targets for vaccine approaches. In general, rare proteins may cause fewer problems than abundant proteins, as only low amounts of immune complexes have the potential to be formed because of a decreased chance of interactions occurring. Soluble proteins are generally preferred over membrane-bound targets because of the absence of antibody-dependent cellular cytotoxicity, which may only be observed with membrane proteins.[21] Moreover, many membrane proteins are receptors, and antibodies can be either antagonistic (prevention of binding to the ligand) or agonistic (activating the receptor through crosslinking) to receptor engagement. This is problematic, as it is virtually impossible to exclude undesired agonistic antibody using a vaccination approach.[44–47] Finally, safety issues associated with the neutralization of the target molecule also have to be considered. These issues are best addressed in studies using target-specific monoclonal antibodies (mAbs), decoy receptors, or receptor antagonists.[44–46] Valuable information can also be obtained from evaluating the clinical manifestations in rare human deficiencies of the target molecule, or in animal models rendered genetically or physiologically deficient for the target molecules.[41,48–52]

TARGETS FOR THERAPEUTIC B-CELL VACCINATION

In accordance with the better safety profile of immunodrugs against secreted antigens,[29] many therapeutic vaccination approaches in humans have targeted such molecules. Meanwhile 18 self-antigens have been targeted in humans by 31 different vaccines in various indications (summarized in Table 41.1). Many of these molecules are also targets for small molecule pharmaceuticals or biopharmaceuticals and as such have been validated as appropriate therapeutic targets.

VACCINE APPROACHES FOR DEMENTIA

There is a critical need to address the rising tide of dementia in the population. The vast majority of dementia cases correlate with increasing age. This fact is of particular importance in developed countries where decreasing birth rates and increasing life expectancy are raising the average age of the population (e.g., in 2007 for the first time in the United Kingdom those older than 65 years of age outnumbered those younger than 16 years of age).[53] As a global trend, the associated healthcare costs associated with dementia represent enormous social and economic strains for both families and governments. Currently, only symptomatic treatments are available, but therapeutic strategies to prevent, mitigate, or delay the onset of dementia are being vigorously pursued.[54]

Although cognitive impairment ranges from mild to severe, neurodegenerative diseases are the most severe and are thought to arise from misfolded/aggregated proteins spreading throughout the brain.[55]

Alzheimer Disease Is a Leading Cause of Dementia

Alzheimer disease (AD) is a major contributor to dementia, with the risk of acquiring AD increasing exponentially with age. At 60 years of age approximately 5% of people are affected, while at 85 years more than 50% suffer dementias. AD and dementias currently affect 47 million people worldwide and more than 5 million Americans, numbers that are expected to increase threefold by 2050, according to the Alzheimer's Association.[56] Current estimates of the costs of therapy, particularly nursing care, are staggering, with approximately $200 billion spent in United States alone.[56,57] One of the most promising therapeutic concepts is active or passive immunization against amyloid plaques.[48]

The major pathological hallmarks of AD are plaques formed by aggregated amyloid-β ($A\beta_{1-40}$ and $A\beta_{1-42}$), cleavage products of the amyloid precursor protein (APP), and other proteins (e.g., tau) that form neurofibrillary tangles. Biochemical and genetic studies of APP and presenilin 1 mutations, all of which enhance amyloid deposition and are associated with early-onset familial AD,[49] strongly support the central role of amyloid plaque forming Aβ in the development of the disease.

In 1999, Schenk and colleagues[50] reported that active Aβ immunotherapy reduces Aβ pathology in APP transgenic mice. In these studies, immunization with aggregated Aβ peptides combined with strong adjuvants resulted in reduced plaque burden[50] and improved mental performance.[58] This finding was confirmed in several transgenic models of AD with active and passive immunization.[59] In light of these results Elan/Wyeth initiated a number of clinical studies with a vaccine consisting of $A\beta_{1-42}$ (AN1792) administered with adjuvant QS21. In Phase I trials Aβ-specific antibodies could be found in more than half of the treated AD patients without notable adverse events.[60]

Subsequently, AN1792/QS21 vaccine was tested in a Phase II trial with 372 AD patients to evaluate the efficacy of the treatment. However, this trial was discontinued prematurely[61] after 6% of the vaccine recipients developed aseptic meningoencephalitis in the clinical study.[62] Subsequent analysis revealed that the side effects did not correlate with antibody titers.[63–65] Moreover, infiltrating T cells were found in postmortem samples from the brain of one diseased patient,[66] which strongly suggested that Aβ-specific T cells were the cause for the side effects observed.[66,67] Considering that this vaccine did not contain a foreign Th cell epitope, induction of an immunoglobulin (Ig) G response had to rely on breaking tolerance of self to induce $A\beta_{1-42}$-specific $CD4^+$ Th cells (see Fig. 41.1), which presumably triggered meningoencephalitis in some of the patients. This was most likely achieved by the combination of fibrillary $A\beta_{1-42}$ aggregates with the strong adjuvant QS21. Intriguingly, individuals who had the highest antibody response in the Phase II trial showed a significantly slower decline in some tests of cognitive function when compared with controls, and despite the severe safety issues observed with AN1792, this vaccine provided some evidence that active vaccination with Aβ may provide some benefit for the treatment of AD.[61–68] Importantly, these studies highlighted the necessity to avoid antigen-specific T-cell responses, and subsequent approaches were designed to avoid inducing T-cell immunity directed against Aβ.

The second-generation vaccines are characterized by short N-terminal Aβ peptides linked to foreign carrier proteins that compensate T-help functions for the efficient induction of IgG

TABLE 41.1 Clinically Tested B-Cell Vaccines Targeting Self Antigens

Target	Indication	Vaccine	Antigen	Organization
$A\beta_{1-40/42}$	Alzheimer disease	AN1792	$A\beta_{1-42}$	Wyeth/Elan
		ACC-001	$A\beta_{1-7}$-CRM197	Wyeth/Pfizer; Elan/Janssen
		CAD106	$A\beta_{1-6}$ -Qb	Novartis/Cytos Biotechnology
		V950	$A\beta_{Nterm}$ -OMPC(?)	Merck Co
		AD01, AD02	Affitope $A\beta_{1-6}$-KLH	AFFiRis/GlaxoSmithKline
		UB311	$A\beta_{1-14}$ fused to UBITh	United Biomedical
		AC-24	$A\beta_{1-14}$/liposome	AC Immune
Tau	Alzheimer disease and MSA	ACI-35	Phospho-tau	AC Immune/Janssen
	AD	AADvac1	Tau-peptide-KLH	Axon Neuroscience
Alpha synuclein	Parkinson disease and MSA	PD01A	α-syn peptide	AFFiRiS
		PD03A	α-syn peptide	AFFiRiS
Angiotensin I/II	Hypertension	AngQb	AngII-Qb	Cytos Biotechnology
		PMD3117	AngI-KLH	Protherics
Renin			Hog renin	Academic Groups
CETP	Hyperlipidemia	CETi	$CETP^{aa461-/476}$ fused to $TT^{aa830-843}$	Avant
hCG	Contraception	HSD-hCG	bHCG-TT	Indian government
FSH		oFSH	Ovin FSH	Indian government
GnRH		LH-RH-DT	GnRH -DT	Academic group
	Prostate cancer	D17DT	GnRH -DT	Aphton
EGF	NSC lung cancer	SAI-EGF	hEGF-TT (inactive)	Micomet/Cancer Vax
HER2	Breast cancer	Her2AutoVac	Truncated HER2 fused to TT epitopes	Pharmexa
Gastrin	Pancreatic Cancer	G17DT/Insegnia	Gastrin 17^{aa1-9}-DT	Aphton
Mucin	Cancer	Theratope/STn-KLH	Sialosyl-Tn -KLH	Oncothyreon/Merck KGaD
Ghrelin	Obesity	GhrQb	$Ghrelin^{aa1-8}$-Qb	Cytos Biotechnology
IgE	Allergic asthma	RP 01	CH2-CH3-CH4 of IgE	Resistentia
IL-1β	Type II diabetes	IL-1βQb	IL-1b mutein-Qb	Cytos Biotechnology
IFN-α	HIV, AIDS	i-IFN-α	IFN-α (inactive)	University of Milan
	systemic lupus erythematosus	IFN-K	rIFN-α-KLH (inactive)	Neovacs
TNF-α	Rheumatoid arthritis	TNF-α-kinoid	rTNF-α-KLH (inactive)	Neovacs
	Crohn disease	TNF-α-kinoid	rTNF-α-KLH (inactive)	Neovacs
	Cachexia	TNFAutoVac	TNF-α with internal TT T-cell epitopes	Pharmexa
	Psoriasis	TNFQb	TNF pep.-Qb	Cytos

Aβ, amyloid beta; CETP, cholesterol ester transfer protein; CRM, cross-reactive mutant; EGF, epidermal growth factor; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HER, human epidermal growth receptor; hCG, human chorionic gonadotropin; IFN, interferon; Ig, immunoglobulin; IL, interleukin; KLH, keyhole limpet hemocyanin; MSA, multiple system atrophy; NSC, nonsmall-cell; OMPC, outer membrane protein C; rIFN, recombinant IFN; rTNF, recombinant TNF; TNF, tumor necrosis factor; TT, tetanus toxoid.

responses without triggering cytotoxic effects categorized by antigen-specific T-cell responses. The follow-up program for AN1792 uses a vaccine consisting of the N-terminal seven amino acids of Aβ covalently linked to the diphtheria toxin cross-reactive mutant (CRM197) protein carrier, which is called ACC-001. Although this peptide is smaller than the minimum length of a T-cell epitope, strong $A\beta_{1-42}$-specific antibody responses were induced in transgenic mice that prevented plaque deposition and improved cognitive function. Several clinical trials involving ACC-001 have since concluded, albeit with limited release of results. In one study repeat administration of ACC-001 at three doses (3 μg, 10 μg, and 30 μg) with or without adjuvant (QS21) was generally safe and well tolerated.[69] In addition, it was noted that inclusion of the QS21 adjuvant was needed to generate high-titer responses. Sustained high-titer anti-Aβ IgG responses were observed, irrespective of the three ACC-001 doses tested.[69] Nevertheless, the company has discontinued the program,[70] presumably because of disappointing efficacy results.[69,71]

Novartis, using VLP technology licensed from Cytos Biotechnology, has one vaccine candidate in development for AD that also targets Aβ. This vaccine, CAD106, consists of $A\beta_{1-6}$ peptide covalently coupled to bacteriophage Qβ VLPs (Qb).[71] Several preclinical studies revealed that the vaccine induced high antibody titers and no Aβ-specific T cells when administered without adjuvant to mice, rabbits, and monkeys. Immunization with CAD106 prevented amyloid cortical plaque deposition in both APP23 and APP24 transgenic mouse models. Moreover, immunization resulted in a reduction of amyloid deposits in aged mice with advanced brain pathology.[72] Available reports from the first studies in humans with this compound suggest that the vaccine is well tolerated and induces Aβ-specific immune responses in the majority of the patients without inducing meningoencephalitis.[73–75] Novartis is planning a new study for treatment (CAD106 and a Beta site Amyloid precursor protein Cleaving Enzyme [BACE] inhibitor) on asymptomatic patients with the hope of delaying the onset of the dementia. Inhibition of BACE1 should

decrease production of $A\beta_{1-42}$, the main component of the plaques that contribute to AD pathology.[76]

Merck & Co. is also testing a vaccine consisting of an N-terminal Aβ peptide conjugated to outer membrane protein C (V950). Increasing doses of V950 formulated in aluminium adjuvant with or without ISCOMATRIX adjuvant are being tested in a multistage Phase I trial. Two other vaccines, AC-24 (AC Immune) and UB-311 (United Biomedical), have achieved preclinical proof-of-concept[77,78] and are in early clinical testing. AC-24 contains $A\beta_{1-15}$ embedded within a liposomal surface and UB-311 consists of $A\beta_{1-14}$ covalently linked to a proprietary helper T-cell technology (UBITh) and is administered together with a mineral salt adjuvant.

The AFFiRiS AD program, acquired by GlaxoSmithKline, is exploring short peptides mimicking the N-terminus of Aβ as immunogens to avoid the induction of autoreactive T cells. Two of these AFFITOPEs (AD01, AD02) demonstrated promising preclinical results[79] and subsequent Phase I trials in humans have shown the vaccine to be safe and well tolerated, but reports of antibody responses have not been published.[80,81] AD02 has proceeded to Phase II clinical testing with the goal of identifying an optimal dosage. The added value of these AFFITOPEs (they are not under patent protection by other groups so there is freedom to operate with yet another Aβ-specific vaccine) needs to be explored further for the aforementioned vaccines (AD01 and AD02) in particular, as it seems that these programs have been stopped.

Passive immunotherapies with mAbs against Aβ are in late Phase III clinical trials, and recently humanized mAb-based immunodrugs, bapineuzumab[82] and solanezumab,[83] which target the Aβ N-terminal and mid-domain, respectively, failed to meet their primary end points in enhancing cognition and improving activities of daily living.[82–84] Johnson & Johnson decided to halt their clinical development of bapineuzumab in August 2012[85] because negative trial results were likely as patients had mild-to-moderate AD and the amyloid pathology was too advanced. However, secondary analysis of solanezumab Phase III data indicated potential clinical benefits in the patient group with mild AD. An additional Phase III study is currently underway to confirm these findings (ClinicalTrials.gov NCT01900665, estimated primary completion October 2016, study completion October 2018).[86]

Using their aducanumab (BIIB037) mAb, Biogen recently observed in a Phase Ib study a statistically significant cognitive benefit in a prospectively defined (early AD) patient population. Furthermore, positron emission tomography (PET) scans indicated the highest amyloid reduction seen to date and the researchers also observed time- and dose-dependent benefits.[87,88]

In essence, what has been learned so far from a large number of clinical trials (see Table 41.2) is that (a) both the quality and quantity of antibody are critical and (b) the patients should not have advanced disease, where it may be unlikely that the damage caused by plaque formation can be reversed. It appears that plaque prevention would be easier to accomplish than to remove existing plaques and be left with the problem of "a hole in the brain," without regenerative solutions. Because suspected side effects would likely result from the interaction of antibodies with plaques, early immunization would appear to be optimal.[89]

A key advance for clinical development of AD vaccines is the ability to image the brain using PET with specific ligands such as (11)C-labeled Pittsburgh Compound-B ([11]C-PIB) to specifically visualize Alzheimer plaques.[90,91] (11)C-PIB is a radiotracer substance that recognizes Aβ plaques and therefore can be used to capture images from the living patients (as opposed to the gold standard, postmortem diagnosis). This imaging technique provides the opportunity to identify patients at early stages of disease, where pathogenesis may still be reversible. Using this technique, patients with familial AD have been demonstrated to have plaque deposition long before the onset of any symptoms.[90–92] In patients treated with mAbs, PET imaging has shown a reduction in plaque load in situ and may have a role as a surrogate marker for efficacy.[87–91] Further clinical validation of the effectiveness and safety of the imaging techniques, together with the identification of additional biomarkers or genetic markers for the disease, would help in assessing the impact of the prophylactic vaccines for the middle-aged or elderly in combating this devastating disease.

Given the mixed results of the mAb and vaccine trials, alternative targets are also being pursued. Additional targets have emerged, including the microtubule-associated protein tau. Misfolded and hyperphosphorylated tau protein aggregates extend to create the neurofibrillary tangles that are, in addition to the plaques, hallmarks of AD. Moreover, tau aggregates with Aβ and other proteins into insoluble inclusions of plaques and lesions. Small mobile forms of tau preceding aggregates are hypothesized to spread tau-related pathology among neurons. Reductions in insoluble tau and improved behavioral performance have been reported in transgenic mice[94,95] immunized with phospho tau peptides.[94–98] More recently, structural determinants of pathogenic tau–tau interactions were identified and provided data on the epitopes that would impair aggregation. A KLH-conjugated tau peptide vaccine administered in an AD experimental mouse model drastically reduced the incidence of pathological hyperphosphorylated tau.[99–101] The Axon Neuroscience SE group recently completed a clinical trial of the KLH-conjugated tau peptide vaccine (NCT1850238) with reported favorable safety results.[100,101] A Phase II study of the tau immunotherapy (AADvac1) is planned.

In addition, AC Immune and Janssen have signed an agreement to take ACI-35, designed to produce antibodies against the pathogenic, misfolded, and phosphorylated versions of tau protein, into Phase II clinical studies. In earlier preclinical testing this vaccine stimulated antibody responses that were highly specific to pathogenic tau and resulted in a reduction of both misfolded and phosphorylated tau and improvement in cognitive clinical parameters in the mouse model. ACI-35 has a T-cell–independent mechanism of action and an excellent safety profile.[102,103]

These approaches are hoped to emulate the successes and avoid the failures of current and previous anti-Aβ strategies, respectively, in addressing neurodegenerative diseases. Moreover, while active immunization with Aβ resulted in the clearance of Aβ, it did not prevent tau pathology or neurodegeneration, prompting the concern that it might be too late to employ Aβ targeting therapies once tau-mediated neurodegeneration has occurred. Tau-directed therapies might circumvent these limitations. Despite intense clinical development, key questions remain about the utility of immunotherapy in slowing or reversing disease progression with an acceptable risk-to-benefit ratio.

Parkinson Disease

Parkinson disease (PD) is a neurodegenerative condition, second in frequency only to AD, manifesting as characteristic movement disorder, associated cognitive impairment, and progressive disability. There are an estimated 7 to 10 million patients with PD worldwide, affecting approximately 1% of individuals older than 60 years.[104–106] Current treatments for PD using levodopa, a dopamine precursor, and other dopamine agonists are effective at managing the early motor symptoms of the disease. However, as the disease progresses,

TABLE 41.2 Clinical Trials With B-Cell Vaccines Against Alzheimer Disease[a]

Vaccine Name	Phase	Treatment Group	Regimen (Month/Route)	Readouts Beyond Immunogenicity, Safety, & Tolerability (Mostly Secondary End Points)	N	Trial No. (NCT)/ Completion Date
AN1792	I	QS21 (50, 100 μg) AN-1792 (50, 225 μg) + QS21 (50, 100 μg)	0, 1, 3, 6, & 16/IM		80	Not registered

[a]All studies are performed in mild to moderate AD patients (if not otherwise stated) and look at immunogenicity, safety, and tolerability plus different mostly exploratory readouts.
[b]Extension studies.
Aβ, amyloid-β; Ad1, adjuvant 1; Ad2, adjuvant 2; AD, Alzheimer disease; ADAS-Cog, Alzheimer Disease Assessment Scale, cognitive subscale; ADCS-ADL, Alzheimer Disease Assessment Scale–activities of daily living; DAD, diagnostic assessment of dementia; IM, intramuscular; ld, low dose; md, medium dose; MMSE, Mini Mental State Examination; MRI, magnetic resonance imaging; n.d., not disclosed; NPI, Neuropsychiatric Inventory agitation subscale; NTB, neuropsychological test battery; PET, positron emission tomography; SC, subcutaneous.

dopaminergic neurons are lost and the drugs become less effective. There are no available alternative treatments at this time. The two major neuropathologic findings in patients with PD are the loss of dopaminergic neurons of the mid brain, particularly the substantia nigra pars compacta, and the presence of Lewy bodies and Lewy neurites, consisting of aggregated alpha-synuclein (α-syn). The abnormal accumulations of fibrillar α-syn in Lewy bodies, and mutations in the gene for α-syn in familial forms of PD, have led to the hypothesis that α-syn has a central role in PD. The accumulation of α-syn correlates with the loss of dopaminergic neurons and the subsequent decline in motor performance, making it a highly relevant molecular target for diagnostic approaches.[107,108]

Similar to AD, researchers have identified mobile pathogenic clusters of protein, consisting of small oligomeric forms of native or misfolded α-syn protein.[108] In vitro studies demonstrated that these mobile pathogenic clusters of protein structures spread in an aggregated phenotype with associated neurotoxicity.[109,110] The potential for the intracerebral interception of aberrant (oligomeric) forms of α-syn might provide a treatment. Blocking the uptake of these molecules protects against α-synucleinopathies in vitro and in animal models.[111,112]

Active immunization against α-syn ameliorated the degenerative pathology of PD[112] in a murine model, paving the way for a Phase I trial of a Parkinson vaccine (PD01A). Initial reports indicate that the vaccine is safe [NCT01568099] and observational Ib and follow up (including booster) studies are underway. In addition, another Phase I study of vaccine (PD03A) plus adjuvant is ongoing [NCT02267434].

The potential also exists for synergistic involvement of tau in PD. Reports have indicated that tau can initiate α-syn aggregation and associated neurotoxicity, much as that seen with Aβ in AD. The potential for heterologous proteins to influence α-syn aggregation has been reported in vitro and cross-therapeutic benefit of drugs for AD, tauopathies, and other aggregation prone neurodegenerative conditions such as Huntington disease (which involves aggregation of the huntingtin protein) may exist for PD and other α-synucleinopathies (and vice versa).[113,114]

Vaccines Against Addiction

Expanding industrial activity in the developing world is boosting economic prosperity. In the modern era the global trend has seen populations becoming less rural and increasingly urbanized. The increasingly sedentary lifestyle, enhanced access to processed (high sugar, high fat) foods, and increased alcohol and tobacco consumption have contributed to obesity and other related health complications, including hypertension, stroke, and type 2 diabetes.

Because behavioral modifications can be very difficult to implement, vaccine approaches to smoking cessation, curbing obesity, and population control are very attractive (see Table 41.1). One example is the potential use of immunotherapy in diabetes management (discussed later in the chapter).[115,116] B-cell vaccines against noninfectious disease targets can be divided into approaches for autoimmune conditions[40–42] and allergies (see later) and for drugs of abuse.[26,43] Vaccines against drugs of abuse aim to induce antibodies that bind the drugs in the blood and prevent positive reinforcement in the brain. In particular, vaccination for smoking cessation has been extensively pursued, mainly with two vaccines: Nabi's Nicotine-exoprotein A conjugate (NicVax) partnered with GlaxoSmithKline and Cytos Biotechnology's Nicotine-Qb conjugate (NicQb or Nic002) partnered with Novartis. In a Phase II study (NCT00369616 by Cytos) with NicQb, the vaccinated subjects in the tertile with the highest antibody levels had a significant increase in continuous abstinence from smoking from months 2 to 6, when compared to the placebo recipients.[43] However, in a subsequent study (NCT00736047) performed by Novartis, the primary end point of decreased smoking, defined as a difference in continuous abstinence at weeks 8 to 12 compared to placebo, was not achieved and the program was discontinued.[117] Likewise, a second vaccine by Nabi Biopharmaceuticals, NicVax, reported a significant increase in continuous abstinence from smoking between week 19 and 26 in the highest antibody responders (top 30% individuals with the highest antibody titers) compared to placebo.[118] This vaccine was tested in two additional Phase III trials (NCT01178346 and NCT01102114) and reproduction of the reduction in smoking results were negative, and therefore Nabi stopped the further development of the vaccine, highlighting again the difficulties in tackling smoking cessation. Although the early efficacy trials appeared promising, the challenge was to induce high antibody titers of high affinity over an extended period. Despite these challenges, Pfizer has recently initiated a new program for a smoking cessation vaccine with a focus on induction of high-affinity antibodies.

Type 1 Diabetes and Tolerogenic Vaccines

Formerly known as insulin-dependent diabetes mellitus, type 1 diabetes (T1D) is a chronic autoimmune disease, caused by the loss of the insulin-producing β cells in the islets of Langerhans. Autoimmunity is the predominant mechanism of T1D, but also involves both genetic susceptibility and environmental triggers. Genetic data implicate the insulin gene and certain signaling genes (PTPN22) and several immune-related genes (e.g., human leukocyte antigen [HLA], IL-2Ra, and cytotoxic T-lymphocyte antigen [CTLA]-4) that correlate with susceptibility to T1D. Environmental triggering factors, such as microorganisms, particularly enteroviruses, have been implicated through epidemiological and other studies.[119–123] Conversely, other microorganisms such as bacille Calmette-Guérin (BCG) vaccine appear to offer protection. Timely detection and intervention are widely believed to maximize the chances for successful intervention and disease prevention. Serum autoantibodies are useful biomarkers, as well as metabolic intermediaries and regulatory T-cell populations.[124]

The following examples highlight current prophylactic trials focusing on environmental triggers. In 2015, the U.S. Food and Drug Administration approved an investigational new drug (IND) application for the conduct of a BCG vaccine trial for the treatment of T1D. The rationale for the trial was to induce elevated levels of TNF to destroy autoreactive T cells that target and destroy insulin-secreting islet cells in the pancreas. With the completion of a proof-of-concept Phase I study that confirmed vaccine safety,[125] a Phase II study is currently underway.[126]

Additional vaccine based-approaches have used synthetic controlled-release biomaterials. In a two-component system comprising of microparticles of poly(lactide-co-glycolide) (PLGA) that are used to encapsulate denatured insulin, and in the second part, peptide hydrogel (PuraMatrix) containing the inflammatory cytokine, granulocyte-macrophage colony-stimulating factor and a Toll-like receptor 9 agonist, cytosine phosphate guanine ODN1826 (CpG), acting as vaccine adjuvants.[127] In vivo tests show that this combination dual-component vaccine provides only modest protection (40% of NOD [nonobese diabetic] mice) compared to control mice that all became diabetic.[127] Based on in vitro analyses, CpG appeared to stimulate an increase in IL-10 production, suggesting the antiinflammatory action as a potential mechanism. Histological analysis of granulomas that formed in mice 1

week following the final of three injections administered subcutaneously, indicated the presence of a broad spectrum of immune cells. This localized infiltration creates opportunity for prerequisite cell–cell interactions necessary for education of immune cells.[127]

Another T1D vaccine being developed and undergoing clinical trials is the MonoPepT1De trial using a proinsulin peptide (PI C19-A3), which is being evaluated in newly diagnosed type 1 diabetic patients. Early 2015 saw completion of a Phase Ib multicenter study of this vaccine (Phase Ib Study of Proinsulin [PI] Peptide Immunotherapy in New-Onset Type 1 Diabetes—NCT01536431). The primary end point was safety of PI C19-A3 in the context of new-onset T1D, with secondary end points assessing "stimulated C-peptide production, HbA_{1c} [glycosylated hemoglobin] levels, mean glucose excursions, quality of life scores and islet cell autoantibody biomarkers of β-cell–specific immune responses."[128]

As can be seen by the above examples, the scientific rationale is rather ill-defined, so there are a number of challenges to licensure of these products.

Type 2 Diabetes and B-Cell Vaccines

Conversely in the case of type 2 diabetes mellitus (T2D) the islet cells are still functioning, but the body becomes resistant to the action of insulin, or the pancreas does not produce adequate supplies, or both. A notable characteristic of T2D is amyloid deposits of peptides derived from islet amyloid polypeptide (also known as amylin) originating from the β cells. Amylin, usually cosecreted with insulin, regulates glucagon secretion and gastric emptying (appetite), and exhibits physicochemical properties that permit it to aggregate and form amyloid fibers. Therefore, a potential strategy to eliminate the amyloid deposits (aggregated amylin)[129] through vaccination, similar to strategies being employed in tackling aggregates in AD[130] might be associated with improved production of insulin. In addition, antiinflammatory strategies have been applied in T2D.[131] Preclinical experiments using an active immunotherapy targeting IL-1β based on the full-length cytokine chemically coupled to bacteriophage Qbeta VLPs had previously demonstrated in vivo neutralization of IL-1β. Immunized animals tolerated the vaccine and exhibited attenuated disease in experimental models of rheumatoid arthritis, multiple sclerosis, and type 2 diabetes.[41,131] Cytos has since completed the Phase I/IIa trial of CYT013-IL1bQb (NCT00924105). The safety and tolerability of the vaccine was subsequently improved by introducing a single point mutation, which markedly reduces biological activity of the cytokine antigen. Cohorts of type 2 diabetes patients have been immunized in a Phase I/II study with a broad range of vaccine doses (10–900 μg) and frequencies (2–8 administrations). The vaccine was shown to be well-tolerated and IL-1β–specific antibody responses could be observed in most patients after as few as one to two injections of the vaccine. In marked contrast, IL-1β–neutralizing responses (indicating higher-affinity antibodies) could only be observed after five or six injections (MF Bachmann, unpublished). However, these neutralizing antibody responses, once induced, were long-lived and slowly declined over several months (up to 40 weeks of observation). Further studies (yet to be concluded) would be required to investigate whether it is possible to accelerate the development of neutralizing antibodies with the inclusion of adjuvants or by using higher vaccine doses.[15]

Hypertension

Persistent hypertension represents the greatest risk factor for the development of coronary heart disease and stroke with potentially lethal outcomes. As a key regulator of blood pressure angiotensin II (AngII) is a therapeutic target of many effective antihypertensive medications, including angiotensin-converting enzyme inhibitors and drugs that block the angiotensin Type I receptor. Despite the availability of these effective medicines, compliance is low with only 30% to 50% of hypertensive patients in the United States taking their medications.[132,133] The asymptomatic nature of this condition makes it difficult for patients to adhere to the therapy.[134] Active immunization represents an attractive alternative with the aim of inducing a durable antibody response to AngII. A vaccine containing the target protein (angiotensin I [AngI]) coupled to a carrier molecule, KLH was evaluated in rats and reduced blood pressure. Subsequent clinical studies (performed by Protherics), however, did not attain desired end point efficacy of reducing blood pressure,[135] likely because of suboptimal humoral responses in humans. A second vaccine study in spontaneously hypertensive rats employed the VLP Qb chemically coupled to AngII as a VLP. High levels of AngII-specific IgG antibodies and improved blood pressure were seen. A subsequent Phase I study confirmed safety[25] and demonstrated that antibody levels peaked 2 weeks after injection and declined to background levels within a few months. Efficacy of this vaccine was then tested in a multicenter, double-blind, placebo-controlled Phase II study in 72 mild to moderately hypertensive patients.[27] Two doses, low and high (100 and 300 μg), of the vaccine formulated in adjuvant (aluminium hydroxide) were used for subcutaneous injection on days 0 and 4 and at 12 weeks. Ambulatory blood pressure measurements over 24 hours were followed prevaccination and after a postvaccination treatment course consisting of the three injections. The higher dose (300 μg) significantly reduced blood pressure compared to baseline and placebo; the reduction was comparable to the response to the small molecular inhibitors of AngII. Daytime systolic and diastolic blood pressures were reduced by 9 and 4 mm Hg, respectively, when compared to placebo recipients. Early morning blood pressures were also reduced.

In an attempt to further improve the efficacy of AngQb, higher doses (up to 900 μg) at increased frequency (biweekly injection) were evaluated in additional Phase II clinical studies (NCT00701649 and NCT00710372). This new regimen induced higher antibody titers but the impact on blood pressure was less than in the previous study. The reduced efficacy correlated with reduced affinity of the antibodies,[27] demonstrating that both antibody affinity and quantity are important.

In summary, active immunization against AngII reduces blood pressure in some hypertensive patients. However, optimization is required to achieve the right balance of antibody affinity and quantity (Cytos Biotechnology Ag, unpublished data).

Anticytokine Vaccines

With increasing success of mAb therapies against different cytokines such as TNF-α, IL-12, and IL-17, several therapeutic vaccination strategies have been applied to this class of molecules. Therapies targeting TNF using mAbs have demonstrated efficacy across a wide range of inflammatory diseases, including rheumatoid arthritis, juvenile idiopathic arthritis, ankylosing spondylitis, psoriasis, Crohn disease, and ulcerative colitis.[8–11,136,137] However, patients treated with anti-TNF mAb frequently develop treatment resistance (secondary failures) with chronic long-term use. In addition, they have cumbersome dosing regimens with frequent injections and are costly.

Tumor Necrosis Factor

Several vaccine trials targeting TNF have been performed but there are few reports in the public domain. In 2014, Neovacs reported their results of a randomized, double-blind, placebo-controlled, multicenter, 140-patient, Phase IIb clinical trial of TNF-Kinoid in rheumatoid arthritis (NCT01040715). The coprimary end points were based on rheumatoid arthritis symptoms scores (the DAS28-CRP and ACR 20 scores). The study confirmed the safety and tolerability of the product and all vaccinated subjects, except one, demonstrated significantly increased levels of anti-TNF binding antibodies. However, the patients did not produce neutralizing antibodies and had no improvement in the clinical symptoms scores. Further data analysis is ongoing.[138]

Cytos reported on the immune response and clinical benefit of a first-generation TNF peptide Qb vaccine for psoriasis.[139] The peptide-based vaccine induced strong antibodies against the peptide, but functional activity against soluble TNF was low.[140] Vaccines based on the entire protein are now being considered for further development. Finally, Pharmexa studied a TNF protein vaccine with an engineered tetanus toxoid–derived T-cell epitope in humans. Although the vaccine was immunogenic, the antibodies only recognized a partially denatured form of TNF and vaccine development was abandoned.[141]

Additional analyses of these studies and further larger placebo-controlled studies are needed to determine if vaccine-induced antibody regimens can compete with existing mAb therapies.

Interleukin-17

An additional problem with anti-TNF immunotherapy is its potential for increasing susceptibility to latent infections (such as tuberculosis and other opportunistic and neoplastic disease).

This has encouraged the search for alternative points of intervention. One attractive and very successful example has been targeting the inflammatory cytokine, IL-17A in patients with moderate to severe psoriasis. Psoriasis is a chronic inflammatory skin disease resulting in poorly differentiated, hyperproliferative keratinocytes. The scaly plaques and reddening (erythema) on the skin vary in severity from minor localized patches (lesions) to complete body coverage, and in some cases can also lead to joint inflammation (approximately 25% of psoriasis patients develop psoriatic arthritis). IL-17 is produced by Th17 cells, a subset of effector T-helper cells. Within the psoriatic lesion, activated antigen-presenting cells produce IL-23 and stimulate Th17 cells to release IL-17. Keratinocytes respond to IL-17 by upregulating proinflammatory chemokines that attract T cells, neutrophils, and mononuclear cells to the lesion. IL-17 can also induce IL-6 from fibroblasts, which stimulates differentiation of naïve Th cells to Th17 cells leading to further IL-17 production, thus creating a potential positive inflammatory feedback loop.[142]

Because it appears that IL-17 plays a key role in the inflammatory immune response in psoriasis, anti–IL-17 mAbs have been demonstrated to moderate the inflammatory response.[90] mAbs that target IL-17 are undergoing Phase III testing and are being compared with licensed anti–IL-12p40 (ustekinumab), and etanercept-targeting TNF.[136,143–145] Early in 2015, Novartis' AIN457, also known as secukinumab (Cosentyx), became the first approved anti–IL-17A monoclonal antibody on the market and is recommended as a "first-line" treatment for moderate to severe psoriasis.

The safety of neutralizing IL-17 is informed by the natural occurrence of individuals with genetic mutations in IL-17 function (lacking functional IL-17F, the IL-17 receptor antagonist IL-17RA or the downstream adaptor protein ACT1),[51] who are prone to skin-limited mild infections, but not systemic bacterial infections, tuberculosis or other mycobacterial infections, viral infections, unusual microbes, and do not have an increased risk of cancer.[51,52]

Preclinical experiments with IL-17–based vaccines in mice show strong neutralizing antibody titers and protection against the induction of rheumatoid arthritis and multiple sclerosis.[38]

These encouraging results have led to the Phase II studies currently underway. More cost-effective vaccine approaches (e.g., based on VLPs) to supplement or even replace IL-17 biologics in psoriasis and other diseases should be further pursued.

CONCLUSIONS

In the last decade a large effort was made to adapt the vaccine concept to chronic diseases that are a major health threat to modern societies. Our improved immunological understanding, together with the development of recombinant technologies, allow scientists to harness this successful therapeutic modality to target self molecules, which, if overproduced, play central roles in the etiology of disease. However, none of these approaches has become a marketed product, and further challenges remain to fully explore this therapeutic concept.

In this context it is important to remember that the quantity and the affinity of antibody needed to neutralize and inhibit self-antigens or drugs of abuse are orders of magnitude higher than those required for the protection against viral infection.[44] Hence major challenges remain to inducing antibodies in sufficient amounts and of appropriate affinity for therapeutic efficacy. Many of the specific requirements for the antibody responses will be target specific and will be influenced by the use of different adjuvants, vaccine carriers, and the vaccine regimens.

A further key consideration in pursuing active immunization strategies for neurodegenerative conditions is the natural limitation of the immune response in the elderly compared to younger adults. Finally, a general theme is bridging the relevance of preclinical data in existing animal models and expanding models to recapitulate mechanistic aspects of the human diseases being studied.

42 Norovirus Vaccines

Jacob F. Kocher, Kari Debbink, Lisa C. Lindesmith, Rachel L. Graham, Hugues Bogaerts, Robert R. Goodwin, and Ralph S. Baric

Human noroviruses (NoVs) have become the leading cause of acute nonbacterial gastroenteritis in countries where rotavirus vaccination has been successfully implemented.[1–5] Overall, NoVs have been identified in 18% of reported acute gastroenteritis cases worldwide.[6] In the United States, NoVs result in approximately 21 million cases of gastroenteritis, 400,000 emergency department visits, 71,000 hospitalizations, 800 deaths, and an annual loss of an estimated 5000 quality-adjusted life years.[7–9] NoV infections are more severe in developing countries, where NoVs have been detected in approximately 5% of pediatric diarrhea episodes and result in an estimated 200,000 pediatric fatalities annually.[10,11] NoVs have also been implicated as a substantial contributor to traveler's diarrhea in tourists and in group-travel environments.[12,13] NoVs often garner attention for outbreaks on cruise ships, but these account for only about 1% of all reported norovirus outbreaks in the United States.[14] In the European Union (EU), it is estimated that NoV infection may cause up to 5.7 million illnesses, 800,000 medical visits, 53,000 hospitalizations, and 102 deaths every year in children younger than age 5 years. This burden is comparable with the burden related to rotavirus before the introduction of rotavirus vaccination and will grow in relative importance as rotavirus vaccines are rolled out progressively in the EU.[15] Simulations suggest that a NoV vaccine could reduce up to 2.2 million NoV cases annually and save up to $2.1 billion in economic burden.[16]

Financially, NoV gastroenteritis results in $284 to $355 million in healthcare costs[9,17] and an estimated $2 to $5 billion in total economic burden[8,16] in the United States and $4 billion in the EU.[16] This estimated total economic burden is only surpassed by nontyphoidal *Salmonella enterica*, *Campylobacter*, *Listeria monocytogenes*, and *Toxoplasma gondii*.[8] Even though NoV cases are believed to be underreported,[18] the known and estimated human and economic burden of NoV infection and gastroenteritis are substantial. NoVs have been referred to as the "perfect human pathogens." They are highly infectious, rapidly and prolifically shed, difficult to avoid, and without etiological treatment; taken together these considerations make NoV-related disease a good target for prevention through vaccination.[19]

NOROVIRUSES

NoVs were first identified in 1972 (Norwalk agent) from fecal isolates from a 1968 gastroenteritis outbreak in Norwalk, Ohio.[20] NoVs are nonenveloped, positive-sense single-strand RNA viruses belonging to the Norovirus genus in the *Caliciviridae* family of viruses. NoVs are divided into six genogroups (GI to GVI) and further subdivided into genotypes (Fig. 42.1A). GI, GII, and GIV NoVs infect humans; of these, GI and GII are the most important for human infection. GII and GIV viruses also infect porcines and canines, respectively, indicating hypothetical zoonotic transmission routes that have not been rigorously evaluated,[21] although antibodies against canine NoVs have been detected in humans.[22]

NoVs have a 7.5- to 8.0-kb genome surrounded by an icosahedral capsid. The genome has a 5′ VPg cap and a 3′ poly(A) tail and contains three open reading frames (ORFs). ORF1 encodes a nonstructural polyprotein. ORF2 encodes the major capsid structural protein, VP1, which self-assembles into 90 dimers to form the icosahedral capsid.[23] ORF3 encodes a minor structural protein, VP2, which increases capsid stability and VP1 expression.[24–26] VP1 is composed of two domains, shell (S) and protruding (P), separated by a short hinge sequence.[27] The P domain is further subdivided into the highly conserved P1 and hypervariable P2 subdomains.[27,28] Variation in the P2 subdomain regulates strain ligand binding and antigenicity.[29–31]

NOROVIRUS TRANSMISSION AND DISEASE

NoVs are classically transmitted by the fecal-oral route,[32] but can also be transmitted via aerosolized vomitus,[33,34] contaminated food or water,[14,35] and fomites because of the ability of NoV to remain stable for weeks on surfaces[36] and up to 2 years in water samples.[37] Chemical disinfection is the only potential intervention in the transmission cycle, but classic hygiene measures, including alcohol-based hand washing, have proved largely ineffective.[38]

Because as few as 18 viral particles are capable of causing infection and each gram of feces may contain up to 5 billion infectious doses,[39] NoVs are highly contagious and easily transmitted in semiclosed communities, such as senior care homes, cruise ships, and military barracks,[7] and are common nosocomial infections in the United States and Europe.[15,40,41] Additionally, up to 30% of NoV infections result in asymptomatic shedding; the role of asymptomatic infection in transmission and outbreaks of norovirus remains unclear.[42,43]

NoV gastroenteritis is commonly referred to as the "stomach flu" and also earned the nickname "winter vomiting disease" based on its distinct winter seasonality pattern in the Northern hemisphere.[44] NoVs have an incubation period of approximately 24 hours[45] and most people with illness are typically symptomatic for 24 to 72 hours.[46] NoV-induced gastroenteritis commonly presents as nausea, (projectile) vomiting, and diarrhea, but can also include cramps, fever, headache, and dehydration.[32,47] NoV-induced gastroenteritis induces longer duration and more frequent vomiting compared with bacterial gastroenteritis.[48,49] Approximately 10% of persons with norovirus gastroenteritis seek medical attention, which might include hospitalization and treatment for dehydration with oral or intravenous fluid therapy. Norovirus infection can also become an important factor contributing to a poor outcome in patients with underlying cardiac and renal conditions.[50]

A systematic literature review of norovirus-associated illness, hospitalization and death among individuals 65 years of age and older indicated that disease severity increased with age, presence of comorbidities, and GII.4 genotype. The burden of norovirus is anticipated to rise as an increasing proportion of society becomes elderly, with an increased need for institutionalized care. Although a self-limiting infection in an immunocompetent patient, chronic NoV infection can develop in immunocompromised hosts,[51–56] which is associated with longer durations of diarrhea and shedding.[50] In rare

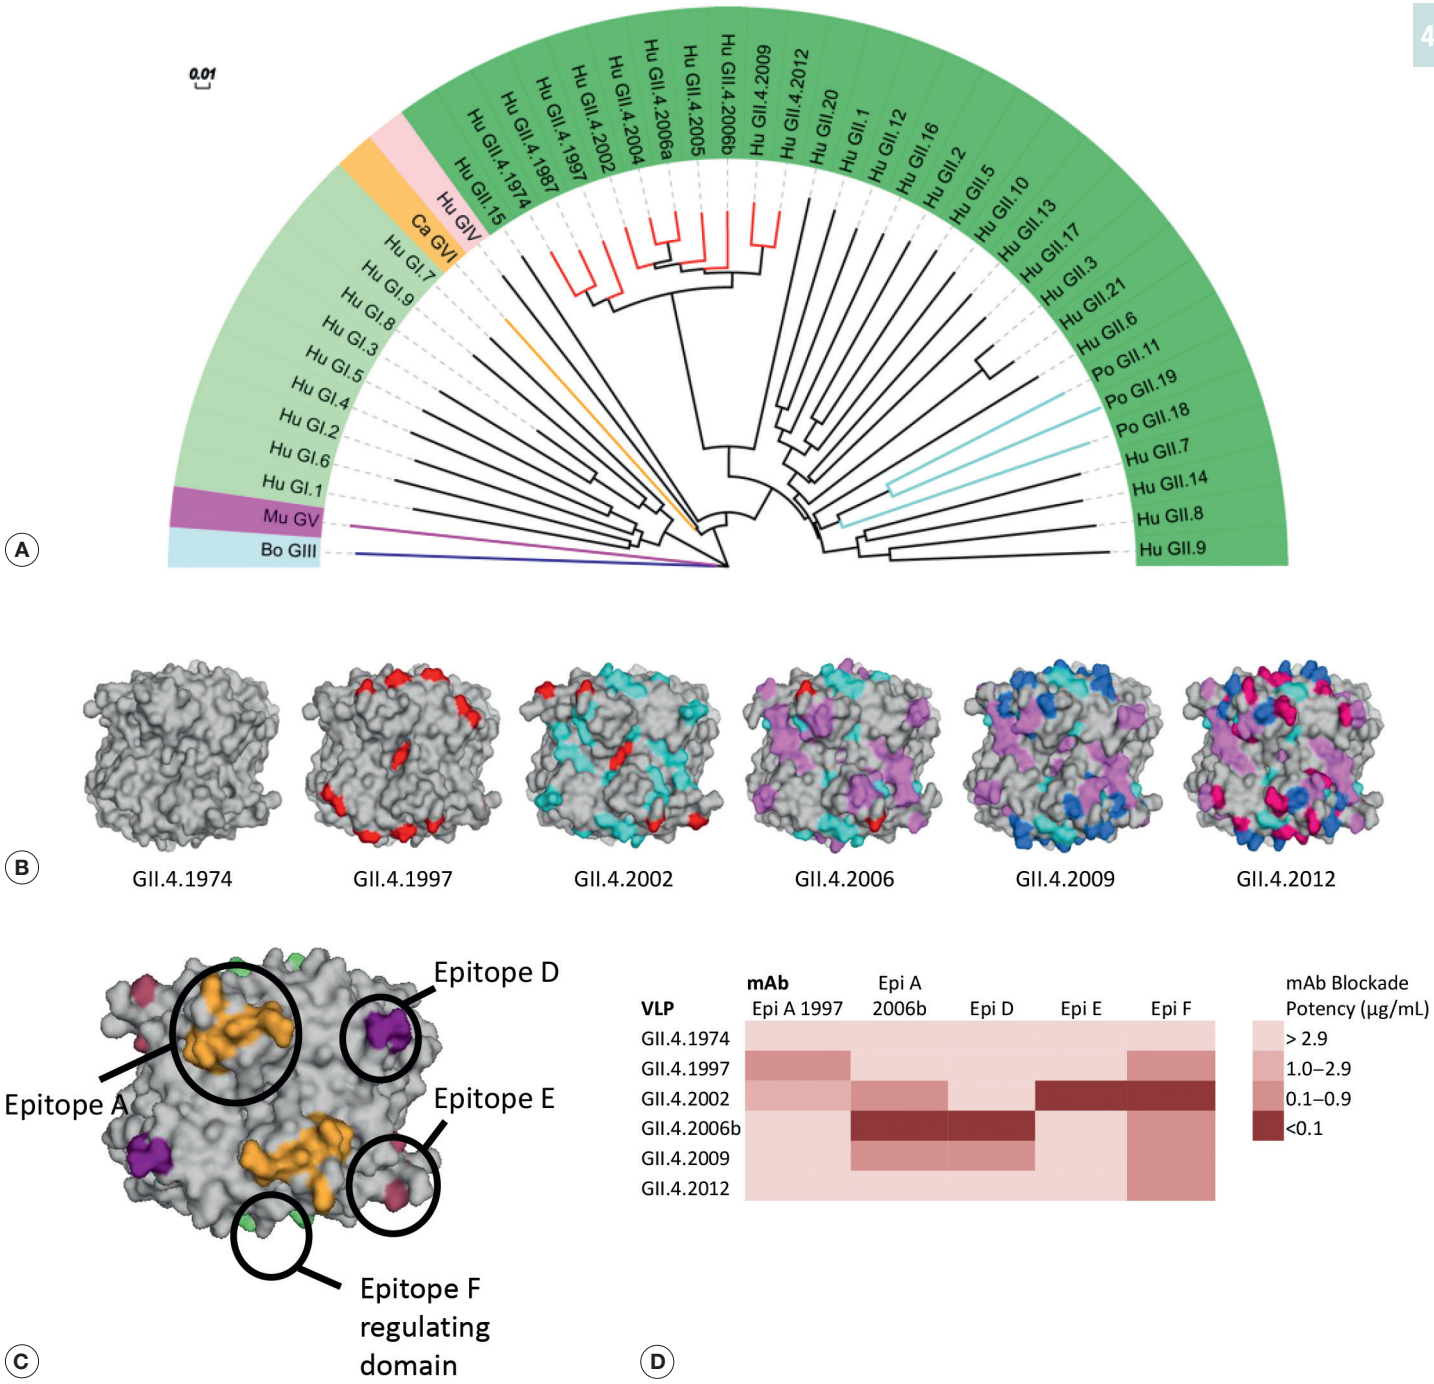

Figure 42.1. Characterization of globally significant GII.4 norovirus (NoV) strains. A, Major capsid gene phylogenetic tree of noroviruses. **B,** Structural models of the GII.4 capsid P dimer over time. Color changes represent amino acid changes compared to GII.4.1974: *red* (GII.4.1997), *teal* (GII.4.2002), *pink* (GII.4.2006), *blue* (GII.4.2009), and *dark pink* (GII.4.2012). **C,** Identified GII.4 blockade domains. Evolving GII.4 blockade epitopes (A, D, and E) and the antibody (Ab) access-regulating domain (NERK motif) of the conserved GII.4 blockade epitope (F) mapped onto the P dimer structure of GII.4.2012. **D,** Sequence changes in the blockade epitopes effect blockade Ab potency. Titers for monoclonal antibody (mAb) blockade across a panel of time-ordered GII.4 virus-like particles (VLPs) is color coded for relative potency from lowest (lightest color) to highest (darkest color) using mAbs that recognize Epitope A in GII.4.1997, Epitope A in GII.4.2006b, Epitope D, Epitope E, and Epitope F. cases, necrotizing enterocolitis and postinfectious irritable bowel syndrome also have been reported in association with norovirus infection,[57–60] although a causal link has not been established.

HISTO-BLOOD GROUP ANTIGENS

Histo-blood group antigens (HBGAs) are receptors or essential cofactors for NoV infection.[61–63] HBGAs are a large family of complex carbohydrates classified by terminal glycosylation moieties: secretor (H), Lewis (Le), and A or B antigen. In individuals who are secretor-positive, HBGAs are expressed on the surface of red blood cells and epithelial cells lining mucosal surfaces and are found free in mucosal secretions. In secretor-negative individuals, only core HBGA chains with minimal branch glycosylation are expressed and secreted.[64] Specific branch glycosylation is associated with susceptibility to NoV infection and NoVs bind HBGAs in strain-specific and genotype-specific patterns in vitro.[65–71] It is hypothesized that in individual HBGA expression levels and patterns, NoV binding patterns and virus titers may regulate infection patterns in human populations. In support, individuals expressing B antigen are more resistant to GI.1 NoV infection,[63] whereas secretor-positive individuals are more likely to be infected with certain NoV genotypes, including GII.4, the dominant genotype causing human disease worldwide. A birth cohort study in Ecuadorian children showed that secretor-negative infants experienced a similar burden of illness as secretors. However, the genotypes responsible for illness were different, indicating that even though a secretor-negative phenotype is associated with a reduced risk of infection, it is not completely protective against all NoV strains.[63,72–75]

CHALLENGES FOR NOROVIRUS VACCINE DEVELOPMENT

Several challenges remain for the development of safe, affordable, and efficacious NoV vaccines. Primarily, consistent cell culture systems and small animal models are lacking. Although advances have been made in the development of a cell culture system, viral replication in these systems remains limited. Previous studies have indicated that NoVs interact with enteric bacteria[76,77] and that murine NoVs infect immune cells.[78,79] Expanding on these observations, Jones and colleagues[80] examined B cells and enteric bacteria as a potential cell culture system. In vitro infection of human B cells with GII.4.Sydney, resulted in a 25-fold increase in genomic copies and production of viral proteins. Intestinal epithelial cells and B cells cocultured in transwell chambers were infected, while intestinal epithelial cells alone were not. Filtration decreased viral replication while culture with free synthetic H-type HBGA or bacteria expressing H-type HBGA resulted in replication similar to unfiltered NoVs.[80] These data suggest NoVs infect immune cells in vitro and commensal bacteria may act as a cofactor for viral attachment or entry. While extremely promising, these results have not yet been duplicated; other limitations to these studies are that replicating viral titers were low and the relation to in vivo infection remains unknown. Further work is necessary to develop robust cell culture systems for human NoVs.

In addition to a cell culture system, animal models that can support human NoV replication and vaccine studies have also been reported. Intraperitoneal injection of GII.4 human NoV resulted in increased viral titers and viral protein detection in splenic and hepatic macrophages of Rag-γc knockout mice.[81] These data indicate that this mouse model may serve as a starting point for production of NoV stocks and for attenuated or inactivated virus vaccine development. However, the model also has several limitations in its current state. First, mice were only susceptible to oral–intraperitoneal or intraperitoneal inoculations and developed a subclinical infection. Additionally, the immunocompromised status of these mice limits the ability to evaluate correlates to protective adaptive immunity and to test vaccine regimens. Thus, this model cannot be a suitable model for NoV pathogenesis or disease. Gnotobiotic pigs challenged with human NoV have also demonstrated utility in evaluating vaccine candidates, although viral replication in this model is limited.[82,83] Chimpanzees inoculated with GI.1 NoV did not show clinical signs of gastroenteritis, but did show similar viral shedding and immune profiles as observed in humans.[84] Both models will likely require the in vivo adaptation of virus to enhance replication and disease severity.

NOROVIRUS IMMUNITY

Understanding NoV-induced immune responses is important to vaccine development. Historically, natural NoV infection was believed to yield short-term homologous protection in humans.[85,86] Long-term memory responses were first described in 2003; bioinformatics modeling suggests memory responses may persist on average for 4 to 8 years.[63,87] These protective immune responses are genotype-specific; repeat infections with NoVs from the same genogroup or heterologous viruses are common[88–91] and aid in the emergence of novel circulating genotypes from season-to-season.[92] Importantly, previous exposure may bias vaccine immune responses toward a previous infecting strain and shape immunity to NoVs (i.e., original antigenic sin), as described for other RNA viruses.[74,75,93,94]

Several immune correlates of protection from human NoV infection and illness upon oral challenge have been identified (Table 42.1). Genetic resistance and mucosal immunoglobulin (Ig) A responses were the first identified correlates.[63,95] Additional studies have expanded these protective immune

TABLE 42.1 Correlates of Protection From Human Norovirus Infection and Disease

Species	Challenge Strain	Correlate	Infection	Symptoms	Reference
Human	GI.1	Salivary IgA	X	X	63, 96
	GI.1	Memory IgG cells		X	96
	GI.1	Blockade Ab titer	X	X	104, 105
	GI.1	HAI titer	X	X	163
	GII.4	Blockade Ab titer	X	X	97, 102
	GII.4	Serum IgA	X	X	97

Ab, antibody; Gn, gnotobiotic; HAI, hemagglutination-inhibiting; Ig, immunoglobulin; Tregs, regulatory T cells.

responses against GI.1 and GII.4 NoV infection and disease. Salivary IgA has been identified as a correlate of protection against both infection and disease in unvaccinated individuals, as well as serum IgA and serum IgG memory B cells.[96,97] Both IgG and IgA antibodies that block binding of NoV capsid protein to HBGA carbohydrates (blockade Abs) were first described as potential neutralizing antibodies in 2002 after infection and vaccination[31,98–101] and are now accepted correlates of protection against infection from GII.4.2009 NoV in humans[102] and GI.1 NoVs in chimpanzees and humans.[84,97,103–105] Intestinal preinfection regulatory T cells are inversely correlated with protection from GII.4.2006b NoV in gnotobiotic pigs.[106] These data provide promise for the development of vaccine-induced immunity.

NoVs are highly diverse and capable of evading host immune responses and herd immunity,[107] complicating vaccine development. GII.4 NoVs account for approximately 60% to 90% of all NoV outbreaks worldwide,[108] with new strains emerging every 2 to 4 years.[31,109] New NoV strains emerge via several mechanisms, including quasispecies and recombination. Quasispecies are formed during viral replication with the error prone RNA-dependent RNA polymerase; antigenic variation and immune evasion primarily occur in the antibody neutralizing/blockade epitopes of the capsid P2 domain, primarily in epitope A.[110–112] NoV quasispecies may also evolve in and emerge from persistent or chronic infections in immunocompromised hosts.[113–118] There is mounting evidence that pandemic NoVs emerge from immunocompromised hosts rather than zoonotic transmission.[119] A representation of the evolution in the P domain of successive epidemic waves of GII.4 NoVs is shown in Fig. 42.1B. These sequence changes correlated to changes in blockade (surrogate neutralization) antibody epitopes (Fig. 42.1C) resulting in loss of reactivity of human monoclonal antibodies and emergence of new GII.4 strains. Fig. 42.1D shows the reactivity of virus-like particles (VLPs) against monoclonal antibodies raised against a panel of VLPs and highlights the loss of antibody reactivity associated with changes in the P2 domain of pandemic GII.4 strains over time. In comparison, monoclonal antibodies raised against a conserved GII.4-predicted neutralizing epitope (F) are highly cross-reactive between antigenically divergent GII.4 strains that have circulated since 1987, suggesting that potential targets for a broadly protective vaccine response exist.[120]

VACCINES IN DEVELOPMENT

NoV vaccine development has been an area of intense research, particularly in the development of consistent systems for viral propagation. Currently, no such cell culture system exists, hindering development of attenuated or inactivated vaccines. Because attenuated or inactivated vaccines are currently economically infeasible, NoV vaccine development has focused on recombinant capsid subunit vaccines, including VLPs and P particles. VLPs and P particles are composed of the full-length capsid and P domain, respectively. VLPs are ~38 nm in diameter, similar to the native capsid,[121] while P particles are only ~20 nm in diameter.[122] Both proteins, lacking the viral genome, are nonreplicating. Viral vectors have also been used as a vehicle to produce and deliver VLPs in vivo.[123] Several formulations of VLPs have been examined in clinical trials; as of this writing, P particles and vectored VLPs have only been studied preclinically.

VIRUS-LIKE PARTICLES

NoV VLPs were first produced for Norwalk virus in 1992[121] and are now a common virus surrogate for numerous areas of NoV research. VLPs are produced via expression of the full-length VP1 capsid protein, both the S and P domains, in an expression vector. VLPs have been produced in a variety of systems, including baculovirus,[121] alphavirus,[124] yeast,[125] tomatoes,[126,127] potatoes,[128] and tobacco.[129,130] Great strides have also been made on improving production and purification of VLPs for wide-scale vaccine production.[131–133] There are several human NoV VLP vaccines undergoing clinical trials, including different VLP formulations and routes of administration.

The most commonly studied NoV candidate vaccines have been VLPs. VLPs have been developed from a variety of strains and inoculated using a multitude of vaccine formulations and routes of administration. An intranasal GI.1 Norwalk-derived VLP vaccine regimen with monophosphoryl lipoprotein (MPL) and chitosan adjuvants developed by LigoCyte Pharmaceuticals, Inc. (now Takeda Vaccines, Inc.) reduced Norwalk-induced gastroenteritis (37% incidence compared to 69% in placebo) and infection (61% incidence compared to 82% in placebo) in adult volunteers ($n = 47$ in vaccine group and $n = 43$ in placebo).[105] The regimen also induced IgA antibody-secreting cells, serum IgG and IgA, and virus-specific memory B cells.[134,135] The only reported side effects were nasal discharge and stuffiness.[105] Although these proof-of-concept results are promising for a vaccine against Norwalk virus, monovalent vaccines do not induce broadly reactive immune responses against other NoV genogroups.[71,91,117,136] The diversity of NoVs and complex serology patterns make broadly reactive vaccine-induced immune responses of paramount importance.[75,98]

Several of the aforementioned challenges to NoV vaccine development are the unknown effect of previous exposure history, viral diversity, and viral evolution. One strategy to overcome these limitations is rational targeting of NoV strains annually, similar to the annual targeting for seasonal influenza vaccines. However, for NoVs, this approach would face significant regulatory hurdles limiting the pace of reformulated vaccine availability. An alternative approach is to broaden the vaccine-induced immune response (Fig. 42.2) to include strains not contained within the vaccine formulation, which can be achieved through several vaccine formulations, including a multivalent VLP cocktail containing VLPs from multiple distinct serotypes (Fig. 42.2A),[98,137–139] a single VLP containing epitopes from multiple strains (Fig. 42.2B),[138,140] or targeting conserved immunogenic regions within the capsid protein (Fig. 42.2C).[120,141] Thus far, multivalent and chimeric NoV vaccine regimens have only been conducted with VLPs.

Chimeric and multivalent vaccines are immunogenic and cross-reactive in rabbits[138] and mice.[140] In one study, VLPs were derived from a consensus sequence of three NoVs: GII.4.2002 Houston, GII.4.2006a Yerseke, and GII.4.2006b Den Haag. A two-dose intradermal immunization of 50-μg consensus sequence VLPs with Alhydrogel adjuvant induced strong humoral responses against GII.4 and non-GII.4 VLPs in rabbits.[138] Similarly, a two-dose regimen of epitope chimeric VLPs derived from GII.4.1987, GII.4.2002, and GII.4.2006b parental strains induced increased and similar blockade antibody responses as individual parental strains and a multivalent VLP cocktail, respectively, in mice.[140]

Chimeric and multivalent candidate vaccines also have been shown to be immunogenic in human volunteers.[93,139,142] A bivalent vaccine consisting of GI.1 and GII.4 consensus VLPs expressed in a baculovirus system and with MPL and alum adjuvants was given intramuscularly to fifty-four 18- to 49-year-old adult human volunteers in a Phase I dose escalation clinical trial. Pain and tenderness at the injection site were the most commonly reported side effects.[139] The priming dose increased mucosal homing plasmablasts and IgA antibody-secreting cells in peripheral blood mononuclear cells and serum antibodies.[139,142] A dose of 50 μg of each VLP

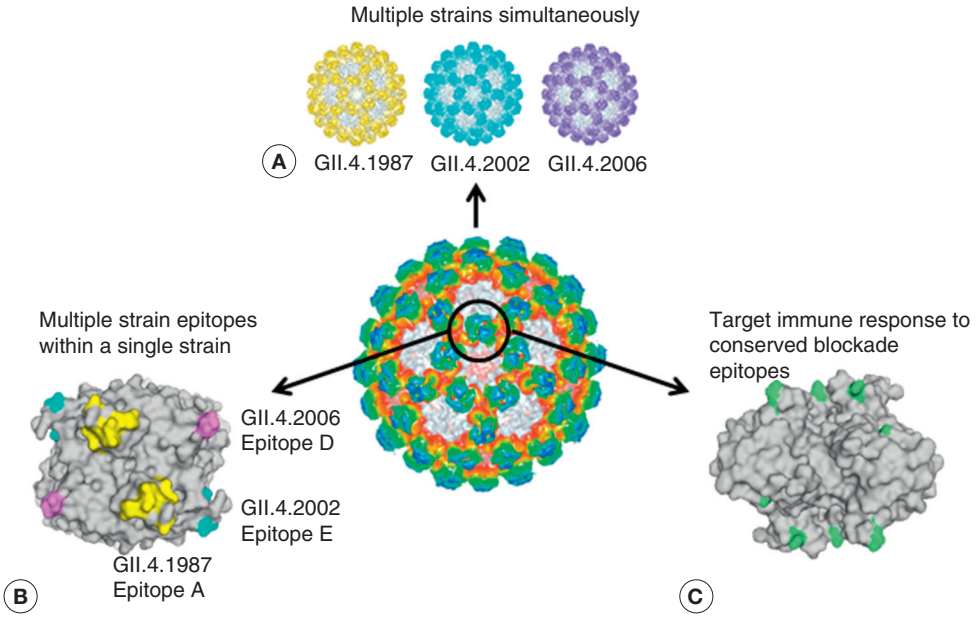

Figure 42.2. Vaccination approaches to broaden the GII.4 blockade antibody (Ab) response. Three immunization approaches lead to generation of blockade Ab responses against multiple GII.4 strains, including GII.4 strains not incorporated in the vaccine formulation: (1) Simultaneous immunization with multiple GII.4 strains **(A)**; (2) immunization with a single GII.4 engineered to contain blockade epitopes from multiple GII.4 strains (P dimer is shown from top) **(B)**; and (3) targeting of conserved blockade epitopes (P dimer is shown from an orientation that allows viewing of the epitope F regulating NERK motif of the conserved epitope in green) **(C)**.

substantially increased anti-GI.1 antibodies and anti-GII.4 antibodies by as much as 118-fold and 49-fold, respectively.[139] The 50-μg dose induced strong blockade antibody responses against NoV strains from GI and GII genotypes, including two novel GII.4 NoV strains that did not circulate in the population before sample collection was completed.[93] Importantly, the host preexisting blockade antibody titers did not appear to impair the vaccine response, and vaccination activated memory antibody responses against GII.4.1997 NoVs, the most ancestral strain VLP tested.[93] Because the boosting dose did not induce further increases in antibody titers and included responses to older NoV strains, the data suggest the first vaccine dose is restimulating the anamnestic response from previous natural exposures.

In a subsequent challenge study, the vaccine ($n = 50$) did not significantly reduce the incidence of protocol-defined illness in adult volunteers challenged with a GII.4.2003 Farmington Hills variant NoV compared to placebo ($n = 48$); however, the vaccine did significantly reduce the severity of disease when evaluated using the modified Vesikari score.[73] The vaccine was more protective against severe forms of acute gastroenteritis than against mild disease, consistent with other vaccines. Vaccination offered several potentially beneficial effects for public health, including fewer subjects with symptomatic disease, and an observed decrease in viral shedding, both in terms of duration and quantity of virus shed.[73] Interpretations of these data are complicated by the low illness rate observed in the placebo subjects, likely a result of preexisting immunity within the population that was protective upon oral challenge. Field efficacy studies are needed to confirm protection against circulating viral strains in the absence of potential protective immunity.

VECTORED VIRUS-LIKE PARTICLES

NoV VLPs can also be produced in vivo by VP1-expressing vectors. Several systems based on alphavirus,[98,123,124] adenovirus,[143,144] vesicular stomatitis virus (VSV),[145,146] and Newcastle disease virus (NDV) have been established.[147] Like VLP vaccines, vectored VLPs may require only one dose to inoculate the host and stimulate sufficient immune responses. However, preexisting host immunity to the vector backbone, such as adenoviruses or VSV, could limit induction of host immune responses.[146,147] Additionally, there are biosafety and security concerns with other vector backbones, including alphaviruses and NDV, which could limit their development and availability. Finally, these vectored NoV vaccines have not been evaluated in an animal challenge model for human NoVs or in human clinical trials.

Initial vector-based VLP delivery systems used Venezuelan equine encephalitis virus replicons (VRPs) and adenoviruses.[98,123,143,144] VRPs inoculated intradermally in mice induced stronger homotypic and heterotypic antibody responses than oral inoculation.[98,123] A three-dose intranasal adenovirus-vectored GII.4.Lordsdale regimen induced virus-specific humoral responses, balanced T-helper cell (Th)1/Th2 responses, and interferon (IFN)-γ production in BALB/c mice.[144] A combination of an adenovirus- or alphavirus-vectored VLP priming and a conventional VLP boosting regimen improved these responses.[123,143] Additionally, multivalent VRPs were the first vaccine strategy to induce blockade antibodies against NoV strains not contained in the vaccine.[98] More recently, VSV and NDV have been explored as potential vectored VLP vaccines.[145–147] Both recombinant VSV- and NDV-expressing NoV VP1 proteins are immunogenic in mice, inducing serum IgG, fecal IgA, proliferating T cells,[146,147] and splenic cytokine-expressing T cells.[147] However, the VSV backbone required coexpression of heat shock protein 70 to attenuate weight loss in mice.[145] Vectored VLPs have produced interesting preliminary immune response results, but their efficacy against NoV challenge has yet to be evaluated.

P PARTICLES

P particles were first developed at Cincinnati Children's Hospital Medical Center in 2004.[148] Expression of the P domain

in an *Escherichia coli* expression system yielded subviral particles that maintained viral binding capability, but, lacking the S domain, did not form VLPs.[149] P particles are composed of 12 P dimers and bind HBGAs.[150] Inoculation of mice with GII.4.VA387-derived P particles induced strain-specific antibodies that blocked VLP binding to HBGAs,[122] indicating their potential as vaccine candidates.

To date, P particles as vaccine candidates have been studied preclinically in murine and porcine models.[106] Studies comparing P particles and VLPs have yielded differing results in mice.[151,152] This discrepancy may be explained by the use of different preparations in the two studies and highlights the lack of understanding of how different P protein multimers may impact antigenicity.[152–154] A three-dose 100-μg intranasal GII.4.VA387 VLP or P particle vaccine with chitosan and MPL adjuvants provided similar cross-variant protection rates against diarrhea following challenge with a GII.4.2006b variant in gnotobiotic pigs.[106,155] P particles did not induce strong IFN-γ producing T cells, but did induce stronger activated $CD4^+$ T cells and intestinal IFN-γ producing $CD8^+$ T-cell responses than VLPs postchallenge.[106] P particles have provided promising immunogenic results and may be an alternative recombinant protein vaccine strategy. However, humoral immunity has not been examined outside of the murine model and P particles do not bind to several human monoclonal antibodies against the epitope A,[141] suggesting that they may present antibody epitopes somewhat differently from native virus and VLPs.

COMBINATION VACCINES

VLPs and P particles have both been examined nonclinically in vaccine regimens targeting multiple viral pathogens. Given the production cost of vaccines, simultaneous immunization against multiple pathogens is ideal and is currently used in several pediatric vaccine formulations. P particles can be manipulated to present other viral antigens in addition to the NoV P domain, while VLP-based combination vaccines have been examined in cocktails.

The first NoV combination vaccines, against influenza and rotavirus, were studied in 2011.[156–158] Parenteral VLP cocktails containing GII.4 and GI.3 NoV VLPs and recombinant rotavirus VP6 induced cross-reactive antibodies against both viruses.[156,159] The most commonly studied combination vaccines have been with the NoV GII.4.VA387-derived P-particle platform.[157,158,160–162] P-particle platforms have induced antibody and T cell immune responses against NoVs and influenza, rotavirus, and hepatitis E virus in mice.[157,158,160–162] Additionally, they have protected against influenza challenge in mice.[161,162] These combination vaccines represent promising approaches, but none have been evaluated for protection against NoV infection and all need to be evaluated in larger animal models or in clinical trials to determine their efficacy.

FUTURE VACCINES

NoVs are the leading cause of acute gastroenteritis and a growing major economic burden worldwide. Fundamental advances into NoV evolution and immunogenicity have provided new metrics and refined antibody and VLP reagents for identifying new pandemic strain emergence events, mechanism of escape from herd immunity, and the potential for refined epitope specific correlates of protective immunity. Historically, the unavailability of consistent cell culture and small animal challenge models has restricted the development of NoV vaccine candidates. Recent advances in both cell culture cultivation and animal model development may eliminate these restraints, although additional improvements are necessary to fully inform future vaccine and therapeutic interventions. The use of recombinant capsid proteins, particularly VLPs, has produced promising results. VLPs effectively mimic binding of the native virion and stimulate host immunity. Norwalk-derived VLPs and multivalent VLP preparations have shown promising results in two human challenge studies by two different routes of administration, providing a potential path forward for evaluation of protection in field efficacy trials.

Recombinant proteins are not limited in their immunogenicity against their parental strains; rather, they have been shown to be cross-reactive and induce functional antibodies against a variety of NoV strains and genotypes. The recent vaccine formulations containing consensus VP1 sequences or chimeric VLPs provide broad immune responses against numerous NoV strains. These vaccine approaches provide the most promise for protection from circulating and emerging NoV strains. Furthermore, vaccines targeting the conserved capsid regions should be investigated as an alternative to chimeric or multivalent vaccines. Although great advances have been made in NoV vaccine development, study needs to be continued. Improvements in cell culture and small-animal models for virus propagation are key to advancing our understanding of NoV disease and immunobiology. Until these systems are validated, clinical trials are the only mechanism for elucidating correlates to protective immunity and vaccine design. As the past decade and one-half was a renaissance in our understanding of norovirus evolution, epidemiology, and molecular biology, it seems likely that the field is poised to make substantial gains not only in understanding of disease processes, but more importantly, in our capacity to control the global disease burden of these important human pathogens.

Addendum

Since submission of this chapter, Ettayebi et al.[164] reported replication of several human norovirus strains in a cell culture system derived from human intestinal stem cell–derived enteroids. Human noroviruses replicated in a strain-specific, secretor-dependent manner. The addition of bile acids to the system increased replication of several NoV strains. Further, human antisera previously shown to block interaction of VLP to carbohydrate ligands neutralized virus replication. These findings provide promise for the potential development of live attenuated or inactivated NoV vaccines.

43 Parasitic Disease Vaccines

Peter J. Hotez and Jeffrey M. Bethony

Parasitic diseases caused by helminths and unicellular eukaryotes (protozoa) are major causes of human disease in the resource-poor nations of the tropics. When measured in disability-adjusted life-years (DALYs, or the number of life-years lost from premature death or disability), the combined burden of disease caused by human parasites is approximately 116 million DALYs, a value that exceeds the DALYs from diarrheal diseases, lower respiratory infections, or HIV and AIDS.[1,2] Among the more critical problems in developing vaccines against these pathogens is maintaining them in the laboratory. With a few exceptions, in vitro culture methods cannot be maintained for these pathogens; frequently, laboratory animals are necessary to maintain the complex life cycles of these parasites. This problem has prevented the production of the large numbers of parasites necessary to develop live attenuated or killed vaccines, as are used for many of the viral and bacterial pathogens.

Over the last decade, investigators in academic, private, and government laboratories began applying modern biotechnology techniques to the study of human parasites. Genome projects have now been completed for most of the neglected parasitic protozoa of global public health importance,[3,4] with proteomic, transcriptomic, and metabolomic research (OMICs studies) increasingly focused on either human parasites or relevant representative species adapted to laboratory animals.[5–7] However, for several reasons, many of these OMICs studies have not yet translated into major vaccine development initiatives. First, most of the parasite genomes are not as amenable to reverse vaccinology approaches as bacterial genomes, primarily because of the absence of simplified eukaryotic expression systems that can simultaneously express hundreds of properly folded antigens.[8] In addition, there is a dearth of animal models for parasite vaccine testing.[8,9] Finally, there has been little commercial interest in the development of human vaccines for neglected tropical diseases.[9,10]

Also, over the past decade, new funds from private philanthropies such as the Bill & Melinda Gates Foundation, together with support from European governments, including the European Union, have reenergized attempts to manufacture and clinically evaluate vaccines for parasitic diseases. These funds have stimulated the formation of several product-development public-private partnerships (PD-PPPs), also known as product development partnerships (PDPs).[10] Aside from the malaria vaccines (see Chapter 35), five human vaccines are currently undergoing or are about to enter clinical development. These include four anthelmintic vaccines (one for hookworm infection and three for schistosomiasis) and several antiprotozoan vaccines for leishmaniasis (Table 43.1). There is also an extensive history of first- and second-generation leishmaniasis vaccines composed of live and killed parasites, respectively.[11,12] In addition, several veterinary vaccines are under development, which could be used to interrupt zoonotic transmission of several parasites to humans, including vaccines for bovine schistosomiasis, pig cysticercosis, canine echinococcosis, and canine leishmaniasis.

ANTHELMINTIC VACCINES

Helminth infections are among the most prevalent infections of humans.[13,14] Approximately 819 million, 465 million, and 439 million individuals worldwide harbor the soil-transmitted nematodes *Ascaris lumbricoides, Trichuris trichiura,* and hookworms (*Necator americanus* and *Ancylostoma duodenale*), respectively,[2] and an additional 252 million or more people are infected with trematodes, especially the schistosomes (primarily *Schistosoma mansoni, Schistosoma japonicum,* and *Schistosoma haematobium*), although the number of individuals infected with these trematodes is thought to be underestimated for a variety of reasons.[15] Together, the nematode and trematode helminths cause almost 10 million DALYs worldwide.[2] In much of the developing world, soil-transmitted helminth infections and schistosomiasis exhibit their highest prevalence and intensity of infection (as measured by worm burden) among children and teenagers. Children who are chronically infected with heavy worm burdens develop deficits in physical, intellectual, and cognitive growth.[14] In addition, hookworm and schistosomiasis are important health problems in pregnancy and contribute to increased maternal morbidity and mortality as well as low birth weight and prematurity.[16]

Among the global efforts to control soil-transmitted helminth (STH) infections and schistosomiasis are concerted efforts to administer either albendazole or mebendazole to target the STH infections, together with praziquantel for targeting schistosomiasis, on a yearly or twice-yearly basis. Because STH infections and schistosomiasis primarily affect school-age children, anthelmintic drugs often are administered as part of school-based health and education efforts.[14] However, although albendazole and praziquantel are often effective at removing current infections, children reacquire new helminth infections several months after treatment.[17] This potentially limits the usefulness of anthelmintic agents as a school-based public health control measure, particularly in light of new evidence for the diminished efficacy of anthelmintic drugs with frequent use or the possible emergence of anthelmintic drug resistance.[18] Moreover, single-dose mebendazole is highly ineffective as a treatment for hookworm infection and trichuriasis.[19] A recent survey of experts concluded that mass drug administration alone will not be sufficient to effect elimination either of STH infection or schistosmiasis.[20]

As an alternative approach to helminth control or elimination, efforts continue to develop anthelmintic vaccines. The goals of anthelmintic vaccination are different from those of conventional antiviral and antibacterial vaccination, as it is unlikely that immunization with defined antigens will elicit sterilizing immunity against these complex metazoan organisms, many of which have several life cycle stages in the human host. Instead, the most important goal is to reduce worm burden to below the disease-causing threshold; that is, to immunize against the disease rather than the infection. For example, the goal is to reduce hookworm burden to below the threshold that results in significant intestinal blood loss and can lead to anemia,[21] or to reduce the schistosome worm burden below the threshold that results in significant egg

TABLE 43.1 Human Antiparasitic Disease Vaccines Entering or in Clinical Development

Disease	Parasite Species Targeted	Vaccine	Major Antigens/Adjuvants	Sponsor/Lead Organization (PDP)
Hookworm infection	*Necator americanus*	Human hookworm vaccine	*Na*-GST-1 (24-kDa recombinant glutathione-*S*-transferase) *Na*-APR-1 (45-kDa recombinant inactivated aspartic protease) Alhydrogel ± GLA or other immunostimulant	Sabin Vaccine Institute PDP HOOKVAC Consortium
Schistosomiasis	*Schistosoma haematobium*	Bilhvax	*Sh28*GST (28-kDa recombinant glutathione-*S*-transferase) Alum formulation	Institut Pasteur and INSERM
	Schistosoma mansoni	*Sm*-TSP-2 schistosomiasis vaccine	*Sm*-TSP-2 (9-kDa recombinant tetraspanin) Alhydrogel ± GLA	Sabin Vaccine Institute PDP
	S. mansoni	*Sm*-14 schistosomiasis vaccine	*Sm*-14 (14-kDa recombinant fatty acid binding protein)	Oswaldo Cruz Foundation (Fiocruz)
Leishmaniasis	*Leishmania* spp	Leish-111f + MPL, or component recombinant antigens	*Leishmania* recombinant polyprotein MPL	IDRI
	Leishmania spp	LEISHDNAVAX	T-cell epitope-enriched DNA vaccine	European consortium of partners led by London School of Hygiene and Tropical Medicine
	Leishmania spp	Adenovirus-based leishmaniasis vaccine	HASPB and KMP11	European consortium of partners
Chagas disease	*Trypanosoma cruzi*	Recombinant protein-based Chagas disease vaccine	Tc24 + second antigen + stable emulsion of GLA or E6020	Sabin Vaccine Institute PDP with Mexican Consortium of partners, led by Carlos Slim Health Institute, with IDRI and Eisai Co, Ltd

APR, recombinant aspartic protease (hemoglobinase); GLA, glucopyranosyl lipid adjuvant; GST, glutathione-*S*-transferase; IDRI, Infectious Disease Research Institute (Seattle, WA); INSERM, French National Institute for Health and Medical Research (Institut National de la Santé et de la Recherche Médicale); MPL, monophosphoryl lipid; PDP, product development partnership.

deposition and subsequent granuloma formation in the liver, intestines, or bladder.[22] Still another approach to vaccination against helminth disease would be to directly block the action of parasite-induced pathogenic processes. In the case of hookworm, this would require blocking parasite-derived virulence factors that cause blood loss, and for schistosomiasis, blocking egg deposition.[22] It is likely that anthelmintic vaccination will not be used in isolation, but will probably be used in conjunction with other control efforts, including conventional chemotherapy as described above.[23]

Hookworm Infection

Human hookworm infection is a leading cause of anemia and malnutrition among children in developing countries,[24] with the greatest number of cases in sub-Saharan Africa, Asia, and tropical regions of the Americas.[14] *N. americanus* is the predominant hookworm worldwide, with *A. duodenale* responsible for most of the remaining cases. Humans become infected when third-stage larvae penetrate the skin and undergo extraintestinal migration in the vasculature and reach the heart and lungs. Migration of the hookworm larvae to the lung is associated with a mild pneumonitis, with the larvae ascending the airways and reaching the larynx before they are coughed and swallowed. The larvae molt twice in the intestine to become adult hookworms, which invade tissue and cause blood loss. Unlike other STH infections, high worm burdens with hookworms occur in both children and adults (including pregnant women),[24] so pediatric deworming has no impact on adult populations or on reducing the transmission dynamics of the infection.

Early attempts at developing a hookworm vaccine relied on the observation that numerous small doses of living third-stage infective larvae (L3) of the dog hookworm *Ancylostoma caninum* could confer resistance against challenge hookworm infections.[25] Resistance was measured by reductions in worm burden, worm size, and worm fecundity (as measured by egg counts in feces). Immunity was never sterilizing, but efficacy was between 60% and 70%. Later it was noted that larger doses of living L3 could be administered over shorter time periods if they were first damaged by ionizing radiation. This provided the basis for commercial radiation-attenuated hookworm L3 vaccines that could be administered to dogs in two doses, with an efficacy of 90%. The canine hookworm vaccine was marketed in the eastern United States during the 1970s, but ultimately it failed as a commercial veterinary product.[25]

Although it is not feasible to develop human antihookworm vaccines using living L3 (damaged or otherwise), studies have been done to identify, isolate, clone, express, and test vaccine antigens from L3 that can reproduce the reduction in worm burdens afforded by the live vaccines.[26–32] One promising class of antigens to emerge from these investigations is the *Ancylostoma*-secreted proteins (ASPs), which are released by host-stimulated L3 and contain amino acid sequences homologous to those of the major antigens from insect venoms.[27,28] In preclinical studies, it was shown that ASP-2 is an immunodominant antigen associated with the irradiated L3 vaccine,[26,29,30] and that it is protective against challenge infections with animal hookworms.[29–31] The ASP-2 from *N. americanus* (*Na*-ASP-2) was expressed in yeast and selected for subsequent process development and pilot manufacture.[30] These studies were conducted by the Sabin Vaccine

Institute PDP. *Na*-ASP-2 was formulated with Alhydrogel and underwent Phase I safety and immunogenicity testing in hookworm-naïve individuals in the United States, where it was shown to be safe and immunogenic.[32] However, a subsequent Phase I safety and immunogenicity study in a hookworm-endemic area of Brazil revealed that this vaccine could induce a generalized urticaria among chronically infected individuals with high levels of prevaccination immunoglobulin (Ig) E to the native form of ASP-2.[33] Given these safety concerns, the larval antigen program was halted in favor of the development of a different class of antigens.[21,22]

An alternative approach to hookworm vaccination currently under development by the Sabin Vaccine Institute PDP takes advantage of the fact that adult hookworms ingest blood.[21,22,24] Several proteolytic enzymes required for the parasite's ability to digest hemoglobin have been shown to line the brush-border membrane of the hookworm's gastrointestinal tract.[34] Vaccination with a recombinant aspartic protease (in this case, a hemoglobinase), aspartic protease (APR)-1 was shown to reduce worm burden, worm fecundity, and host blood loss after hookworm challenge infection in dogs.[35] By site-directed mutagenesis, an enzymatically inactivated hemoglobinase from *N. americanus* (*Na*-APR-1) was also shown to induce neutralizing antibodies against multiple hookworm species and protect dogs against heterologous hookworm infection.[36] In addition, a unique glutathione-*S*-transferase from *N. americanus* (*Na*-GST-1) was shown to exhibit a unique heme- and hematin-binding function and is hypothesized to be required for parasite heme detoxification. A recombinant *Na*-GST-1 expressed in yeast is highly protective in laboratory animals.[21,22,37,38] Phase I studies in the United States, nonhookworm endemic areas of Brazil, and hookworm (*N. americanus*) endemic areas of Brazil show that *Na*-GST-1/Alhydrogel is safe and immunogenic . The *Na*-APR/Alhydrogel has shown to be safe at an interim time point 30 days after the third immunization (unpublished observation).

These studies provide the scientific basis of an adult hookworm-vaccine antigen development program for both antigens to be coadministered. Through a new HOOKVAC Consortium, supported by the European Commission, both formulations will also undergo Phase I testing in West-Central Africa (Gabon). Ultimately, the final human hookworm vaccine will probably be composed of *Na*-GST-1 and *Na*-APR-1, combined and formulated with Alhydrogel (and possibly a second immunostimulant such as a synthetic Toll-like receptor 4 [TLR4] agonist known as GLA [glucopyranosyl lipid A]), with a vaccination strategy that may be linked either to the Expanded Programme on Immunization or to anthelmintic chemotherapy in preschool or school-age children.[21,22] A cost-effectiveness study confirms the potential economic value of a hookworm vaccine.[39]

Schistosomiasis

Schistosomes are snail-transmitted, waterborne parasitic platyhelminths (order Trematoda). High rates of infection occur near bodies of fresh water, such as tributaries of the Nile River in Egypt and the Dongting and Boyang lakes in China,[40,41] with the largest number of cases occurring in Africa. Revised estimates indicate that more than 400 million cases may occur in Africa,[15] with roughly two-thirds of the cases resulting from *S. haematobium*, the cause of urogenital schistosomiasis, and one-third from *S. mansoni*, the cause of intestinal schistosomiasis.[42] Africa's schistosomiasis accounts for more than 90% of the world's cases, with most of the remainder caused by *S. mansoni* in Brazil, and elsewhere in Latin America, or *S. haematobium* and *S. mansoni* in the Middle East, and approximately 1% caused by the *S. japonicum* complex (including *S. japonicum* and *Schistosoma mekongi*) in East Asia.[40] The human schistosomes are typically distinguished by their snail vectors, location in the host vasculature, and egg morphology. Members of the *S. japonicum* complex also have important domestic animal reservoir hosts (pigs, cattle, water buffaloes). Asexual reproduction of the parasites occurs in the freshwater snail intermediate hosts that release large numbers of free-swimming, infective larval schistosomes (cercariae) into the water (Fig. 43.1). The cercariae invade human skin, lose their tail, and then (now called schistosomula) spend the next few weeks migrating through the bloodstream and lungs until they reach the liver, where they differentiate into male and female schistosomes. Male and female worm pairs migrate through the portal vasculature until they reach their final destination in the mesenteric (*S. mansoni* and *S. japonicum* complex) or bladder venules (*S. haematobium*). The worm pairs release eggs, which exit from the body in feces or urine and then hatch in fresh water. Most of the morbidity associated with schistosomiasis occurs when the eggs fail to exit from the human host and become trapped in the intestinal or bladder wall or in the liver, where they elicit granulomas and host fibrosis. In the liver, Symmers pipestem fibrosis from chronic *S. mansoni* or *S. japonicum* infection leads to portal hypertension and hepatosplenomegaly. In the bladder, *S. haematobium* eggs stimulate formation of multiple granuloma, resulting in hematuria and an obstructive uropathy leading to chronic urinary tract infections, hydronephrosis, and kidney failure.[40] Chronic bladder fibrosis from the *S. haematobium* eggs is also associated with squamous cell carcinoma of the bladder.[43] *S. haematobium* eggs also cause granuloma formation in the uterus and cervix, leading to female genital schistosomiasis, which is an important risk factor for HIV/AIDS in Africa.[44] In addition, chronic schistosomiasis is associated with a wide variety of other sequelae, especially in children, including anemia, chronic pain, undernutrition, growth failure, and cognitive deficits. The full burden of disability-related outcomes in endemic schistosomiasis is only beginning to be fully appreciated.[45]

A number of different approaches have been taken to design antischistosomal vaccines. As in other systems, the administration of radiation-attenuated cercariae results in the best protection to date in mice. According to Wilson and Coulson,[46] the development of the Th1/Th2 paradigm for T-helper (Th) cell differentiation was extremely influential in interpreting the radiation-attenuated vaccine model. The two major patterns of cytokine synthesis correlate with the induction of cell-mediated (Th1) or humoral (Th2) immunity, thus providing a possible explanation for the separate and often reciprocal regulation of these responses in chronic schistosomiasis infection. This dichotomy in Th cell differentiation, together with subsequent identification of T-regulatory (Tr) cells and Th3/Tr1 (downregulatory interleukin [IL]-10 and transforming growth factor β production) extensions, provides the framework for the mechanisms operating in the radiation-attenuated vaccine model. It is clear that under appropriate conditions, the radiation-attenuated vaccine can elicit a partially protective Th1 or Th2 response. If such responses were directed against different parasite stages (larval and adult) and at different sites (skin, lung, mesentery), they might act additively or even synergistically to provide a very high level of protection. According to Wilson and Coulson, it is also possible that these responses to the radiation-attenuated vaccine might actually prove mutually exclusive, in which case it would be necessary to opt for the one that gave the maximal level of protection.

A second important step forward would be the identification and cloning of the antigens that mediate the respective Th1 and Th2 mechanisms induced by the radiation-attenuated vaccine.[46] The task would then be to formulate the relevant

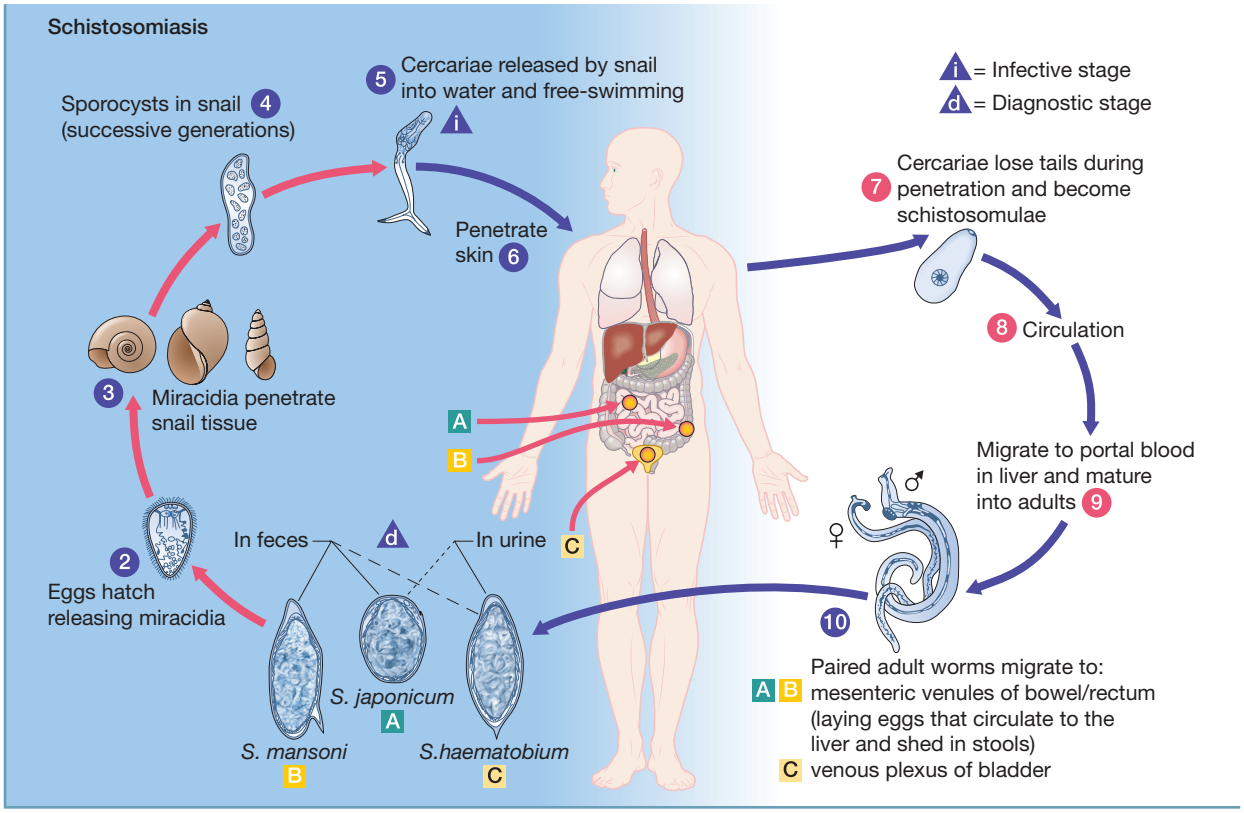

Figure 43.1. Life cycle of human schistosomes. *(From the Public Health Image Library of the Centers for Disease Control and Prevention, http://phil.cdc.gov/phil/details.asp?pid=3417.)*

antigens to invoke the desired responses, perhaps by means of two distinct and sequential vaccination procedures. In short, the radiation-attenuated vaccine model offers the possibility that, by manipulating the cytokine profile, we can bias the immune response in a protective direction. More specifically, if vaccination deflects the Th response in either a Th1 or Th2 direction, it will produce a measure of protection.[46]

Vigorous attention has been focused on potential vaccine antigens from several schistosomula stages. Vaccination with stage-specific schistosomula surface antigens has resulted in protection (reductions in worm burden or egg counts) that is usually less than 40%.[47] Somewhat better protection has been achieved using antigens shared between schistosomula and adult schistosomes, including parasite-derived myosin (63 kDa), paramyosin (97 kDa), triose phosphate isomerase (28 kDa), glutathione-*S*-transferases (GSTs; 26 and 28 kDa), a fatty acid–binding protein (14 kDa), and a 23-kDa surface protein. To date, most of these proof-of-concept vaccine studies have been conducted in mice challenged with either *S. mansoni* or *S. japonicum*. However, because Asian schistosomiasis is associated with significant animal reservoirs, including cattle, water buffaloes, and pigs, several veterinary vaccine trials have been conducted in China in these reservoir hosts, with a goal of developing an *S. japonicum* transmission-blocking vaccine.[47] To date, the recombinant antigen-based vaccine trials have been conducted with numerous adjuvants, including Freund's complete adjuvant, alum, bacille Calmette-Guérin (BCG), saponin, Quil A, and *Bordetella pertussis*. Because of the suggested role of interferon (IFN)-γ and Th1 cellular immune responses in mediating protection, there have been some efforts to bias the host cytokine profile at the time of vaccination. Some success has been reported in this regard using IL-12 as an adjuvant and with DNA immunizations.[41,47] The molecular basis of immunity with the schistosomula antigens is largely unstudied, except for new evidence that paramyosin may function as an Fc receptor for the parasite, allowing it to adsorb host immunoglobulin to shield it from the host immune response. Therefore, an antiparamyosin immune response may somehow interfere with the parasite's immune escape mechanisms.[48]

A second approach to vaccination against schistosomiasis has been to target the fecundity of female adult schistosomes so as to diminish egg excretion into target host organs. Success with this approach has been reported by immunizing mice, nonhuman primates, and large-animal reservoir hosts, including pigs and water buffaloes, with 26-kDa and 28-kDa variants of a GST.[47,49] If levels of egg excretion can be reduced by vaccination of animal reservoir hosts, this approach might be sufficient to reduce *S. japonicum* transmission.[47] Alternatively, it has been proposed that egg deposition and granuloma formation in the human host might be manipulated by immunotherapy, because granuloma formation around the schistosome egg depends heavily on host cytokines, including tumor necrosis factor and Th2-associated cytokines.

During the late 1990s, the World Health Organization's (WHO) Special Programme for Research and Training in Tropical Diseases (WHO/TDR) initiated murine trials of six vaccine candidates for *S. mansoni:*

- A 28-kDa GST, as noted earlier[49,50]
- A 97-kDa paramyosin[51]
- An irradiated larvae-associated vaccine antigen, the 62-kDa IrV-5,[52] which is a derivative of a 200-kDa molecule with extensive homology with human myosin

- A 28-kDa triose phosphate isomerase[53]
- A 23-kDa integral membrane antigen (Sm-23) that is part of a superfamily of proteins that includes CD9 and TAPA-1, first described in hematopoietic cells[54]
- A 14-kDa fatty acid–binding protein that was thought to also have protective immune cross-reactivity with the liver fluke, *Fasciola hepatica*.[55]

None of these candidate proteins reached the requirement set by WHO/TDR of generating a 40% or better reduction in challenge-derived worm burdens relative to nonimmunized controls.[56] However, it was recommended that work should continue on these antigens, including progression to clinical or veterinary trials.

In terms of vaccines now entering the clinic, a membrane-spanning *S. mansoni* surface protein (tetraspanin), known as *Sm*-TSP-2, has been identified. *Sm*-TSP-2 results in a 60% to 70% worm burden reduction in mice and is selectively recognized by IgG_1 and IgG_3 antibodies in putatively resistant individuals, but not in chronically infected individuals living in endemic areas of Brazil.[57] Furthermore, schistosomes treated with double-stranded RNA encoding *Sm*-TSP-2 display a vacuolated and disrupted tegument and are unable to fully develop in mice.[58] The extracellular domain of *Sm*-TSP-2 has been expressed in yeast, and, under the auspices of the Sabin Vaccine Institute PDP, this antigen is undergoing clinical testing as a vaccine formulated with Alhydrogel (with GLA as a possible immunostimulant) for intestinal schistosomiasis.[22] An additional membrane-spanning tegumental antigen now also in Phase I clinical trials is the *Sm*-14, a fatty acid–binding protein.[59]

For urogenital schistosomiasis, a group at the Institut Pasteur in Lille, France, has produced the 28-kDa GST from *S. haematobium* (Sh28GST) in yeast under current good manufacturing practices and has embarked on clinical testing.[49] Sh28GST was selected on the basis of protection studies in primates,[49] and studies in humans, which showed that IgG_3 to Sh28GST correlates with an age-dependent decrease in egg output in *S. haematobium* infection.[60] Among human volunteers, two subcutaneous injections of 100 μg of recombinant Sh28GST at 28-day intervals on alum did not result in any significant toxicity, and resulted in an immune response characterized by antibodies that neutralized the enzymatic activity of Sh28GST.[49,61] Studies are underway to evaluate the clinical efficacy of this vaccine, known as Bilhvax, in infected patients in sub-Saharan Africa, with an aim to determine if there is synergy with praziquantel chemotherapy. Beyond these candidate vaccines now in clinical trials, Sm-p80, the large subunit of *S. mansoni* calpain has undergone extensive preclinical testing in baboons and has been shown to cross-protect against *S. haematobium*.[62,63]

Larval Tapeworm Infections: Cysticercosis and Echinococcosis

The pork tapeworm, *Taenia solium*, is a major parasite of veterinary and medical importance. When humans serve as an intermediate host, *T. solium* can cause an important human infection known as neurocysticercosis. Because transmission of *T. solium* from pigs to humans can be interrupted, neurocysticercosis has been identified as a potentially eradicable disease, and increasing attention is being placed on efforts to control transmission of the parasite. One way to control the disease is to prevent infection in pigs by vaccinating them, thereby breaking the parasite's life cycle and removing the source of infection for humans. Several approaches to development of transmission-blocking veterinary vaccines against *T. solium* are being examined, the most promising of which is the application of recombinant oncosphere antigens.[64] Efforts are also underway to develop canine vaccines for the adult stages of *Echinococcus granulosus* as a means to interrupt transmission of the disease to humans and prevent hydatid cysts.[64]

ANTIPROTOZOAN VACCINES

Aside from malaria (see Chapter 35), the major parasitic protozoan infections include the vector-borne kinetoplastid protozoan infections, resulting in leishmaniasis, Chagas disease, and human African trypanosomiasis, which cause almost 5 million DALYs and 70,000 deaths; and the intestinal protozoan infections led by cryptosporidiosis and amebiasis, associated with approximately 10 million DALYs and 150,000 deaths.[1,2,65] Giardiasis is yet another important intestinal protozoan infections for which there are no disease burden estimates published by the Global Burden of Disease Study published in 2010. The same is true for toxoplasmosis. In terms of human vaccines, only leishmaniasis vaccines have advanced into clinical development.[66] There is also interest in a canine leishmaniasis vaccine to prevent zoonotic transmission to humans.[67]

Leishmaniasis

Leishmania species are flagellated kinetoplastid protozoan parasites transmitted by the bite of a female sandfly. There are cutaneous (CL), mucocutaneous, and visceralizing (VL) forms of human leishmaniasis. CL and mucocutaneous leishmaniasis in the Western Hemisphere (predominantly in Central and South America) are caused by members of the *Leishmania mexicana* and *Leishmania braziliensis* complex, whereas CL in the Eastern Hemisphere (predominantly in India, central Asia, and parts of Africa and the Middle East) is caused by members of the *Leishmania tropica* and *Leishmania major* complex. Recently, as a consequence of the conflict in Syria, it is estimated that more than 100,000 cases of CL caused by *L. tropica* may have occurred there. VL, also known as kala-azar, is caused by *Leishmania donovani* in India, Bangladesh, Nepal, East Africa, and China; by *Leishmania infantum* in central Asia, North Africa, and southern Europe; and by *Leishmania chagasi* in Latin America. Many, if not most, investigators now consider *L. infantum* and *L. chagasi* as identical species and sometimes refer to the organism as "*Leishmania chagasi infantum*." Members of the *L. donovani* complex are important emerging opportunistic pathogens in patients with AIDS. Recent estimates indicate that between 200,000 and 400,00 cases of VL occur annually, while 700,000 to 1.2 million cases of CL occur annually, with 10 million people living with leishmaniasis.[2,68]

Leishmanization, the ancient Middle Eastern and central Asian practice of injecting live *Leishmania* parasites as a means of actively immunizing against disease, predates vaccination and may be as old as variolation. It relies on inoculating a person with live parasites using a thorn or other sharp instrument to artificially create a cutaneous lesion. Alternatively, an arm or other body part is deliberately exposed to the bite of sandflies.[11] The procedure causes mild disease (typically 1 to 2 cm in diameter) at an unexposed site, frequently the arm or buttocks, that heals over a period of 3 to 4 months. Successful leishmanization prevents the possibility that a cosmetically disfiguring lesion ("Delhi boil" or "oriental sore") might appear on the face. Leishmanization strategies were developed in Israel by Saul Adler at Hebrew University and in the former Soviet Union.[12] One such leishmanization "vaccine" is registered in Uzbekistan.[11] In the 1980s, leishmanization was reintroduced as an emergency public health measure during the Iran–Iraq war, when approximately 2 million people were inoculated.[69] The Iranian leishmanization program was

subsequently halted when it was learned that up to 3% of the induced lesions lasted for more than a year; in some instances, the lesions never healed, even with subsequent antiparasitic antimonial chemotherapy.[69] To date, leishmanization is the only vaccine with proven efficacy in humans.[12] Several live attenuated strains of *L. major* are also under development as potential vaccines.[12] Among the hurdles that potentially block further refinement of leishmanization and related practices are the difficulties in standardizing the virulence of the vaccine and the constant risk of developing severe and persistent lesions, especially in individuals with HIV/AIDS and other immune deficiencies.[12]

In an effort to establish a safer anti-*Leishmania* immunization procedure, Iran launched a national vaccine development program during the early 1990s. A first-generation vaccine comprising killed *Leishmania* parasites was prepared under good manufacturing practices by the Razi Vaccine and Serum Research Institute (Hessarak, Iran). The cell bank for the vaccine was derived from the same strain of *L. major* used previously for the wartime leishmanization program. The *L. major* parasites were killed by autoclaving and were then formulated with BCG. In a randomized, double-blind trial, the safety and efficacy of a single injection of the vaccine was compared with a BCG control in 3637 schoolchildren.[69] Children with a prior history of CL or those with a positive skin test reaction against leishmanial antigen were excluded from the study. The Iranian trial demonstrated the vaccine's safety, although its efficacy was not apparent until 6 months after the injection. It has been suggested that there was some protective effect from BCG in the immediate postvaccination period. Also of interest was the observation that protection was better among boys who, because of Iranian dress and customs, presumably are exposed to a greater number of sandfly bites than girls.[69] Based on these results, additional trials are underway to evaluate multiple injections of the killed vaccine, as well as new formulations with alum and IL-12. A trial to evaluate the killed vaccine against *L. donovani* is also underway in Sudan. In South America, killed *Leishmania amazonensis* and *L. mexicana* vaccines were being produced by Biobras (Brazil) and Instituto de Biomedicina (Venezuela), respectively. Biobras was since purchased and the leishmaniasis vaccine program was halted.[66] In reviewing the data from several clinical trials of vaccines composed of whole-parasite antigens, Coler and Reed[70] conclude that the efficacy varies from 0% to 75% against CL, but it is only 6% against VL. A Phase III clinical trial in Ecuador and Colombia showed that the *L. amazonensis* vaccine was safe but not efficacious.[12] A metaanalysis concluded that killed whole-parasite vaccines do not confer significant protection against human leishmaniasis.[71]

Earlier studies on whole-organism leishmania vaccines have stimulated efforts by several laboratories to reproduce vaccine protection using second-generation recombinant subunit antigens. Several antigens have been identified on the basis of their surface localization, recognition by T-cell clones, and immunoscreening using patient sera.[66,70] A number of candidates have shown promise in mice, particularly when formulated with IL-12 or other costimulators of Th1 immunity. In some cases, vaccination with antigens (either alone or in combination) encoded by plasmid DNA elicits more potent and durable immunity.

Development of a human leishmaniasis vaccine has been advanced most by a group at the Infectious Disease Research Institute (IDRI), a PDP in Seattle, Washington. The IDRI group has developed several lead candidate vaccines currently undergoing human trials in the United States, Latin America (including Brazil, Colombia, and Peru), and India.[66] The most extensive testing has been done on a polyprotein composed of three priority candidate antigens, *L. major* thiol-specific antioxidant, *L. major* stress-inducible protein 1 (LmSTI1), and *Leishmania* elongation initiation factor. For VL, both Leish-111f + MPL-SE and a *Leishmania* sterol 24-C-methyltransferase formulated in adjuvant are also under development.[72,73] Some of these candidates as well as additional ones are also under development as canine vaccines to prevent zoonotic transmission to humans. In parallel, a European group based at the University of York in England, the Humboldt University, and the Robert Koch Institut in Berlin, Germany, are developing an adenovirus-derived leishmaniasis vaccine for VL composed of two antigens—HASPB and KMP11—which are in Phase I trials,[74] while through a European Union consortium of partners (LEISHDNAVAX) a multiantigen T-cell epitope-enriched DNA vaccine is being developed.[75] Finally, some additional success has been reported in the development of transmission-blocking vaccines based on immunization with sandfly salivary gland proteins.[76–78] The Sabin Vaccine Institute PDP is developing some of these candidates as potentially cost-effective CL vaccines.[79]

Chagas Disease

Chagas disease (American trypanosomiasis caused by *Trypanosoma cruzi*), like leishmaniasis, is another kinetoplastid of great public health and economic importance. An estimated 7.5 million people are infected in the Americas, where it is a leading cause of disabling cardiomyopathy,[2] including hundreds of thousands of people infected in the United States where transmission can occur.[80] Several thousand imported cases of Chagas disease are also present in Spain and elsewhere in southern Europe, Australia, and Japan. A recent cost analysis indicates that a cost-effective preventive Chagas disease vaccine would have substantial economic benefit.[81] Equally compelling are modeling studies suggesting that a therapeutic vaccine given to *T. cruzi*–infected individuals to prevent or delay chagasic cardiomyopathy would be both cost-effective and cost saving.[82] Several experimental vaccine candidates, including DNA vaccines, recombinant proteins, and some peptides and carbohydrates are under development as preventive and therapeutic vaccines,[83–86] but none have progressed to clinical trials. In mice, protective immunity is associated with strong Th1 responses to defined *T. cruzi* antigens. Because of the questionable benefit of currently available drugs for the treatment of seropositive individuals to delay or prevent chagasic cardiomyopathy, there is an urgent need for new approaches, including immunotherapy or therapeutic vaccines that stimulate *T. cruzi*–specific Th1 immunity.[87] A therapeutic vaccine is under development by the Sabin Vaccine Institute PDP, in collaboration with a consortium of Mexican partners, including the Carlos Slim Health Institute, the Southwest Electronic Energy Medical Research Institute, and Eisai Co., Ltd, together with the Japanese Government.[87]

Amebiasis

Amebiasis, secondary to intestinal and hepatic infection with *Entamoeba histolytica*, is a leading neglected tropical disease in low- and middle-income countries. Human infection occurs through the ingestion of parasite cysts and subsequent invasion by trophozoites. Amebic colitis results from ulcerating mucosal lesions that result from chemical invasion caused by the release of parasite-derived proteases and hyaluronidases. Metastatic spread to the liver occurs when the trophozoites gain access to the afferent circulation that drains the colon into the portal vein. Immunizations using both native and recombinant forms of the parasite Gal-lectin have shown great promise in protecting laboratory animals, including gerbils, against *E. histolytica* challenge infections.[88] Other candidates,

including a serine-rich protein and a 29-kDa reductase antigen, have shown promise.[88] To date, however, no human testing of a vaccine for amebiasis has been initiated.[88] In addition to vaccinating against amebiasis, there has also been some interest in developing vaccines against primary amebic meningoencephalitis caused by the free-living ameba, *Naegleria fowleri*. The nfa1 gene, which encodes a 13-kDa recombinant protein on parasite pseudopodia has emerged as a promising vaccine candidate.[89]

Toxoplasmosis

Toxoplasmosis is one of the most common infections of humans, with some estimates suggesting that 6 billion people have been infected with *Toxoplasma gondii*.[90] Currently, the highest global prevalence and incidence may occur in South America,[90] although there is a dearth of information on the true global disease burden of human *T. gondii* infection.[2] In the United States, an estimated 1 million new infections occur each year, resulting in an estimated 20,000 cases of retinal infection and 750 deaths.[90] Several research groups have developed promising approaches for a human toxoplasmosis vaccine. Because, like *Leishmania* and *T. cruzi*, *T. gondii* is an intracellular parasite, such efforts are primarily directed at stimulating *T. gondii*–specific Th1 immunity and generating long-lived IFN-γ–producing $CD8^+$ T cells.[91]

In preclinical studies, several approaches have shown promise. They include viral vectors and constructs capable of expressing *T. gondii* antigens,[92] DNA vaccinations,[93] live attenuated parasites,[94] and pairing recombinant antigens with Th1-stimulating adjuvants.[94] Transmission-blocking approaches from zoonotic reservoir hosts including cats and livestock used for food have also been proposed.[94–97] There is an urgent need to better define the target product profile for toxoplasmosis vaccines with respect to target populations—that is, preventing congenital infections versus producing therapeutic vaccines for immunocompromised individuals—and to gain consensus on lead candidate antigens, as well as to determine how to best overcome genetic restrictions to the human immune response.[97,98] No human vaccine trials are underway.

44 Pertussis Vaccines

Kathryn M. Edwards and Michael D. Decker

HISTORY OF DISEASE

Pertussis (whooping cough) is a bacterial respiratory infection caused by *Bordetella pertussis,* a Gram-negative bacillus. Its major manifestation is a protracted cough that lasts many weeks, marked by characteristic intense paroxysms that often terminate in an inspiratory "whoop." Absent vaccination, nearly all children will contract pertussis. The first known description of an outbreak of pertussis is that of Guillaume De Baillou, who described an epidemic in Paris in the summer of 1578[1] that primarily affected infants and young children, resulting in many deaths. In Britain during the early 16th century, a disease known as chyne-cough was probably pertussis, and the terms whooping cough and chincough appeared in the London Bills of Mortality in 1701.[2] The causative organism was first grown by Jules Bordet and Octave Gengou in 1906, and the first crude vaccines appeared soon thereafter.[3]

WHY THE DISEASE IS IMPORTANT

Although pertussis affects all age groups, it is most hazardous for infants, who account for nearly all pertussis hospitalizations and deaths. Before widespread use of pertussis vaccines prepared from inactivated whole bacterial cells, there were as many as 270,000 cases of pertussis reported each year in the United States, with 10,000 deaths.[4] The occurrence of pertussis declined markedly after universal pertussis vaccination of children with whole-cell vaccine in the 1940s, to a nadir of 1010 reported cases in 1976.[5] Reported cases have since progressively increased, with more than 48,000 cases reported for 2012, the highest total since 1959.[6–10] However, because pertussis still frequently goes undiagnosed, it is likely that the actual number of cases in all age groups greatly exceeds the number reported. Globally, pertussis remains an important public health problem. The World Health Organization (WHO) estimated that despite universal vaccination programs, in 2008 some 16 million cases of pertussis occurred worldwide annually (95% of these occurring in developing countries), resulting in about 195,000 pediatric deaths.[11] In a more recent position paper, WHO estimated that pertussis was still causing around 63,000 deaths in children younger than 5 years.[11a] Both projections are based on many assumptions, but taken together they show that pertussis remains an important cause of child mortality.

BACKGROUND

Clinical Description

Infants and Young Children

The incubation period of pertussis is commonly 7 to 10 days (range: 4 to 21 days), with an insidious onset and initial symptoms indistinguishable from a minor upper respiratory infection (the catarrhal stage). Fever is usually minimal throughout the course of infection. The cough, initially intermittent, progresses within 1 or 2 weeks to become paroxysmal. The paroxysms increase in both frequency and severity, and then gradually subside over a period of 2 to 6 weeks, but sometimes longer.

During the paroxysmal stage, a series of rapid coughs without intervening inspiration will often be followed by the characteristic whoop, caused by the desperate effort to inspire through a narrowed glottis. The characteristic whoop is much less common in young infants. During a paroxysm, cyanosis may occur and vomiting may follow. After the episode, the child is often exhausted; several paroxysms may occur successively within a few minutes. Between paroxysms, the child may be playful and appear quite normal. Paroxysms can be induced by eating, laughing, crying, and a variety of other stimuli, and are usually worse at night.

For an infant with suspected pertussis, it is imperative that the clinician witnesses a paroxysm to ensure that apnea or respiratory arrest does not occur before determining that the child can be managed as an outpatient. Recovery is gradual. The paroxysms become less frequent and milder, and the whoop disappears. Nonparoxysmal cough may persist for many weeks and intercurrent viral infections can trigger a recurrence of the paroxysms.

In the absence of immunization, most children experience the full-blown disease; however, some children appear to develop either clinical immunity or serologic evidence of prior infection without a history of clinical pertussis, suggesting that mild atypical cases do occur.[12,13] Pertussis should be considered in all unvaccinated children admitted to hospital with cough and lower respiratory tract disease.[14]

One of the largest studies to characterize the symptoms associated with pertussis in infants and children was conducted from October 1990 to September 1996 in Germany, during active surveillance for a pertussis vaccine trial.[13] *B. pertussis* was isolated in 2592 patients (age range: 6 days to 41 years); 50.7% were female. In unvaccinated patients, 90.2% had paroxysmal cough, 78.9% demonstrated whooping, and 53.3% presented with posttussive vomiting. Fever was uncommon; only 5.7% had a temperature of 38°C or higher. Leukocytosis and lymphocytosis were characteristic of pertussis, and values above the age-specific mean were observed in 71.9% and 75.9% of unvaccinated children, respectively.

Winter and colleagues compared risk factors associated with fatal pertussis among 53 infant pertussis patients younger than 120 days of age in California, matched with 183 nonfatal hospitalized cases by age, county of residence, and closest symptom onset date.[15] Fatal cases had significantly lower birth weight, younger gestational age, younger age at time of cough onset, and higher peak white blood cell and lymphocyte counts. Fatal cases were less likely to have received macrolide antibiotics and more likely to have received steroids or nitric oxide and to develop pulmonary hypertension, seizures, encephalitis, and pneumonia. Additionally, exchange transfusion, extracorporeal membrane oxygenation, and intubation occurred significantly more frequently among fatal cases. In multivariate analyses, peak white blood cell count, birth weight, intubation, and receipt of nitric oxide were predictors of death. This chapter underscores that early recognition of pertussis in young infants and treatment with appropriate antibiotic therapy are important in preventing death.

Adolescents and Adults

Prior to widespread vaccination against pertussis, it was believed that only young children were susceptible to pertussis. We now understand that near-universal pertussis among children ensured that adolescents and adults were exposed to the bacterium sufficiently often to maintain their immunity through subclinical infection. Moreover, pertussis among adolescents and adults is not often associated with whoops, obscuring the correct diagnosis. The clinical characteristics of pertussis in older adolescents and adults were highlighted in a large Canadian study.[16] Females comprised 71% of the reported cases, probably reflective of their frequent contact with children. Nearly 60% of the older adolescents and adults reported prior pertussis vaccination, with fewer than 10% having had prior natural infection. Subjects with confirmed pertussis had a median of 56 days of cough and 43 days with violent cough. Vomiting was seen in 46% of the subjects, night cough in 84%, and apnea for 30 seconds after cough in 14%. Adults had higher rates of complications than adolescents, including pneumonia.

German household-contact studies conducted during active surveillance for pertussis vaccine trials also highlighted the signs and symptoms of adult pertussis.[17,18] Of 79 German adults with symptomatic pertussis, 34% (27) had been diagnosed with natural pertussis as children; 91% (72) had cough with their present illness, 80% (63) had cough lasting longer than 21 days, and 0.01% (1) had a cough for 8 months.[18] Prolonged paroxysmal cough was experienced by 63% (50), cough resulting in sleep disturbance was reported by 52% (41), cough followed by vomiting occurred in 42% (33), and whoops occurred in 8% (6). The adults often expectorated "glassy, viscous mucus." Malaise was reported in 30% (24) and arthralgia in 15% (12). Fourteen percent (11) of patients reported attacks involving flushing and sweating that lasted 1 to 2 minutes, occurring several times a day, and continuing for 2 to 8 weeks. In addition, family studies of children with culture-confirmed pertussis disease and seroprevalence studies have shown that asymptomatic infections are common in adolescents and adults.[19–21]

Complications and Sequelae

Infants and Children

In the German study cited earlier, the overall rate of major complications in infants and children was 5.8%, with 23.8% of infants younger than 6 months of age having complications.[13] The major complications of pertussis disease can be grouped into three categories: pulmonary, neurologic, and nutritional. Of these, pulmonary complications are the most frequent.[13]

Pulmonary Complications. The vast majority of full-blown pertussis patients exhibit some degree of atelectasis or bronchopneumonia. Pathologically, the pneumonia is both interstitial and alveolar, and the usual exudate is primarily mononuclear.[22] Pneumonic involvement may be sufficiently severe to compromise respiratory function and cause death. An autopsy series in 15 infants succumbing to pertussis reported necrotizing bronchiolitis, intraalveolar hemorrhage, and fibrinous edema.[23] Marked leukocytosis was noted, and most sections showed luminal aggregates of leukocytes in small pulmonary arteries, veins, and lymphatics. Immunohistochemical stains revealed abundant extracellular bordetellae in the cilia of the trachea, bronchi, and bronchioles, and intracellular bacteria in alveolar macrophages and ciliated epithelium. Although coinfections with other viral or bacterial organisms were reported in some patients in this series, the predominant histopathologic findings in the respiratory tract did not differ between those who were or were not co-infected. These observations suggest that most pneumonia associated with pertussis is caused by the organism itself. In addition, there has been an increasing appreciation for the role of pulmonary hypertension as an unexplained complication of pertussis in young infants.[24–32] Infants younger than 6 weeks of age with pulmonary hypertension have the highest mortality.

Outcomes of children infected with pertussis and admitted to intensive care units at 25 academic centers have been summarized. A total of 127 patients were identified; median age was 49 days and 105 patients (83%) were younger than 3 months old. Fifty-five patients (43%) required mechanical ventilation and 12 patients (9.4%) died during initial hospitalization. Pulmonary hypertension was found in 16 patients (12.5%) and was present in 75% of patients who died, compared with 6% of survivors ($P < .001$). Median white counts were significantly higher in those requiring mechanical ventilation ($P < .001$), those with pulmonary hypertension ($P < .001$), and nonsurvivors ($P < .001$). Age, sex, and immunization status did not differ between survivors and nonsurvivors. Fourteen patients (11%) received leukoreduction therapy (exchange transfusion [12], leukophoresis [1], or both [1]); survival benefit was not apparent.[33] Generally, children who survive pneumonia or pulmonary complications are left with no permanent lung damage.[34]

Neurologic Complications. Acute pertussis encephalopathy, generally occurring during the paroxysmal stage, is characterized by seizures and altered consciousness, and usually results from hypoxia or intracranial bleeding associated with paroxysmal cough. In a series of infants hospitalized with pertussis in Canada, seizures were seen in 21% of fatal cases but in none of the survivors.[35] A study in Denmark found that hospitalization for pertussis was associated with a 1.7-fold increase in risk of epilepsy at age 10 years.[36] Only limited data on the incidence of encephalopathy are available; estimates from population-based studies have ranged from 8 to 80 per 100,000 cases.[37,38] According to the Centers for Disease Control and Prevention (CDC), encephalopathy occurs in 0.4% of children younger than 12 months of age who are hospitalized with pertussis.[39] Approximately one-third of children with pertussis encephalopathy succumb to the acute illness, one-third survive with permanent brain damage, and one-third recover without obvious neurologic sequelae.[40]

Nutritional and Other Minor Complications. Nutritional deficiencies resulting from repeated vomiting can also be problematic. Inability to maintain adequate caloric intake in already malnourished children who develop pertussis is a particularly severe problem in developing countries.[41,42] Minor complications of pertussis include subconjunctival hemorrhages and epistaxis secondary to the paroxysms, edema of the face, and ulcers of the lingual frenulum resulting from protrusion of the tongue during paroxysms. Suppurative otitis media also occurs frequently, caused by the usual upper respiratory bacteria, not *B. pertussis*.

Adolescents and Adults

Complications of pertussis were reported in 18 (23%) of the 79 adult patients in one study.[18] These complications included otitis media (four patients), pneumonia (two patients), urinary incontinence (three patients), rib fracture (one patient), and severe weight loss (one patient). Telephone interviews of 314 adolescents and 203 adults with laboratory-confirmed pertussis in Massachusetts found that 100%

reported cough, which was paroxysmal for 74% and 84% of adolescents and adults, respectively; 77% and 84%, respectively, reported problems sleeping, 56% and 54% reported vomiting, 3% and 28% reported urinary incontinence, 33% of each group reported weight loss, 1% and 4% reported rib fracture, and 1% and 6% reported loss of consciousness.[43] Other known complications of pertussis in adults include triggering of migraines,[44] carotid artery dissection,[45] cough syncope,[46] and loss of memory.[47,48] Death from pertussis is rare in adolescents and adults, but it has been reported.[7,49,50]

Bacteriology

The causative agent of pertussis is *B. pertussis*, a small, Gram-negative, pleomorphic bacillus. Although the organism was identified before the turn of the 20th century in stained preparations of respiratory secretions and in pathology specimens from children with clinical pertussis,[51] the organism was not recovered in culture until 1906 by Bordet and Gengou.[3] The original culture medium, called Bordet-Gengou medium, is still used in some clinical laboratories, although more complex synthetic media are employed in many laboratories to grow this relatively fastidious organism. The antigens that *B. pertussis* produces are summarized below (see also Table 44.1).

Two other organisms in the genus *Bordetella* are *Bordetella parapertussis* and *Bordetella bronchiseptica*. *B. parapertussis* is responsible for a pertussis-like syndrome in humans, which usually is less severe than pertussis. *B. bronchiseptica* produces respiratory illnesses in domestic animals (e.g., kennel cough in dogs). These three species are very closely related genetically, and there is evidence that *B. pertussis* evolved from an ancestral strain of *B. bronchiseptica*.[52,53] Of all the *Bordetella* species, only *B. pertussis* synthesizes pertussis toxin (PT). Although the chromosomes of *B. parapertussis* and *B. bronchiseptica* contain the PT loci, they are transcriptionally silent because of defective promotors.[54,55] Some have suggested that the curious absence of descriptions of pertussis before the 16th century may represent the adaptation of an animal organism to humans as recently as 5 centuries ago.[52] However, the association of *B. pertussis* with humans may be more ancient than previously assumed.[56]

A *Bordetella* species first described in 1995, *Bordetella holmesii*, is associated with bacteremia, meningitis, endocarditis, pericarditis, pneumonia, arthritis, and respiratory illness with pertussis-like symptoms, mainly in asplenic and immunocompromised patients.[57–62] Infection with *B. holmesii* is frequently misidentified as being caused by *B. pertussis*, the cause of whooping cough, because routine diagnostic tests for pertussis are not species specific. Although no fatal cases of *B. holmesii* infection have been reported, secondary invasive infections caused by opportunistic organisms can cause substantial morbidities, even in previously healthy individuals. Antimicrobial treatment can be problematic because *B. holmesii* is less susceptible to macrolides (used empirically to treat pertussis) and third-generation cephalosporins (often used to treat invasive pulmonary infections). *B. holmesii*'s adaptation to human beings is continuing, and virulence might increase, creating a need for better diagnostic assays and epidemiological surveillance.[63]

Bordetella hinzii, a cause of respiratory disease in poultry, has been isolated from the blood of a patient with AIDS and from the respiratory secretions of a patient with cystic fibrosis.[64–66]

TABLE 44.1 Key Components of the *Bordetella pertussis* Organism

Component	Biological Activity
Pertussis toxin[a]	A secreted exotoxin that induces lymphocytosis, sensitivity to histamine, pancreatic islet cell activation, and immune enhancement
Filamentous hemagglutinin[b]	Involved in attachment to ciliated respiratory epithelium
Fimbriae[b]	Involved in attachment to ciliated respiratory epithelium
Pertactin[b]	An outer-membrane protein that promotes adhesion to ciliated respiratory epithelium
Adenylate cyclase	Inhibits phagocytic function
Tracheal cytotoxin	Causes ciliary stasis and cytopathic effects on tracheal mucosa
Dermonecrotic or heat-labile toxin	Causes dermal necrosis and vasoconstriction in animals
BrkA (*Bordetella* resistance to killing genetic locus, frame A)	An outer-membrane protein that mediates adherence and resists complement
Endotoxin	Contributes to fever and local reactions in animals and, probably, in humans

[a]Inactivated version is included in all current acellular pertussis vaccines.
[b]Inactivated version is included in some current acellular pertussis vaccines.

Key Components of the Organism

Pertussis Toxin. PT is a major contributor to the pathogenesis of pertussis and is generally believed to play an important role in the induction of clinical immunity. PT is an oligomeric structure composed of five different subunits, S1 through S5. Structurally, it belongs to the A-B class of bacterial toxins. The S1 component (A protomer) catalyzes the adenosine diphosphate ribosylation of guanosine triphosphate–binding regulatory proteins involved in signal transduction in the eukaryotic cell. The A protomer is largely responsible for the recognized biologic activities of PT, including promotion of lymphocytosis, stimulation of islet cells,[67] sensitization to histamines, clustering of Chinese hamster ovary cells, and heat-labile adjuvant properties. The B oligomer is a ring-shaped structure that consists of one copy each of subunits S2, S3, and S5, and two copies of S4. S5 serves to link the two dimers, S2-S4 and S3-S4.[68] The primary function of the B oligomer is to facilitate the attachment of PT to the ciliated cells of the respiratory tract.[69,70] The entire PT molecule is required for the enzymatic activities of the A protomer.[67,71] PT produced by different serotypes of *B. pertussis* appears to have a single biologic and serologic identity.[72] PT appears to play several major roles in the pathogenesis of pertussis, although the precise mechanisms are not entirely clear. First, it facilitates attachment of *B. pertussis* to ciliated respiratory cells. Second, it appears to contribute to cell toxicity. Third, it plays a role in enhancing respiratory tract colonization by inhibiting neutrophil and monocyte migration and delaying the induction of specific immune responses.[73] Thus, *B. pertussis* appears to have evolved a strategy to establish acute infection and extend the period of infectiousness, even in the face of antibody.[74–76] Interestingly, intravenous injection of substantial quantities of active PT into adult human volunteers caused no adverse effects.[77]

PT is a strong immunogen. Antibodies to it are associated with clinical immunity to pertussis, and many investigators believe these antibodies to be the most important mediators of clinical protection.[78] In the laboratory, antibodies to PT protect mice after intracerebral challenge with live *B. pertussis* (the mouse protection test) or after aerosol challenge.[67,79]

Studies in mice immunized with PT subunits or passively given monoclonal antibodies to PT and then challenged with pertussis have demonstrated that exposure to the entire molecule is required for optimal protection.[67,70,71,80] PT is chemically or genetically inactivated (toxoided) for incorporation into acellular pertussis vaccines. Chemical detoxification of PT, as opposed to genetic inactivation, alters the tertiary and quaternary structure of PT, thereby modifying the conformational epitopes. Postvaccination levels of serum antibodies recognizing clinically relevant epitopes may depend on the method of detoxification, with potential clinical implications.[81]

Many investigators have documented shifting prevalences of various PT and promoter region alleles, and in particular shifts away from the alleles contained in vaccines (both acellular and whole-cell),[82–87] but there is no convincing evidence that these changes have reduced vaccine effectiveness.

Filamentous Hemagglutinin. Filamentous hemagglutinin (FHA), a large, hairpin-shaped molecule, is synthesized as a 367-kDa precursor that is modified at both ends and cleaved to form the mature 232-kDa protein. In vitro studies suggest that FHA is an adhesin with four separate binding domains that facilitate binding to monocytes and macrophages, ciliated respiratory epithelial cells, and nonciliated epithelial cells.[88] Data suggest that FHA may also have an immunomodulatory function. The interaction of FHA with receptors on macrophages suppresses the proinflammatory cytokine interleukin (IL)-12 via an IL-10–dependent mechanism and results in persistence of the organism by curbing the protective T-helper cell type 1 (Th1) response.[89] FHA also stimulates proinflammatory and proapoptotic responses in human monocytes and respiratory epithelial cells.[90] Mutant organisms deficient in FHA adhere poorly in vitro.[88,91,92] Mice immunized with FHA are protected against lethal respiratory challenge with pertussis, but not against intracerebral challenge.[79,93] FHA is a strong immunogen, and serum antibodies to FHA are found after natural infection and after immunization. One review highlights that both FHA and fimbriae (FIM) play a critical role in adherence to respiratory epithelium and contribute to persistence in the lower respiratory tract during natural disease by modulating the host immune response.[94]

Fimbriae and Agglutinogens. *Bordetella* organisms express filamentous, polymeric protein cell-surface structures called FIM. Two serotypes of FIM, serotype 2 and serotype 3, are most commonly observed on clinical strains. Antibodies to the FIM agglutinate (clump) *B. pertussis* cells in a serotype-specific manner; for this reason, type 2 and type 3 FIM are considered important agglutinogens.[95] However, antibodies to other surface antigens, including lipopolysaccharide and pertactin, are also agglutinins. Accordingly, the terms FIM and agglutinogens should not be considered synonymous and should not be used interchangeably. More than a dozen agglutinogens are present on the cell envelope of *Bordetella*, and agglutinogen patterns differ among the three species. As many as eight are found in *B. pertussis*, six of which are unique to that species, but only agglutinogens 1, 2, and 3 are considered to be of importance in disease pathogenesis and immunity.

Serotyping *B. pertussis* on the basis of agglutination reactions has been useful in seroepidemiological studies; more recently, monoclonal antibodies to type 2 and type 3 FIM have been used for this purpose.[96] In vivo studies have shown that FIM-negative strains of *B. pertussis* are defective in their ability to multiply in the nasopharynx and trachea of mice.[97] *B. bronchiseptica* strains devoid of FIM but unaltered in expression of FHA and other putative adhesins are unable to colonize animal trachea.[98] Serum antibodies to the FIM are found almost universally after natural disease or immunization. There is accumulating evidence regarding the role of antibodies to FIM in clinical immunity. Data supporting such a role are that the efficacy of whole-cell pertussis vaccines appeared to be compromised in the absence of a match between the agglutinogens in the vaccine and those of prevalent *B. pertussis* strains.[99] There is some in vitro evidence of shifts in serotypes of *B. pertussis* on serial culture.[100]

There is also evidence that a change in serotype occurs during the course of clinical pertussis in some instances.[101] Seroepidemiologic data from the United Kingdom indicated that, between 1941 and 1953, the circulating strains of *B. pertussis* contained agglutinogens 1, 2, and 3. By 1968, however, 75% of isolated strains contained only agglutinogens 1 and 3.[102] There is suggestive evidence (but no proof) that this change resulted from the use of vaccines that contained relatively little agglutinogen 3.[101,103,104] One product that contained considerable agglutinogen 3 was far more effective than the others in preventing pertussis during this time. Subsequent manufacturing changes that incorporated more agglutinogen 3 resulted in higher clinical efficacy.[101] It is, of course, possible that serotype differences are markers for some other antigenic differences in strains of *B. pertussis;* however, the biologic activities of PT from different serotypes of *B. pertussis* did not appear to differ.[72]

Antibody to fimbrial proteins (FIM) appears to be strongly correlated with protection from clinical disease, based on the results of household contact studies among humans,[105] mouse model studies,[106] and in vitro investigations.[107] Because of the evidence that the agglutinogens play some role in the induction of clinical immunity to pertussis, the WHO has recommended that whole-cell pertussis vaccines contain FIM types 2 and 3.[108,109]

Pertactin. Pertactin (PRN), originally known as the 69-kDa protein, is a surface-associated protein that is exported to the outer membrane, where it undergoes proteolytic cleavage.[110] Similar proteins are produced by *B. parapertussis* and *B. bronchiseptica*.[111] PRN participates in attachment through its arg-gly-asp motif to facilitate eukaryotic cell binding[111–113] and invasion,[114] and is recognized as one of the nonfimbrial agglutinogens. PRN is highly immunogenic. Antibodies to it are found after natural disease and immunization with vaccines containing this protein.[115,116] Mice that have been protected passively with antibodies to PRN are highly resistant to an otherwise fatal aerosol challenge with virulent *B. pertussis*.[117] However, in the intracerebral mouse protection test, mice immunized with PRN are protected only when also immunized with FHA.[111]

Studies from The Netherlands show that genetic variations in PRN (and PT) molecules exist, with a shift over time in the circulating strains toward variants not represented in the pertussis vaccines used in the community.[118] Subsequent mouse-model studies show that the Dutch whole-cell pertussis vaccine is less effective against some PRN variants than others. In contrast, a study from France indicates that, despite lyophilization, multiple Sanofi Pasteur whole-cell vaccine lots stored since 1984 had conserved genomes and still expressed the major toxins and adhesins.[119] Studies from the same investigators confirmed that the vaccine lots were highly immunogenic in mice.[120] Additional studies from other geographic areas have been performed to determine whether selection pressure may have contributed to variation in the PRN molecule, leading to less-effective vaccines.[121,122] A study from Sweden evaluating pertussis strains from 1970 to 2003 found no evidence of a reduction in the effectiveness of the vaccination program as a result of bacterial polymorphism.[123] *B. pertussis* isolates not expressing PT or PRN were detected for the first time in 2007 in France, a country with widespread use of

acellular vaccines. Nonexpression was the result of deletion of the entire *ptx* locus, insertion of IS481 in the *prn* gene, or deletion of a part of the *prn* gene. These isolates were found to be less pathogenic in animal and in vitro models.[124]

A recent study evaluated *B. pertussis* isolates collected from four Australian states during a pertussis outbreak from 2008 through 2010. A total of 194 organisms were typed by single-nucleotide polymorphism analysis; multilocus variable number tandem repeats analysis; and fim3, prn, and ptxP sequence analyses. Results suggested increasing selective pressure favoring alleles not contained in the acellular pertussis vaccines used in Australia.[87] Another report from Australia found that 96 (30%) of 320 *B. pertussis* isolates collected from 2008 to 2012 did not express PRN. Multiple mechanisms of PRN inactivation were documented, including IS481 and IS1002 disruptions, a variation within a homopolymeric tract, and deletion of the PRN gene. These findings suggest that PRN-deficient *B. pertussis* arose independently multiple times, rather than representing expansion of a single PRN-negative clone. This pattern is consistent with continuing evolution of *B. pertussis* in response to vaccine selection pressure.[125]

Studies from other countries have also demonstrated an increasing prevalence of PRN-deficient *B. pertussis* isolates in countries using acellular pertussis vaccines targeting this virulence factor.[82,83,126–129] Laboratory studies in mice demonstrate that isolates not producing PRN are capable of sustaining longer infection as compared to PRN-producing isolates, which might thereby provide a selective advantage to PRN(−) strains.[126]

A newer study evaluated the emergence of PRN-deficient isolates in six European countries. From 2007 to 2009, very few isolates were PRN-deficient; prevalence increased in the Netherlands and Sweden from 2010 to 2012. The PRN-deficient isolates were genetically diverse and different mutations were found to inactivate the PRN gene, suggesting that PRN deficiency was subject to positive selective pressure.[127]

The prevalence of PRN-deficient *B. pertussis* has increased sharply in the United States. Screening of 1300 isolates from outbreak and surveillance studies (historical isolates collected from 1935 to 2009, isolates from the 2010 California pertussis outbreak, U.S. isolates from routine surveillance between 2010 and 2012, and isolates from the 2012 Washington pertussis outbreak) identified 306 PRN-deficient isolates. The prevalence of PRN-deficient isolates increased to more than 50% of collected isolates in 2012. Sequence analysis of PRN-deficient isolates revealed various types of mutations in the PRN gene, including two deletions, single nucleotide substitutions resulting in a stop codon, an inversion in the promoter, and a single nucleotide insertion resulting in a frame-shift mutation.[128] The prevalence of PRN-deficient *B. pertussis* has continued to increase since 2012; of 753 isolates collected from eight U.S. states between May 2011 and February 2013, 640 (85%) were PRN-negative. Patients infected with PRN-producing strains were significantly younger (more likely to be an infant or young child), more likely to report apnea, and more likely to be hospitalized (6% in the PRN-producing group compared to 3% in the PRN-deficient group). Case-patients having received at least one pertussis vaccine dose were twice as likely to have PRN-deficient *B. pertussis* compared with unvaccinated case-patients (adjusted odds ratio [OR] = 2.2; 95% confidence interval [CI], 1.3–4.0). For appropriately vaccinated case-patients at least 1 year of age, the adjusted OR increased to 2.7 (95% CI, 1.2–6.1).[129] Taken together, these data suggest that loss of PRN may confer selective advantage, while possibly decreasing clinical severity modestly.

There has been concern that the effectiveness of PRN-containing acellular pertussis vaccines might be reduced against PRN-deficient strains. However, the most recent vaccine effectiveness data from the CDC found that the effectiveness of acellular pertussis vaccine against PRN(−) and PRN(+) strains did not significantly differ.[130] It should be noted that these data were obtained in the United States, where children receive acellular pertussis vaccines containing PT, FHA, and PRN or PT, FHA, PRN, and FIM2–3. Different results might be obtained in countries using different vaccines containing fewer pertussis antigens.

All acellular pertussis vaccines developed through 2016 contain one or more of the bacterial components discussed above (PT, FHA, PRN, and FIM); none contain any of the components described below.

Adenylate Cyclase. Adenylate cyclase toxin (ACT) is a large molecule with different functional domains, including an adenylate cyclase enzyme and a hemolysin, responsible for the hemolysis observed around *B. pertussis* colonies on solid media containing blood. The toxin, present in all virulent strains of *B. pertussis,* is synthesized as a protoxin monomer that is cleaved into an active molecule, allowing it to enter a variety of eukaryotic cells. Once inside the cell, it is activated by calmodulin and catalyzes the production of large quantities of cyclic adenosine monophosphate (AMP). Purified adenylate cyclase inhibits chemotaxis, chemiluminescence, and superoxide anion generation by monocytes and neutrophils in vitro, and in vivo it augments production of cyclic AMP from adenosine triphosphate in the phagocyte, resulting in an excessive accumulation of cyclic AMP and paralysis of the various phagocytic functions.[55,131] Studies show that macrophage cytotoxicity may also result from the induction of apoptosis, and not solely from accumulation of cyclic AMP.[132] In vivo studies show that, compared with wild-type organisms, mutants in adenylate cyclase are defective in their ability to cause lethal infection. These findings suggest that adenylate cyclase serves as an antiinflammatory and antiphagocytic factor during infection. In the mouse model of aerosol infection, PT and adenylate cyclase appear to be the two most important virulence factors.[133]

Adenylate cyclase is immunogenic.[134] Mouse models of intracerebral and aerosol challenge show that prior active immunization with adenylate cyclase is similar in protective efficacy to whole-cell vaccine.[135] In addition, these models show that adenylate cyclase antibodies interfere with the multiplication of organisms.[135] Mills and colleagues also showed that adenylate cyclase promotes innate IL-1β production via activation of the NALP3 (Natch domain, leucine-rich repeat, and PYD-containing protein 3) inflammasome and, thereby, polarizes T-cell responses toward the Th17 subtype, which promotes clearance of the bacteria from the respiratory tract.[136]

ACT is not included in any current acellular pertussis vaccines because of protein stability issues and uncertainty regarding the benefit of its inclusion. Wang and colleagues immunized mice with ACT and found that the majority of resulting unique antibodies bound the C-terminal repeat-in-toxin (RTX) domain. Sera from mice immunized with the RTX domain showed similar neutralizing activity as ACT-immunized mice,[137] suggesting that RTX may present an alternative to use of the entire ACT molecule as a vaccine candidate.

Tracheal Cytotoxin. Of the virulence factors produced by *Bordetella* organisms, only tracheal cytotoxin induces paralysis and destruction of respiratory ciliated epithelium, the hallmark of pertussis disease. Tracheal cytotoxin is a fragment released from the peptidoglycan of the *B. pertussis* cell wall.[138,139] Its activities were studied in vitro in tracheal organ and cell cultures and found to induce mitochondrial bloating, disruption of the tight junctions, extrusion of the ciliated epithelial

cells, and little or no damage to the nonciliated cells.[55] There is also evidence to suggest that this cytopathology is the result of tracheal cytotoxins increasing the production of nitric oxide, which diffuses into ciliated cells, causing cell death.

Heat-Labile Toxin. Heat-labile toxin, so called because it is inactivated at 56°C, is also known as the dermonecrotic or mouse-lethal toxin because of its effects in experimental animals.[140] It is produced by all virulent *Bordetella* species. Located intracellularly, it can be recovered by disruption of *B. pertussis* cells. The mechanism of production of cutaneous lesions after injection of the toxin in animals appears to be vasoconstriction.[141] Heat-labile toxin is lethal to mice when injected intravenously. The role, if any, of heat-labile toxin in the pathogenesis of pertussis is unknown. No consistent effects on cells have been recognized in vitro. It is a weak immunogen, antibodies to it are nonprotective in animal challenge tests, and its absence does not diminish the lethality of experimental pertussis infection in mice.[133]

BrkA. BrkA (which stands for *Bordetella* resistance to killing genetic locus, frame A), another outer membrane protein of *B. pertussis* similar in structure to PRN, protects the bacterium against classical-pathway, complement-mediated killing.[142,143] It is ubiquitously expressed by highly prevalent clinical isolates of *B. pertussis*, and antibodies to BrkA augment killing of *B. pertussis*.[144] Although increased susceptibility to complement during acute bacterial growth would seem to mark the organism for elimination, antibody is needed for classical complement activation. Antibody after a primary infection takes some time to develop, and rapid multiplication might arise before killing could occur. In contrast to the primary infection, if antibody has already been stimulated by natural disease or vaccine, a secondary response can be generated rapidly and killing might occur. This may explain why pertussis tends to be a milder disease after vaccination or after earlier natural infection.[145] Vaccination of mice with BrkA alone does not protect against *B. pertussis* challenge. However, the protection provided by vaccination with a combination of PT, FHA, and BrkA is comparable to that afforded by a combination of PT, FHA, and PRN. As PRN and BrkA are similar in structure, they seem to confer comparable protection in the mouse model when combined with other pertussis antigens.[146]

Endotoxin. The endotoxin or lipopolysaccharide of *B. pertussis* exhibits many of the in vivo activities of endotoxins produced by other Gram-negative organisms, but its role in pathogenesis or in recovery is unclear.[147] Organisms with incomplete endotoxin production have shown decreased colonization of the respiratory tract in the mouse model,[148] and monoclonal antibodies to lipopolysaccharide are protective in the mouse model.[149] The endotoxin content of whole-cell vaccines may have contributed to the immediate adverse systemic and local reactions to those vaccines.[150]

Pathogenesis

Current knowledge of the components of *B. pertussis* and their actions permits construction of a reasonable hypothesis regarding the pathogenesis of whooping cough in humans.[55,151,152] *B. pertussis* overcomes the mucosal immune defenses of the upper respiratory tract and causes disease in healthy persons. The organisms have a marked tropism for, and attach strongly to, the ciliated cells through several adhesins. Although PT and FHA are important attachment proteins, fimbrial proteins, PRN, and BrkA participate in this process as well.[88,91,110,152–154] The organism can be internalized by the epithelial cells but generally does not penetrate submucosal cells or invade the bloodstream. Toxins produced by the organism enter the bloodstream and produce systemic effects.

PT, adenylate cyclase, and BrkA have marked effects on host immune function.[131,142,153,155] Adenylate cyclase induces production of high levels of cyclic AMP, disrupting the functions of several cell types of the immune system; PT inhibits chemotaxis of phagocytic cells into the site of inflammation; and BrkA protects the bacterium against classical complement attack.[142] Tracheal cytotoxin and heat-labile toxin are probably involved in the damage to the tracheobronchial epithelium that is so characteristic of the disease.[139,140] The successful persistence of pertussis appears to result from its ability to interfere with almost every aspect of the immune system, from the inhibition of complement- and phagocyte-mediated killing to the suppression of T- and B-cell responses.[156,157]

Although this pathogenic sequence may explain the respiratory manifestations of pertussis, the pathogenesis of the encephalopathy that can complicate clinical disease remains unclear.[158] Suggested pathogenic mechanisms have included anoxia secondary to severe paroxysms, metabolic disturbances, hypoglycemia, minute intracranial hemorrhages,[158] or a direct toxic effect on the brain.[159]

Animal Models

One of the greatest challenges in studying the pathogenesis of pertussis has been the development of animal models that accurately reflect human disease. Most laboratory animals do not cough and are not naturally infected with *B. pertussis*. However, the availability of many genetically distinct mouse strains and a wealth of mouse-specific reagents have made mice a commonly used model. Although mouse models do not mimic classical whooping cough disease, they have provided valuable insights into the importance of several virulence factors, the roles of various host immune factors in controlling infection, and the potential efficacy of vaccines.[160,161] Early studies in the murine respiratory infection model demonstrated that humoral immunity alone was not sufficient to confer protection against *B. pertussis* infection and that T-cell immunity was also required.[162] Using mice with targeted disruptions of the interferon gamma (IFN-γ) receptor, IL-4, or immunoglobulin heavy-chain genes, Mills and colleagues demonstrated an absolute requirement for antibody in bacterial clearance and a critical role for IFN-γ in immunity generated by previous infection or immunization with the whole-cell pertussis vaccine.[160] Passive immunization experiments suggested that protection early after immunization with acellular pertussis vaccines was mediated by antibody against multiple protective antigens. In contrast, more complete protection was conferred by previous infection or immunization with the whole-cell pertussis vaccines than with acellular vaccines and reflected the induction of Th1 cells.

Suckling pigs have also been used to model infant pertussis. The inoculation of *B. pertussis* into their lungs results in low-grade fever, mild cough, lymphocytosis, and pneumonia.[163] The administration of passive antibody to the piglets provides protection from pertussis challenge, mimicking the role of maternal antibody in disease prevention.[164,165]

Rodents, rabbits, and swine are not natural hosts for *B. pertussis* or *B. parapertussis*, but they are frequently infected with *B. bronchiseptica*. Because of the close phylogenetic relationships between all three of these subspecies and the conservation of many known virulence factors, several groups have used natural *B. bronchiseptica* infection in these animals to study features of pathogenesis that are common to all three organisms.[166,167] These models have revealed roles for several conserved virulence determinants and regulatory factors and

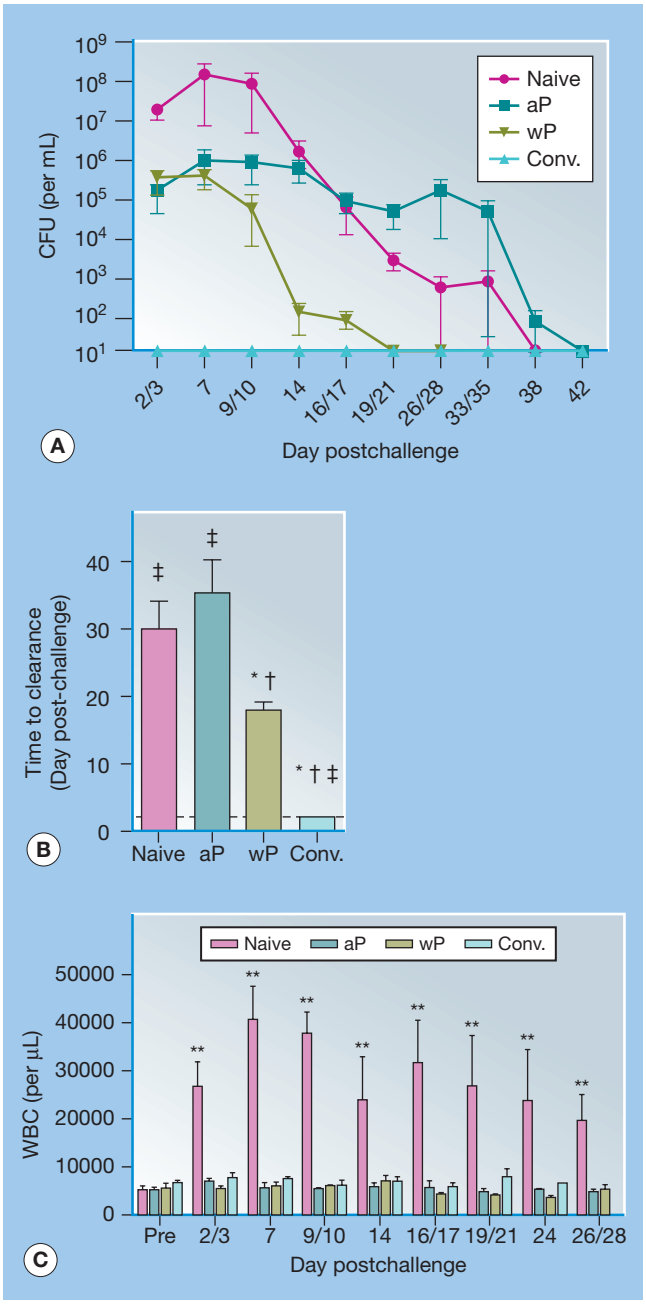

Figure 44.1. Effect of vaccination or convalescence on colonization and leukocytosis among challenged baboons. Naïve animals, acellular pertussis (aP)-vaccinated animals (half given Daptacel, half Infanrix), whole-cell pertussis (wP)-vaccinated animals, and previously infected (convalescent [conv.]) animals were directly challenged with *B. pertussis* (n = 3–4 per group). **A,** Colonization was monitored by quantifying *B. pertussis* cfu per mL in biweekly nasopharyngeal washes with a limit of detection of 10 colony-forming units (CFU) per mL. For each animal the time to clearance is defined as the first day that no *B. pertussis* CFU were recovered from nasopharyngeal washes. **B,** The mean time to clearance is shown for each group (n = 3 per group). Because no *B. pertussis* organisms were recovered from the convalescent animals, the mean time to clearance was defined as the first day of sampling (day 2, indicated by the dashed line). *P < .05 vs naïve; †P < .05 vs aP; ‡P < .05 vs wP. **C,** The mean circulating white blood cell counts before and after challenge are shown for each group of animals (n = 3–4 per group). **P < .01 vs preinfection from same group. *(From Warfel JM, Zimmerman LI, Merkel TJ. Acellular pertussis vaccines protect against disease but fail to prevent infection and transmission in a nonhuman primate model.* Proc Natl Acad Sci U S A. *2014;111:787–792.)*

have also shown that several factors are functionally interchangeable between *B. pertussis* and *B. bronchiseptica*.[157,168–170]

The most exciting advance in modeling human pertussis has been the development of the baboon (*Papio anubis*) model.[171] Administration of *B. pertussis* into the nasopharynx of weanling baboons results in low-grade fever, paroxysmal cough, lymphocytosis, stimulation of PT-specific antibodies, and protection from subsequent pertussis challenge. This model has also facilitated the study of transmission of the pertussis organisms through direct contact or aerosol spread.[172,173] Baboons vaccinated with acellular pertussis vaccine (half given Daptacel, half Infanrix) and subsequently challenged with *B. pertussis* were protected from clinical illness but were still able to transmit disease to susceptible baboons caged nearby (Fig. 44.1).[173] These studies clearly show that acellular pertussis (aP) vaccination provides protection against the development of disease but not against colonization or transmission of organisms to other baboons, suggesting that asymptomatic humans immunized with aP vaccine might similarly be capable of transmitting pertussis to susceptible infants and children. This model has great appeal for the further investigations of the mechanisms of transmission and disease and for the testing of new vaccines and therapeutic drugs. In addition, carefully monitored human pertussis challenge studies also have been proposed to further the understanding of the pathogenesis of pertussis and the extent of protection afforded by aP vaccines.[165]

Modes of Transmission; Carriage

Transmission occurs when airborne bacteria reach the ciliated respiratory epithelium of a susceptible host. It was traditionally believed that transmission occurred only from symptomatic patients, and that chronic carriage did not occur.[174] However, silent transmission within families has been demonstrated[21] and the baboon model has shown that asymptomatic animals can efficiently spread infection. Further evidence supporting the applicability of this finding to humans is provided by outbreak reports within populations with prolonged close contact that found case-detection rates using sensitive polymerase chain reaction (PCR) assays to be very high, yet many "cases" identified by PCR were vaccinated, did not have classic pertussis symptoms, and experienced little morbidity. The authors reporting one such outbreak concluded that "a positive PCR result might simply have reflected transient nasopharyngeal carriage of *B. pertussis*."[175] In an outbreak among Israeli soldiers, 20% of those who were either asymptomatic or previously symptomatic but now healthy were PCR-positive for *B. pertussis*.[176]

Zhang and colleagues performed a cross-sectional study in four disparate provinces of China involving 629 schoolchildren 7 to 15 years of age. The study was conducted during the summer school break, none of the surveyed areas were experiencing known pertussis outbreaks, and all participants were asymptomatic. Of the 629 participants, two (0.3%) were culture-positive and 30 (4.8%) were PCR-positive for *B. pertussis*; for *B. parapertussis*, the corresponding results were one (0.2%) and 13 (2.1%), respectively. *B. holmesii* was not detected.[177] The extent to which these results can be generalized to other populations is unknown, absent additional

studies of the incidence, prevalence, or duration of *B. pertussis* carriage. However, these and other[178,179] studies make it clear that, contrary to traditional belief, *B. pertussis* carriage can occur and may play an important role in transmission, as suggested by the baboon model.

Diagnosis

The etiologic agent responsible for an infectious disease is generally determined by culture of the organism, detection of antigens or nucleic acids produced by the organism, or measurement of the immune response to the organism. Even when using all these criteria, the confirmation of *B. pertussis* infection is still one of the most difficult diagnostic challenges facing the clinician, particularly in previously immunized adolescents and adults. Pertussis organisms can typically be detected by culture or PCR of nasopharyngeal specimens obtained early in the illness and prior to antibiotic therapy, when the symptoms are similar to those of the common cold (and thus not likely to trigger specimen collection, except in an outbreak setting). By the time of appearance of a cough severe enough to arouse suspicion of pertussis, nasopharyngeal organisms have typically decreased in number to the point where cultures and non-PCR antigen detection methods are unlikely to be positive. The sensitivity of PCR can be sufficient to permit detection for several weeks into the illness, but detection in low copy number may represent a clinical false positive from environmental contamination from vaccine strains or other bacterial strains.[180]

Bacteriologic Diagnosis

Culture. Culture of *B. pertussis* from the nasopharynx of symptomatic patients is compelling evidence of disease and remains the gold standard for laboratory diagnosis.[181,182] The greatest likelihood of isolating the organism is achieved by immediate inoculation of a nasopharyngeal aspirate specimen obtained early in the illness onto fresh media in a laboratory experienced with handling *B. pertussis*. At best, these conditions are difficult to meet, but even under optimal circumstances, the organism is frequently not recovered because of its fastidious nature and its disappearance early in the disease process.[183–187]

Because the human nasopharynx is colonized with many other respiratory bacteria, the use of selective media containing antibiotics such as cloxacillin and cephalexin will increase the yield of positive pertussis cultures by suppressing normal flora.[185] Two media are specialized for pertussis cultures: Bordet-Gengou medium, containing defibrinated horse blood and cloxacillin; and Regan-Lowe medium, containing charcoal agar, defibrinated horse blood, and cephalexin. The latter medium may provide better yield,[188] although some have found no difference.[185] Direct plating of the specimen at the bedside or clinic has been shown to increase the yield of positive cultures, but Regan-Lowe transport medium can be used if plated by 72 hours after inoculation.[187]

It has been shown that nasopharyngeal aspirates yield better samples than nasopharyngeal swabs; Dacron swabs are better than calcium alginate because the latter inhibit PCR assays, and cotton swabs are toxic to the bacteria.[182] Incubation of the cultures for at least 7 days can increase the yield. As noted, however, "although the culture is the gold standard for the diagnosis of pertussis, its diagnostic sensitivity is insufficient even when technical conditions are optimal."[182]

Prior therapy with erythromycin or sulfamethoxazole reduces the likelihood of positive cultures. Immunized persons with pertussis have lower rates of positive cultures than unimmunized control subjects, and isolation rates are negatively correlated with increasing age,[189] further complicating the diagnosis of pertussis in partially or fully immunized adolescents or adults.

Antigen Detection: Direct Fluorescent Antibody Test and Polymerase Chain Reaction. Antigen detection tests offer the distinct advantage that organisms do not have to be viable and can be detected later in the disease and in the presence of antibiotics. The initial antigen detection test was the direct fluorescent antibody (DFA) test, which in experienced laboratories had a specificity of 99.6%, but its sensitivity was only 61% when compared with culture.[182,185,186,190–192] The development of highly sensitive and specific PCR assays have made the DFA test obsolete.

PCR assays identify unique gene sequences of various *Bordetella* species in respiratory secretions.[185,186,193–199] Although demanding of scrupulous technique to avoid cross-contamination, this rapid, highly sensitive, and specific diagnostic method has become the standard tool for laboratory identification of pertussis and permits identification of *B. pertussis* after initiation of antibiotics[200] and for several weeks later than possible by culture. However, the use of PCR must be coupled with rigorous quality-assessment programs supported both by appropriate epidemiologic investigations of suspected outbreaks and by an ongoing culture-confirmation program to which a selected subset of specimens is submitted.[201] False-positive results can arise through a variety of mechanisms, including poor technique in sampling, transport, or assay; environmental contamination with bacterial DNA (including from nearby use of vaccine); and poor choice of target.[175,180,197–199,202–206] Thus, it is important that disease categorization be based on appropriate clinical case definitions[207] and not merely on PCR positivity alone.

Numerous PCR assays have been developed, and the continued rapid evolution of this field makes a detailed review inappropriate here. However, a few principles can be delineated. Although nasopharyngeal aspirates are preferred for culture specimens of infants, Dacron or rayon nasopharyngeal swabs perform equally well for PCR for older children, adolescents, and adults and may be transported dry.[199] PCR assays typically target either specific genes or various insertion sequences; those targeting insertion sequences typically offer better sensitivity.[199] Available multiplex PCR assays that detect a variety of organisms from a single specimen often target only the IS481 sequence; the current preference for epidemiological and clinical purposes is to target two or three repeated insertion sequences (including IS481, pIS1001, hIS1001, or IS1002) to increase specificity and allow for discrimination among clinically relevant *Bordetella* species.[199,203,204]

Serologic Diagnosis

Serologic tests for antibodies to various components of the *B. pertussis* organism have been used extensively to diagnose pertussis in children, adolescents, and adults.[182,185,190,208–210] Serologic testing has improved our understanding of the clinical spectrum of pertussis, particularly by demonstrating asymptomatic, mild, or atypical infections in partially immune persons.[21,211–213] Serosurveys have been used to examine the natural history of pertussis in populations at various ages,[214–223] and they have been useful in monitoring pertussis during regional outbreaks.[224] They have also been helpful in monitoring clinical outcomes in pertussis vaccine trials, because partially immune persons may experience pertussis infection but display few or no symptoms.[189] Finally, serologic studies have enabled an understanding of the role of pertussis in the etiology of cough illness in adolescents and adults.[225,226] Serologic tests include complement

TABLE 44.2 Adolescents and Adults[a] with Prolonged Cough Illness (7–56 Days) Who Met Various Case Definitions for Laboratory Confirmation or Evidence of Pertussis

Case Definition	Criterion	No. Positive/ No. Tested	Prevalence, % (95% CI)	Mean Age, Years (Range)
1	Culture positive for *Bordetella pertussis*	2/440	0.5 (0.1–1.8)	18.4 (12.6–24.1)
2	PCR positive for *B. pertussis*	3/314	1.0 (0.2–3.0)	24.0 (12.6–37.8)
3	Fourfold increase in antibody titer	7/393	1.8 (0.8–3.8)	28.1 (12.3–70.6)
4	Antibody titer, >99.99 percentile for control values	36/440	8.3 (5.9–11.2)	36.6 (14.1–69.4)
5	Antibody titer, >3 SDs greater than GMT for control subjects	84/440	19.1 (15.6–23.0)	39.0 (12.3–87.7)

[a]Includes all subjects with at least one biological specimen.
CI, confidence interval; GMT, geometric mean titer; PCR, polymerase chain reaction; SD, standard deviation.

fixation, agglutination, toxin neutralization, and enzyme-linked immunosorbent assays (ELISAs),[185] but ELISA methods are used most frequently because they are the easiest to perform and standardize and they can detect specific isotype responses. Considerable effort has been expended to develop a standardized ELISA method that can be used in the evaluation of vaccine candidates and in the diagnosis of pertussis disease.[227–233]

The most conclusive serologic evidence of an infection is the demonstration of a significant rise in specific antibodies between the acute and convalescent samples. However, pertussis presents a problem because the diagnosis is often not considered early in the course of the disease; by the time it is, a substantial rise in serum antibodies has already occurred, thus compromising the likelihood of a significant increase between the acute and convalescent serum specimens. Indeed, it has been demonstrated that fourfold decreases in antibody between the "acute" and convalescent specimens can also be seen with culture-confirmed pertussis.[210] An approach that avoids this problem of specimen timing is based on comparing the result of a single serum specimen to a prespecified threshold.[211–214,234–238] Typically, the threshold is determined by assay of sera from a control population not suspected to have pertussis and is set to a value that exceeds the mean of the control population by a selected factor (typically, two or three standard deviations). This approach has been followed both in studies[211–214] and for public health purposes.[222,234,235] For many years, the Massachusetts Department of Public Health Laboratory has provided a single-sample pertussis serology assay with a specific cutoff value to diagnose pertussis in adolescents and adults[234] and CDC notes that "CDC and FDA [U.S. Food and Drug Administration] have developed a serologic assay that has been extremely useful for confirming diagnosis, especially during suspected outbreaks. Many State Public Health Labs have included this assay as part of their testing regimen for pertussis."[235]

In an attempt to standardize the serologic assays, a WHO reference preparation for human pertussis serology was made available and used by a number of pertussis laboratories throughout the world.[232] Several reports have recommended that for single-sample serology, immunoglobulin (Ig) G–anti-PT antibodies below 40 IU/mL are not indicative of recent contact, whereas levels above 100 IU/mL can be used as an indicator of recent contact with the bacteria.[239,240] IgG–anti-PT antibodies are primarily measured, with IgA–anti-PT serving as an additional test for equivocal IgG results (IgG >40 and <100 IU/mL). A 2010 study found commercial assays to be of variable quality and in need of further standardization.[241] However, in 2015 good agreement was reported between two commercial laboratories in the United States and the CDC laboratory, and between U.S. Public Health laboratories and the CDC.[242–244]

The choice of case definition, including clinical, laboratory, and epidemiological criteria, strongly influences the number of subjects diagnosed with pertussis and thus estimates of pertussis disease prevalence. The effect of laboratory criteria is illustrated by the study of Senzilet and colleagues,[16] who enrolled patients 12 years of age or older with persistent cough of 1 to 8 weeks' duration from nine health units in eight Canadian provinces. Only two cases were diagnosed by positive culture, and three additional cases were detected with PCR. When serologic measures were used, seven had a fourfold rise in titer between the acute and convalescent samples, but 36 persons had a single antibody titer that exceeded the 99.99th percentile for controls, and 84 had single antibody titers that exceeded three standard deviations from that of the control subjects. As shown in Table 44.2, the calculated prevalence of pertussis disease in this population was highly dependent on the case definition.[16] The complexities of assigning case definitions have been comprehensively reviewed.[244]

A somewhat different problem is presented by the use of serologic testing to detect pertussis in field trials of pertussis vaccine. Given the different serologic methods used among the various efficacy studies, direct comparisons of efficacy rates between such studies should be made with caution.[245] Another concern with serologic diagnosis is that, although it may be appropriate for nonimmunized control subjects, detection of antibody increases may be compromised in those who were recently immunized, because immunization itself leads to increases in antibody titers. In this situation, the evaluation of antibodies against an antigen of *B. pertussis* that was not included in the vaccine can be useful, if an appropriate antigen and assay exist. This was particularly helpful in the efficacy trials with the monovalent PT vaccine in Sweden, where antibody responses to other pertussis antigens could be used to detect pertussis infection in recipients of the monovalent vaccine.[246]

Treatment and Prevention With Antibiotics

Guidelines for the treatment and postexposure prophylaxis (PEP) of pertussis exist.[247,248] The central tenets of these guidelines are that the administration of macrolides early in the course of illness will reduce the duration and severity of symptoms, lessen the infectivity, and reduce the risk of death and that the judicious use of antimicrobial agents for PEP will eradicate *B. pertussis* from the nasopharynx of symptomatic or asymptomatic persons.[4,15,247–256] Although many persons with untreated pertussis will spontaneously clear *B. pertussis* by 3 to 4 weeks after the onset of cough, untreated and

unvaccinated infants can remain culture positive for 6 weeks or even longer.[257,258,258a] Erythromycin, a macrolide antibiotic, was originally the antimicrobial of choice for treatment or prophylaxis of pertussis, but it has unpleasant gastrointestinal side effects and has largely been supplanted by azithromycin, with reduced side effects.[259–261] For both treatment and PEP, the standard therapy is a 5-day course of azithromycin.[247,248,262] For persons intolerant of macrolides and older than 2 months, trimethoprim-sulfamethoxazole is the alternative agent.

Among young infants, erythromycin poses a risk of infantile hypertrophic pyloric stenosis (IHPS), but azithromycin has also been implicated.[263–265] In a study using the military health system database, medical records of infants born between 2001 and 2012 who were prescribed either oral erythromycin or azithromycin as outpatients in the first 90 days of life were screened for evidence of IHPS. Of 1,074,236 treated children, 2466 developed IHPS. The adjusted ORs for developing IHPS following erythromycin or azithromycin exposure in the first 14 days of life were 13.3 (95% CI, 6.80–25.9) and 8.26 (95% CI, 2.62–26.0) respectively; exposure between 15 and 42 days of life had adjusted ORs of 4.10 (95% CI, 1.69–9.91) and 2.98 (95% CI, 1.24–7.20), respectively. There was no association with IHPS for either macrolide between 43 and 90 days of life.[265] Accordingly, all infants younger than 1 month (and preterm infants until a similar postconceptional age) treated with a macrolide should be monitored for development of IHPS from initiation until 1 month after completion of therapy.[248]

Whether to administer PEP should be determined on the basis of the infectiousness of the patient, the duration and intensity of the exposure, the consequences of pertussis in the exposed person, and the possibility of contact with persons at high risk for severe pertussis, such as young infants. PEP given to asymptomatic household contacts within 21 days of onset of cough in the index patient can prevent symptomatic infection. Symptomatic contacts should be treated as if they have pertussis. PEP also should be administered in exposure settings that include infants younger than 12 months or women in the third trimester of pregnancy. A recent cost utility analysis suggested that PEP is a cost-effective strategy compared with no intervention and plays an important role in contact management.[266] From a healthcare payer perspective, azithromycin therapy had the most beneficial health outcomes among all age groups and was also the lowest-cost strategy among infants; accordingly, azithromycin therapy was recommended as the optimal therapy for all contact groups.[266]

One final concern with the use of macrolides, and particularly erythromycin, is antibiotic resistance. Erythromycin resistance was first recognized in Arizona in 1994.[267] Since then, additional erythromycin-resistant and even azithromycin-resistant isolates have been reported and new mutations described.[268–273] Resistance in some areas is high; investigators in Xi'an, China, found 14 of 16 isolates to have minimum inhibitory concentrations of greater than 256 μg/mL.[273] However, resistance appears to remain rare in Europe and North America.[274,275]

In summary, macrolides are recommended for both therapy and PEP of household and other close contacts, regardless of vaccination status, and for healthcare workers with a known or likely exposure to pertussis.[276–278] Prophylaxis reduces, but does not eliminate, the risk of pertussis.[279,280] Prophylaxis in a household is substantially more effective if given before the appearance of the first secondary case.[280] Cases and inadequately vaccinated contacts younger than 7 years should be excluded from school, daycare, and similar settings until they have received at least 5 days of prophylaxis or therapy.[276]

EPIDEMIOLOGY

Pertussis is an endemic disease with epidemic peaks occurring every 2 to 5 (typically, 3 to 4) years.[6,281–283] There is no consistent seasonal pattern.[282–288] Pertussis is acquired through transmission of large respiratory droplets generated by coughing or sneezing. Transmission by the indirect route from airborne droplet nuclei or organisms on fomites or in dust occurs extremely rarely, if ever. Persons are most infectious during the catarrhal phase and the early paroxysmal phase. Whooping cough is highly contagious: as many as 90% of susceptible household contacts acquire the disease. Rates of transmission in school settings range from 50% to 80%. Pertussis may occur at any age. Infants are susceptible to pertussis within the first few weeks or months of life, which is when mortality is highest. For many years, it was assumed that one attack of pertussis provided lifelong immunity. Before widespread vaccination, this belief was reflected by the age distribution of pertussis: approximately 20% of all whooping cough cases occurred in infants younger than 1 year, and nearly 60% occurred among children of ages 1 to 4 years.[286] However, anecdotal information indicated that second attacks of pertussis did occur in the prevaccine era, such as in older persons exposed to grandchildren with the disease, although these instances were rarely described and incompletely documented.[289] More recent data suggest that second attacks of pertussis are not uncommon.[290,291]

Widespread pertussis vaccination of children and the consequent reduction in the incidence of disease did not appear initially to have altered the periodicity of epidemic cycles,[281,284,292] suggesting that vaccination has had little impact on transmission.[285,293] However, analyses of more recent and complete data showed a lengthening of the interepidemic interval in the United Kingdom during a time of whole-cell vaccine use, consistent with a reduction of transmission.[294] It has also been argued that acellular vaccine use in Sweden reduced pertussis transmission,[295] but subsequent data show otherwise,[296] perhaps reflecting different epidemiological patterns following nationwide introduction of effective infant vaccination in a country with widespread pertussis circulation versus the steady-state situation some years later. Regardless, it is clear that endemic circulation of *B. pertussis* continues in the community despite universal childhood vaccination programs.

Incidence of Pertussis

United States and Canada

Disease caused by *B. pertussis* was once a major cause of morbidity and mortality among U.S. infants and children. From the 1920s (when pertussis was first a reportable disease) until the early 1940s, there were 115,000 to 270,000 cases of pertussis reported each year, with 5000 to 10,000 deaths (in all likelihood, pertussis infection occurred nearly universally among children, with only the more severe cases being reported). These figures represented approximately 150 cases and six deaths per 100,000 population.[4] As pertussis vaccine came to be used commonly in infants and children, the incidence of pertussis markedly decreased (Fig. 44.2).[4,282] By the 1970s, the annual incidence of reported disease had been reduced by 99%, and the lowest annual number of cases of pertussis—1010—was reported in 1976. Reported cases began to increase in the 1980s. Cyclical peaks in U.S. pertussis incidence were noted in 1983, 1986, 1990, 1993, 1996, 2002, 2004, 2010, and 2012, with each peak surpassing the last and with progressively higher inter-peak case counts.[10] For year 2012, reported cases totaled 48,277; for year 2013, reported

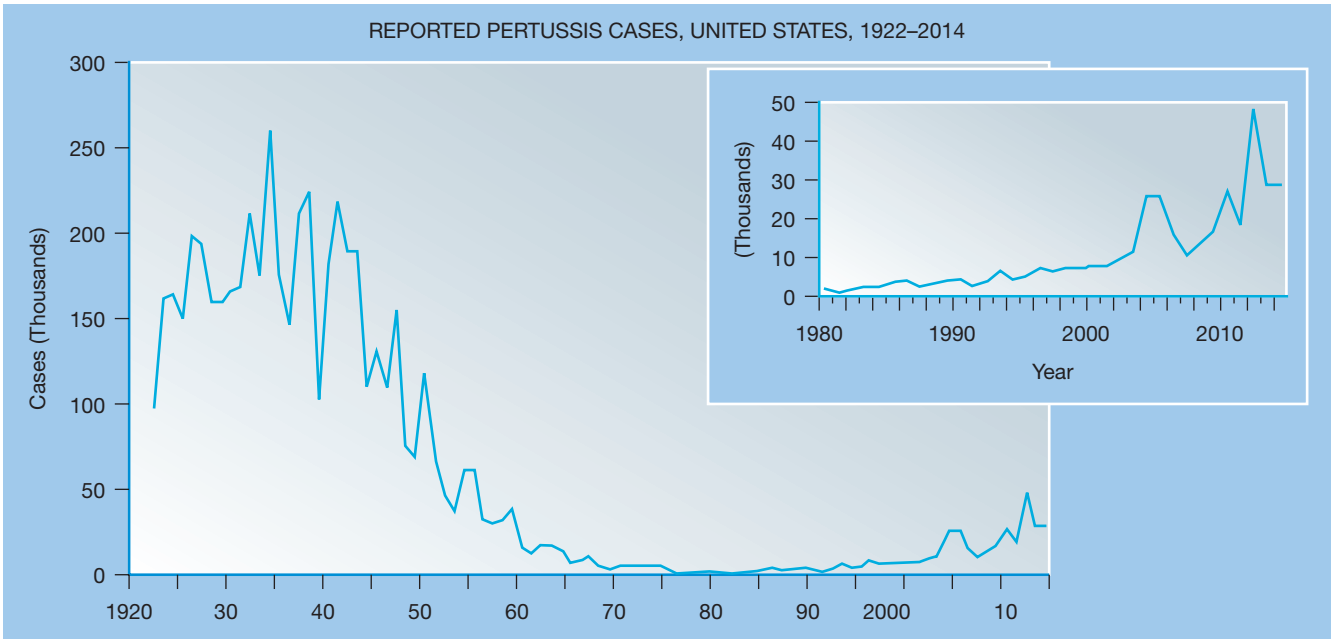

Figure 44.2. Number of reported cases of pertussis, by year, in the United States from 1922–2014. *(Data for 1922 to 1996 from W. Orenstein, personal communication, Centers for Disease Control and Prevention; data for subsequent years from the respective issues of Final Report of Notifiable Diseases, published annually in Morbidity and Mortality Weekly Report [see also www.cdc.gov].)*

cases totaled 28,639; for 2014, reported cases totaled 32,971; for 2015, reported cases totaled 18,166 (provisional).[10] The 2012 case count represented the most reported cases since 1955 and included 20 deaths, the majority of which occurred among infants younger than 3 months of age. Incidence rates were highest among infants and second highest among children 7 to 10 years of age; rates also increased among adolescents 13 and 14 years of age.

Graphs of incidence by age-group make it clear that several patterns have succeeded each other over the decades (Fig. 44.3). Prior to routine vaccination, as noted, nearly all reported cases were among infants and young children. Beginning in 2002, a disproportionate increase was seen in cases among adolescents (11 to 19 years of age), which led to institution of adolescent Tdap (tetanus, diphtheria, and aP vaccine) booster vaccination programs[7] with a subsequent decline in proportional pertussis rates among adolescents.[10] However, an increase in cases among children 7 to 10 years of age began within a few years thereafter. Fig. 44.4 shows U.S. annual childhood pertussis cases by year of age for each year from 2002 to 2009; beginning in 2005, a "marching cohort" effect can be seen in the 6- to 11-year age range, with case counts increasing annually both in each birth cohort over time and in each year of age across the years. For example, if we follow the children who were 7-year-olds in 2005 (the magenta bars in the figure), we see that they experienced increasing pertussis cases as they became 8, 9, and 10 years of age in 2006, 2007, and 2008, respectively. In 2009, many of them received their adolescent dose of Tdap vaccine as 11-year-olds, and case counts in their cohort dropped. In addition, if we look at a given age (e.g., 8-year-olds) from year to year, we see case counts are also higher in each succeeding cohort. When age-specific incidence rates are evaluated with respect to the pertussis vaccines each cohort received in infancy, a correlation can be seen between the arrival at age 7 years of the first cohort that received only aP vaccines and the progressive increase of pertussis cases in the group 7 to 11 years of age (Fig. 44.4). Numerous studies have documented this increase in pertussis

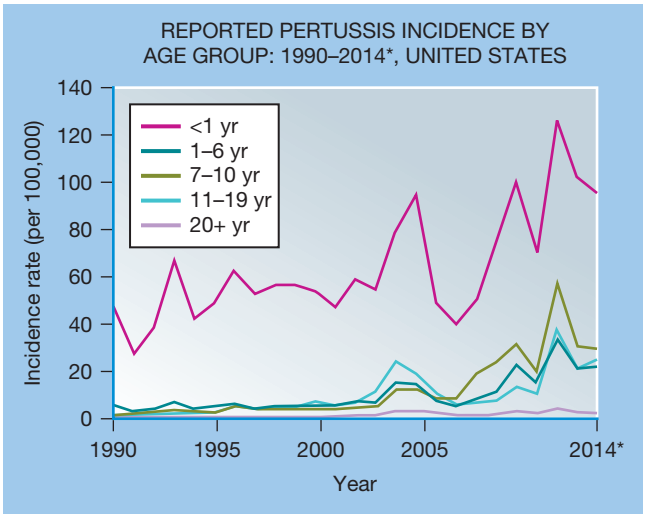

Figure 44.3. Reported pertussis incidence by age group, 1990–2014. See text for explanation. *Data for 2014 are provisional. *(From presentation by Liang JL, "Cocooning" and Tdap vaccination, Advisory Committee on Immunization Practices, Atlanta, GA, June 25, 2015. activity beginning at age 7 years among the cohorts given only acellular vaccines, and also that the effectiveness of the adolescent Tdap booster has waned more quickly among this cohort than among their predecessors who were primed with one or more doses of whole-cell pertussis vaccine.[297–310]

Infants continue to experience the highest age-specific incidence of pertussis, and as noted, are at the greatest risk of morbidity or mortality. Although the Advisory Committee on Immunization Practices (ACIP) has recommended that all

pregnant women receive Tdap during the third trimester of each pregnancy,[311,312] this recommendation has not yet been in place for sufficient time to show an effect on age-specific incidence rates in the youngest children (Fig. 44.3).

The increase in U.S. pertussis cases in recent years has been marked both by an increased number of endemic cases and larger, more frequent outbreaks. Since 2010, large outbreaks have been reported from multiple states, including California in 2010 and 2014 (Fig. 44.5),[313,314] Minnesota in 2012,[303] Oregon in 2012,[304] Washington in 2011,[301,315] and Wisconsin in 2012.[299] There has been considerable debate regarding the extent to which this increase in pertussis case counts reflects actual increases in disease incidence versus improved clinician awareness and recognition, more sensitive and more readily available diagnostics (e.g., PCR), and improved reporting.[283,316–318] Although it seems clear that improved awareness and diagnosis have contributed to the upsurge in reported cases, it also seems clear that these factors are insufficient to explain neither the marching cohort effect and the shifting of age-group incidences over time (see Figs. 44.3 and 44.4), nor the notable increase in large outbreaks. Concern has been raised regarding the role of vaccine refusal, which is more prevalent in certain communities and schools and may contribute to the initiation and growth of outbreaks.[319]

The epidemiology of pertussis in Canada has shown some differences from that of the United States, likely partly because of differing available vaccines and differing population characteristics. It is thought that the increase in pertussis disease in Canada in the 1980s and early 1990s was the result of whole-cell vaccines that were less protective than previously believed.[192,224,320–322] Support for this concern was provided by the pertussis vaccine efficacy trials conducted in Europe in the early 1990s, which found adequate efficacy after three doses of one U.S. whole-cell vaccine,[323] but quite low efficacy for the other whole-cell vaccine.[324,325] These results were consistent with U.S. surveillance data from 1992 to 1994, which found an overall whole-cell pertussis vaccine efficacy of 64% after three doses and of 82% after four or more doses.[326] Following introduction of aP vaccines in Canada, pertussis incidence rates dropped substantially and remained relatively low until 2012, when increased rates accompanied by regional outbreaks were observed.[327–329] Increases in incidence were noted in all age groups, with the highest rates in those younger than 1 year and those aged 10 to 14 years.[327] The lesser increase in those aged 15 to 19 years might reflect the Canadian recommendation for Tdap at 14 to 16 years of age.

Europe

Pertussis surveillance systems and procedures vary throughout Europe, although the European Centre for Disease Prevention and Control (ECDC) is seeking to standardize laboratory procedures for pertussis surveillance.[330] Because surveillance ranges from passive reporting to sentinel systems to laboratory surveillance, and case definitions range from clinical judgement without laboratory confirmation to PCR confirmation of cases meeting defined clinical criteria, neither case counts nor incidence rates can be compared from country to country and are not reported here.

Most European countries replaced whole-cell with aP vaccines during the 1990s, and many have noted increased reports of pertussis in recent years.[331–335] The ECDC noted in 2011 that pertussis reports had increased for the first time since 2008, and then 2012 saw twice as many reported pertussis cases as

in 2011.[334,336] Increases were most notable among young children and adolescents. Of note, the increase in pertussis incidence in 2012 was greater in Poland, the only included country still using whole-cell vaccine, than in the remaining countries, all of which were using acellular vaccine. England and the Netherlands experienced pertussis outbreaks in 2012. England, with a 10-fold increase in pertussis, declared a national pertussis outbreak in April 2012. The increased burden was seen particularly in adolescents and young infants, prompting the introduction in England of a national maternal vaccination program in September 2012.[332]

Africa, Asia, and Latin America

Outside North America, Europe, and Australia, national pertussis surveillance is even more variable—if it is performed at all.[337] Although it is likely that the burden of global pertussis morbidity and mortality lies most heavily on low- and middle-income countries, surveillance data are inadequate and a systematic review protocol has been proposed to evaluate the burden and trends of pertussis in those countries.[338] The WHO estimated that pertussis caused approximately 63,000 deaths in children younger than 5 years of age in 2013, but noted that "there is considerable uncertainty over these estimates in view of the paucity of reliable surveillance data, particularly from developing countries."[11a] With rare exception, no country in the African, Eastern Mediterranean, or Southeast Asian WHO regions conducts systematic pertussis surveillance; consequently, it is not possible to know whether changes in reported case counts in these countries represent fluctuations in disease recognition, types or usage of diagnostic tools, likelihood of reporting, or actual incidence. It is known that pertussis outbreaks occurred in Pakistan in 2004–06, India in 2007, and Afghanistan in 2007–08.[337]

Within the Western Pacific WHO region, pertussis is a reportable disease in countries including China, Republic of Korea, Taiwan, Japan, Australia, and New Zealand; in some of these countries, reporting is passive and largely based on clinical suspicion without laboratory confirmation. In the Republic of Korea, passive surveillance showed declining reports of pertussis from 1955 through 1999, with increases thereafter, particularly in 2009–11 (the last year available).[340] However, it has been shown that the Korean surveillance system underestimates pertussis (as is the case in most countries).[341] Outbreaks of pertussis were noted in Australia and Japan from 2008 to 2011 and New Zealand from 2011 to 2013; increased pertussis activity was also noted during this period in China and Taiwan.[337]

Australia conducts comprehensive laboratory surveillance for pertussis, and has noted large increases in pertussis rates in recent years (e.g., increasing from 47.2 to 173.3 cases per 100,000 population in 2006 and 2011, respectively).[342] The steepest increases were seen in children 2 to 4 years of age (reflecting the discontinuation in 2003 of the 18-month dose) and children 6 to 9 years of age (thought to reflect the shorter duration of protection associated with an all-acellular-vaccine schedule).[342,343] It is difficult to assess the contribution of improved laboratory methods to these increased case counts. During the same time period in which the case counts increased by some 80,000, the number of cases identified by PCR also increased by some 80,000,[318] suggesting that a positive PCR result may have led to the reporting of pertussis cases that previously would have gone uncounted.

Pertussis is a nationally notifiable disease throughout Latin America, and although surveillance is passive, laboratory support (culture and PCR) is provided in most countries. Nonetheless, surveillance system sensitivity is variable and uncertain. During the last decades of the 20th century, there were substantial improvements in vaccine coverage and corresponding declines in rates of reported pertussis.[344,345] However, in the first decade of the 21st century, pertussis case counts began rising in many countries of Latin America, including Argentina, Brazil, Chile, Colombia, Costa Rica, and Mexico.[345–349] Most countries recognize their pertussis surveillance is inadequate, and efforts to improve surveillance are ongoing.[345,349] PCR methods were introduced initially in Argentina and Costa Rica and are now used in essentially all the major countries of Latin America. As in other parts of the world where the introduction of PCR was often accompanied by a surge in reported pertussis cases, there was a surge in Latin America. However, improved detection does not entirely explain the increases in reported pertussis seen over the past decade in Latin America. For example, pertussis rates in Argentina increased from 0.7 to 5.7 per 100,000 population from 2002 to 2005; half the increase was recorded before the introduction of PCR at the end of 2004.[347] By 2011, the reported case rate was 8.3 per 100,000 population.[337] Increases were seen among adolescents and adults as well as infants. Brazil has also seen increasing pertussis cases, but the increase could be entirely related to the decline in vaccination coverage between 2006 and 2012.[345,346] Chile and Columbia also noted increases in reported pertussis during 2010–12. In contrast, no notable increases in pertussis have been observed in the Central American countries of El Salvador, Guatemala, Honduras, and Panama.[345] Of note, the public vaccination programs of all the Latin American countries mentioned thus far used whole-cell pertussis vaccines throughout this time period; only Mexico and Costa Rica were using aP vaccines (Mexico since 2007 and Costa Rica since 2010). Both countries experienced rising rates of pertussis prior to introducing aP vaccines. For the time period from introduction of aP vaccines through 2014, apart from an increase in case counts in Mexico coincident with the adoption of PCR testing in 2011,[345] neither country reported increases in pertussis activity other than the usual temporal fluctuations. However, neither country has yet used aP vaccine long enough for acellular-primed populations to reach preadolescence.

High-Risk Groups

Pertussis in Infants and Young Children

Although anyone can acquire pertussis, the highest attack rates and most hospitalizations and deaths occur among infants. More than 80% of U.S. infants with reported pertussis who are younger than 2 months of age are hospitalized.[350] From 2009 through 2014, there were 81 deaths attributed to pertussis in the United States; of these, 61 (75%) were infants younger than 3 months of age, two were infants 3 to 11 months of age, four were children 1 to 4 years of age, and six (10%) were 55 years of age or older.[351–354] Infants are also much more likely than older patients to manifest the complications described earlier. Indeed, it may be said that the primary goal of all pertussis vaccination programs is to prevent disease in infants.

Pertussis in School Children, Adolescents, and Adults

Prior to the institution of pertussis vaccination, it was believed that pertussis was solely a disease of infancy and childhood, and that the infection resulted in durable—perhaps lifelong—immunity. Those misimpressions likely arose because the circulation of *B. pertussis* in the community was so common that nearly all persons were infected as infants or children and were regularly boosted subclinically thereafter. In countries with longstanding pertussis vaccination programs, the age

distribution of pertussis has changed markedly. For example, from 1990 to 1993, 44% of U.S. cases occurred among children younger than 1 year of age, 22% occurred among children ages 1 to 4 years, 10% occurred among children ages 5 to 9 years, and 24% occurred among persons 10 years of age and older.[326] Then, during the late 1990s and early 2000s, the incidence in adolescents increased disproportionately. In 2000, the reported rate in persons 11 to 19 years of age was higher than in children 1 to 6 or 7 to 10 years of age.[350] The annual incidence of pertussis in persons aged 11 to 19 years increased from 5.5 per 100,000 in 2001, to 6.7 in 2002, and to 10.9 in 2003.[288] Some of these increases were likely the result of the growing recognition of pertussis as a cause of persistent cough in adolescents and adults and to the use of serologic methods to diagnose pertussis among adolescents and adults. Studies in the United States, Australia, Canada, and Germany in the early 1990s demonstrated that pertussis occurred commonly among adults.[16–18,212,222,237,290,355–358] Serologic evidence of recent pertussis was found in 26% of 218 Australian adults referred for investigation of chronic cough,[357] 26% of students presenting to a university health service with cough of at least 6 days' duration,[212] 26% of adults presenting to a Chicago clinic with unexplained cough,[355] and 21% of adults presenting to an emergency department in Nashville, Tennessee, with cough persisting 2 weeks or longer.[357] Of adult patients in a large California healthcare plan who were referred for chronic cough, 12.4% had serologic evidence of recent pertussis,[358] representing an incidence of 176 per 100,000 person-years—a rate greater than the overall annual incidence of reported pertussis (157 per 100,000) in the United States in the prevaccine era. Nearly 20% of 442 Canadian adolescents and adults with cough illness lasting longer than 7 days were diagnosed with laboratory-confirmed or suspected pertussis.[16] These reports highlight that chronic cough may be the sole manifestation of pertussis among adolescents and adults and that the diagnosis of pertussis in this age group often relies on serologic or PCR confirmation and rarely on culture of the organism.[357] The increase in reported pertussis among adolescents and adults was seen both in populations vaccinated with whole-cell vaccines and in populations largely unvaccinated and thus protected by natural immunity, and likely reflected several factors, including enhanced suspicion and recognition, improved reporting, and increased use of improved diagnostic tools. The most important factor, however, probably was the waning of natural or vaccine-induced immunity coupled with the reduced prevalence of pertussis in immunized childhood populations, which provided fewer opportunities for the reinforcement of immunity by casual exposure to infected children.

Further insight into the epidemiology of pertussis in a highly vaccinated population comes from a 1996 serosurvey of 600 normal healthy persons ages 1 to 65 years.[214] There was an expected peak in PT and FHA titers in the 4- to 6-year-old children, reflecting the administration of booster doses of pertussis vaccine, but also a second, larger peak in the 13- to 17-year-old group, suggesting that natural exposure to pertussis is frequent during the adolescent years. Similar findings have been obtained in a variety of countries.[215–219]

Additional data were provided by a multicenter, randomized, double-blind trial of a Tdap vaccine conducted in the late 1990s.[226] In that study, 2781 healthy subjects between the ages of 15 and 65 years received either Tdap or hepatitis A vaccine (control group) and were monitored for 2.5 years for cough illnesses. Of 1390 control subjects, 1284 (92%) experienced at least one cough illness lasting 5 days or longer. Using culture, PCR, and serologic methods, nine control subjects (0.65%) were diagnosed with *B. pertussis* infection. Based on these data, the incidence of pertussis in the control group was 368 cases per 100,000 person-years; extrapolating these rates to the total U.S. population, nearly 1 million cases of pertussis occurred in persons 15 years of age and older each year.[226]

The continued increase of pertussis in adolescents led to the institution of adolescent Tdap vaccination programs in the United States and other countries, which appeared initially to be successful.[359] However, as discussed previously, a new and unexpected epidemiological pattern emerged in the U.S. epidemics of 2010–14, which showed progressively increasing pertussis rates in schoolchildren 7 to 10 years of age, along with apparently reduced duration of protection following the adolescent Tdap dose.[350] The CDC's "2014 Provisional Pertussis Surveillance Report"[360] shows that the proportion of reported cases and the incidence per 100,000 population (in parentheses) by age were: age younger than 6 months, 10.4% of reported cases (incidence rate: 150.9/100,000); age 6 to 11 months, 2.8% (incidence rate: 40.4/100,000); age 1 to 6 years, 18.7% (incidence rate: 22.2/100,000); age 7 to 10 years, 16.9% (incidence rate: 29.5/100,000); age 11 to 19 years, 33.0% (incidence rate: 25.1/100,000); and age 20+ years, 17.8% of reported cases (incidence rate: 2.2/100,000).[354] As noted above, this pattern has also been seen in countries such as Australia, as populations primed and boosted only with aP vaccines have aged into preadolescence and adolescence.

It should not be thought, however, that a short duration of protection is seen only after acellular-vaccine usage; protection by whole-cell vaccine or even natural infection can be less durable than traditionally thought. For example, Kayina and colleagues found that pertussis prevalence rose substantially during and after the fifth year of life among Ugandan children given three infant doses of whole-cell vaccine.[361]

Reservoirs of Infection

B. pertussis is spread directly from human to human via respiratory droplets, and humans are the only natural reservoir; fomites are not known to play any meaningful role. Frequently, asymptomatic adults have been implicated in the spread of infection to susceptible children.[355,362–368] In one report, four children with confirmed pertussis infection and their 18 family members were evaluated for *B. pertussis*. The attack rate for pertussis infection in the contacts was 83%, but two-thirds of the previously immunized contacts found to be infected were asymptomatic.[21] Symptomatic infection was characterized by a higher PT antibody response, and asymptomatic infection by a higher FHA antibody response. These data suggest that, after pertussis immunization, immunity to disease is greater than protection from infection, a result consistent with the baboon data cited earlier.

An international study of laboratory-confirmed infant pertussis cases and their household and nonhousehold contacts using PCR and serology identified sources of infection for 48% of 95 infants in the primary analysis and up to 78% in sensitivity analyses. Parents accounted for 55% of source cases, followed by siblings (16%), aunts or uncles (10%), friends or cousins (10%), grandparents (6%), and part-time caretakers (2%).[366] A study in the United States conducted by the CDC during enhanced pertussis surveillance in several states determined that for the period 1999 to 2002, a source of infection was identified for 264 infant cases; the mother was the source in 32% and another family member in 43%. Of the sources with reported ages, 17% were age 0 to 4 years, 7% were age 5 to 9 years, 20% were age 10 to 19 years, 21% were age 20 to 29 years, and 35% were older than 30 years of age.[364] In 2015, the CDC updated these data with a report covering the period 2006–13.[365] Of 569 infants with an identified source of infection, the source was the mother for 21%, the father for 10%,

and a sibling for 36%. Mothers predominated as the source until 2008, after which point siblings were the predominant source. These data reflect the increasing incidence of pertussis in children 7 to 10 years old and are consistent with the hypothesis, supported by baboon data cited earlier, that children primed and boosted with acellular vaccines are protected from disease but not from colonization that can result in transmission.

Significance of Pertussis as a Global Public Health Problem

Despite global vaccination programs, pertussis remains endemic worldwide. Case counts, although far below those of the prevaccine era, are rising in many countries, adding to the already substantial human and economic burdens of pertussis. A U.S. study in 2000 evaluated 69 affected families in Monroe County, New York, and estimated the adverse financial effect of pertussis was $2115 per family.[369] Another study estimated that in the absence of a vaccination program, the medical costs of pertussis among German children 1 to 6 years of age would total nearly DM900 million (1994 prices) per year.[370] In the developing world, the greater burden is human, not economic. Crowcroft and colleagues estimated that in 2000, the disability-adjusted life-years lost globally from pertussis (12.7 million) exceeded those of other diseases such as lung cancer (11.4 million) and meningitis (5.8 million).[371] Data collected by the WHO's Expanded Program on Immunization (EPI) in 1992 indicated that 850,000 of the approximately 110 million children born annually in the developing world during the 1980s succumbed to pertussis before their fifth birthdays. In 1994, the WHO estimated that 40 million pertussis infections resulted in 5 million episodes of pneumonia, 360,000 deaths (a nearly 60% reduction from the earlier estimate), and 50,000 patients with long-term neurologic complications (including permanent brain damage).[372] In 2002, WHO estimated 45 million cases of pertussis with 301,408 childhood deaths.[371] The most recent (2008) estimates from the WHO indicated that approximately 16 million cases of pertussis occurred worldwide, 95% of which were in developing countries, and that approximately 195,000 children died from the disease, reflecting the growth in immunization programs and continued reduction in the burden of pertussis.[11]

PASSIVE IMMUNIZATION

Transplacental

Antibodies to PT and FHA readily cross the placenta and are found in infant sera in concentrations comparable to or higher than those in maternal sera.[373–375] The half-life of transplacental antibodies is approximately 6 weeks, with disappearance by 4 months of age, depending on titers.[376,377] However, despite efficient placental transfer, the low maternal pertussis antibody levels that are seen in the absence of pertussis booster vaccination soon before or during pregnancy, and the rapid decay of maternally derived antibodies in infant sera, leave infants with little humoral antibody protection against pertussis.[378] The excellent placental transfer of pertussis antibody provides the potential for neonatal and infant protection against pertussis when maternal antibody levels are high.[371]

The concept of boosting maternal antibody levels was first explored in the early 20th century, with active pertussis vaccination of pregnant women during the third trimester.[379–382] No adverse maternal or neonatal events were documented, and elevated antibody titers were seen in both mother and infant. However, high preexisting pertussis antibody levels in infants suppressed the subsequent immune responses to primary infant immunization with diphtheria, tetanus, and whole-cell pertussis (DTwP) vaccines and led to the rejection of maternal immunization at that time. In contrast, ecological studies of antibody responses to aP vaccines in infants with high versus low maternal antibody titers have not shown this suppression[376,383] (however, even the high maternal antibody levels in these studies were materially lower than those seen among women vaccinated during pregnancy).

The modern development of active immunization of the pregnant woman to protect the newborn from pertussis is discussed in detail in "Vaccination in Pregnancy" below.

Therapeutic

Before the widespread use of pertussis vaccine and the availability of antibiotics, passive immunization using whole serum was employed in an effort to prevent the spread of disease to exposed susceptible people and to modify the course of the illness in those who had already acquired whooping cough.[384] Most of the studies of preventive efficacy in exposed persons were not controlled; a few studies that did include control subjects suggested that as many as 40% of recipients were protected.[22,78,384]

The subsequent development of methods for purification of serum immunoglobulins led to the commercial production of pertussis hyperimmunoglobulin, composed largely of IgG. Although this preparation was widely used for prophylaxis and treatment, controlled studies indicated that it had no effect, and production was discontinued.[385,386] Then, Sato and Sato demonstrated that both monoclonal and polyclonal antibodies to PT improved survival of suckling mice after aerosol challenge with live pertussis organisms.[79] The ability to generate high-titer immunoglobulin by immunizing adults with less reactogenic aP vaccines led to a reassessment of the use of immunoglobulin as therapy for pertussis. In 1991, Granstrom and colleagues conducted a double-blind, randomized, placebo-controlled trial of a pertussis immunoglobulin prepared from adults immunized with an aP vaccine containing either PT or PT plus FHA.[387] A significant reduction in the duration of whoops was demonstrated in the recipients of the pertussis immunoglobulin compared with placebo recipients (8.7 vs 20.6 days; $P = .0041$). A pertussis immunoglobulin was prepared by the Massachusetts Biologic Laboratories using sera from adults immunized with monovalent pertussis toxoid vaccine. It was initially evaluated in the mouse aerosol model of pertussis and then in Phase I trials in infants. A multicenter, randomized, placebo-controlled clinical trial of the product was conducted, and 25 infants hospitalized with pertussis were enrolled in the 24 months before the study was terminated because of expiration of the product and lack of additional new product. All infants tolerated the product without safety concerns, but no differences were noted in the number or rate of improvement of symptoms between the immunoglobulin recipients and placebo controls.[388] More recently, several monoclonal antibodies that recognize protective PT epitopes were characterized and studies of these monoclonal antibodies in animal models suggest that they may confer a therapeutic benefit.[81,389]

ACTIVE IMMUNIZATION

History

The isolation and propagation of *B. pertussis* on artificial media in 1906 led to the development of a vaccine for the prevention of whooping cough. Initial steps to develop a vaccine were

empirical, but an improved understanding of the different growth phases of the organism led to refinement in the methods of vaccine production and resulted in a whole-cell vaccine prepared in a standardized and reproducible fashion. Whole-cell pertussis vaccines were first licensed in the United States in 1914 and became available combined with diphtheria and tetanus toxoids in 1948. They were recommended and widely used for routine vaccination of children. During the 1980s and 1990s, knowledge of the components of the pertussis organism and their biological roles expanded and led to the development of the aP vaccines, largely in response to concerns regarding adverse local and systemic adverse events reported after the whole-cell pertussis vaccines. In 1996, less reactogenic aP vaccines were licensed and recommended for routine use among infants and now are the only pertussis vaccines licensed in the United States.[5]

Development of Whole-Cell Vaccines

Whole-cell pertussis vaccines are suspensions of killed *B. pertussis* organisms. One of the first clinical trials of a whole-cell vaccine conducted during an epidemic of pertussis in the Faroe Islands provided evidence of efficacy.[390] In the 1930s, steps taken to improve pertussis vaccines included increasing the number of bacteria in the vaccine, using standardized culture media, inactivating the organisms by "gentler" methods, and using fresh, rapidly growing Phase I organisms as the inoculum.[51,78]

Early on, a major stumbling block in the development and assessment of pertussis vaccines was the lack of a suitable means, other than clinical trials, for assessing the potency of the vaccine. After World War II, Kendrick designed the mouse protection test, in which mice were immunized with pertussis vaccine and then challenged by intracerebral inoculation of living *B. pertussis* organisms. This test, also called the Kendrick test, reproducibly measured vaccine potency (correlated with protective efficacy in humans), and it was used for many years until the introduction of the acellular vaccines required a new standard.[391–393] Whole-cell pertussis vaccines produced in the United States varied somewhat in their methods of production and generated different levels of antibody responses.[51,321] In the United States, whole-cell pertussis vaccine was almost always administered to children in combination with diphtheria and tetanus toxoids. The vaccine was adsorbed onto an aluminum salt, which resulted in enhanced immunogenicity and reduced reactogenicity.

Development of Acellular Vaccines

Because of the common occurrence of minor but burdensome local reactions, and the less common but more severe systemic reactions, coupled with public anxiety over complications after immunization with whole-cell vaccine, new, less reactogenic pertussis vaccines were sought. An improved understanding of the biology of *B. pertussis* and the isolation of individual components of the organism important in disease pathogenesis and induction of clinical immunity led to the production of new vaccines. Sato and colleagues in Japan designed the first purified component (acellular) pertussis vaccines.[394] The initial vaccines consisted predominantly of FHA, along with smaller amounts of inactivated PT and, in some cases, fimbrial proteins and PRN, and were known as Takeda-type vaccines (named after the originating Japanese manufacturer). They were soon followed by additional acellular vaccines containing equal quantities of PT and FHA (termed Biken-type vaccines, after the originating Japanese manufacturer). Criteria for the licensure of the acellular vaccines in Japan included low toxicity in the mouse, documentation of potency in the mouse, diminished systemic and local reactivity in children, and antibody production in children similar to or exceeding that of the whole-cell vaccine. Household-contact studies and pertussis surveillance after implementation of the acellular vaccines gave clear evidence of effectiveness. Since 1981, aP vaccines have been used exclusively in Japan and have been very effective.[394–402]

The encouraging results in Japan stimulated other industrialized nations to evaluate the Japanese acellular vaccines and to develop other acellular vaccines. Nearly two dozen aP vaccines were designed, many were evaluated in immunogenicity and reactogenicity trials, and the efficacy and safety of a number were evaluated in field trials. These vaccines varied from one another with respect to their source, number of components, quantity of each component, method of purification, method of toxin inactivation, incorporated adjuvants, and excipients (Tables 44.3 and 44.4).[403] Unfortunately, identifying the optimal formulation for an acellular vaccine has proved difficult, because no simple method exists to determine the protective capability of a pertussis vaccine. The results of the mouse intracerebral protection test correlate reasonably well with the clinical protection afforded by whole-cell vaccine, but the test does not predict the efficacy of aP vaccines.[283] Guiso and colleagues found that the results of intranasal challenge in a murine model correlated with efficacy of selected aP vaccines,[404] suggesting the possible usefulness of such tests in the preclinical evaluation of candidate vaccines. Because the intracerebral mouse protection test does not provide a valid measure of the protective capability of the aP vaccines, the potency of individual lots of these vaccines produced for the U.S. market is evaluated by measurement of the antibody response to PT (plus FHA, PRN, and fimbrial proteins, as applicable) in immunized mice, using an ELISA. Although human immunologic correlates of protection have been avidly sought, these efforts have met with only partial success, as described later in this chapter. aP vaccines have entirely replaced whole-cell pertussis products in the United States, Canada, and Australia, in most of Europe, and in some Asian and Latin American markets (Table 44.5).

Vaccine Producers

The vaccine industry has undergone dramatic consolidation over the past 20 years; both long-established companies and new biotechnology startups have been acquired by, or merged into, successor companies. These changes render nomenclature problematic. For vaccines currently marketed, we use the name of the current manufacturer, even when describing studies conducted by a predecessor company. For products of historical interest, we use the name of the company that produced them, even if that company is now owned by or operates under a successor name. To further assist the reader, Table 44.6 lists the current major vaccine manufacturers along with the names of predecessor, component, or acquired companies.

Internationally Available Whole-Cell Pertussis Vaccine Preparations

Despite availability of acellular vaccines, whole-cell vaccines remain the most widely used globally for infant and childhood vaccination. Whole-cell vaccines are generally efficacious, relatively inexpensive to manufacture, and have been produced locally in many regions of the world. However, the evolving recommendations of the WHO's EPI program and the prequalification by WHO of several whole-cell based DTwP/*Haemophilus influenzae* type b (Hib)/hepatitis B (HB) vaccines have led to widespread use in EPI countries of these

TABLE 44.3 Key Characteristics of Selected Acellular Pertussis Vaccines[a]

Manufacturer or Distributor	Vaccine[b]	Evaluated in MAPT	Pertussis Antigen per Dose (μg)				Diphtheria Toxoid[c]	Tetanus Toxoid[c]
			PT	FHA	PRN	FIM		
Sanofi Pasteur (Canada)[d]	Tripacel; Daptacel	Yes	10	5	3	5	15	5

[a]Compositions may differ in various markets; local suppliers should be consulted as necessary. Some products are no longer available but are included because knowledge of their composition is important to understanding the results of the efficacy trials.
[b]Trade names (most common trade names, if multiple names exist) except as follows: HCPDT is the "hybrid" formulation of Tripacel, evaluated in the 1993 Stockholm trial (otherwise, used only in combinations); JNIH-6 and JNIH-7 were the acellular vaccines used in the 1986 Swedish trial; SKB-2 was an experimental two-component DTaP evaluated in the 1992 Stockholm trial.
[c]Measured in limit of flocculation units per dose.
[d]FIM component is a mixture of FIM-2 and FIM-3. In MAPT, PT was 10 μg; FHA, 5 μg.
[e]A Biken vaccine, similar to Tripedia.
[f]Contains approximately 40 μg (but not more than 60 μg) of pertussis antigen proteins, consisting of ~86% FHA, ~8% PT, ~4% PRN, and ~2% FIM-2.
DTaP, diphtheria and tetanus toxoids and acellular pertussis; FHA, filamentous hemagglutinin; FIM, fimbrial proteins; HCPDT, hybrid component pertussis-diphtheria-tetanus vaccine; MAPT, Multicenter Acellular Pertussis Trial; PRN, pertactin; PT, pertussis toxin.

TABLE 44.4 Additional Characteristics of Selected Acellular Pertussis Vaccines[a]

Manufacturer or Distributor	Vaccine[b]	How Toxoided	Aluminum (mg)	Diluent	Preservative	Trace Constituents
Sanofi Pasteur (Canada)	Tripacel; Daptacel	Glutaraldehyde	0.33[c]	PBS	Phenoxyethanol	Glutaraldehyde, PS
Sanofi Pasteur (Canada)	HCPDT	Glutaraldehyde	0.33[c]	PBS	Phenoxyethanol	Glutaraldehyde, PS
Sanofi Pasteur (France)	Triavax; Triaxim	Glutaraldehyde	0.30[d]	N/A	Thimerosal	N/A
Sanofi Pasteur (USA)	Tripedia	Formaldehyde	0.17[e]	PBS	None	Formaldehyde, gelatin, PS
Baxter Laboratories	Certiva	H_2O_2	0.50[d]	PBS	Thimerosal	None
Chiron Vaccines	Acelluvax[f]	Genetic	1.0[d]	N/A	Thimerosal	N/A
GlaxoSmithKline	Infanrix	Formaldehyde[g]	0.625[d,g]	Saline	Phenoxyethanol	Formaldehyde, PS
Japan National Institutes of Health	JNIH-6	Formaldehyde	0.08	PBS	Thimerosal	Formaldehyde
Japan National Institutes of Health	JNIH-7	Formaldehyde	0.075	PBS	Thimerosal	Formaldehyde
SmithKline Beecham Biologicals	SKB-2	Formaldehyde	0.50[d]	Saline	Phenoxyethanol	Formaldehyde, PS
Wyeth Pharmaceuticals	Acel-Imune	Formaldehyde	0.23[h]	PBS	Thimerosal	Formaldehyde, gelatin, PS

[a]Compositions may differ in various markets; local suppliers should be consulted as necessary. Aluminum content is per dose. Some products are no longer available, but are included because knowledge of their composition is important to understanding the results of the efficacy trials.
[b]Trade names (most common trade name, if multiple names exist) except as follows: HCPDT is the "hybrid" formulation of *Tripacel* evaluated in the 1993 Stockholm trial (otherwise, used only in combinations); JNIH-6 and JNIH-7 were the acellular vaccines used in the 1986 Swedish trial; SKB-2 was an experimental 2-component DTaP evaluated in the 1992 Stockholm trial.
[c]As aluminum phosphate.
[d]As aluminum hydroxide.
[e]As aluminum potassium sulfate.
[f]Pertussis components are formaldehyde-stabilized. Aluminum content was 0.35 mg in MAPT.
[g]PT component detoxified with both formaldehyde and glutaraldehyde. In MAPT, aluminum content was 0.50 mg.
[h]A mixture of aluminum hydroxide and aluminum phosphate.
DTaP, diphtheria and tetanus toxoids and acellular pertussis; HCPDT, hybrid component pertussis-diphtheria-tetanus vaccine; MAPT, Multicenter Acellular Pertussis Trial; N/A, information not available; PBS, phosphate-buffered saline; PS, polysorbate-80; PT, pertussis toxin.

TABLE 44.5 Pertussis Immunization Schedules Recommended by Selected National Authorities, as of June 2015[a]

Country	Primary Immunization Schedule	Pediatric Boosters	Adolescent-Adult Tdap[b]	Tdap in Pregnancy[c]
GLOBAL: MOST COUNTRIES IN AFRICA, THE MIDDLE EAST, AND ASIA (EXCEPT AS SHOWN OTHERWISE HEREIN)				
EPI programs	3 doses DTwP (most as DTwP-Hib-HB)	Some: DTwP at 18 mo to 4 y		
NORTH AMERICA				
Canada	2, 4, 6 mo: DTaP (in a combination)	18 mo: DTaP (in a combination) 4–6 y: TdaP-IPV or DTaP-IPV	14–16 y. If not received at that age, then 1 dose when able	Optional ≥26 wk; encouraged if outbreak or no prior Tdap
United States	2, 4, 6 mo: DTaP (alone or in combination)	15–18 mo and 4–6 y: DTaP (alone or in combination)	11–12 y. If not, then 1 dose when able	At 27–36 wk of each pregnancy
Mexico	2, 4, 6 mo: DTaP-IPV-Hib	15–18 mo: DTaP-IPV-Hib 4–6 y: DTwP		Yes
EUROPE				
Austria	3, 5, 12 mo: DTaP-IPV-Hib-HB	7–10 y: DTaP-IPV	Every 10 y, 18–60, then every 5 y	
Belgium	2, 3, 4 mo: DTaP-IPV-Hib-HB	15 mo: DTaP-IPV-Hib-HB 5–7 y: DTaP-IPV	14–16 y; 1 dose for all adults	At 24–32 wk of each pregnancy
Czech Republic	9, 13, 17 wk: DTaP-IPV-Hib-HB	18 mo: DTaP-IPV-Hib-HB 5 y: DTaP	10 y: DTaP-IPV-Hib; 1 Tdap for adults	
Denmark	3, 5, 12 mo: DTaP combination	5 y: DTaP-IPV or Tdap		
Finland	3, 5, 12 mo: DTaP-IPV-Hib	4 y: DTaP-IPV	14–15 y: TdaP	
France	2, 4, 11 mo: DTaP-IPV-Hib-HB	6 y: DTaP-IPV	11–13 and 25 y: Tdap-IPV	
Germany	2, 3, 4 mo: DTaP combination	11–14 mo: DTaP combination 5–6 y: Tdap	9–17 y: Tdap-IPV 1 Tdap as adult	
Greece	2, 4, 6 mo: DTaP combination	15–18 mo: DTaP combination 4–6 y: DTaP or Tdap	11–12 y; Tdap or Tdap-IPV once as adult	
Hungary	2, 3, 4 mo: DTaP-IPV-Hib	18 mo: DTaP-IPV-Hib 6 y: DTaP-IPV	11 y	
Iceland	3, 5, 12 mo: DTaP-IPV-Hib	4–5 y: DTaP-IPV	14 y	
Ireland	2, 4, 6 mo: DTaP-IPV-Hib-HB	4–5 y: DTaP-IPV	11–14 y	At 27–36 wk of each pregnancy
Israel	2, 4, 6 mo: DTaP-IPV-Hib	12 mo: DTaP-IPV-Hib 7 y: DTaP-IPV	14 y	At 27–36 wk of each pregnancy
Italy	3, 5–6, 11–13 mo: DTaP combination	5–6 y: DTaP-IPV	10 y after primary series	
Luxembourg	2, 3 mo: DTaP-IPV-Hib-HB 4 mo: DTaP-IPV-Hib	13 mo: DTaP-IPV-Hib-HB 5–6 y: Tdap-IPV	15–16 y and every 10 y thereafter: TdaP-IPV	
Netherlands	2, 3, 4 mo: DTaP-IPV-Hib-HB	11 mo: DTaP-IPV-Hib-HB 4 y: DTaP-IPV		
Norway	3, 5, 11–12 mo: DTaP-IPV-Hib	6–8 y: DTaP-IPV	15 y	
Poland	7–8 wk, 3–4 mo, 5–6 mo: DTwP (DTaP for risk groups)	16–18 mo: DTwP 6 y: Tdap		
Portugal	2, 4, 6 mo: DTaP-IPV-Hib	18 mo: DTaP-Hib 5–6 y: DTaP-IPV		
Russia	3, 4.5, 6 mo: DTwP	18 mo: DTwP		
Slovakia	2, 4, 10 mo: DTaP-IPV-Hib-HB	5 y: DTaP-IPV	12 y: Tdap-IPV

TABLE 44.5 Pertussis Immunization Schedules Recommended by Selected National Authorities, as of June 2015[a] *(Continued)*

Country	Primary Immunization Schedule	Pediatric Boosters	Adolescent-Adult Tdap[b]	Tdap in Pregnancy[c]
Spain	2, 6 mo: DTaP-IPV-Hib-HB 4 mo: DTaP-IPV-Hib	18 mo: DTaP-IPV-Hib 6 y: Tdap	13 y + every 10 y: Tdap	Per local epidemiology
Sweden	3, 5, 12 mo: DTaP combination	5–6 y: DTaP-IPV	14–16 y	
Switzerland	2, 4, 6 mo: DTaP-IPV-Hib	15–24 mo: DTaP-IPV-Hib 4–7 y: DTaP-IPV	11–15 y 25–29 y	
United Kingdom	2, 3, 4 mo: DTaP-IPV-Hib	3–5 y: DTaP-IPV		At 28–32 wk of each pregnancy
CENTRAL AND SOUTH AMERICA (MOST COUNTRIES NOT SHOWN FOLLOW A SCHEDULE SIMILAR TO ONE OF THE FOLLOWING)				
Argentina	2, 4, 6 mo: DTwP-Hib-HB	15–18 mo: DTwP-Hib 6 y: DTwP	11 y	At 26 wk of pregnancy
Brazil	2, 4, 6 mo: DTwP-Hib-HB	15 mo: DTwP-Hib-HB 4–6 y: DTwP		In each pregnancy
Chile	2, 4, 6 mo: DTwP-Hib-HB	18 mo: DTwP-Hib-HB 6 y: Tdap	13 y	
Columbia	2, 4, 6 mo: DTwP-Hib-HB	18 mo and 5 y: DTwP		At 21 wk of each pregnancy
El Salvador	2, 4, 6 mo: DTwP-Hib-HB	15 mo: DTwP-Hib-HB 4 y: DTwP		In each pregnancy
Nicaragua	2, 4, 6 mo: DTwP-Hib-HB	18 mo and 6 y: DTwP		
Panama	2, 4, 6 mo: DTaP-IPV-Hib-HB	15–18 mo: DTwP-Hib-HB 4 y: DTwP	10 y	In 3rd trimester of each pregnancy
Peru	2, 4, 6 mo: DTwP-Hib-HB	18 mo and 4 y: DTwP		
Uruguay	2, 4, 6 mo: DTwP-Hib-HB	15 mo: DTwP-Hib-HB 5 y: DTwP	12 y	In each pregnancy
ASIA (MOST COUNTRIES NOT SHOWN GENERALLY FOLLOW THE EPI SCHEDULE)				
Australia	2, 4, 6 mo: DTaP-IPV-Hib-HB	18 mo: DTaP 4 y: DTaP-IPV	10–15 y	In each pregnancy
China	3, 4, 5 mo: DTaP	18–24 mo: DTaP		
Indonesia	2, 3, 4 mo: DTwP or DTwP-HB			
Japan	3, 4, 5–11 mo: DTaP	18 mo: DTaP		
Korea, Republic of	2, 4, 6 mo: DTaP	15–18 mo and 4–6 y: DTaP	11–12 y	
Malaysia	2, 3, 5 mo: DTaP-IPV-Hib	18 mo: DTaP-IPV-Hib		
New Zealand	6 wk, 3 mo, 5 mo: DTaP-IPV-Hib-HB	4 y: DTaP-IPV	11 y: Tdap	
Taiwan	2, 4, 6 mo: DTaP-IPV-Hib	18 mo: DTaP-IPV-Hib 5 y: Tdap-IPV		
Thailand	2, 4, 6 mo: DTwP-HB	18–24 mo and 4–5 y: DTwP		

[a]Compiled from multiple sources. In many countries, products based on whole-cell pertussis vaccine are used in the national or public programs (shown in the above table), whereas products based on acellular vaccines often are used in private practice. In such countries, recommended schedules for private practice typically are based on U.S. or Western European schedules. As of June 2015, spreadsheets providing global immunization schedules and coverage rates were available from WHO at http://www.who.int/entity/immunization/monitoring_surveillance/data/schedule_data.xls?ua=1 and http://www.who.int/entity/immunization/monitoring_surveillance/data/coverage_estimates_series.xls, respectively. The European Centre for Disease Control offers online European vaccine schedules at http://vaccine-schedule.ecdc.europa.eu/Pages/Scheduler.aspx (click through the requests for credentials).

[b]Based on cost considerations, most jurisdictions recommend only a single adolescent-adult dose of Tdap (except for pregnant women). However, many practitioners elect to give Tdap whenever a tetanus, diphtheria, or pertussis booster is indicated.

[c]An entry is made in this column only when there is a specific recommendation for usage in pregnancy.

DTap, diphtheria and tetanus toxoids and acellular pertussis; DTwP, diphtheria and tetanus toxoids and whole-cell pertussis vaccine; EPI, Expanded Programme on Immunization; HB, hepatitis B vaccine; Hib, *Haemophilus influenzae* type b vaccine; IPV, inactivated poliovirus vaccine; Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine.

TABLE 44.6 Current Major Vaccine Manufacturers and Their Merged, Acquired, or Component Companies

Name as of June 2015	Former, Merged, Acquired, or Component Companies or Names
AstraZeneca	MedImmune
CSL	Novartis (influenza assets only)
GlaxoSmithKline	Glaxo; Glaxo Welcome; RIT (Recherche et Industrie Thérapeutiques); SmithKline Beecham; SmithKline–RIT; Welcome. Acquired Novartis Vaccines (except influenza assets) in 2015, thus acquiring Behring; Biocine; Chiron Vaccines; Evans Vaccines; Medeva Vaccines; Powderject Vaccines; Sclavo; Zhejiang Tianyuan Bio-Pharmaceutical Co., Ltd
Johnson & Johnson	Acquired Crucell NV in 2011, thus acquiring Berna Biotech; Berna Products; Rhein Biotech; SBL Vaccin AB; Swiss Serum and Vaccine Institute (SSVI)
Merck & Co	Schering-Plough; Organon
Sanofi Pasteur	Aventis Pasteur; Connaught Laboratories; Pasteur Merieux; Pasteur Merieux Connaught; Acambis (including Berna Products; OraVax; Peptide Therapeutics); Shantha Biotechnics; VaxDesign
Pfizer	Baxter International (meningococcal serogroup C and tickborne encephalitis vaccines); Redvax GmbH; Wyeth Pharmaceuticals, including American Home Products; Lederle Laboratories; Praxis; Wyeth-Ayerst Laboratories; Wyeth Lederle; Wyeth Vaccines
Serum Institute of India	Bilthoven Biologicals (formerly, Dutch Vaccine Institute)

combination vaccines, most of which are manufactured in Asia (see Chapter 15).

In determining its pertussis immunization strategy, each country has to evaluate the costs, relative efficacy, and rate of adverse reactions of both whole-cell and acellular vaccines, in light of prevailing recommendations (see later) and its own circumstances.

Internationally Available Acellular Pertussis Vaccine Preparations

aP vaccines are available as diphtheria, tetanus, and acellular pertussis (DTaP) vaccines, Tdap vaccines, and as multicomponent combinations that add additional antigens to those backbones. The multicomponent combination vaccines are discussed in Chapter 15; in the present chapter, we provide details concerning the base DTaP and Tdap vaccines. Vaccines discussed in this section are those marketed internationally as of early 2016. In some jurisdictions, their trade names may vary from those provided here; local suppliers should be consulted as necessary.

Constituents and Stability, Storage and Handling, Dosage and Route

Details of the composition and other key characteristics of selected current or historically important DTaP vaccines are shown in Tables 44.3 and 44.4. Unless otherwise noted, all vaccines listed should be stored refrigerated at 2°C to 8°C; do not freeze. The standard dose of each vaccine is 0.5 mL given intramuscularly in the anterolateral thigh (infants and young children) or the deltoid (older recipients). It is inappropriate to give a partial dose in the hope of reducing adverse effects.

Currently Available Preparations for Pediatric Use (6 Weeks to 7 Years of Age)

Daptacel, Pentacel, and Pediacel—Sanofi Pasteur. Daptacel is the U.S. trade name for a DTaP vaccine manufactured by Sanofi Pasteur Ltd (Toronto, Canada). The aP vaccine component contains approximately 10 µg PT, 5 µg FHA, 3 µg PRN, and 5 µg of combined FIM-2 and FIM-3. Daptacel is supplied in thimerosal-free single-dose vials. Daptacel is marketed in many countries under various names (Tripacel, Triacel, or Pertacel). A version of this vaccine containing 20 µg PT, 20 µg FHA, 3 µg PRN, and 5 µg of combined FIM-2 and FIM-3 is used in combination vaccines that also incorporate inactivated polio vaccine (IPV) and HB components and marketed as Pentacel (liquid DTaP-IPV used to reconstitute lyophilized Hib) and Pediacel (a fully liquid version of the vaccine).

DTaP/IPV/Hib/HB—MCM Vaccine Co. This new fully-liquid vaccine produced by a joint venture of Merck and Sanofi Pasteur incorporates 20 µg PT, 20 µg FHA, 3 µg PRN, 5 µg of combined FIM-2 and FIM-3, and IPV from Sanofi Pasteur with Hib and HB components from Merck (see Chapter 15).

Infanrix—GlaxoSmithKline. Infanrix is a DTaP vaccine manufactured by GlaxoSmithKline Biologicals (Rixensart, Belgium). The aP vaccine component contains not less than 25 µg PT, 25 µg FHA, and 8 µg PRN. The vaccine is supplied in single-dose thimerosal-free vials or prefilled syringes. Infanrix is marketed in many countries, most often in combination with Hib, HB, or IPV (e.g., Infanrix Tetra, Infanrix Penta, Infanrix Hexa; see Chapter 15). In the United States, the combination of Infanrix, HB vaccine, and IPV is marketed as Pediarix.

Triavax—Sanofi Pasteur. Triavax is manufactured by Sanofi Pasteur SA (Lyon, France) and contains approximately 25 µg PT and 25 µg FHA. The vaccine is not available as a standalone DTaP but is marketed in many countries in combination with other components such as Hib, HB, and IPV (e.g., Tetraxim, Pentaxim, or Hexaxim; see Chapter 15).

Currently Available Preparations for Adolescent and Adult Use

The following vaccines were developed for use in adolescents and adults, but have also been found useful in some jurisdictions for preschool boosting of previously primed children (e.g., at age 4 to 6 years).

Adacel—Sanofi Pasteur. Adacel (marketed in Europe as Covaxis) is an adolescent-adult formulation of Sanofi Pasteur's five-component aP vaccine. It is identical to Daptacel (Tripacel) except that it contains reduced quantities of PT (2.5 µg) and diphtheria toxoids (2 lf [limit of flocculation]).

Adacel is licensed for use in most countries for persons 4 years of age or older (in the United States, persons 10 to 64 years of age) and is supplied in thimerosal-free, single-dose vials. Combined with IPV, the product is marketed as Repevax.

Boostrix—GlaxoSmithKline. Boostrix is an adolescent-adult formulation of GlaxoSmithKline's three-component aP vaccine. It differs from Infanrix by containing reduced quantities of PT (8 µg), FHA (8 µg), PRN (2.5 µg), diphtheria (2.5 lf), and tetanus (5 lf) toxoids, and adjuvant (<0.39 mg aluminum). Boostrix is licensed in most countries for persons 4 years of age or older (in the United States, persons 10 years of age and older). Outside the United States, it is also available combined with IPV as Boostrix-IPV.

Other Acellular Pertussis Preparations. Several additional aP vaccines were developed during the 1980s and 1990s but were not licensed, and a number of vaccines that once were licensed have been removed from the market. Interested readers are referred to the third edition of this text[405] for further details. Manufacturers in Asia have developed a variety of aP vaccines for their local markets. For example, in China, at least five locally produced aP vaccines are licensed, along with vaccines from GlaxoSmithKline and Sanofi Pasteur.[406] It is likely that some of these Asian aP vaccines will eventually be offered for export (probably as components of larger combinations; see Chapter 15).

Vaccine Schedule Deviations

Deviation from the approved vaccination schedule should be avoided for multiple reasons. The approved schedule represents the schedule best attuned to the national epidemiological situation and concerning which there is the best available information regarding safety and effectiveness. Administration earlier than recommended may result in lower effectiveness or higher risk of adverse events. Administration later than recommended increases the opportunity for intercurrent infection before vaccines can be administered. However, a delay between doses should not interfere with the final immunity achieved by any of the pertussis vaccines. There is no need to start the series over again, regardless of the time between doses. Partial doses should not be given; there is no evidence that doing so reduces the frequency of serious adverse events, and efficacy may be impaired.

Interchangeability of Vaccines

Few data are available demonstrating the effects of a change during the scheduled immunization series from one brand of DTaP to another, but there are theoretical reasons why switching formulations might reduce effectiveness. Recommendations from ACIP and the American Academy of Pediatrics Committee on Infectious Diseases (Red Book Committee) therefore have indicated a preference to use the same brand of DTaP vaccine for all doses of the vaccination series for a given child. However, the recommendations also state that, if the vaccine provider does not know, or does not have available, the brand of DTaP previously administered to a child, any of the licensed DTaP vaccines may be used to complete the vaccination series. Moreover, the one published study evaluating a change from one DTaP (Tripedia) to another (Infanrix) during the primary series found no adverse effect on safety or immunogenicity.[407] As a practical matter, interchange of the various aP vaccines has become commonplace, fueled by periodic changes in public distribution systems, the vagaries of patient migration and shifting provider purchases, and intermittent shortages of one vaccine or another.

Simultaneous Administration With Other Vaccines

DTwP and DTaP vaccines, or combination vaccines incorporating those components, are routinely administered concomitantly with other vaccines appropriate to the age and previous vaccination status of the child, with the injections given at separate sites using separate syringes. Most studies have found that the adverse reactions after multiple simultaneous vaccinations are only slightly greater than would be expected from the most reactogenic vaccine alone.[408–410] Further reductions in adverse reactions can often be obtained by using vaccines that combine multiple antigens (see Chapter 15), thereby reducing the number of injections given. Although reduced immunogenicity to the pertussis antigens has occasionally been seen when given in combination or association with one or more of the other vaccines, no data exist to suggest that concomitant administration of any of these other vaccines decreases the efficacy of pertussis vaccine. Because whole-cell pertussis vaccine has adjuvant properties, replacement of the whole-cell component with acellular vaccine has resulted in reports of diminution of the immune responses to some of the simultaneously administered vaccines (see Chapter 15), without evidence of impairment of efficacy.

RESULTS OF VACCINATION: WHOLE-CELL PERTUSSIS VACCINES

Although the results of some of the whole-cell pertussis vaccine arms in the efficacy trials in Europe demonstrated surprisingly low efficacy rates,[411,412] most authorities agree that the widespread use of the whole-cell vaccine has had enormous benefits.[252,413,414] These benefits include the rapid decline in morbidity and mortality from pertussis after implementation of whole-cell vaccine programs; the recurrence of disease in countries where whole-cell immunization was discontinued, acceptance rates declined, or vaccines became ineffective; the inverse correlation of the pertussis attack rates and the number of immunized children; and the lower attack rates in previously immunized children than in unimmunized children under both endemic and epidemic conditions.

Immune Responses to Whole-Cell Vaccines

Humoral Immunity

Data from the WHO indicate that 64% of countries use whole-cell pertussis (wP)-containing vaccines in their public programs, including 96% in the African Region and 100% in the Southeast Asia Region, with most administering a pentavalent combination DTwP-HB-Hib vaccine. Although many of the world's children are immunized with locally produced wP vaccines, few data exist to compare their safety, immunogenicity, and efficacy. Most authorities had presumed that all whole-cell vaccines were very similar and that one was as immunogenic and effective as another, given the standardization of many aspects of vaccine production and the fact that all licensed vaccines pass the intracerebral mouse challenge test (which was first introduced in 1940s). When significant differences in immune responses were noted with wP products produced by different manufacturers in the United States and Canada, it became apparent that all whole-cell vaccines were not the same.[321,415,416] The European aP vaccine efficacy trials used several different whole-cell vaccines, which differed widely in efficacy. Thus, it appears possible that some of the wP vaccines produced in various countries in the world might be less effective than others, and this could affect the global burden of pertussis disease.

Another concern with wP vaccines is the negative impact of high maternal antibody levels on infant immune responses. It has been demonstrated that the magnitude of the primary antibody response to whole-cell vaccine in infants depends on the preimmunization (transplacental) levels of antibody to PT, with higher circulating levels of maternally derived antibody being associated with significantly lower levels of postimmunization antibody.[376] In contrast, PT antibody responses to an acellular vaccine containing 12.5 µg each of PT and FHA were superior to those of the whole-cell vaccine and were not affected by prevaccination antibody levels.[376] There have been no studies in developing countries that evaluate the impact of maternal antibody on immune responses to primary immunization in young children with locally produced whole-cell vaccines. Such studies are needed if maternal Tdap is to be used in developing countries where infants will be routinely receiving wP vaccines in the primary series.

Although humoral immune responses to the pertussis antigens have been repeatedly demonstrated in recipients of the wP vaccines, as detailed below, the immune responses rapidly wane and do not provide durable protection against future reinfection. Despite considerable progress in our understanding of immune responses to *B. pertussis*, no unequivocal immunological correlates of protection against pertussis have been identified.

Controlled Clinical Trials of Whole-Cell Vaccines

It is well documented by controlled clinical trials that wP vaccine provides protection against clinical whooping cough in the majority of immunized people. The first convincing evidence was provided by studies in the Faroe Islands during two epidemics.[390] These studies showed that pertussis vaccine not only protected against disease but also ameliorated the severity of disease in immunized persons who contracted the illness. Although studies with early vaccines produced inconsistent results,[22,252,414,417] clinical trials after standardization of the vaccines by the mouse intracerebral challenge test[413] demonstrated consistent efficacy.[413,418,419]

In more recent years, a number of field trials of aP vaccines (see "Efficacy Trials, 1992 to 1997" later) have incorporated wP vaccines as controls and have provided some of the best data ever obtained about the efficacy of the conventional whole-cell vaccines. As mentioned previously, these studies showed that whole-cell vaccines vary substantially in efficacy. The following estimates reflect efficacy after three doses and, to the extent possible, consistent case definitions; however, none of these studies was fully blinded and randomized, and the estimates may be generous. The Mainz[420] and Munich[421] studies produced efficacy estimates of 98% and 96%, respectively, for the German-produced Behringwerke vaccine; the U.S.-made Wyeth-Lederle whole-cell vaccine was reported to be 83% efficacious in the Erlangen trial[323,422]; and the Senegal trial reported the French-made Sanofi Pasteur whole-cell vaccine to be 96% efficacious.[423] In each of these trials, the whole-cell vaccine was more efficacious than the acellular product.

In marked contrast, the U.S.-made Connaught whole-cell vaccine had very low rates of efficacy after three doses: 48% in Sweden and 36% in Italy.[324,325] In the Swedish study, efficacy was nearly 74% for the first 6 months after the third dose of vaccine but declined rapidly after that time.[324] A British national survey of reported whooping cough from 1989 to 1990 determined that the efficacy rates of the Wellcome whole-cell vaccine, administered at 3, 5, and 10 months of age, were 87% and 93% during epidemic and nonepidemic periods, respectively.[424] Efficacy declined with age but remained high until the age of 8 years. A repeat survey was conducted in 1994 to determine whether efficacy had been altered by the change to an accelerated schedule of immunization at 2, 3, and 4 months of age with no subsequent booster. Efficacy was not altered and was 94% overall for those subjects between 6 months and 5 years of age.[425] This accelerated schedule was also associated with a reduced rate of adverse reactions.[426]

Other Evidence of Effectiveness of Whole-Cell Vaccines

Secular Changes in Morbidity and Mortality

There is no question that the widespread use of wP vaccine in developed countries has resulted in a remarkable decline in reported pertussis.[252,284,292,427] However, it is also clear that mortality rates from pertussis were declining in some countries even before the advent of the vaccine.[252,414,428,429] The latter reductions probably reflect improved social and economic conditions, better nutrition, and declines in concomitant infections that may have enhanced pertussis mortality.

Effects of the Withdrawal of Pertussis Immunization

Strong evidence of the benefits of pertussis vaccine was provided by unintended experiments that occurred in three developed countries when vaccine use was curtailed or abandoned. Japan initiated widespread immunization against pertussis in 1950, and over the ensuing years the numbers of reported cases and the numbers of deaths declined remarkably.[284,430] However, beginning in 1975, adverse events temporally associated with administration of wP vaccine to young children led to a near-boycott of the vaccine, and epidemic pertussis recurred. Hundreds of children died of pertussis during this period.[284] A similar experience occurred in England and Wales, in the context of negative publicity surrounding adverse events associated with vaccine. Rates of vaccine acceptance fell from approximately 75% to nearly 25% during the mid-1970s, major epidemics of pertussis ensued, and numerous children died.[292,431] In Sweden, the administration of pertussis vaccine was suspended in 1979 when pertussis outbreaks occurred despite high vaccination coverage, suggesting poor efficacy of the existing vaccine. The incidence of whooping cough then increased more than fourfold from 1980 to 1985, with several major outbreaks in subsequent years.[432,433] With the advent of routine pertussis immunization using acellular vaccines after completion of the vaccine efficacy trials in Sweden, pertussis rates again declined.[434]

Pertussis Rates in Vaccinated and Unvaccinated Communities

Further evidence of the efficacy of wP vaccine is provided by the observation that the reported incidence of pertussis disease varies inversely with vaccine acceptance rates. A study in England and Wales prior to replacement of wP with aP vaccines found that communities with low pertussis vaccine acceptance rates (<30%) had a 59% higher reported incidence of pertussis among children than did areas with high (>50%) acceptance rates; areas with intermediate acceptance rates had intermediate pertussis rates.[435] These findings were not explained by differences among the communities such as crowding and social class; indeed, after adjustment for these two social indicators, the inverse correlation with immunization status and pertussis disease burden was even stronger. In the United States, where infant immunization for pertussis has been routine since the late 1940s, national surveillance demonstrated a greater than 95% reduction in pertussis; surveillance data from 1992 to 1994 found an overall wP vaccine

efficacy of 64% after three doses and of 82% after four or more doses.[326]

Pertussis Attack Rates in Immunized and Unimmunized Children During Outbreaks

Additional evidence for the efficacy of wP vaccine is provided by community outbreaks of pertussis in which the attack rates of the disease in immunized children were compared with the rates in those who were incompletely or never immunized.[292,436] Although the methods of ascertainment and analysis vary, most studies indicate that the efficacy of three or more doses of wP vaccine in protecting children against clinical disease during outbreaks is 80% to 90%, with incomplete immunization offering partial protection.[436] In children who contracted pertussis despite wP immunization, the disease was milder and complications were far less frequent, although younger infants and children are more likely to have received inadequate or no immunization.[437,438] Studies conducted in Senegal also documented that breakthrough cases of pertussis among children vaccinated with wP vaccine were of lesser severity and reduced infectivity than those seen in unimmunized children.[439,440]

Herd Immunity After Immunization

Because wP vaccine is not 100% effective, it might be considered curious that morbidity and mortality from clinical pertussis have been negligible in countries with widespread immunization programs. This is a particularly interesting finding because surveillance statistics and studies demonstrating pertussis to be a common cause of protracted cough illness in adolescents and adults suggest that *B. pertussis* remains ubiquitous in these countries.[212,214,234,356–358] Attempts to model mathematically the decline in pertussis incidence attributable to widespread immunization with vaccines of 85% efficacy have underestimated the rates of decline of the disease.[441] Although other factors, such as social and economic changes, very likely play a role, the most probable explanation is herd immunity, a complex phenomenon that varies among different infectious diseases and is difficult to measure with precision[442] (see Chapter 77). Herd immunity undoubtedly explains the cycles of outbreaks of pertussis every 3 or 4 years; after an outbreak, several years are required for the proportion of susceptible persons to increase to a level that facilitates a new wave of spread in a population. Studies describing higher rates of pertussis disease in immunized children living in communities with large numbers of unimmunized children provide additional evidence for the role of herd immunity.[443] More recently, Rohani and colleagues demonstrated an increase in the interepidemic period after the initiation of whole-cell vaccination in England and Wales, an indication of reduced transmission and strong herd immunity provided by whole-cell vaccines.[444] In addition, Broutin and colleagues, using aggregated incidence data from multiple countries, demonstrated a 1.3-year increase in the interepidemic period following the inception of wP vaccination programs.[445] These studies, and others, afford strong evidence that whole-cell vaccination reduces not only disease, but also transmission and thus induces herd immunity.[444–446]

Duration of Immunity After Whole-Cell Vaccines

A number of studies have evaluated the duration of protection after immunization with whole-cell vaccine. Those that provide the longest period of evaluation indicate that protection declines by 50% over a period of 6 to 12 years.[447–449] These data are consistent with the previously cited incidence and serosurvey data among whole-cell vaccinated subjects that suggest an increase in rates of pertussis among 13- to 17-year-olds, representing an interval of 7 to 12 years since last vaccination.[214] It is likely that the duration of protection is influenced by the specific wP vaccine used, the number of doses given, the vaccination schedule, and the level of circulating *B. pertussis* capable of stimulating an anamnestic response in previously immunized persons.

Adverse Events With Whole-Cell Vaccines

Despite their clear benefits in reducing the substantial mortality and morbidity of pertussis, the whole-cell vaccines have long been recognized as one of our most reactogenic vaccines. They commonly cause reactions that are minor but burdensome, occasionally cause reactions that are transient but frightening, and uncommonly cause more serious, generally self-limited, adverse effects. For some time, there was substantial suspicion that whole-cell vaccines might be causally related to devastating outcomes such as encephalopathy or sudden infant death syndrome (SIDS), but several careful epidemiologic studies have largely dispelled these concerns.[450–452] In addition, the identification of Dravet syndrome among some children who had the onset of seizures after wP vaccine has provided new insights into cases of encephalopathy after vaccination. Dravet syndrome is an epileptic encephalopathy linked to mutations in SCN1A (neuronal sodium channel α_1 subunit) and is characterized by the onset in infancy of seizures and developmental decline. A study in a large California healthcare system found that the causative mutation arose de novo at a rate of 1 per 20,000 live births (95% CI, 1/9600 to 1/45,700).[453] Several investigations have found SCN1A mutations among some patients previously diagnosed with alleged vaccine encephalopathy from wP vaccine.[454,455]

Untoward events after wP immunization began to be of increasing concern to the public and to physicians in the early 1970s, particularly in countries where widespread vaccination had eliminated most disease. Vaccine-associated adverse events loomed large in the eyes of young parents and physicians who had never witnessed the morbidity and mortality of whooping cough. Widespread publicity about the alleged dangers of pertussis vaccine, coupled with declining disease rates in some countries and doubts about vaccine efficacy in others, resulted in near-abandonment of wP vaccine in several countries. Consequently, pertussis disease recurred.[284,292,432] In the United States, strong school-entry immunization laws enabled vaccination rates to be maintained despite widespread publicity about these concerns. However, extensive litigation over alleged personal injuries caused by the vaccine cost millions of dollars and contributed to the cessation of pertussis vaccine production by several manufacturers.

Establishing or disproving cause and effect, particularly for events of major consequence, proved difficult. Although the original allegations of causation were largely anecdotal and based on the fallacious assumption that subsequences and consequences were synonymous, they raised great concern and stimulated the search for an improved vaccine. The relationships between wP vaccine and fatal or disabling events were difficult to evaluate because of the rarity of such events; because vaccine was administered to infants at an age when disorders such as encephalopathy, infantile spasms, neurologic conditions, and SIDS were most likely to occur; because these disorders can arise from other causes; and because an absolute negative can never be proven. Earlier estimates of the rates of adverse events were not optimal because of lack of consideration of background rates, ill-defined criteria, and uncertainty of denominators. However, in the 1980s, more rigorous epidemiologic or interventional studies greatly

improved the understanding of the incidence and spectrum of adverse events after wP vaccine. Many of these studies, particularly those related to serious untoward events, were evaluated by a special committee of the Institute of Medicine (IOM) of the U.S. National Academy of Sciences.[450–452] Although these evaluations were reassuring to healthcare providers and to parents, it was the development of less reactogenic aP vaccines and their replacement of the whole-cell products that put an end to the long debate in developed countries over adverse events associated with whole-cell vaccines. wP vaccines remain widely used in developing countries, where concerns regarding adverse events do not seem to be as common.

Because of space limitations and the replacement of whole cell vaccines by acellular ones in most developed countries, we have restricted the discussion of adverse events associated with whole-cell vaccines to a summary of the key studies and conclusions. Readers interested in a more thorough review of these data are referred to earlier editions of this text.[405,456,457]

Nonfatal, Nondisabling Reactions

Common Reactions. Minor local reactions, consisting of redness, swelling, and pain at the site of injection, occur in about half of DTwP recipients. Reactions occur five times more frequently after DTwP than after DT.[458–461] Similarly, minor systemic reactions such as fever, irritability, and drowsiness are significantly more common after DTwP than after DT (diphtheria and tetanus toxoids–pediatric).[458–461] Approximately half of the children who received wP vaccine experienced some minor fever, with less than 1% having an elevation in temperature to 40.5°C.[458–462]

Participants in the Multicenter Acellular Pertussis Trial (MAPT; see later) experienced somnolence at rates of 62% for whole-cell recipients and 43% for acellular vaccine recipients,[462] suggesting that the somnolence was, at least in part, an effect of the DTwP vaccine. Some children were reported to have an unusual, high-pitched cry. Others had a period of excessive crying, which lasted several hours or longer after an injection of whole-cell vaccine. This incessant, inconsolable crying usually begins within 12 hours. Persistent crying of 1 hour or more occurred in both the DTwP and DT groups in the study by Cody and coworkers[461] but was at least four times more common after DTwP. Among those with persistent crying, the cry was described as high-pitched or unusual in 3.5% of the children.[460–462]

These common reactions after wP vaccines varied somewhat in frequency and severity among lots[463] and manufacturers. The vaccine schedule followed may also have affected the incidence and severity of adverse reactions. In 1990, the schedule for DTwP vaccination in the United Kingdom was changed from 3, 5, and 10 months of age to 2, 3, and 4 months of age. The new schedule was associated with a substantial reduction in postvaccination fever and injection-site redness.[426] With the accelerated vaccination schedule in the United Kingdom, reaction rates for the whole-cell vaccine did not differ significantly from those of several acellular vaccines.[426]

Reaction rates also varied with the number of prior DTwP injections. In the Cody and colleagues study, local reactions increased in frequency with successive doses, including the preschool booster.[460,461,463] The incidence of fever also increased with successive doses through the 18-month booster, but was lower with the preschool booster at 4 to 6 years. On the other hand, persistent, inconsolable crying occurred most frequently with the initial dose and less often thereafter. In the MAPT, the incidence and severity of fever increased substantially with successive primary doses of the reference whole-cell vaccine.[462,464] Redness increased modestly; frequency of pain, fussiness, anorexia, vomiting, and use of antipyretics did not materially increase or decrease with successive doses; and drowsiness decreased.[462] In general, children who experienced local or systemic reactions after wP vaccine had an enhanced likelihood of experiencing the same reaction with a subsequent dose.[465]

Uncommon Reactions. DTwP was associated with febrile seizures (0.06% in the Cody and coworkers trial),[461] and seizures occurred at increased rates after DTwP in children with personal or family histories of convulsions.[461,465–472] However, simple febrile convulsions, although distressing, are considered to be benign,[473] with no evidence that seizures after DTwP induced persistent epilepsy.[474]

Another worrisome but uncommon reaction to DTwP was a strange shock-like state, termed a hypotonic-hyporesponsive episode (HHE), that usually had its onset within 12 hours of inoculation and lasted for several hours but always resolved.[475] Neither death nor adverse sequelae have been observed after HHE episodes. Cody and colleagues detected an incidence of HHE of 0.06%.[461,463] However, the mechanism of HHE is unknown, and HHE has been reported with other vaccines, including aP products, as described later.

Serious Reactions Allegedly Caused by Whole-Cell Pertussis Vaccine

Encephalopathy. The most serious reaction attributed to wP vaccine was acute encephalopathy. The National Childhood Encephalopathy Study, conducted in Great Britain from 1976 to 1979, examined whether the frequency of DTwP vaccination in children with encephalopathy was greater than expected. Based on 11 subjects who appeared to have neurologic residua 18 months after wP vaccination, it was estimated that acute encephalopathy with permanent brain damage occurred at the widely quoted rate of 1 per 310,000 doses, with a 95% CI of one in 54,000 to 5,310,000 doses. However, subsequent investigations cast doubt on most of these 11 diagnoses.[476–478] At 10-year follow-up, the rates of death or other sequelae in these subjects were similar whether or not the onset of acute neurologic illness was temporally associated with DTwP vaccination.[479]

The results of the National Childhood Encephalopathy Study have been subjected to extensive analysis, reanalysis, challenge, and debate.[478–484] None of this scrutiny has confirmed a causal relationship between pertussis vaccine and permanent neurologic damage. Several subsequent U.S. studies also failed to show a relationship between wP vaccine and acute encephalopathy leading to brain damage.[468,472] In 1994, the IOM concluded that the "balance of evidence is consistent with a causal relation between DT[w]P and chronic nervous system dysfunction in children whose serious acute neurologic illness occurred within 7 days of DT[w]P vaccination."[451] However, the IOM was not able to determine whether the wP vaccine increased the number of children with chronic neurologic illness or was simply a precipitating event in children who would have nonetheless developed chronic neurologic dysfunction as a result of underlying brain or metabolic abnormalities.[485,486] In a 2015 report from the U.S. National Vaccine Injury Compensation Program, medical records of children younger than 2 years of age with seizures or encephalopathy allegedly caused by an immunization from 1995 through 2005 were reviewed. There were 165 claims with sufficient clinical information for review. The majority of claims were associated with wP vaccines, and many of the children with alleged vaccine injury had preexisting neurologic or neurodevelopmental abnormalities, suggesting genetically determined epilepsy. The authors of the article recommended that

genotyping should be performed in all children who present with seizures and encephalopathy after vaccination.[485]

Infantile Spasms. Infantile spasms, which occur in approximately 40 per 100,000 infants,[487] have been reported in temporal association with wP vaccination.[488] Because infantile spasms typically occur between 2 and 8 months of age, an association is occasionally seen by chance alone. Four studies demonstrated no foundation for concern that DTwP causes infantile spasms.[282,477,489–491]

Sudden Infant Death Syndrome. Because SIDS occurs most often in the first 6 months of life,[492] it is to be expected by chance alone that some instances would be observed within a day or two of receipt of DTwP. Several early reports suggested clustering of SIDS cases within a few days after the administration of DTwP,[493–497] but subsequent studies found no evidence of a causal relationship between SIDS and receipt of DTwP.[22,498–505] The IOM panel, after a careful review of all studies, also concluded that no causal relationship existed.[450,506]

Other Serious Conditions. The IOM panel examined the evidence concerning an association between DTwP and a variety of syndromes. Table 44.7 summarizes their conclusions.[451,507]

TABLE 44.7 Institute of Medicine Conclusions Regarding Causation of Serious Adverse Events by Diphtheria and Tetanus Toxoids Plus Whole-Cell Pertussis Vaccines

Event	Conclusion
Evidence indicates causation	Anaphylaxis Prolonged or inconsolable crying Febrile seizures
Evidence consistent with causation	Acute encephalopathy Hypotonic-hyporesponsive episodes
Evidence does not indicate causation	Afebrile seizures Hypsarrhythmia Infantile spasms Reye syndrome Sudden infant death syndrome
Insufficient evidence to draw a conclusion	Aseptic meningitis Chronic neurologic damage Epilepsy Erythema multiforme or other rashes Guillain-Barré syndrome Hemolytic anemia Juvenile diabetes Learning or attention disorders Peripheral mononeuropathy Thrombocytopenia
No evidence available either way	Autism

U.S. National Childhood Vaccine Injury Act

Increasing litigation over alleged vaccine injuries and withdrawal from the marketplace of vaccines by several DTwP manufacturers prompted the U.S. Congress in 1986 to pass the National Childhood Vaccine Injury Act, which provides compensation for certain untoward events that occur within specified time periods after vaccination. In 1995, program rules were revised in light of the report of the IOM committee.[450,506] The replacement of wP with aP vaccines has markedly reduced the rates of adverse reactions temporally associated with pertussis vaccine,[507] resulting in a corresponding decline in vaccine injury claims associated with pertussis-containing vaccines.[508] Recent reports from the Vaccine Injury Compensation Program document that the claims of seizures and encephalopathy were much greater following wP than aP vaccines.[485]

RESULTS OF VACCINATION: ACELLULAR PERTUSSIS VACCINES

Immune Responses to Acellular Vaccines

Humoral Immunity

Numerous immunogenicity and reactogenicity studies have been published evaluating aP vaccines. However, making comparisons among them is difficult because of variations in study design, study populations, and serologic assays. To provide such comparisons and facilitate selection of candidate vaccines for anticipated efficacy trials, the National Institute of Allergy and Infectious Diseases (NIAID) sponsored the MAPT in six of its Vaccine and Treatment Evaluation Units from 1991 to 1992. Thirteen acellular and two whole-cell vaccines were evaluated in the MAPT, including all but one of the acellular vaccines subsequently evaluated in efficacy trials. Although that vaccine was not available for the MAPT, it was evaluated thereafter at one of the Vaccine and Treatment Evaluation Unit sites using the MAPT protocol, procedures, and data forms; sera were evaluated in one of the MAPT reference laboratories. Immunogenicity and reactogenicity results from that study are presented here, along with the MAPT results, to provide the most complete available comparison of these vaccines.

Healthy infants enrolled in the MAPT were randomized to receive one of the study vaccines (Table 44.8) at 2, 4, and 6 months of age. Two wP vaccines, one made by Lederle Laboratories (the reference or control vaccine) and the other by Massachusetts Public Health Biologic Laboratories were evaluated. Sera were obtained before the first immunization and 1 month after the third immunization. Serologic assays included ELISA antibody to PT, FHA, PRN, and fimbrial proteins; Chinese hamster ovary cell toxin neutralization and agglutination assays; and assays of diphtheria and tetanus antitoxin.[403]

Each vaccine produced significant increases in antibodies directed against its included antigens, which most often equaled or exceeded those produced by the reference whole-cell vaccine (see Table 44.8).[403] Nonetheless, postimmunization antibody levels differed substantially among the acellular vaccines. For PRN and fimbrial proteins, and to some extent for FHA, antibody levels tended to correlate with the quantity of antigen included in the vaccine. For PT, postimmunization antibody levels did not correlate well with the quantity of antigen in the vaccine, suggesting that manufacturing techniques were important in determining the immunogenicity of the particular PT component of each vaccine. As shown in Table 44.8, the two vaccines containing a recombinant genetically modified PT stimulated the highest antibody responses.[12]

TABLE 44.8 Antibody Levels 1 Month After the Third Dose of Vaccine: Results From the Multicenter Acellular Pertussis Trial and a Follow-up Trial[a]

Manufacturer or Distributor	Vaccine[b]	Geometric Mean Antibody Level (95% CI) After Immunization at 2, 4, and 6 Months			
		PT	FHA	PRN	FIM
Sanofi Pasteur (Canada)	Tripacel	36 (32–41)	37 (32–42)	114 (93–139)	240 (204–282)

[a]Results for Certiva are from a separate study conducted at an MAPT study center after completion of the MAPT, using the MAPT protocol, procedures, and data forms; sera were assayed at one of the MAPT reference laboratories.
[b]For those vaccines without known trade names, designation reflects source and composition of vaccine.[403] For branded products, note that the licensed vaccine's formulation may differ from that of the vaccine evaluated in MAPT.
[c]Contains genetically inactivated PT component.
CI, confidence interval; FHA, filamentous hemagglutinin; FIM, fimbrial proteins; MAPT, Multicenter Acellular Pertussis Trial; N/A, not available; PRN, pertactin; PT, pertussis toxin.
Modified from Edwards KM, Meade BD, Decker MD, et al. Comparison of 13 acellular pertussis vaccines: overview and serologic response. Pediatrics. *1995;96:548–557.*

No acellular vaccine was most or least immunogenic with respect to all included antigens.

The Connaught wP vaccine that was subsequently used in the European vaccine efficacy trials was not included in the MAPT studies, but was subsequently shown to have lower efficacy than the acellular vaccines and to be poorly immunogenic.[509]

Cell-Mediated Immunity

T-cell immune responses to aP vaccine antigens were assessed during the trials of aP vaccines conducted in Italy and Sweden in the 1990s.[324,325] These investigations documented that robust T-cell immunity was stimulated in infants after aP, that the T-cell immunity persisted longer than the serum antibody, and that T-cell responses were boosted by natural infection.[510–514] These human T-cell studies confirmed similar results obtained in mouse models.[89] Immune responses to wP vaccine more closely mirrored those seen after natural pertussis infection, with both natural infection and wP vaccination inducing Th1-polarized responses. Responses after aP vaccines were predominantly Th2.[511,513,515–518] A recent study boosted individuals immunized with either DTwP or DTaP with Tdap and demonstrated that the Th1 or Th2 preference shown after the primary series was not changed with Tdap boosting.[518a]

A small cohort of children had humoral and cell-mediated immunity (CMI) responses evaluated on multiple occasions during the Italian aP vaccine efficacy trial. A marked decline in anti-PT IgG was noted over time, whereas substantial increases were noted in the CMI responses to the same antigen more than 42 months after vaccination.[514,519] Tran Minh and Edelman in Finland evaluated pertussis-specific T-cell responses in adolescents at both 1 month and 3 years after an aP booster dose and found persistently elevated CMI responses 5 years after the boost.[520,521]

Sharma and Pichichero reported that DTaP-induced $CD4^+$ T cells in infants were functionally and phenotypically different from those of adults.[522] Smits and colleagues also demonstrated that T-cell proliferation in response to pertussis antigen stimulation was comparable for children primed with wP or aP, although the time since the last booster vaccine was significantly longer for the wP-primed children, and more children had detectable cytokine responses after wP priming than aP priming.[523] This work suggested that priming with wP induced longer-lasting immunity than priming with aP.

Recently, a more complicated picture has emerged, as summarized in an excellent review article by Fedele and colleagues, who demonstrated a robust T-cell response, with both proliferation and IFN-γ–positive $CD4^+$ T cells, in nearly one-third of vaccinees 5 years after primary vaccination with two aP vaccines.[524] Schure and colleagues showed that there is an increase in cytokine production after booster vaccination of children primed with wP vaccine but not in children primed with aP vaccine.[525] These investigators also reported that in 9-year-old children given a second aP booster 5 years after a preschool booster, T-cell responses did not increase.[526] Schure and colleagues suggested that the enhancement of T-cell immunity during the 5 years following the booster at 4 years of age was probably stimulated by natural boosting in the community by circulation of *B. pertussis*, which could explain

the persistence of protection in aP vaccine recipients despite a substantial waning of both antibody and T-cell responses induced by the primary immunization.[524] Fedele and colleagues speculated that the duration of immunity to aP vaccines introduced in Europe in the mid-1990s was overestimated initially because asymptomatic natural boosting occurred because of high rates of natural *B. pertussis* circulation. Now, with reduced circulation of *B. pertussis* in high-income countries with comprehensive vaccine coverage, T-cell responses are not boosted and pertussis has resurged.

Over the past several years, the understanding of T-cell immune responses to *B. pertussis* has expanded broadly, stimulated by observations made in animal models. In particular, murine models of *B. pertussis* infections have clearly demonstrated the cooperative role played by Th1 and Th17 T-helper cells following natural infection or wP vaccination in protection against pertussis.[161] In contrast, aP vaccines induce a mixed Th2 and Th17 response, with the Th2 component not appearing to materially improve protection.[527] Recent evidence from the baboon model of pertussis has uncovered a major deficit in protective immunity induced by aP vaccination. In this model, immune responses induced by immunization with wP vaccines prevent disease and enhance clearance after infection, although not as effectively as a previous natural pertussis infection.[173] In contrast, immune responses after aP vaccines prevent disease, but do not prevent infection or transmission of *B. pertussis* to naïve baboons. It has not yet been conclusively established in either the baboon or human that the failure of aP vaccines to prevent subsequent infection reflects a failure to induce appropriate cellular immune responses, but the mouse data suggest that this will be the case.

Because the immunological data in humans are limited, additional efforts should be made to compare the immune responses in DTwP- and DTaP-vaccinated children using current technologies, including systems biology approaches, to build models of the interactions that lead to protection, and to use next-generation RNA sequencing to highlight differences in short-term transcriptional responses to either wP or aP vaccination that could contribute to the observed differences in long-term protection.[528]

Immune Correlates of Protection

Regulatory authorities rely on end point clinical trials to establish the effectiveness of a vaccine, unless a correlate of protection (e.g., an immunological measure) has been established that reliably predicts the effectiveness of subsequently produced vaccine. The establishment of an immune correlate of protection is important for all vaccines, but it is particularly needed for aP vaccines because the old gold standard to establish the potency of vaccines, the intracerebral mouse protection test, does not appear to predict aP vaccine potency adequately. Immune correlates of protection typically are established in randomized, placebo-controlled efficacy trials in which the attainment of a particular postvaccination level of immunity is correlated with prevention of disease. Early studies from the United Kingdom had suggested that measurable agglutinin titers in serum after whole-cell vaccination correlated with protection against pertussis disease.[393,529] One of the stated goals of the 1986–87 Swedish efficacy trial evaluating the one- or two-component Japanese-made aP vaccines was to establish serologic correlates of protection. However, much to everyone's dismay, postvaccination antibody levels of PT and FHA did not correlate with clinical protection. A number of possible explanations were proposed for this disappointing result.[530] Postimmunization antibody levels may have poorly predicted antibody levels at the time of exposure, reflecting the lack of data on the kinetics of antibody decline after immunization; antibody assays may have been conducted using the wrong epitopes; or perhaps protection was conferred not by humoral antibody but by CMI or mucosal immunity.

In several of the aP vaccine efficacy trials conducted in Europe in the mid-1990s, efforts were made to determine immune correlates of protection. A nested household study was conducted as part of the 1992 Stockholm efficacy trial, which included a DT (placebo) arm, a U.S. DTwP vaccine, a two-component acellular vaccine, and a five-component acellular vaccine. Serum samples obtained at 1 and 2.5 years of age and within 4 months before exposure, or acute serum samples obtained at least 6 months after the third dose, were used as preexposure serum samples for 209 household-exposed children.[105] The results of this study indicated that vaccine efficacy against typical pertussis after household exposure to *B. pertussis* was 75% for the five-component acellular vaccine, 42% for the two-component vaccine, and 29% for the licensed U.S. whole-cell vaccine when compared with the DT placebo (it is expected that efficacy estimates from a household contact study will differ from those obtained in a prospective randomized trial, given the highly variable nature and intensity of household exposure). Logistic regression analyses of serologic data demonstrated statistically significant correlations between clinical protection and the presence in preexposure sera of IgG antibodies against PRN, FIM-2/3, and PT. Subjects with PT antibody levels exceeding the authors' analytic threshold of 5 units/mL, but with FIM and PRN antibodies below that threshold, had a computed vaccine efficacy of 46%; those with PT and FIM levels above the threshold had an efficacy of 72%; those with PT and PRN levels above the threshold, 75%; and those with all three antibody levels above the threshold, 85%. The authors concluded that multicomponent pertussis vaccines of proven high efficacy used in the Swedish efficacy trials induced higher antibody levels against PRN and FIM-2/3 than did the less efficacious vaccines evaluated in the same trials, and that anti-PRN, anti-FIM-2/3, and anti-PT may be used as surrogate markers of protection against pertussis for multicomponent acellular and whole-cell vaccines.

A different U.S.-licensed DTwP vaccine, a four-component acellular vaccine, and an open-label control group were compared in a randomized, controlled trial conducted in Erlangen, Germany.[323,531] Sera were collected from vaccinees after the third and fourth doses of vaccine and at comparable time periods in DT vaccine recipients. In addition, sera were collected from a random sample of subjects in each vaccine group at approximately 3-month intervals to construct antibody kinetics curves. This allowed estimation of the specific levels of antibody to PT, FHA, PRN, and FIM-2 at the time of exposure in the household setting. The imputed geometric mean antibody titers to PT, PRN, and FIM-2 at the time of household exposure to pertussis infection were higher ($P < .07$ or lower) in noncases compared with cases. A multivariate classification tree analysis of serologic data found that only PRN and PT were significantly associated with protection. Subjects with an imputed PRN value of 7 enzyme-linked immunosorbent assay unit (EU)/mL or less had a 67% chance of infection, regardless of the PT value. No subjects with a PRN value of 7 EU/mL or greater and a PT value of 66 EU/mL or greater were infected, but, if the PRN value was 7 EU/mL or greater and the PT value was 66 EU/mL or less, the predicted probability of being infected was 31%. Logistic regression analysis also found that high versus low PRN values were associated with prevention of illness after household exposure. In the presence of antibody to PRN, PT, and FIM-2, the additional presence of antibody to FHA did not contribute to protection.

The similarities in the findings of these two studies are noteworthy, but it must be remembered that no efficacious one- or two-component aP vaccines were evaluated in these studies; the results may inform us well as to the correlates of protection for the specific vaccines evaluated but fail to elucidate correlates that are generalizable to all aP vaccines. As Hewlett and Halperin[532] stated in their editorial accompanying the publication of these data, "Overinterpretation of these data is a significant risk and must be assiduously avoided." They cautioned that a vaccine containing PT alone was shown to be efficacious in the Göteborg trial and that the presence of PRN and fimbrial proteins in that trial were not essential to protection.[532]

Since the efficacy studies of the pertussis vaccines in Europe in the 1990s, there has been considerable progress in our understanding of the mechanisms of immune responses to *B. pertussis*, but no unequivocal immunological correlates of protection against pertussis have been identified. Serum antibody titers are important but not sufficient to represent a correlate of protection,[105,531] and the fact that maternal vaccination in pregnancy has been shown to protect the newborn is convincing evidence that IgG antibody alone can provide protection. It has also been shown that mucosal IgA antibodies can play a role in pertussis immunity.[533] Moreover, serum antibodies wane more rapidly after infection or vaccination with wP or aP vaccines than does protection,[514,517,534] and the nature of the cellular immune response appears to be important in determining protection. All these findings suggest that T-cell responses play a role in protection and should be further investigated as correlates of protection.[524]

Controlled Clinical Trials of Acellular Vaccines

Results are available from nine large efficacy trials of aP vaccines that were initiated between 1985 and 1993 in Europe or Africa. These trials differed in many ways: type of study, study population, prevalence of pertussis and other diseases in the community, number of immunizations, timing of immunizations, choice of comparison or control vaccines, methods of surveillance, case definitions, and details of the laboratory support used to evaluate fulfillment of the case definition. These differences confound interpretation of the trials and prevent a simple, direct comparison of their primary efficacy results.

Although these studies were performed several decades ago, they would be difficult or impossible to replicate today and thus continue to provide the best available information regarding the absolute and relative performance of aP and wP vaccines in the context of populations primed solely by wP or natural infection. In evaluating these efficacy trials, there are several independent goals: to position correctly the evaluated vaccines in the spectrum of available vaccines, to draw inferences concerning the influence on efficacy of various vaccine characteristics, and to draw inferences concerning the effect of various study design characteristics on vaccine evaluation. A study that poses difficulties in accomplishing one goal may nonetheless be useful for accomplishing other goals. The objectives of the pertussis vaccination program also play a role in evaluating measurements of efficacy. If the societal goal is focused on the prevention of severe disease, then a study's inability to detect mild illness (or to determine efficacy against that end point) may not be important. However, if the goal is to prevent pertussis infection, then mild illnesses must be detected, even though such illnesses may be more difficult to ascertain than classical whooping cough. To the extent that vaccines modify but do not prevent illness, the case definition chosen could have a major impact on interpretation of the efficacy, and hence the benefits, of the vaccine.

1986 Swedish Efficacy Trial

The first large-scale efficacy trial of acellular vaccine was conducted in 1986 in Stockholm, Sweden, where routine pertussis immunization had been discontinued in 1979 and pertussis had become endemic.[432] The randomized, double-blind, placebo-controlled trial (Table 44.9) evaluated a Biken vaccine containing 23.4 µg each of PT and FHA (denoted JNIH-6; see Tables 44.3 and 44.4),[433,538] a monocomponent Japanese National Institutes of Health vaccine prepared for the purposes of this study and containing 37.7 µg of PT (denoted JNIH-7),[433,538] and vaccine diluent given as a placebo.[189] There was no whole-cell control group. A two-dose schedule was used; infants were enrolled and immunized at 5 to 11 months of age, with the second dose given 8 to 12 weeks later.

Antibody responses to PT were dose dependent, being higher in the children who received the monovalent vaccine; FHA antibody rose only in the bivalent vaccine group. Efficacy for both vaccines was less than anticipated (Tables 44.10 and 44.11); for culture-confirmed cough of any duration, efficacy was 69% for the two-component vaccine and 54% for the monocomponent vaccine.[189]

During the surveillance period, four vaccinees (one JNIH-7 recipient and three JNIH-6 recipients) died of bacterial infections.[538] Review of hospitalizations for infection found no differences among the study groups. Analyses of immunoglobulins from prevaccination and postvaccination sera showed no abnormalities, nor did leukocyte counts obtained in a subsample of subjects 2 to 4 months after the second dose.

In January 1989, the Swedish National Bacteriology Laboratory withdrew the acellular vaccine licensure application, citing both the impression that efficacy was lower than that of whole-cell vaccines and the possible association with deaths resulting from serious bacterial infections. The laboratory called for studies that would directly compare acellular and whole-cell vaccines.[545]

In light of these safety concerns and of animal data suggesting that PT might enhance the susceptibility of animals to bacterial infection,[546] several studies were conducted that demonstrated, if anything, a decreased risk of severe invasive bacterial disease after pertussis vaccine[547–549] and no increased risk of minor infections.[548] Data from Japan indicated that there was no enhanced risk from the acellular vaccines.[550] Thus it appeared that the four deaths were chance events, with no causal relationship to vaccination.

Subsequent Follow-up and Analyses. Later evaluations of various case definitions and confirmatory criteria showed that the two-component and monocomponent vaccines were 81% and 75% effective, respectively, in preventing culture-confirmed disease with at least 21 days of coughing spasms.[539] Estimates of efficacy were profoundly influenced by case definition, ranging (using the monocomponent vaccine as an example) from 5% efficacy in preventing spasmodic cough lasting 1 day or longer to 100% efficacy in preventing culture-confirmed pertussis with spasmodic cough lasting 28 days or longer, with whoops on at least 1 day.[539]

It was also found that prior receipt of pertussis vaccine reduced the likelihood of positive pertussis cultures or significant antibody rises in patients with cough. Thus, pertussis infection could be confirmed more readily in placebo recipients than in vaccinees, which tended to bias efficacy estimates upward.

Although the initial results from the 1986 Swedish trial suggested that the efficacies of the monocomponent and two-component vaccines did not differ substantially, long-term follow-up showed the two-component vaccine to be

TABLE 44.9 Overview of Nine Acellular Pertussis Vaccine Efficacy Trials

Schedule (2 doses, relatively late in infancy) makes comparisons to other trials difficult. Later analyses revealed differential sensitivity of culture and of serology in vaccine vs placebo groups.
Stockholm, 1992[324]	SKB-2 Tripacel[e]	Connaught[d]	DT	2, 4, 6 mo	23.3 mo 23.8 mo	Telephone every 6–8 wk	Parents instructed to report	Stockholm 1992 and Italy are the benchmark studies: prospective, fully randomized and blinded, with both whole-cell and placebo (DT) control groups. Each study evaluated 2 candidate acellular vaccines head-to-head, using the same immunization schedules and nearly identical case definitions and diagnostic procedures.
Italy, 1992[325]	Infanrix, Acelluvax	Connaught[d]	DT	2, 4, 6 mo	17 mo	Telephone every month	Parents instructed to report	
Stockholm, 1993[536]	SKB-2 Acelluvax HCPDT[e]	Wellcome	None	88% at 3, 5, 12 mo; 12% at 2, 4, 6 mo	7.2 mo 21.5 mo 21.5 mo	Clinic visits at 5, 12, 18 mo	Daily check of culture reports	No placebo control group, thus no absolute efficacy estimates, hampering comparisons to other studies. Formulation of Connaught Canada 5-component vaccine changed since Stockholm 1992; however, Acelluvax arm presumably comparable to Italy.
RANDOMIZED, FULLY BLINDED, CONTROLLED STUDIES								
Göteborg (Sweden), 1991[246]	Certiva	None	DT	3, 5, 12 mo	17.5 mo	Telephone every month	Parents instructed to report	Vaccination schedule and lack of whole-cell control group hamper comparisons to other studies.
OTHER STUDIES								
Senegal, 1990[423]	Triavax	Pasteur Merieux	DT	2, 4, 6 mo	21 mo	Field worker visit every week	None	Prospective, double-blind, randomized for relative risk of DTaP vs DTP. Absolute efficacy based on case-contact study using nonrandomized DT/no vaccine group that was unblinded to parents and, probably, to field workers performing initial case detection. Investigating physicians said to be blinded.
Erlangen (Germany), 1991[323]	Acel-Imune	Lederle[d]	DT	3, 5, 7, 17 mo	25.6 mo	Telephone every 2 weeks	Parents instructed to report to PMD	Prospective, double-blind, randomized for relative risk of DTaP vs DTP. Absolute efficacy based on comparison to a nonrandomized DT group that was unblinded to parents and, occasionally, to investigators
Mainz (Germany), 1992[420]	Infanrix	Behringwerke or SmithKline Beecham	DT	3, 4, 5 mo	23 mo	None	Physician report of contact by parent	Household contact study. Vaccine assignment not randomized; parents and physicians responsible for initial case detection not blinded. Central case investigators were said to be blinded
Munich, 1993[421,537]	Tripedia	Behringwerke	DT	3, 5, 7 mo	N/A	None	Physician report of contact by parent	Nonrandomized (vaccine chosen by parents), unblinded (parents and investigators knew vaccine status) case-control study

[a]Descriptive name given for those without trade name. See Tables 44.3 and 44.4 for further details.
[b]Mean duration of surveillance. Subjects were eligible for inclusion as cases from time of last dose (Stockholm 1992, Stockholm 1993), from 28 to 30 days after last dose (Stockholm 1986, Italy, Göteborg, Senegal, Mainz), or from 14 days after last dose (Erlangen) of DTaP.
[c]Passive unblinded surveillance, augmented with inquiries mailed to parents every 6 months and follow-up of positive cultures reported to the National Bacteriology Laboratory, continued for an additional 3 years.
[d]U.S.-licensed whole-cell vaccine.
[e]Tripacel and HCPDT are similar, except that Tripacel contains 10 μg PT and 5 μg FHA, as compared to 20 μg of each in HCPDT.
DT, diphtheria and tetanus toxoids vaccine; DTaP, DT plus acellular pertussis vaccine; DTP, DT plus whole-cell pertussis vaccine; HCPDT, hybrid component pertussis-diphtheria-tetanus vaccine; N/A, not available or not applicable; PMD, private physician.

TABLE 44.10 Results of Nine Acellular Pertussis Vaccine Efficacy Trials, Based on Case Definition Most Similar to That of the WHO[a]

Study	Case Definition[b]	Vaccine[c] (No. of Components)	Efficacy (95% CI)			Comment
			Cases	Absolute %	Relative Risk	
RANDOMIZED, FULLY BLINDED, CONTROLLED, COMPARATIVE STUDIES						
Stockholm 1986[535]	≥21 days cough + ≥9 coughing spasms on at least 1 day + positive culture	JNIH-6 (2) JNIH-7 (1)	10 12	81 (61–90) 75 (53–87)	— —	Differential sensitivity of culture, lack of serologic or epidemiologic link criteria may bias estimates upward
Stockholm 1992[324]	≥21 days paroxysmal cough, plus either: positive culture, confirmed by SA or PCR; 2-fold PT or FHA IgG rise; or epidemiologic link to culture-positive case	SKB-2 (2) Tripacel[d] (4) Connaught DTP	159 59 148	59 (51–66) 85 (81–89) 48 (37–58)	0.83 (0.66–1.1) vs DTP 0.29 (0.21–0.40) vs DTP —	Because of unusually low DTP efficacy, relative risks difficult to compare to other studies
Italy 1992[325]	≥21 days paroxysmal cough, plus either: positive culture, confirmed by SA or PCR; 4-fold CHO or 2-fold PT or FHA IgG or IgA rise; no epidemiologic link criterion	Infanrix (3) Acelluvax (3) Connaught DTP	37 36 141	84 (76–89) 84 (76–90) 36 (14–52)	0.25 (0.17–0.36) vs DTP 0.25 (0.17–0.36) vs DTP —	Because of unusually low DTP efficacy, relative risks difficult to compare to other studies
Stockholm 1993[536]	≥21 days paroxysmal cough plus positive culture (no information on confirmation); no serologic or epidemiologic link criteria	HCPDT[d] (4) Acelluvax (3) SKB-2 (2) HCPDT[d] (4) SKB-2 (2)	13 21 99 38 99	— — — — —	0.85 (0.41–1.79) vs DTP 1.38 (0.71–2.69) vs DTP[e] 2.3 (1.5–3.5) vs DTP 0.62 (0.31–1.2) vs Acelluvax 2.0 (1.4–2.8) vs Acelluvax[e]	Comparison is to the Wellcome DTP used in this study (see Table 44.10). Acelluvax, unchanged from Italy, provides a link to the Italy study (and thus to Stockholm 1992)
RANDOMIZED, FULLY BLINDED, CONTROLLED STUDIES						
Göteborg 1991[246]	≥21 days paroxysmal cough plus either: positive culture confirmed by SA, PCR; 3-fold PT or FHA IgG rise; epidemiologic link	Certiva (1)	72	71 (63–78)	—	Lack of FHA in vaccine enhanced sensitivity of serologic criteria, improving accuracy of estimate
OTHER STUDIES						
Senegal 1990[423]	≥21 days paroxysmal cough plus either: positive culture confirmed by DIF; 2-fold PT or FHA IgG rise; epidemiologic link	Triavax (2) PMC-Fr DTP	24 7	74 (51–86) 92 (81–97)	2.42 (1.4–4.3) vs DTP —	Few cases, thus broad CIs. Open DT group may bias absolute efficacy estimates upward
Erlangen 1991[323]	≥21 days cough with paroxysms, whoop, or vomiting, plus confirmation[f]	Acel-Imune (4) Lederle DTP	≤45 ≤18	78 (60–88) 93 (83–97)	1.5 (0.7–3.4) vs DTP[258] —	Open DT group, incomplete case ascertainment may bias absolute efficacy estimates upward
Mainz 1992[420]	21 days paroxysmal cough plus either: positive culture confirmed by DIF or SA; 2-fold PT or FHA IgG or IgA rise	Infanrix (3)	7	89 (77–95)	4.7 (0.6–37.3) vs DTP	Few cases, thus broad CIs. Note how misleading relative risk is if DTP result is close to 100%
	Behring, SKB DTP	1	98 (83–100)	—	—

TABLE 44.10 Results of Nine Acellular Pertussis Vaccine Efficacy Trials, Based on Case Definition Most Similar to That of the WHO[a] *(Continued)*

Study	Case Definition[b]	Vaccine[c] (No. of Components)	Efficacy (95% CI)			Comment
			Cases	Absolute %	Relative Risk	
Munich 1993[421,537]	21 days paroxysmal cough plus either: positive culture confirmed by SA; epidemiologic link; no serologic criteria	Tripedia (2)	4	93 (63–99)[g]	2.0 (N/A) vs DTP	Few cases, thus broad CIs. Lack of serologic criteria, blinding, or randomization may bias efficacy estimates upward
	Behring DTP	1	96 (71–100)	—	—	—

[a]Results shown are for complete primary infant immunization series (3 doses, except Stockholm 1986, 2 doses); effects of any booster dose are not included. Some results obtained by recalculation from data provided in the referenced source; such results may repr esent crude, rather than adjusted, efficacies. Blank cells: not applicable or no data. WHO case definition: ≥21 days paroxysmal cough, plus bacteriologic, serologic, or epidemiologic confirmation that cough is caused by *Bordetella pertussis*.

[b]Unless otherwise noted: All cultures were nasopharyngeal; FHA rises were considered diagnostic only if culture (and PCR, if done) were negative for *Bordetella parapertussis*; EPI link means documented contact with a culture-confirmed (PCR-confirmed, for Senegal) case within 28 days before or after illness onset in the subject (for Erlangen or Munich, no time limit was specified). Criteria shown are for the case definition most similar to that of the WHO; different criteria may have been used for alternative case definitions.

[c]Descriptive name given for those without trade name. Letters before hyphen indicate source; characters after hyphen indicate number and type of components. All one-component vaccines contain PT; all two-component vaccines contain PT and FHA; three-component vaccines contain PT, FHA, plus either PRN or FIM (as indicated by the letter P or F, respectively); four-component vaccines contain PT, FHA, PRN, and FIM. "F2" signifies that two fimbrial proteins are included. See Tables 44.3 and 44.4 for further details.

[d]*Tripacel* and HCPDT are similar, except that *Tripacel* contains 10 μg PT and 5 μg FHA, as compared to 20 μg of each in HCPDT.

[e]For time from first dose to soon after the third dose, when SKB-2 recipients were unblinded and boosted with another vaccine.

[f]Confirmation criteria: Positive culture (confirmed by PCR in last year of study); "significant" PT IgG or IgA result; or household contact to a culture-confirmed case. "Significant" serologic result defined as a ratio of convalescent to acute antibody level that exceeded the 95th, 99th, or 99.9th percentile of a distribution of similar ratios determined among randomly selected subjects at roughly the same time postimmunization. Selection of the percentile limit was determined by how many, and which, antibody ratios were elevated. Efficacy rates reflect adjustment for single adult households and households in which all siblings were unimmunized. Other published efficacy estimates[323] may have used FHA, PRN, or FIM IgG or IgA values or fourfold agglutinin rises as well, and may not have reflected such adjustment.

[g]Differs from efficacy reported in FDA-approved patient package insert, which is based on the primary case definition (≥21 days of any cough) rather than the WHO definition.

CHO, Chinese hamster ovary cell assay; CI, confidence interval; DIF, direct immunofluorescence; DTP, diphtheria and tetanus toxoids and whole-cell pertussis vaccine; epi link, epidemiological link; FHA, filamentous hemagglutinin; FIM, fimbrial proteins; HCPDT, hybrid component pertussis-diphtheria-tetanus vaccine; Ig, immunoglobulin; N/A, not available or not applicable; PCR, polymerase chain reaction; PMC-Fr, Pasteur Merieux Connaught-France; PRN, pertactin; PT, pertussis toxin; SA, slide agglutination; SKB, SmithKline Beecham; WHO, World Health Organization.

significantly more efficacious (Fig. 44.6).[433] The study was unblinded after 15 months of active observation, and then passive surveillance continued for an additional 3 years, during which time vaccine efficacy ranged from 77% to 92% for the bivalent vaccine and from 65% to 82% for the monovalent vaccine, depending on the case definition (see Table 44.11).[433] Clinical protection after aP vaccine was maintained for at least 4 years.[433]

The monocomponent vaccine, with 50% more PT, appeared to be more effective than the two-component vaccine in preventing the most severe manifestations of disease. Its efficacy exceeded that of the two-component vaccine for every case definition involving whoops (see Table 44.11), a difference that was statistically significant for 28 or more days of cough with whoops.[539] On the other hand, the two-component vaccine appeared to be more effective in preventing mild or moderate disease (e.g., shorter durations of cough or cough without whoops).[433,521,535,551] Thus, efficacy was influenced by both the choice of antigens and the quantity of antigen included.

The initial efficacy results[189] gave the impression that the acellular vaccines were substantially less efficacious than whole-cell vaccine.[189,433,535] As a result, Japan remained the only country in which they were licensed. However, results of later studies suggested that efficacy would have been higher had a standard three-dose schedule been used. Importantly, inclusion of a whole-cell control group might have led to

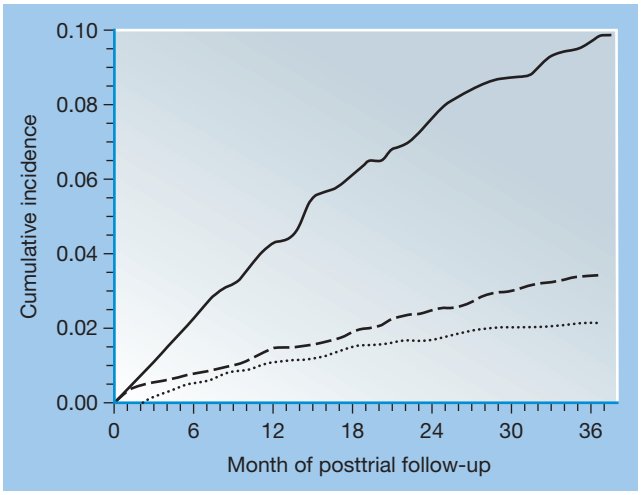

Figure 44.6. Cumulative incidence curves for culture-confirmed pertussis during unblinded posttrial follow-up, in the placebo group *(solid line)*, in the monocomponent (JNIH-7) vaccine group *(dashed line)*, and in the two-component (JNIH-6) vaccine group *(dotted line)*. Unblinded follow-up started August 27, 1987, and ended September 9, 1990. *(From Storsaeter J, Olin P. Relative efficacy of two acellular pertussis vaccines during three years of passive surveillance. Vaccine. 1992; 10:142–144.)*

			Absolute (%)	Relative Risk
OTHER STUDIES				
Senegal	Triavax	≥21 days any cough, confirmed as in Table 44.10[423]	31 (7–49)	1.54 (1.23–1.94) vs DTP
		As above, plus epi link cases confirmed by PCR[423]	53 (23–71)	1.87 (1.38–2.52) vs DTP
		≥8 days paroxysmal cough, confirmed as in Table 44.10[544]	—	3.26 (2.08–5.10) vs DTP
		≥21 days paroxysmal cough, confirmed as in Table 44.10[423]	74 (51–86)	2.42 (1.35–4.34) vs DTP
		As above, plus epi link cases confirmed by PCR[423]	85 (66–93)	2.80 (1.36–5.74) vs DTP
Erlangen	Acel-Imune	≥7 days any cough, confirmed as in Table 44.10[323]	62 (38–77)[d]	3.1 (N/A) vs DTP
		≥21 days paroxysmal cough, confirmed as in Table 44.10[323]	78 (60–88)	1.5 (0.7–3.4) vs DTP
Mainz	Infanrix	≥1 day paroxysmal cough[420]	64 (51–73)	—
		≥7 days paroxysmal cough, confirmed as in Table 44.10[420]	81 (68–89)	—
		≥21 days paroxysmal cough, with or without confirmation[420]	83 (71–90)	—
		≥21 days paroxysmal cough, confirmed as in Table 44.10[420]	89 (77–95)	4.7 (0.6–37.3) vs DTP
Munich	Tripedia	≥21 days any cough, confirmed as in Table 44.10[421]	80 (63–89)[e]	4.0 (N/A) vs DTP
		≥21 days paroxysmal cough, confirmed as in Table 44.10[421]	93 (63–99)	2.0 (N/A) vs DTP

[a]Results shown are for complete primary infant immunization series (3 doses, except Stockholm 1986, 2 doses); effects of any booster dose are not included. Some results obtained by recalculation from data provided in the referenced source; such results may represent crude, rather than adjusted, efficacies. Lower confidence limits less than zero are shown as zero. Blank cells: not applicable or no data. WHO case definition: ≥21 days paroxysmal cough, plus bacteriologic, serologic, or epidemiologic confirmation that cough is due to *Bordetella pertussis*. See Tables 44.9 and 44.10 for additional details, including confirmation methods used by each study.

[b]Descriptive name given for those without trade name. Letters before hyphen indicate source; characters after hyphen indicate number and type of components. All one-component vaccines contain PT; all two-component vaccines contain PT and FHA; three-component vaccines contain PT, FHA, plus either PRN or FIM (as indicated by the letter P or F respectively); four-component vaccines contain PT, FHA, PRN, and FIM. "F2" signifies that two fimbrial proteins are included. See Tables 44.3 and 44.4 for further details.

[c]Definition most similar to that of the WHO (≥21 days paroxysmal cough, confirmed as pertussis by culture, serology, or epidemiologic link to a culture-confirmed case) is shown in boldface; see Table 44.10 for details. Göteborg criteria: Positive culture; or IgG against both PT and FHA ≥6000 in a single convalescent specimen; or two major criteria; or one major and one minor criterion. Major criteria: 3-fold rise in PT or FHA IgG; household contact with confirmed pertussis. Minor criteria: 3-fold change in PT or FHA IgA or IgM; positive PCR. Unless otherwise specified, subjects were eligible for inclusion as cases from time of last dose (Stockholm 1992, Stockholm 1993), from 28 to 30 days after last dose (Stockholm 1986, Italy, Göteborg, Senegal, Mainz), or from 14 days after last dose (Erlangen) of DTaP (see Table 44.9 for vaccination schedules).

[d]Not adjusted for single-adult households and households in which all siblings were unimmunized (see Table 44.10).

[e]This result, which is based on the primary case definition rather than the WHO definition, is the one reported in the FDA-approved patient package insert.

CI, confidence interval; DTP, diphtheria and tetanus toxoids and whole-cell pertussis vaccine; epi link, epidemiological link; FDA, U.S. Food and Drug Administration; FHA, filamentous hemagglutinin; FIM, fimbrial proteins; HCPDT, hybrid component pertussis-diphtheria-tetanus vaccine; Ig, immunoglobulin; N/A, data not available; PCR, polymerase chain reaction; PRN, pertactin; PT, pertussis toxin; WHO, World Health Organization.

markedly different conclusions regarding the relative efficacies of these vaccines.

World Health Organization Case Definition of Pertussis. In response to the demonstration in the 1986 Swedish trial of the strong influence of pertussis case definitions on estimates of vaccine efficacy, and in expectation of the efficacy trials that would be conducted to evaluate the new acellular vaccines being developed, the WHO convened a group of pertussis experts in January 1991 to develop a consensus case definition of pertussis for use in clinical trials. The resulting WHO case definition required the presence of paroxysmal cough for at least 21 days plus confirmation that the cough illness actually was caused by pertussis. This confirmation could be based on laboratory results (e.g., a positive culture for *B. pertussis* or a significant rise in a specific antibody, such as IgG or IgA, against PT, FHA, or FIM-2 or -3) or on an epidemiological link (e.g., a household contact with a laboratory-confirmed case within 28 days before or after the onset of illness in the subject).[552] The consensus statement recognized that future laboratory developments might add to the tools available for bacteriologic or serologic confirmation (e.g., PCR, assay of antibody to PRN).

Although the WHO case definition played an essential role in improving comparability of subsequent field trials, its limitations must be recognized. First, it improved but did not eliminate the problem of differential sensitivity of the case definition with respect to detecting pertussis in the various arms of a comparative trial. The yield of positive pertussis cultures was lower in immunized than in unimmunized pertussis patients and varied inversely with the efficacy of the vaccine.[324,540,543,551,553] Thus, a cough illness that was really pertussis was more likely to be confirmed by culture in the unvaccinated group than in the vaccinated group. This disparity led to a disproportionate discarding of true pertussis cases in the vaccinated group, which resulted in falsely elevated estimates of vaccine efficacy. Similarly, the differences between a less-effective and a more-effective vaccine were likely to be exaggerated because more cases would have been confirmed by culture in the group that received the less-effective vaccine. Those subjects who already had a substantial increase in the level of a pertussis antibody, as a result of the receipt of a highly

immunogenic vaccine, were less likely to show a fourfold (or other diagnostic) rise in antibody titers after infection than those subjects who did not receive a vaccine containing that antigen (or a vaccine substantially less immunogenic with respect to that antigen).[543,551] When comparing two vaccines—one that stimulates the antibody being tested and one that does not—there will be a diagnostic bias favoring the vaccine that stimulates the antibody. If both vaccines contain the antigen in question, the bias will favor the more immunogenic vaccine.

Second, setting the clinical cutoff at "paroxysmal cough of 21 days or more" has been shown to result in the removal of a substantial number of laboratory-confirmed pertussis cases from efficacy calculations.[433,539,554] Because mild cases are more common in vaccinees than in control subjects, it might be argued that the effect is to inflate efficacy estimates, reducing the ability to discriminate among vaccines. However, if the intent is to measure the vaccine's efficacy in preventing classical whooping cough, and mild disease is of lesser interest, then this quality is not a defect.

Third, the case definition permits the use of a variety of serologic assays for confirmation as well as the future use of additional serologic assays or other bacteriologic techniques to detect *B. pertussis* organisms. Although commendable, this flexibility means that studies that differ in the laboratory tools employed for case confirmation, and thus in the sensitivity and specificity of case confirmation, nonetheless may characterize themselves as using the WHO case definition. Thus, as always, the burden is on the reader to consider carefully the methods used in each trial.

Efficacy Trials, 1992 to 1997

After the 1986 Swedish clinical trial, worldwide efforts to develop additional aP vaccines continued, culminating in eight additional efficacy trials initiated between 1990 and 1993 (see Table 44.9). Four of the trials were randomized, prospective, and fully blinded; of these, three incorporated a whole-cell control arm and evaluated several candidate acellular vaccines head to head. The four remaining trials each evaluated only a single vaccine, using a variety of study designs; all made use of placebo (DT or no vaccine) groups that were neither randomized nor fully blinded.

Key characteristics of all nine efficacy studies are summarized in Tables 44.10 and 44.11. For each trial, Table 44.10 presents results for the case definition that we consider most similar to the WHO standard case definition, and Table 44.11 presents selected results reflecting a variety of alternative case definitions or surveillance intervals. For studies not incorporating a placebo control group (e.g., DT), only relative risks (usually calculated relative to a DTwP vaccine used in the same trial) are available. However, relative risks must be interpreted with great caution and can be directly compared across trials only if the reference vaccines (e.g., DTwP) are identical. Unfortunately, no two studies conducted without placebo control groups incorporated a common DTwP vaccine, and thus relative risks can be compared meaningfully only within the studies that evaluated multiple acellular vaccines.

Sweden and Italy, 1992 to 1993. Of the 13 acellular vaccines evaluated in the MAPT, four were selected, on the basis of evaluations of their safety, immunogenicity, and purity, for evaluation in two NIAID-funded efficacy trials conducted in Sweden and Italy.[324,325] These two NIAID-sponsored studies were of rigorous design and served as the benchmarks against which others were compared. The studies were prospective, double-blinded, and randomized, and they incorporated both placebo (DT) and whole-cell control arms. The two studies used closely coordinated protocols, serologic assays, and case definitions (although the Italian case definition did not include epidemiologically linked cases, and preexposure sera were not collected routinely in Italy as they were in Sweden). Infants were immunized at 2, 4, and 6 months of age, and no booster was given. Each study compared two candidate acellular vaccines head to head. The control whole-cell vaccine used in both was produced by Connaught Laboratories and was licensed for use in the United States. Unfortunately, this was not one of the wP vaccines studied in the MAPT trial.

During the main follow-up period of the Swedish study (hereafter referred to as Stockholm 1992), 737 cases of pertussis were diagnosed that met the primary case definition. Efficacy was 59% for the SmithKline Beecham bivalent vaccine (SKB-2), 85% for the Aventis Pasteur five-component vaccine (Tripacel), and 48% for the Connaught whole-cell vaccine (see Table 44.10).[324] The efficacy of the five-component vaccine was sustained during the 2 years of follow-up, whereas the efficacy of the whole-cell vaccine declined substantially.

The performance of the two-component vaccine was much lower than had been anticipated. (JNIH-6, a similar vaccine, was 81% effective in the 1986 trial, using the most similar case definition.) It was noted that the SmithKline Beecham two-component vaccine produced significantly less antibody to PT in Sweden than it had in the MAPT,[555] prompting the investigators[324] and other reviewers[555] to speculate that the vaccine's performance in Stockholm 1992 may, in part, have reflected characteristics unique to the batch of vaccine used in that trial.

The five-component vaccine was 78% effective against laboratory-confirmed pertussis with at least 1 day of cough, suggesting substantial protection against mild or atypical pertussis. In contrast, for this case definition the two-component and Connaught whole-cell vaccines were 42% and 41% effective, respectively.[324]

During the main follow-up period of the Italian trial, 288 cases of pertussis met the primary case definition. The GlaxoSmithKline (Infanrix) and Chiron Vaccines (Tri Acelluvax) three-component acellular vaccines were both 84% effective; efficacy for the Connaught whole-cell vaccine was 36%.[325] After completion of the main follow-up period, unblinded surveillance of the study cohort continued. During the first 9 months of extended follow-up, efficacy of the two vaccines differed significantly: 36 cases were detected among recipients of the GlaxoSmithKline vaccine, as compared with 18 among recipients of the Chiron vaccine (efficacies of 78% and 89%, respectively).[495] However, a more complete analysis that incorporated results through April 1997 found no material differences in long-term efficacy. For the GlaxoSmithKline and Chiron vaccines, respectively, efficacies by year of observation were as follows: for 1994, 82.7% and 82.1%; for 1995, 81.5% and 85.9%; and for 1996, 87.6% and 87.7%.[556] Additional follow-up through 6 years of age demonstrated continued high efficacy of these vaccines.[557] (In retrospect, one wonders about the impact of circulation of wild-type pertussis organisms on persistence of immunity in these vaccinated subjects.)

The similarity in efficacy of the three multicomponent vaccines is noteworthy, particularly given their substantially different compositions (see Tables 44.3 and 44.4). Tri Acelluvax had only one-fifth the PT, one-tenth the FHA, and one-third the PRN content of Infanrix (but the PT was genetically inactivated rather than being a toxoided natural protein and immune responses to this recombinant PT were robust in the MAPT trial). The Canadian five-component vaccine, Tripacel, had far less than half the PT, FHA, and PRN of Infanrix but contained FIM-2 and FIM-3. These facts strongly suggest that the efficacy of an aP vaccine is influenced by both the choice of components and the particular characteristics of those components.

Sweden, 1993 to 1996. After completion of the immunization phase of Stockholm 1992 (but before completion of the surveillance phase), the Swedish investigators launched another NIAID-supported, prospective, randomized, double-blind trial (referred to as Stockholm 1993) that compared four vaccines: (a) the two-component SmithKline Beecham vaccine evaluated in Stockholm 1992; (b) a five-component Sanofi Pasteur Canada vaccine (hybrid component pertussis-diphtheria-tetanus vaccine [HCPDT]) similar to the one evaluated in Stockholm 1992 (Tripacel) but reformulated to contain more PT and FHA; (c) the three-component Chiron acellular vaccine (Tri Acelluvax) evaluated in Italy; and (d) a different whole-cell vaccine, the Medeva Wellcome whole-cell vaccine (now produced by Evans Medical) used in the United Kingdom.[536] Because of the safety and efficacy of aP vaccine demonstrated in Stockholm 1992, Stockholm 1993 did not incorporate a placebo group. Conducted in 22 of 25 Swedish counties, the trial randomized 82,892 children to be immunized at 3, 5, and 12 months of age (the Swedish schedule for DT). Surveillance was predominantly passive; detected rates of pertussis were markedly lower than in Stockholm 1992. Surveillance was terminated early for the group receiving the two-component SmithKline Beecham vaccine, and the subjects were immunized with the Canadian five-component acellular vaccine when results from the Stockholm 1992 study showed the two-component vaccine to be of substantially lower efficacy than the others.

The relative performances of the evaluated vaccines are shown in Tables 44.10 and 44.11 (the absence of a placebo control group precludes calculation of absolute vaccine efficacies). Relative risks of culture-confirmed *B. pertussis* infection with at least 21 days of paroxysmal cough were 0.85 and 1.38 for the five-component and three-component vaccines, respectively, as compared with whole-cell vaccine. The relative risk of pertussis occurring between administration of the second dose (at 5 months of age) and third dose (at 12 months of age) of vaccine was 1.42 for the five-component vaccine, 3.13 for the three-component vaccine, and 7.81 for the two-component vaccine (as compared with whole-cell vaccine). Efficacy of the two-component vaccine differed significantly from that of the other three.

The Stockholm 1993 study provides important new data, but several factors complicate the direct comparison of its results to those of other trials. As noted, there was no placebo control group, precluding calculations of absolute efficacy. The Wellcome whole-cell vaccine was not used in any other efficacy trial. The five-component Aventis Pasteur Canada vaccine evaluated was the "hybrid" formulation developed for use in combination vaccines, containing twice the PT and four times the FHA as in the "classical" formulation. The SmithKline Beecham two-component vaccine was used in Stockholm 1992, but surveillance of this group was terminated early in the second Stockholm study. Thus the Chiron three-component vaccine represents the only link to the prior trials.

Based on the Stockholm 1992 and Italy 1992 trials (see Table 44.10), Infanrix, Tri Acelluvax, and the classical (CLL-4 F_2) formulation of Tripacel appear to be of equal efficacy. In Stockholm 1993, however, the relative risk of typical pertussis with the reformulated (hybrid or HCPDT) version of Tripacel was 0.62 (95% CI, 0.28–1.29) compared with Tri Acelluvax. For combined mild and severe pertussis, the hybrid five-component vaccine was equal to the whole-cell vaccine but significantly better than Tri Acelluvax.[558] Taken together, these observations suggest that the hybrid formulation of Tripacel is more efficacious than the classical formulation, and accordingly, that increasing the amount of PT and FHA in a vaccine can increase its efficacy. Of note, serologic studies performed on small subsets of subjects in the 1992[540] and 1993[543] Stockholm trials found significantly higher FHA responses with the hybrid formulation used in 1993 compared with the classical formulation used in 1992. There were no differences in antibody responses to the SmithKline Beecham bivalent vaccine lots used in the 1992 and 1993 trials.

Göteborg, Sweden. A randomized, double-blind, placebo-controlled trial sponsored by the National Institute of Child Health and Human Development (NICHD) was conducted in Göteborg, Sweden, from September 1991 to July 1994. This trial evaluated the monocomponent (PT toxoid only) acellular vaccine (Certiva) developed by the NICHD and manufactured at that time by North American Vaccine.[246] Children were immunized with DTaP or DT at 3, 5, and 12 months of age; there was no whole-cell control group.

During the period from 30 days after the third (12-month) vaccination to the end of the study, 72 DTaP and 240 DT recipients met the WHO case definition, for an efficacy of 71%. Other case definitions produced efficacy estimates ranging from 54% to 77%, depending on the stringency of the definition. A nested analysis of subjects with household exposure to pertussis found 66% efficacy after two doses and 75% efficacy after three doses.[559] During an additional 6 months of surveillance after unblinding of the study (representing a period averaging 18.5 to 24.5 months after the third injection), efficacy was 77% for the full cohort and 76% in a nested household-contact study.[543]

Because this vaccine included only PT toxoid, serologic rises of antibodies to FHA were an unbiased indicator of possible pertussis. Thus, pertussis could be identified more readily among vaccine recipients than if the vaccine had contained FHA. Other vaccines to which this vaccine is compared may have benefited from a lower case-ascertainment rate in the vaccine groups, biasing their efficacy estimates upward.

The only other efficacy trial that immunized subjects at 3, 5, and 12 months of age was Stockholm 1993. However, comparing results with that study cannot readily be done; the two studies evaluated no acellular vaccines in common, and there was no DT arm in Stockholm 1993 or whole-cell arm in Göteborg.

Follow-up for 2 years after immunization showed no diminution in protection among the DTaP group, as compared with the DT group.[543] Subsequent mass immunization in the Göteborg area using the PT toxoid vaccine resulted in significant decreases in *B. pertussis* isolates and hospitalizations in all age groups.[295] However, pertussis returned to Greater Göteborg during the second half of 1999, with a peak in 2004 (see "Duration of Immunity After Acellular Vaccines," later).[560,561] A recent surveillance report from Sweden (largely reflecting use of multicomponent aP vaccines) indicates that pertussis has decreased in nonvaccinated infants during the period from 2003 to 2012 ($P < .001$), indicating either reduced circulation of *B. pertussis* or herd immunity both in those too young to be vaccinated and those older than three months. Hospitalization rates have also decreased in this age group ($P < .001$). In the period 1998 to 2012, 70% of all cases in infants younger than age 3 months and 99% of cases with apnea caused by pertussis were admitted to hospital. Median duration of hospitalization was 7 days for unvaccinated versus 4 days for vaccinated infants 3 to 5 months of age.[562]

Munich, Germany. An unblinded, nonrandomized, case-control study sponsored by Sanofi Pasteur was conducted in 63 German pediatric practices from February 1993 to May 1995.[421] A cohort of children was enrolled prospectively to receive, according to parental choice, either the Aventis Pasteur-Biken two-component DTaP (Tripedia), the Behringwerke

DTwP, a DT vaccine, or no vaccine at approximately 3, 5, and 7 months of age.

All infants 2 to 24 months of age who came to a participating pediatrician with cough for 7 days or more, or with suspected exposure to pertussis, had nasopharyngeal specimens obtained for culture (whether the children were part of this cohort or not). There were 11,237 such children, including 3245 who were part of the prospective vaccine efficacy cohort. Children whose cultures were positive and whose cough persisted for 21 days or more were each matched with four control patients from the same practice who were born within 30 days of the subject. Pertinent clinical, demographic, and immunization data were entered into a conditional logistic regression analysis to calculate the relative odds of pertussis while controlling for confounding factors.

Eighty-seven subjects met the case definition of 21 or more days of paroxysmal cough plus either positive culture or household contact with a laboratory-confirmed case. These persons were matched to 344 control subjects. Eighty-one of the case subjects and 186 of the control subjects had received no pertussis vaccine; 4 and 55, respectively, had received three doses of DTaP; and 1 and 61, respectively, had received three doses of DTwP. Adjusted estimates of efficacy were 96% for the DTwP and 93% for the DTaP.[421]

That this study was not randomized or completely blinded raises certain issues. Although its efficacy estimates reflect adjustment for recognized risk factors that differed between cases and controls, it is impossible to identify or adjust for unrecognized bias or confounding. The analysis rested on comparing the proportions of vaccinated patients in two groups: those patients who were brought in because of possible pertussis, and control subjects who were selected in a systematic manner. If unvaccinated children were more likely than vaccinated children to be brought to the pediatrician with a suspect cough, they would be overrepresented in the case (but not control) groups, biasing upward the estimates of efficacy for DTaP and DTwP. It is reassuring that 76% of cultures in the prospective cohort were from infants receiving DTaP, and infants receiving DTaP comprised 75% of the cohort, suggesting that any bias was negligible. We know that vaccinated children who develop pertussis have a milder illness, so it is less likely that these children would have been brought in for culture. Because case confirmation depended on obtaining a positive culture, this may have also increased the risk of diagnostic bias (as described after the 1986 Swedish trial).

These factors, coupled with the small number of cases detected, suggest that the point estimates of efficacy from the Munich trial should be interpreted with caution. Some reassurance, however, is derived from the fact that the Munich and Mainz studies generated similar estimates of efficacy for the control whole-cell vaccine that was common to both.

The Munich investigators continued to follow the study cohort through the end of 2001. During the period from 2 years through 6 years (1997–2001) after the fourth dose of pertussis vaccine (given at 15 to 24 months of age), the crude overall efficacy against typical pertussis (defined as 21 or more days of paroxysmal cough) was 93% (95% CI, 79–98%) for those receiving Tripedia, and 96% (95% CI, 76–99%) for those receiving the Behring whole-cell vaccine; adjusted for various confounders, the respective efficacies were 96% (95% CI, 85–99%) and 97% (95% CI, 81–99.6%). Protection was materially lower among those not receiving four doses: crude and adjusted efficacies for those receiving three or fewer doses of Tripedia were 82% (95% CI, 7–96%) and 83% (95% CI, −5% to 97%), respectively. Adjusted efficacy against milder pertussis (defined as ≥7 days of any cough) was 71% (95% CI, 45–84%) for those receiving four doses of Tripedia and 80% (95% CI, 40–93%) for those receiving four doses of Behring whole-cell vaccine. (Note that long-term follow-up results from the various efficacy trials should not be compared directly to the results obtained in the original trials, given the substantial differences in surveillance methods and sensitivities.)

Erlangen, Germany. A prospective, randomized, double-blind clinical trial conducted from May 1991 to December 1994 in Erlangen, Germany, compared two vaccines produced by study sponsor Wyeth-Lederle: the Lederle-Takeda four-component DTaP (Acel-Imune) and the U.S. DTwP that served as the control whole cell vaccine in the MAPT.[323,422] Participants were immunized at approximately 3, 5, 7, and 17 months of age. Infants whose parents declined pertussis immunization received a German DT vaccine at approximately 3, 5, and 17 months of age and served as the control group for estimates of absolute efficacy.

Based on a case definition of 21 or more days of cough with paroxysms, whoop, or posttussive vomiting plus either positive culture, positive serology, or household contact with a culture-proven case, efficacies after three doses of vaccine were 78% for DTaP and 93% for DTwP.[323] (The abstract of this trial's published report cites an efficacy of 83% for the DTaP, but that figure reflects the benefit of a fourth booster dose of vaccine and thus is not comparable to the data presented for the other trials.) As reported in the FDA-approved labeling for Acel-Imune, the relative risk of pertussis was 1.5 for DTaP compared with DTwP.[422] A household-contact study nested in the overall trial found efficacy rates similar to those reported from the cohort study.[563]

Although this study also used an unblinded, nonrandomized placebo control group for estimates of absolute efficacy, the potential for ascertainment bias may have been reduced by the use of active surveillance (telephone calls every 2 weeks) to detect possible cases. In a follow-up analysis that has implications for all the efficacy studies, the local physicians who served as study investigators were stratified into three groups on the basis of the proportion of their patients who underwent investigation for pertussis.[564] For subjects attended by physicians who sought pertussis diligently, efficacy of the DTaP in preventing laboratory-confirmed pertussis with 7 or more days of cough was only 40%, whereas efficacies were 78% and 75% in the physician groups of moderate and low diligence, respectively. These results are not surprising, in that the less-diligent physicians detected only the more obvious (i.e., more severe) cases, and it has long been known that the efficacy of pertussis vaccine appears higher when one uses case definitions that focus on more severe disease. Nonetheless, this analysis has illuminated the extent to which fairly subtle differences in diagnostic diligence can markedly alter estimates of efficacy, confounding efforts to compare the results of different studies.

The Lederle-Takeda acellular vaccine was a four-component vaccine, but it predominantly consisted of FHA (86%; approximately 35 μg), with very little PT, fimbrial proteins, or PRN, as reflected by both its formulation (see Table 44.3) and its immunogenicity (see Table 44.8). It appeared to be of somewhat lower efficacy than the three-component vaccines evaluated in Italy (although the 95% CIs do overlap). If so, this represents further evidence that the quantity of the individual components can be as important as the number of components in determining the efficacy of the vaccine.

After unblinding of the study, physicians and parents of approximately one-third of study participants agreed to respond to semiannual questionnaires regarding cough illness and pertussis among study participants. Surveillance from 1995 through 2000 showed no diminution in pertussis protection in either the DTaP or the DTwP group, as compared with the DT group.[565]

Niakhar, Senegal. A prospective, randomized, double-blind study conducted in Senegal from 1990 to 1994 compared a two-component DTaP produced by study sponsor Aventis Pasteur (Triavax) with that company's European DTwP in children immunized at 2, 4, and 6 months of age.[423] Estimates of absolute efficacy were derived from a nested case-contact study that compared rates of pertussis (after exposure to an index case) among study subjects and nonstudy children (who thus had received either DT or no vaccine) living in the same villages and housing compounds. Surveillance detected 197 DTaP and 123 DTwP recipients who met the primary case definition of confirmed pertussis (see Table 44.10) with cough for 21 or more days, yielding a relative risk of pertussis 1.54 times higher in the DTaP than in the DTwP group. Requiring the cough to be paroxysmal (the WHO definition) reduced the case counts to 41 and 16, respectively, for a relative risk with DTaP of 2.42 compared with DTwP. When cases were stratified by age, the relative risk of meeting the primary case definition was 1.16 for children younger than 18 months versus 1.76 for older children, suggesting that protection waned more quickly among DTaP than DTwP recipients.

The case-contact study included 197 DTaP recipients, 190 DTwP recipients, and 17 unvaccinated children exposed to pertussis, of whom 24, 7, and 8, respectively, met the WHO case definition; the absolute efficacy estimates were 74% for DTaP and 92% for DTwP. Because of the small number of cases, confidence limits for these estimates are wide (95% CIs, 51–86% and 81–97% for DTaP and DTwP, respectively). In addition, although field surveillance workers and physician evaluators were blinded to the vaccination status of the randomized children, it is clear that parents knew whether their children had been vaccinated, a situation that may have increased case detection among unimmunized children. For both reasons, the relative rates are likely to be more reliable than the absolute efficacy estimates.

Initial reports from the investigators cited efficacies of 85% to 86% for DTaP and 95% to 96% for DTwP,[566] and some early reviews echo those figures.[567,568] However, these higher efficacies are based on a requirement that epidemiologically linked cases be confirmed by PCR, a case definition more strict than that of the WHO.

Mainz, Germany. A prospective household-contact study was conducted from October 1992 to September 1994 in six areas of Germany, in which 22,505 children had been immunized with study sponsor GlaxoSmithKline's three-component aP vaccine (Infanrix) in a prior safety and immunogenicity trial. Other children in these regions were unimmunized against pertussis or had been immunized with the Behringwerke whole-cell vaccine at 3, 4, and 5 months of age, in accord with the standard German schedule. Passive surveillance for pertussis identified households that contained both an index case of pertussis and at least one contact 6 to 47 months old who could be evaluated. Prospective surveillance of the 360 eligible contacts identified 104 secondary cases of pertussis (defined as 21 or more days of spasmodic cough plus either culture or serologic confirmation of *B. pertussis* infection): 96 of the 173 unvaccinated children, 7 of the 112 DTaP recipients, and 1 of the 75 DTwP recipients. The corresponding estimates of vaccine efficacy were 89% for the DTaP and 98% for the Behringwerke DTwP.[421]

The use of a household-contact study design largely eliminated the potential for ascertainment bias that would otherwise arise from the fact that study groups were not blinded or randomized, because family members were intensely surveyed by blinded field supervisors for pertussis in households with an index case. The simplest explanation for the higher efficacy estimate for Infanrix in this study (89%) than in the more rigorous, prospective Italian trial (84%) is that the small number of cases in this study reduced the precision of the estimate, as reflected by the wide confidence limits (95% CI, 77–95%).

Conclusions From the Efficacy Trials

Although the efficacy trials and other studies greatly enriched our understanding of pertussis vaccines, they left many important questions unresolved. Despite attempts to standardize key variables, no two studies are perfectly comparable. For example, as shown in Fig. 44.7, not only is the estimate of efficacy affected by case definition (being higher with stricter case definitions), but the various vaccines differ profoundly in the degree to which their efficacies vary with changes in case definition. Moreover, no study has evaluated a multicomponent vaccine directly against versions of itself that contain alternative components or different quantities of each component. Because of the trend toward combination vaccines, the drive to eliminate thimerosal use, and continued consolidation in the vaccine industry, there are only three broadly distributed aP vaccines: the French two-component, the Belgian three-component, and the Canadian five-component vaccines. National surveillance data have clearly demonstrated the ability of each vaccine to accomplish excellent control of pertussis during the ages covered by the childhood vaccination series.[123,569]

Onset of Protection and Effect of Vaccine Schedule. It appears that some protection (perhaps 15% to 20%) accrues with the first dose, and substantially more with the second dose (Table 44.12). A reanalysis of data in the Technical Report of the Stockholm 1993 trial indicates that the incidence of pertussis was markedly lower after the second dose than after the first dose, and it was reduced somewhat further by the third dose (Table 44.12).[541]

In general, three doses appear to be necessary for good protection and, for most of the vaccines and schedules, a booster dose at around 15 months of age provides substantial additional benefit. There is probably little difference between schedules that immunize at ages 2, 4, and 6 months; 3, 5, and 7 months; or even 2, 3, and 4 months (unless maternal Tdap vaccination is practiced). Immunizing at 3, 5, and 12 months of age gives a little less protection in the second half-year of life and better protection thereafter, as one would intuitively expect.

After conclusion of the efficacy trials, Sweden implemented nationwide aP vaccination, using a variety of vaccines in various counties over time. Gustafsson and colleagues reported the results of 7 years of follow-up of national pertussis surveillance.[570] From 2001 to 2004, pertussis rates per 100,000 person-years were 225 in the unvaccinated, 212 after one dose (3 months), 31 after two doses (5 months), and 19 after three doses (12 months). These studies suggested that the incidence of confirmed pertussis was increasing in children older than 6 years and suggested that a booster dose (now recommended) was warranted between 5 and 7 years of age.[570] Reports from both Göteborg and Stockholm, Sweden, supported these conclusions.[560,561,570]

Choice of Vaccine. For those providers free to choose among vaccines, we recommend consideration of five factors (some may not apply in every situation): efficacy, rate of adverse effects, cost, convenience (e.g., how the vaccine is supplied), and service (e.g., reliability of supply, provision of educational materials). Choices can then be made on the basis of the relative weights assigned to each of those factors.

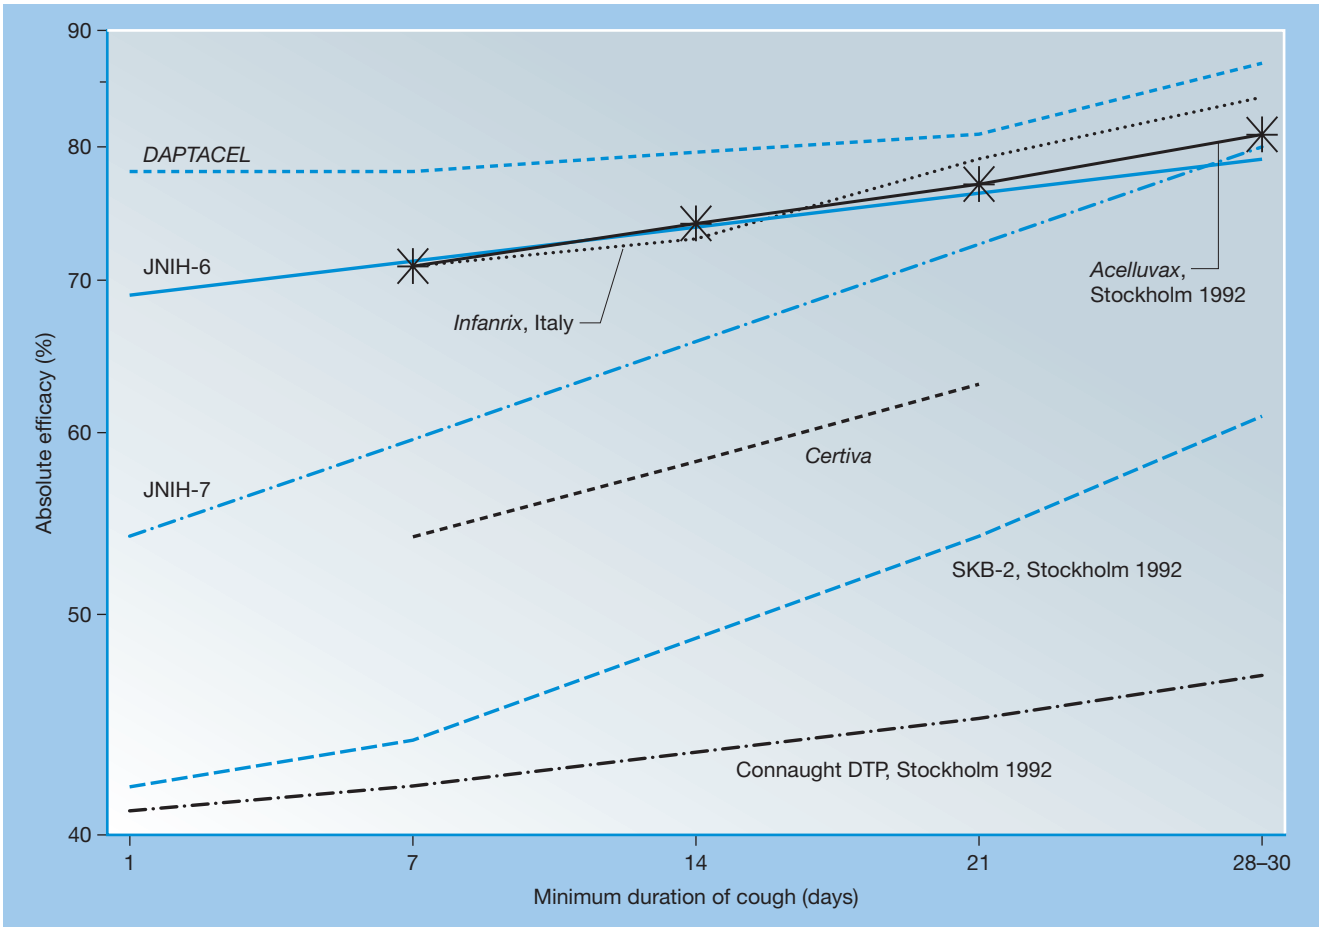

Figure 44.7. Efficacy vs minimum duration of cough (as case definition). Efficacy of pertussis vaccines evaluated in prospective, randomized trials (names defined in Table 44.3) for preventing various durations of any cough associated with culture-confirmed pertussis. A slope of zero (horizontal line) would indicate equal protection for mild and severe disease; steeper slopes reflect less protection for mild than for severe disease. Because estimates were obtained in separate studies, only the slopes, and not the actual values, should be compared. *(Courtesy Michael D. Decker.)*

TABLE 44.12 Incidence of Pertussis (Per Million Days at Risk) by Dose, Stockholm 1992 Efficacy Trial

Interval	SKB-2	Acelluvax	HCPDT	Evans-Medeva WCV
PRIMARY ANALYSES (FOLLOW-UP FROM STUDY START UNTIL OCTOBER 1996)				
Dose 1 to dose 3	N/A	8.1	6.7	4.4
Dose 3 to study end (~21 mo)	N/A	1.8	1.1	1.3
SECONDARY ANALYSES (FOLLOW-UP FROM STUDY START UNTIL JULY 28, 1995, WHEN SKB-2 GROUP WAS REIMMUNIZED WITH HCPDT)				
Dose 1 to dose 2	19.6	16.0	16.9	11.3
Dose 2 to dose 3	14.3	5.8	2.6	1.8
Dose 3 to early termination (~7 mo)	4.2	1.3	1.0	0.5

HCPDT, hybrid component pertussis-diphtheria-tetanus vaccine; SKB, SmithKline Beecham; WCV, whole-cell vaccine.
Data from Olin P, Gustafsson L, Rasmussen F, et al. Efficacy Trial of Acellular Pertussis Vaccines: Technical Report Trial II, with Preplanned Analysis of Efficacy, Immunogenicity and Safety. *Stockholm, Sweden: Swedish Institute for Infectious Disease Control; 1997.*

Duration of Immunity After Acellular Vaccines. Long-term follow-up of subjects in the 1986 Swedish efficacy trial did not demonstrate any decline in efficacy of the JNIH-6 or JNIH-7 vaccines through the end of the fourth year after immunization (although it did make clear the higher efficacy of the JNIH-6 vaccine).[433] In the Stockholm 1992 trial, efficacy of the Aventis Pasteur five-component vaccine was sustained above 80% during 2 years of follow-up, whereas that of the control whole-cell vaccine declined sharply.[324] Gustafsson and colleagues, also reported that pertussis incidence remained low for 6 years after aP vaccination in Stockholm.[570] During 6 years of extended follow-up in the Italian trial, efficacies of both the Chiron and the GlaxoSmithKline three-component vaccines were fully maintained.[325,556] Follow-up of subjects given Certiva in the Göteborg trial showed that protection remained unchanged for at least 2 years after the third dose,

but an increase in disease was noted in late 1999, with a peak in 2004.[560,561] Follow-up of the Erlangen cohort for 6 years showed no diminution in protection for either the Lederle-Takeda DTaP or the Lederle DTwP. Five-year follow-up results for the Aventis Pasteur–Biken vaccine used in the Munich cohort also demonstrated persistent protection. As these studies were all conducted in areas with high rates of circulating natural pertussis, one cannot rule out the impact of potential boosting by asymptomatic infection.

When pertussis incidence rose in Sweden for those who were 7 and 8 years old,[570] a booster dose was recommended at 5 to 6 years of age. In addition, the long-term effects of aP vaccines, monitored in an enhanced surveillance project, were discussed at an international workshop in Stockholm in November 2008.[560,561] The Swedish experience clearly demonstrated that aP vaccines were effective but immunity waned and booster doses were needed.

Follow-up studies in the Göteborg area, where the monovalent PT vaccine was used, demonstrated a reemergence of pertussis from the end of 1999, with a peak in 2004, followed by a decrease when booster doses were introduced to both 6- and 10-year-old children from 2005 to 2006. Pertussis was prevalent in all age groups, with the highest documented incidence in infants younger than 12 months. Many of the pertussis-infected subjects had received three doses of the pertussis toxoid vaccine in the mass vaccination project, with a mean time from the last dose of monovalent PT vaccine of 5 years. In total, there were 128 hospitalizations, 106 of which were of infants. The authors concluded that pertussis had not been eliminated from the Göteborg area, and that booster doses were needed to circumvent waning immunity after vaccination.[560,561] Currently, booster doses of pertussis vaccine are routinely recommended in Sweden at 5 to 6 years and again at 14 to 16 years of age.

Recent reports from Japan, where only aP vaccine is used, suggest that the incidence of pertussis in adults has gradually increased since 2002, with outbreaks reported in college campuses, high schools, and offices.[571–573] In 2009, the incidence in infants younger than 1 year and in adults both increased.[574] The current immunization schedule in Japan incorporates a three-dose primary schedule with a booster 6 months after the primary series. No pertussis booster is given in adolescence or adulthood.

Since 2010, a number of pertussis outbreaks have been noted in Australia and the United States. These outbreaks resulted in the largest numbers of pertussis cases in over half a century and were remarkable for the large number of cases among older children and young adolescents, the age groups representing the first cohorts vaccinated solely with aP vaccine. Although many have pointed out the potential roles in this increased reporting of greater awareness of pertussis and widespread availability of more sensitive pertussis diagnostic methods, epidemiological features such as the "marching cohort" effect argue that the switch from DTwP to DTaP has played a major role.

During Australian pertussis outbreaks from 2009–11, high rates of pertussis were seen in 5- to 14-year-old children.[575] In Queensland, the highest age-specific notification rates of pertussis were noted among children 6 to 11 years old, higher than rates noted in infants.[576] To assess the reasons for this change, Sheridan and colleagues compared pertussis reporting rates to the pertussis vaccines used in the primary immunization series in infants in the 1998 birth cohort in Queensland, a group that might have been primed either with DTwP or DTaP.[577] A total of 58,233 children were born in 1998 and identified in the regional vaccine registry. Of these, 40,694 (69.9%) received at least three doses of any pertussis-containing vaccine during their first year of life. There were a total of 267 pertussis cases reported from this cohort between 1999 and 2011. Children who received a three-dose primary series with DTaP had higher rates of pertussis than those who received a three-dose primary series with DTwP (Fig. 44.8). In those children who received mixed courses that included both DTwP and DTaP, rates of pertussis were highest for children receiving DTaP as their first dose. Children who received a mixed course with DTwP as the initial dose had incidence rates that were between rates for the pure DTwP and DTaP cohorts. The impact of this difference in priming persisted for more than a decade.[577]

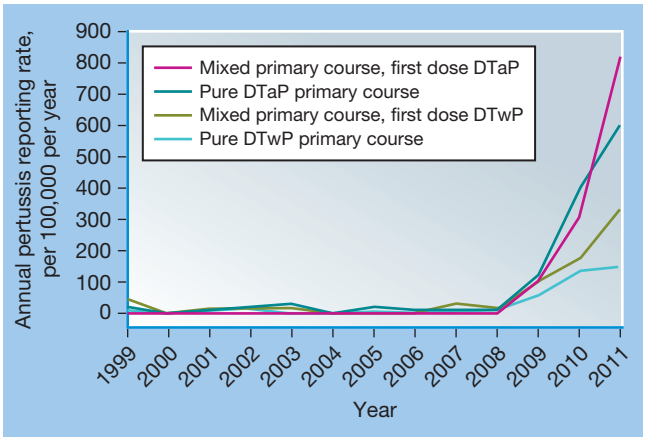

Figure 44.8. Queensland, Australia pertussis reporting rates from 1999–2011 by primary course of pertussis vaccination for children born in 1998. DTaP indicates diphtheria-tetanus-acellular pertussis; DTwP, diphtheria-tetanus-whole-cell pertussis. Children who received a three-dose primary series with DTaP had higher rates of pertussis than those who received a three-dose primary series with DTwP. In those children who received mixed courses that included both DTwP and DTaP, rates of pertussis were highest for children receiving DTaP as their first dose. Children who received a mixed course with DTwP as the initial dose had incidence rates that were between rates for the pure DTwP and DTaP cohorts. *(From Sheridan SL, Ware RS, Grimwood K, et al. Number and order of whole cell pertussis vaccines in infancy and disease protection. JAMA. 2012;308:454–456. Copyright 2012, American Medical Association.)*

In the United States, outbreaks have also been reported from California, Wisconsin, Oregon, and Washington, with the emergence of increasing numbers of cases in children between 7 and 10 years of age, many fully vaccinated with aP-containing vaccines.[313,316,578,579] During 2012, nearly 50,000 cases of pertussis were reported in the United States, the highest number in 57 years.[10] Infants had the highest rate of reported disease, followed by children 7 to 10 years old, and then adolescents.

A case-control study from Kaiser Permanente Northern California was conducted among children who were vaccinated with DTaP, comparing children with PCR-confirmed pertussis with two sets of controls, those who were PCR-negative and closely matched controls from the general population of health-plan members.[580] A total of 277 PCR-positive children, 4 to 12 years of age, were compared with 3318 PCR-negative controls and 6086 matched controls. PCR-positive children were more likely to have received the fifth DTaP dose earlier than PCR-negative controls ($P < .001$) or matched controls ($P = .005$). These data indicated that after the fifth dose of DTaP, the risk of acquiring pertussis increased by an average of 42% each year.

In the context of the California 2010 outbreak, Misegades and colleagues conducted a case-control study of 682

suspected, probable, or confirmed pertussis cases in children 4 to 10 years of age versus 2016 controls and found that receipt of all five recommended doses of aP vaccine was 88.7% (95% CI, 79.4–93.8%) effective. Efficacy declined with time since receipt of the fifth dose, from 98.1% within 1 year to 71.2% 5 or more years later.[581]

Witt and colleagues reviewed data from Kaiser Permanente Northern California to determine whether prior vaccination with wP-containing vaccines provided better protection compared to receipt of aP-containing vaccines.[305] Their data showed a much higher risk of pertussis associated with an aP-only series, which was somewhat lessened by the administration of a sixth dose of aP vaccine. In addition, receipt of one or more wP doses markedly augmented the durability of immunity from subsequent aP doses. They concluded that "a wholly acellular pertussis vaccine series was significantly less effective and durable than one that contains at least one dose of the traditional whole cell vaccine." These findings are strikingly similar to those obtained from Australia, which found high pertussis notification rates corresponding to the first birth cohorts that received aP vaccines for both their primary and booster vaccinations. It is also important to note that these outbreaks have occurred within the context of high vaccine coverage. In Australia, 92% of children 5 years of age in 2013 had received four doses of pertussis-containing vaccine,[582] and in the United States, 83% of children 19 to 35 months of age in 2012 had received four doses of pertussis-containing vaccine.[583] More recently, Klein et al.[583a] analyzed data from their large integrated healthcare system for the period 2010–15, during which two large pertussis outbreaks occurred. By comparing pertussis rates among adolescents who did or did not receive Tdap, they found that Tdap effectiveness declined from 69% during the first year after vaccination to 9% by 4 or more years after vaccination.

Adverse Events With Acellular Vaccines

Numerous safety and immunogenicity studies of the acellular vaccines have been conducted in infants and children[584–590] and have invariably found the acellular vaccines to be associated with lower rates of adverse reactions than whole-cell vaccine. Although most trials have not compared one acellular vaccine with another to detect differences in the rates of adverse reactions, the MAPT evaluated 13 acellular and two whole-cell vaccines and thus offers the best comparison of common reactions with these vaccines.[462] The various efficacy trials maintained surveillance for severe adverse events among much larger numbers of infants and thus supplement the MAPT data by providing more precise estimates of rates for these less common events.

Common Adverse Events: Comparative Rates. The MAPT included all acellular vaccines studied in the efficacy trials except one, a monovalent PT vaccine similar to Certiva, produced by North American Vaccine. Fortunately, this vaccine was evaluated using the MAPT protocol in a subsequent trial at one of the MAPT study sites, which allows it to be directly compared with the other vaccines (Table 44.13). Among the acellular vaccines, there were significant differences with respect to redness, swelling, pain, and vomiting but not with respect to fussiness, drowsiness, anorexia, or antipyretic use.[462] No acellular vaccine was consistently the most or least reactogenic. Compared with the reference whole-cell vaccine, all the acellular vaccines were associated with significantly lower rates and severity of every reaction except vomiting.

Common and Severe Adverse Events: Data From the Efficacy Trials. Table 44.14 summarizes the adverse reaction data from the efficacy trials, organized by vaccine. Definitions and methods may have differed from study to study, and thus caution should be used in comparing rates between trials. Note also that Table 44.14 presents reaction rates per dose of vaccine, whereas the rates presented in the following paragraphs are per subject (these two approaches will produce different rates unless every child with a reaction has the same reaction with every dose). Detailed information is provided only for currently available products; readers desiring information regarding other products are referred to the fourth edition of this text.[457]

Infanrix—GlaxoSmithKline. In the Italian trial, adverse events were significantly more common among recipients of DTwP than DTaP or DT. Temperature of 40.5°C or greater was seen in 6.8% of recipients of DTwP, 0.8% of recipients of Infanrix, 1.1% of recipients of Tri Acelluvax, and 1.3% of recipients of DT; crying for 3 or more hours in 11.5%, 1.9%, 1.3%, and 0%, respectively; and HHE in 1.7%, 0.2%, 0%, and 1.3%, respectively.[591] Seizures within 48 hours of vaccination occurred in one Infanrix recipient and in three DTwP recipients.[325]

Triavax—Sanofi Pasteur, France. In the Senegal efficacy study, Triavax and Sanofi Pasteur's French whole-cell vaccine were each given to approximately 2200 children. Persistent crying was significantly more common among whole-cell recipients (eight vs zero episodes). Two subjects in each group experienced febrile seizures within 48 hours of vaccine administration. No episodes of HHE or anaphylactic reactions were seen. In the pilot study preceding this trial, fever, crying, and local reactions were significantly more common with whole-cell than acellular vaccine.[423]

Daptacel (Tripacel)—Sanofi Pasteur Ltd, Canada. Of the 2552 children given the classical (CLL-4 F_2) formulation of Tripacel in Stockholm 1992, one (0.04%) had HHE and another was withdrawn as a result of pronounced local reactions.[324] There were seven episodes of convulsions, but none occurred within 48 hours of vaccination, making a causal association unlikely. Of 17,686 children given the hybrid (HCPDT) formulation of Tripacel in Stockholm 1993, 0.04% had fever of 40°C or greater, and 0.02% had convulsions within 48 hours of vaccine administration.[536] Minor local and systemic reactions were significantly less common with HCPDT than with whole-cell vaccine. The investigators made a special effort to detect HHE in Stockholm 1993, and thus higher HHE rates were recorded for vaccines evaluated in that study than for the same, or similar, vaccines evaluated in other studies. HHE rates were, for Tripacel, 0.47 per 1000 in Stockholm 1993 (hybrid formulation) versus 0.13 per 1000 in Stockholm 1992 (classical formulation); and for Tri Acelluvax, 0.26 per 1000 in Stockholm 1993 versus 0.07 per 1000 in Italy 1992.

Tripedia—Sanofi Pasteur, USA. Of 12,514 children given Tripedia in the Munich trial, 2.2% experienced the following adverse events related to vaccination: fever, 0.9%; local reactions, 0.4%; unusual crying, 0.3%; irritability, 0.3%; somnolence, 0.2%; crying for more than 3 hours, 0.04%; HHE, 0.02%; and febrile seizure, 0.01%.[289,421] Ten children given Tripedia had culture-confirmed invasive bacterial disease, but the rate of disease was not significantly higher than that seen in the control group.

Severe Adverse Events: National Surveillance Data. The claims paid by the Japanese Vaccine Compensation System provide a comparison of severe neurologic reactions and deaths with whole-cell versus acellular vaccine and with immunization beginning at 3 months versus 2 years.[397,398,592] Changing the age of administration of whole-cell vaccine from 3 months to 2 years was associated with a dramatic reduction

[a]Results for Certiva are from a separate study conducted at an MAPT study center after completion of the MAPT, using the MAPT protocol, procedures, and data forms.
[b]Number of pertussis components, for those vaccines without known trade names. For branded products, note that the licensed vaccine's formulation may differ from that of the vaccine evaluated in MAPT. See Table 44.3 and its footnotes for details.
[c]Moderate (cried or protested to touch) or severe (cried when leg moved).
[d]Moderate (prolonged crying and refused to play) or severe (persistent crying and could not be comforted).
[e]An unweighted average of the 11 specific rates shown to the left of this value. Has the effect of giving more weight to less serious reactions but provides a crude overall comparison that may be useful.
[f]Of the 11 specific rates, the number for which this vaccine's reaction rate exceeded the average for all DTaPs evaluated in the MAPT (see the next-to-last row of the table). Treats small differences and large differences as though they were the same, but provides a crude overall comparison that may be useful.
DTaP, diphtheria, tetanus, and acellular pertussis; MAPT, Multicenter Acellular Pertussis Trial.

[a]Note that duration of surveillance or definitions of adverse reactions may vary from trial to trial. Thus, comparisons within trials are more valid than comparisons across trials.
[b]Temperature ≥40°C, except: ≥40.5°C for Erlangen; for Munich, rate of "fever" was 2.8/1000 but "fever" was not defined.
[c]Crying persisting ≥3 hours, but duration not specified for Erlangen and Göteborg.
[d]Within 48 hours of vaccination.
DT, diphtheria and tetanus toxoids vaccine; DTaP, DT plus acellular pertussis vaccine; DTP, DT plus whole-cell pertussis vaccine; HHE, hypotonic-hyporesponsive episode; N/A, data not available.

in compensable adverse neurologic events and deaths; a further reduction occurred with the change from whole-cell to acellular vaccine. The data strongly suggest that this low rate of serious adverse events was maintained after the initiation of immunization with acellular vaccine at the age of 3 months in 1989. Severe neurologic events and deaths were both reduced more than eightfold during 13 years of acellular vaccine use, as compared with the preceding 11 years of whole-cell vaccine use.

The public health system provided all immunizations and conducted uniform surveillance for postimmunization adverse events in Alberta, Canada during the years preceding and following the transition from whole-cell to aP vaccines. Before July 1, 1997, a pentavalent DTwP-IPV-Hib combination vaccine was used in the province; beginning July 1, a DTaP-IPV-Hib combination was used (this combination, Pentacel, is based on the HCPDT version of Tripacel that was studied in Stockholm 1993). The switch to the acellular combination was associated with an 89% reduction in fever greater than 40°C, an 82% reduction in unusual cry, and a 74% reduction in HHE.[593] These results were confirmed by Scheifele and Halperin, who evaluated emergency department visits and hospitalizations at tertiary-care pediatric centers across Canada and found an 86% decline in febrile seizures and a 75% decline in HHE coincident with the transition from whole-cell-based to acellular-based combination vaccines in Canada.[594]

Similar data, albeit less dramatic, are available from the U.S. Vaccine Adverse Event Reporting System (VAERS), maintained by the CDC and the FDA.[595] From 1991 to 1993, rates of reported adverse events after the fourth and fifth doses in the pertussis immunization series were significantly lower for DTaP than for DTwP. These events included fever (1.9 vs 7.5 events per 100,000 vaccinations), seizures (0.5 vs 1.7), and hospitalization (0.2 vs 0.9), for a total of 2.9 versus 9.8 cases per 100,000 vaccinations for DTaP and DTwP, respectively.[596] There were three reports of encephalopathy after DTwP, but none after DTaP. A follow-up report, covering the period between January 1, 1995 (when whole-cell vaccine was in exclusive use), and June 30, 1998 (when acellular vaccine was in predominant use), revealed steadily declining annual numbers of VAERS reports involving immunization against pertussis, from 2071 in 1995 to 491 in the first half of 1998.[597] Another subsequent report demonstrated the lack of association of DTaP vaccines with seizures in early childhood using data compiled from 1997 to 2006 in the seven managed-care organizations that participate in the Vaccine Safety Datalink.[598]

Finally, the U.S. National Vaccine Injury Compensation Program reported in 2015 that most claims between 1995 and 2005 of seizure disorders or encephalopathy following vaccination were associated with DTwP receipt. In addition, many of the children with alleged vaccine injury had preexisting neurologic or neurodevelopmental abnormalities.[485,486,599] These data offer additional evidence of an improved safety profile for acellular vaccines.

Safety of Booster Doses Given to Children Primed With Acellular Vaccine. A continuation study of the MAPT evaluated the safety and immunogenicity of a fourth dose of acellular vaccine given at 15 to 20 months to children who had been primed with either aP or wP vaccine at 2, 4, and 6 months of age.[600] For children who received four consecutive doses of an acellular vaccine, fever and injection-site redness, swelling, and pain were seen more frequently with the fourth dose than with the primary series. Of children given a booster with acellular vaccine, those who had been primed with

acellular vaccine had local redness and swelling significantly more frequently than did those who had been primed with whole-cell vaccine. However, children who received four consecutive doses of whole-cell vaccine had significantly higher rates of irritability, redness, swelling, and pain after the booster than did either of the groups that were given a fourth dose of acellular vaccine. None of 1293 evaluated children experienced seizures, HHEs, or fever greater than 40.6°C. Also of note, several cases of swelling of the entire limb were observed after administration of the fourth dose of acellular vaccine to children previously primed with DTaP.

A report from Germany of entire-limb swelling occurring after the fourth dose of one three-component DTaP appeared in 1997.[601] Among children from whom adverse reactions were specifically solicited, the rate of entire-thigh swelling was 2.4%, whereas it was reported to occur in only 0.5% of those not specifically followed for reactions. With this report in mind, Rennels and colleagues evaluated the cases of entire-limb swelling after the fourth dose of DTaP vaccine in MAPT.[602] Although extensive swelling reactions had not been anticipated in MAPT and had not been prospectively studied, parents in MAPT had been provided with diary cards that contained a section for them to report other reactions of concern. Parents of 20 (2%) of the 1015 children who had received the same DTaP vaccine throughout the primary and booster series described swelling of the entire thigh after the fourth dose. In contrast, none of the 246 children primed with DTwP and boosted with DTaP were reported to have entire-thigh swelling. Differences in rates between the whole-cell– and acellular-primed groups were significant (P = .02). An interesting observation was that 40% of these children with whole-limb swelling were judged by their parents to have experienced no pain, and 40% were judged not to have erythema, despite the extensive swelling reactions. The only significant association between rates of entire-thigh swelling after dose 4 and the composition of the associated vaccine was with the quantity of diphtheria toxoid (P = .02). Antibody levels to pertussis toxoid, diphtheria toxoid, and tetanus toxoid were evaluated for subjects with extensive swelling and three controls per case in an attempt to determine whether the swelling might be the result of an Arthus reaction. No difference was noted in the comparative distribution of prevaccination and postvaccination antibody titers between cases and controls, but sample sizes were small. In contrast, a large study of children given a fifth dose of Tripedia found that higher prevaccination antibody titers were associated with a higher frequency of large local reactions.[603] Thus, there is some evidence that high IgG antibody levels before booster vaccination might play a role in the large limb swelling and may be related to excessive antigen content.

Children enrolled in MAPT were also studied after the fifth dose of DTaP.[604] Given the 5-year interval between initial enrollment and the fifth dose, many children were not located for enrollment in the study. None of 121 children given five doses of the same DTaP, versus four (2.7%) of 146 children receiving a mixed DTaP series, were reported to have experienced swelling of the whole upper arm after the fifth dose (P = .13). For children with swelling after the fifth dose, the onset of swelling was noted by parents on days 1 and 2 after vaccination and generally resolved by day 4, with no sequelae.

Rennels and colleagues reanalyzed data from the fourth-dose and fifth-dose MAPT studies and found no consistent relationship between the quantity of aluminum in various DTaP vaccines and their rates of extensive swelling.[605] Further review of the literature regarding extensive swelling reactions revealed other sporadic reports in early studies of DTaP vaccines in Japan[606] and Sweden.[607] The proposed explanation at that time was that the immunizations had been given by the deep subcutaneous and not the intramuscular route. This observation was supported by the report that shorter needle length was associated with increased local reactions.[608] However, in the MAPT studies, extensive swelling was seen with nine of the 12 DTaP vaccines (containing from one to five pertussis antigens), which were given intramuscularly by experienced vaccine-study nurses.[602]

In a randomized, blinded study of DTaP-IPV and Tdap vaccines (similarly formulated except for the concentrations of PT, diphtheria toxoid, and IPV) among children 4 to 6 years of age, Scheifele and colleagues found that rates of large injection-site reactions and of pain were lower by half to two-thirds in the group receiving the Tdap vaccine.[609] Children with large reactions were more likely to have relatively elevated prevaccination antibody levels to PT, PRN, or diphtheria toxin. Similar findings were reported by Knuf and coworkers in children receiving booster doses of DTaP during the second year of life: local reactions were reduced after vaccines containing smaller quantities of antigens.[610]

Rennels and colleagues enrolled children who had suffered large swelling reactions after the fourth dose of DTaP and assessed whether large local reactions occurred after the fifth dose of DTaP.[611] Of 20 children with extensive local reactions after dose 4, only four experienced entire upper arm swelling and seven had swelling greater than 5 cm after dose 5. These reactions were well tolerated and supported revaccination.

Summary of Adverse Events. Almost every study has found minor local and systemic adverse reactions to be less common with acellular than with whole-cell vaccine. Although HHEs and seizures are seen after acellular vaccine, they occur less frequently than after whole-cell vaccine.

Rates of rare adverse effects cannot be determined reliably even with large efficacy trials, and they require postmarketing surveillance for their determination. Of course, adverse events temporally but not causally associated with vaccination will continue to occur at their background rates regardless of the vaccine used. Among children primed and boosted with acellular vaccine, reaction rates increase successively with each booster dose but remain lower than those seen among children primed and boosted with whole-cell vaccine.

Vaccination of Adolescents and Adults

Numerous aP vaccines have been evaluated in adolescents and adults and shown to be safe and immunogenic.[460,612–616] As noted previously, Tdap vaccines have been licensed in various jurisdictions for immunization of adolescents and adults under the brand names Adacel, Boostrix, Covaxis, and (combined with IPV) Repevax. Many national advisory bodies have recommended universal adolescent Tdap booster vaccination and substitution of Tdap for tetanus-diphtheria (Td) for some or all adult booster immunizations. Adolescents and adults in close contact with babies, including parents and other close family members, healthcare workers, and daycare workers have also been recommended to receive Tdap.

In some jurisdictions, Tdap is licensed or recommended for use instead of DTaP at the 4- to 6-year booster, to reduce the adverse reactions.

Immunogenicity in Adolescents and Adults

A multicenter trial sponsored by the U.S. National Institutes of Health (NIH) evaluated the immunogenicity among adults of varying strengths of five aP vaccines (variants of Certiva, Tri Acelluvax, Infanrix, Acel-Imune, and a PT-FHA vaccine supplied by the Massachusetts Public Health Biologic Laboratories).[616,617] These studies and others demonstrated excellent

immunogenicity of the acellular vaccines in adults, even with dosages substantially lower than the standard pediatric dose, and no interference was noted with diphtheria or tetanus antibody responses in any of the groups. In the NIH dosage-ranging study, dosage-related increases in serum antibody levels against known pertussis vaccine antigens were seen in all vaccine groups.[616,617] For several vaccines, significant antibody responses were seen against antigens not known to be present in the vaccines, suggesting that the vaccines contained trace quantities of these antigens and were stimulating an anamnestic response in these adults, who had been immunized in childhood with whole-cell vaccine. An immunogenicity study in adults older than 65 years of age found Tdap to be immunogenic when administered alone or coadministered with influenza vaccine or conjugate meningococcal vaccine.[618,619]

Efficacy in Adolescents and Adults

An NIH-sponsored study, the APERT trial, evaluated the efficacy of an aP vaccine in adolescents and adults.[226] This prospective trial, conducted at eight centers across the United States, randomized 2781 healthy subjects ages 15 to 65 years to receive either an aP vaccine (Boostrix minus the Td components) or hepatitis A vaccine. For 2 years, subjects were actively followed for pertussis illness with phone calls every 2 weeks (a total of more than 58,000 person-months of surveillance). Serum specimens were obtained at routine intervals; for any cough illness lasting 5 days or longer, nasopharyngeal aspirates were obtained for culture and PCR.

The aP vaccine was well tolerated, with fewer than 5% of subjects reporting minor local or systemic adverse reactions. The study and control groups did not differ in the rate of severe adverse events, none of which were considered vaccine related. Local reactions were detected more commonly in women than in men.

Cough illnesses lasting 5 or more days were reasonably common (more than one per every 2 person-years) and were seen equally in both study groups. There were four well-documented pertussis infections per 1000 patient-years of follow-up; the incidence was highest in subjects 15 to 30 years of age and in those with cough illnesses of longest duration. A variety of case definitions were evaluated based on the strength of the laboratory evidence (positive culture, PCR, or rise in pertussis-specific antibodies in paired acute-convalescent specimens). There was a significantly lower incidence of pertussis in aP vaccinees than controls; the point estimate of vaccine efficacy was 92% (95% CI, 32–99%). The rate of pertussis seen in the APERT trial is quite consistent with rates identified in other studies of adult pertussis (see "Epidemiology," earlier) and suggests that between 1 and 1.5 million pertussis illnesses occur per year in the United States among adolescents and adults.[226]

The effectiveness of Tdap was also evaluated in an outbreak of pertussis in a school in the U.S. Virgin Islands. There were 51 confirmed or probable cases of pertussis among 499 students, for an attack rate of 10%. Disease clustered in grades 6 to 12, with a peak attack rate of 38% among 10th graders. Of 266 students 11 years of age with complete immunization data, 31 (12%) had received Tdap. Forty-one unvaccinated students (18%) had confirmed or probable pertussis, compared with 2 (6%) of the vaccinated students (relative risk, 2.9). Vaccine effectiveness was determined to be 65.6% (95% CI, 35.8–91.3%). This study suggested that Tdap provided protection against pertussis, but that increased coverage would be needed to realize the full benefit of the vaccine program.[620]

The effectiveness of a three-component Tdap was also evaluated among high-school students 12 to 19 years of age in Australia in 2005.[297] Vaccine effectiveness, measured 2 years after Tdap receipt and adjusted for potential confounding factors, was 85.4% (95% CI, 83.0–87.5) for laboratory-confirmed notified cases. Nearly all these students would have received DTwP for some or all of their prior childhood vaccinations.

A case-control study was also conducted from January 2006 to December 2011 at Kaiser Permanente among PCR-confirmed cases of pertussis in members 11 years of age and older.[298] Tdap vaccination rates were 24.0% in PCR-positive cases and 31.9% in PCR-negative controls, with an adjusted estimate of effectiveness of Tdap vaccination against pertussis of 53.0% (95% CI, 41.9–62.0%) when compared with PCR-negative controls and 64.0% (95% CI, 55.5–70.9%) when compared with Kaiser Permanente Northern California controls.

Thus, the efficacy of Tdap vaccines has been demonstrated, and their routine use to boost immunity in adolescents and adults has been recommended (see below; see also discussion below regarding waning protection). Healthcare workers, child-care workers, adolescents and adults in households containing children (particularly newborns), and pregnant women are among the high-priority target groups for immunization.[621,622]

Cocooning

"Cocooning," the vaccination of postpartum mothers and other close infant contacts with Tdap booster vaccine, has been proposed as a method to prevent infant disease and has been recommended by many national advisory groups.[623–626] However, implementation of cocooning is challenging.[626a] Those responsible for medical care of a newborn may be unable or unwilling to provide vaccinations to persons not otherwise their patients. Even when efforts are made to overcome structural barriers, outcomes can be disappointing, as noted below. In addition, the data showing that aP-vaccinated baboons colonized with *B. pertussis* were protected from pertussis disease but able to transmit pertussis to susceptible baboons may mean that protected family members nonetheless can provide a pathway for infant infection. Even if this is true, however, cocooning still would benefit the infant by reducing the risk of exposure to actively infected, coughing family members.

A number of published studies have assessed its impact. An evaluation of the impact of a cocoon program during a pertussis epidemic in New South Wales, Australia found that cocooning reduced the risk of pertussis in infants younger than 4 months of age by 51% (95% CI, 10–73%).[627] A study conducted during an Australian pertussis outbreak from 2011–12 was unable to demonstrate a benefit for the infant of cocoon vaccination.[628] A study in Basel, Switzerland found that despite vigorous educational efforts, cocooning remained incomplete in 93% of families and in most families less than 50% of the infant's close contacts received pertussis vaccination.[629] Healy and colleagues assessed the impact of a cocooning program at a metropolitan hospital in Houston, Texas and found postpartum immunization and cocooning did not reduce pertussis illness in infants 6 months of age and younger.[630]

Vaccination in Pregnancy

The difficulties of cocooning further stimulated interest in pertussis vaccination during pregnancy, which has never been a contraindication to Tdap or Td vaccination. Studies of Tdap vaccination during pregnancy show that the infant benefits from high levels of transplacentally derived maternal antibody, which provides protection during the period of greatest risk, before the infant vaccination series begins. Maternal Tdap vaccination during pregnancy results in some modest

reduction in pertussis immune responses to the first and second infant DTaP doses, but shrinking—and probably immaterial—differences in infant pertussis antibody levels after the third and fourth (toddler) doses, as detailed below.

One study of maternal Tdap vaccination during pregnancy collected maternal and cord sera at birth. Newborns of mothers who received Tdap during pregnancy had significantly higher concentrations of diphtheria antitoxin ($P < .001$), tetanus antitoxin ($P = .004$), and antibodies to PT ($P < .001$), FHA ($P = .002$), PRN ($P < .001$), and FIM-2/3 ($P < .001$) than newborns from mothers who did not receive Tdap.[631]

A double-blind, randomized, active-controlled maternal pertussis vaccination trial conducted by the NIH documented the safety of vaccine administration to both mother and infant, the antibody titers achieved in the mother and the infant, and the relatively modest impact of maternal vaccination on the infant responses to primary DTaP vaccination.[632] Preliminary data from a similar maternal pertussis vaccination trial in Canada also were encouraging.[633] In light of these data and the ongoing problem of infant pertussis, in 2011 ACIP recommended Tdap vaccination of all pregnant women.

To evaluate vaccination of pregnant women in Wisconsin following the recommendation that all pregnant women receive Tdap during each pregnancy, health insurance claims data for approximately 49% of Wisconsin births were analyzed.[634] The percentage of women who received Tdap during pregnancy increased from 13.8% of women delivering during January 2013 (63.1% of whom received Tdap 2 to 13 weeks before delivery) to 51.0% of women delivering during March 2014 (90.9% of whom received Tdap 2 to 13 weeks before delivery).

In response to a large pertussis outbreak in England with several infant deaths, a national vaccination program for Tdap vaccination of pregnant women was implemented in October 2012. To evaluate effectiveness, laboratory-confirmed cases and hospital admissions for pertussis in infants between January 1, 2008, and September 30, 2013 were collected.[635] Vaccine effectiveness was 90% (95% CI, 82–95%) when the analysis was restricted to cases in children younger than 2 months of age. The authors concluded that this effectiveness probably resulted from protection of infants by both passive antibodies and a reduction in maternal pertussis exposure. In addition, a separate case-control study determined that maternal pertussis vaccination was 93% effective (95% CI, 81–97%) in preventing pertussis infection in infants younger than age 8 weeks.[636] Vaccination during the third trimester was found by Winter et al.[637a] to be 85% more effective than postpartum vaccination of the mother at preventing pertussis during the first 8 weeks of life. Moreover, among pertussis-infected infants, hospitalization was significantly less likely and hospital stays were significantly shorter if the mother had been vaccinated during pregnancy.[637b]

Adverse Reactions in Adolescents and Adults

A NIH-sponsored multicenter trial evaluated the immunogenicity and reactogenicity in adults of varying strengths of five aP vaccines (variants of Certiva, Tri Acelluvax, Infanrix, Acel-Imune, and a PT-FHA vaccine supplied by the Massachusetts Public Health Biologic Laboratories).[617] All vaccine dosage strengths were well tolerated, although dosage-related increases in the rates of injection-site symptoms and the duration of injection-site discomfort were seen in some subjects. Late-onset or biphasic reactions, generally minor, were noted in this study, as they had been in some prior studies. The frequency of these late reactions seemed to be greater for the higher-strength dosages and for vaccines with more antigens.

Large-scale clinical trials of the Tdap vaccines demonstrated generally similar reaction profiles for Tdap as for Td vaccines; in other words, the addition of purified aP components to Td added essentially nothing to the adverse reaction profile. Biphasic or late reactions were generally not seen, and large local reactions were rare or not seen.[637–639] However, it should be noted that these studies were conducted in adolescents and adults who had been primed with whole-cell vaccine and who had received zero, one, or at most two prior injections of acellular vaccine. The safety of a Tdap vaccine was evaluated in adolescents previously vaccinated with five doses of aP-containing vaccine. Pain (63.6%), redness (51.7%), and swelling (41.4%) were more frequently reported after the sixth dose than after earlier doses. In contrast, large injection-site swelling (swelling of >100 mm, arm circumference increase of >50 mm, or diffuse swelling interfering with daily activities) occurred in only three adolescents and resolved without sequelae.[640]

The question of the minimal safe interval between prior diphtheria, tetanus, or pertussis vaccination and Tdap was addressed in a large-scale study conducted in Prince Edward Island, Canada.[641] All consenting provincial schoolchildren ($N = 7156$) in grades 3 to 12 (except 10th graders, who received the vaccine the prior year) were given Tdap, and reactions were compared according to time since prior vaccine (range, 18 months to >10 years, the latter serving as the comparison group). No variation in adverse reactions was found based on time since last Td; a slight increase in redness and swelling was found for those who had previously received DTaP, compared with those who had previously received only DTwP.

These findings were confirmed in another study reported from an outbreak in a hospital where more than 4000 healthcare workers were immunized with Tdap, half of whom completed a safety survey.[642] Adverse events after Tdap were not significantly greater in those vaccinated with other tetanus-containing vaccines less than 2 years versus 2 or more years previously. The authors concluded that a short interval between Td/tetanus toxin and a single dose of Tdap was safe.

A very large safety study was conducted among 13,427 10- to 18-year-old adolescents enrolled in the Northern California Kaiser Permanente Health Care Plan who received Tdap vaccination as part of their normal healthcare. No increased risk for medically attended neurologic reactions (OR, 0.962; 95% CI, 0.533–1.733) or allergic reactions (OR, 1.091; 95% CI, 0.441–2.729) was observed after Tdap vaccination. When compared with matched historical Td recipients, no increase in new-onset chronic illnesses (OR, 0.634; 95% CI, 0.475–0.840) was seen after Tdap, and no deaths were reported.[643]

A large study was reported from the CDC-funded Vaccine Safety Datalink in which the safety of Tdap vaccine was monitored weekly among subjects ages 10 to 64 years from 2005 to 2008. Encephalopathy-encephalitis-meningitis, paralytic syndromes, seizures, cranial nerve disorders, and Guillain-Barré syndrome were selected as outcomes based on previous reports and biologic plausibility. The risk after Tdap was not significantly higher than the risk after Td, providing reassurance that Tdap was similar in safety to Td for the outcomes studied.[644]

A Vaccine Safety Datalink study conducted in seven large U.S. health maintenance organizations evaluated the safety of Tdap in persons 65 years of age and older. Although there was a small increased risk of medically attended inflammatory or allergic events in the first 6 days following Tdap compared to other time periods, it was not more common than following Td.[645]

SAFETY OF TDAP DURING PREGNANCY

After Tdap vaccines were recommended for routine administration to pregnant women, the CDC implemented ongoing

collaborative studies to evaluate whether vaccination with Tdap during pregnancy adversely affected the health of the mothers or their offspring. In mid-2015, the CDC reported that "Data from the various monitoring activities support the safety of Tdap during pregnancy."[646] The Vaccine Safety Datalink site in California evaluated whether maternal Tdap vaccination during pregnancy was associated with increased risks of adverse obstetric events or adverse birth outcomes.[647] Of 123,494 women with singleton pregnancies ending in a live birth between January 1, 2010, and November 15, 2012, a total of 26,229 (21%) received Tdap during pregnancy and 97,265 did not. Receipt of Tdap during pregnancy was not associated with increased risk of hypertensive disorders of pregnancy, preterm birth, or being small for gestational age, but a slightly increased incidence of chorioamnionitis was observed. This finding has not yet been replicated in another study.

The most comprehensive data on the safety of maternal Tdap administration come from the United Kingdom following implementation of routine maternal vaccination.[648] In an observational study, 20,074 pregnant women (median age, 30 years) received the pertussis vaccine and were matched with a historical unvaccinated control group. There was no evidence of an increased risk of any of an extensive predefined list of adverse events related to pregnancy. In particular, there was no evidence of an increased risk of stillbirth. These safety data are reassuring but ongoing safety assessment will continue.

INDICATIONS, RECOMMENDATIONS, AND COVERAGE RATES

Immunization of Infants and Children

DTaP vaccines, given alone or as part of larger combinations, have entirely replaced DTwP vaccines in North America, Europe (except for Poland), and some Asian and Latin American countries, and are commonly used in the private sector worldwide. DTwP combination vaccines are the standard of care in Africa, much of Asia, and many Latin American countries. Table 44.5 provides details regarding pertussis vaccination schedules for many countries around the world.

The September 2015 pertussis guidance document from the WHO recommended that national programs currently administering wP vaccination should continue to use wP vaccines for the primary series, because surveillance and modeling data suggest that the use of aP vaccines may result in a resurgence of pertussis after a number of years and such resurgence may also lead to an increased risk of death in those too young to be vaccinated. WHO further recommended that a switch from wP to aP for the primary infant immunization should only be considered if the inclusion in the national immunization schedules of additional periodic booster or maternal immunization can be assured and sustained.[11a]

United States and Canada

In the United States and Canada, unless specifically contraindicated (see "Contraindications and Precautions" later), every infant should receive pertussis vaccine at ages 2, 4, and 6 months and at 15 to 18 months (in Canada, 18 months is preferred). A booster (based on DTaP in the United States and either DTaP or Tdap in Canada) is indicated at 4 to 6 years of age.[5,649] Dose 4 can be administered as early as 12 months of age, provided at least 6 months have elapsed since dose 3. The timing of infant vaccination is determined by birth age, without regard to prematurity.[408,650] Children whose vaccination series has been interrupted need not have prior doses repeated but should have the series resumed at the earliest opportunity. Combination vaccines incorporating DTaP and other antigens are detailed in Chapter 15.

Europe

There are nearly as many vaccination schedules used in Europe as there are countries. Most countries recommend three doses of a DTaP combination vaccine in the first 6 months of life, followed by a booster in the second year of life. Those following the "Scandinavian schedule" recommend doses at 3, 5, and 12 months of life, with no booster in the second year. Most countries in Western Europe recommend a booster at 4 to 7 years of age, whereas most in Eastern Europe do not.[651]

Asia, Africa, and Latin America

Among the countries in the WHO's Western Pacific and Southeast Asian regions, DTaP vaccines, alone or in combination, were used as of 2016 in Australia, Brunei, China, Japan, Malaysia, the Marshall Islands, Micronesia, New Zealand, Niue, Palau, Republic of Korea, and Singapore; all other countries in those regions were using whole-cell vaccines, mostly DTwP-Hib-HB combinations. All countries give three doses in the first 6 months of life, but only a few give a dose of pertussis-containing vaccine in the second year of life. Only Australia, India, the Republic of Korea, and some of the Oceanic republics offer a booster at 4 to 6 years of age.

In the WHO Africa Region, only Mauritius and South Africa use aP vaccines. Every country gives three doses of vaccine in the first 6 months of life (most following the EPI 6-, 10-, 14-week schedule). Only Algeria, Cape Verde, Equatorial Guinea, Gambia, Mauritius, South Africa, and Zimbabwe give a dose in the second year of life, and none give a dose at age 4 to 6 years.

In Latin America, DTaP combination vaccines are used in the public programs of Argentina (but only for premature babies), the Bahamas, Costa Rica, Mexico, and Panama. Every country gives three doses of vaccine in the first 6 months of life (most at 2, 4, and 6 months). All countries except Belize and Haiti give a dose in the second year of life; all except Antigua and Barbuda, Chile, Cuba, Ecuador, Grenada, Saint Lucia, and Saint Vincent and the Grenadines give a dose at 4 to 6 years of age (at 3 years of age for Dominica).

Percent of Children Receiving Three Doses of DTwP or DTaP

The WHO provides estimated vaccine coverage rates at http://www.who.int/immunization/monitoring_surveillance/data/en/. These estimates are derived from reports submitted by countries, estimates of WHO country managers, and the literature. For countries with well-established surveillance systems, the WHO data track closely with other available estimates. However, WHO estimates may reflect unduly optimistic reports from countries with less robust vaccination and surveillance programs.

The WHO reports that 2014 DTP3 coverage rates were 90% or greater for most countries in the Americas, but below 80% for Guatemala, Haiti, and Venezuela. In Europe, all but five countries had coverage rates of 90% or greater; only Ukraine (78%) was below 80%. In the Western Pacific region, about half of countries have rates of 90%; rates in the Philippines and four small island nations fall below 80%. In the eastern Mediterranean and Southeast Asian regions, rates in about half of countries are 85% or greater, but Iraq, Pakistan, Somalia, and Syria fall below 75%. Finally, rates in most countries in Africa fall between 65% and 85%, but rates in the

Central African Republic, Chad, Equatorial Guinea and South Sudan fall below 50%.

Immunization of Adolescents and Adults

Tdap vaccines, developed expressly to allow pertussis immunization of adolescents and adults, are now widely used for a variety of indications: among adolescents, to address the increased risk of pertussis seen in many countries in that age group; for the preschool booster dose at ages 4 to 6 years, instead of DTaP vaccine, to reduce adverse events; during the third trimester of pregnancy, to augment transplacental antibodies and reduce the risk of pertussis among neonates; among those age 7 years or older who are pertussis vaccine-naïve or are at high risk of pertussis because of medical, occupational, or other characteristics; for close contacts of high-risk persons, including healthcare workers and those with anticipated contact with infants; and in lieu of Td vaccine, for any persons desirous of augmenting their pertussis protection.

United States and Canada

In 1999, Newfoundland and Labrador implemented a school-based program to provide Tdap vaccine in Grade 9.[652] In 2003, the Canadian National Advisory Committee on Immunization (NACI) recommended that Tdap replace Td in the adolescent booster programs and that all adolescents and adults should receive a dose of Tdap in lieu of Td.[653] ACIP made similar recommendations beginning in 2005[7] and progressively extended their recommendations to cover groups such as healthcare workers, persons in close contact with infants, postpartum women, the elderly, and so on.[9,311,623,654] In 2011, ACIP recommended Tdap during pregnancy for women who had not previously received Tdap,[655] and in 2012 recommended a dose of Tdap in the third trimester of every pregnancy.[656] NACI does not recommend universal Tdap during pregnancy, but does recommend Tdap for all women beyond 26 weeks of pregnancy who have never received Tdap or who are at risk from a pertussis outbreak.[649]

Presently, ACIP recommends a single dose of Tdap for all persons age 11 years or older; all women in every pregnancy, as early in the third trimester as possible; and for initiation or completion of a primary pertussis vaccination series in persons age 7 years or older with an unknown or incomplete tetanus and diphtheria vaccination series.[657,657a] In 2014, 88% of adolescents 13 to 17 years of age had received a Tdap.[658] NACI recommendations are the same except that the adolescent dose is recommended at 14 to 16 years of age, Tdap is an optional alternative to DTaP at age 4 to 6 years, and the pregnancy recommendations differ as detailed above.[659] Apart from doses recommended during pregnancy, neither ACIP nor NACI recommend more than a single life-time dose of Tdap. However, because those recommendations rest on economic considerations rather than any actual contraindication, many practitioners elect to use Tdap whenever Td might otherwise be indicated.[660]

Europe

In 2002, the Austrian Standing Commission on Immunization noted the increasing incidence of pertussis in adolescents and adults and called for routine use of Tdap at 7 years, 14 to 15 years, and every 10 years thereafter. As of 2015, the recommendation has changed to call for a Tdap at 7 to 9 years, 13 years, then every 10 years between 18 and 60 years, and every 5 years from age 65 years on. This represents the most extensive currently recommended Tdap schedule; some Western European countries recommend one dose in adolescence and another in adulthood, most recommend only one or the other, and most Eastern European countries have no adolescent or adult Tdap recommendation.[651] As of September 2015, vaccination during pregnancy was recommended by Belgium, Ireland, Israel, and the United Kingdom, and under consideration by several other countries.

Asia, Africa, and Latin America

As of September 2015, Tdap is not recommended by any country in the Southeast Asian or African WHO regions for uses other than maternal vaccination. In light of the September 2015 WHO recommendation that "Vaccination of pregnant women is likely to be the most cost-effective additional strategy for preventing disease in infants too young to be vaccinated and appears to be more effective and favourable than cocooning,"[11a] Tdap is recommended during pregnancy in India and Thailand and under consideration elsewhere.

In the Western Pacific region, Tdap is recommended during early adolescence in Australia, Hong Kong, the Marshall Islands, Micronesia, New Zealand, Palau, Republic of Korea, and Singapore, and is recommended during pregnancy in Australia, the Philippines, Republic of Korea, Taiwan, and New Zealand.

In Latin America, adolescent Tdap is recommended in Argentina, the Bahamas (also every 10 years), Chile, Panama, and Uruguay. Tdap during pregnancy is recommended in Argentina, Brazil, Colombia, Costa Rica, El Salvador, Mexico, Panama, Paraguay, Suriname, and Uruguay. Additional Tdap recommendations include: Argentina, healthcare workers; Costa Rica, women of childbearing age; Panama, high-risk groups and healthcare workers; and Paraguay, high-risk groups.

Use of Vaccine in Outbreaks: Children

Immunization initiated after a pertussis exposure does not protect from that exposure; in an outbreak, however, exposure opportunities are ongoing and the existence of an outbreak should reinvigorate efforts to ensure that potentially exposed persons are fully vaccinated for age. An accelerated infant vaccination schedule (e.g., at 4, 8, and 12 weeks of age) may be indicated.[276] There is no evidence that supplemental doses of pertussis vaccine are required during an outbreak for the protection of most children who have received pertussis immunization in accord with the recommended schedule, and ACIP does not recommend supplemental pertussis vaccination during an outbreak for persons already fully immunized for age. However, this approach implicitly assumes that DTaP or Tdap has been given within the preceding 6 to 10 years, a condition that will become progressively less true over time. Accordingly, local public health authorities will need to consider their specific circumstances during an outbreak and may wish to recommend a repeat Tdap for those whose last prior Tdap is considered too remote. In addition, supplemental immunization for children who have immunologic or cardiopulmonary compromise, however, may be considered if the benefits of vaccination are believed to outweigh the risks of adverse reactions.

CONTRAINDICATIONS AND PRECAUTIONS

Most Infants and Children

Older recommendations regarding contraindications and precautions for pertussis vaccination reflected concerns stemming from the wP vaccine and are not supported by recent data with acellular vaccines. At present, there are but two true

contraindications to the use of pertussis vaccine: anaphylaxis or encephalopathy after administration of a vaccine containing a pertussis component.[248,458]

An anaphylactic reaction occurring immediately after administration of DTaP or DTwP is a contraindication to further vaccination with separate diphtheria, tetanus, or pertussis (acellular or whole-cell) components, absent proof as to which of these three components was responsible. Given the importance of tetanus vaccination, referral to an allergist for tetanus toxoid desensitization may be indicated. Acute encephalopathy occurring within 7 days after administration of DTwP or DTaP, not attributable to another identifiable cause, is a contraindication to further pertussis immunization. DT vaccine should be administered for the remaining doses in the vaccination schedule, although it may be appropriate to delay vaccination until the patient's neurologic status clears.[248,458]

The following are now considered precautions, not contraindications, to pertussis vaccine: temperature 40.5°C or greater within 48 hours of pertussis vaccination and not attributable to another identified cause; collapse or shock-like state (HHE) within 48 hours; persistent, inconsolable crying lasting 3 or more hours within 48 hours after vaccination; and convulsions occurring within 3 days, with or without fever. Decisions regarding the further administration of pertussis vaccine should be guided by an individualized evaluation of benefits and risks.[248,458] The risks are likely to be substantially lower if acellular, rather than whole-cell, pertussis vaccine is used.

A family history of seizures, of adverse reactions to vaccine, or of allergy to vaccine is not a contraindication to the receipt of DTwP or DTaP. Administration of pertussis vaccine should be deferred briefly for children with moderate or severe acute illnesses, with or without fever; they may be vaccinated as soon as they recover. Children who are immunocompromised or are receiving immunosuppressive therapy may be vaccinated with DTwP or DTaP. If immunosuppressive therapy will be discontinued soon, deferral of vaccination until 1 month after therapy may permit better immune responses.

Children with Neurologic Disorders

As discussed (see "Adverse Events with Whole-Cell Vaccines" earlier), pertussis vaccine may precipitate febrile convulsions and may unmask neurologic disorders that would soon have become evident anyway, but it does not appear to cause or worsen chronic neurologic disorders. Because children with neurologic impairments are as needful—indeed, perhaps more needful—of protection from pertussis disease, any decision to decline pertussis vaccination should reflect a careful consideration of risks and benefits, particularly in light of the increasing incidence of pertussis.[248,458] It may be appropriate to delay pertussis vaccination of infants with neurologic disorders until their status is clarified, but again careful consideration is required. The highest risk of pertussis is in the first 6 months of life, whereas the risk of febrile convulsions is higher thereafter; both factors therefore argue for adherence to the standard primary immunization schedule.

Children with prior convulsions should probably have pertussis vaccine deferred until the cause of the convulsions is assessed and any necessary treatment is established. Febrile seizures unrelated to pertussis vaccine are not a contraindication to further vaccination, nor is a family history of seizures.[458] Administration of acetaminophen at a dose of 15 mg/kg should also be considered at the time of vaccination and every 4 hours for the ensuing 24 hours to reduce the risk of fever associated with vaccination.[458]

The prophylactic use of antipyretic drugs was evaluated to determine whether they decreased fever in children after vaccination and whether they impacted the immune response to the vaccines. The percentage of children with temperature 38°C or higher after at least one dose was significantly lower in the prophylactic paracetamol (acetaminophen) group than in the no-treatment group. Antibody geometric mean concentrations were significantly lower in the prophylactic paracetamol group than in the no-treatment group after primary vaccination for all 10 pneumococcal vaccine serotypes, protein D, antipolyribosyl-ribitol phosphate, antidiphtheria, antitetanus, and anti-PRN. After boosting, lower antibody geometric mean concentrations persisted in the prophylactic paracetamol group for antitetanus, protein D, and all pneumococcal serotypes apart from 19F. The authors recommended that "although febrile reactions significantly decreased with prophylactic antipyretic drugs at the time of vaccination, they should not be routinely recommended since antibody responses to several vaccine antigens were reduced."[459]

False Contraindications to DTaP

A number of situations have been considered incorrectly to be contraindications to DTaP, and deferral of pertussis vaccination on these bases is inappropriate: redness, swelling, or pain at the injection site; temperature less than 40.5°C; mild acute illness, even involving diarrhea or low-grade fever; current antibiotic therapy; recent exposure to an infectious disease; prematurity; personal or family history of allergies; and family history of SIDS, convulsions, or adverse event after pertussis vaccination.[458] Prior pertussis infection is not a contraindication to vaccination. Going ahead with vaccination would provide protection if the prior illness was not in fact pertussis.

Adolescents and Adults

For adolescents and adults, the only contraindications to Tdap vaccine are a history of serious allergic reaction to a component of the vaccine and a history of encephalopathy not attributable to another identifiable cause within 7 days after pertussis vaccination. Precautions include a history of a vaccine-related Arthus reaction, Guillain-Barré syndrome, or progressive neurologic reaction; in such cases, individualized consideration should be given to risks and benefits.

Other reactions after pediatric vaccination, including high fever, syncope, seizure, HHE, and large local reaction, are not contraindications or precautions, nor is a prior diagnosis of pertussis.

PUBLIC HEALTH CONSIDERATIONS

Disease-Control Strategies

There is but one disease-control strategy for pertussis: vaccination. But with which vaccine? Numerous wP and aP vaccines have been evaluated in efficacy trials. Which ones should be used?

In North America and Europe, acellular vaccines are widely used and have largely or entirely replaced the whole-cell vaccines. Despite a high rate of vaccine coverage, pertussis is the only vaccine-preventable disease currently increasing in the United States and in other developed countries. Expanded Tdap booster vaccinations in adolescents and adults are recommended, but it is not clear that this will control pertussis disease. In most countries, multivalent combination vaccines are used (see Chapter 15).

Outside North America and Europe, many countries use acellular vaccines (usually as combinations) in the private market, but few countries have implemented them in their

national vaccination programs. Such countries will have to apply their own relative weights when evaluating the comparative costs, efficacies, and adverse effects of the acellular and whole-cell vaccines. Many countries may decide that their present whole-cell vaccine offers unsurpassed efficacy at low cost; if the vaccine is well accepted by the public, no change is indicated. However, with the increasing availability of combination vaccines, these decisions are likely to become even more complex (see Chapter 15).

Eradication or Elimination

Humans are the only reservoir for pertussis, and chronic carriage is not known to occur. In principle, then, pertussis can be eradicated. Acellular vaccines are suitable for use among all age groups, but it remains to be seen whether their widespread use can interrupt transmission of pertussis in a region. Global eradication, although perhaps possible, is clearly many years away.

FUTURE VACCINES

Different approaches have been proposed during the last decade to achieve better pertussis control. These approaches include returning to the whole cell vaccine, the addition of new pertussis antigens to the current acellular vaccines, the addition of adjuvants to the current vaccines, and the development of live-attenuated pertussis vaccines. None of these new options have yet led to a new licensed pertussis vaccine, but the various efforts will be briefly reviewed.

Adjuvanted Vaccines

Currently licensed DTaP vaccines contain alum as an adjuvant that elicits a strong Th2-type immune response. However, the observation that a strong Th1 response appears to play a crucial role in the clearance of *B. pertussis* has led to the proposal of combining new novel adjuvants with DTaP to elicit a more Th1-skewed response.[661,662] A Canadian study tested the impact of various adjuvants (polyphosphazene microparticles containing pertussis toxoid, cytosine phosphate guanine [CpG] oligodeoxynucleotides, and a synthetic innate defense regulator peptide) on pertussis immune responses in mouse models and found significantly higher levels of proinflammatory cytokines in macrophages.[663] Mouse-challenge studies demonstrate significantly lower bacterial loads with adjuvanted vaccines compared to unadjuvanted vaccine formulations (additional adjuvants evaluated include MF59, monophosphoryl lipid A, and other Toll-like receptors, and immunostimulatory molecules).[663–665]

Gracia and colleagues evaluated, in mice, CpG oligodeoxynucleotides, polyphosphazenes, and cationic innate defense regulator peptides as adjuvants when combined with genetically detoxified PT. The adjuvants induced increased serum antibody titers that persisted for longer than 22 months.[662] UK investigators have also demonstrated that CpG oligodeoxynucleotides, alone or combined with aluminum hydroxide, enhanced humoral and T-cell responses.[666]

Another report demonstrated that the addition of CpG oligonucleotides could overcome suppression of infant immune responses to PT by maternally derived antibodies, supporting the potential for novel vaccine adjuvants to improve protection.[667]

Finally, an Australian group assessed the immune enhancement provided by a nanoparticle formulation of PT and IgA, which induced significantly higher serum antibody titers when compared with the conventional alum-adjuvanted PT formulation. The authors concluded that this formulation had potential application as a nasal vaccine delivery system.[668,669]

The effect of adding novel adjuvants to the current DTaP vaccines has not been studied in humans to date, but offers the potential to improve immune responses.

New Antigens

Argentine investigators have reported the evaluation of two unique pertussis proteins as vaccine candidates, IRP1–3 and AfuA. These surface-exposed, highly immunogenic pertussis proteins are involved in iron uptake and are expressed under physiological conditions. Inclusion of IRP1–3 and recombinant AfuA in an experimental vaccine enhanced greater protection against pertussis challenge in a murine model, compared to vaccine without these proteins, suggesting that they might be good candidates for inclusion in a vaccine.[670,671]

Adenylate cyclase has been proposed as another antigen that might be added to an aP vaccine. Studies in a mouse model of this antigen showed that a recombinant form of adenylate cyclase lacking enzymatic activity enhanced protection against intranasal administration of *B. pertussis* and that both Th1 and Th2 immune responses to *B. pertussis* antigens were induced.[672]

Another intriguing approach is the use of outer membrane vesicles containing naturally incorporated bacterial surface antigens such as PRN and PT.[673] Roberts and colleagues showed that the administration of intranasal or intraperitoneal outer membrane vesicles derived from *B. pertussis* induced protection against pertussis challenge in a mouse model.[674]

De Gouw and colleagues have evaluated *B. pertussis* biofilm-derived membrane proteins.[675] It was found that a protein termed *Bordetella* intermediate protein A (BipA) was the most abundant surface-exposed such protein and that antibodies to BipA were present in convalescent serum of whooping cough patients. Vaccination of mice with recombinant BipA generated opsonizing antibodies and significantly reduced colonization of the mouse lung.

Many experts have noted the attractive qualities of the genetically inactivated PT, such as used in the three-component vaccine *Acelluvax* evaluated in the Italian efficacy trial, and it is likely to be incorporated into newly developed aP vaccines. Robbins and colleagues have proposed a new vaccine that would conjugate genetically inactivated PT to a *Bordetella* oligosaccharide, to provide more durable protection.[676]

Detoxified or Live-Attenuated Pertussis Vaccines

B. pertussis genetically modified to inactivate or eliminate certain toxic moieties might offer a vaccine with immunologic benefits approaching those of wP vaccine while resembling aP vaccines in safety.[677,678] The most advanced candidate at present is a live-attenuated pertussis vaccine termed BPZE1, which is an approach that may have a number of advantages over the current parenteral inactivated vaccines. First, nasal administration to young children is appealing with the avoidance of injections, although tetanus and diphtheria toxoids would still need to be administered by injection. Second, mucosal administration stimulates local immunity that could counteract pertussis organisms in the nasopharynx at the site of infection.[667] In a mouse model, BPZE1 stimulated comparable antibody responses to those seen after two parenteral administrations of aP.[679] Protection mediated in this model was found to be associated with both antibody and Th1 and Th17 $CD4^+$ cells, but not $CD8^+$ T cells.[680] Protection of mice against *B. bronchiseptica* has also been shown with this vaccine, invoking similar mechanisms as seen with pertussis.[681] Mice immunized with the live-attenuated strain were protected for

1 year after immunization, suggesting that the live-attenuated vaccine induced long-lasting antibody responses.[682] Finally, a prime-boost regimen in mice of intranasal BPZE1 followed by aP injection resulted in enhanced immune responses with a strong Th1–Th17 response that was maintained after repeated aP administrations.[683] Human studies with live-attenuated strains have begun.[684,685] A Phase I study found successful colonization of 7 of 36 adults given BMZE1 intranasally, with good cellular immune responses. A second clinical trial is underway.[685]

45 Plague Vaccines

E. Diane Williamson and Petra C.F. Oyston

During the last two millennia, the bacterium *Yersinia pestis* has been responsible for social and economic devastation on a scale unmatched by other infectious diseases or armed conflicts. The first reliable reference is to the Justinian plague (542–750 AD), which originated in central Africa and spread throughout the Mediterranean Basin. The second pandemic, the Black Death, which started on the Eurasian border in the mid-14th century, may have caused 25 million deaths in Europe (25–30% of the population), persisted on the continental land mass for several centuries, and culminated in the Great Plague of London in 1665. The third pandemic started in China in the mid-19th century, spread east and west, and caused 10 million deaths in India alone. Credible estimates indicate that overall almost 200 million deaths could be attributed to plague,[1] which swept across Europe in these three major epidemics.[2] The disease occurred in both bubonic and pneumonic ("Black Death") forms. The bubonic form spreads as a result of transmission of the bacterium from rodents to humans via the bites of infected fleas (usually the rat flea, *Xenopsylla cheopsis*[2]). The close contact of humans with infected rats undoubtedly contributed to the spread of the disease by this route. In some instances, bacteremic spread of plague bacilli to the lungs leads to the development of the secondary pneumonic form of the disease; subsequent person-to-person transmission by respiratory droplets can result in rapid epidemic spread of primary pneumonic plague.[3] It is the pneumonic form of the disease that is most feared and that is associated with a mortality rate approaching 100% when untreated.[4,5] A recent report has suggested that the plague-causing bacterium existed long before previous estimates.[6] Bacteria morphologically similar to *Y. pestis* have been identified on the proboscis and compacted in the rectum of a flea that had been preserved in amber, and estimated to date back 20 million years. If these bacteria are indeed *Y. pestis,* they may be ancient strains that evolved as rodent parasites that are now extinct, as genomic data indicate that the flea–animal–human transmission cycle for *Y. pestis* evolved some 20,000 years ago. Wagner and colleagues retrieved teeth from two victims of the Justinian plague and compared the DNA sequences obtained against a database of more than 130 *Y. pestis* strains from the second and third pandemics.[7] This study identified differences in genome sequences, indicating that the transmission of *Y. pestis* from rodents to human beings was a lineage of *Y. pestis* independent of the lineage that caused the Black Death some 800 years later.

For reasons that are not fully understood, epidemics of urban plague have dramatically waned, but data from the 1990s reported by the World Health Organization (WHO) indicate that plague was still a significant public health problem, especially in Africa, Asia, and South America (Fig. 45.1).[8,9] During 2005, an outbreak of pneumonic plague at a diamond mine in Northern Congo caused 114 confirmed infections among the miners, 54 of whom died.[10] The outbreak was limited only by the dispersal of miners fleeing in panic from the area.[10] Between 2005 and 2009, more than 12,500 cases of plague were reported to the WHO, with a fatality rate of 6.7%, from 16 countries.[11] The majority of these cases (>97%) were reported from eight African countries, with fewer than 150 cases each from Asia and the Americas, resulting in 23 and six deaths on these continents, respectively. During 2009, the United States reported 27 plague cases resulting in five deaths, while an outbreak in the Qinghai Province of China, associated with the marmot hunting season, resulted in 12 cases of pneumonic plague with three deaths.[11] During 2010, more than 30 cases of plague, predominantly bubonic but with some pneumonic and septicemic cases also, were reported in Peru.[12] Between January 1, 2010, and December 21, 2015, 3,248 cases of plague in humans were reported, resulting in 584 deaths.[12a] As of February 2016, the three most endemic countries are reported to be Madagascar, Democratic Republic of Congo, and Peru.[12a] During 2014, 119 cases of plague were reported in Madagascar with at least 40 deaths.[13]

During 2015, there was a greater-than-usual incidence of plague reported from the United States, with a total of 11 cases reported from Arizona, California, Colorado. Georgia, New Mexico, and Oregon, and three deaths reported.[14] These cases were predominantly bubonic and were attributed to exposure to fleas that had bitten infected wild animals.

Thus, even in the 21st century, plague still occurs episodically in parts of the world where environmental conditions permit. In plague-endemic areas of the world, vaccines may be useful in preventing plague in people at high risk, as well as in those who are involved in research and diagnosis of the disease.

BACKGROUND

Clinical Description

Bubonic Plague

Bubonic plague is the form of disease typically transmitted to humans by an infected flea, that flea having previously fed on an infected rodent. In some circumstances, infection can occur via open wounds that are exposed to infected material through handling and other direct contact.[4] Within 2 to 6 days of infection, the patient develops a fever, headache, and chills.[15] Occasionally, lesions develop at the site of inoculation. The classic feature of bubonic plague is the development of swollen and tender lymph nodes called *buboes,* from the Greek word *bubon,* meaning groin. The buboes are often located within the inguinal and femoral lymph nodes, which drain the original site of infection on the lower extremities.[4] Bacteremia is common in patients with bubonic plague, typically resulting in blood culture counts ranging from fewer than 10 and up to 4×10^7 colony-forming units (CFU)/mL.[4] High levels of bacteremia are often associated with gastrointestinal symptoms such as vomiting, nausea, abdominal pain, and diarrhea.[4] Early intervention during the course of disease with antibiotics such as streptomycin, gentamicin, tetracycline, chloramphenicol, or the fluoroquinolones, usually leads to rapid recovery.[16]

Septicemic Plague

Primary septicemic plague is a clinical diagnosis in a patient who has acute toxic illness, large numbers of *Y. pestis* in the bloodstream, and no identifiable anatomical site of infection, such as a peripheral bubo.[15] Clinically, the disease appears

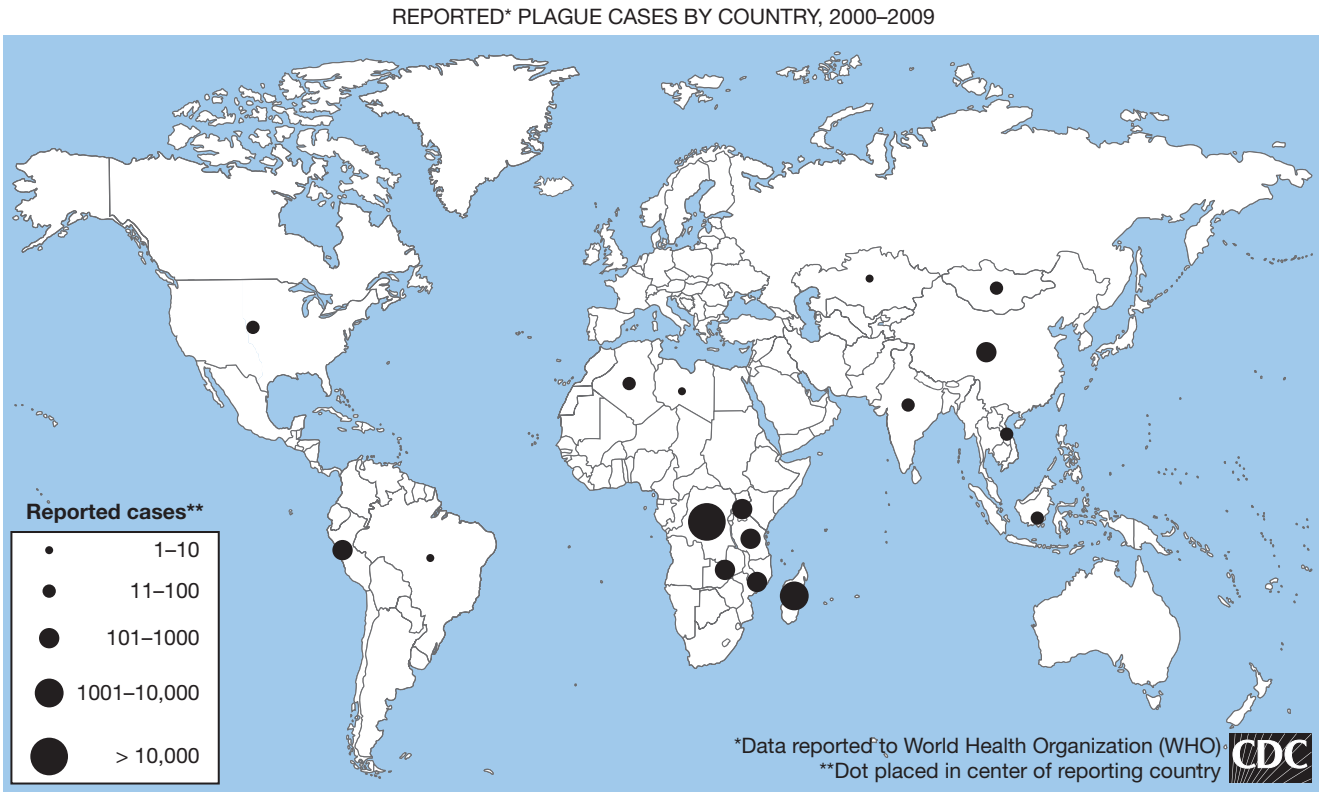

Figure 45.1. Occurrence of plague in the modern world. *(Modified from Division of Vector-borne Diseases, Centers for Disease Control and Prevention [CDC], Atlanta, GA, 1998.)*

similar to other gram-negative septicemias, with elevated temperature, chills, headache, malaise, and gastrointestinal disturbances. In the absence of aggressive treatment, life-threatening complications of the systemic inflammatory response syndrome occur, such as disseminated intravascular coagulation with bleeding, adult respiratory distress syndrome, shock, and organ failure. Owing to the absence of localizing signs, the diagnosis of primary plague sepsis may be delayed and result in a high case fatality rate. The overall case fatality rate for persons with plague sepsis approaches 20% to 40%.

Pneumonic Plague

Some colonization of pulmonary tissues occurs in most untreated fatal cases of plague, with the potential to develop into a secondary pneumonic plague. However, most of these patients do not develop a transmissible plague pneumonia.[15] However, when there is colonization of the alveolar spaces after a respiratory exposure, a suppurative pneumonia develops, and during the terminal stages of disease there is coughing with the production of a highly infectious, watery, and bloody sputum. Pneumonic plague is the most widely feared form of the disease because it is suggested that *Y. pestis* can be spread from person to person as respiratory droplets formed during coughing.[17] A number of experiments with animals (guinea pigs, lemurs, and nonhuman primates) have demonstrated the potential for the cross-infection of control animals from infected animals showing the symptoms of pneumonic disease.[18–22] More significantly, good evidence supporting the potential for the airborne spread of infection in humans has been derived from an analysis of an outbreak of pneumonic plague in Madagascar.[23] In this outbreak, four cases of pneumonic plague were attributed to contact with one patient who had developed secondary pneumonic plague. These four infected individuals apparently then transmitted the disease to 11 others, one of whom transmitted the disease to two further individuals.[23] In total, 18 individuals contracted pneumonic plague resulting from this single individual and eight died.

The available evidence indicates that the inhalation of airborne droplets containing *Y. pestis* by susceptible individuals leads to the development of pneumonic plague within 1 to 3 days.[15] The rapidity with which the infection spreads between individuals, along with the relatively short incubation period, makes control of the disease difficult and antibiotic therapy may be ineffective once the pulmonary symptoms have developed.[4,15,16] Primary pneumonic plague is now rare; in the United States, the few cases that have been reported in recent years have been in veterinarians and owners of domestic cats who have contracted pneumonic plague from their pets[4,5] or in individuals who have been exposed to infected wild animals. Nevertheless, the potential for pneumonic plague to spread quickly in human populations is evident (e.g., from the 2005 outbreak in the Northern Congo diamond mine[9] and in the later outbreak in Peru in 2010).[12]

Bacteriology

The etiological agent of plague is *Y. pestis*, a gram-negative bacterium that is a member of the family Enterobacteriaceae. The bacterium is able to grow at temperatures between 4°C and 40°C and has nutritional requirements for L-isoleucine, L-valine, L-methionine, L-phenylalanine, and glycine. The species has been subdivided into three biovars (*Orientalis, Mediaevalis,* and *Antigua*) on the basis of the ability to convert nitrate to nitrite and to ferment glycerol; however, all three biovars show similar virulence in animal models.[4] The genus *Yersinia* also includes *Yersinia enterocolitica* and

Yersinia pseudotuberculosis species, both of which are pathogens of humans but rarely cause disease with a fatal outcome.[1,16] Newer studies show that *Y. pestis* evolved from *Y. pseudotuberculosis* (most probably serotype 1b) between 1500 and 20,000 years ago.[24] Recent attempts to reconstruct the genome sequence of the medieval *Y. pestis* from DNA isolated from the teeth of victims of the Black Death, using the contemporary CO92 strain as a reference, have not indicated major genetic differences between medieval and the CO92 strain of *Y. pestis*, although this approach could not rule out the loss of genomic regions that may have existed in the ancient strain.[25] The results from independent studies reporting the analysis of DNA from the eras of the Justinian and Black Death plagues classify these samples as most similar to the Orientalis biovar.[26–28] An intermediate form, termed *Pestoides*, has been identified. Genome sequence analysis reveals that Pestoides strains do not contain the full complement of plasmids associated with *Y. pestis* and retain chromosomal loci found in *Y. pseudotuberculosis* but lost in *Y. pestis*.[29,30] Pestoides isolates are virulent, particularly by aerosol routes,[29,30] but can show attenuation by systemic routes[30] and are enzootic strains maintained in rodents of the superfamily *Muroidea* comprising rats, mice, hamsters and gerbils.[31]

Evolution of *Y. pestis* has been by the inactivation of a range of genes that are thought to be required for an enteric lifestyle and acquisition of new virulence factors.[32] The acquired virulence genes appear to be located primarily on two plasmids. Both *Y. pestis* and *Y. pseudotuberculosis* possess a 70-kilobase (kb) virulence plasmid called pYV that carries a type III secretion system operon.[33,34] *Y. pestis* possesses two further unique plasmids, a 9.5-kb plasmid, pPCP1, and the 100- to 110-kb pFra plasmid.[1] The *pla* gene on pPCP1 encodes a surface-bound protease (plasminogen activator), which has potent fibrinolytic activity (Fig. 45.2).[1] The possession of the pPCP1 plasmid has recently been used to date the evolution of *Y. pestis* from *Y. pseudotuberculosis*.[35] Although the oldest Pestoides strains (E and F) do not possess the pPCP1 plasmid, Angola and Pestoides A strains, which arose later, do contain the pPCP1 plasmid. Furthermore, Angola and Pestoides A strains do not possess a later sequence change in the Pla protein which optimizes its function in disseminating bacteria in vivo; this indicates that the pPCP1 gene was acquired by *Y. pestis* relatively early in its evolution from *Y. pseudotuberculosis*, and before it was fully adapted to its flea-vectored lifestyle. The pFra plasmid shows extensive sequence homology with plasmid pHCM2, possessed by some strains of *Salmonella enterica* serovar Typhi.[36] However, some regions of pFra appear to be unique to *Y. pestis*, and one of these regions includes the *caf* operon responsible for synthesis of the protein capsule expressed by *Y. pestis* at 37°C.[37]

Pathogenesis

Plague has a complex lifestyle, cycling between arthropod and mammalian hosts, with the primary mammalian hosts being rodents: humans are accidental hosts. As a result of this lifestyle, the organism has had to develop sophisticated strategies to ensure transmission from infected rat to the flea, then from the flea to a new host. The rat flea (*Xenopsylla cheopis*) ingests bloodborne bacteria from the infected rodent, and growth of the bacteria leads to blockage of the flea's foregut. The hemin storage system is thought to play an important role in the formation of this blockage,[38] with the result that mutants of *Y. pestis,* lacking the hemin storage locus, established long-term infection of the flea's midgut but failed to colonize the proventriculus, preventing the efficient transmission of bacteria.[38] The blockage prevents digestion of the blood meal, and further ingestion of blood leads to regurgitation of bacteria-contaminated material from the flea into a mammalian host.[39] In achieving its transmission, the pathogen results in the death of both mammalian host and flea vector. High levels of septicemia in the infected mammal are required to allow the infection of a subsequent flea vector, and efficient transmission from the flea is required to infect the mammal.[40] However, in situations in which humans and rodents are in close proximity or when the rodent population is reduced, either as a result of the disease or rodent control measures, humans and other warm-blooded mammals serve as alternative hosts. In this respect, *Y. pestis* differs from the other human pathogenic *Yersinia* species in that it is an obligate parasite. The organism circulates in a "sylvatic" form in wild rodent populations, typically causing a fatal disease in mice and squirrels and a milder, subclinical infection in gerbilline and dipodids[41] such as the Jerboas. Other reservoirs of infection include prairie dogs, rabbits, and members of the cat family, including the domestic cat.[4]

Thus the infection of humans usually occurs as the result of a bite from an infected flea and it has been suggested that as many as 24,000 bacteria are delivered into the host with a single bite.[4] However the "blocked" flea model alone cannot account for the rates of spread of plague during plague endemics and it is thought that unblocked fleas are also able to transmit infection, by a so-called early phase transmission process.[42] This would allow the flea to transmit bacteria to its

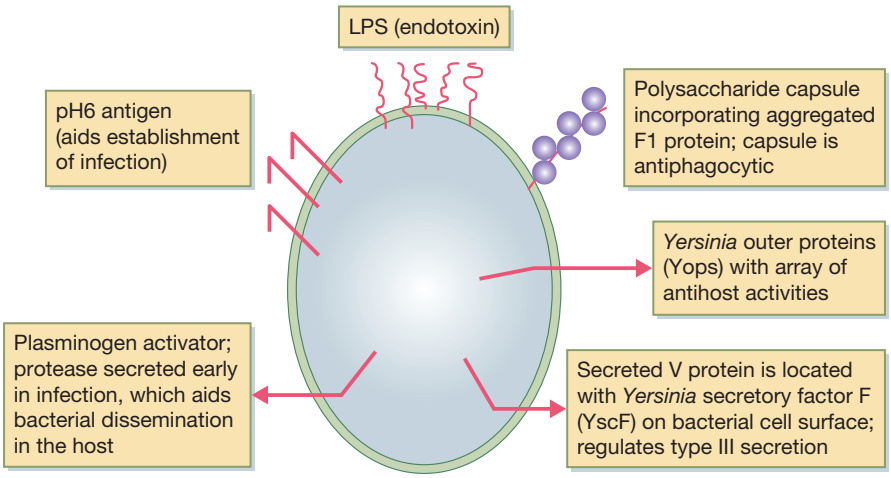

Figure 45.2. Virulence factors expressed by *Yersinia pestis*. LPS, lipopolysaccharide.

host in a much shorter time interval after its latest blood meal and would promote sylvatic epizootics and possibly also maintain endemic disease in man at times of low flea burdens or where human flea populations *(Pulex irritans)* predominate. To date, only three factors have been positively confirmed as essential for transmission from flea to mammal: a murine toxin, an extracellular polysaccharide, and a lipopolysaccharide core modification locus. The murine toxin has phospholipase D activity that is essential for survival in the flea midgut,[43] whereas the extracellular polysaccharide and lipopolysaccharide (LPS) core modifications are required for biofilm formation and blockage of the flea.[38,44] However transcriptional analysis of *Y. pestis* in the flea gut identified a wide range of genes, such as the insecticidal-like toxin genes, that were differentially regulated, expression of which meant that the bacteria regurgitated into a new host had increased resistance to innate immune effectors.[45]

Upon infection of a new host, the plague bacilli are vulnerable to phagocytosis by polymorphonuclear leukocytes or monocytes. However, bacteria from fleas showed significantly lower levels of phagocytosis than bacteria grown in vitro, indicating the importance of the complex influence of growth in the flea on pathogenesis.[45] The insecticidal-like toxins were key components in resisting phagocytosis in the early stages of infection,[45] before the antiphagocytic type III secretion system could be induced.

There is controversial evidence that preferential phagocytosis in monocytes/macrophages may be facilitated by the chemokine receptor CCR5,[46–48] prevalent on monocytes/macrophages and dendritic cells, but not on polymorphonuclear leukocytes. A specific role for Ccr5 in plague pathogenesis remains uncertain, appearing possible from in vitro bacterial uptake studies, but less likely from in vivo susceptibility studies in Ccr5 knockout mice. Ccr5 is a coreceptor with CD4 facilitating entry of another infection, HIV, into host cells.[46–48]

The plague bacteria are killed within polymorphonuclear leukocytes, but persist within monocytes and express various virulence determinants, thereby allowing growth and eventual release from the monocytes.[49] One such virulence determinant is the pH6 antigen, a fibrillar adhesin induced by the low phagosomal pH (pH of 4.5),[50] which enhances resistance to phagocytosis.[51] The F1 capsule likely also plays a key role in avoiding phagocytosis.[52] However, mutants of *Y. pestis* that are unable to produce F1 antigen are still able to cause disease in the mouse, although they have reduced virulence.[53] It appears that possession of the locus encoding the F1 antigen increases transmissibility from the flea,[54] although this is not observed following needle challenge in a laboratory setting.

The dominant antiphagocytic effect is a result of induction of the type III secretion system carried on the large virulence plasmid. Type III system effectors, historically called *Yersinia* outer membrane proteins (Yops), are secreted into host target cells and result in phagocyte killing. The function of many of the Yops has been determined in this well-characterized secretion system, which serves as a paradigm for all type III secretion systems.[33] For example, the YopE protein is a cytotoxin that is transferred into host cells after bacterial contact[55]; the YopH protein is a tyrosine phosphatase that has antiphagocytic cell activity.[55] The V antigen component of the type III system appears to play several roles in the pathogenesis of disease. It is present at the tip of the injectisome that delivers Yops into the host cell.[56] Additionally, V antigen secreted from *Y. pestis* exerts a local immunomodulatory effect in the host, by downregulating the production of interferon-γ and tumor necrosis factor-α.[57,58]

Another major virulence factor required for dissemination from the site of infection is the plasminogen activator (Pla). Pla is an outer membrane located protease, required to break down the physical barriers of connective tissue in the host and thus Pla is essential in the dissemination away from the injection site of the bolus of *Y. pestis* injected by the flea; this has driven the selection of a "rough" phenotype of LPS which lacks an O antigen.[59,60] While rough LPS is rare among gram-negative bacteria, it allows for the functionality of Pla. On the other hand, when O antigen expression is forced, it blocks the activity of Pla, and is thus attenuating by both dermal and respiratory routes of infection,[61,62] but not following intravenous inoculation.[63] Pla interacts with the DEC-205 receptor on antigen-presenting cells to promote uptake, and it appears that dissemination only occurs after phagocytosis.[62]

The bacteria disseminate from the site of primary infection into regional lymph nodes that drain these tissues. Within the lymph node, further growth of the bacteria, accompanied by a massive inflammatory reaction, leads to lymphadenopathy and the formation of buboes. In the bubo, bacteria are predominantly extracellular, mainly because of the type III secretion system, which is highly expressed in the lymph node.[54] An ability to proliferate in the bubo requires efficient iron-acquisition systems. *Y. pestis* possesses 10 iron-acquisition systems, which are actively used in the bubo.[54]

Eventually, the bacteria are disseminated by the lymphatic system, gain access to the bloodstream, and colonize pulmonary tissues, which may lead to development of the pneumonic form of the disease. Untreated, pneumonic plague is almost invariably fatal, inducing an overwhelming septicemia that triggers septic shock in the host. However, the precise mechanisms that lead to death of the host have not been identified. Systemic induction of nitric oxide synthase may be the terminal event, as seen with other gram-negative septicemias.[64]

Although pigmentation-negative strains of *Y. pestis* are usually avirulent and attenuated, the risk of reversion to virulences was recently highlighted by the fatal case of a laboratory worker who was unknowingly suffering from hemochromatosis and who was exposed to the attenuated pgm^- (pigmentation) *Y. pestis* laboratory strain KIM. This individual developed and died from plague, presumably from the complementation of the haem deficiency by the individual's medical condition.[65]

Models of Disease and Protection

Y. pestis causes disease in a wide variety of laboratory animals,[4] including mice, Brown Norway rats,[66] guinea pigs, and nonhuman primates.[67] Additionally, several species, such as the black-footed ferret[68] and the prairie dog,[69] have been actively immunized against plague. Most experimental work has been carried out in the mouse model of disease, however the model may not faithfully mimic human disease because of the unique susceptibility of mice and rats to the murine exotoxin.[70] Although this limitation might be resolved by using the guinea pig model of disease, the protracted nature of the disease in the guinea pig[71] suggests that the mouse model is a better indicator of the infection that occurs in animal reservoirs. In a comparative study with mice and guinea pigs, it was concluded that mice were more suitable for the evaluation of plague vaccines[72] and this species was approved by the U.S. Public Health Service for the testing of plague vaccines. Disease arising from the delivery of *Y. pestis* by the subcutaneous route (median lethal dose [LD_{50}]: 1–2 CFU[73]) is considered to mimic bubonic plague, whereas the exposure of mice to the bacteria via inhaled aerosols results in the pneumonic form of the disease (LD_{50}: 2×10^4 CFU[74]). The efficacy of the original Cutter Killed Whole Cell (KWC) vaccine was determined by measuring the ability of sera passively transferred from immunized mice, guinea pigs, monkeys, or humans to protect naïve

mice against *Y. pestis*, with the derivation of a mouse protection index (MPI).[75] A potency test based on active immunization and organism challenge in the mouse model is being developed to test the efficacy of a next generation subunit plague vaccine.

Diagnosis of Plague

The clinical diagnosis of plague is supported by laboratory tests. Bacteriological diagnosis of plague is usually made on the basis of the analysis of aspirates taken from a bubo, or from blood or sputum samples. The most straightforward analysis involves Gram or Wayson staining of air-dried smears on microscope slides.[76,77] After staining, *Y. pestis* cells appear as small gram-negative rods with a characteristic bipolar staining (safety-pin appearance). Culture on Congo Red agar, ideally at 26°C to 28°C, results in so-called bull's-eye colonies, which have a red pigmented central region and paler margins.[77] However, culture methods are generally considered to be too slow (typically taking 48 hours) in the context of the rapid progression of the disease (especially pneumonic plague) and a presumptive diagnosis should be made before such tests are completed.

A variety of confirmatory tests for *Y. pestis* have been proposed, including the use of fluorescent antibody to the capsular F1 antigen, passive hemagglutination tests, the use of the polymerase chain reaction, and enzyme-linked immunosorbent assay (ELISA).[73,78–80] These tests can be used with samples such as bubo aspirates for the rapid diagnosis of disease.[78] An exciting development is the demonstration that an immunogold-chromatography dipstick can be used for the direct analysis of bubo aspirates, serum, or urine samples.[81] Such tests have subsequently been sent to endemic countries to evaluate their use for the rapid detection of plague.[82] Conceivably, such tests might be used outside the laboratory and at the patient's bedside for the rapid diagnosis of plague.

Treatment and Prevention With Antimicrobials

The successful treatment of plague is dependent on the prompt commencement of therapy during the early stages of the disease. In cases of bubonic plague treated with antibiotics, the fatality rate is generally less than 5%. In contrast, the successful treatment of septicemic or pneumonic plague is less certain because of the rapidity with which the disease develops and the difficulties of making an early diagnosis.

A number of antibiotics, including streptomycin, tetracycline, and ciprofloxacin, are approved by the U.S. Food and Drug Administration (FDA) for the treatment of plague.[76,83] For the treatment of plague meningitis, intravenously administered chloramphenicol is the antibiotic of choice because of its ability to cross the blood-brain barrier.[76,83] However, alternatives include streptomycin (or gentamicin) with or without doxycycline or a fluoroquinolone such as ciprofloxacin or levofloxacin.[84–87] The fluoroquinolones ciprofloxacin and levofloxacin have been licensed by the FDA for the indication of inhalational plague.[88]

For all antibiotics, a 10-day course is recommended. In mice infected with *Y. pestis* by the airborne route, successful treatment of disease with ciprofloxacin was dependent on the commencement of antibiotic dosing within 24 hours of exposure to the pathogen.[83]

Improvements in the condition of patients suffering from bubonic plague are seen within 2 to 3 days, but buboes may remain for several weeks after successful treatment. A strain of *Y. pestis* showing plasmid-mediated resistance to tetracycline, streptomycin, chloramphenicol, and sulfonamides has been isolated from a case of bubonic plague in Madagascar.[89] The failure of a patient to respond to treatment with one or more of the antibiotics named above, should alert the clinician to the possibility of an antibiotic-resistant strain of *Y. pestis*.

Family members and other close contacts with individuals suffering from plague should be maintained under surveillance for at least 7 days after their last possible exposure to *Y. pestis*. It may be appropriate to use tetracycline or doxycycline prophylactically for 7 days in these individuals, especially if the primary case is pneumonic plague. The prophylactic use of antibiotics is recommended even in individuals who have been previously vaccinated with the KWC vaccine and who might have been exposed to airborne *Y. pestis*[5] because of the limited ability of this vaccine to provide protection against pneumonic disease.[90]

EPIDEMIOLOGY

Endemic foci of animal plague occur mainly in semi-arid regions of the world (see Fig. 45.1). The main foci have been identified in the southwestern United States, the former Soviet Union, South America, South Africa, and Asia. Not surprisingly, these are the regions of the world that also report the highest incidence of human plague. Each year there are several thousand reported cases of the disease worldwide,[91] with a fatality rate between 5% and 15%,[8,9] and plague has been classified as a reemerging disease by the WHO with endemic regions as described above. There was an apparent increase in the incidence of disease during the 1990s, although it is possible that this increase was the result of more efficient diagnosis and reporting of cases. However, recent statistics on the global incidence of plague serve as a reminder that the disease can suddenly reemerge in endemic regions.[11] A significant outbreak of plague occurred at Surat in India in 1994. Serological testing of individuals during this outbreak showed that there were 876 presumptive cases of plague and 54 fatalities.[4,92] In the last few decades, however, the major incidence of plague activity in the world has shifted from Asia to Africa[10] where plague is now endemic in many countries.[93] As of February 2016, the three most endemic countries were reported to be Madagascar, Democratic Republic of Congo, and Peru.[12a] An outbreak of plague cases in northeast Tanzania was reported in 1980[94] and by 2004 more than 7000 cases, predominantly of bubonic plague, had occurred, illustrating a prolonged incidence of disease in this country. Data from this outbreak indicated that the risk of infection for children 10 to 14 years of age was twofold higher than in adults and women were more often infected than men.[93] This female-to-male susceptibility was also reported for outbreaks in Kenya and Mozambique,[95] although in Madagascar the opposite was true.[96] Whether there are true gender effects on susceptibility or result from social, occupational, or environmental risk factors is unclear. In Tanzania, plague outbreaks appear to be associated with the wet season, whereas in Madagascar the occurrence of plague cases correlates with the cool dry season.[93] In the United States, a new trend in plague epidemiology appears to be related to the residential encroachment on former rural areas that contain enzootic foci,[4] putting humans at risk of exposure to flea bites or in close contact with infected wild rodents or other animals.

Potential Use as an Agent of Bioterrorism

Plague vaccines have also attracted considerable attention because of the potential for *Y. pestis* to be used as an agent of biological warfare or bioterrorism.[76] It is likely that *Y. pestis* used in this way would be disseminated by the airborne route, and would cause pneumonic plague. A 1970 report by the WHO[97] indicated that, in a worst-case scenario, the

airborne release of 50 kg of *Y. pestis* over a city of 5 million would result in 150,000 cases of plague. Of these, 36,000 would be expected to die. The released bacteria would remain viable for 1 hour. Disease that resulted from the deliberate release of *Y. pestis* in this way would appear within 1 to 6 days of exposure and most probably within 2 to 4 days.[76] The initial symptoms would resemble other severe respiratory illnesses,[76] which might make early diagnosis and appropriate treatment difficult. The indicators of an attack with *Y. pestis* would include the clustering of cases, the death of rodents in the area, the incidence of disease in individuals without known risk factors, and disease in areas where plague is not known to be endemic.[76] The unpredictable nature of such attacks and the potential for epidemic spread of disease from the index case would make the availability of vaccines and immunoprophylactics important and is discussed later in this chapter.

PASSIVE IMMUNIZATION

Early studies showed that serum from human volunteers immunized with purified F1 antigen or with a KWC vaccine would provide passive protection of mice against a parenteral challenge with 100 LD_{50} of *Y. pestis*.[98,99] Newer studies have reported that the passive administration of antiserum or monoclonal antibodies against the F1 and V antigens protects mice previously challenged parenterally with *Y. pestis*,[100–102] demonstrating the potential of postexposure immunoprophylaxis. However, there is currently no licensed immunoprophylaxis or immunotherapies for plague.

ACTIVE IMMUNIZATION

Killed Whole-Cell Vaccines

Killed *Y. pestis* organisms have been used as a vaccine since 1897, when Waldemar Haffkine inoculated himself with an experimental vaccine. A KWC vaccine for human use was first produced in the United States in 1946 (Army Vaccine). Improvements to this vaccine led to the plague vaccine United States Pharmacopoeia (USP), which was produced from the virulent 195/P strain of *Y. pestis*.[103] During the 1990s, there were several commercial suppliers of KWC vaccines against plague. Plague vaccine USP, which contains formaldehyde-killed bacteria, was initially manufactured by Cutter Laboratories, then in 1994 was manufactured by Greer Laboratories, and in 1999 production of this vaccine was discontinued. An alternative KWC vaccine was manufactured by the Commonwealth Serum Laboratories (CSL Australia)[104] and until November 2005 was licensed for clinical use in Australia. This vaccine contained heat-killed bacteria (*Y. pestis* strain 195/P) resuspended in saline containing 0.5% weight per volume of phenol to a concentration of 3×10^9 organisms/mL. The vaccine was given subcutaneously as two 0.5-mL doses separated by an interval of 1 to 4 weeks, with some modifications for children (Table 45.1). Booster doses at 6-month intervals of this vaccine were also recommended. However, currently there is no licensed plague vaccine for general use, although the recombinant subunit vaccine candidates discussed below, have investigational new drug status.

TABLE 45.1 Schedules and Dosages of the Commonwealth Serum Laboratories Killed Whole-Cell Vaccine

Age of Recipient	Volume Administered			
	First Dose	Second Dose	Third Dose	Booster Dose
6 mo–2 y	0.1 mL	0.1 mL[a]	0.1 mL[a]	0.1 mL[b]
3–6 y	0.2 mL	0.2 mL[a]	0.2 mL[a]	0.2 mL[b]
7–11 y	0.3 mL	0.3 mL[a]	0.3 mL[a]	0.3 mL[b]
>12 y	0.5 mL	0.5 mL[a]	—	0.3 mL[c]

[a]One to 4 weeks after previous dose.
[b]At 6-month intervals after dose 3.
[c]At-6 month intervals after dose 2. Dose can be reduced to 0.1 mL intradermally for individuals who have reactions to previous doses of the vaccine.

Live Attenuated Vaccines

The first live attenuated *Y. pestis* strain used as an experimental vaccine was produced in 1895 by Yersin, but was never tested in humans for fear of reversion to virulence. Subsequently, the EV76 strain was developed from the EV strain which had been isolated in Madagascar from a human bubonic plague victim in 1926. Attenuation was achieved following 6 years of in vitro passage.[105] The EV76 strain and its derivatives have been used to vaccinate humans since 1908, especially in the former Soviet Union and the French colonies. However, the genetic lesion that results in attenuation of EV76 has not been defined. The strain is known to be a pigmentation *(pgm)* mutant that prevents the bacterium from assimilating hemin[4] and also results in changes in the surface properties of the bacterium.[38] Other live vaccine strains include the Tjiwidej smooth strain developed in the 1930s,[106] where attenuation resulted from the loss of V antigen expression.[107] This strain was used in limited field trials in Madagascar and Java.[105] At present, however, no live vaccine is commercially available or licensed for use in humans because of the risks of reversion and severity of disease caused by these strains.[105]

The safety of these vaccines was also assessed. Inoculation with the EV strain resulted in reactions ranging from local swelling and erythema of up to 15 cm diameter, with a rise in temperature accompanied by headache, weakness, and malaise, severe enough to require hospitalization in some cases. Although immunization with these strains protected against both bubonic and pneumonic infections, the risks associated with the vaccines appeared to outweigh the benefits.

Subunit Vaccines

Vaccines consisting of purified recombinant proteins are now in advanced development and represent the next generation of plague vaccines. One such vaccine, including recombinant F1 and V proteins administered in an alhydrogel-adjuvanted liquid formulation, has successfully undergone Phase II clinical trials. The F1 and V proteins, naturally produced by the parent organism as virulence factors, have been cloned and expressed under good manufacturing practices conditions in avirulent *Escherichia coli*[108–111] and purified prior to coadsorption to alhydrogel. The resulting vaccine has been demonstrated safe and immunogenic in a total of 145 clinical trial volunteers to date. A variation of this vaccine, where the C terminus of F1 is genetically fused to the N-terminus of V to produce a recombinant fusion protein (rF1-V), is currently in advanced development.[112] A major advantage of such subunit formulations enriched for protective antigens, compared with KWC vaccine formulations, is the reduced immunization regimen required with the rapid induction of protective immunity and reduced reactogenicity. Such subunit vaccines are also versatile and could be formulated for administration by noninvasive routes. To date, formulation of the rF1 and rV subunits for oral delivery has achieved approximately 60% protection against challenge in the mouse model.[113]

RESULTS OF VACCINATION

Immune Responses

The immune responses to KWC vaccine formulations were mainly directed against the F1 antigen, as the content of V antigen in these vaccines was low or undetectable.[114] The titer of the F1 antibody, determined by passive hemagglutination, correlated with protection against plague challenge in animal models.[115] Ninety percent of animals with anti-F1 passive hemagglutination titers of 128 survived challenge with 1×10^3 to 5×10^5 CFU of *Y. pestis*, whereas the proportions of animals with titers of 32 to 64 or 16 that survived were 46% and 6%, respectively. Passive immunization studies with sera from immunized animals[75] or humans[116] also suggest that anti-F1 passive hemagglutination titers of 1 : 128 or greater were protective. However, the accepted standard involves passive immunization of mice with antisera and the demonstration of an acceptable MPI. Studies of the Greer Laboratories' vaccine suggest that 55% to 58% of individuals develop an antibody response with an acceptable MPI after two vaccinations[5]; however, even after multiple vaccinations, averaging five per subject, 8% of individuals failed to develop any antibody response.

The rationale for combining the F1 and V antigens in the next-generation vaccine is to induce an immune response to counteract the key virulence mechanisms demonstrated during natural infection. Evidence from animal models[114] and from clinical trials[117] indicates that both antigens are immunogenic and that they are additive in their effect. The current lead vaccine candidate is a recombinant genetic fusion of the F1 and V antigens (rF1/V) adsorbed to alhydrogel.[112] Earlier published work outlined the combination of recombinant F1 and V antigens, adsorbed to alhydrogel (rF1+rV),[114] and is presented below.

Clinical Immunogenicity

The human immune response to the rF1-V vaccine has been assessed in more than 400 healthy volunteers; the vaccine has been shown to be safe and immunogenic.[118] Immunogenicity of the rF1-V vaccine has been assessed by titration of antibody titer and assay of antibody functionality, including the ability to protect naive animals by passive transfer of antiserum before plague challenge.[119] Similarly, the rF1 + rV vaccine has been assessed during Phase I safety and immunogenicity trials in 32 healthy volunteers progressing to Phase II trials.[117] The data from the first trial have been published and show that all the subjects produced F1 and V-specific immunoglobulin (Ig) G after the initial dose, which peaked after the booster dose (day 21), with the exception of one individual in the lowest dose-level group, who responded to rF1 only.[117] The assessment of functional antibody has been aided by the identification of a mouse monoclonal antibody (mAb) directed against a protective B-cell epitope in V antigen, which provides solid protection against live organism challenge in the mouse.[117] Human antibody as well as a reference macaque antibody, was found to compete with this mAb for binding to rV in vitro and also to protect naïve mice by passive transfer.[117] This suggests that recognition of this protective B-cell epitope in the V antigen is conserved between mouse, macaque, and humans. Total IgG to rV in human volunteers and the titer of IgG competing for binding to rV, correlated significantly at days 21 and 28 ($P < .001$).[117] Protection afforded by passive transfer of immune human sera into mice also correlated significantly with the IgG titers to both rF1 and rV at days 21 ($P < .001$) and 28 ($P < .03$), as determined by regression analysis (Fig. 45.3).[117] Thus potential serological immune correlates of protection have been identified and

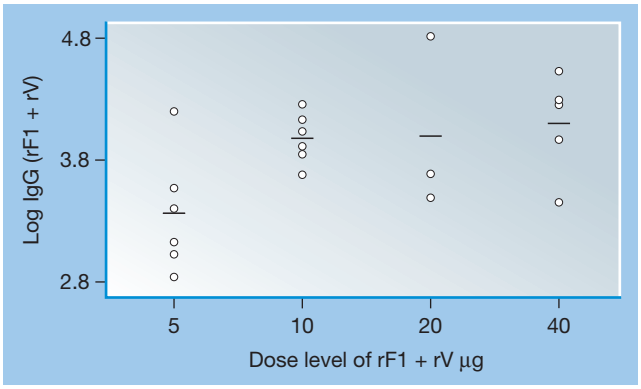

Figure 45.3. Correlation between vaccine dose level and response in Phase I clinical trial of rF1+rV vaccine. Volunteers were administered a priming immunization and a booster dose on day 21. The IgG response was measured by combining areas under the curve for Log_{10} IgG responses to rF1 and to rV, measured in the period between day 21 (prior to the booster dose) through day 70 of the immunization schedule. *(From Williamson ED, Flick-Smith HC, LeButt CS, et al. Human immune response to a plague vaccine comprising recombinant F1 and rV antigens.* Infect Immun. *2005;73:3598–3608.)*

can be used as surrogate markers of protection in future clinical trials of the rF1/V vaccine, for which conventional Phase III efficacy trials will not be possible.[119] Surrogate markers of protection, which rely on the induction of cell-mediated immunity (CMI) mechanisms, may also be required, based on the indications from animal models.[67,120] However, assays of CMI during large trials rely on fresh whole-blood samples, which can be difficult to obtain. Flow cytometric analysis of such samples in subjects responding to vaccination showed no significant changes in markers of cellular activation, but advances in flow cytometric technology may well improve sensitivity of detection, making it a viable approach to monitor CMI development.[117]

INTEGRATION OF CLINICAL AND NONCLINICAL DATA

None of the plague vaccines that have been developed have been subjected to a randomized, clinically controlled field study in humans.[121] Although controlled clinical studies are desirable, the sporadic and relatively low incidence of plague means that such studies would be difficult to conduct. Thus, evidence for the efficacy of vaccines must be based on comprehensive studies in several animal models and on the evidence that the vaccines can induce antibody in humans that can passively protect challenged animals. Additionally, anecdotal data from Vietnam have proven informational. From 1961 to 1971, many thousands of Vietnamese civilians developed plague (333 cases/10^6 person-years of exposure), but the incidence of disease in KWC-vaccinated U.S. troops based in Vietnam during this period was low.[122] (The total of eight cases represents one case per 10^6 person-years of exposure.[5,122]) Although this difference in the incidence of disease might be attributed to different exposures of these populations to *Y. pestis*, it is worth noting that many military personnel developed murine typhus, which is also transmitted by *X. cheopis*.[5] Furthermore, serological studies indicated that some immunized individuals were exposed to *Y. pestis* and developed subclinical infections.[122] The effectiveness of KWC vaccines against the pneumonic form of the disease is more questionable, as pneumonic plague has been reported in vaccinated individuals.[97,123]

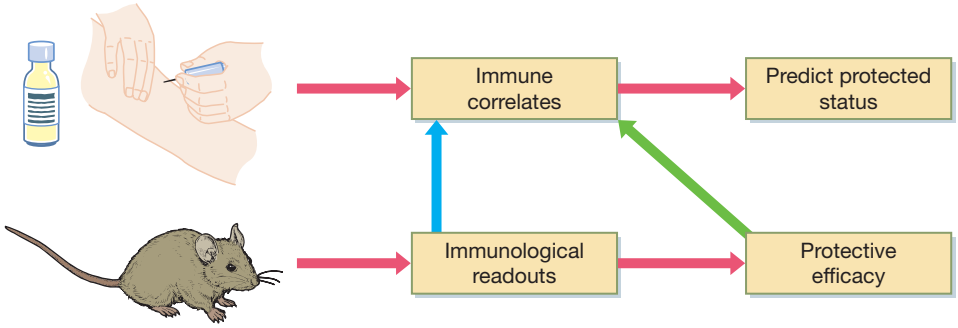

Figure 45.4. Integration of nonclinical and clinical studies with the identification of immune correlates of protection.

Thus for diseases such as plague, where the logistics of a clinical field trial are difficult and efficacy testing is neither practical nor feasible, the only recourse to predict efficacy in humans is to compare the immunological readouts from the clinic with those gained from nonclinical studies, particularly where the latter can be related to a measurement of protective efficacy, to derive immune correlates of protection (Fig. 45.4). Based on these data, surrogate markers, which would correlate with protective immunity, can be sought from clinical studies.[124] The nonclinical evidence that indicates the efficacy of the subunit vaccines in relevant animal models is reviewed in the next section.

Protective Efficacy in Nonclinical Studies

In the murine model of disease, immunization with two doses of a KWC vaccine provided solid protection against a subcutaneous challenge with 5000 LD_{50} of *Y. pestis* and partial protection (60% survival) against a subcutaneous challenge with 50,000 LD_{50} of *Y. pestis*.[73] In contrast, when mice were challenged with approximately 18 LD_{50} of *Y. pestis* by the airborne route, none of the mice that had been immunized with two doses of the KWC vaccine survived.[90] Although these data alone do not necessarily indicate a deficiency of the vaccine to protect against pneumonic plague in humans, when viewed alongside the reports previously cited, the overall evidence is that a KWC vaccine is more effective against bubonic plague than pneumonic plague. All these studies, however, have been carried out using $F1^+$ strains of *Y. pestis*. The efficacy of this vaccine to protect against $F1^-$ strains of *Y. pestis*, which are rarely encountered in natural infections, has not been fully tested.

Immunization of mice with the EV76 live attenuated vaccine strain induced protection against both subcutaneous and inhalation challenges with virulent strains of *Y. pestis*,[73] and appeared superior to the performance of the KWC vaccine (Table 45.2). The enhanced protection offered by the live vaccine over a KWC vaccine, might be the result of three factors. First, the KWC vaccine does not contain detectable levels of V antigen[114] and no ex vivo lymphoproliferative memory response or serum IgG to the V antigen could be detected in KWC vaccinees.[125] Second, the chemical or heat inactivation of the bacterium required in KWC vaccines might have caused structural changes in other surface components such as the F1 antigen.[74] Third, local responses to vaccination with EV76 in mice suggest that a limited local infection is initiated and that the duration of exposure to the antigenic complement is therefore prolonged. The immune response induced by the live attenuated vaccine may be more similar to a natural infection than that induced by KWC preparations.

A significant amount of work has now been carried out in the mouse,[126] guinea pig,[71] and macaque[127–132] models from which immune correlates have been proposed. Although a titer of neutralizing antibody provides protection against exposure, it is clear that the development of CMI is also critical to full protection and eventual clearance of the bacterial challenge from the host.

TABLE 45.2 Protection Afforded by Killed Whole Cell Vaccine, EV76 Vaccine, or F1- and V Antigen Subunit Experimental Vaccine Against Parenteral or Inhalation Challenge With *Yersinia pestis* Strain GB

Vaccine	Protection (% Survival) Against Challenge (LD_{50})	
	Subcutaneous Route	Inhalational Route
Control	0 (10^1)[a]	0 (10^2–10^3)[b]
Killed whole cell vaccine	60 (2×10^6)[a]	80 (19)[d]
EV76	100 (2×10^9)[a]	100 (150)[c]
F1 + V	100 (2×10^9)[a]	100 (10^2–10^4)[b,d]

[a]Tested in Balb/c strain mice.[104]
[b]Tested in Balb/c, CBA, C57Bl6, and CB6F1 strain mice.[121]
[c]Tested in Porton strain outbred mice by intranasal route of challenge.[69]
[d]Tested in Porton strain outbred mice.[115]
EV76, attenuated live vaccine strain of *Yersinia pestis*; F1 + V, subunit vaccine containing the F1 and V antigens of *Y. pestis*.

Intraperitoneal or intramuscular immunization with native F1 or rF1 antigens adjuvanted with alum induced an immune response that protected mice against a subcutaneous challenge with as many as 10^5 CFU of virulent *Y. pestis*.[74,114] Although the F1 antigen also induced protection against inhalation challenge with 100 LD_{50} of an $F1^+$ strain of *Y. pestis*,[74] there was concern that a vaccine based solely on the F1 antigen would not provide protection against naturally occurring but virulent $F1^-$ strains of *Y. pestis* (although only one such naturally occurring strain has been reported). Immunization of mice intraperitoneally with the V antigen adjuvanted with alum induced protection against a subcutaneous challenge with 4×10^6 CFU of *Y. pestis*.[108] A significant advantage over the F1 antigen is the ability of the V antigen to induce protection against virulent $F1^-$ strains of *Y. pestis*; protection provided by the V antigen vaccine against 1000 or more LD_{50} of either virulent $F1^+$ or $F1^-$ strains of *Y. pestis* given by the inhalation route has been reported.[133]

To protect against $F1^-$ virulent strains of plague, recombinant truncated V protein (rV10, lacking residues 271 to 300), has been tested and demonstrated to provide protection against pneumonic plague in mice, rats, guinea pigs and nonhuman primates.[134] In the mouse model, immunization with a combination of 80 μg F1+ 80 μg V subunits rapidly induced

protective immunity so that protection against 100 LD_{50} of *Y. pestis* KIM could be achieved up to 1 day after immunization, while postexposure immunization gave partial protection.[135]

The protection afforded individually by the F1 or the V antigens was overcome by very high subcutaneous challenges (10^9 CFU of *Y. pestis*) in the immunized mouse.[114] However, protection against this challenge was achieved after intraperitoneal immunization in multiple doses with a mixture of both the F1 and V antigens.[114] The combined vaccine also protected mice against 100 LD_{50} of *Y. pestis* given by the inhalation route (see Table 45.2), suggesting that the vaccine might provide protection against pneumonic plague in humans.[90] The advantages of such a combined subunit vaccine lie not only with the enhanced level of protection afforded against disease but also with the ability of the vaccine to confer protection against both $F1^+$ and $F1^-$ strains of *Y. pestis*.

A systematic study using mice of four different haplotypes and both genders showed that all animals responded to immunization to the rF1 and rV antigens with high antibody titers.[136] The response to either antigen was affected by the conformation of the protein[110,137] and the ratio of rF1 to rV, with an optimal response when rF1 was in a twofold molar excess to rV.[138] Mice could also mount an antibody response to both of the antigens when the C-terminal of the F1 antigen was genetically fused to the N-terminus of the V antigen.[112]

The rF1+rV vaccine has also been used successfully to immunize guinea pigs and nonhuman primates. Antibody titer to rF1+rV in guinea pigs also correlated with protection and passive transfer of specific antibody (IgG) from the guinea pig into naïve mice, protected the latter against challenge.[71] Cynomolgus macaques immunized with the combination of rF1 and rV antigens produced high titers of specific antibody which competed with the V-specific and protective mAb7.3 for binding to V antigen and also passively protected naïve mice against challenge[127] and was used as a positive control in assays assessing the impact of passive transfer of human serum.[117]A newer study shows that the immunization of cynomolgus macaques with rF1+rV or rF1–V in alhydrogel fully protected them against pneumonic plague following inhalation exposure to *Yersinia pestis*.[128,130,131]

MECHANISM OF PROTECTIVE IMMUNITY

The mechanism by which the rF1+rV vaccine induces protective immunity has been the subject of considerable investigation during the past few years. The F1 capsule is thought to inhibit phagocytosis of the bacterium by preventing complement-mediated opsonization.[52,139] In addition, it is also possible that antibody induced to the F1 antigen promotes antibody-dependent cellular cytotoxicity. Some vaccinated animals do appear to harbor the pathogen even in a mutated $F1^-$ form.[74] The KWC vaccines were less effective than purified F1 antigen in inducing high titers of antibody to F1.[74,114] Antibody against the V antigen may also be of overriding importance in protection against plague, as immunization with V antigen restores the ability of the host to produce tumor necrosis factor-α and γ-interferon in response to infection.[58] Therefore, immunization with the V antigen would enable the host to mount a vigorous inflammatory response and enable host phagocytes to clear bacteria opsonized by antibody to the F1 antigen. Additionally because V antigen forms part of the injectisome of the type III system[56] and is exposed on the bacterial surface,[140] it remains extracellular for sufficient time to be targeted by antibody induced by vaccination or passively transferred.[100–102] Antibody to V antigen can inhibit the translocation of Yops by *Y. pestis* into the host cell,[141] and this inhibitory effect is dependent on the binding of antibody to the bacterial cell surface and attributed to the promotion of phagocytosis of *Y. pestis* by polymorphonuclear leukocytes.[141] Although protection against plague in the mouse model correlates with the specific IgG titer to the subunits (specifically of the IgG_1 subclass in the mouse, in response to this alhydrogel-adjuvanted vaccine),[138] there is no doubt that the mechanism of protection following immunization with the rF1+rV proteins also involves T-cell memory, which has been demonstrated in the mouse model.[125,138,142] In the mouse, the T-cell response to alhydrogel-adsorbed F1+V is biased toward T-helper type 2 (Th2) cells and is highly protective. In contrast, delivery of the F1+V proteins formulated in the Ribi adjuvant system to IL4T mice (genetic knockouts for the interleukin [IL]-4 receptor) induced predominantly a Th1 response. The passive transfer of this antibody into B-cell–deficient knockout mice, with no intrinsic ability to produce antibody, protected the mice fully against live organism challenge.[143] Furthermore, a targeted gene deletion in the Stat4 signaling pathway (preventing the ligation of the Stat4 receptor with IL12 signaling) and abrogating a Th1 response, resulted in reduced protection, whereas mice with a targeted gene deletion in the Stat6 pathway and no Th2 activity, were fully protected against challenge.[144] Thus, it appears that antibody is highly protective against this predominantly extracellular pathogen, but CMI,[145] and particularly a balanced Th1/Th2 response,[144] provides an optimal strategy for protection. Recent data supports this assumption as mice immunized with the rF1-V vaccine and depleted of tumor necrosis factor-α and γ-interferon just prior to challenge had very poor survival compared with immunized-only controls,[120] indicating key roles for these Th1 cytokines in the development of protective immunity.[146,147]

Correlates of Protection and Surrogate Markers of Efficacy

In summary, correlates of protection to the rF1/V vaccine reside in both antibody-mediated and cellular mechanisms, which do not act independently. Knowledge of mechanisms derived from nonclinical models of vaccination and infection can lead to the identification of potential surrogate markers of efficacy.[148] Assays of surrogate markers of efficacy might include the in vitro inhibition of the cytotoxicity of a *Y. pseudotuberculosis* construct expressing *Y. pestis* V antigen,[149] the passive transfer of human immune serum into a naïve animal model,[117] and an assessment of CMI using ex vivo peripheral blood mononuclear cells and a secondary recall response in an enzyme-linked immunosorbent spot or similar format. Much work is ongoing to identify statistically valid immune correlates of protection for plague and to use these to establish surrogate markers of efficacy. With an increasing understanding of the molecular basis of pathogenicity and of the innate and adaptive immune response mechanisms required to counter *Y. pestis*, progress will continue to be made in this area and expedite the development of next generation vaccines.

Indications for Vaccine Use

Vaccination is recommended for use in individuals who are working with fully virulent strains of *Y. pestis* (e.g., researchers and laboratory workers) and for persons in regular contact with the wild animal hosts of plague or their fleas in endemic areas. It may also be considered for use in personnel who are deployed to work in endemic areas (e.g., emergency workers, military personnel, field workers, and agricultural consultants), especially if they might be exposed to epizootic plague arising from some acute geological disturbance.[5] However, vaccination against plague is not a statutory requirement for travel to any country. The vaccination of populations in

plague-endemic areas of the world is not routinely indicated, because the incidence of disease is relatively low and most cases of disease are of the bubonic form, which, once diagnosed, can be treated with antibiotics. The previously available KWC vaccines had limited utility in controlling sporadic plague epidemics, because they required several months to induce protective immunity. However, the response to the new rF1/V vaccine is more rapid, so that once licensed, it would be feasible to use it in outbreaks or in the indigenous populations in areas with intense plague activity that cannot be controlled by other measures. Additionally, a licensed subunit vaccine for plague would be of benefit as a deterrent to the use of *Y. pestis* as a potential bioweapon. Although antibiotics can provide protection against disease, it is not clear if sufficient quantities could be stockpiled to allow the treatment of large populations for long periods of time. In addition, there is concern over the appropriateness of long courses of broad-spectrum antibiotics being used in large numbers of individuals. It seems likely that antibiotics will have a clear utility for the protection of relatively small numbers of individuals while vaccination would be more appropriate for entire populations. At the present time it seems unlikely that routine mass vaccination of entire populations, in the absence of any clear indication of an impending attack, would be undertaken. However, if vaccines were to provide protection of the civilian population, they would need to be available on short notice and to induce a rapid protective response.

Postexposure Prophylaxis

The previously available KWC vaccines were not suitable for postexposure use because several months were required to complete the primary vaccination schedule and induce optimal immunity. Even rF1/V vaccine, which induces relatively rapid immunity, is unlikely to provide postexposure protection in an infected and previously unvaccinated individual. The use of antibiotics should be considered in the case of possible exposure to *Y. pestis,* even in vaccinees who had previously completed the full KWC vaccination schedule, as this vaccine type offered poor protection against pneumonic plague. However, real prospects exist for the future development of passive immunotherapy for postexposure prophylaxis.

Precautions and Contraindications

The KWC vaccine formulations were contraindicated in individuals who had a history of hypersensitivity to any of the vaccine components (e.g., beef protein, soya, casein, sulfite, phenol, or formaldehyde). The safety and efficacy of the KWC vaccine formulations in people younger than 18 years or in pregnant women was not known, as is the case for the rF1/V vaccine.

Persistence of Immunity

Few studies have examined the duration of immunity to *Y. pestis* after immunization with KWC vaccines. However, it is generally considered that immunity is short lived and that booster immunizations were needed at 6-month intervals to ensure that a protective response was maintained. A single dose of the live attenuated vaccine derivatives of strain EV76 could protect against bubonic and pneumonic plague for up to a year.[150] Nonclinical data indicate that immunization with the combined rF1+rV vaccine induces durable immunity up to 9 months after a single immunization in the mouse model.[125] Cynomolgus macaques immunized with rF1+rV were observed to have functional IgG titers able to compete with mAb7.3 for binding to the V antigen more than 1 year after immunization.[127] The establishment of an immunization regimen and the need for a booster immunization requires similar monitoring of volunteers during clinical trials of the rF1-V vaccine for the persistence of immunity.

Safety

The KWC vaccines were known to be reactogenic in humans.[151,152] The manufacturer of the Cutter vaccine reported that reactions such as malaise, headaches, local erythema, and induration, or mild lymphadenopathy occurred in approximately 10% of vaccinees; this frequency of side effects was also reported by other workers.[105] Data provided by the manufacturer of the Greer vaccine suggested that more than 10% of vaccinees suffered side effects. Allergic reactions induced by immunization with KWC vaccines, evidenced mainly as urticaria, occurred infrequently.[151] One study found that the frequency of side effects was much greater in individuals who had previously been immunized with the live EV vaccine.[105]

In a review of the use of live, attenuated vaccines such as EV76, Meyer and associates,[153] reported that in one study in the former Soviet Union, a febrile response was reported in 20% of human vaccinees, accompanied by headache, weakness, and malaise. Erythema surrounding the site of vaccination was frequently reported, reaching dimensions of 15 × 15 cm. Some severe systemic reactions required hospitalization. Numerous unsuccessful attempts were made to reduce the incidence of side effects in clinical studies, by administering the vaccine by different routes, including scarification, inhalation, and intraocularly.[153] Of equal concern is the finding that the EV76 strain is capable of causing disease in some animal species. Russell and colleagues reported that immunization of mice with *Y. pestis* EV76 induced severe side effects and occasional death (approximately 1%).[73] The vaccine was reported to also cause fatal infections in vervets.[153]

By comparison, the rF1+rV vaccine was shown to be safe and well-tolerated in the first reported clinical Phase I trial in 32 healthy volunteers.[117] Four dose levels were assessed, and no serious or severe adverse events attributable to the vaccine were reported. Further clinical trials of the rF1/V formulation vaccine are ongoing in larger numbers of subjects to investigate the safety and immunogenicity of the formulation, as well as to predict its efficacy through surrogate markers of protection.[119]

FUTURE DEVELOPMENTS

With the discontinuation of production of a KWC vaccine formulation, the most likely vaccine replacement in the medium term is a formulation of a combination of the recombinant F1 and V antigens, which is expected to induce more rapid and comprehensive immunity. Indeed, this subunit vaccine may be the first nonlive vaccine to protect against the most dangerous form of the disease, pneumonic plague. Currently being developed as an injectable alhydrogel-adsorbed formulation, there is potential for alternative formulation of the recombinant fusion protein for self-administration and/or for mucosal delivery. A considerable body of work has now been conducted on the polymeric microencapsulation of the F1 and V antigens and the mucosal delivery of these formulations to achieve protective immunity.[142,154]

As well as permitting more flexibility in route of administration, polymeric encapsulation is advantageous in that it enhances vaccine stability and removes the need for cold chain storage. Many refinements have been made to optimize these formulations; the antigens have been either mixed for

coencapsulation or they have been separately encapsulated and mixed after encapsulation. In each case, both subunits have retained immunogenicity[155] and protective efficacy.[137,156] Further refinements have included the substitution of polymers conferring particular properties of stability and hydrophobicity and controlling particle size and loading.[126] A microsphere formulation suitable for nasal or parenteral administration has been derived that is fully protective against an inhalational challenge with *Y. pestis* after two separate[157] or even a single immunizing dose[158] in the mouse model. Liposomal encapsulation of the plague subunit vaccine offers an alternative approach to mucosal delivery.[154] Alternatively, a spray-dried powder formulation of rF1/V has been shown highly immunogenic in mice by intradermal or intramuscular delivery.[159] The delivery of vaccines by advanced transdermal patch is a possibility[160] and would provide an alternative noninvasive approach to vaccination with the rF1 and rV subunits.[161]

The most promising approach to an oral vaccine for plague is the use of *S. enterica* serovar *Typhimurium* expressing the *caf* operon, which induced a high level of protection against subcutaneous challenge with *Y. pestis*.[162,163]

Additional Subunits

There have been many unsuccessful attempts to identify additional protective subunit proteins. *Yersinia* secretory protein F (YscF) along with V antigen form the injectisome of the type III system and immunization with YscF provides some protection against plague in the mouse.[164] Additionally, the vaccination of mice with a Yop translocon complex comprising Yops B, D, and E protects against infection with F1$^-$ *Yersinia pestis*.[165] Thus it may be beneficial to add YscF to a future subunit vaccine formulation to maximize the protective efficacy achievable.

Additionally, a newer study shows that immunization with *Y. pseudotuberculosis,* which lacks the Lcr plasmid, can provide protection against plague, suggesting that protective antigens other than F1 antigen and components of the type III system exist.[166]

Live Attenuated Vaccines

The finding that the live EV76 vaccine induces protection against plague, although its use is accompanied by unacceptable local and systemic side effects,[153] has prompted additional work to develop stably attenuated strains of *Y. pestis* for vaccines. Work toward this goal has been based on the finding that other gram-negative pathogens can be attenuated by the introduction of mutations into genes essential for bacterial growth, virulence, or survival in the host, and that the nature of the attenuating mutation can influence the immunogenicity and reactogenicity of these vaccines. Strains of *Y. pestis* with mutations in the *aroA*,[167] *phoP*,[168,169] or *htrA*[170] genes have been constructed and tested but show only a modest reduction in virulence in mice and would not be suitable for development of a live attenuated vaccine in humans. However mutation of the *dam* gene resulted in a 2000-fold attenuation of *Y. pestis* and mice exposed to sublethal doses of the mutant were protected against a subsequent challenge with fully virulent *Y. pestis*.[171] Even more impressively, a *pcm* mutant of *Y. pestis*, which is believed to be defective in its response to environmental stresses, was more than 10^7-fold attenuated in mice.[172] The immune response induced after immunization with the *pcm* mutant was superior to that induced by the EV76 strain, suggesting that this might be an efficacious and safe alternative to the EV76 vaccine. The elucidation of the *Y. pestis* genome sequence has identified a wide range of other genes that might be inactivated to yield a live attenuated vaccine.[32] For example, organisms with genes encoding mutations in lipoprotein *(lpp)* and an acyltransferase involved in modification of LPS *(lpxM)* are attenuated and might be useful vaccine candidates.[150,173] For a live attenuated vaccine to be safe, multiple mutations in independent pathways are required to reduce any risk of reversion to virulence. The effect of combining attenuating mutations is hard to predict, as the multiple mutations may overly attenuate and induce poor immune responses.

An alternative strategy would be to use a closely related species with lower virulence and exploit cross-immunity. For example, an attenuated *dam* mutant of *Y. pseudotuberculosis* induced a robust protective immune response against challenge with *Y. pestis*.[174] A naturally arising attenuated strain lacking the high pathogenicity island, the *Y. pseudotuberculosis* superantigens, and type IV pili was similarly able to induce a protective response against plague.[175] In addition to reduced risk as a result of using a less-virulent strain, another advantage of this approach is that the immunity was induced following oral dosing, indicating that a needle-free vaccine is achievable.

46 Pneumococcal Conjugate Vaccine and Pneumococcal Common Protein Vaccines

Keith P. Klugman, Ron Dagan, Richard Malley, and Cynthia G. Whitney

The original demonstration by Avery and Goebel, in 1929, that capsular polysaccharides were immunogenic when linked to a protein[1] and, 60 years later, the demonstrated efficacy of *Haemophilus influenzae* type b (Hib) conjugate vaccines in the 1990s (see Chapter 23) led to an extraordinary public health intervention in the year 2000 when conjugated pneumococcal polysaccharide vaccines were introduced for the prevention of pneumococcal disease in infants. Acute respiratory infections are the major global cause of death in young children and led, in 2013, to an estimate of 935,000 (with a range of uncertainty of 817,000 to 1,057,000) deaths annually, in children younger than 5 years of age.[2] A second study of lower respiratory tract mortality in children younger than 5 years of age projected a similar mortality estimate in 2013 (905,100 deaths, with a 95% uncertainty interval of 797,900 to 1,015,900 deaths).[3] Although pneumonia remains the leading infectious cause of death in infants, pneumonia deaths are declining with nearly half of the reduction in child mortality from 2000 to 2013 attributable to reductions in pneumonia, diarrhea, and measles.[2] An updated estimate of lower respiratory tract mortality in children younger than 5 years in 2015 suggests that deaths are now 703,900 (95% uncertaintly range, 651,000–763,000).[3a] While increased access to antibiotics likely played a major role, the introduction of both Hib and pneumococcal conjugate vaccines (PCVs) has also had a substantial impact. Advances in methodology, using efficacy data from the trials of pneumococcal conjugate vaccination conducted in both developed and developing countries, allow an estimate of residual mortality attributable to the pneumococcus in children younger than 5 years of age in 2013 of 264,000 (uncertainty range, 155,700–365,800). The attribution of pneumococcal deaths, however, was likely underestimated as the effectiveness of PCV against pneumococcal pneumonia may be less than its effectiveness against invasive disease, which was used in the calculation.[3] A revised 2015 estimate of the pneumococcal pneumonia mortality in children younger than 5 years taking this observation into account provides an estimate of 393,000 pneumococcal deaths, with an uncertainty range of 228,400 to 532,300 deaths.[3a]

This chapter reviews pneumococcal polysaccharide-protein conjugates, isolated pneumococcal proteins, and whole-cell pneumococcal vaccines as avenues for wider coverage and increased efficacy compared with pneumococcal polysaccharide vaccine (PPV). Conjugate vaccines are the most advanced of these approaches with large-scale, randomized clinical trials in multiple countries confirming their efficacy against invasive disease[4–11] and otitis media.[11–13] Conjugate vaccines are also widely available in most developed countries, with a rollout to more than 50 of the 73 Global Alliance for Vaccines and Immunization (GAVI)–eligible developing countries by the end of 2015. The overall effectiveness of conjugate pneumococcal vaccines has resulted in large part from the impact on vaccine serotype-specific carriage and thus reduced transmission of vaccine types in the community. In the United States, immunization of young children has led to the virtual elimination of vaccine-type disease in both children and adults,[14,15] and more than a 90% reduction in hospitalization for nonbacteremic pneumonia is attributable to herd protection immunity of adults resulting from the vaccination of children.[16] At the same time as protection is largely limited to the specific vaccine serotypes, vaccine effectiveness has been reduced by replacement carriage resulting from nonvaccine serotypes and replacement disease resulting from the disease potential of those serotypes. The impact of PCVs on herd protection in developing countries is also being seen.[17] The first randomized trial of PCV in the elderly has demonstrated efficacy against both bacteremic and nonbacteremic pneumonia caused by vaccine types.[18] The development of pneumococcal proteins as vaccines is still at an early stage, and other approaches, such as vaccines targeting the development of T-cell immunity, including a killed whole-cell vaccine, are either in preclinical or early clinical development. A vaccine that combines conjugated pneumococcal polysaccharides with additional nonconjugated pneumococcal proteins finished a Phase II trial in 2015. The vaccine was safe and immunogenic, but there was no impact of the proteins on pneumococcal carriage.[18a]

PATHOGENESIS

With the possible exception of the great apes,[19] humans are the only natural host of the pneumococcus. However, other mammals, such as pets (e.g., horses, dogs, cats, and guinea pigs), zoo animals (e.g., dolphins), and laboratory animals (e.g., mice and rats)[20] can acquire the organism from their handlers. The organism lives in the nasopharynx of humans, from whence it can be transmitted by respiratory droplets to other individuals. In most cases, pneumococci are carried asymptomatically before being cleared from the nasopharynx. The duration of carriage is age- and serotype-dependent.[21–23] In some cases, usually shortly after the acquisition of carriage, pneumococci can cause mucosal disease by local spread to the middle ear (causing otitis media), the sinuses (causing sinusitis), or the lungs (causing pneumonia). In addition, pneumococci may cause systemic infections with considerable risk of mortality, including bacteremia and meningitis and less commonly infections in joints, bones, and soft tissues.

The pneumococcal capsular polysaccharide is the most important virulence factor for *Streptococcus pneumoniae*,[24,25] although not the only one.[26] The polysaccharide capsule significantly increases the resistance of pneumococci to phagocytosis by several mechanisms, including shielding from antibodies and complement. The capsule promotes adherence to epithelial cells in animal models. Strains of pneumococci that lack a detectable capsule can cause conjunctivitis,[27] but are infrequently isolated in cases of invasive disease. Pneumococcal virulence depends in part on several serotype-specific characteristics, such as the chemical composition and molecular size of the capsular polysaccharide.[23,28] The different pneumococcal serotypes vary in virulence, depending on their ability to activate the alternative and classical complement pathway, to deposit and degrade the complement components on the capsule, and to resist phagocytosis[29,30]; they also differ

in their ability to induce antibodies. Antibodies to the capsular polysaccharides are protective, as has been amply demonstrated in animal models and in clinical trials of conjugate vaccines.[31,32]

BACKGROUND

The reader is referred to Chapter 47 for a discussion of the clinical and bacteriologic aspects of pneumococcal disease.

EPIDEMIOLOGY

Pneumococcal Infections in Children Prior to Conjugate Vaccines

Before the introduction of seven-valent PCV7 in the United States, *S. pneumoniae* caused approximately 17,000 cases of invasive disease per year in children younger than 5 years of age, resulting in 700 cases of meningitis and 200 deaths.[33] The annual incidence of invasive pneumococcal diseases was highest in children 6 to 11 months of age, at 235 per 100,000,[33] declined to 35.2 per 100,000 in children between 2 and 4 years of age, and reached its lowest levels in children 5 to 17 years of age (3.9 per 100,000).[34] A similar distribution of incidence by age was seen in Canada, although the rates for the youngest children were somewhat lower, peaking at 161.2 per 100,000 for children 6 to 17 months of age.[35]

In Europe, the highest levels of infection were in children in the second 6 months of life, then in those 2 years of age or younger, and declining steadily thereafter into the teenage years.[36,37] However, the measured incidence of pneumococcal infections has generally been much lower in Europe than in the United States.[38] For example, in England and Wales, the annual incidence of invasive pneumococcal diseases in infants between 6 and 11 months of age was 35.8 per 100,000 in the late 1990s,[39] compared with 235 per 100,000 in the United States. In Finland, the annual incidence of invasive pneumococcal diseases was 45.3 per 100,000 among those younger than 2 years of age.[37] This difference in incidence was thought to be largely a consequence of the common practice of obtaining blood cultures in outpatients in the United States, whereas in Europe they generally only get blood cultures during hospitalization.[40]

Bacteremia without focus is more common in young children than in older persons,[33,36,37,41] and this diagnosis comprises 60% to 70% of invasive pneumococcal disease diagnosed in young children in the United States.[33,42,43] Pneumonia and meningitis are the next most common, but meningitis remains the diagnosis with the highest case fatality rate.[36,41,44] After the introduction of the Hib vaccine causing a marked decline in Hib disease, *S. pneumoniae* became the leading cause of bacterial meningitis and occult bacteremia in the United States.[45,46] As children grow older, the proportions of pneumococcal infections classified as meningitis and bacteremia without focus decline, and the proportion of pneumonia increases.[42,44,47,48]

In the United States before the introduction of PCV, there were approximately 15 million office visits annually for the diagnosis of acute otitis media (AOM),[49] with costs estimated at US$5 billion per year.[50] *S. pneumoniae* was the most commonly reported bacterial cause of AOM, with the proportion of the pneumococcus as an etiologic agent recovered from middle ear fluid by tympanocentesis varying from 18% to 55% in published studies.[51–54]

The burden of pneumococcal disease has been greatest for those populations in which the plain PPV has been the least immunogenic: children younger than 2 years of age; the elderly (≥65 years); immunocompromised individuals, including those infected with HIV, and those with malignancies; there is also a significant burden in individuals with functional or anatomic asplenia and those with chronic cardiovascular, pulmonary, or liver diseases.[33,55–57] Among individuals without underlying illness, children younger than age 2 years are most vulnerable to pneumococcal infections. There is evidence that this level of risk is increased further by spending time in crowded or communal settings, such as daycare centers.[43,58]

Children from specific minority groups suffer disproportionately. Although the overall incidence of invasive pneumococcal disease in children younger than 2 years of age in the United States before licensure of PCV7 was 167 cases per 100,000 person-years, black children of the same age had an incidence of 400 per 100,000 person-years, Alaskan Native children had an incidence of 624 per 100,000 person-years, and Native American children had an overwhelming incidence of 2396 cases per 100,000 person-years (Table 46.1),[33] although rates in Navajo children have declined.[47] Asians, blacks, and Hispanics also had a greater risk of pneumococcal pneumonia than whites.[59] Similar to the United States, indigenous people in Australia had much higher rates of pneumococcal disease with indigenous children younger than 2 years of age having an incidence of invasive pneumococcal diseases of 2053 cases per 100,000 person-years.[60] Nonindigenous children in Australia had rates intermediate between those of Europe and the United States.[61] Minority populations in Israel, including the Bedouins, also had a higher incidence of pneumococcal infections, although the difference was not as pronounced as in Australia and the United States.[62] This difference may be socioeconomically based because minority groups in Israel are not a single ethnic population but, as a group, have higher birthrates, more crowded living conditions, less education, and lower socioeconomic status than the majority Jewish population.[62,63]

Boys are more likely than girls to contract pneumococcal infections,[47,63–66] and there are often seasonal peaks in incidence with infection more likely in the winter.[48,62] Recently documented influenza or another respiratory viral infection has been reported to be a risk factor for severe pneumococcal pneumonia[67] and invasive disease.[68] Recent ear infections, indicating the middle ear is an important route of *S. pneumoniae* invasion, and a lack of breastfeeding are also associated with increased incidence of invasive pneumococcal diseases.[43]

TABLE 46.1 Incidence of Invasive Pneumococcal Disease in Children in the United States Before the Introduction of Pneumococcal Conjugate Vaccine by Age and Ethnic Group

	Incidence per 100,000 Person-Years			
Age (yr)	All Races	Blacks	Alaskan Natives	Native American (Navajo or Apache)
<2	167	400	624	2396
2–4	36	116[a]	98[b]	227[b]
5–9	6	9	23	54
10–19	3	5	5	35

[a]Age 2–3 years.
[b]Age 2–5 years.
Modified from Advisory Committee on Immunization Practices. Preventing pneumococcal disease among infants and young children. Recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Morb Mortal Recomm Rep. *2000;49(RR-9):1–35.*

Children with cochlear implants have a risk of pneumococcal meningitis approximately 40 times higher than the rate in the general population of children.[69] The risk was highest among children using a specific spacer, which was subsequently discontinued, and in those with middle ear malformations associated with cerebrospinal fluid leaks. A study in Denmark suggested that deaf children without cochlear implants have a fivefold increased risk of meningitis relative to hearing children.[70]

Most deaths among children from pneumococcal disease occur in developing countries.[71] In developing countries, carriage of pneumococci frequently occurs before 2 months of age[72] (in contrast, children in the United States acquire their first strain on average at 6 months of age), a larger proportion of invasive diseases occur by 6 months of age than in industrialized countries,[73–75] and neonatal infections are not uncommon.[74]

A compromised immune system, whether caused by HIV infection, malignancy, asplenia, or primary immunodeficiencies, is a major risk factor for pneumococcal disease. Infection with *S. pneumoniae* occurs more than 100 times more frequently in HIV-infected children than among the general population.[76–78] Meningitis or recurrent bacterial sepsis can be the first indicator of AIDS in pediatric patients,[79,80] and otitis media is reported to be three times more frequent in HIV-infected children than in uninfected children.[81] In the United States, rates of invasive pneumococcal diseases for HIV-infected children younger than 3 years of age are 12.6 times higher than in HIV-negative children,[71] and in children younger than 5 years of age are 2.8 times higher than in HIV-negative children. In both children and adults, the introduction of highly active antiretroviral therapy (HAART) reduced the incidence of pneumococcal infections in HIV-infected patients, but rates remain elevated compared with HIV-uninfected persons.[57,82–86]

In South Africa, the incidence of pneumococcal bacteremia was 36.9-fold higher in HIV-infected children than in HIV-negative children before introduction of antiretrovirals and PCV.[85] The rates of pneumococcal bacteremia doubled between 1987 and 1997 as the rates of HIV infection rose.[86] Overall, the disease spectrum is similar in HIV-positive and HIV-negative populations, except that pneumonia is more common in HIV-infected children.

Individuals with sickle cell disease and other hemoglobinopathies resulting in functional asplenia are also at increased risk for serious infections with *S. pneumoniae*.[87–89] Without immunization, the rate of invasive pneumococcal disease in children with sickle cell disease is 30 to 100 times greater than that of healthy children of similar age. Even with the use of PCV and PPV, invasive pneumococcal disease among children with sickle cell disease who are younger than 5 years of age is 10-fold more frequent than in children without sickle cell disease,[90,91] and the case-fatality rate is much higher in children with sickle cell disease[92] or other forms[92] of anatomic or functional asplenia than in children with normal splenic function.

Children with nephrotic syndrome also are more susceptible to pneumococcal disease, with the majority of infections occurring within the first 2 years after presentation. *S. pneumoniae* is responsible for 50% to 60% of sepsis and peritonitis in children with nephrotic syndrome.[93] Patients who have received a bone marrow transplant are also more vulnerable to pneumococcal disease than the general public,[94] in part because they often have impaired opsonization function and lose protection from previous immunizations because of T-cell and B-cell depletion[95]; in addition, solid-organ transplant also confers a higher risk of invasive pneumococcal disease.[96] Of interest, the increased risk of pneumococcal infection in patients with Hodgkin disease can persist long after the underlying condition has been successfully treated.[97]

Serotype Distribution

Forty serogroups comprising 97 serotypes[98] have been described for *S. pneumoniae*. Among this large number of serotypes, a relatively small number account for most of the invasive disease in young children around the globe (Fig. 46.1).[99] Candidates for conjugate vaccines have been designed based on the relative percentages of disease-causing serotypes. To date, conjugate vaccines containing the saccharides of 7, 10, and 13 serotypes have been licensed; the first to be licensed in 2000 was a seven-valent vaccine (PCV7), sold under the trade name Prev(e)nar by Pfizer. The 10-valent vaccine (PCV10, Synflorix, sold by GlaxoSmithKline) is licensed in many other countries, but not in the United States. The 13-valent (PCV13, Prevenar 13, Pfizer) was licensed in the United States in 2010 and replaced PCV7. Table 46.5 (see later) lists the serotypes included in each of these vaccines.

Although comprehensive information about serotypes is not available for some regions, a recent systematic review summarized the information available from children younger than age 5 years before introduction of pneumococcal conjugate vaccines.[99] The review included 169 studies in the final analysis, representing 70 countries and 60,090 serotyped isolates. According to this analysis, serotypes 14, 6B, 1, 23F, 5, and 19F, in that order, were the most common serotypes found among sterile-site isolates from around the world. However, the distribution of disease-causing serotypes varied somewhat with location, age, and clinical presentation. Before the introduction of PCV7, serogroups in the seven-valent vaccine were responsible for more than 80% of invasive pneumococcal diseases in young children in the United States and Canada, and for 50% or more in all other regions; 10-valent and 13-valent vaccine formulations covered more than 70% of the invasive strains in all regions. Serotype 6A accounts for a substantial portion of disease, but within-serogroup cross-reactivity with serotype 6B in PCV7 and PCV10 provides protection.[100–103]

Serotypes 1 and 5 are encountered much more frequently in the developing world than in the developed world, although in the last decade serotype 1 disease has increased in Western Europe and has also been found among children living in

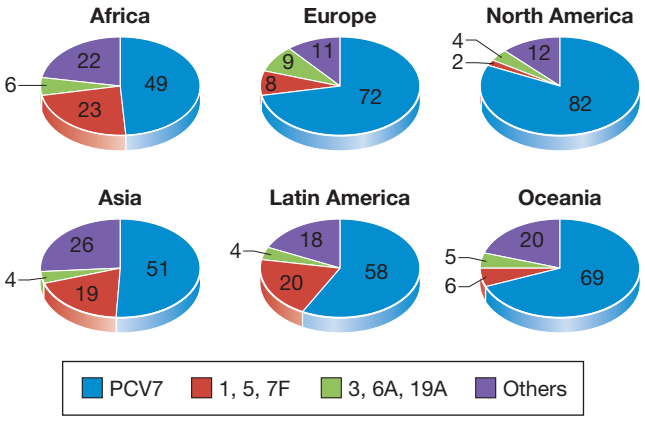

Figure 46.1. Systematic evaluation of serotypes causing invasive pneumococcal disease among children <5 years: the pneumococcal global serotype project. *(From Johnson HL, Deloria-Knoll M, Levine OS, et al. Systematic evaluation of serotypes causing invasive pneumococcal disease among children under five: the pneumococcal global serotype project.* PLoS Med. *2010;7:e1000348.)*

Utah.[104,105] Differences in blood culture practice may also affect the observed distribution of serotypes: virulent serotypes that are more likely to cause severe disease requiring hospitalization would have a higher apparent prevalence in regions that perform blood cultures only on hospitalized patients. This may be the case for serogroups 1, 5, and 7, which were isolated at similar (low) rates in the United States and Europe, although the most common serotypes/groups (14, 6, 19, 18, 23, 9, and 4) had a much higher incidence in the United States before PCV use.[40] For example, serotype 1 caused 5% of reported invasive pneumococcal diseases in Western Europe and only 0.5% of invasive pneumococcal diseases in the United States before conjugate vaccine introduction, yet the rate of serotype 1 disease was approximately 0.9 per 100,000 person-years in each region.[40] This pattern indicates that serogroups 1, 5, and 7 cause severe rather than mild disease in both regions and supports the idea that certain serogroups are intrinsically highly virulent.[40] This could also account, in part, for the high prevalence of serotypes 1 and 5 in the developing world, where, as in Europe, blood cultures are rarely performed on an outpatient basis.

Serotype distributions change with age. A narrower range of serotypes are responsible for disease in young children[106,107] than in older children and adults, and in most regions, 50% of invasive pneumococcal disease is caused by three serotypes in young children and by four or five serotypes in older children and adults.[106] Serotypes 1, 5, and 18C are responsible for a larger portion of invasive pneumococcal disease in children.[47,63,108–110]

In addition to varying with age, certain serotypes are more likely to be associated with particular clinical presentations, although none of the most prominent serotypes is found exclusively in one clinical site, and all have the potential to invade multiple sites.[106] Note that age and site of isolation may not be independent because, for example, young children are much more likely to present with meningitis than older children, and serotypes isolated from young children are therefore more likely to be found in the cerebrospinal fluid (CSF) than serotypes isolated from older children. Generally speaking, serogroups 6, 10, and 23 are more likely to be isolated from CSF, whereas serogroups 1, 4, and 14 are more often isolated from blood than from CSF.[106,111] Severe pneumonia is more likely to be associated with serotypes 1 and 3,[112] although both pneumonia and these serotypes are more common in older children than the very young. Serotypes 19F, 23F, 14, and 6B are consistently among the six serotypes most frequently isolated from children with AOM, although their relative frequency varies by study. Serotype 3 is also a frequent AOM isolate in some areas, but not others.[48,66,113–116]

Antibiotic Resistance

Antibiotic resistance also varies with age, race, and geographic location. Globally, the northern European countries of Norway, Sweden, Denmark, The Netherlands, and Switzerland have consistently low rates of resistance; in contrast, France, Spain, Hong Kong, Singapore, and South Africa have high rates of resistance.[117] In the United States, resistant strains are found more frequently in the southern states of Tennessee and Georgia than elsewhere.[118,119] The highest percentage of resistant strains occurs in children younger than 5 years of age with high rates of antibiotic use since the 1990s.[118,119] After 2000, increases in nonvaccine serotype 19A strains resistant to multiple antibiotics were seen in countries using seven-valent PCV7, such as the United States,[119,120] but also in countries that had not yet introduced PCV7.[121] The amount and types of antibiotics used have been correlated with increased resistance.[119,122,123] The serotypes most likely to become resistant (6A, 6B, 9V, 14, 19A, 19F, and 23F)[119,121,124] were those that were frequently carried and most likely to cause AOM, and resistance rates are higher in isolates from middle ear fluid and sinuses than from normally sterile sites.[125] This may be because pneumococci in these regions are exposed to antibiotics more extensively than serotypes that cause invasive disease, both because they are carried for longer periods and because AOM is frequently treated with antibiotics. The serotypes with the highest rates of resistance were included in the PCV7 vaccine or were within the same serogroups, and introduction of PCV7 reduced disease caused by resistant infections in the United States and in developing countries, both among children and among older persons through reduced transmission.[17,126]

HISTORY OF VACCINE DEVELOPMENT AND VACCINE FORMULATIONS

Over the past 25 years, several PCV formulations have been tested in clinical trials; these vaccines differ in their included serotypes and carrier proteins (see Table 46.5).

The number of pneumococcal serotypes included in current vaccines and vaccine candidates in clinical development ranges from seven to 15, fewer than the 23 serotypes included in PPV. Although it would be preferable to include a larger number of different polysaccharides in a conjugate vaccine, doing so is technically challenging. Moreover, the total amount of carrier protein in the final vaccine may need to be limited because too much of some carrier proteins can impair the antibody response to the polysaccharide antigens.[127–129] In many countries, the incremental benefits in coverage for young children gained by increasing the number of serotypes remains low after 10 serotypes have been included; however, the 10 serotypes selected for inclusion may vary geographically and over time.

Prevnar 13 (Pfizer), a pneumococcal 13-valent vaccine, is a sterile suspension of saccharides of the capsular antigens of *S. pneumoniae* serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F, individually linked to nontoxic diphtheria CRM_{197} protein. Each serotype is grown in soy peptone broth. The individual polysaccharides are purified through centrifugation, precipitation, ultrafiltration, and column chromatography. The polysaccharides are chemically activated to make saccharides, which are directly conjugated by reductive amination to the protein carrier CRM_{197}, to form the glycoconjugate. CRM_{197} is a nontoxic variant of diphtheria toxin isolated from cultures of *Corynebacterium diphtheriae* strain C7 (β197) grown in a casamino acids and yeast extract-based medium. CRM_{197} is purified through ultrafiltration, ammonium sulfate precipitation, and ion-exchange chromatography. The individual glycoconjugates are purified by ultrafiltration and column chromatography and analyzed for saccharide to protein ratios, molecular size, free saccharide, and free protein. The individual glycoconjugates are compounded to formulate Prevnar 13. Potency of the formulated vaccine is determined by quantification of each of the saccharide antigens and by the saccharide to protein ratios in the individual glycoconjugates. Each 0.5 mL dose of the vaccine is formulated to contain approximately 2.2 μg of each of *S. pneumoniae* serotypes except 4.4 μg of 6B saccharides, 34 μg CRM_{197} carrier protein, 100 μg polysorbate 80, 295 μg succinate buffer, and 125 μg aluminum as aluminum phosphate adjuvant.[130]

The first licensed PCV7 from Wyeth, also conjugated to CRM_{197}, included 2 μg each of the polysaccharide serotypes. Several conjugate vaccines that were tested in clinical trials are no longer in development. Merck developed a seven-valent vaccine containing polysaccharides of the same serotypes as the Wyeth product, conjugated to a meningococcal outer membrane protein (OMP) modified from *Neisseria meningitidis,*

and Wyeth produced a CRM_{197}-conjugated nine-valent vaccine containing 2 μg each of polysaccharide from serotypes 1 and 5 in addition to the serotypes in the seven-valent vaccine. Sanofi Pasteur developed an 11-valent vaccine that added serotypes 3 and 7F; in this vaccine (PncD/T), some of the saccharides (for serotypes 3, 6B, 14, and 18C) were conjugated to diphtheria toxoid and the others (for serotypes 1, 4, 5, 7F, 9V, 19F, and 23F) were conjugated to tetanus protein. Other potential carrier proteins that have been tested in animal studies include bovine serum albumin, human immunoglobulin (Ig) G, complement C3d, keyhole limpet hemocyanin, flagellar protein of *Salmonella*, pertussis toxoid, and pneumolysin toxoid.[131–134] The conjugation chemistry and manufacturing protocols vary for each preparation.

GlaxoSmithKline designed an 11-valent vaccine in which 1 μg of each saccharide was conjugated to protein D (9–16 μg per dose of vaccine) derived from nontypeable *H. influenzae* as a carrier protein for eight of the 10 serotypes (1, 4, 5, 6B, 7F, 9V, 14, and 23F), while serotypes 18C and 19F are conjugated to tetanus toxoid (5–10 μg) and to diphtheria toxoid (3–6 μg), respectively. All conjugates are adsorbed onto 0.5 mg aluminum phosphate. This vaccine protected against both pneumococcal and *H. influenzae* otitis media. However, serotype 3 proved not to be protective against AOM in the clinical trial[12]; consequently, GlaxoSmithKline proceeded with the clinical development of a 10-valent version, containing serotypes 1, 5, and 7F in addition to those in the seven-valent vaccine. This 10-valent version (PCV10, sold under the name Synflorix) is currently licensed in many countries globally and is prequalified by the World Health Organization (WHO). This vaccine is not licensed in the United States, but was used for a time in Quebec. Merck has an investigational 15-valent vaccine that has completed Phase I trials in adults and toddlers. A Phase II trial in infants comparing immunogenicity to PCV13 was completed and the immunogenicity was reported in infant macaques.[135] This vaccine is also conjugated to CRM_{197}, and in addition to the serotypes in the 13-valent vaccine, includes serotypes 22F and 33F. The vaccine contains 2 μg of each serotype, except for 4 μg of serotype 6B, and had aluminium phosphate as an adjuvant. It is currently undergoing reformulation.

The Serum Institute of India has a 10-valent CRM_{197} conjugate PCV in human trials in India and The Gambia. The vaccine has been formulated to include important serotypes in developing countries and includes serotypes 1, 3, 5, 6A, 6B, 7F, 14, 19A, 19F, and 23F. Panacea in India has a vaccine in human clinical trials which is conjugated to CRM_{197} and comprises the same serotypes as the GlaxoSmithKline PCV10, while SK Chemicals in South Korea is also testing a number of CRM_{197}-based conjugates in human trials. A seven-valent PCV that includes serotypes 1 and 5 has been tested in humans in Cuba.[136]

IMMUNOGENICITY

Measurement of Immunogenicity

For many encapsulated bacterial pathogens, antibodies against capsular polysaccharides are protective against disease. In pneumococcal infections, this has been demonstrated indirectly by the increased incidence of serious pneumococcal infections in groups with lower antibody concentrations (e.g., infants and the elderly, patients with hypogammaglobulinemia or agammaglobulinemia, and patients recovering from bone marrow transplantation). Direct evidence of the protective effect of anticapsular antibodies comes from studies where passively administered antibodies have provided protection from otitis media or invasive pneumococcal disease.[137,138] Furthermore, vaccines that induce antibodies to pneumococcal capsular polysaccharides are protective against invasive pneumococcal infections (see Chapter 47).

The two most important serologic methods used to quantify and evaluate the function of antibodies induced by vaccination are IgG quantification by enzyme immunoassay (EIA) and measurement of opsonophagocytic activity (OPA) of antibodies from the sera of vaccinated individuals. The EIA method has been validated extensively,[140] a link between antibody concentration and efficacy against invasive pneumococcal disease has been established,[141,142] and a process for cross-laboratory standardization of the assay has been completed.[143] The OPA assay provides important information about the functional activity of the antibodies and has also been the focus of intensive standardization efforts.[144]

Additional tests, such as isotype and subclass analysis, determination of the avidity of antibodies and serotype cross-reactivity, provide qualitative information about the immune mechanisms evoked by the vaccines, but they have not yet been standardized, and their value in predicting protective efficacy still needs to be evaluated and/or validated. Further information about the characteristics of the immune response to the vaccines can be obtained through demonstration of the induction of immunologic memory as well as by analyzing cellular and mucosal immune responses to the vaccination. Important information about immunity can also be obtained through challenge studies in animal models.

Enzyme Immunoassay

Immune responses to pneumococcal vaccines have been evaluated by radioimmunoassay and EIA, both of which measure the binding of antibodies to pneumococcal polysaccharide antigens. The radioimmunoassay technique is no longer in use. EIA is a sensitive, convenient, and rapid method even for a large number of samples. Concentrations of IgA, IgM, and IgG isotypes,[145] as well as of IgG subclasses,[146] can be determined using a reference serum. The United States Food and Drug Administration (FDA) previously made available a reference serum from pooled human sera (89SF). More recently, a new serum pool was formulated by the FDA (007Sp) and validated by the WHO; it replaced 89SF as the pneumococcal reference standard.[143]

All current EIA protocols have an absorption step to remove anti–C-polysaccharide antibodies,[140,147–149] the presence of which was the main limitation of radioimmunoassays. However, it has recently been recognized that, to some extent, similar problems exist with EIA, in that some sera contain polyreactive antibodies that recognize pneumococcal polysaccharides of different serotypes.[147,150,151] These antibodies are especially prevalent in the sera of individuals who have naturally acquired antibodies and are less prevalent in the sera of those immunized with pneumococcal vaccines. They are most probably directed to contaminants in the pneumococcal polysaccharide preparations that are used as antigens in the assays or directed to polyreactive epitopes present in the polysaccharide antigens. Inhibiting antibody binding using soluble polysaccharides of another serotype (e.g., of serotype 22F) removes these polyreactive antibodies, improves the specificity,[147] and increases the linear correlation between anticapsular polysaccharide antibody concentration and OPA.[147,152] Consequently, neutralization with 22F is now included in the EIA protocol. This change has caused some confusion regarding the need to change threshold values for protection as discussed below. Further complicating the picture for the Merck 15-valent vaccine in development,

which contains serotype 22F, is an electrochemiluminescence assay that was developed using serotypes 25 and 72 for preadsorption.[153]

The IgG antibody response in early infancy is mainly of the IgG_1 subclass. After the PCV booster dose in the second year of life, IgG_2 antibodies also start to appear, and the response in adults to both pneumococcal polysaccharide and conjugate vaccines is mainly of the IgG_2 subclass.[146,154–156] In adults, some differences have been found in the IgG_1:IgG_2 ratio elicited after vaccination with pneumococcal polysaccharide and various conjugate vaccines.[155] However, the relevance of these findings for estimating the T-cell dependence of the response in infants and the functional activity of antibodies remains to be elucidated.

Avidity

Antibody avidity describes the strength with which an antibody binds to a complex antigen. Several methods have been described for determining relative antibody avidity to different types of antigens.[157–162] In EIA techniques, the binding of antibody to the coated antigen may be prevented by competitive inhibition using decreasing concentrations of free antigen or, more usually, by eluting the antibody from the antigen by a dissociating agent, such as thiocyanate, urea, or diethylamine. Thiocyanate anion and urea interfere with the antibody-antigen binding primarily through disrupting the hydrophobic bonds; diethylamine is a protein-denaturing agent. Two avidity assays based on pneumococcal EIA and using sodium thiocyanate elution have been developed. Because the elution assays are based on dissociation of antibody-antigen complexes of low avidity, they allow the ranking of the antibodies by their avidity.

The avidity of antibodies induced in infants after pneumococcal conjugate vaccination increases from postprimary samples to prebooster samples and increases further over time.[157,163,164] Experience with Hib conjugate vaccines suggest that measurement of antibody avidity is also useful in assessing the induction of memory.[160]

Opsonophagocytic Activity

Because opsonin-dependent phagocytosis is the primary host defense mechanism against *S. pneumoniae*, a variety of techniques to measure the OPA of antibodies to pneumococci have been developed.[152,165–167] The intent of measuring OPA is to assess the function of antibodies rather than just their quantity because a proportion of antibodies measured in EIA have no functional activity. In support of the likely improved utility of OPA over EIA is the observation in animal models that OPA provides better correlation with protection than the concentration of IgG antibodies as measured by EIA.[168,169] In humans, sera from the Finnish otitis media trial, reanalyzed using an OPA assay, revealed that the OPA titers predicted the observed low efficacy for serotype 19A, whereas the enzyme-linked immunosorbent assay (ELISA) titers did not.[170] Furthermore, the cross-reactive IgG response to serotype 19A in the seven-valent vaccine, which was not associated with protection against invasive pneumococcal disease, lacked significant OPA activity.[171] Of importance, EIA results may have limited relevance in older adults, who often have more nonfunctional anticapsular antibodies than infants and children. Interest in OPA has increased in recent years. It is the primary assay to evaluate the functional activity of the immune response to PCV, and OPA responses are an essential part of the registration of new conjugate vaccines.

The classic OPA is an assay to determine the titers of sera that reduce the number of live bacteria by more than half through opsonophagocytosis. Early studies were performed using human polymorphonuclear leukocytes as the effector cells, but recent assays have also been adapted to use cultivable phagocytes (e.g., HL-60 or NB-4 cells). Romero-Steiner and associates[165] developed an OPA assay for pneumococcal antibodies, in which they used rabbit complement and HL-60 cells as phagocytes. This method has become a reference against which other assays are compared. Additional OPA techniques, including radioisotopic, flow cytometric, microscopic, and viability (or killing) assays, have been tested. The killing OPA method, which measures the killing of live bacteria by effector cells, is regarded to be the most biologically relevant.[152,172] There is also more information about the validation and performance of the killing-type OPA than about the flow cytometric OPA. In general, the results obtained by the various techniques correlate well, and an assessment of assays from six laboratories showed acceptable agreement between their assays.[144]

With increasing need for high-throughput and automated functional assays, multiplexed methods for OPA have been developed. The Romero-Steiner assay has been validated to measure seven serotypes simultaneously, using fluorescent dye to quantify the bacterial killing.[173] Another approach is to measure phagocytosis by flow cytometry, using fluorescently labeled bacteria or latex particles,[166] and a multiplexed phagocytosis assay for three to four different serotypes has been developed using bacteria or latex beads coated with different polysaccharides.[174] Still another type of multiplexed OPA is based on a killing-type OPA, using pneumococcal strains resistant to clinically irrelevant antibiotics.[173,175–177]

The correlation between the IgG EIA antibody concentration and OPA results is relatively strong in immune sera[156,165,178,179] but is weaker at low antibody concentrations.[155,168,178,180] In general, the correlation between antibody concentration and OPA seems to be good in infants who have been immunized with conjugate vaccines,[31,154] but is weaker in unimmunized children and in adults.[155,181,182] Correlations between EIA and OPA results are high for vaccine serotypes but lower for cross-reacting serotypes such as 6A and 19A.[183] One reason for the poor correlation is that antibodies detected by standard EIA are not functionally active.[150,181,184]

As discussed below, a recent indirect cohort method was used to attempt to identify an aggregate correlate of protection using OPA.[142] The variation of serotype-specific OPA values that correlated with protection was too great, however, and thus no such value could be defined.

Immunologic Memory

Memory is traditionally characterized by the presence of IgG antibody elicited in a previously naïve individual (such as an infant), by evidence of priming after immunization, or by affinity maturation. For the purposes of vaccine evaluation, the simplest method of demonstrating memory is often the increased concentration and IgG dominance of an antibody response after a booster dose.[185] The increase of geometric mean concentration (GMC) in a primed individual with immunologic memory is much stronger than that seen if the same vaccines were given at the same age without precedent priming.[184,186–191]

The maturation of antibody avidity and increased OPA have also been evaluated in studies of pneumococcal vaccines.[160,179] The avidity of antibodies is increased in children who receive a pneumococcal conjugate booster but not a polysaccharide vaccine booster.[157,192] This suggests that the conjugate triggers a T-cell response, but the T-cell–independent PPV only triggers the existing memory B cells.[155,189,192]

Antibody response may be higher after the polysaccharide booster than after the conjugate booster.[193,194] Whether this has any clinical advantage is not clear. Theoretically, a conjugate booster may stimulate the generation and expansion of high-affinity clones of B memory cells, whereas use of a polysaccharide booster could result in depletion of the memory pool.[195] Long-term (5-year) follow-up of children receiving polysaccharide vaccine did not, however, show reduction in PCV responses or the pool of polysaccharide-specific memory B cells.[195a] Evidence in support of this idea was found in a comparison of memory B cells following polysaccharide versus conjugate pneumococcal vaccination of adults.[196] Therefore, some have argued that boosting with a conjugate may prove important for the persistence of immunity, although this has not been conclusively shown. It is also important to note that the use of the polysaccharide booster may be associated with more pronounced reactogenicity.[193]

The response to the booster dose to either PCV or PPV is rather vigorous at 24 months of age, as seen in the increase in GMCs of anticapsular antibodies in samples taken 7 to 10 days (but not yet at 4 days) after immunization, provided the children had received primary doses with the conjugate.[187,188,197] A comparison of a booster dose at 12 months of age between PCV13 and PCV10, given to those previously primed with the same vaccine in infancy, suggests that the memory B cell response to PCV13 appeared superior to PCV10 for most serotypes common between the vaccines.[198] The clinical relevance of this observation, if any, related to impact on carriage or duration of protection has not been established. The priming effect is less impressive in healthy adults,[134,199] maybe because adults often have already encountered the antigen and become primed, either through carriage of the bacterium or other, cross-reacting antigens. Some indications of priming can be seen also in patients with HIV,[200,201] after bone marrow transplant,[97,202] and sickle cell anemia.[87]

Whether mucosal memory is induced by PCVs is still under examination. In one United Kingdom study, the salivary IgA concentrations against pneumococcal serotypes were only slightly higher in the vaccinated group than in the control group that did not receive PCV7, but there was a significant increase in mucosal antibodies after a booster dose of polysaccharide.[203] Mean-fold rises after the polysaccharide vaccine were lower for serotypes not included in the conjugate, suggesting that the conjugate vaccine had primed children for memory responses.[203] However, two other studies found no clear differences in salivary antibody responses between children primed with conjugates and those who received their first pneumococcal vaccine during the second year of life.[184,204] Follow-up data from the Finnish Otitis Media Vaccine Trial (FinOM), an AOM efficacy trial, showed that PCV7 induced both salivary IgG and IgA responses to the vaccine serotypes. By 4 to 5 years of age, IgA concentrations were similar in both the vaccinated group and the nonvaccinated control group,[205] most probably reflecting natural stimulation through repeated episodes of colonization.

Whether immunologic memory plays an important role in vaccine-induced protection against pneumococcal disease remains controversial. The experience with Hib immunization in infants supported the view that, in addition to the potent herd immune effect, priming may have provided some protection against disease because very young children were protected despite low antibody concentrations.[206] However, priming and memory to the Hib polysaccharide induced by natural exposure in the prevaccine era[207] or Hib conjugate vaccine[208,209] may not be sufficient for protection against disease, as the United Kingdom's experience with Hib strongly suggests. To explain the observation of a rise in failures of the Hib vaccine between 1999 and 2003, the introduction of an acellular pertussis–containing Hib conjugate vaccine without a booster suggested that this vaccine primed well but was associated with lower immunogenicity.[210,211] In contrast, no such increase in failures was noted in countries that adopted this new vaccine but did not eliminate the booster dose. Similarly, studies of the serogroup C *N. meningitidis* conjugate vaccines in the United Kingdom demonstrate lower effectiveness 1 year after vaccination, suggesting that priming of the immune response and memory responses may not be sufficient to prevent invasive disease.[212] It is possible that the lack of efficacy against serotype 1 pneumococcal disease in the PCV9 trials in Africa may also reflect failures in the second year of life after a primary vaccination schedule without a booster.[213] Because of the observed delay in antibody response in primed subjects after exposure, a memory response may not be rapid enough to protect against an isolate that has the capacity to rapidly invade the bloodstream soon after establishing nasopharyngeal colonization. Thus, the role of immunologic memory in conferring long-term protection against invasive bacterial disease remains controversial.[209]

Animal Models

In addition to in vitro assays, many animal models have been developed to study the immunogenicity and efficacy of pneumococcal conjugate and novel protein vaccines, including rodent (mice and rats), rabbit, chinchilla, or infant monkey models.[214–223] In the immunogenicity studies, animals are bled before and after active immunization with an experimental vaccine to obtain sera or cells for various analyses.[217–219,221,224] The functionality of antibodies can also be evaluated in animal models.[168,214,220,225–227] Animals may be passively or actively immunized and subsequently challenged with bacteria to determine protective efficacy.[214–216,224]

Many different strains of pneumococci can be used for colonization and challenge studies, although there are marked serotype-dependent differences with respect to their capacity to colonize the nasopharynx or cause invasive disease in animal models. Various routes of challenge have been employed, in attempts to mimic the human situation of nasopharyngeal colonization, otitis media, bacteremia, pneumonia, and meningitis. For nasopharyngeal colonization, inocula using clinical isolates can result in sustained colonization for several days to weeks. Using the same challenge protocol but under anesthesia and with a larger inoculum (50 µL or more), mice aspirate the inoculum, which subsequently leads to lung infection and, depending on the strain used, possibly also sepsis (particularly if lower numbered serotypes are used). Adult and infant mice and rats have been used in passive-protection models to determine the protective capacity of human antipneumococcal antibodies against bacteremia, meningitis, or death.[168,169,224,228–230]

In addition, special mention should be made of a human model of intentional pneumococcal exposure that permits an evaluation of the immune responses that are either associated with resistance to colonization or response to exposure.[231,232] Use of this model demonstrated the nasal inoculum required to establish colonization in healthy adults (50% colonizing dose estimated at 10^3–10^4 colony-forming units [CFU]), defined the duration of colonization (range: 0–122 days) and analyzed the mucosal and systemic humoral response to a single carriage event. Such studies could be particularly useful in the future for testing of vaccines that target carriage. Indeed, this model has been used for evaluation of the protective effect of PCV13 against carriage[233] and is, at the time of this writing, being used for the evaluation of a protein-based vaccine candidate being developed by Genocea Biosciences.

Infants and Young Children

Infants are the main target group for PCVs; consequently, most clinical trials have focused on the safety and immunogenicity of candidate vaccines in infants. Various dosing schedules have been examined and the available literature on immunogenicity, efficacy, and effectiveness of different schedules has been systematically reviewed.[234] Although aggressive schedules starting with vaccination at birth were studied,[235–237] they have not been approved. In early infancy, passively acquired maternal antibodies seem to interfere with the response to the first doses of conjugates, although there is no evidence of interference for any serotype after completion of the entire immunization series.[238] In the Expanded Programme on Immunization (EPI) schedule, the conjugate is given at the ages of 6, 10, and 14 weeks. The schedule that has been studied most extensively is a three-dose primary immunization series either at 2, 3, and 4 months or at 2, 4, and 6 months of age, followed by a booster dose during the second year of life. Reduced vaccination schedules at 2, 4, and 12 months or at 3, 5, and 11 to 12 months of age have also been studied. Although three doses were originally considered necessary for an optimal immune response to conjugate vaccines,[235,239] studies indicate that even one dose of conjugate vaccine may be sufficient, at least in circumstances where carrier priming and early stimulation with high carriage of pneumococci is common.[240–242] Direct studies comparing different schedules are few, but in general, some conclusions can be drawn: (a) a short interval between doses (i.e., 1 month) often results in lower antibody response than a longer one (i.e., 2 months)[243]; (b) for some serotypes (in particular serotypes 6B and 23F), reduced schedules may show significantly lower immunogenicity, when immunogenicity prior to the booster dose in a two-dose regimen is compared with a three-dose regimen[234,242–249]; and (c) although a single dose in infancy is immunogenic, it is inferior to a two- or three-dose regimen for all serotypes.[242] In this regard, further evaluation of the quality of antibodies and induction of memory, as well as of the determination of the optimal age of vaccination, would be of interest.[250,251] Although most of the early data on immunogenicity were derived from the seven-valent and nine-valent CRM_{197}-conjugated vaccines (PCV7 and PCV9), data on other early PCVs (conjugated to diphtheria toxoid, tetanus toxoid, and OMPC) are available. Recently, studies conducted for the licensure of *H. influenzae* protein D (PHiD-CV, PCV10), and the 13-valent CRM_{197} conjugate vaccine) suggest that they elicit antibody responses somewhat lower than PCV7 in infants and toddlers (Table 46.2).[4,12,13,171,194,252–260] Thus, the addition of more serotypes contained in PCV10 or PCV13 results in a wider spectrum of immune response to the additional serotypes with generally minor compromise to the response of the seven serotypes in PCV7.

In general, anticapsular antibody GMCs increase fivefold to 10-fold after the initial series, relative to the preimmunization concentrations. The antibody concentrations achieved are usually only sustained for a few months and decline during the second year of life to about the preimmunization levels. However, a dose of the pneumococcal vaccine, either polysaccharide or conjugate, administered during the second year of life to children primed with any of the conjugates, generally induces an approximately 10-fold increase in antibody concentrations. Typical ways to describe the immunogenicity results are reverse cumulative distribution curves (Fig. 46.2) or radial diagrams ("logograms") (Fig. 46.3). Table 46.2 compiles representative immunogenicity data after the primary immunizations from selected pivotal trials (either efficacy trials or trials used for licensure of new vaccines after PCV7 introduction [relevant to PCV10 and PCV13]).

Two doses of PCV7 given at either 2 and 4, 3 and 5, or 4 and 6 months of age as a primary series, together with a booster at 11 to 12 months, seem to induce an immune response and induction of immunologic memory comparable to those noted with the standard four-dose schedule in both normal and preterm infants.[242,244–250,261–263] Thus, the marked booster response, after two doses in infancy, even for the least immunogenic serotypes, has led many countries to adopt a two-dose infant series and a booster rather than the initially licensed schedule of three infant doses and a booster. The WHO has now recommended the two primary doses plus a booster series as an alternative to the three-dose primary series typically used in EPI schedules.[264]

In addition to the vaccination schedule and number of doses, the characteristics of the target population also affect the immune response. Direct comparisons are difficult, however, because both the vaccination schedules and the laboratories performing the serologic assays are usually not consistent in all the studies. Similar comparisons were conducted with PCV7 and PCV9 vaccines containing either seven or nine serotypes, which were evaluated in studies conducted in the United States, Finland, and South Africa and showed greater immunogenicity in South Africa than in Finland and the United States.[4,265–267]

PCV immunogenicity is clearly associated with geographic region and vaccine protection, but the magnitude varies with serotype.[268,269] Children in studies from Asia, Africa, and Latin America had significantly higher antibody responses compared to those from Europe and North America.[269] The reasons for these differences could derive from many factors, such as the differences in the nasopharyngeal microbiome of the children, priming effect of tetanus toxoid given to pregnant women, earlier pneumococcal acquisition, differences in concomitant vaccine administration, and genetic differences among populations. Similar differences were noted in immune responses to Hib conjugate vaccines in earlier studies.

The IgG responses of children with invasive pneumococcal disease (IPD) have been measured and values compared between those previously immunized with PCV versus unimmunized children.[270] Vaccinated children with IPD are less likely to have greater than 0.35 μg/mL of antibody to the infecting serotype compared with other serotypes. These children with IPD proved hyporesponsive to their infecting serotype in subsequent exposure to PCV, although recurrent disease was rare (0.2%).[270]

Preterm Infants

Preterm infants seem to respond to the PCV satisfactorily, although the immunogenicity of the vaccine in preterm infants is usually lower than in term infants.[252,261,271–273] The Advisory Committee on Immunization Practices (ACIP) in the United States recommends in its guidance document that PCVs be given to preterm infants at their chronologic age, consistent with the schedule recommended for full-term infants.[274] It may be particularly important to offer a timely booster dose of PCV13 to such infants.[268,273–276] The response of preterm infants after booster depends on the number of doses in the primary series; infants who received only two doses in the primary series had lower rates of seroprotection after the primary series than children who received a three-dose primary series but had higher levels of seroprotection after boost.[276a]

Neonatal Immunization

Neonatal administration of PCV does not lead to tolerance of subsequent doses[277] and postprimary responses are similar[277] or slightly lower[238] than PCV administered to older infants.

Impact of Maternal Immunization on Immunogenicity in Infants

In a randomized trial of PCV9 in pregnant women, administered at 30 to 35 weeks of pregnancy, serotype-specific IgG was significantly raised in infant cord blood compared to infants whose mothers received placebo.[278] Infants then received PCV7 at 2, 4, 6, and 12 months. At 7 months of age, the IgG responses to the initial three-dose series of PCV7, were significantly reduced for all serotypes among infants of immunized mothers, compared to infants of mothers who received placebo. Robust booster responses to PCV7 were measured 1 month after the 12-month dose. The mean levels of IgG remained lower in infants of vaccinated mothers compared to those born to control mothers for serotypes 6B, 18C, 19F, and 23F. These data suggest that high levels of passively acquired maternal antibody suppress the primary responses to those serotypes in their infants. Responses to serotypes 1 and 5, not given to the infants, remained elevated compared to infants of controls through 6 and 13 months of age. Data from infants born to mothers receiving tetanus, diphtheria, and pertussis (Tdap) during pregnancy had reduced responses to CRM based PCV conjugate compared to historical controls whose mothers did not receive Tdap.[279]

Older Children, Adults, and the Elderly

GMCs for most serotypes in infants 1 year of age receiving two doses of PCV and older children receiving a single dose of PCV7 were comparable to the immune responses of infants who received three doses of conjugate in the Northern California Kaiser Permanente (NCKP) efficacy study.[4] Based on these data, the official recommendation in the United States is to use PCV7 at 2, 4, 6, and 12 to 15 months of age. For children 12 to 23 months of age, two doses were recommended at least 2 months apart, and for those 24 months through 9 years of age, one dose was considered sufficient. Similar recommendations have been made for PCV13 for the primary schedule.[274] Vaccination is recommended for all children 2 to 59 months of age and those 60 to 71 months of age with underlying medical conditions (Table 46.3). Children who received one or more doses of PCV7 were recommended to complete the schedule with PCV13. A supplemental dose of PCV13 was recommended for those children 14 to 59 months of age who had completed their four-dose PCV7 schedule. For children with underlying medical conditions, a supplemental dose of PCV13 was recommended up to age 71 months (the recommendation for PPV23 remained for children 2 to 18 years of age who have received their full schedule of PCV13).[274] For older children not previously given PCV7, those 7 to 11 months of age were recommended to get three PCV13 doses, the first two at least 4 weeks apart and the second two at least 8 weeks apart, with the third dose at 12 to 15 months. Children 12 to 23 months of age should receive two doses at least 8 weeks apart, and those 24 months of age or older should receive a single dose, or two doses at least 8 weeks apart if they have underlying medical conditions (Tables 46.3 and 46.4).[274] In February 2013, the ACIP recommended routine use of PCV13 for children 6 to 18 years of age with immune-compromising conditions, functional or anatomic asplenia, CSF leaks, or cochlear implants who have not recently received PCV13, regardless of whether they previously received PCV7 or PPV23.[280] The recommendation was for a single PCV13 dose first, followed 8 or more weeks later by a PPV23 dose. A second PPV23 dose is recommended 5 years after the first PPV23 for children with anatomic and functional asplenia,

[a]13-Valent pneumococcal conjugate vaccine.
[b]23-Valent pneumococcal polysaccharide vaccine.
[c]Since 2010 the recommendation is that all healthy children younger than 5 years of age receive PCV13; PPV23 is not recommended for healthy children younger than 2 years of age.
[d]Including congestive heart failure and cardiomyopathies.
[e]Including chronic obstructive pulmonary disease, emphysema, and asthma.
[f]Including B-(humoral) or T-lymphocyte deficiency, complement deficiencies (particularly C1, C2, C3, and C4 deficiencies), and phagocytic disorders (excluding chronic granulomatous disease).
[g]Diseases requiring treatment with immunosuppressive drugs, including long-term systemic corticosteroids and radiation therapy.
From Advisory Committee on Immunization Practices, 2010 and 2013. Frenck R, Thompson A, Senders S, et al. 13-Valent pneumococcal conjugate vaccine in older children and adolescents either previously immunized with or naïve to 7-valent pneumococcal conjugate vaccine. Pediatr Infect Dis J. *2014;33(2):183–189.*

TABLE 46.4 Recommended Schedule for Administering Doses of 13-Valent Pneumococcal Conjugate Vaccine (PCV13) to Children <24 Months by PCV Vaccination History and Age

Age at This Visit (mo)	**Vaccination History: Total Number of PCV7 and/or PCV13 Doses Received Previously**	**Recommended PCV13 Regimen[a]**
2–6	0	3 Doses, 8 wk apart; fourth dose at age 12–15 mo
	1	2 Doses, 8 wk apart; fourth dose at age 12–15 mo
	2	1 Dose, 8 wk after the most recent dose; fourth dose at age 12–15 mo
7–11	0	2 Doses, 8 wk apart; third dose at 12–15 mo
	1 or 2 before age 7 mo	1 Dose at age 7–11 mo, with a second dose at 12–15 mo, ≥8 wk later
12–23	0	2 doses, ≥8 wk apart
	1 before age 12 mo	2 doses, ≥8 wk apart
	1 at ≥12 mo of age	1 dose, ≥8 wk after the most recent dose[b]
	2 or 3 doses before age 12 mo	1 dose, ≥8 wk after the most recent dose[b]
	4 doses of PCV7 or other age-appropriate vaccine, complete PCV7 schedule	1 supplemental dose ≥8 wk after the most recent dose

[a]Minimum interval between doses is 8 wk except for children vaccinated at <1 y of age, for whom minimum interval between doses is 4 wk.
[b]No additional PCV13 doses are indicated for children aged 12 to 23 mo who have received two or three doses of PCV7 before age 12 mo and at least one dose of PCV13 at age ≥12 mo.
PCV7, 7-valent pneumococcal polysaccharide-protein conjugate vaccine.

HIV infection, or other immunocompromising condition. If these children previously received one or more doses of PPV23, they should be given a single PCV13 dose 8 or more weeks after last PPV23 dose. These recommendations are based on immunogenicity studies in both immunocompetent and immunocompromised children 6 to 18 years of age.[281–285]

To date, there is some evidence that conjugate vaccines are more immunogenic than the PPV vaccine in adults, although this has not been consistently shown.[286] In early studies, a five-valent PCV vaccine elicited a greater response than PPV to some serotypes (6B, 18C, and 23F) but not others (14 and 19F).[133,198] In more recent studies, the IgG and opsonophagocytic responses to PCV7 and PCV13 were either similar or higher than those to PPV.[287–291] In a dose ranging study by Jackson and colleagues,[287] administration of a 1-mL dose (double the infant dose, so 4 μg of all serotypes except 8 μg of serotype 6B) demonstrated an enhanced immune response, but no further immunologic advantage was seen with a 2-mL dose (fourfold greater than the infant dose). In adult Alaskan natives, PCV did not induce higher IgG and opsonophagocytic responses when compared with PPV and provided no benefit when given before PPV.[292] There is also some evidence that the baseline level of antidiphtheria antibodies is associated with the response to the PCV7 vaccine: adults with higher diphtheria antibody levels have higher responses to the conjugate.[293] Repeated PCV doses in adults seem to induce comparable immunogenicity to the first dose.[288,290] Receipt of PCV 6 months[294] or 1 year after PPV led to a diminished response to PCV compared with PPV-naïve adults.[288,294] The order of immunization of adults with the conjugate versus polysaccharide vaccine appears to matter, with conjugate vaccination first conferring a booster response to a later dose of polysaccharide, while an initial dose of polysaccharide vaccine leads to a reduced response to PCV.[288,294–296]

Because most adults have preexisting antibodies to pneumococcal polysaccharides and to the carrier protein, the initial vaccination with the conjugate acts as a booster.

Maturation of pneumococcal antibody avidity is prominent after the vaccination of infants, but the presence of mature antibodies before vaccination of adults results in only modest increases in avidity. In a study of different pneumococcal conjugates, the avidity index was stable in adults, whereas clear increases occurred in children after both primary and booster immunizations with PCV.[155] Other reports have noted no avidity maturation in elderly subjects vaccinated with PPV,[297] or young adults vaccinated with either PPV or PncD/T conjugate.[298]

Although both IgG and OPA responses to the PncT conjugate and to the polysaccharide vaccine appeared to be similar in a group of patients with chronic obstructive lung disease and in healthy adults[299]; in patients recovering from pneumonia, there was better persistence of antibody after PCV7 than after PPV23 when assessed 6 months after immunization. This study also found little utility in combining PCV and PPV regimens.[300] In patients with chronic obstructive pulmonary disease there was an improved persistence at 1 to 2 years postimmunization of functional activity for the common types except 19F in individuals given PCV7 compared to those given PPV23.[301] Improved OPA persistence was also seen in hospitalized frail elderly a year post PCV followed by PPV23 given 6 months later, compared to 1 year post-PPV23 alone, but these data are confounded by the shorter time post-PPV23 in the combined immunization group.[302] These data do suggest that in nonimmunocompromised adults, there may be an advantage of PCV over PPV, particularly in the duration of antibody response and the response to revaccination. A conjugate vaccine of comparable valency to PPV23 would thus likely be a significant advance, but for the reasons outlined earlier would pose technical and financial challenges.

Immunocompromised Individuals

In the absence of immunogenicity data in immunocompromised individuals, the immunogenicity cutoffs for immunocompetent individuals have been applied to the immunocompromised population.

HIV. PCVs have been tested in HIV-positive children in different populations. It appears that the immune status of the child (measured by the CD4 count) and the existing viral load impact the response to the immunization.[303] The responses after the first two PCV vaccinations are rather modest in children with advanced HIV, but are higher than those seen in a similar population after the polysaccharide vaccine.[304,305] Three doses of PCV7 are immunogenic in young HIV-infected children; children with milder HIV disease tend to have better responses.[253,304] Among HIV-infected infants with a CD4 percentage greater than 25, there was no impact of antiretroviral therapy on IgG responses, although functional responses were better in those receiving antiretroviral therapy.[306] Yet, the functional OPA responses remain less than those seen after PCV in HIV-unexposed, uninfected infants. There also may be some functional deficits in the quality of antibodies made by HIV-exposed but uninfected children.[306] One study suggested that more than one dose of conjugate vaccine was needed to elicit immunologic memory in children with HIV infection (see Table 46.3).[304] Memory is retained in most HIV infected children on HAART 4 to 5 years after sequential exposure to two doses of PCV followed by a single PPV dose.[307]

In a study from Uganda,[308] HIV-infected adults received two doses of the PCV7 vaccine and postvaccination antibody concentrations were directly correlated with the CD4 cell count, particularly after a second dose. Past receipt of PPV did not impact the response to the conjugate. Similarly, PCV13 given to HIV infected adults previously exposed to PPV23 had significant immune responses regardless to the number of their previous PPV exposures.[309] In a trial among HIV-infected Malawian adults, PCV7 vaccine induced both systemic and mucosal responses, similar to the responses seen in HIV-uninfected subjects. A second dose of conjugate did not provide any additional benefit.[310] The antibodies were functionally active, as measured by OPA.[311] Supplementation with zinc or vitamin A before immunization did not change the response in HIV-positive adults.[312] Among HIV-infected adults with CD4 counts between 200 and 500/μL and a viral load of less than 10,000 virus/mL, priming with PCV increased the titer and duration of response to PPV.[313] Furthermore, this enhanced response was correlated with Th1 lymphoproliferative responses to the CRM carrier.[314] Conversely, immunization with PCV after previous PPV among HIV-infected adults resulted in higher IgG responses than those randomized to receive a second dose of PPV, but the duration of difference in antibody response was limited, with no differences seen between the two groups when titers were measured 6 months postvaccination.[315] There was no variance in vaccine responses by black or white ethnicity among trial participants.[316] PCV appears to induce higher levels of antibody with longer persistence in HIV-infected adults on antiretrovirals than in those receiving PPV.[317]

Other Immunocompromising Conditions. In infants with sickle cell disease, PCV7 vaccine induced significant and comparable increases in serum antibody concentration compared to control infants without sickle cell disease.[90] In older children with sickle cell disease, two doses of the conjugate vaccine

followed by a PPV booster resulted in higher GMCs and OPA titers than one dose of PPV alone.[87] Patients with ataxia-telangiectasia, who usually have low T-cell and B-cell counts, as well as low levels of pneumococcal antibodies, responded to PPV vaccination with a booster-type response if polysaccharide was given after a dose of the conjugate. However, the antibody concentrations were lower than those observed in control subjects.[318,319]

Asplenic patients with β-thalassemia who have previously received PPV23 have significant B memory cell responses producing IgG, but not IgM. Of particular concern, though, was the observation that B-cell responses post-PCV13 in these patients were inversely related to the number of previous PPV23 doses and to the time since the last PPV23 dose, consistent with the idea that PPV23 commits existing B cells to antibody production but depletes the B-cell memory pool.[320] Two studies examined the immune response to PncOMPC in adults previously treated for Hodgkin disease. Although the response to a single dose of seven-valent PncOMPC vaccine was lower than to a polysaccharide vaccine,[97] the conjugate appeared to induce immunologic priming in this patient group.[201] In adults with chronic lymphocytic leukemia, responses to PCV were detected in 40% of cases before the onset of hypogammaglobulinemia associated with chemotherapy.[321]

Adults with allogeneic or autologous stem cell transplantation have an antibody response to a three-dose schedule of PCV7.[322] Immunization of the donor before transplantation (or the patient before stem cell collection) enhances antibody responses pretransplantation,[323,324] and revaccination posttransplantation induces a greater than 80% immune response to PCV7.[325] Among adult allogeneic bone marrow transplant recipients, responses to PCV and PPV are generally poor, but PCV resulted in longer periods with detectable antibody when compared with responses to PPV.[326] Although early immunization with PCV at 3 months posttransplantation was as immunogenic as waiting for 9 months, antibodies at 24 months posttransplantation were lower for the early immunization group, supporting waiting 6 to 9 months after transplantation to vaccinate.[327] Current guidelines suggest three to four doses of PCV a month apart starting at 6 to 9 months posttransplantation followed by one dose of PPV.[328]

In pediatric solid-organ transplant recipients, two doses of PCV7, followed by one dose of PPV, increased pneumococcal antibody concentrations. The first conjugate dose seemed to do the job; neither the second dose of conjugate nor the dose of polysaccharide increased the levels further, suggesting that additional closely spaced PCV or PPV does not add significant benefit. Final responses were, however, significantly lower in solid-organ transplant recipients than in the healthy control group.[329] In renal transplant recipients, PCV7 was marginally more immunogenic than PPV; OPA responses were not different,[330] antibodies waned significantly over 3 years, and PCV did not increase the durability of the immune response when compared with PPV receipt.[331] The prime boost strategy was no better than PPV alone in terms of immunogenicity among liver transplant recipients.[332] There may be some heterogeneity in responses with the different types of solid-organ transplants since multiple doses of PCV and a prime boost strategy improved the immunogenicity after cardiac transplantation.[333]

Duration of Immunity

Over a 5.3-year follow-up after primary immunization with PCV9 of South African infants at 2, 4, and 6 months of age with no booster in the second year of life, antibodies to the seven-valent vaccine serotypes remained significantly elevated compared with placebo-control subjects.[334] Titers greater than 0.35 μg/mL (see "Correlates of Protection" later) were detected among 44% to 95% of children who received placebo in infancy, depending on serotype. The lowest titers were noted for serotype 4, suggesting that long-term immunogenicity for types rarely carried, such as types 1, 4, and 5, could be problematic, particularly in the absence of a booster dose in the second year of life. Even among HIV-infected children, higher antibody titers were detected 5.3 years postimmunization than in HIV-infected unimmunized control subjects, but the percentage of children with titers greater than 0.35 μg/mL was lower in HIV-infected than in HIV-uninfected children and ranged from 19% to 81%.[334]

Variables Influencing the Immunogenicity of Conjugate Vaccines

Composition of the Vaccine

The immunogenicity of a conjugate vaccine is dependent on its chemical characteristics.[336–338] In pneumococcal conjugates, polysaccharides seem to be more immunogenic than oligosaccharides.[189,339,340] Other variables influencing immunogenicity include the inherent properties of carrier proteins, the nature of the chemical linkage of the carbohydrate to the protein carrier,[341,342] conformational changes in epitopes after conjugation,[327,335] the availability of antigenic structural components,[337,339] the presence of free polysaccharides or carrier proteins in the vaccine,[343,344] and the carbohydrate-to-protein ratio.[345]

Clear-cut differences exist in the antibody responses to different capsular-type polysaccharides in the conjugate vaccines.[13,197,252,267,345,346] In studies with Finnish children, the magnitude of the IgG response to serotype 6B appears to be rather consistent between the different vaccines, but large differences can be found for other serotypes, particularly 14 and 19F.[347] In general, in infants, serotypes 6B and 23F appear to be poorly immunogenic, whereas serotype 19F induces a relatively high antibody concentration, although higher OPA titers are not seen. Serotypes 3 and 18C are usually satisfactory immunogens even after the first dose, although a poor booster response is seen for serotype 3 antibodies. No marked increase in anti-6B IgG can be seen in infants after a single dose, and even two doses are markedly inferior to three doses.[242–244] For serotype 4, there is a marked response after the first dose and a further increase after the second dose, but not after the third dose. Serotype 19F induces an antibody response after the second dose, and the third dose does not increase the mean antibody concentrations.

Dose-responses have been published for four-valent PncT and PncD vaccines (containing 1, 3, or 10 μg of each polysaccharide). For PncT vaccine, no dose dependency was seen after the primary immunization, whereas the booster response was highest in the group primed with the lowest dose of the conjugate vaccine.[191] In contrast, the highest dose of PncD induced the strongest response after primary immunization, but, as with the PncT vaccine, the booster response was greatest in the group primed with the lowest dose.[190] When a tetravalent *H. influenzae* protein D PCV was tested in three doses (0.1, 1.0, and 10.0 μg of each polysaccharide), the 0.1 μg dose was superior to the 10 μg dose; for serotype 14, the response increased with increased polysaccharide content, and for serotype 19F the 1.0 and 10.0 μg were equal and superior to that of the 0.1 μg.[348] Thus, the dose response in the various PCVs is not always predictable and may well depend on the carrier and the serotypes.

The optimal carrier may be different for each serotype. Thus far, direct comparisons have been made only between diphtheria and tetanus carriers. Polysaccharides from serotypes 3, 9V, and 14 evoke a better response in infants when conjugated to

diphtheria toxoid, and polysaccharides from serotype 4 induce a stronger response when conjugated to tetanus protein.[266,349] No carrier-specific differences in immunogenicity have been shown for serotypes 6B, 18C, 19F, and 23F. Furthermore, the conjugates seem to have different capacities to induce a mucosal immune response: whereas diphtheria toxoid conjugates induce a better mucosal response, tetanus conjugates seem more efficient in inducing systemic responses.[184]

Immunity to carrier proteins is beneficial for the improved immunogenicity of conjugate vaccines. Early priming with carrier proteins enhances the immune response to polysaccharides in subsequent immunizations with conjugates.[344,350–352] In a study in the Philippines,[240] antibody concentrations at 9 months of age were similar after one dose or three doses of an 11-valent tetanus/diphtheria conjugate vaccine.[240] The most plausible explanation for the good immunogenicity and persistence of antibodies, despite the lower number of doses, is carrier-priming with previous diphtheria-tetanus-pertussis vaccine. Although the T-cell immunity against carrier proteins is essential for responses to polysaccharides, B-cell immunity to carrier protein may become detrimental upon induction of anticarrier antibodies.[353,354] In a situation where polysaccharide- and protein-specific B cells compete to capture conjugates, high amounts of antibodies to carrier proteins may result in a suppressed immune response to polysaccharides.[343,344,352,354–356] This is a reasonable argument for minimizing the amount of antigen and for developing mixed-carrier vaccines.

Aluminum adjuvants, used in all marketed conjugate products, except in two standalone Hib vaccines, bias the immune system to a T-helper cell type 2 (Th2) response and enhance the immune response. The addition of an aluminum hydroxide adjuvant to the PncT/PncD vaccine increased the IgG response and functional activity of antibodies in studies in Finland and Israel.[357]

Table 46.5 describes the composition of the three PCVs licensed to date.

Concurrent Administration With Other Vaccines

High coverage of infant and toddler populations with PCVs and Hib-conjugated vaccines has partly been fostered by their ability to be coadministered or mixed together with other routinely administered vaccines. However, conjugate vaccines can induce immune interference (enhancement or impairment) of humoral immune responses to coadministered antigens.[355,356] Two common interference mechanisms are (a) carrier-induced epitopic suppression, whereby preexisting immunity to a carrier (conjugate protein) suppresses subsequent responses to the hapten/saccharide linked to the same carrier and (b) bystander interference, whereby coadministration of vaccine combinations containing a given conjugate protein induce interference that extends to unrelated antigens that are part of the combination vaccine.[355]

The best recognized form of immune enhancement occurs when vaccines using tetanus toxoid (TT) as the conjugate protein are coadministered with Hib-TT. Anti-PRP (polyribosylribitol-phosphate) antibody concentrations increase when Hib-TT is coadministered with meningococcal serotype C TT conjugate (MenC-TT), or with protein D PCV.[358–363] Conversely, immune responses to TT-conjugated pneumococcal polysaccharides and MenC-TT decrease in the presence of excessive amounts of coadministered TT through carrier-induced epitopic suppression.[364,365] Immune enhancement mechanisms also contribute to increased responses to vaccines using diphtheria toxoid variant (CRM_{197}) as conjugate proteins. In general, CRM_{197} and TT, when engaged as carrier, lead to higher antipolysaccharide responses than does DT, as exemplified by Hib-TT/CRM versus Hib-DT,[366] and meningococcal ACWY-TT/CRM versus ACWY-DT.[366–368] However, unlike TT, DT/CRM_{197} conjugates need T-cell enhancement via DT/CRM_{197} priming or coadministration to maximize immune response.[241]

Conjugate vaccines using CRM_{197}, although less likely than those using TT or DT to have reduced responses to polysaccharides through carrier-induced epitopic suppression, are more likely to induce interference through another yet unclear mechanism, termed *bystander interference*.[355,356] This phenomenon affects vaccines coadministered with the CRM_{197} conjugate vaccines, with Hib-TT and hepatitis B vaccines being particularly vulnerable to this interference. Bystander effects are probably mediated by T-cell mechanisms shared between DT and CRM_{197} and are spreading to other coadministered antigens.

TABLE 46.5 Composition of the Three Currently Licensed Pneumococcal Conjugated Vaccines[a]

Vaccine	Commercial Name	Polysaccharide Content (μg) and Protein Carrier													Adjuvant

[a]Information as described in product monographs presented for licensure.

Immune interference in general, and that observed with conjugate vaccines in particular, are most marked when vaccines are coadministered with combination vaccines containing acellular pertussis antigens (i.e., diphtheria, tetanus, and acellular pertussis [DTaP]), as compared with whole-cell pertussis combinations (i.e., diphtheria and tetanus toxoids combined with whole-cell pertussis [DTwP]).[355,356,364] PncD/T was immunogenic during infancy when given in the presence of DTwP.[269,369] However, when DTaP was present in the concomitantly administered vaccine, a reduction in the immunogenicity of the primary response to pneumococcal polysaccharides conjugated to TT was observed.[364] No similar reduction was seen in relation to the polysaccharides conjugated to DT in the same vaccine. The phenomenon was attributed to a disturbance in the rather complicated balance between the immunogenic properties and amounts of carrier protein and the adjuvant effect of whole pertussis vaccine, which was removed when switching to acellular pertussis vaccines.[364] Because of this finding, Sanofi Pasteur decided to abandon the development of the PncD/T vaccine.

When studies are compared, CRM_{197}-conjugated vaccines coadministered with DTaP vaccines and Hib-TT consistently demonstrate reduced anti-PRP responses compared with schedules where CRM_{197} is not coadministered, as is exemplified in Table 46.6. In contrast, coadministration of Hib-TT with conjugate vaccines that do not contain CRM_{197} demonstrate anti-PRP responses that remain unaffected or are enhanced.[358–362]

In addition to the potential interference induced by the introduction of PCV into the infant immunization program, the effect of increasing the DT or TT component of the pneumococcal vaccine on immunogenicity needs to be considered, especially when introducing extended-spectrum PCVs with additional conjugated polysaccharides. Head-to-head studies of PCV13-CRM (34 μg CRM_{197}) versus PCV7-CRM (20 μg CRM_{197}) show a modest reduction in post–dose-three anti-pneumococcal GMCs in PCV13-CRM for at least four of the seven serotypes in PCV7, in particular serotype 6B.[258,259,370] When PCV7-CRM was administered concomitantly with a tetravalent conjugated meningococcal-CRM vaccine (Menactra, meningococcus A, C, Y, W_{135} conjugated to DT), a marked reduction in the immune response to all pneumococcal seven polysaccharide antigens was observed when compared to the arm receiving PCV7-CRM alone (FDA statistical review evaluation BLA 125084/395). These observations suggest dose-dependent carrier-induced epitopic suppression in the pneumococcal response by CRM_{197}. The mechanisms involved in suppression of immune responses are not explained. Table 46.7 depicts some of the observed interference phenomenon related to conjugate vaccines.

In addition to the complexity of multiple vaccines coadministered in infants, it has been observed that some coadministered drugs, such as acetaminophen, can also markedly interfere with the immune response to PCV, Hib, and diphtheria, tetanus, and pertussis vaccines.[371]

With the introduction of new conjugated vaccines using CRM_{197}, there is a need to further evaluate potential interference either by carrier-induced epitope suppression or by the bystander interference mechanism. However, although interference may often be seen when vaccines are coadministered in infancy, it is rarely of clinical importance. In the setting of less immunogenic vaccine combinations and their coadministration with other vaccines, the booster dose assumes greater importance. The role of the booster dose of Hib in the second year of life has been highlighted in postmarketing surveillance studies[372] and by public health experience in the United Kingdom. However, the extent to which carrier-induced epitopic suppression or bystander effects are negated or persist upon boosting is not well studied.

Correlates of Protection

Challenges in the Search for Correlates

Determination of serologic correlates or surrogates of protection against pneumococcal diseases has proven complicated.

TABLE 46.6 Effect of CRM_{197} Bystander Interference on the Immune Response to Coadministered Hib-TT

Vaccines Administered	Schedule (mo)	No. of Participants	Anti-PRP[a] Response (μg/mL)		Reference
			% ≥0.15	GMC (95% CI)

CRM, carrier protein in conjugate vaccine; DTaP2, DTaP3, or DTaP5 refers to 2-component, 3-component or 5-component diphtheria-tetanus–acellular pertussis vaccines, respectively; DTwP, diphtheria-tetanus–whole-cell pertussis vaccine; HBs, anti–hepatitis B surface antibody; Hib, *Haemophilus influenzae* type b; MenA, meningococcal A; MenC, meningococcal C; MenY, meningococcal Y; MenW-135, meningococcal W-135; PCV, pneumococcal conjugate vaccine; Pn, pneumococcal polysaccharide; PRP, polyribosyl-ribitol-phosphate; Ref, reference; TT, tetanus toxoid.

First, even if the level of a specific antibody is considered to be an adequate surrogate in a particular setting,[185,373] the level may vary between serotypes and the disease in question. Second, the quantitative assessment of the antibody titer alone may be insufficient, and measurement of the qualitative characteristics of the antibodies should also be included in the analyses.[347,374,375] Finally, induction of immunologic memory must be considered as immunologic memory can be induced even with a weak antibody response.[160,209,376,377]

Traditionally, methods for assessing the association between immunogenicity and the prevention of disease have relied on comparisons of aggregate measures, such as comparison of vaccine efficacy and GMCs of antibodies. An alternative possibility for the definition of a protective level is to combine information about the incidence of disease and antibody concentrations in different subgroups of the study population. Correlates of protection should ideally be sought on the individual level by collecting longitudinal follow-up data on children who contract pneumococcal infection despite vaccination. They should also be sought in populations by comparing cross-sectional information on antibody concentrations and estimates of protection in the same group of subjects.

Two comprehensive reviews have been published on the principles and methods of correlates of protection and their use in the licensure of PCVs. One was written by WHO experts and academic researchers,[185] the other by scientists from the FDA and National Institutes of Health.[378] A universally stable and accepted method of measuring OPA antibody titers is practically impossible to achieve, as this is a bioassay with many potential variables. Furthermore, OPA does not measure IgG only and can, for example, be influenced by high IgM levels. On the other hand, when measured in infants and young children post–PCV administration, serotype-specific anti-IgG concentrations measured by ELISA correlate well with OPA titers in many studies with a few exceptions (e.g., anti-19A ELISA antibodies obtained post–serotype 19F administration may increase considerably, but the respective OPA titers usually will not).

Serologic Correlates

Once an effective vaccine has been licensed and routinely recommended, it is difficult to conduct additional controlled studies to demonstrate the efficacy of new vaccines directed against *S. pneumoniae*. Then, immunologic correlates of protection become critical for predicting the efficacy of new vaccines.[141]

For this purpose, noninferiority of immunologic correlates based on efficacy against IPD was chosen. Establishing noninferiority based on serologic criteria becomes difficult, however, because there is no clear agreement on the concentration of antibody or titer in vaccines that may be used in a noninferiority model to predict whether vaccine is effective.

Pneumococcal disease is multifaceted. IPD is the first outcome against which the PCVs were aimed, and efficacy against IPD is considered the gold standard when calculating or assuming serologic correlates. However, the most common pneumococcal disease outcome is not IPD, but mucosal infections such as pneumonia or otitis media. Furthermore, nasopharyngeal carriage is the main player in pneumococcal spread and development of antibiotic resistance. Even if serologic correlates of efficacy against IPD were established, they would not accurately predict efficacy against mucosal infections. Effectiveness of PCVs is greatly dependent on reduction of carriage and spread; consequently, correlates that predict protection against IPD may not necessarily accurately predict effectiveness.

The first assumption needed to establish a threshold concentration of antibody that predicts protection is that antibody concentration after the primary series will be the reference used to predict protection. The second assumption is that the relationship between risk of disease and antibody concentration is expressed in a stepwise manner rather than as a continuous function. Neither of these assumptions actually holds completely true. The multiplicity of antigens in the current vaccines and the fact that newer formulations contain additional antigens for which no licensed product is available for comparison adds complexity to the decision process.[185]

One proposed possibility for addressing the multiple immunologic end-point comparisons is to assign a weighted average based on the ranking of serotypes by their epidemiologic and clinical significance.[379] This has resulted in a pooled model based on three efficacy studies, the NCKP PCV7 study in the United States,[4] the American Indian PCV7 study,[5] and the PCV9 South Africa study.[7] These three studies showed efficacy of 97.3%, 78.8%, and 90.0%, respectively, and the lowest serologic estimate for PCV7 serotype protection was 0.2, 1.0, and 0.68 μg/mL, respectively. The pooled antibody concentration from these three studies was 0.35 μg/mL.[141,379] A subsequent controlled PCV9 study from The Gambia showed vaccine efficacy of 86% for IPD, with protective antibody estimate of 1.20 μg/mL. The three studies in high-risk populations (American Indians, South Africa, and The Gambia) suggest that such populations may require higher antibody levels to achieve an equivalent protective efficacy against IPD than do Californian infants, or that more antibody is needed to protect against meningitis and pneumonia than is needed to protect from bacteremia without a focus.[141] Variations between laboratories and different analysis caused some disagreement with regard to the pooled antibody concentration cutoff for the protective antibody levels. Thus, some use the value of 0.35 μg/mL, while others use the cutoff value of 0.20 μg/mL.[380] More recently, the indirect cohort method has been used to develop serotype-specific correlates for protection from IPD in England and Wales.[142] This work suggested a correlate of 0.6 μg/mL as an aggregate for the PCV7 types and 0.8 μg/mL as an aggregate for all PCV13 types excluding serotype 3 for which the correlate was 2.8 μg/mL and where the protective effectiveness for serotype 3 was not significant. These data also suggest that correlates of immunity for serotypes 6B and 23F are lower than 0.35 μg/mL, at 0.16 and 0.2 μg/mL respectively. Finally, OPA values varied so much between serotypes that no aggregate correlate of protection using OPA was attempted.

The practical approach for licensure of new PCVs containing additional serotypes beyond the PCV7 is as follows: For the common 7 serotypes, noninferiority is established for each serotype by direct comparison of the response in the new PCV compared with the licensed vaccine. For each of the six additional serotypes in PCV13, the difference in proportions above the cutoff level between the new vaccine and the established vaccine is calculated using the serotypes with the lowest proportion above the cutoff level (usually for serotype 6B) among the established vaccine as the reference group. For each serotype, noninferiority would be described if the lowest boundary of the 95% confidence interval for the difference is greater than −0.10%.[379]

The protective level is best applied to the population rather than individuals; thus, if a high proportion of individuals in a population achieves anticapsular antibody concentrations above the protective threshold, one can predict a high level of protection for IPD in that population. In a particular individual, the outcome of an encounter with the pneumococcus may vary depending on multiple host and pathogen factors.[141]

As stated above, the situation with mucosal infections and carriage is not identical to that of IPD. Several studies suggest that there is a need to achieve higher concentration after primary immunization series to protect against AOM and carriage than against IPD. In AOM, generalized linear modeling has been used to study the association between the antibody concentrations to serotypes 6B, 19F, and 23F and the risk of AOM caused by the homologous serotypes in the 5 months after immunization.[31] The association was most clear-cut for serotype 23F and poorest for serotype 19F. Even low antibody concentrations (GMC 0.5 μg/mL) predicted vaccine efficacy of 50% for serotype 6B, whereas a GMC of 2 μg/mL was required for the same efficacy for serotype 23F. For serotype 19F, the results suggested that much larger concentrations (GMC >10 μg/mL) might be required to achieve protective efficacy. Thus, these results indicate different behavior for different serotypes, discouraging the setting of a unique serologic correlate of protection for all serotypes. In addition, the concentration needed to protect against AOM seems to be higher than the concentration that is protective against IPD.

For protection against carriage, it has been clearly demonstrated, like the case of AOM, that the concentrations needed for protection are higher than those needed for IPD. Furthermore, complete protection may be associated with concentrations higher than those attained after PCV administration with the current vaccines.[32,381] In addition, serotype-to-serotype variation in protection, in relation to achieved antibody concentrations, has been observed.

To date, no studies have been able to demonstrate any correlation of antibody concentrations with protection against pneumonia or nonpneumonia lower respiratory infections. The lower efficacy of PCV13 in adults against vaccine-type nonbacteremic pneumococcal pneumonia than against vaccine-type IPD[18] also suggests that the cutoff of 0.35 μg/mL may be too low to predict efficacy against nonbacteremic pneumococcal pneumonia.

In summary, although correlates of protection were drawn in IPD, and have been used for licensure, many questions still remain. As of this writing, no correlations have been determined for mucosal disease and carriage responsible for most of the *S. pneumoniae* pneumococcal disease burden. Furthermore, post-PCV introduction effectiveness is greatly dependent on indirect protection conferred by reduced carriage and spread of vaccine serotype *S. pneumoniae*, but no correlates predicting such an effect are known. However, it is suggested that if higher functional antibody concentrations are achieved after the primary immunization series, a higher reduction in mucosal disease carriage will take place, resulting in higher and faster population protection through herd immunity.

Mucosal Antibody Response

Although it is generally assumed that host defense at a mucosal site contributes to protection, it has been difficult to determine the relative importance of mucosal antibodies in preventing pneumococcal invasive disease and/or colonization. Nonetheless, analysis of mucosal immunity has been an important focus for the understanding of the protection provided by the conjugate vaccine,[382] and also is being evaluated for protein-based or whole-cell vaccines (see "Human Experiences with Natural or Vaccine-Derived Pneumococcal Protein Antigens" later). These antibody responses can be analyzed either by measuring anticapsular or noncapsular antibodies from mucosal membranes and secretions, or through demonstration of specific antibody-secreting cells (ASCs) in lymphatic tissues or in the peripheral blood.

ELISAs can be applied to mucosal secretions and saliva, but there are two specific challenges. One is the instability of the secretions as there are many degradative enzymes present, especially in saliva. The other challenge is the wide individual variation in the concentration of the samples because of unknown dilutions of the samples. The first challenge can be dealt with through the use of enzyme inhibitors and by storing the samples at −70°C, and the second by relating the concentration of specific antibodies to the total antibody concentration in the sample.

Parenterally administered pneumococcal capsular vaccines, both polysaccharide and conjugate, induce mucosal antibody responses. Serotype-specific salivary antibodies

are found rarely after primary immunization but more frequently after a booster either with the conjugate or with polysaccharide vaccine.[184,204,383–385] The IgG detected in saliva is thought to be derived from the serum, with high serum IgG concentrations transudating into the mucosal secretions and is supported by comparable serum and salivary IgG concentrations.

As B cells are continuously circulating through the lymphatics and blood and back to the peripheral tissues, cells committed to mucosal sites are also present in the peripheral blood for a limited period before homing in to different sites. The appearance of these ASCs can be measured with an enzyme-linked immunospot assay (ELISPOT) in peripheral blood after an antigen challenge, with the magnitude of this response thought to reflect the immune response at mucosal sites.[386–391]

A high number of IgA ASCs detected by ELISPOT is considered to be an indicator of the mucosal IgA response after parenteral pneumococcal vaccination. The response to parenteral protein vaccines is generally dominated by IgG-producing cells,[390] whereas the response to polysaccharide antigens is dominated by IgA-producing cells.[390–392] The IgA/IgG ratio of the ASC response to a polysaccharide that is conjugated to a protein carrier is altered toward a pattern typical of T-cell–dependent antigens.[386,392] For the PPV vaccine, the response is dominated by the IgA ASCs,[388] but after the conjugate vaccines, the IgG ASC responses are higher.[216,389] The ASC responses to the PncT and PncD conjugate vaccines in toddlers are lower than those seen in adults after conjugate vaccine but comparable to those in adults after PPV vaccine. In toddlers, the ASC response is clearly dominated by IgA-secreting cells.[388]

Cellular Responses

The improved immunogenicity of the conjugates compared with the pure polysaccharide vaccines is thought to be caused by the engagement of $CD4^+$ lymphocytes because of the presence of the carrier protein. This cellular response has been evaluated by measuring lymphocyte proliferation and the production of different cytokines (e.g., interferon [IFN]-γ and various interleukins [ILs]) after stimulation with the polysaccharide and protein components of the conjugated vaccines.[346,393] These studies demonstrate, as expected, that conjugate vaccines can induce proliferative and cytokine responses to the carrier proteins but not to the polysaccharide components.

The importance of the cellular component of immunity is well illustrated by animal experiments and more recent human studies. Age-dependent Th2-cytokine responses can be observed in mice immunized with the conjugate; the lack of response to the polysaccharide alone in neonatal mice seems to be associated with absence of carrier-specific IL-5 production. These results suggest that immunization with pneumococcal conjugate induces carrier-specific T-cell responses that increase with age and determine the levels of the antibody response to the polysaccharide component.[394] A randomized controlled trial in Papua New Guinea demonstrated that neonatal immunization with the seven-valent conjugate primes T-cell responses to the protein carrier and polarizes T-cell responses toward Th2.[236]

At the same time, data from humans and animal models have emerged to provide support for the existence of an antibody-independent T-cell response that confers resistance to pneumococcal colonization. In adult patients with chronic obstructive pulmonary disease, naturally acquired and vaccine-induced antibodies to pneumococcal antigens (capsular and noncapsular) do not predict resistance to pneumococcal colonization, suggesting the existence of other mechanisms.[395] In mice, acquired immunity to colonization after mucosal exposure to either live or killed unencapsulated whole-cell pneumococcal vaccine[396] was antibody independent and $CD4^+$ T-cell dependent. Mice that genetically lack antibodies, IFN-γ, or IL-4 maintained whole-cell vaccine-induced immunity to colonization, but mice treated with neutralizing anti-CD4 or genetically lacking the IL-17A receptor were not protected by these exposures. A likely effector cell is the IL-17A–producing $CD4^+$ Th17 cell,[397,398] which was previously implicated in resistance to pathogens such as *Candida albicans*,[399] *Bordetella pertussis*,[400] *Mycobacterium tuberculosis*,[401] and *Staphylococcus aureus*.[402,403] Memory $CD4^+$ Th17 cells are absent in individuals with autosomal dominant hyperimmunoglobulin E (Job) syndrome because of a mutation in the *STAT3* gene.[404] Consistent with murine data, Job syndrome patients are at high risk of candidal, staphylococcal, and pneumococcal infections.[405,406] A proposed mechanism of protection by Th17 cells involves the release of IL-17A, IL-22, and other related cytokines, which help recruit and activate neutrophils to the site of infection, enhancing clearance of the organism.[407] Whether such cellular responses demonstrated in mice also mediate protection to pneumococcal colonization in humans remains to be proven, but it is noteworthy that systemic and mucosal IL-17A responses to pneumococcal antigens have been demonstrated in humans.[397,408]

Schedules

Schedules of PCV are an area of intense debate, and the arguments around selecting them—in terms of immunogenicity; impact on carriage; and effectiveness in prevention of the of IPD, pneumonia, and otitis media—are made under separate headings. The gold standard vaccination schedule of 3+1 (three doses in infancy, generally 2 months apart with a booster in the second year of life) was used in the licensure trials for PCV in the United States.[4,5] A dose-sparing schedule of 2+1 (two infant doses, generally 2 or more months apart with a booster in the second year of life) has been extensively studied for effectiveness. It appears effective in conferring protection, with the caveat that before herd protection is established, there may be a period of increased susceptibility to the less immunogenic serotypes, such as serotype 6B, between 6 and 12 months of age. A variant of 2+1 (two infant doses with a booster at 9 months) has also been proposed to bring it in line with the WHO infant EPI schedule. This could also be considered a variant of the 3+0 schedule that was tested in two large efficacy studies in Africa. In the South African study, three doses were given at 6, 10, and 14 weeks of age, and in The Gambia study, at 2, 4, and 6 months of age because of delays in presentation for vaccination.[6,7] A limitation of the shortened 3+0 schedule for countries with a significant burden of disease caused by serotype 1 is that no evidence of protection was found in the African randomized trials for serotype 1 using this schedule for serotype 1 episodes occurring after 18 months of age.[213] This observation led to the introduction of a 6-week, 14-week, plus 9-month (modified 2+1) schedule in South Africa. Serotype 1 has declined in South Africa (by 57% in infants younger than 2 years of age and by 33% in adults 25–44 years of age) since this schedule was introduced,[17] but given the epidemic nature of serotype 1, confirmatory data of long-term serotype 1 effectiveness using a booster at or after 9 months of age remains under investigation. A systematic review of the data compiled through 2012 on dosing schedules found that, in general, three- and four-dose schedules were comparably effective against carriage, invasive disease, and pneumonia in the setting of an established vaccination program with high coverage rates.[409–411]

EFFICACY AND EFFECTIVENESS

Invasive Disease

Several studies have now examined the efficacy of PCVs in preventing invasive disease. In a double-blind pivotal licensure study conducted in northern California, 37,868 infants were randomized to receive either the PCV or a meningococcus group C conjugate vaccine the control.[4] Study vaccine was given at 2, 4, 6, and 12 to 15 months of age, along with other routine childhood vaccines. The primary outcome measure was the incidence of IPD defined by culture from a sterile site caused by vaccine serotypes. To be included in the main efficacy analysis, invasive disease must have been caused by a vaccine serotype, occurred more than 14 days after the third dose of the vaccine, and occurred in a subject vaccinated according to protocol. Children younger than 16 months were considered to be fully vaccinated if they had received three or more doses of vaccine; children 16 months old or older were considered to be fully vaccinated after receipt of a fourth dose. In addition to the per-protocol analysis, an intention-to-treat (ITT) analysis was performed that included all invasive disease caused by any pneumococcal serotype occurring after randomization, regardless of vaccination status.

In the per-protocol analysis, 40 cases of IPDs were seen in the study population, with 39 in the control group. This represents a vaccine efficacy of 97% (95% confidence interval [CI], 83% to 100%; $P < .0001$; Table 46.8). The one vaccine failure was a child who had received four doses of vaccine, yet developed bacteremic pneumonia caused by serotype 19F. In the ITT analysis, there were 52 cases of vaccine-serotype IPDs, three of which were in vaccinated children, representing a vaccine efficacy of 94%. The three failures included the one described above, a case of serotype 19F disease in a child who developed leukemia after vaccination and was receiving immunosuppressive chemotherapy, and a partially vaccinated child who developed a serotype 6B infection 317 days after a single dose of vaccine. Point estimates of serotype-specific efficacy were obtained for four vaccine serotypes and ranged from 85% for serotype 19F to 100% for serotypes 14, 18C, and 23F.

In this prelicensure study, there was no evidence of an increased risk of disease caused by nonvaccine serotypes. Nine cases of IPDs resulting from nonvaccine serotype were detected, six in the control group and three in vaccinated children. Only one case was caused by a potentially cross-reactive serotype in a vaccinated child. Overall, in an ITT analysis, including disease caused by both vaccine and nonvaccine serotypes, an 89.1% reduction was seen in the burden of IPDs in children who had received at least one dose of conjugate vaccine.

Efficacy of PCV7 also was analyzed separately for the low-birth-weight and preterm infants who had been included in the NCKP study.[271] No difference in mean age of administration of vaccine was seen in the low-birth-weight and preterm infants compared with normal-birth-weight and full-term infants. For low-birth-weight infants who received the control vaccine, the relative risk of IPDs was 2.6 compared with normal-birth-weight infants, and for preterm infants, the relative risk was 1.6 compared with full-term infants. However, no low-birth-weight or preterm recipient of pneumococcal vaccine contracted an IPD, as compared with six low-birth-weight infants and nine preterm infants in the control group.

A community-randomized, controlled efficacy trial of PCV7 was conducted between April 1997 and October 2000 among Navajo and White Mountain Apache children,[55] who had at that time, some of the highest rates of IPD in the world. As in the NCKP study, meningococcal conjugate vaccine was used as a control. A per-protocol analysis was performed of the 5792 children younger than 2 years who were enrolled in the primary efficacy study. Eight cases of vaccine-serotype invasive disease occurred in the control group, compared with two in the PCV7 group, yielding an efficacy of 76.8% (95% CI, –9.4% to 95.1%). In an ITT analysis, 11 cases of vaccine-serotype disease occurred in the control group, compared with two cases in the PCV7 group, for an efficacy of 82.6% (95% CI, 21.4% to 96.1%). This study was stopped early when PCV7 was approved for licensing in the United States, resulting in lower statistical power than planned; however, these efficacy estimates demonstrate that the vaccine provided significant benefit, even in this high-risk population.

The efficacy of PCV9, containing serotypes 1 and 5 in addition to the PCV7 serotypes, was tested in a large randomized, double-blind study in South Africa in children with and without HIV infection.[77] A total of 39,836 children received vaccine or placebo at approximately 6, 10, and 14 weeks of age, and follow-up was continued until 15 cases of vaccine-serotype IPD occurred in fully vaccinated HIV-negative children. The vaccine was highly efficacious in this per-protocol analysis: 13 of the cases were in children who received placebo, and two were in children who received PCV7, for an efficacy of 85% (95% CI, 32% to 98%). The efficacy was similar in an ITT analysis (83%; 95% CI, 39% to 97%; $P = .003$). Efficacy was lower, but still highly significant, against vaccine-serotype IPD in HIV-infected children (65%; 95% CI, 24% to 86%; $P = .006$) and against any IPD in all children (50%; 95% CI,

Data for Philippines from Lucero MG, Nohynek H, Williams G, et al. Efficacy of an 11-valent pneumococcal conjugate vaccine against radiologically confirmed pneumonia among children less than 2 years of age in the Philippines: a randomized, double-blind, placebo-controlled trial. *Pediatr Infect Dis J*. 2009;28:455–462.

Data for Finland from Palmu AA, Jokinen J, Borys D, et al. Effectiveness of the ten-valent pneumococcal *Haemophilus influenzae* protein D conjugate vaccine (PHiD-CV10) against invasive pneumococcal disease: a cluster randomised trial. *Lancet*. 2013;381:214–222.

Data for Latin America from Tregnaghi MW, Sáez-Llorens X, López P, et al. Efficacy of pneumococcal nontypable *Haemophilus influenzae* protein D conjugate vaccine (PHiD-CV) in young Latin American children: A double-blind randomized controlled trial. *PLoS Med*. 2014;11:e1001657.

23% to 68%) and HIV-positive children (53%, 95% CI, 21% to 73%). The incidence of IPD caused by antibiotic-resistant pneumococci also decreased by 56% (95% CI, 21% to 77%). The decrease was most prominent in HIV-infected children, who nonetheless continued to have a higher rate of infection with resistant strains than HIV-negative children. In a further analysis of long-term efficacy after 6.16 years of follow-up, efficacy remained high at 77.8% (95% CI, 34% to 93%) but declined from 65% to 39% among HIV-infected children (95% CI, −8% to 65%). Vaccine efficacy was, however, retained overall against serotype 6A, and this protection was clear even in the HIV-infected children (vaccine efficacy: 79%; 95% CI, 39% to 93%).[334]

The same nine-valent vaccine was evaluated for efficacy against IPD in a large, randomized, double-blind study in The Gambia.[6] Infants between 6 weeks and 1 year of age were given three doses of vaccine or placebo mixed with diphtheria, pertussis, and tetanus DPTHib vaccine; hepatitis B and oral polio vaccines were given concurrently. Vaccine efficacy against any vaccine-serotype IPD was 77% (95% CI, 51% to 90%) and against vaccine-serotype meningitis or sepsis was 92% (95% CI, 44% to 100%). Efficacy against IPD of all serotypes was 50% (95% CI, 21% to 69%), reflecting an absolute reduction of approximately two episodes per 1000 child-years. Although there was a relative reduction in IPD caused by vaccine-related serotypes and a relative increase caused by nonvaccine serotypes, neither difference was significant. In the placebo group, 65% of IPD was caused by the nine vaccine serotypes and 48% by serotypes contained in PCV7.

Efficacy of the PCV10 conjugate vaccine against IPD has been demonstrated in a large, double-blinded, cluster randomized trial in Finland. There were 78 clusters within which 47,369 children younger than 19 months of age were enrolled. Among children younger than 7 months of age at enrollment, the children in 26 control clusters received hepatitis B vaccine as a control; among these children there were 12 cases of IPD caused by vaccine types for an incidence of 56.4 cases of vaccine type IPD per 100,000 children. Among 30,528 vaccinated children in the 52 clusters where PCV10 was given, there were no cases among vaccinees in 26 clusters receiving 3+1 doses and only one case of serotype 7F disease among the 26 clusters receiving a 2+1 schedule at 3, 5, and 12 months. The single failure was just 12 days after the first dose of vaccine. These data translate to a vaccine efficacy of the 3+1 schedule of 100% (95% CI, 83% to 100%). The efficacy of the 2+1 schedule was 92% in the ITT analysis (95% CI, 58% to 100%).[412]

Pneumonia and Other Respiratory Infections

Several of the IPD studies also examined vaccine efficacy against pneumonia (see Table 46.8). In the NCKP trial, pneumonia was a secondary outcome measure. Cases of pneumonia were identified by the presence in the NCKP database of a diagnosis of pneumonia, "bronchopneumonia," or "viral pneumonia" by the treating physician in the outpatient, emergency room, or hospital where the patient was seen. Based on the interpretations of radiologists at the point of care, the conjugate vaccine was found to significantly reduce the number of episodes of pneumonia in which there was a positive chest film to 8.3 per 1000 person-years, for an estimated efficacy of 17.7% (95% CI, 4.8 to 28.9; $P = .01$).[59] Radiographs obtained for this study were then reevaluated using the criteria established by the WHO in 2001 for interpreting chest radiographs, which are intended to standardize radiologic diagnoses for epidemiologic purposes.[413] Of the 2841 original sets of radiographs, 2446 were digitized and analyzed according to the WHO criteria. The standardization increased the vaccine efficacy estimate to 25.5% (95% CI, 6.5% to 40.7%; $P = .011$).[8]

In the South African trial of PCV9,[77] the efficacy of the vaccine in reducing radiographically defined pneumonia was a primary end point and was 20% (95% CI, 2% to 25%; $P = .03$) in the ITT analysis and 25% in fully immunized children without HIV infection (95% CI, 4% to 41%). This reduction was in addition to any protection afforded by the Hib vaccine, which was provided to all subjects. The vaccine efficacy did not reach statistical significance in children infected with HIV (13%; 95% CI, −7% to 29%; $P = .19$), but subsequent secondary analyses showed that only 39% of the pneumonia prevented by the vaccine among HIV infected children was included in the radiographically defined end point. In an ITT analysis of clinical pneumonia, excluding bronchiolitis, vaccine efficacy among HIV-infected children remained at 15%, but because of the larger number of children meeting this definition (379 vaccinees vs 446 control subjects), the difference was significant (95% CI, 5% to 24%; $P = .004$).[414]

Pneumonia was also a primary outcome measure of the Gambian PCV9 trial.[6] It was defined radiographically as the presence of a dense or fluffy opacity that occupied some or all the lung, presence of fluid in the lateral pleural space, or both and defined clinically as a history of cough or breathing difficulty of less than 14 days' duration, with a raised respiratory rate or chest-wall in-drawing. Overall, the vaccine reduced first episodes of radiologic pneumonia by 37% (95% CI, 27% to 45%) and reduced first episodes of clinical pneumonia by 7% (95% CI, 1% to 12%). The absolute reduction in radiographic pneumonia was 15 cases (95% CI, 10% to 19%) per 1000 child-years in the per-protocol analysis, which was more than seven times higher than the absolute reduction in IPD (≈2 per 1000 child-years), indicating a high burden of preventable pneumonia. In addition, the vaccine resulted in a 16% reduction in mortality in young children, suggesting that pneumococcal pneumonia and bacteremia contribute to a substantial number of deaths.

PCV9 has also been shown to reduce respiratory infections other than pneumonia. In a study of children 12 to 35 months old attending daycare in Israel,[415] vaccinated children had a relative risk of upper respiratory infection, including rhinorrhea, pharyngitis, and sinusitis, of 0.85 (95% CI, 0.76–0.96; $P = .009$) and of lower respiratory infection, including bronchitis, cough, and asthma as well as pneumonia, of 0.84 (95% CI, 0.72–0.98; $P = .024$). The effectiveness of the vaccine in preventing these infections indicates that *S. pneumoniae* plays a role in diseases more commonly associated with viral infection. This role has been supported by evidence from the large South African efficacy trial[416,417] in which vaccination with PCV9 significantly lowered the risk of confirmed viral pneumonia by 22% to 58%, depending on the causative virus, presumably because pneumococcal coinfection contributes to the pathogenesis of a large proportion of pneumonias thought to be viral. The vaccine prevented 45% of confirmed hospitalizations caused by influenza,[416] which suggests a potential role for PCV in protection from pandemic influenza, in which postinfluenza pneumococcal mortality may be significant.[418] A similar reduction (48%; 95% CI 1% to 76%) in hospitalization associated with the 2009 pandemic influenza was found in PCV7 recipients in a case-control study of PCV7 effectiveness from Spain. In the following season during which extensive herd protection would be expected, there was no further evidence of PCV7 effectiveness against influenza hospitalization.[419] Another secondary analysis of the South African trial data suggested that children with culture-confirmed tuberculosis may also be at increased risk of pneumococcal pneumonia, which was also prevented by the PCV9 vaccine.[420]

In the only randomized trial to date of pneumococcal conjugate vaccination in Asia, an 11-valent Sanofi Pasteur investigational vaccine conjugated to tetanus and DT, which has not been licensed, was compared with placebo in 12,191 children in Bohol, Philippines. The vaccine efficacy against radiologically confirmed pneumonia in fully immunized children (three doses at least 1 month apart between 6 weeks and 6 months of age) was 23% (95% CI, −1% to 41%; $P = .06$). Significant protection was seen in the first year of life (34%; 95% CI, 5% to 54%; $P = .02$) but not the second year (3%; 95% CI, −44% to 34%; $P = .88$).[9] A secondary spatial analysis of that study showed increasing vaccine efficacy from −14% (−13% to 38%) to 55% (11% to 79%) as the distance of the child from the primary hospital increased from less than 1.5 km to greater than 8.5 km, suggesting that less access to healthcare increases the fraction of X-ray–confirmed pneumonia attributable to the pneumococcus, and that ensuring good PCV coverage in areas with poor access to care may maximize program benefits.[421]

The PCV10 vaccine conjugated to protein D was evaluated in a clinical trial in Argentina, Colombia, and Panama, and demonstrated vaccine efficacy against the WHO-confirmed definition of pneumonia[413] in the ITT analysis of 23.4% (95% CI, 9% to 36%) and 26% (95% CI, 8% to 40%) in the fully immunized cohort.[11]

Acute Otitis Media

S. pneumoniae, together with nontypeable *H. influenzae* (NTHi), is the most commonly reported bacterial pathogens in AOM. *S. pneumoniae* is isolated from the middle ear fluid in 20% to 60% of patients.[51,52,422] By choosing seven to 13 common serotypes, approximately 50% to greater than 90% of the AOM pneumococcal serotype isolates could be covered.[422] Thus in theory, pneumococcal vaccines could cover between 10% and greater than 50% of all cases of AOM. However, several sometimes contradictory factors play a role in the overall effectiveness of PCV against AOM.

Large-scale efficacy trials of PCV were conducted in three sites, each with different designs, and thus not comparable for many outcomes. One trial using PCV7-CRM conjugate was conducted in the NCKP Health Services.[4,423] The second was conducted in Finland (the FinOM study) with two vaccines: PCV7-CRM and PCV7-OMPC.[13,194] The third was conducted in the Czech Republic, using PCV11–protein D vaccine (PCV11; PHiD-CV) (the Pneumococcal Otitis Efficacy Trial [POET] study).[12] All three studies were double-blinded, randomized, controlled studies, with an arm that did not receive any PCV. In all three studies, healthy infants in the PCV arms received three PCV doses during the first 6 months of life and a booster early in the second year of life (2, 4, 6, and 12 months or 2, 4, 5, and 12 to 15 months of age).

In the NCKP trial, infants were followed between 8 months and 3.5 years of age. Although the trial was not primarily intended to look at AOM, computerized data on AOM visits could be retrieved to assess the effect of PCV7-CRM on AOM visits. In contrast, the FinOM and POET studies were designed primarily to determine the effect of PCV on AOM. In the FinOM study, the children were followed up to age 24 months, and diagnosis of AOM was standardized as follows: AOM was defined by the presence of a tympanic membrane that was visibly abnormal in terms of color, position, or mobility, suggesting middle-ear effusion; plus at least one of the following symptoms or signs of acute infection: fever, earache, irritability, diarrhea, vomiting, acute otorrhea not caused by otitis externa, and other symptoms of respiratory infection. The FinOM study was somewhat complex because one arm received PCV7-CRM, another arm received PCV7-OMPC, and a third arm received no PCV (the control arm). Furthermore, the PCV7-OMPC arm was further randomized after three PCV7-OMPC doses to receive either a fourth PCV7-OMPC or a 23-valent polysaccharide vaccine (PS-23) dose as a booster.[13,194] In the POET study, follow-up continued until age 24 to 27 months. In this study, the diagnosis of AOM was standardized, but the follow-up in the POET study was passive because parents were advised to consult their pediatrician if the child was sick, had ear pain, or had spontaneous ear discharge. Furthermore, the trigger to be defined as a case was performance of a tympanocentesis after the child was referred to the otolaryngologist. Thus, the study population in the POET study was enriched with complex, severe, recurrent, or nonresponsive otitis media (OM). This point is important, as complex OM is a more advanced and a late-stage form of OM that cannot be compared to AOM. In contrast, the studies in California and Finland included all OM cases and most were uncomplicated. Therefore, the POET study cannot be directly compared with the two others.[424]

The NCKP and FinOM studies suggested that PCV7-CRM could reduce overall AOM by 6% (95% CI, −4% to 16%) to 7% (95% CI, 4% to 9%) (Table 46.9). In contrast, the PCV7-OMPC did not show any reduction in overall AOM.

The POET study, which was enriched with complex OM cases, showed an overall reduction of 34% in AOM episodes. The reduction in AOM caused by vaccine serotypes, determined by tympanocentesis or culture of spontaneous ear drainage, was quite similar among all three studies, ranging between 56% and 67%. PCV7-CRM vaccine also reduced the cross-reactive serotype 6A, whereas the PCV7-OMPC did not show any cross-protection, and PCV11 was not conclusive. In the FinOM study, the administration of both PCV7-CRM and PCV7-OMPC was associated with a higher occurrence of AOM caused by nonvaccine pneumococcal serotypes, *Moraxella catarrhalis* and *H. influenzae*. This was not the case in the POET study, where AOM caused by NTHi decreased by 35% and nonvaccine pneumococcal type did not increase.[12] In recurrent OM, PCV7-CRM had an efficacy of ≈9%,[4,13] while in the NCKP study there was a more marked reduction of 20.1% (95% CI, 1.5–34.2)[4] and in the FinOM study there was a 39% reduction[425] in frequent recurrences. The greatest impact of PCV7-CRM was seen on chronic middle ear effusion, a form of chronic OM, necessitating insertion of ventilation tubes.[379] Furthermore in a follow-up study,[426] the effectiveness of PCV7-CRM and PCV7-OMPC in reducing tympanostomy tube placement in patients 2 to 13 years of age was assessed. PCV-CRM showed a 34% reduction in tube placement (95% CI, 1% to 52%) versus only a 6% reduction (95% CI, −28% to 31%) for PCV7-OMPC. After age 5 years, none of the vaccines showed any more impact but the benefits achieved by the PCV7-CRM were sustained up to age 13 years. The PCV11–protein D showed an efficacy of 56% against all-case recurrent AOM, but this finding was not statistically significant because of insufficient sample size. Whether the results of the POET study that included reduction of *H. influenzae* cases of OM, culture-negative cases, and recurrent cases were different than those of other studies because of the use of a PCV conjugated to *H. influenzae* protein D or because of a different study design, potentially capturing more chronic cases, was not clear. The PCV11–protein D vaccine did not protect against OM caused by serotype 3, and this was the reason behind changing the formulation of the protein D conjugate vaccine to contain only 10 instead of 11 serotypes. More recently, the efficacy of the PCV10 vaccine (similar to PCV11, but with two serotypes conjugated to CRM_{197} and absence of serotype 3 antigen) was studied in Panama.[11] This double-blind, placebo-controlled study suffered from several methodological problems, such as the very small outcome events available for analysis, the

TABLE 46.9 Double-Blinded Efficacy Studies Against Acute Otitis Media Before the Introduction of Vaccine to Widespread Use

AOM, acute otitis media; CI, confidence interval; CRM, protein carrier in conjugate vaccine; ITT, intention to treat; ND, not determined; PCV, pneumococcal conjugate vaccine; PP, per protocol; Ref, reference; OMP, outer membrane protein.

relatively late age of onset of the OM cases, and the relatively higher proportion of culture-negative events, which suggest, like the POET study, a higher proportion of complex OM cases. In the context of these limitations, the study demonstrated that PCV10 was efficacious against pneumococcal (vaccine efficacy 56% [95% CI, 22% to 75%]) and overall AOM (vaccine efficacy 19% [95% CI, 4% to 31%]), probably mainly complex cases, on the same order of magnitude as PCV11.

An additional trial was conducted in an underprivileged and somewhat more compromised population in the United States, the Navajo and White Mountain Apache population.[427] In this double-blind study, infants were randomized to receive either PCV7-CRM or meningococcus C-CRM vaccine. The methodology of the study did not allow it to reach statistically significant conclusions, but its findings support those of the three larger-scale studies conducted with PCV7-CRM described above. The ITT efficacy findings were: overall OM, −3.3% (95% CI, −21.4 to 12.0); number of medical visits resulting from severe episodes, 13.7% (95% CI, −3.4 to 49.5); and ventilation tube insertion, 22.2% (95% CI, −215.7 to 83.0). Thus, although not statistically significant, the trend toward higher efficacy with more complex outcomes was seen in this study, as in the previously described studies. Furthermore, when cultures were taken from spontaneously draining ears, 11 isolates were of vaccine-type (VT) serotypes, eight of which were in the control group (64% efficacy, 95% CI, −34% to 90%), similar to previously observed findings. Thus, when combined these five studies suggest only moderate efficacy against all-cause OM cases, and higher efficacy against more-complex OM.

Another relatively small study in Sweden lends support to this notion. Ninety-six children with AOM occurring before 6 months of age (implying high risk of recurrent OM and complex OM) were assessed.[428] The subjects were randomized in a nonblinded manner to receive either PCV7 ($n = 46$) or no vaccine ($n = 50$). The children were followed up closely. A total of 363 OM episodes were recorded. In PCV7 vaccinated subjects, the incidence of OM was reduced by 26% ($P = .03$), emergency visits resulting from suspected OM were reduced by 36% ($P = .01$), and the proportion of children needing ventilation tube placement dropped by 50% ($P = .02$). These findings support the above described greater efficacy of PCV7 against complex and chronic OM versus simple AOM.

Three prelicensure efficacy trials were conducted in toddlers. The first was a double-blind, randomized study in healthy Israeli daycare center toddler attendees who received PCV9 or meningococcus C–CRM vaccine (two doses for toddlers 12–17 months old and one dose for toddlers 18–35 months old). The children had approximately 18 encounters per child during the successive 2 years (monthly visits in first year and bimonthly visits the year after).[14] In addition, the parents responded to a questionnaire that included data on respiratory infections, as well as AOM episodes. Although the AOM diagnosis was not confirmed by study physicians and not standardized, the double-blind approach permitted a comparison between the two arms. There was a 17% reduction (95% CI, −2% to 33%; $P = .078$) in the number of episodes in the PCV9 recipients and a reduction of 20% (95% CI, 14% to 26%; $P < .001$) in the length of time the children were on antibiotic treatment for AOM.[415] Two additional studies were conducted in The Netherlands and in Belgium in toddlers and young children (1–7 years of age) with a history of two or more AOM episodes in the year before enrollment (i.e., children with established complex OM before enrollment).[429,430] The children were randomized in a double-blind manner to receive either PCV7-CRM (two doses in children 1–2 years old and one dose in children 3–7 years old, followed by PPV23 6–7 months later) or hepatitis A and B vaccines. The children were followed for 24 weeks by the family physicians or specialists, when symptomatic. In both studies, PCV7-CRM did not reduce overall AOM cases, despite the reduction seen in pneumococcal AOM.[429] In the Dutch study, there was a reduction of 33%, with a 56% reduction in vaccine serotypes and a 17% reduction in nonvaccine serotypes. However, none of these values were statistically significant, probably because of the small numbers. The findings from the three studies on toddlers suggested that PCVs are effective in toddlers, especially in those with higher risk conditions such as daycare attendance, but when a recurrent AOM is already established, PCVs may not be effective against disease, or even against development of effusion.[431]

A single trial of PCV9 administration to pregnant women at 30 to 35 weeks gestation was designed to prevent clinical visits for OM in their infants during the first 6 months of life. Infants also received PCV7 at 2, 4, and 6 months. As mentioned above, the immunogenicity of PCV7 was reduced in these infants, and while 89% of infants in the placebo group were free of clinically diagnosed AOM by 6 months of life, only 74% of the infants of vaccinees remained free of the diagnosis by 6 months of age ($P = .03$). There was thus an excess of OM associated with maternal PCV which was ascribed by the authors to the lower immunogenicity of PCV given to the infants of mothers who received maternal PCV compared to the controls, who also got PCV7 but whose mothers did not get PCV9.[278]

It is not easy to assess the reduction of AOM burden once PCVs are implemented, for several reasons. First, pneumococci are not the only pathogens in OM and, in most cases, tympanocentesis is not performed, and thus the contribution of the pneumococcal component to the overall OM reduction cannot be assessed. Second, AOM is difficult to diagnose with the current skills of many practicing physicians, and overdiagnosis, as well as underdiagnosis, are common. Third, because tympanocentesis is not accepted as a routine procedure in most practices, it is often performed in selected cases (i.e., nonresponsive OM or complex OM). On the other hand, the indirect protection through reduction in vaccine serotype carriage (herd protection) may positively impact disease reduction because reduction of circulation of VT serotypes in the community means reduced early exposure of VT serotypes, resulting in protection against diseases even in the nonvaccinated infants who have not yet reached the age of PCV vaccination.[432,433] Preventing early otitis potentially reduces the resulting recurrent and complex OM.[434]

Because AOM may be mild or even asymptomatic and its diagnosis is difficult, assessing true OM incidence after vaccine implementation is impractical. Therefore, studies on post-PCV implementation impact of OM almost exclusively examined complex cases of OM (recurrent, nonresponsive, spontaneously draining or chronic representing mostly sequelae of AOM), or simply measured visits resulting from OM or OM-related morbidity (e.g., otolaryngologist visits, ventilation tube insertion, hearing tests) that are easier to detect. As described above, in this context, it is important to remember that in the prelicensure studies, the efficacy/effectiveness of PCV against complex and chronic OM (more likely to be captured by post-PCV surveillance than all-cause AOM), ranged from approximately 10% to 39% of all-case OM, representing a significantly higher efficacy than that against overall OM incidence (ranging from −1% to 7%).

Several studies looking at OM after PCV7 implementation reported reduced proportions of VT serotypes, increased proportions of non-VT serotypes, increased nonpneumococci organisms (i.e., *H. influenzae* and *M. catarrhalis*), and reduced antibiotic-resistant pneumococci.[51,435–439] However, because

these increased proportions could also be observed because of reduced proportions of VT pneumococci, the studies could not appropriately document the true vaccine effect on OM incidence.[438,439] On the other hand, a nationwide study in the United States showed that by 2002–03 (2–3 years post–PCV7-CRM introduction), rates of OM-related outpatient visits of children younger than age 2 years had decreased by 20%.[440,441] For some high-risk populations, such as the American Indians and Alaska natives, the figures were a bit more confusing.[331] When complex otitis was measured in the United States, most studies showed a significant reduction compared to the pre-vaccination era, although with wide variability. One study found a 17% and 28% decline in frequent OM in two birth cohorts from Tennessee and upstate New York shortly after PCV7-CRM introduction.[442] A study made up of more than 500,000 person-years of children younger than 2 years of age found reductions of 42.7% and 41.9% in ambulatory visits related to OM and antibiotic-prescribing related to this entity, respectively.[443]

PCV7 was introduced in other countries a few years later than in the United States, but results from the other countries support the post-PCV7 implementation findings from the United States. In Canada, a 13.2% reduction in claims for OM attributable to PCV7 was reported 3 years after implementation of PCV7 in children younger than age 5 years.[444] In Italy, PCV7 was implemented in the Liguria administrative region in 2003, with a claimed 38% reduction in hospitalizations associated with AOM in children younger than 2 years.[445] In Australia, in the 2.5 years after routine PCV7 introduction, a significant adjusted reduction in myringotomy with ventilation tubes insertion was seen in 23%, 16%, and 6% of children (the CIs were not reported) younger than 1, 1, and 2 years of age, respectively.[446] In France, carriage of PCV7 serotypes during OM (an indirect measure of PCV7 impact on OM) was reduced by 16% and 35% in year 1 and year 3, respectively, after PCV7 introduction.[439] In Greece, in years 3 to 5 after PCV7 introduction, overall rates of otorrhea visits per 10,000 pediatric emergency room visits decreased by 38%, mainly as a result of the decline in pneumococcal cases (48%), all results being significant at less than 0.001.[447] A study including children participating in the Norwegian mother and child cohort study, recruiting pregnant women between 1999 and 2008 and using maternal reports of AOM among others, showed an adjusted relative risk for OM of 0.86 (95% CI, 0.81 to 0.91) for children who received three or more PCV7 doses by 12 months of age.[448] Between 12 and 18 months of age the relative risk for AOM was 0.86 (95% CI, 0.81 to 0.91), and for ages 18 to 36 months, it was 0.92 (95% CI, 0.90 to 0.94). Thus, there is growing evidence that widespread implementation of PCV7 reduced AOM disease burden, at least in developed country populations.

Despite the apparent success of PCV7, there were several outstanding problems and uncertainty with this vaccine. First, the extent of replacement disease was not determined in OM. Numerous reports pointed to at least two serotypes that have been important in OM, even before PCV7 implementation and which became dominant postimplementation: serotypes 19A and 3.[422,432,433,435,438,449–451] Furthermore, serotype 19A became more multidrug resistant during the decade of PCV7 use. It seems plausible that serotype 19A increased substantially because of dual pressure. The first was "vaccine pressure" by PCV7, by reducing competition of 19A with PCV7 serotypes, and the second was "antibiotic pressure" promoting the spread of resistant and multiresistant serotype 19A. These conditions, coupled with the relative high virulence of serotype 19A, made it one of the most prominent causes of OM after PCV7 introduction (and especially complex OM and its complications, in particular mastoiditis).[432,433,438,449,451–457]

PCV7 was replaced by the more extended-spectrum PCV13. The importance of the latter to OM was that it contained three additional serotypes that are common in OM (serotypes 3, 6A and 19A). Serotypes 6A and 19A were the most common in OM after the PCV7 effect, although serotype 6A was reduced but not eliminated by PCV7. In addition, these serotypes are commonly antibiotic multiresistant. The following studies from the United States, France, and Israel demonstrated the additional effect of PCV13 beyond that of PCV7.

A study assessed trends in OM-related healthcare use in children younger than 6 years old in the United States during the PCV era (2001–2011) by analyzing claims in a large managed healthcare plan.[458] An overall downward trend in OM-related cases from 2001 to 2011 was observed. The significant reduction in visit rates in 2010–2011 in children younger than 2 years old coincided with the uptake of PCV13. These early post-PCV13 promising results were supported by findings from France,[459] where pneumococcal carriage during OM episodes (as an indirect measure of pneumococcal OM effect) was determined. The study was conducted during the transition between PCV7 and PCV13 (October 2010 through March 2011) by 58 pediatricians who obtained 943 nasopharyngeal cultures in children 2 to 24 months old. Of these children, 69% received one or more PCV13 doses. Among PCV13 recipients, overall pneumococcal carriage and carriage of the additional PCV13 serotypes was lower than that in PCV7 recipients (54% vs 65%, respectively, $P = .002$; and 10% vs 21.1%, respectively, $P < .001$). Significantly lower carriage was found for single serotypes 19A, 7F, and 6C (cross-reacting with 6A in PCV13). A third population-based prospective study in Israel[460] assessed children, mainly with complex OM, using middle ear fluid cultures. The unique study design permitted longitudinal assessment of the population-based incidence of the various conditions studied. The study, initiated 5 years before PCV7 (2004–08) introduction, described the initial impact of PCV7 (2010–11) and then the PCV13 impact (2012–13) on overall OM, pneumococcal OM, and serotype-specific pneumococcal OM. Compared to the pre-PCV period, OM caused by PCV7 serotypes +6A decreased by 73%, but this was associated with an increase in the additional PCV13 serotypes (1, 3, 5, 7F, and 19A) by 25% ($P < .001$). However, after introduction of PCV13, compared to pre-PCV period, rates of PCV7+6A and additional PCV13 diseases dropped by 96% and 85%, respectively ($P < .001$). The overall pneumococcal OM rates decreased by 31% during the PCV7 period, and then during the PCV13 period there was a 77% decrease ($P < .001$). The respective figures for the reduction in all-cause OM with middle ear fluid culture was 60% ($P < .001$).[460,461] As early post–PCV13 introduction data accumulated, it became clear that PCV13 added significantly to PCV7 in the impact on OM, especially when complex OM was measured.

As mentioned previously in the chapter, the efficacy of PCVs against simple, AOM is significantly lower than that against complex OM, expressed as recurrent/nonresponsive, spontaneously draining, and chronic OM (measured by the impact on ventilation tube insertion). The current understanding it that early occurring OM is most often caused by *S. pneumoniae*, whereas complex OM, especially in its more chronic manifestation, is not simply pneumococcal, but rather a mixed infection, expressed as a biofilm, with NTHi as the main pathogen.[462,463] This might explain why early vaccination with PCVs successfully reduces occurrence of complex OM, including chronic manifestations, which are only rarely caused by VT serotype,[462] through prevention of early *S. pneumoniae* disease leading to secondary infections, where NTHi and potentially other bacteria outnumber *S. pneumoniae*. The studies from The Netherlands and Belgium[429,431] showing that after recurrent OM is already established PCV7 could not

reduce further diseases, lend support to this notion. Also, the success of the protein-D conjugated PCV11 (POET study)[12] against *H. influenzae* otitis might be explained by the high likelihood that most captured children probably had complex OM that might have been prevented by early vaccination and prevention of the primary pneumococcal infections. Recent post PCV7 introduction observations also support this notion. In Greece, visits to clinics because of spontaneously draining ears were measured (rates per 10,000 all-culture visits).[447] The pre-PCV7 (2000–03) and post-PCV7 (2005–08) years were compared. The reduction in all-cause OM was 38% and 48% in *S. pneumoniae* OM, with *H. influenzae* cases also reduced by 20% (all $P < .001$).

In southern Israel, a population-based, prospective, observational study compared rates of OM episodes for which middle ear fluid was obtained in the pre-PCV period (2004–08) to that after PCV7 and PCV13 introduction.[460,461] In the fourth year after PCV7 introduction (and 2.5 years after it was replaced by PCV13), the incidence reductions were: overall OM, 60% (95% CI, 55% to 64%); PCV13 serotype OM, 93% (95% CI, 55% to 64%); non-PCV7 vaccine serotype, 14% (95% CI, –41% to 11%); all-pneumococcal OM, 77% (95% CI, 70% to 82%); NTHi OM, 63% (95% CI, 55% to 64%); and culture-negative OM 48% (95% CI, 36% to 57%). Although these are observational studies comparing pre- and postvaccine introduction, they strongly support the notion that early pneumococcal vaccination, by reducing early pneumococcal OM, prevents all-cause complex OM, including those caused by organisms beyond VT serotype pneumococci. Longer follow-up and more observations are needed to confirm these important early findings.

Effect on Carriage

Direct Effect of PCVs on Colonization

The first study demonstrating that PCV could reduce colonization of the serotypes included in the vaccine was conducted in Israel and published in 1996.[464] In this study, one and two doses of PCV-OMPC7 were compared with a single PPV23 dose in toddlers 12, 15, or 18 months of age. The PPV23 group did not have any effect on carriage; in contrast there was a marked reduction in carriage in the group receiving PCV-OMPC7, which persisted for 1 year. However, at the same time an increase in carriage of serotypes not included in the vaccine (non-VT serotypes) was observed. This study and similar observations from The Gambia[465] led to the assumption that PCVs can reduce carriage of VT serotypes and may increase the carriage of non-VT serotype (replacement phenomenon). The study also supported previous observations that nonconjugate polysaccharide vaccines are incapable of reducing carriage.[466] Further clinical trials confirmed that observation, using a variety of conjugates, age groups, locations, and schedules. Table 46.10 summarizes some representative early studies.[254,265,465,467,468] The overall pattern to be observed in these studies was a reduction in VT carriage, sometimes seen only after the booster dose, and an increase in the carriage of non-VT, so that the overall carriage rate did not change significantly or was slightly reduced.

Several trials were conducted in toddlers in the 1990s using either PCV7 or PCV9. In a series of studies in daycare center attendees in Israel,[32,469,470] a reduction in both acquisition and prevalence of VT (and serotype 6A) serotypes were seen in PCV9 recipients, compared with control subjects (receiving meningococcus C–CRM vaccines). At the same time, a marked increase of prevalence and acquisition of non-VT serotypes was also observed. No effect on duration of carriage was seen. The effect of the vaccine on carriage persisted for the duration of the follow-up (2 years). Serotype-specific protection against increased carriage of serotypes 6A, 6B, 9V, 14, and 23F was demonstrated.[32] In The Netherlands and Belgium,[429,430] PCV7, followed by a PPV23 booster, administered to children 1 to 7 years old with recurrent AOM, resulted in a marked reduction of VT carriage with an increase in non-VT carriage.

One study from Israel assessed the potential additional reduction of carriage by PCV13 as compared with PCV7.[471] In this randomized, double-blinded study, 881 children received PCV13 and 873 received PCV7 (per-protocol analysis) at ages 2, 4, 6, and 12 months, and nasopharyngeal cultures were obtained at ages 2, 4, 6, 7 12, 13, 18, and 24 months. Blood was drawn at ages 7 and 12 months. There was a 43% (95% CI, 44% to 51%) reduction in the cumulative acquisition of the additional PCV13 serotypes, combined (1, 3, 5, 6A/6C, 7F, or 19A): 21.8% versus 38.4% in the PCV7 versus PCV13 group, respectively. Serotype 5 was not prevalent enough for evaluation, and for serotype 3 no reduction was observed. Similar findings were seen when prevalence of carriage was assessed. For the common PCV7/PCV13 serotypes excluding 19F, no significant difference in carriage between the two groups was found. Thus, PCV13 showed an added benefit in reducing carriage of VT pneumococci in vaccine recipients.

An important point is to determine whether postvaccination antibody concentrations (serotype-specific) correlate with acquisition of VT nasopharyngeal carriage. Two studies, conducted in Israeli toddlers with PCV9[27] and in American Indian infants and toddlers with PCV7[343] showed an inverse correlation between serotype-specific anticapsular IgG and the risk for nasopharyngeal acquisition of the corresponding pneumococcal serotypes. As part of the analysis of a study comparing PCV13 with PCV7 on the effect on pneumococcal carriage,[462] an additional analysis was conducted on 1410 to 1530 serum samples to investigate the potential correlation between nasopharyngeal acquisition and serum IgG concentrations.[461] PCV7/PCV13 was given at ages 2, 4, 6, and 12 months. IgG concentrations were measured after dose 3 and nasopharyngeal cultures were obtained at ages 7, 12, 13, 18, and 24 months. New acquisition rates decreased as IgG concentrations increased for all studied serotypes ($P < .001$ for 6A, 14, 23 F; $P = .010$ for 6B; $P = .089$ for 19F). For example, for serotype 6B, the calculated proportion of children who will acquire this serotype before age 2 years, if the antibody concentration was 0.35 μg/mL was 9.1% (95% CI, 6.4% to 12.8%); the respective figures for 2.54 μg/mL (50th antibody percentile) and 10.15 μg/mL (90th antibody percentile), were 5.8% (95% CI, 4.7% to 7.2%) and 4.2% (95% CI, 2.9% to 10.2%). The respective figures for serotype 19F for 0.35 μg/mL 50th antibody percentile (2.74 μg/mL) and 90th antibody percentile (7.37 μg/mL) were carriage in 14.0% (95% CI, 9.4% to 20.3%), 10.0% (95% CI, 8.6% to 11.7%), and 8.5% (95% CI, 6.5% to 11.0%). In this study, two populations were enrolled—Bedouin and Jewish infants. The Bedouin infants had significantly higher carriage rates than the Jewish infants, but the immune responses were similar across ethnic groups and the decreased acquisition rates of the studied serotypes by increasing IgG concentrations with each group were similar across the ethnic groups for most serotypes. Thus, the efficacy against acquisition and carriage of VT-serotype pneumococci inversely correlated with the serotype-specific antipolysaccharide antibody concentrations achieved by PCV administration.

Recently, because of the desire to reduce the number of PCV doses in various universal programs, the potential effect of a lower number of doses (compared with the gold standard of three doses in infancy and one booster dose in the second

NS, not significant; PnTT4, tetravalent PCV (6B, 14, 19F, 23F) conjugated to tetanus toxoid; PnDT4, tetravalent PCV (6B, 14, 19F, 23F) conjugated to diphtheria toxoid; PCV-CRM5, pentavalent PCV (6B, 14, 18C, 19F, 23F) conjugated to CRM_{197}; VT, vaccine type.

year) raised some concerns because of the correlation between postvaccination antibody concentrations and acquisition and carriage of VT serotypes. Several studies were conducted to evaluate this question.[246,409] Four studies with head-to-head comparisons of reduced versus standard dosing regimens were conducted. A study, conducted in Fiji, compared zero doses to one, two, and three PCV7 doses (given at 6 weeks, 6 and 14 or 6, 10, and 14, respectively), with and without a PPV23 booster at 12 months.[472] A significant difference in VT-carriage prevalence between the two- and three-dose groups at 9 months was found: the three-dose group had significantly lower VT carriage (odds ratio [OR] 0.30; 95% CI, 0.09 to 0.9). At 6, 12, and 17 months of age, VT carriage among the two- and three-dose groups was not significantly different. The PPV23 booster did not have any impact on VT carriage measured at age 17 months. Another study, conducted in The Gambia, compared one, two, and three PCV7 doses (given at 2 months; at 2 and 3 months; and at 2, 3, and 4 months); all children received a PPV23 booster at 10 months.[473] At 11 months, the group receiving three PCV7 doses showed a borderline significant reduction in VT carriage compared with the group receiving two PCV7 doses (10.0% vs 16.7%, $P = .056$). However, at 5 and 15 months, the VT-carriage prevalence was not significantly different among children who received two or three doses. The third study, conducted in Israel with PCV7, compared a 3+1 schedule (2, 4, 6, and 12 months) with 2+1 schedule (4, 6, and 12 months), a 0+2 schedule (12 and 18 months), and a 3+0 schedule (2, 4, and 6 months).[474,475] Between 7 and 12 months of age (prebooster), the mean VT prevalence was nonsignificantly lower in the 3+1 group when compared with the 2+1 group (22.6% vs 28.4%, $P = .089$). The 0+2 group between 7 and 12 months, before children were vaccinated, had a mean VT prevalence of 35.2%, which was significantly higher than prevalence in the 3+1 group ($P < .001$). Between 13 and 18 months (i.e., after the booster dose) and between 19 and 30 months, the 3+1 and 2+1 groups had equivalent VT prevalence, but both groups had significantly lower VT prevalence than the 0+2 group. When the 3+1 and the 3+0 schedules were compared, at 13 months, all GMCs were significantly lower in the 3+0 compared to 3+1 ($P < .001$). During the first year of life, carriage of VT serotypes was similar in the two groups, but lower than in unvaccinated controls ($P < .001$) (0+2 who received the final dose at 12 months of age). From age 12 months to 30 months, despite the absence of booster in the 3+0 group and the significantly higher GMCs in the 3+1 group, no differences in carriage rates were seen between the groups. A fourth study, conducted in The Netherlands, compared children who received PCV7 at 2 and 4 months (2+0), at 2, 4, and 11 months (2+1), and unvaccinated controls.[475,476] At 12, 18, and 24 months of age, children in the 2+0 and 2+1 groups had significantly less VT carriage than unvaccinated controls. Although children in the 2+1 group had a significantly lower prevalence of VT carriage at 18 months (16%) than the 2+0 group (24%, $P = .01$), no difference was found at 24 months.

The question with regard to the duration of protection from carriage acquisition is still not fully answered. A study was conducted in the United Kingdom to assess whether the reduction in nasopharyngeal carriage of VT serotypes induced by PCV7 given to infants persisted beyond 2 years of age. The study was performed as an unblinded controlled study in children 2 to 5 years old who had received three PCV7 doses in infancy and a PPV23 booster at 13 months of age; they were compared with unimmunized control children. Nasopharyngeal cultures were taken in the summer and the winter. In the summer, the rates of VT-serotype carriage in vaccinated and control subjects were 10.0% and 13.5%, respectively, and in the winter, the rates were 30.0% and 31.5%, respectively. Thus, no real difference could be found between vaccinated and control subjects in VT serotypes (or overall pneumococcal) carriage at this age. However, the role of PPV23 versus a PCV as booster was not assessed. In South Africa, long-term carriage after a primary series of three PCV9 doses (6, 10, and 14 weeks of age) or placebo was assessed. A random subset of children, who had received three doses of study vaccine per protocol during the trial, was enrolled in the long-term carriage study in a fashion blinded to the study personnel. It was found that by age 5.3 years, the PCV9 no longer significantly reduced nasopharyngeal colonization by VT serotypes. In addition, HIV-infected children had a higher prevalence of colonization by *S. pneumoniae* (71.6%) than did HIV-negative children (50.9%). A nested study in American Indian children 1 to 7 years of age who had participated in a group-randomized efficacy trial reported that 27 months postvaccination children from communities randomized to receive PCV7 had lower carriage prevalence than the unvaccinated control subjects: 10.3% versus 17.1% ($P = .01$).[477] Thus, it seems that protection from acquisition of carriage can be achieved for some limited time (probably 2–3 years) after a full PCV schedule, but additional studies are needed.

PCV impact on carriage likely is mediated by protection against acquisition, reduction in the density of carriage by antibody, and induction of mucosal memory B cells.[478] In the mouse, the duration of carriage appears to be antibody-independent, Th17 cell-mediated immunity.[408]

Thus, the direct effect of PCV7 is an overall reduction of carriage of VT serotypes, with a parallel increase in non-VT serotypes (termed *replacement*). This phenomenon is expected to be of great magnitude, resulting in herd immunity against vaccine serotype disease on the one hand, but a potential for replacement disease on the other hand, and the magnitude of the effect is dependent on vaccination coverage. Future studies of PCV impact on carriage will include a broader analysis of PCV impact on the nasopharyngeal microbiome. Initial data of PCV impact show a short-term increase in bacterial diversity in the nasopharyngeal microbiome with an impact on a number of genera including other streptococci, *Haemophilus* species, *Staphylococcus* species, and anaerobes.[479]

Indirect Effect of Pneumococcal Conjugate Vaccine on Pneumococcal Colonization

The reduction of VT serotypes and the replacement by non-VT serotypes, instigated in the nasopharyngeal flora by vaccination, does not exist in isolation.[466] Pneumococci are constantly on the move in the population, being transmitted and acquired at high rates, especially in young children. The impact of vaccination on the transmission of pneumococci were first demonstrated in Israel in a series of studies where vaccination of daycare center attendees reduced carriage of VT pneumococcus in their younger siblings.[470,480] In a group-randomized efficacy trial of PCV7 conducted in the Navajo and Apache reservations,[481] there was a significantly lower carriage rate of VT serotypes among the vaccinated children compared with the placebo recipients in the communities allocated to no vaccination.[481] Furthermore, even when the vaccinated children were carriers of VT serotypes, they were less densely colonized with VT serotypes than unvaccinated control children (OR 0.61 [95% CI, 0.38 to 0.99]).[482] Adults and unvaccinated children younger than 5 years of age living in households with a PCV7 vaccinee were less likely to be colonized with VT serotypes (OR for adults 0.57 [95% CI, 0.33 to 0.99]; OR for children 0.57 [95% CI, 0.26 to 0.98]) than were those living in a household with unvaccinated control children. No such effect was seen in children 5 to 17 years of age. Decreases in VT

serotypes were offset by increases in carriage of non-VT. Among adults, those living in a household with a trial participant who was colonized with VT pneumococcus and randomized to receive PCV7 were less likely to be colonized with the same serotype than those in the households randomized to the unvaccinated control group (OR 0.34 [95% CI, 0.11 to 0.99]), suggesting that even with carriage of VT, children receiving PCV7 were less infectious than unvaccinated children.

An initial study in The Gambia[483] found no reduction of carriage of VT-related serotypes and no increase in the carriage of non-VT serotypes in the younger siblings of PCV9 recipients compared with siblings of placebo recipients (relative risk 0.95 [95% CI, 0.78 to 1.16], 0.97 [95% CI, 0.73 to 1.29], and 1.03 [95% CI, 0.87 to 1.22] for VT serotypes, VT-reduced serotypes, and non-VT serotypes, respectively). However, a follow-up study in The Gambia provided evidence of herd immunity in adults when the children received PCV7.[484] There was a significant, but only limited, additional benefit on VT carriage when vaccinating adults with PCV, and there were no data presented on the extent, if any, to which vaccination of adults contributed to herd protection. As time elapsed after introduction of PCV vaccination, a new postvaccination type of flora becomes prevalent in the population and spread beyond the vaccinated age group to younger infants and adults. After the introduction of PCV7 in the United States, the first demonstrations of indirect effect on a population level were published from Massachusetts and Alaska.[485–487] Additional studies from other developed countries showed a decline in carriage of VT serotype and an increase in non-VT serotypes in children younger than 5 years of age, after introduction of PCV7.[488–493] In addition, herd protection against carriage following PCV7 introduction in infants was observed among both HIV-infected and HIV-uninfected adults in South Africa.[494] Similarly, reduction in carriage of VT in neonates and infants too young to be vaccinated was also reported.[495] In addition, unvaccinated children in the age targeted for vaccination also showed similar trends.[492] Following PCV13 introduction in the United States, significant herd protection against the additional six types was demonstrated at 65% to 75% coverage with PCV13.[496] Herd protection against carriage in unvaccinated individuals has now been documented as a result of the use of PCV10 in both developed and developing countries.[497–499] However, in all reports of indirect effects of PCV7 on reduction of VT serotypes, an increase in carriage of non-VT was seen at the same time. The coverage of PCV in infants required to induce herd protection is likely to vary by the vaccine used, number of doses given, and the pattern of transmission in the community. For PCV13, using a 3 + 1 schedule, data from Massachusetts showed herd immunity (defined as significant a drop in PCV13 type carriage in underimmunized children) when full vaccination reached 75% of children, while similar drops in carriage among the Navajo were identified at 58% full immunization coverage.[499a,499b]

The replacement serotypes were the non-VTs seen in the area before vaccination and included serotypes/groups 3, 11A, 15 (A, B, and C), 35B, and the vaccine-related serotype 19A.[120,488,489,491] Now that both PCV13 and PCV10 have rolled out globally, it remains to be seen which additional non-VT serotypes or clones will evolve and spread globally.

Effect of Dosing Schedule on Pneumococcal Vaccine Effectiveness

The two commercially available conjugate vaccines, PCV10 and PCV13, are licensed in the United States, Europe, and elsewhere on four-dose schedules, including three primary doses plus a booster at approximately 1 year of age.[130,500] In Europe, and increasingly elsewhere, PCV13 and PCV10 are approved for use on a schedule of two primary doses plus a booster at 1 year of age when part of a "routine immunization program." Both conjugate vaccines are prequalified by the WHO for use in developing countries. The WHO initially recommended that conjugate vaccines be used on a schedule of three doses without a booster, the standard EPI schedule[264]; more recently WHO added a recommendation for a schedule of two primary doses plus a booster as an alternative.[501]

In practice, schedules used in routine immunization programs differ. In the United States and most Canadian provinces, the vaccine is given to infants on a four-dose schedule, with doses at 2, 4, 6, and 12 to 15 months, identical to the schedule used in the United States vaccine trials.[4,5] In other settings, three doses are used, either given during the first 6 months of life without a booster (e.g., Australia) or as two doses during that period, followed by a booster after 1 year of age (e.g., the Canadian Province of Quebec and many Latin American and European countries). In Africa, schedules of three doses given at 6, 10, and 14 weeks (e.g., Rwanda) or at 6 and 14 weeks and 9 months (South Africa) are used.

The number and timing of doses that will provide optimal prevention of disease is unclear, and may be different for different settings.[502] Data from early adopting countries all show substantial disease reduction using several different schedules. Three doses given at 6, 10, and 14 weeks were efficacious, except for serotype 1, in clinical trials in Africa.[6,7] The Australian schedule of three doses at 2, 4, and 6 months without a booster has been shown to quickly reduce invasive disease both in young children and in adults through herd effects.[503] Likewise, the four-dose schedule led to rapid and sustained reductions in the United States and Canada,[14,504] and marked reductions in pneumonia hospitalizations in children occurred quickly after introducing a "2+1" (two primary doses plus a booster) schedule in Quebec Province in Canada[505] and in the United Kingdom.[506] In these settings, the true impact of the recommended vaccine schedule alone is difficult to discern because the initial national programs included catch-up campaigns that offered vaccine to all children younger than age 2 years, which likely helped to quickly reduce disease burden. Data are becoming available on the effectiveness of different schedules in developing country settings, including a rapid reduction in invasive disease among HIV-infected and -uninfected children in South Africa on a schedule of doses at 6 and 10 weeks with a booster at 9 months,[17] and a rapid reduction in pneumonia hospitalizations in Brazil on a schedule of three primary doses with a booster.[507]

Comparable to immunogenicity studies, several from the United States shortly after seven-valent conjugate vaccine introduction found small but statistically significant differences between the effectiveness of a two- or three-dose primary series. One study of invasive disease occurring in vaccinated children showed a disproportionate number of serotype 6B cases among children who had only received one or two primary doses compared with children receiving three primary doses or a full four-dose series.[508] A study of lower respiratory tract infections found that compared with children who had received two primary doses, children who had received three doses had 7.8 fewer hospitalizations and 57 fewer outpatient visits (per 1000 children) among those born in 2002; no difference in hospitalization rate was seen after the booster dose for the 2002 birth cohort or at any time for the 2003 birth cohort, a finding the authors attributed to herd effects that were more impactful later as more children became vaccinated.[509] Other studies also found a booster dose to be beneficial, including a large case-control study from the United States. In this study, a variety of schedules were found to be

protective against invasive disease compared with no vaccine, but a schedule of three doses plus a booster dose after 12 months was significantly more protective than three doses without a booster.[103] A systematic review of the literature found some differences in immunogenicity between three- and four-dose schedules, but few differences in effectiveness in routine program settings, although few data are available from head-to-head studies of vaccine effects on clinical outcomes.[234]

SAFETY

Children Younger Than 2 Years of Age

The safety of PCVs has been most extensively examined in children younger than 2 years of age because most of the pivotal licensure trials were performed in this age group. For seven-valent conjugate vaccine, local reactions (including swelling, redness, and induration) were observed but were generally mild and self-limiting. The rates of local reactions after receipt of PCV13 were similar to the rates observed in recipients of PCV7,[370] whereas the rates of local reactions after PCV10 vaccine were somewhat higher than seen for PCV7.[510]

Fever is generally more frequent in infants receiving PCV than in control subjects.[4,271,339,370,511] The incidence of fever (>38°C) after receipt of PCVs varies widely but appears to be somewhat higher with both PCV10 and PCV13 than PCV7.[378,511] Generalized systemic symptoms, such as irritability, drowsiness, and crying more than usual, have been seen in recipients of all three licensed conjugate vaccines,[378,510,512] but these symptoms have usually been mild. Other events that could possibly be attributed to conjugate vaccine include urticaria, rash, excessive crying, hypotonic-hyporesponsive episodes, cyanosis, and transient granulocytopenia.[13,236,267,513]

In the NCKP efficacy trial of PCV7,[4] the frequency of uncommon events requiring medical attention after vaccination was evaluated through the use of comprehensive hospitalization and emergency room utilization databases. The events in 92 diagnostic categories were followed for 30 days after vaccination in hospitalized children and for 60 days after in children were seen in the emergency department. Adverse events that were severe, unexpected, or possibly had been caused by the study vaccine were followed up through chart review, parent contact, or both. Significant differences were seen only for febrile seizures and elective admissions. Febrile seizures requiring hospitalization were more common in recipients of PCV7 than control subjects, but only in those patients who had received DTwP at the same time; there was no difference in rate of seizure between recipients of PCV7 and infants in the control group, who had received a concomitant DTaP vaccine. There was no clustering of febrile seizures within the 3-day period after vaccine administration, and the rates of seizure in this study were below the historical rates of seizure seen after DTwP vaccination.[33] Rates of sudden infant death syndrome (SIDS) also were similar to or lower than those expected from historical data. Elective admissions, including ventilatory ear tube placement, occurred more frequently in the control group.[4] In an analysis of selected categories of outpatient clinic visits, control subjects had significantly more seizures overall than PCV7 recipients, but no specific seizure subcategory was different between the two groups, and there was no temporal clustering of the seizures relative to vaccination. Similarly, although there was an excess of generalized seizures among vaccinees in the South African trial, there were less seizures in the "unspecified" seizure category and no excess of seizures overall.[7] In the trial in South Africa, hyperactive airway disease and asthma were noted 79% more frequently in recipients of PCV9 (nominal P = .009), but no temporal association to receipt of vaccine was apparent.[77] This was not observed in trial of PCV9 in The Gambia nor in the NCKP or Navajo trials of PCV7.[514]

There was an excess of visits to the clinic or hospital associated with respiratory infections in the first week after the first PCV compared to controls vaccination in the South African, The Gambian, and Philippine trials,[6,7,9] but this excess was not noted in the Navajo[5] or in the NCKP trial.[4]

Seizures were also specifically examined among cases reported to the Vaccine Adverse Event Reporting System (VAERS), a repository for reports of adverse events seen after vaccinations given in the United States. The reports are voluntarily submitted by manufacturers, healthcare workers, and patients; consequently, the reports must be interpreted with caution. Wise and colleagues[515] reported on data submitted to VAERS in the first 2 years after licensure of PCV7, during which time an estimated 31.5 million doses of the vaccine were administered in the United States. Of 4154 reports made within 3 months of PCV7 vaccination of children 17 years of age and younger, there were 393 reports of seizures; 159 of these were considered serious (including three deaths). Fifty-seven (14.5%) of the total seizures and 15 of the serious seizures (9.4%) occurred in children who had received PCV7 alone, without concurrent vaccinations. Additional details of case history and follow-up were obtained for the first 98 reports of seizure. Seventy-nine of these cases (80.6%) either had fever at the time of the seizure or had a history of seizures. The three children who died had seizures without known cause, although one had a previous diagnosis of "gross motor delay"; the other two were fraternal twins.

The 4154 reports in the VAERS database represent a rate of 13.2 adverse events per 100,000 vaccinations temporally, although not necessarily causally, related to receipt of the vaccine. Serious adverse events comprised 14.6% of these reports (n = 608, including 117 deaths). This is consistent with the rate of serious adverse events (14.2%) reported for other vaccines.[516] The majority of reports involved minor adverse events that had been observed in clinical trials. In 23 cases, rechallenge with a subsequent dose of vaccine produced the same event encountered after a previous dose, suggesting a causal relationship. These 23 cases included seven cases of fever, irritability, or other nonspecific symptoms; four cases of respiratory symptoms; four cases of prolonged or abnormal crying; three cases of gastrointestinal disturbance; two possible allergic reactions; two seizures; and one case of alopecia. In addition, there were 14 reports of anaphylactic reactions, 78 cases with possible thrombocytopenias (12 with platelet counts less than 20,000/mm^3), and six cases of serum sickness. For each of these categories, alternative explanations were present in some cases, but not in all cases. Of the 117 deaths, 73 (62.4%) did not have an identified cause, although 59 of these were classified as SIDS or possible SIDS. Of the 44 deaths in which the cause was identified, seven were caused by pneumococcal infections (six in partially vaccinated children).

More recently, an excess of febrile seizures was reported to the Vaccine Safety Datalink in the United States, when the 2010–11 trivalent influenza vaccine was administered with PCV13 to children 6 months to 2 years of age. The Centers for Disease Control and Prevention (CDC) estimated an excess of 60 such seizures per 100,000 children receiving both vaccines simultaneously, with the seizures typically occurring the day after immunization.[517]

Older Children and Adults

In the United States and some other countries, catch-up vaccination is recommended for healthy children up to 23 months of age who did not receive pneumococcal vaccine as

infants,[33] but vaccination of older children without previous vaccination or who did not respond to vaccination with PPV could prevent considerable additional disease. In 115 Spanish children who received a single dose of vaccine between 24 and 36 months of age,[518] local reactions of erythema, induration, and tenderness occurred in 32% to 40% of the vaccinees. Approximately one-third of these reactions were severe, but most resolved within 3 days of vaccination. Eight children (7%) had fever of 38°C or higher within 72 hours of vaccination, a lower rate than seen in younger children.[4,236,513]

Pain at the injection site was the most common adverse reaction in children 2 to 18 years of age, occurring in 20% to 56% of patients,[293,519] but there were no significant differences in those receiving the conjugate vaccines and control vaccines. The incidence and severity of local reactions may be reduced by using a deep intramuscular route to inject the vaccine,[275] and a study eliminating alum adjuvant from the vaccine appeared to decrease the incidence of local reactions in toddlers,[275] although it increased the incidence in adults.[520] Reactogenicity does not increase with repeated doses.[519,521] Fever is seen more frequently in children receiving PPV vaccine than conjugate vaccines, but temperature higher than 38°C is infrequent in any group.[64,324,519]

The safety of various doses of PCV7 was studied in older adults who had previously received PPV.[288,522] Increases in PCV7 dose were associated with increases in both local and systemic adverse events, but among systemic symptoms, only general muscle aches and pains were significantly different between the lower and higher PCV7 doses. Swelling, pain, and limited movement all increased significantly with dose of PCV7, but tended to be encountered less frequently after PCV7 than after PPV vaccination. Earlier studies[133,199] found no differences in symptoms produced by PCV7 and PPV in older adults, although younger adults experienced more pain and headache after PCV7 than after PPV.[199] Thirteen-valent conjugate has been evaluated in adults. In this population, fever was infrequent, and the most common reaction observed was mild local tenderness.[289] The Phase III trial bore out these earlier data with no excess of serious adverse events in the PCV recipients and no serious adverse events associated with the vaccine administration, although minor systemic and local adverse events were increased.[18] Any local redness occurred in 4.9% of vaccinees, an excess of 3.7% over controls ($P < .001$) with moderate redness (5–10 cm) occurring in 1.7%, a 1.4% excess over the controls ($P = .007$). Any local swelling occurred in 6.8% of vaccinees, an excess of 5.6% over controls ($P < .001$), with moderate swelling (5–10 cm) occurring in 2.6%, an excess of 2% over controls ($P < .001$). Local pain was common at 36.1%, an excess of 30% over controls ($P < .001$) with moderate pain (interfering with activity) occurring in 7.7%, an excess of 7.1% over controls ($P < .001$). Some limitation of arm movement was found in 14.1% of vaccinees, an excess of 10.9% over controls ($P < .001$), but moderate limitation, defined as inability to raise the arm above the head but able to raise it above the shoulder, was less common at 1.7% in vaccinees, an excess of 1.2 % over controls ($P < .02$). In terms of systemic adverse events that were mild or moderate, there was a small excess of any fever at 2.9%, an excess of 1.7% over controls ($P = .02$). There was a small excess of fatigue reported (3.9%, $P = .03$) and a small excess of rash (2.5%, $P < .001$). New generalized muscle pain that was sufficient to interfere with activity occurred in 5.9% of vaccinees, an excess of 3.1% over controls ($P < .001$).[18]

Special Groups

Several studies examined reactogenicity of PCVs in children with immunodeficiencies. In a study of children infected with HIV, those receiving PCV7 did not have significantly more reactions than those receiving control vaccine,[511] but swelling, redness, pain, fever, and irritability of at least moderate severity were significantly more frequent after the first and second doses of PCV7 than after the corresponding doses of placebo (56.7% vs 20.0% [$P = .02$] and 53.3% vs 13.3% [$P = .01$], respectively). Among the 30 HIV-positive children randomized to receive PCV7, three had severe reactions to vaccination (severe induration, erythema, and limited leg movement; limited leg movement and high-pitched crying; and temperature of 39.9°C). Among 15 HIV-positive children randomized to placebo, one had a fever of 39.5°C. All four children with severe symptoms had symptomatic HIV disease at baseline. In an earlier study of five-valent PCV vaccine in HIV-positive and HIV-negative children older than 2 years of age,[305] only minor adverse reactions were observed.

The reactogenicity of PCV7 is not different between children with and without sickle cell disease[87,90]; however, children with sickle cell disease who had a three-dose primary series of PCV7 had slightly stronger reactions to a PPV booster than those who had a single dose at 12 months.[110] Children with solid-organ transplants experienced less pain at the injection site than healthy control children, but no serious adverse events were seen in either group.[313]

Preterm infants receiving PCV7 had fever higher than 38°C, swelling, tenderness at injection site, irritability, loss of appetite, vomiting, diarrhea, and hives more frequently than preterm infants receiving control meningococcal vaccine.[276] However, these reactions were not severe enough to preclude the use of PCV7 in preterm infants. A smaller study[261] found no significant differences between preterm and full-term infants in local or systemic reactions when vaccine was given at 3, 5, and 11 months after birth, although both groups had fewer adverse events after the third (booster) dose than after either of the two primary doses. A recent study on safety and immunogenicity of PCV13 conducted among 100 preterm and 100 full-term neonates found similar safety profiles in both groups.[273]

Few data are available on the safety of PCV administration during pregnancy. However, PCV9 was well tolerated in 74 pregnant women in a single trial.[278]

PUBLIC HEALTH CONSIDERATIONS

Epidemiologic Effects of Vaccination

Effect of Vaccination in Children Younger Than 5 Years of Age

Use of PCV has had a profound effect on pneumococcal disease in the United States, the first country to include PCV as part of the routine childhood immunization schedule. The effects were seen very quickly after vaccine introduction in 2000. In a multicenter study conducted in 2002 of children requiring hospitalization for IPD, 77% fewer cases in children younger than 2 years of age were caused by vaccine serotypes than seen during 1994 to 2000.[523] Surveillance in the NCKP population identified no cases of invasive disease caused by vaccine serotypes among children younger than 1 year of age between April 2002 and March 2003, compared with rates between 51 and 98 cases per 100,000 person-years before vaccine licensure.[524] According to the CDC's Active Bacterial Core Surveillance (ABCs), a population-based surveillance system measuring IPD in approximately 20 million people in eight states, overall rates of IPD (both VT and non-VT) among children younger than 5 years of age had dropped 75% from prevaccine levels by 2003. Rates of disease caused by all serotypes in this age group fell from 96.7 cases per 100,000

population during 1998 and 1999 to 23.9 cases per 100,000 population in 2003 and after introduction of PCV13 in 2010, all serotype disease reduced below 20 per 100,000 (Fig. 46.4).[525] Between 2004 and 2007, overall disease rates among children younger than 5 years remained relatively stable; invasive disease caused by PCV7 serotypes became very unusual (0.4 cases per 100,000 population in 2007), and an increase in disease caused by nonvaccine serotype 19A occurred, which accounted for the lack of change in overall disease rates between 2004 and 2007.[14] In 2010, the U.S. immunization program changed from PCV7 to PCV13, and for the period July 2012 to June 2013, the incidence of total invasive disease and invasive disease caused by serotypes in PCV13 but not in PCV7, declined by 64% (95% interval estimate 59% to 68%) and 93% (95% interval estimate 91% to 94%), respectively, compared with incidence rates expected among children younger than 5 years old if PCV7 had been continued.[487]

Use of conjugate vaccine in children has also reduced the differences in risk of IPD between certain racial and ethnic groups. According to ABCs data, rates of invasive disease fell 77% overall in white children younger than 2 years of age between 1998 and 2002, and fell 89% in black children in the same interval; incidence among black children younger than 2 years of age went from 3.3 times the rate among white children in the prevaccine period to 1.6 times higher in 2002.[526] Among Navajo children living in the American Southwest, rates of vaccine serotype disease between 1995 and 1997 were 210 and 263 cases per 100,000 children younger than 1 year of age and 1 to 2 years of age, respectively. Between 2004 and 2006, no vaccine serotype cases occurred in this age group.[527] In addition, rates of disease caused by nonvaccine serotypes did not change significantly after vaccine introduction. In Alaska, surveillance by CDC's Arctic Investigations Program identified a large drop in disease caused by vaccine serotypes among the Alaska Native population.[486] After vaccine introduction, VT invasive disease fell 91% among Alaska Native children younger than 2 years of age (from 275 cases per 100,000 children to 25 cases per 100,000 children) and by 80% among non-Natives the same age (from 101 cases per 100,000 children to 20 cases per 100,000 children), eliminating the disparity in disease caused by vaccine serotypes. However, after the initial report, an increase in non–vaccine-serotype disease was seen among Alaska Natives, primarily among those living in the rural Yukon–Kuskokwim region and reduced the overall benefits of pneumococcal vaccination in this population.[528]

A large amount of data on vaccine impact are now available from outside the United States. Surveillance from 12 centers across Canada (the IMPACT [Incident Management of Patients, Actions Centered on Treatment] Program) found a 56% decrease in the number of cases among children younger than 5 years of age, from 269 in 2000 to 119 in 2007, including a 92% decrease in PCV7 cases in children younger than age 5 years.[503] In Australia, the incidence of invasive disease decreased 74% between 2002 and 2007 (from 98.1 to 25.1 per 100 000 children); the reduction was more pronounced in nonindigenous children (84.7 to 19.5 per 100 000 children) than indigenous children (129.1 to 82.3 per 100 000 children).[529] In Europe, results of studies from the first few years after vaccine introduction are demonstrating findings similar to those seen in other regions,[530] although in some settings, the emergence of serotype 1 disease has partly offset reductions seen by PCV7 implementation.[531] United Kingdom researchers have shown effectiveness against invasive disease for PCV13 overall and serotype-specific effectiveness for four of the vaccine antigens, including 84% effectiveness of the first two primary doses or the booster dose against serotype 1.[142] Longitudinal data on PCV13 impact in England and Wales show significant reductions in all IPD across all ages, including an impact on serotype 3 despite the lack of impact on serotype 3 found in the indirect cohort study.[142,532] Data are now becoming available showing benefit of PCVs for reducing invasive disease in developing countries, including effect of PCV7 and PCV13 on invasive disease in South Africa.[17] In Israel, the IPD impact of PCV7 was more pronounced in children with sepsis and meningitis than in those with pneumonia, with IPD among pneumonia

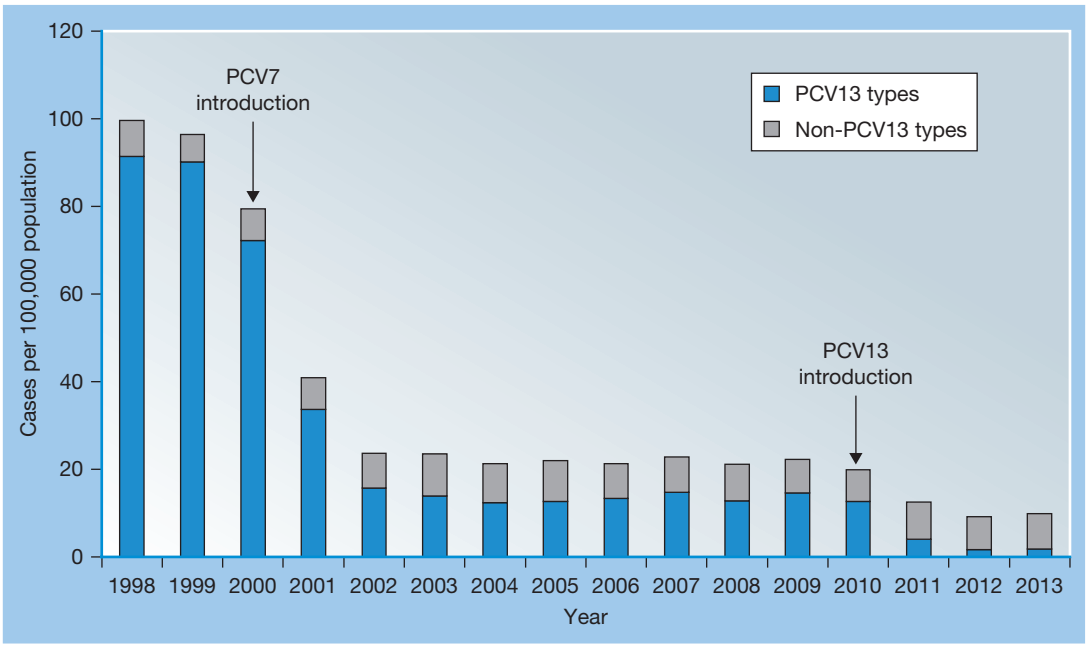

Figure 46.4. Rates of invasive pneumococcal disease among U.S. children <5 years, 1998–2013, showing PCV13 and non-PCV13 serotypes. *(From Moore MR, Whitney CG. Use of pneumococcal disease epidemiology to set policy and prevent disease during 20 years of the Emerging Infections Program.* Emerg Infect Dis. *2015;21[9]:1551–1556.)*

cases reducing only after protection was provided for the additional serotypes in PCV13.[534]

While there are increasing reports on PCV impact on IPD from many countries, the specific impact of PCV on pneumococcal meningitis has been less clearly described. The reduction of pneumococcal meningitis resulting from PCV7 led to group B streptococcus emerging as the major numerical cause of bacterial meningitis in children younger than 5 years of age in the United States.[535] In contrast in France, PCV7 had impact on meningitis in children younger than 2 years of age, but there was an increase in pneumococcal meningitis during the PCV7 period in children 2 to 5 years of age because of the additional PCV13 types 7F and 19A.[536] Early data on PCV13 impact on pneumococcal meningitis in the United States suggests that vaccine types and ceftriaxone resistance are decreasing after PCV13, but that nonvaccine types are increasing. These data suggest that nonvaccine types remain a risk for pneumococcal meningitis in susceptible patients.[536a]

Studies from multiple countries now also show that changes have occurred in the epidemiology of noninvasive pneumococcal syndromes, in particular pneumonia, after vaccine introduction. A study using the Nationwide Inpatient Sample, the largest available inpatient database in the United States, and an interrupted time-series analysis found large reductions in hospitalizations coded as all-cause and pneumococcal pneumonia among children when comparing 1997–1999 (pre-PCV7 years) to 2001–2004 (post-PCV7 years).[537] By the end of 2004, all-cause pneumonia hospitalization rates had declined 39% in children younger than 2 years of age, a drop of 506 hospitalizations per 100,000 children younger than 2 years of age, or approximately 41,000 pneumonia hospitalizations prevented per year. Pneumococcal pneumonia rates (2% of episodes) declined by 65% in children younger than 2 years of age, or approximately 17 fewer hospitalizations per 100,000 children per year. In Australia, hospital discharges with the primary diagnosis of pneumonia fell 38% (95% CI, 36% to 40%) and 29% (95% CI, 26% to 31%), respectively, among children younger than 2 years of age and 2 to 4 years of age during the 30 months after universal funding for seven-valent conjugate vaccine, representing approximately 4700 fewer hospitalizations for pneumonia over the 30-month period.[538] Likewise, hospitalizations fell 69.4% for lobar pneumonia and 8.2% for all-cause pneumonia in children younger than 2 years of age in the 15-month period after provision of seven-valent vaccine for all children younger than 5 years in Quebec Province in Canada.[505] Early data since the introduction of pneumococcal conjugates are showing benefits in pneumonia, including reports of reductions in pneumonia hospitalizations in Brazil following PCV10 introduction,[507] and in the United States following PCV13 introduction.[539]

Indirect Effects

There is increasing global evidence that herd effects are an important part of the public health benefit of PCV use. The first report demonstrating herd effects was from the NCKP population early after vaccine licensure in the United States. Data from this population indicated that the reduction in disease was greater than the percentage of children who had been vaccinated.[540] By early 2001, only 34% of children younger than age 5 years had received one or more doses of conjugate vaccine, and only 14% were fully vaccinated. Despite this low coverage, disease caused by vaccine serotypes had dropped to 18 cases per 100,000 children from a baseline incidence of 42 to 60 cases per 100,000 children in this age group. The indirect effect of infant vaccination on IPD among persons 5 years of age and older has been clearly demonstrated in the United States during the period 2000–13 during which the IPD burden was halved (Fig. 46.5). Analyses of CDC data through 2007 showed that invasive disease caused by vaccine

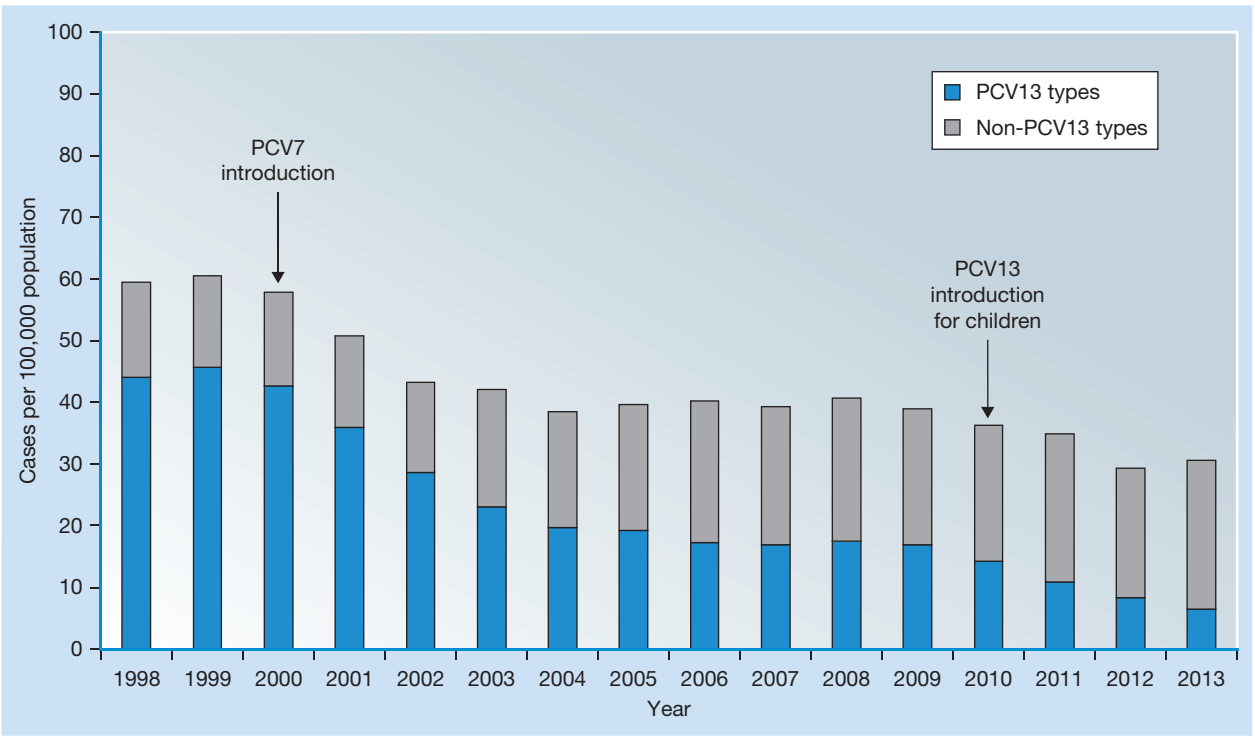

Figure 46.5. Rates of invasive pneumococcal disease among adults >18 years, Active Bacterial Core surveillance 1998–2013 showing PCV13 and non-PCV13 serotypes. *(From Moore MR, Whitney CG. Use of pneumococcal disease epidemiology to set policy and prevent disease during 20 years of the Emerging Infections Program.* Emerg Infect Dis. *2015;21[9]:1551–1556.)*

serotypes had dropped by 87% to 94% among age groups 5 years of age and older.[14] Between the 1998/1999 baseline years and 2007, the overall disease rates fell 43%, 40%, 18%, and 37% among persons ages 5 to 17 years, 18 to 49 years, 50 to 64 years, and 65 years and older, respectively.[14] An examination of adults in the conjugate vaccine era indicated that disease was seen more commonly in persons with comorbid conditions, indicating that the population of adults benefiting from herd effects were somewhat healthier than those who continued to get invasive disease.[541] Infants too young to be vaccinated also are protected through herd effects.[542]

A random effects metaanalysis revealed significant reductions in invasive disease caused by vaccine serotypes among adults 2 years after PCV7 vaccine introduction in children, but data have been mixed on whether there is an overall benefit for disease rates when disease caused by both VT and non-VT serotypes is included. Point estimates suggest reductions in overall IPD among adults from 2 years post PCV introduction in infants, but the CIs have included 1 to 6 years postintroduction.[543] While herd impact on PCV7 types has been thus reliably demonstrated, the extent of replacement disease in adults has varied geographically presumably reflecting disease among adults with comorbidities who remain at risk for disease with non-VTs. A lack of overall disease reduction in adults after conjugate vaccine introduction for children in some studies was the result of a low baseline percentage of invasive disease caused by conjugate vaccine serotypes, such as was seen among Alaska Native or Navajo adults,[486,527] and a large disease outbreak caused by a non-VT serotype in Canada.[544] In England and Wales where there was initial skepticism about an overall impact on IPD in all ages, as the baseline measure of IPD was increasing pre-PCV, modeling to adjust for case ascertainment revealed a 56% overall reduction in IPD post-PCV13 compared to the pre-PCV7 baseline (15.63 vs 6.85 per 100,000; incidence rate ratio [IRR] 0.44, 95% CI, 0.43–0.47).[532]

A study from the United States was the first to document significant herd effects for prevention of nonbacteremic pneumonia in older adults.[16] In this study, which used a very large administrative database, investigators found a reduction of 54% (95% CI, 53% to 56%) for nonbacteremic pneumonia hospitalizations among adults 65 years of age and older. A model included in this report estimated a total reduction of 788,838 (95% CI, 695,406 to 875,476) hospitalizations for pneumococcal pneumonia between 2000 and 2006, with 90% of the reduction in hospitalizations and mortality attributed to herd effects among adults 18 years of age and older. Reductions in all-cause pneumonia hospitalization among adults have been documented in Australia without a booster given to infants in the second year of life.[538] In the United States with a 3+1 immunization schedule, significant pneumonia hospitalization reductions have been confirmed a decade after PCV7 introduction, with an estimate of 168,000 fewer hospitalizations annually.[545] Further significant reductions in pneumonia hospitalizations encoded as pneumococcal have been demonstrated post-PCV13 in the United States.[546]

Effect on Resistance

There are several mechanisms by which widespread use of the new conjugate vaccine might affect antibiotic-resistant pneumococci. Serotypes included in the vaccine cause the majority of disease caused by resistant strains,[547] so reducing infections caused by these serotypes reduces resistant infections.[7] In addition, the vaccine reduces acquisition of vaccine serotypes in the nasopharynx,[465,470] reducing the opportunity for vaccine-serotype strains to be exposed to the selective pressures of antibiotics. As the vaccine reduces transmission of vaccine-serotype strains from vaccinated children to others, vaccinating a subset of the population reduces the overall number of infections caused by resistant vaccine-serotype strains.[548] Finally, by preventing infections, vaccination reduces the need for antibiotics mainly for respiratory tract infections,[412,415,423,549,550,550a] thereby reducing the selective pressure that antibiotic use provides. On the other hand, the acquisition of non-VTs in the nasopharynx exposes them to the selective pressure of antibiotics, and resistance emerges in the residual non-VTs. Overall, the burden of resistance is reduced, but may evolve with time to the same proportion of resistant strains or higher than previously encountered.[547]

Initial reports after PCV introduction in the United States demonstrated a reduction in the proportion of resistant strains in both children and adults.[126] In northern California, penicillin nonsusceptible strains with minimum inhibitory concentrations greater than or equal to 2 μg/mL were seen in 15% of pneumococcal isolates causing disease in all age groups in 2000, compared with 5% of strains in 2003; erythromycin resistance was prevalent in 28.9% of strains at baseline, compared with 15% after vaccine introduction.[4] Stephens and associates[548] evaluated trends in macrolide-resistant invasive disease in an ABC site in Atlanta, Georgia. Large decreases in the incidence of macrolide-resistant disease were seen in children younger than age 2 years (82%) and in children ages 2 to 4 years (71%) after vaccine introduction. The predominant clone causing macrolide-resistant disease in Atlanta had a *mefE* (macrolide efflux gene)-mediated mechanism for resistance and was serotype 14, a seven-valent PCV7 serotype. The decrease in macrolide-resistant pneumococcal disease was largely due to a reduction in disease caused by this clone.

Data from the ABCs Emerging Infections Program Network found that rates of IPD caused by penicillin-nonsusceptible strains dropped 78% in children younger than 5 years of age from a peak of 33.8 cases per 100,000 in 1999, before conjugate vaccine introduction, to 7.5 cases per 100,000 in 2004.[126] Rates of invasive disease caused by penicillin-nonsusceptible strains and strains not susceptible to multiple antibiotics among persons older than 65 years peaked in 1999 at 16.4 per 100,000 and then decreased by 49% to 8.4 cases per 100,000 in 2004; effects on resistance were most pronounced among children younger than 2 years of age (see Fig. 46.4). Although the incidence of nonsusceptible strains fell as VT pneumococci began to disappear from the community, the proportion of resistance among residual strains causing disease in children began to increase.[126]

In Alaska, rates of disease caused by penicillin-resistant, cotrimoxazole-resistant, erythromycin-resistant, and multidrug-resistant strains dropped in children younger than 5 years of age, consistent with the reduction in disease caused by vaccine-serotype strains.[486] Studies of carriage in young children in Alaska however, showed that although carriage of cotrimoxazole-resistant strains in children fell after vaccine introduction, carriage of penicillin-nonsusceptible strains was not significantly changed.[486,487]

In a multisite study, the proportion of pneumococcal strains from children with OM caused by vaccine serotypes dropped from 76% in 1999 to 52% in 2002, but no change was seen in the proportion of isolates that were resistant to penicillin.[435]

The reversal in the trend to a reduction in the proportion of resistant strains in the United States and elsewhere after PCV7 introduction was related to the emergence of a small number of antibiotic-resistant nonvaccine serotypes. In the United States the most important was serotype 19A, the burden of which increased from 0.8 cases per 100,000 per year from 1998 to 2.5 cases per 100,000 per year in 2003.[120]

Serotype 19A seen in the United States was part of a global clone that had undergone a capsular switch from 19F to 19A, acquired the *ermB* gene in addition to *mefA*, conferring high-level macrolide resistance, and high-level resistance to β-lactams, including injectable third-generation cephalosporins such as ceftriaxone.[120] The only oral agents that could be used to treat OM caused by these resistant strains were fluoroquinolones.[433] Multiresistant serotype 19A post-PCV7 introduction was also a problem in other parts of the world, such as France and Spain.[552–554] Other serotypes not included in the PCV7 vaccine also emerged as antibiotic-resistant in the United States, including serotype 6C[555] as well as serotypes 15A, 23A, and 35B.[556] Although the emergence of antibiotic-resistant pneumococci has occurred over the past half century independent of PCV selection, and will continue to do so, the changes in serotypes carried in the nasopharynx of PCV-immunized children contributed to the selection of resistance in these serotypes. The introduction of PCV13 in 2010 had a major impact in reducing this trend. In a double-blinded, randomized study comparing efficacy of PCV13 and PCV7 on carriage of antibiotic-nonsusceptible *S. pneumoniae*, Dagan and colleagues described the superiority of PCV13 over PCV7 against acquisition and carriage of serotypes 6A, 19F, and 19A, all three with high rates of antibiotic resistance. PCV13 administration resulted in significantly lower carriage than PCV7 during infancy and toddlerhood of penicillin, macrolide, clindamycin, tetracycline, and multidrug nonsusceptible *S. pneumoniae*.[557] This predicted reduction in diseases caused by antibiotic-nonsusceptible *S. pneumoniae*. Furthermore, indirect protection in all ages regardless of vaccination status was also predicted. Indeed, reduction of disease caused by antibiotic-resistant *S. pneumoniae* of the additional PCV13 serotypes was observed as early as within 3 years postintroduction of PCV13, in the United States, France, South Africa, and Israel.[15,17,439,558,559] A trend of increasing antibiotic-susceptibility with each serotype, including both PCV13 and non-PCV13 serotypes, was observed.[559,560]

Serotype Replacement

At best, conjugate vaccines as currently designed can only protect against a limited number of the 97 known pneumococcal serotypes. Carriage studies have shown that PCV vaccination has reduced carriage of VT pneumococci among children in the community.[485–487,561] The concomitant increase in carriage among children of pneumococcal serotypes not covered by the vaccine means that nonvaccine serotypes may be transmitted and potentially cause disease more often than they did before routine use of conjugate vaccine. An increase in disease caused by nonvaccine serotypes in the wake of a reduction in VT disease is known as "replacement disease." To what extent replacement disease occurs depends in part on the ability of the nonvaccine serotypes to cause disease; studies of invasiveness that have analyzed distributions of serotypes associated with carriage and with invasive disease have shown that certain serotypes are much more likely to cause invasive disease than others.[562]

The first evidence for replacement disease came from a clinical trial in Finland evaluating two conjugate vaccines for prevention of AOM among children younger than 2 years. The first analysis evaluated the seven-valent PCV7; compared with a control group receiving hepatitis B vaccine, children receiving PCV had 57% fewer OM episodes caused by serotypes in the vaccine and 51% fewer episodes caused by cross-reactive serotypes, but these changes were accompanied by a 33% increase in episodes caused by other pneumococcal serotypes and an 11% increase in those caused by *H. influenzae*.[13] In the analysis of seven-valent PncOMPC, the efficacy against OM caused by vaccine serotypes was similar (56%) to that of PCV7 (57%).[195] More episodes of OM caused by non–vaccine-serotype pneumococci and *H. influenzae* occurred among children receiving pneumococcal vaccine (121 and 315 episodes, respectively) than receiving hepatitis B vaccine (95 and 287 episodes, respectively), but the differences were not statistically significant between the two groups. A shift in pneumococci causing OM was also seen in Pennsylvania, where in 2001 children receiving at least two doses of PCV were noted to be more likely to have AOM caused by non-VTs (47%) than children who had not received conjugate vaccine (21%).[537]

The first report of significant replacement invasive disease among children came from an eight-center study monitoring hospitalizations for invasive disease among children younger than 2 years in the United States.[523] While noting a 77% decrease in VT disease between baseline (1994–2000) and 2002, they also found a 66% increase in non–vaccine-serotype disease. Isolates of nonvaccine serogroups 15 and 33 had the largest increases. In Utah, an increase in cases caused by serogroup 3 was noted among children enrolled in a large healthcare system, along with an increase in the incidence of empyema and severe invasive disease from 2001 to 2003 compared with prevaccine years.[105]

Data from the CDC's ABCs program have shown that rates of invasive disease caused by non-VTs in children younger than 5 years increased 128% between the 1998–99 average and 2007.[14] In this large sample, the main serotype causing replacement disease in children was serotype 19A, a serotype structurally similar to vaccine serotype 19F but for which the vaccine provides no cross-protection.[563] An analysis comparing pneumococcal genotypes before and after conjugate vaccine introduction noted that the increase in serotype 19A was a result of the serotype 19A clone most prevalent in the United States becoming more common as a cause of disease and also to the emergence of new clones with capsular serotype 19A that were previously identified as having only vaccine serotypes.[563] This analysis suggests that pneumococci may have adapted to vaccine use by acquiring genetic material that allowed a switch in expressed capsular type.

Surveillance data from Alaska Native children indicate that this group is particularly prone to replacement disease. An increase in non-VT disease among Alaska Native children younger than 2 years of age began as early as 2003, 2 years after universal introduction of PCV7. Between 1995 and 2000 and 2004 to 2006, among children younger than 2 years of age, rates of invasive disease caused by nonvaccine serotypes increased from 95 to 229 cases per 100,000, substantially reducing the overall benefit of PCV7.[564] In contrast, replacement disease has not been as evident among non–Native Alaskans, suggesting that environmental, socioeconomic, or genetic factors may explain some of the differences seen in the two groups. Replacement disease has not been problematic among other indigenous populations, such as Australian Aboriginals[565] or Navajo residing in the American Southwest.[527] Although disease rates among Alaska Native children are among the highest reported, the overall size of the population is small, such that rate calculations are based on relatively few cases; therefore, more data are needed to better understand the trends in this population.

Evidence suggests that nonvaccine serotypes are more likely to cause disease in persons with comorbidities including immune system disorders. Children with comorbidities were more likely to be infected with non-VTs post-PCV13 in Massachusetts and these children with comorbidities were more likely to be hospitalized.[566] Some of the most dramatic increases in nonvaccine serotypes documented after conjugate vaccine introduction have been among adults 18 to 64 years

of age with HIV or AIDS.[567] In this very-high-risk population, overall rates of IPD (all serotypes) declined 25% between 1998–99 and 2007. The overall decline was the result of an 88% reduction in disease caused by the seven serotypes in the vaccine and a 60% increase in disease caused by nonvaccine serotypes. A comparison group of adults 18 to 64 years of age without HIV or AIDS noted a very similar percent reduction in vaccine-serotype disease (91%), but this group had a smaller (28%) increase in non-VT disease.

In July 2010, the WHO convened a meeting of experts to discuss the issue of replacement disease and to review data on invasive disease trends from several countries that had introduced conjugate vaccine.[568] The latest data were reviewed from Australia, Canada, England and Wales, South Africa, and the United States and included information from both indigenous and nonindigenous populations. The data were collected through systems that varied in size, methods, background incidence rates, the prevaccination proportion of invasive disease caused by vaccine serotypes, vaccination schedules, and the use of catch-up programs for older children. In each setting, children benefited overall from vaccine introduction; the overall incidence of IPD among children targeted for vaccination declined after vaccine introduction. The overall reduction in each case was the result of large declines in vaccine-serotype disease and, in some but not all datasets, smaller increases in disease caused by serotypes not covered by conjugate vaccine. The increases in non–vaccine-serotype disease were seen mostly in hospitalized patients. Among older children and adults, an overall indirect benefit was not seen in all settings. In some sites, overall rates were lower after conjugate vaccine introduction; all sites saw reductions in vaccine-serotype invasive disease, but increases of variable size in non–vaccine-serotype disease resulted in either no change or an increase (one site) in the overall rate of IPD in others. After reviewing the data, participants concluded that vaccine-induced serotype replacement likely explains some of the observed increases in non–PCV-serotype disease but that other factors, such as population immunity, secular trends in disease, and changes in surveillance system sensitivity, also contributed to the pattern observed. The group concluded that they could not discern the relative contribution of vaccine-induced replacement disease versus observed trends in non–vaccine-serotype disease related to these other factors and that more data are needed as the newer conjugate vaccines were implemented. A follow-up analysis using 21 datasets, largely from high-income settings, found that replacement disease occurred but that overall benefits in young children were seen quickly after PCV7 introduction and remained up to 7 years after vaccine introduction; benefits were also seen among adults but were less consistent and delayed relative to benefits among children.[543] The first long-term observation post-PCV13 from England and Wales, which has documented an overall reduction in IPD in all ages, has identified replacement of non-PCV13 serotypes across many age groups, but the early impact is in children younger than 5 years of age as reductions in PCV13 serotypes were largely complete by 2015, thus emphasizing continuing replacement in that age group. The significant increases in any age group were serotypes 8, 10A, 12F, 15A, and 24F.[532]

Disease Control Strategies

Pneumococcal disease is endemic globally. Nearly all young children will have one or more mild infections caused by *S. pneumoniae.* Severe infections most often occur sporadically rather than in outbreaks clustered together by place and time. Therefore, including PCV in the routine childhood vaccination schedule is likely the optimal strategy for controlling pneumococcal disease.

In 2000, the first year seven-valent PCV7 was licensed, the United States introduced the vaccine for all children younger than 2 years.[569] Beginning in 2006, with expansion of supply, a large number of countries began introducing seven-valent PCV7. With the licensure of PCV10 and PCV13, beginning in late 2009, national programs using seven-valent PCV7 began switching to PCV10 or PCV13 as they became available, and additional national programs began adopting the newer vaccines. As of September 2014, 110 countries have included PCV in their routine infant immunization programs (Fig. 46.6).[570] As of December 2014, 44 low-income countries had introduced PCV10 or PCV13, using funding from a unique donor program called the Advance Market Commitment.[571]

Outbreaks of severe pneumococcal disease, including bacteremia, sepsis, and pneumonia, can occur. Most outbreaks occur in closed settings where people are in prolonged close contact, such as jails, long-term care facilities, childcare centers, or homeless shelters.[572] In these settings, control measures include improved infection control coupled with vaccination; conjugate vaccine or 23-valent polysaccharide vaccine might be appropriate, depending on the serotype and ages of persons involved. Use of antibiotic prophylaxis might be helpful, depending on the susceptibility profile of the strain causing the outbreak and whether the nature and timing of cases suggests that the at-risk population requires protection while vaccines are taking effect. Care must be taken with use of antibiotic prophylaxis, however, because widespread antibiotic use can lead to circulation of resistant strains.[551] In some outbreaks, the presence of a viral cofactor may suggest that other prevention measures might be helpful, such as use of influenza vaccine.

Pneumococcal Conjugate Vaccine Immunization of Adults

Adult PCV13 vaccination has been recommended for adults with underlying immunodeficiency and most recently for all adults 65 years of age or older by the ACIP in the United States.[573] There has been significant debate about the advantages of conjugate vaccine use in adults in terms of immunogenicity and potential effectiveness compared with PPV vaccination.[286] A large-scale, randomized, double-blind trial, CAPITA (Community-acquired Pneumonia Immunization Trial in Adults), has provided data on the efficacy of PCV in adults.[18] This trial was performed in The Netherlands and 84,496 adults, 65 years of age or older were randomized to receive a single intramuscular dose of the same PCV13 vaccine formulation given to infants or placebo. Patients with evidence of being immunocompromised were excluded, and the per-protocol analysis excluded patients who developed an immunocompromising illness during the trial. VT disease was assessed by the culture of strains from sterile sites, or the detection of serotype-specific antigen in urine.[574] X-rays confirmed that community-acquired pneumonia caused by VTs occurred among 49 vaccinees and 90 placebo recipients for a vaccine efficacy of 45.6% (95% CI, 22% to 63%). Efficacy against IPD was 75% (7 vs 28 cases; 95% CI, 41% to 91%). Cumulative efficacy against VT community-acquired pneumonia, nonbacteremic and noninvasive community-acquired pneumonia, as well as VT IPD are shown in Fig. 46.7. Overall impact on x-ray confirmed pneumonia in a modified ITT analysis was modest and not significantly different in PCV13 vaccine recipients and controls (5.1%; 95% CI, −5% to 14%). The immunization of infants with PCV7 followed by PCV10 in The Netherlands may have reduced the contribution of VTs to x-ray–confirmed pneumonia in the adults, which is consistent with the low overall impact on pneumonia. There was no impact on mortality. In supplementary analyses, there was no impact on the

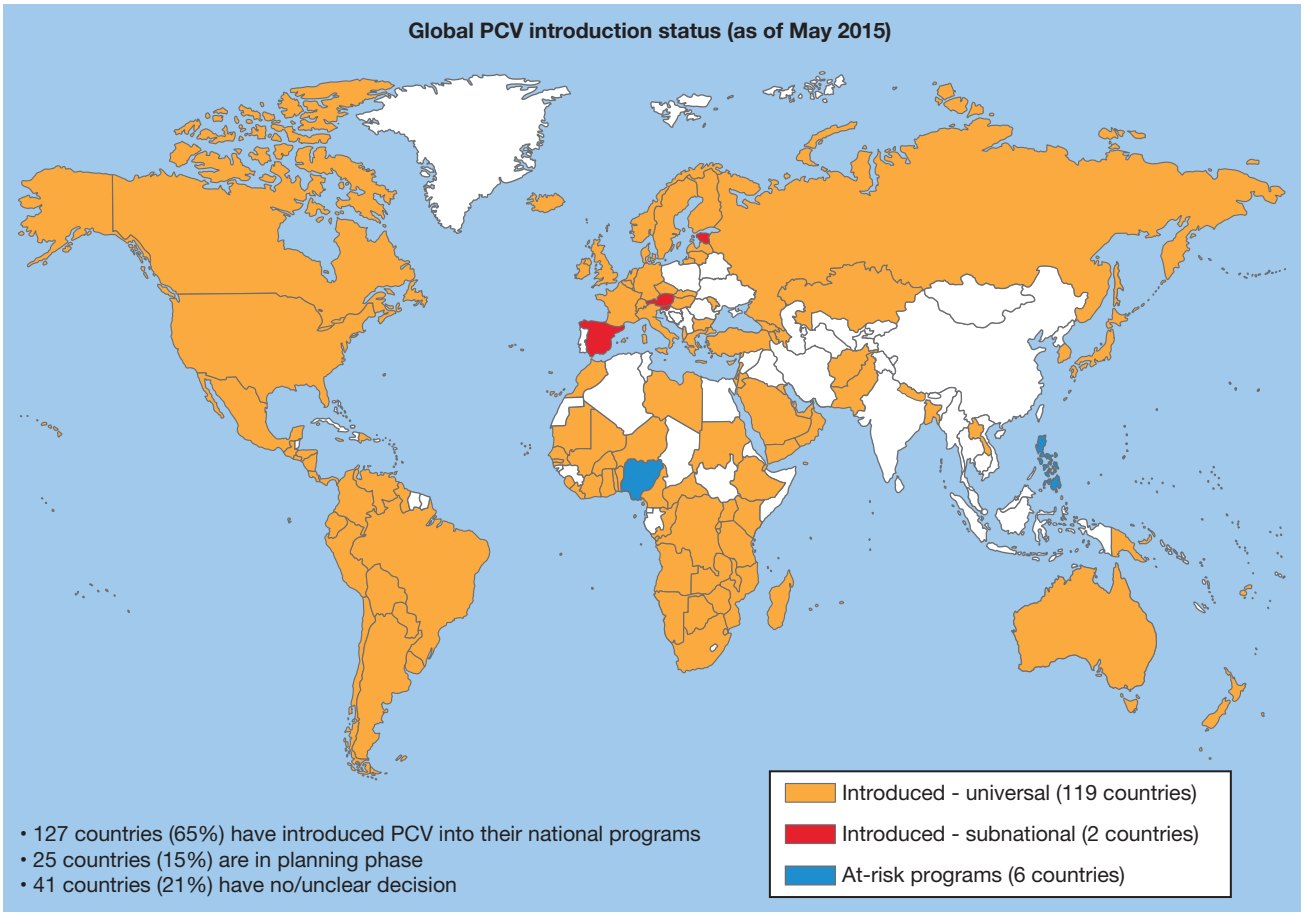

Figure 46.6. Countries that have introduced pneumococcal conjugate vaccines (PCVs) in their national immunization programs—worldwide, 2015. As of May 2015, 127 countries (65%) have introduced PCV into their national programs, 25 countries (15%) are in planning phase, and 41 countries (21%) have no/unclear decision. *(From International Vaccine Access Center [IVAC, Johns Hopkins Bloomberg School of Public Health. Vaccine Information Management System [VIMS] Global Vaccine Introduction Report, May 2015.)*

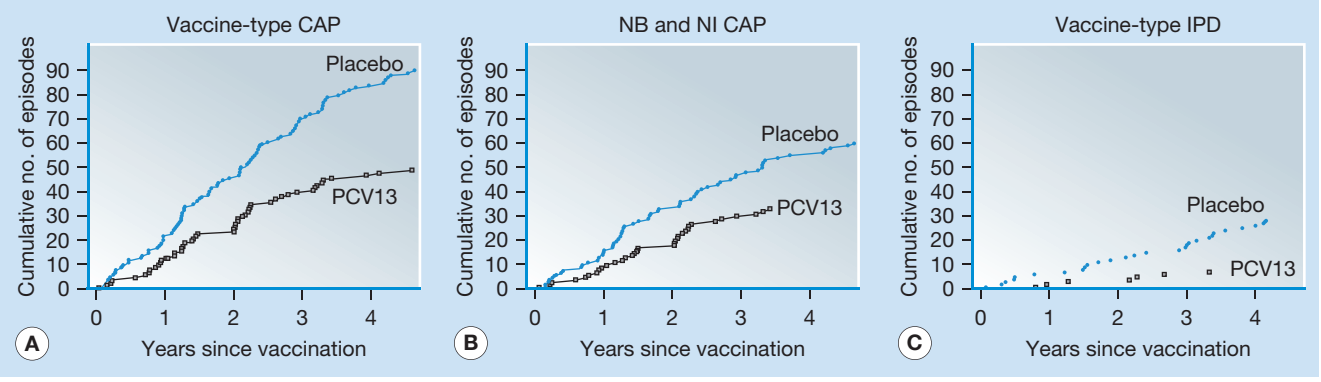

Figure 46.7. Post hoc analysis of the cumulative episodes of the primary and secondary efficacy end points in the per-protocol population. CAP, community-acquired pneumonia; IPD, invasive pneumococcal disease; NB, nonbacteremic; NI, noninvasive. *(Modified from Bonten MJ, Huijts SM, Bolkenbaas M, et al. Polysaccharide conjugate vaccine against pneumococcal pneumonia in adults. N Engl J Med. 2015;372[12]:1114–1125.)*

primary end point of VT community-acquired pneumonia in those older than age 85 years (six vaccinees vs three controls); nor in those who developed immunodeficiency during the trial (14 vaccinees vs 11 controls). In terms of serotype-specific protection, most efficacy was seen against serotypes 3, 7F, and 19A (of the overall difference of 51 cases between vaccinees and controls, 36 were to these three serotypes). As mentioned in the "Safety" section above, there were more local reactions, but no excess of severe adverse events in the vaccine group. The data suggest that PCV prevents nonbacteremic pneumonia in otherwise healthy 65- to 85-year-olds, but that the efficacy against all-cause community-acquired pneumonia is limited

when children are receiving PCV in the same community. The magnitude of the impact on VT IPD was similar (75%) to that seen in infants given PCV, but the data suggest that PCV impact on VT nonbacteremic pneumonia is less than that against IPD (45% vs 75% in this study).

There are data supporting the efficacy of PCV in the prevention of IPD in HIV-infected adults who have already experienced a previous episode of IPD.[575] Because the PCV7 serotypes have almost disappeared as a cause of IPD in adults in the United States after PCV immunization of adults, the impact of PCV13 immunization in infants on the preventable disease burden of PCV13 immunization in adults in the United States may be time limited. The recommendation for use in adults was therefore time-limited with a review expected in 2018 once the residual burden of vaccine-preventable disease is clarified. The impact of PCV13 on herd protection of the additional six serotypes requires further study, although an early report showed decreasing rates among adults of serotypes 19A and 7F, the two most common serotypes, after PCV7 introduction in the United States.[15] Little is currently known about the risks of imported carriage of PCV13 serotypes on disease among susceptible adults in the United States or other countries where these types are close to elimination. The risks of travel by susceptible adults to countries where these serotypes remain common also have not been evaluated. These factors need to be considered both in the licensure decisions around PCV13 vaccines for adults and in their potential indications for use.

Cost-to-Benefit Information

The cost of PCV was considered quite high when it was initially introduced, although since then other vaccines of higher cost, such as human papillomavirus vaccine, have been introduced. In the developing world, the unit cost remains high compared with EPI vaccines, and only subsidies through the GAVI and other programs have allowed its use in this setting.

Vaccine cost-effectiveness is dependent on many factors, including disease incidence, vaccine efficacy, herd effects, disease sequelae, number of doses, and cost per dose of the vaccine. Any of these factors may change over time as prices change, as more is learned about vaccine efficacy or herd effects, or when standards of medical care improve. Consequently, any determination of cost-effectiveness is limited by the time-specific and place-specific variables that were used for the analysis. In addition, there are significant nonmedical costs associated with pneumococcal disease, most notably the cost of work-time lost by parents caring for ill children.[576]

In the year 2000, Lieu and associates[576] were the first to analyze the potential cost-effectiveness of the seven-valent PCV using data from the NCKP randomized trial as well as the opinions of a panel of experts.[576] The analysis was based on a comparison of "vaccination" with "no vaccination," assuming the use of four doses for routine vaccination of healthy infants and one dose for catch-up vaccination of children older than age 2 years. In addition, the conservative assumption was made that a vaccinated infant would experience reductions in pneumococcal diseases only until the child's fifth birthday and that vaccination of children would not protect unvaccinated persons (no herd effects). From the societal perspective, vaccination of healthy infants would result in savings if the vaccine cost $46 or less per dose. From the healthcare payer perspective, net savings would occur if the vaccine cost $18 or less per dose.

An updated analysis looked at cost-effectiveness in the United States for the first 5 years of routine use and showed that the actual cost-effectiveness has been better than predicted by this earlier estimate because of the "herd effect" and consequent reduction in disease among unvaccinated children and adults.[577] Without incorporating herd effects in this more recent model, conjugate vaccine was estimated to have averted 38,000 cases of invasive disease during its first 5 years of use, at a cost of US$112,000 per life-year saved. After incorporating the reductions in invasive disease for unvaccinated persons, the vaccine prevented 107,000 cases of invasive disease at a cost of US$7800 per life-year saved. Similar analyses have been performed for other countries, which have demonstrated similar results.[578,579] An analysis of PCV cost-effectiveness in developing countries suggests the vaccine would greatly reduce mortality and be highly cost-effective at between US$1 and US$5 dollars per dose.[580]

A recent analysis was conducted of the impact of the PCV10 manufactured by GlaxoSmithKline as compared with PCV7.[581,582] This simulation model predicted, as expected for a higher-valency vaccine, that there would be a higher impact of PCV10 on invasive disease than has been observed for PCV7. For OM, the contribution of protection against nontypeable *H. influenzae* increased the impact of this vaccine against OM significantly. Since nontypeable *H. influenzae* is a major cause of OM in the developed world, this has been the most important cost-saving determinant of the PCV10 vaccine in this setting. In another study comparing the impact of PCV13 against both PCV10 and PCV7, PCV13 was predicted to be most cost-effective.[583] This study did not take into account any impact of the 10-valent PHiD-CV vaccine against OM caused by nontypeable *H. influenzae*. In reality, whether the 13-valent or 10-valent vaccine is more cost-effective will depend on the relative importance of the additional serotype coverage provided by the 13-valent vaccine versus the impact of PHiD-CV against nontypeable *H. influenzae*. At this point, it is too soon after the introduction of these two vaccines to reliably make this assessment.

Efforts are underway to find financing to cover costs of introducing new vaccines, including PCV, in developing countries. In an analysis that estimated the funding needs for childhood immunization in developing countries during the 2004 to 2014 period, the total costs of providing immunization for the poorest countries would be approximately US$14 to US$17 billion, accounting for phasing in of new vaccines. Vaccine-related costs represented the largest share of this amount (US$7.1 to US$9.3 billion), with US$4.3 to US$6.5 billion for a set of new vaccines, including PCV. These estimates were for all 75 countries eligible for support from GAVI and covered existing vaccines that were considered priorities (diphtheria/tetanus/pertussis, hepatitis B, Hib, and yellow fever) as well as future vaccines likely to be available during 2004 to 2014 (meningococcal A and C, rotavirus, human papillomavirus, malaria, *S. pneumoniae*, and tuberculosis).[584] The sustainability of these programs will depend both upon the ability of developing countries to assume responsibility for paying for PCV and the ability of manufacturers to supply vaccine to these countries at an affordable price.

FUTURE VACCINES

Problems With Conjugates

Despite the good safety record of PCVs and their demonstrated high efficacy against invasive infections, several limitations remain. One of the issues is that conjugate vaccines are only capable of protecting against infection with bacteria that express polysaccharide capsule types that are included in the vaccine. Current formulations in use or in clinical development cover up to 75% to 90% of strains prevalent

in children.[38,40,99,106,112] However, this figure is lower in certain geographic areas and in older age groups. Another issue is the potential for replacement disease with nonvaccine serotypes to reduce the overall benefit seen from reduction in disease caused by vaccine serotypes.[585] The third major issue is the complexity of conjugate vaccines production, the major reason only a limited number of companies are manufacturing conjugate vaccines and the higher price than for other vaccines.

To improve and expand the immunogenicity of the conjugate vaccines, new components in the conjugate and novel adjuvants have been tested in animal studies.[32,569,586,587] Innovative administration routes are being evaluated. Intranasal immunization with various adjuvants induces strong antibody responses both in serum and on mucosal surfaces in mice, protecting them against lethal infections.[214,586,587] Even though these strategies may circumvent some of the problems of conjugates, they do not address the issues of coverage, replacement, or complexity of vaccine production. Therefore, other types of immunogens, including whole-cell pneumococcal bacteria, DNA vaccines, and protein antigens, are being evaluated as novel pneumococcal vaccine candidates, both in animal models and in humans. One killed whole-cell–based vaccine has proven effective in a mouse model,[569] successfully completed a Phase I clinical trial in healthy U.S. adult volunteers, and is undergoing a Phase II trial in Kenyan adults and toddlers. Attempts to develop pneumococcal DNA vaccines are still limited by the generic problems of immunogenicity associated with naked DNA in humans. The extensive work performed on protein vaccine candidates will be discussed in more detail below.

Protein Antigens

Protein-based vaccines are attractive for several reasons. They are expected to be immunogenic in early infancy and in the elderly because of their T-cell–dependent nature and, if the proteins are well conserved across all pneumococcal strains, the afforded coverage theoretically could be broader than that of conjugate vaccines. Enhanced protection against colonization and avoidance of the replacement phenomenon are also potential advantages. In addition, the cost of goods would likely be lower than that of conjugates because they would have fewer components than multivalent conjugate vaccines, allowing wider global use.

The list of pneumococcal proteins that have been evaluated for their potential as vaccine candidates is extensive. Although exceptions can be found, these candidates tend to have several characteristics in common: significant contributions to bacterial virulence, conservation across all or most sequenced pneumococcal strains, and little homology to human proteins. In general, the candidate antigens have been promising when used as immunogens in a rodent models of invasive disease, colonization, or both. These proteins have been studied alone, in combination with other candidates, such as carrier proteins for pneumococcal conjugates. Some examples are provided below and the field has been reviewed.[588]

Pneumococcal surface protein A (PspA) is a surface protein with variable molecular size, ranging from 67 to 99 kDa in different pneumococcal strains. It is present on the surface of pneumococci and is required for full virulence in animal models.[589,590] It is serologically highly variable, and the structure of the *pspA* gene is mosaic.[591] The high degree of variability exhibited by PspA may indicate the importance of this surface protein as a natural target for host defense. Based on the relatedness of the nucleotide and amino acid sequences, the different PspA molecules are grouped into three families, which are further subdivided into clades.[591] More than 98% of the PspA molecules typed to date are members of families 1 and 2.

Because of the variability of the PspA protein, a potential PspA-based vaccine would likely need to contain PspAs of more than one pneumococcal strain or be based on conserved regions of the molecule to be able to protect against all pneumococci.[592]

The mechanism of action of PspA has been carefully investigated. The aminoterminal region of PspA functions as a specific receptor for lactoferrin. It has been suggested that by binding lactoferrin, pneumococci are able to interfere with the host's immune functions.[593] PspA inhibits the activation of complement by *S. pneumoniae* facilitating pneumococcal survival and host invasion.

PspA is immunogenic and has been shown to elicit protective immunity in mice[594–598]; after intranasal immunization mice are protected against pneumococcal carriage and subsequent invasive disease.[599] Animal models show that PspA has the ability to elicit cross-protection against heterologous strains.[590,596,598] In addition, human antisera from a Phase I vaccine trial protected mice against challenge with pneumococcal strains of various PspA types.[600] However, further development of a PspA vaccine was halted because of concerns about areas of low-sequence homology with human cardiac myosin with the potential to generate cardiac disease or autoimmunity.[601] *Pneumococcal surface protein C (PspC)* plays an important role in pneumococcal pathogenesis by functioning as an adhesin.[602] It also binds soluble host factors, such as the secretory component, the third component of complement, and complement factor H.[603–606] The gene for this protein is present in approximately 75% of *S. pneumoniae* strains.

PspC is one of a dozen pneumococcal choline-binding proteins (CBPs) that are attached to the bacterial surface by docking noncovalently with the phosphorylcholine of the cell wall. These CBPs also include PspA, CbpA (*C*3-*b*inding *p*rotein *A*), SpsA (*S. pneumoniae s*ecretory Ig*A* binding *p*rotein), Hic (factor *H*-binding *i*nhibitor of *c*omplement), and LytA (major pneumococcal autolysin).[602,603,607,608] Sequence analysis has shown that PspC, CbpA, Hic, PbcA, and SpsA are variants of the same CBP.[609]

When used as an immunogen in a mouse model,[610] PspC, protects against challenge with pneumococcal strains expressing both PspA and PspC, as well as those expressing only PspA, suggesting cross-protection.[609]

Pneumococcal choline-binding protein A (PcpA) is a bacterial surface antigen thought to play a role in pneumococcal adherence to pulmonary epithelial cells.[611] Immunization with PcpA is protective in murine models of sepsis and pneumonia. and it is being considered as a component of a three-valent pneumococcal protein-based vaccine, as discussed below.

Pneumococcal surface adhesin A (PsaA) is a 37-kDa surface lipoprotein that contributes to pneumococcal virulence. Initially, PsaA was thought to be a pneumococcal adhesin, but genomic sequence comparison[612] and studies on the crystal structure of PsaA[613] revealed that it is a component of an adenosine triphosphate–binding cassette-type (ABC-type) permease membrane transport system, and responsible for the uptake of Mn^{2+} (and possibly Zn^{2+}) into the bacterium.[614] Many genes for such metal transporters exist in the pneumococcal genome. Some of these proteins, such as Adc and PsaA, are particularly important for pneumococcal virulence and may be attractive candidates for further evaluation.[614]

The loss of host adhesion observed in $PsaA^-$ mutants is thus probably indirect evidence that PsaA appears to have a regulatory role in adhesion by affecting the expression of CBPs on the surface of pneumococci; mutants lacking the *psa* operon

demonstrate a complete absence of PspC/CbpA.[615] It has been suggested that PsaA might play an important role in regulating the expression of oxidative stress response enzymes and intracellular redox homeostasis.[616]

In animal models, PsaA is immunogenic and protective against IPD.[617–619] It is highly effective against nasopharyngeal carriage in mice when administered intranasally; however, as with other proteins, combinations of antigens containing PsaA are far more effective than when PsaA is used alone.[620]

Pneumolysin (Ply) is a 53-kDa intracellular toxin produced by all clinical pneumococcal isolates. This toxin has several properties that may contribute to virulence: Ply inhibits neutrophil bactericidal activity by reducing chemotaxis, phagocytosis, and the respiratory burst.[621] It also inhibits the lymphocyte proliferation response to mitogens, the synthesis of all Ig classes,[622] and ciliary function in human respiratory tract.[623,624] Ply induces separation of the tight junctions of alveolar epithelial cells.[625] Ply also activates the classic complement pathway, which leads to complement consumption, allowing pneumococci to evade opsonophagocytosis, the essential mechanism for clearance of pneumococci from the lung.[626] Ply also induces Toll-like receptor 4–dependent inflammatory responses and apoptosis in eukaryotic cells.[627] What role each of these properties plays in pathogenesis is unclear; a serotype 1 strain causing invasive disease in Scotland was found to express a nonhemolytic Ply.[628]

Mutants deficient in Ply are less virulent than parental wild-type strains in some animal models.[629] Immunization with Ply prolongs the survival of mice after challenge with pneumococci of different serotypes.[630–632] Mice immunized with combinations of pneumococcal virulence proteins including Ply have significantly longer survival times than mice immunized with any of the antigens alone.[619] Conjugation of pneumolysoid toxoids or recombinant Ply with pneumococcal capsular polysaccharides may confer broader protective immunity than conjugates using nonpneumococcal proteins.[131,211,212,633,634] Constructs of pneumolysoid–pneumococcal protein fusions conjugated to polysaccharides confer enhanced protection against pneumococcal disease and colonization.[635] As discussed below, vaccines containing detoxified Ply are currently undergoing clinical trials.[636–638]

Neuraminidase enzymes (NanA and *NanB)* cleave sialic acid residues from host glycolipids and gangliosides, causing damage to host tissues. This action may reveal new receptors for pneumococcal adhesins, facilitating both adhesion and invasion.[639] NanA is a cell-surface–associated enzyme with sialidase activity produced by all clinical isolates of pneumococcus.[640,641] NanA has the potential to cause great damage to the host by cleaving the terminal sialic acid residues from a wide variety of glycoproteins, glycolipids, and oligosaccharides present on host cell surfaces.[642] It has been suggested that NanA plays a role in pneumococcal carriage and AOM. NanA may enhance pneumococcal colonization by decreasing the viscosity of mucus.[642] or by exposing new host cell receptors for pneumococcal adherence.[643–645] NanA does promote brain endothelial cell invasion.[646,647] Immunization of mice with purified NanA confers some protection against challenge with virulent pneumococci.[648] In a chinchilla model, immunization with NanA resulted in significant reduction in nasopharyngeal colonization and in OM with effusion.[649]

A more recently described group of pneumococcal vaccine candidates, the *pneumococcal histidine-triad proteins,* contain similar surface-exposed proteins capable of protecting mice against fatal pneumococcal infection. This protein family has various names based on the conserved histidine triad motif (HxxHxH) repeated several times in the proteins. The proteins have been named the Php family (for pneumococcal histidine protein; PhpA, PhpB, and PhpC),[650] the Pht family (for pneumococcal histidine triad; PhtA, PhtB, PhtD, and PhtE),[651] and BVH3 and BVH11.[652]

These proteins are immunogenic and protective against pneumococcal challenge in animal models. The immunization of mice with PhtA (BVH11–3), PhtB/PhpA (BVH11), or PhtD (BVH11–2) induced protection against IPD.[651] Immunization of mice with recombinant PhpA protein significantly reduced nasopharyngeal colonization and protected mice against bacteremia and death after intranasal challenge with pneumococci.[650] Another study reported that immunization of mice with the recombinant proteins BVH3 and BVH11 elicited protection against both experimental pneumococcal sepsis and pneumococcal pneumonia.[653] More recently it was shown that natural anti-PhtD human antibodies transferred to mice protected against lethal intranasal challenge.[654] As discussed below, vaccines containing PhtD have been studied in humans, with favorable safety profiles in adults and toddlers.[636–638]

The discovery of a mobile genetic element encoding a *pilus-like* structure in pneumococcus and the demonstration of a role for the pilus in virulence in mouse models have led to the consideration of pilus antigens as vaccine candidates.[655,656] In *S. pneumoniae*, pili are encoded by two genomic islets (pilus islet 1 and pilus islet 2), but these are present in only a subgroup of pneumococcal isolates. Mutants of pilus islet 1 demonstrate reduced virulence in different models. The pilus appears to be an inflammatory structure, but it remains to be determined whether the resulting inflammation promotes or reduces the ability of the bacterium to colonize or invade.[656]

Pilus islet 1 was found to be associated with certain serotypes and correlates very tightly with genotype.[657] After the introduction of the conjugate vaccine in the United States, the prevalence of pilus islet 1 in clinical isolates dropped dramatically,[658] but rebounded to pre-PCV7 prevalence levels in Massachusetts within 7 years.[659]

Mice immunized with the three structural proteins that constitute pilus islet 1 (encoded by *rrgA, rrgB,* and *rrgC*) were protected against invasive disease resulting from piliated strains.[660] The low prevalence of piliated pneumococci may limit the usefulness of these antigens, but it has been proposed that they may be used in combination with more conserved pneumococcal proteins in a multicomponent vaccine.[661]

Two newer antigenic discovery approaches have been described. In one, investigators screened pneumococcal protein libraries for immunogenic targets by identifying antigens recognized by antibody from convalescent sera of patients recovering from IPD.[662] Two antigens were identified, "protein required for cell wall separation of group B streptococcus" (PcsB) and serine/threonine protein kinase (StkP). Another strategy used a proteomic approach to identify antigens recognized by $CD4^+$ Th17 cells from murine or human hosts exposed to pneumococcus. This approach identified different targets than those selected by antibody-mediated approaches and demonstrated that animals could be protected from colonization with a $CD4^+$ T-cell and IL-17A–dependent approach.[408]

Human Experiences With Natural or Vaccine-Derived Pneumococcal Protein Antigens

Over the past few years, there have been numerous reports on the natural development of antibodies to many of these pneumococcal proteins in humans, including children.[663–672] Concentrations of antibodies to PsaA are lower in children with

pneumococcal AOM than in those with nonpneumococcal AOM [664] and in children with pneumococcal carriage than in noncarriers.[663] Similarly, a low concentration of PspA antibodies was detected in children with invasive pneumococcal infection as compared with children with nonpneumococcal invasive infection.[668] The presence of salivary IgA antibodies (but not serum IgG antibodies) to PspA was associated with a decreased risk of pneumococcal OM during the following 6 months.[673] Increases in anti-PsaA and anti-Ply concentrations are seen in adults with pneumococcal pneumonia, the increase being more evident in those with bacteremic pneumonia. On the other hand, anti-PspA levels showed a twofold increase in only 15% of Finnish children with IPDs. Studies in Filipino children did not support the notion that natural immunity protects against OM, although there were some hints that antibodies to Ply were associated with a reduction of pneumococcal carriage.[674]

Human adults have been shown to naturally produce antibodies to PhtA and PhtB.[653] Likewise, pneumococcal colonization has been shown to induce the development of natural antibodies in infants.[675] Antibodies to PhtA and PhtD have been detected in convalescent-phase sera from patients with pneumococcal bacteremia.[651]

McCool and associates[231] provided evidence that serum IgG and/or secretory IgA targeting the variable terminal region of PspA were associated with reduced likelihood of carriage and that experimentally induced nasal colonization in human adults induced serum IgG antibodies to both PspA and CbpA.[232] Finnish researchers showed that high serum anti-PsaA levels predicted low risk of progression to OM in colonized children older than 9 months of age, but predicted a greater likelihood of subsequent OM in younger infants.[664] In a British study, anti-CbpA and anti-Ply serum levels and salivary IgG antibody levels were higher in children undergoing adenoidectomy who were culture negative for pneumococci than in those obtained from children who were colonized with pneumococcal organisms.[676]

Whether these antibodies provide protection to children against pneumococcal colonization or are just associated with resistance to colonization remains uncertain. As described above, data in mice and humans suggest that, independent of antibodies, $CD4^+$ T cells directed against pneumococcal antigens may provide resistance to colonization.[397,398] Adenoidal cells obtained from children at the time of surgery demonstrated that children colonized with pneumococci had lower $CD4^+$ T-cell proliferative responses to Ply than those who were not colonized.[677] It has also been shown that children in Sweden and Bangladesh readily develop Th17 responses to a pneumococcal proteins.[678]

Despite decades of research in this area, there have been only a few trials of pneumococcal proteins in humans, with even fewer published results. A Phase I clinical trial demonstrated that a recombinant family 1 PspA protein was safe and elicited persistent antibody to the PspA protein in vaccinated volunteers.[679,680] These antibodies, when transferred to immunocompromised mice, protected against challenge with pneumococci expressing either family 1 or family 2 PspAs. As noted above, clinical trials of combination vaccines containing PcpA, detoxified Ply, and PhtD have been performed in adults and toddlers[636–638] with favorable safety profiles to date. PhtD and Ply are being studied in combination with PCVs in collaboration among GlaxoSmithKline, Programs for Appropriate Technology in Health (PATH), the Gambian Medical Research Council, and the London School of Hygiene and Tropical Medicine. A Phase II clinical study in The Gambia of this combination PCV+protein vaccine candidate to be safe and immunogenic but without impact of the proteins on pneumococcal carriage.[18a]

A protein-based candidate pneumococcal vaccine consisting of two lipoproteins (SP_2108 and SP_0148) and a protein of unknown function (SP_1912) was evaluated in a Phase I clinical trial. These proteins were identified by Genocea Biosciences in collaboration with PATH and Boston Children's Hospital, based on a proteomic analysis of the Th17 responses from immune mice or human adult volunteers.[408,681] The combination of these three proteins elicited robust Th17 responses and TH17-dependent protection against colonization in mice.[408] The lipid motif on the two lipoproteins, which activates Toll-like receptor 2, appears to be critical for optimal immunogenicity and protection in the murine model.[682] Following these studies, lipidated versions of the three proteins were formulated on aluminum hydroxide and successfully evaluated in a double-blind, dose-escalating Phase I clinical trial. This vaccine was studied in a Phase IIa clinical trial of intentional human challenge in healthy adults to evaluate the effect of the vaccine on the frequency, magnitude and duration of pneumococcal colonization, with nonsignificant results presented, but not published to date.

Killed Whole-Cell Vaccine

In general, because different virulence factors of S. *pneumoniae* may act at different stages of pneumococcal colonization and/or infection, it is likely that immunization with a combination of proteins may be the best approach. An extension of this idea involves the possibility of using a killed whole-cell pneumococcal vaccine, where a large number of pneumococcal antigens would be presented at once. Published reports of numerous trials using this type strategy date back to 1911[683] and a metaanalysis of these studies suggests efficacy of this approach.[683] Since then, work in mice has demonstrated that immunization with killed whole cells, using a variety of routes (intranasal, oral, sublingual, transcutaneous, subcutaneous, and intramuscular) and with adjuvants (enterotoxins, enterotoxin mutants, or nontoxic subunits or Toll-like receptor agonists by the mucosal route, and aluminum hydroxide by the parenteral route), provides robust and reproducible protection against nasopharyngeal colonization (via $CD4^+$ T cells) and invasive disease (via antibodies).[684] A good manufacturing practices–grade killed whole-cell vaccine administered parenterally with aluminum hydroxide conferred protection in mouse models of carriage or aspiration pneumonia/sepsis.[224] This vaccine was studied in a Phase I safety and immunogenicity trial in healthy adult volunteers in the United States at three different concentrations. The vaccine was well tolerated and induced both antibody and Th17 responses. Passive transfer experiments in mice, using sera pre- and postimmunization, showed vaccine-induced protection against type 3 invasive disease and sepsis.[685] Following these promising results, a Phase I/II age deescalation clinical study was begun in Kenya, to evaluate, in addition to safety and immunogenicity outcomes, the potential impact of the whole-cell vaccine on pneumococcal carriage in toddlers. Although the ultimate target of the vaccine is infants, an early sign in toddlers of a possible impact on reduction of carriage, or duration of carriage, would be very promising. At the same time, it is important to recognize that further development of this vaccine will require more direct evaluation of efficacy against pneumococcal disease. Several issues will need to be considered, such as a careful definition of the outcome of interest (pneumonia, sepsis, meningitis), the ethical considerations surrounding the evaluation of the whole-cell vaccine versus PCV, as well as the setting of the trial (either in a PCV-experienced or -naïve pediatric population).

Combination Strategies

These above considerations will determine the feasibility and size of any pivotal trial of both the whole-cell and the protein-based pneumococcal vaccines as correlates of protection for whole-cell vaccine and protein-based vaccines are not established. The development of these vaccine candidates will likely require large double-blind, randomized trials with a precisely defined disease outcome in infants and children. Estimates of the size of the trial vary according to whether the population is PCV-experienced or -naïve, and whether both arms of the study would also be receiving PCV.

As an alternative approach, the inclusion of conserved pneumococcal proteins as components of polysaccharide-protein complexes has been considered. In particular, Plys and PspA have been evaluated as potential carrier proteins in various conjugates in mice,[216,634,686] with promising results. These strategies, which may offer broader coverage against the pneumococcus than traditional conjugates wherein the protein carrier is an irrelevant protein (such as CRM_{197}, diphtheria or TT), still represent very complex and expensive manufacturing processes, potentially limiting their applicability in the developing world setting. The possibility of protein-epitope damage by chemical conjugation to diverse polysaccharides has also been raised.

To address these issues, alternative strategies for associating polysaccharides to proteins in a more efficient and less complex fashion have been studied. Liquidia Technologies described its Particle Replication In Non-wetting Templates (PRINT) technology as a tool to form nanoparticle-based virtual conjugates[687] and initiated preclinical evaluations of this vaccine in rodent and rabbit models. Another approach in which affinity interactions between biotinylated polysaccharides and rhizavidin-fused pneumococcal proteins are used to form polysaccharide-protein macromolecular complexes has been presented.[688] The manufacture of these constructs is highly efficient and significantly less complicated than chemically coupled polysaccharide–protein vaccines, which may offer important advantages for the developing world. Immunological responses to the polysaccharides in these affinity complexes are notable for $CD4^+$ T-cell dependence, as well as for the generation of boostable antibody responses and affinity maturation. In addition, both antibody and $CD4^+$ Th17 responses to the proteins are generated, thus raising the possibility of broad, serotype-independent antibody- and Th17-mediated protection against invasive disease and colonization, respectively. The MAPS (Multiple Antigen Presentation System) technology was licensed by Boston Children's Hospital to a biotechnology company (Affinivax, Cambridge, MA) for the development of novel vaccines for both the developing and developed world. In particular, a program to design, manufacture, and test a low-cost, multivalent pneumococcal vaccine received support from the Bill and Melinda Gates Foundation and PATH. Clinical trials of a MAPS-based multivalent pneumococcal vaccine are planned to start in 2017.

CONCLUSIONS

Since its rollout in children, pneumococcal conjugate vaccine has provided significant protection against invasive disease and pneumonia due to the vaccine serotypes. These benefits have extended to all age groups through the induction of herd protection by immunization of infants and toddlers. The reduction in disease has provided significant public health benefits to the populations where these vaccines have been used and there is a priority for additional populations, especially in Asia, to receive these vaccines. The benefits appear to extend beyond the previously known burden of pneumococcal disease to prevention of previously suspected, but unmeasured secondary pneumococcal infections that complicate disease due to influenza, respiratory syncytial virus, and other copathogens. At the same time, the limited serotype coverage of the vaccines have allowed replacement disease with non-VTs. The extent of the replacement has been limited in most settings, but continued surveillance is needed. Further expansion of the serotypes in these vaccines and consideration of protein based vaccines on their own, or as adjuncts to pneumococcal conjugates, have moved beyond preclinical studies in animals and are now in human clinical trials.

47 Pneumococcal Polysaccharide Vaccines

John D. Grabenstein and Daniel M. Musher

Since the late 19th century, the study of *Streptococcus pneumoniae* and pneumococcal infections has occupied a central position in developing a scientific basis for controlling infectious diseases.[1–7] The organism was first isolated and grown in the laboratory almost simultaneously by Sternberg and Pasteur in 1881. During the next decade, the pneumococcus was shown to be the chief cause of lobar pneumonia. In the early 20th century, the importance of humoral immunity in prevention of infectious diseases was recognized, in large measure as a result of studies of *S. pneumoniae*, and there was the beginning of an understanding of the potential protective effects of antisera and vaccines.

The first large-scale clinical trial of a pneumococcal vaccine, which evaluated a crude whole-cell formulation, was conducted in 1911, at a time when the importance of serotype-specific immunity was not understood.[7] During the following decades, scientists discovered the pivotal role of serotype-specific antibody to pneumococcal capsular polysaccharides and began developing effective polyvalent pneumococcal polysaccharide vaccines (PPSVs).

PPSVs are considered poorly immunogenic in children younger than 2 years of age, the age group traditionally with highest incidence of invasive pneumococcal disease (IPD). To improve the immune response to the capsular polysaccharide in young children, following the model established for a vaccine to prevent infection caused by *Haemophilus influenzae* type b, vaccines in which capsular polysaccharides are conjugated to one of several proteins were developed. A protein-conjugate pneumococcal vaccine (PCV) that contained conjugated capsular polysaccharides from seven common pneumococcal serotypes (PCV7) was administered to children in the first year of life and shown to be highly effective in preventing IPD caused by corresponding serotypes.[8,9] Because PCV also stimulates mucosal immunity and prevents nasopharyngeal colonization, widespread use of the PCV7 has also provided substantial protection for children who were not vaccinated, as well as for unvaccinated adults, a phenomenon that is called an indirect (also called herd or community) effect.[10–13] After evaluating six additional conjugated polysaccharides, PCV13 was licensed for children in the United States in 2010, replacing PCV7. In 2011 and 2012, PCV13 gained an indication for use in adults in various countries.[14]

As in prior editions of this book, PCVs are discussed in Chapter 46. PCVs are routinely recommended for children throughout the world. Consequently, that chapter includes a discussion of pneumococcal infections in children. This chapter focuses on the use of unconjugated PPSVs and their effect on pneumococcal infections in adults, but the epidemiologic impact of PCV in children informs the use of PPSV23 and is reviewed here briefly.

BACKGROUND

Clinical Pneumococcal Infections

S. pneumoniae is a commensal that asymptomatically colonizes the nasopharynx, and is also a major cause of a diverse array of infections. The organism causes infection either by direct extension from the nasopharynx (e.g., pneumonia, otitis media, sinusitis) or by invasion with bacteremic spread into normally sterile fluids (e.g., bacteremia, septic arthritis). Meningitis or spontaneous bacterial peritonitis may occur by direct spread or from hematogenous spread. IPD is defined by isolation of *S. pneumoniae* from a normally sterile site, such as blood, cerebrospinal fluid (CSF), pleural fluid, or synovial fluid.

Bacteriology and Pathogenesis

The microorganism initially observed by Sternberg and Pasteur was called *Pneumococcus* by Fränkel in 1886.[1] It was renamed *Diplococcus pneumoniae* in 1920 because of its distinctive morphology. Its name was changed again to *Streptococcus pneumoniae* in 1974 because of its many similarities to other streptococci.

Avery, MacLeod, and McCarty used the pneumococcus in 1944 to demonstrate that DNA is the active substance responsible for the genetic transformation of pneumococci from rough (nonencapsulated) to smooth (encapsulated) strains. This is one of the cornerstones of modern molecular biology.[15–17] Other biologic markers, such as type specificity and antibiotic resistance, are genetically transferable.

Pneumococci are relatively fastidious, facultative anaerobic organisms that grow in short chains in broth culture. Microscopically, they appear as lancet-shaped gram-positive diplococci or chains of cocci (Fig. 47.1). Growth requires a source of catalase, obtained by adding red blood cells to the growth medium, to neutralize the hydrogen peroxide produced by the bacteria. On blood agar, colonies characteristically produce a zone of α (green) hemolysis, which differentiates *S. pneumoniae* from group A (β-hemolytic) streptococci, but not from α-hemolytic (viridans) streptococci. Pneumococci are distinguished from other α-hemolytic streptococci by two key reactions: optochin susceptibility and solubility in deoxycholate (bile). Pneumococci, but not most other streptococci, are inhibited by optochin and undergo lysis by bile salts. Some pneumococcal isolates, however, are resistant to optochin.[18] Therefore, solubility of the colony in bile is usually regarded as definitive for routine diagnostic purposes.

Capsular Polysaccharides

The capsular polysaccharide on the cell surface (Fig. 47.2) is the major factor responsible for the virulence of *S. pneumoniae*.[19–22] The capsule interferes with phagocytosis by preventing complement C3b–mediated opsonization of bacterial cells. Antibodies to the capsular polysaccharides are protective. More than 90 pneumococcal serotypes have been identified on the basis of antigenic differences in the capsular polysaccharide. Current antipneumococcal vaccines are based on formulations of various capsular polysaccharide antigens derived from selected serotypes; selection is based on the frequency with which specific capsular polysaccharides cause disease in the target population.

Traditionally, capsular serotypes were defined by the Quellung reaction, using polyclonal rabbit sera. The Quellung reaction is, however, not sufficiently sensitive to distinguish

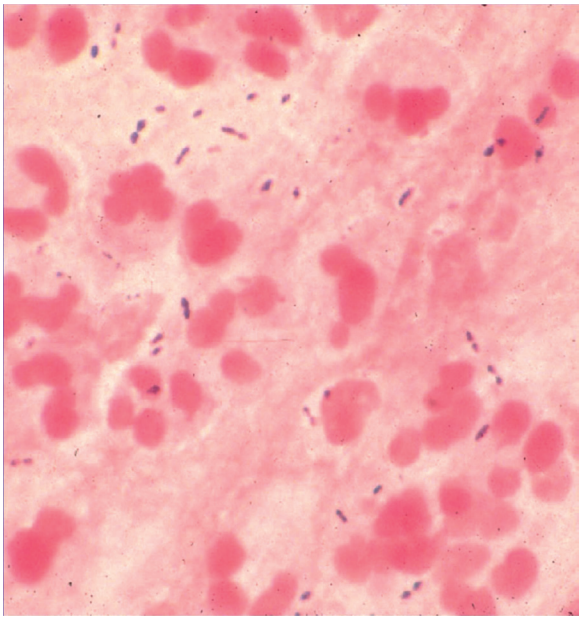

Figure 47.1. Microscope image (×440) of a Gram-stained specimen of sputum showing proteinaceous background, polymorphonuclear cells, and gram-positive, slightly elongated cocci singly and in pairs. Culture yielded *Streptococcus pneumoniae* as the predominant organism. *(Courtesy Daniel M. Musher.)*

serotypes with small structural differences, and more recently, molecular techniques have been used to identify new pneumococcal serotypes, such as 6C, which was indistinguishable from serotype 6A using the Quellung reaction.[22a]

The cell wall of *S. pneumoniae* consists primarily of a peptidoglycan backbone that is covalently linked to teichoic acid on the outer surface of the cell wall and is present in all isolates.[19,20,23] C-polysaccharide plays a major role in stimulating the inflammatory response associated with pneumococcal infections.[24,25] It reacts with a specific β-globulin in human serum (C-reactive protein) in the early stages of the inflammatory response and activates the alternative complement pathway. Antibody to C-polysaccharide appears early in life and can be found in most children and adults, but antibodies directed against C-polysaccharide do not protect against pneumococcal infection.[26]

On the basis of functional genomic analysis, it is estimated that the pneumococcus contains more than 500 surface proteins. The role of several pneumococcal proteins in the pathogenesis of *S. pneumoniae* infections has been extensively studied. These proteins, such as pneumolysin (not a surface protein, but a well-recognized virulence factor),[19,21] pneumococcal surface protein A (PspA), pneumococcal surface protein C (PspC), pneumococcal surface antigen A (PsaA), neuraminidase enzymes, and histidine-triad proteins, are the targets for a new generation of protein-based vaccines. The potential advantages of such vaccines include greater cross-protection among different capsular serotypes. More information on these virulence proteins and the current state of pneumococcal protein vaccine development may be found in Chapter 46.

Diagnosis

The diagnosis of IPD is established by isolation of the organism from blood or another normally sterile site (e.g., cerebrospinal, pleural, or synovial fluid). The diagnosis of noninvasive pneumococcal infections, such as nonbacteremic pneumococcal pneumonia, is more complicated. Approximately 75% of cases of pneumococcal pneumonia are not associated with detectable bacteremia. The finding of *S. pneumoniae* in sputum by Gram stain and culture in a patient who presents with a pneumonia syndrome enables the diagnosis of presumptive pneumococcal pneumonia. However, there are significant limitations to diagnostic tests of sputum. At least 40% of patients are unable to produce an adequate expectorated sputum specimen at time of hospitalization for pneumonia, and, once antibiotics have been administered for longer than 18 hours, the diagnostic yield from sputum Gram stain and culture is less than 25%.[27,28]

A rapid immunochromatographic assay reliably detects cell-wall polysaccharide from *S. pneumoniae* in urine from 60% to 80% of patients who have bacteremic pneumococcal pneumonia and 50% to 60% of those with pneumococcal pneumonia but with negative blood cultures.[29–31] In adults, there are few false-positive results. The assay is less reliable in children who have a heavier colonization burden and who, therefore, have many false-positive results.[32–35] This test is also approved for the rapid diagnosis of pneumococcal meningitis through testing of CSF samples, with a sensitivity of at least 95% and a specificity of 100%.[36–38] The test has also been used to detect *S. pneumoniae* antigen in pleural fluid specimens,[39–41] bronchoalveolar lavage fluid samples (with utility limited by contamination via nasal colonization),[42] and blood cultures.[43]

The newest approach to diagnosing pneumococcal infections has been to use nucleic acid–amplification techniques.[44] Although polymerase chain reaction (PCR)-based assays are highly sensitive, their use to detect *S. pneumoniae* in respiratory samples can be limited by nonspecificity of the gene targets, some of which may also be present in other organisms, such as *Streptococcus pseudopneumoniae*[45] and nonpneumococcal viridans group streptococci that are oropharyngeal colonizers, leading to false-positive results. More importantly, the test may also detect asymptomatic pneumococcal colonization; consequently, a positive test may not indicate pneumococcal infection.[46–54] The first concern may be addressed by the use of gene targets found only in *S. pneumoniae*.[55] The second concern may potentially be addressed by the use of quantitative real-time PCR methods to prevent false-positive results resulting from colonization with small numbers of organisms.[56,57] In patients with meningitis, PCR is highly sensitive and specific for detection of *S. pneumoniae* in CSF samples.[58,59]

Treaent and Resistance

The definition of penicillin susceptibility of pneumococci depends on the site of infection, specifically whether central nervous system infection is thought to be present.[60] In the absence of meningitis, susceptible isolates are inhibited by less than 2 μg/mL penicillin (minimum inhibitory concentration [MIC]). Isolates with a MIC of 2 μg/mL are called *intermediate* and those with a MIC greater than 4 μg/mL are called *resistant*. In cases of central nervous system (CNS) infection, organisms with a MIC of 0.06 μg/mL or less are called *susceptible* and those with a MIC of 0.12 μg/mL or greater are regarded as *resistant*, even though that may be considered an overly strict definition. At present, in cases of non-CNS infection, greater than 95% of pneumococcal isolates are susceptible.[61] In cases of meningitis, 10% to 15% of pneumococcal isolates are penicillin-resistant. Consequently, infections outside the CNS that are known to be caused by the pneumococci can be treated with parenteral penicillin, if appropriate, or other recommended antibiotics.

EPIDEMIOLOGY OF PNEUMOCOCCAL INFECTION

Invasive Pneumococcal Disease

As with many other infectious diseases, rates of IPD are highest at the extremes of age. In 2013, the Centers for Disease Control and Prevention (CDC) Active Bacterial Core surveillance (ABCs) program estimated the following rates (per 100,000 population) by age in the United States: 15.2 for children younger than 1 year; 15.1 for 1-year-olds; 6.9 for 2- to 4-year-olds; 1.6 for 5- to 17-year olds; 2.8 for 18- to 34-year-olds; 8.0 for 35 to 49-year-olds; 17.2 for 50- to 64-year-olds; and 30.2 for persons 65 years of age and older (Fig. 47.3).[13,62] In 2013, the case-fatality ratio of IPD in persons 65 years of age and older was 14%, compared with 1.6% in children younger than 5 years. A total of 33,500 cases and 3500 deaths resulting from IPD are estimated to occur in the United States annually. Pneumonia with bacteremia accounts for the majority (67%) of cases of IPD. Bacteremia without a focus and meningitis account for 19% and 6% of cases, respectively.

Although IPD occurs all 12 months of the year, the incidence in adults increases in the winter. This seasonal variation is closely associated with viral respiratory infections that are also more common in winter. Exposure of children to respiratory viruses and bacteria during the school year is probably a major factor. This increase is not clearly attributable to lower ambient temperature or air pollution. Factors such as photoperiod-dependent variation in host susceptibility may also be involved.[63,64] Although most IPD is community acquired, IPD can be nosocomially acquired. A population-based study in Finland reported that nosocomial pneumococcal bacteremia accounted for 10% of hospitalized pneumococcal bacteremia cases.[65] Numerous pneumococcal outbreaks have been reported, most often from settings of clustered living or working conditions.[66–69]

Pneumococcal Pneumonia

In the preantibiotic era, *S. pneumoniae* caused 95% of cases of pneumonia. This number has steadily declined, such that recent studies document pneumococcus as a cause in approximately 8% to 10% of patients who are hospitalized for pneumonia.[70,71] In most studies of the etiology of hospitalized community-acquired pneumonia (CAP) in adults, *S. pneumoniae* ranks first among bacterial causes.[72–105] However, an etiologic agent is not identified in 50% or more of patients with CAP.

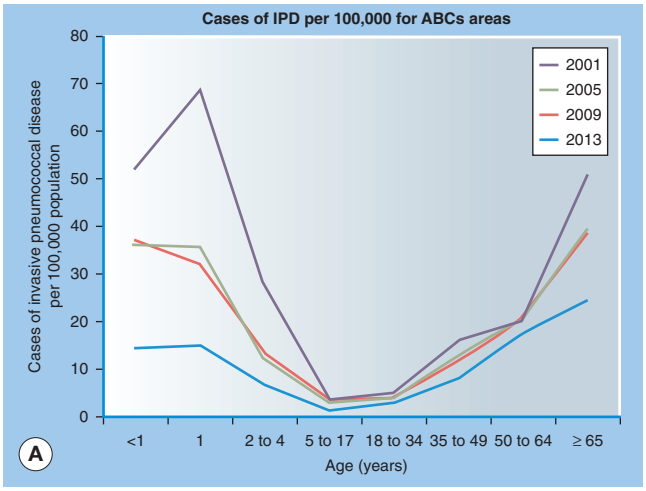

Figure 47.3. A and **B,** Incidence of invasive pneumococcal disease (IPD) caused by any serotype by age cohort for selected calendar years in Active Bacterial Core surveillance (ABCs) areas, cases, and deaths. Data for 1997 not shown in this graphic because extreme values would make interpretation of the other annual reductions difficult to discern. For 1997, in the pre-PCV7 era, the incidence rate of IPD case per 100,000 population were 143 for <1179 for 1 year of age, and 62 for 65 years of age and older. The incidence rate of IPD death per 100,000 population were 4.0 for younger than age 1 year, 0.9 for 1 year of age, and 11 for 65 years of age and older. PCV7 was licensed for children in 2000 and PCV13 was licensed for children in 2010. *(Modified from serial annual reports: Centers for Disease Control and Prevention. Active Bacterial Core surveillance (ABCs) Surveillance Reports, Emerging Infections Program Network, Streptococcus pneumoniae, 1997, 2001, 2005, 2009, and 2013. Available at: http://www.cdc.gov/abcs/reports-findings/surv-reports.hl.)*

An assessment of the clinical and economic burden of pneumococcal disease in older U.S. adults identified the burden of CAP (outpatient and hospitalized) in adults 50 years of age and older in the United States from published studies and then assumed that 30% of such cases were caused by *S. pneumoniae*. This study estimated that *S. pneumoniae* accounts for approximately 500,000 cases of nonbacteremic pneumococcal pneumonia (and an additional 29,500 cases of IPD) in adults 50 years of age and older in the United States each year, leading to US$3.7 billion in direct costs annually based on 2004–07 inputs.[106] Estimates included in this model are not consistent with the lower values for pneumococcal etiology of CAP found in several recent U.S. studies, thus limiting the validity of the model's output.[70,71,107] More recent data on the etiology of CAP in the United States and certain other developed countries suggest that pneumococcus may be responsible for 10% to 15% of cases.[70,71,107] Decreased cigarette smoking and greater use of PPSV23 in older adults and PCVs in children have contributed to this decline, but other unidentified factors also appear to play a role.

Risk Factors for Pneumococcal Disease

Those at the extremes of life in age are particularly susceptible to pneumococcal infection, as shown in Fig. 47.3.

Certain racial and ethnic groups are at increased risk. Several studies in the United States show substantially higher rates of IPD in blacks than in whites.[108–117] Even higher rates of invasive disease have been reported among the White Mountain Apaches in Arizona,[118,119] the Alaskan Native population,[120–123] and aboriginal populations in Australia.[124–127] The biologic explanation for these ethnic predispositions remains to be elucidated, but, in addition to genetically mediated susceptibility, environmental factors may play a role (e.g., crowding, exposure to respiratory irritants). Crowding, physical exhaustion, and stress contribute to well-documented outbreaks of pneumococcal pneumonia in adults.[66–69] These conditions, together with malnutrition and general poor health, help explain outbreaks among prisoners. Some of these, together with age, contribute to outbreaks of pneumococcal pneumonia in nursing homes.

Cigarette smoking is a strong and independent risk factor for IPD in adults. A case-control study of immunocompetent adults 18 to 64 years of age found a fourfold higher risk of IPD in current smokers and a 2.5-fold higher risk of IPD in those with passive exposure to smoke compared with adults who had never smoked and had no passive exposure.[114] Persons with chronic pulmonary diseases (such as chronic obstructive pulmonary disease, emphysema, and asthma) are at increased risk. By damaging pulmonary clearance (and perhaps by increasing bacterial adherence to epithelial cells), influenza virus infection strongly predisposes to pneumococcal pneumonia; other upper and lower respiratory viruses may also do so, albeit to a lesser degree.

Diseases that compromise the ability to generate antibody responses to new antigens render individuals especially susceptible to IPD. Best studied are patients with multiple myeloma, lymphoma, Hodgkin disease, and HIV infection, even before the onset of AIDS. In persons with HIV/AIDS in the pre–HIV-treatment era, the age-adjusted incidence of IPD was several hundred-fold greater than in the non–HIV-infected population, approaching 500 per 100,000 per year.[113,128] Transplant recipients are also at high risk of IPD, with an overall incidence of 146 cases of IPD per 100,000 per year.[128,129] The risk is highest in liver (354 cases per 100,000) and lung (239 cases per 100,000) transplant recipients.[130–133] A question of great relevance to the present discussion is whether such subjects would generate lasting antibody levels after receiving a pneumococcal vaccine (see below and Chapter 69).

Conditions that interfere with function of polymorphonuclear phagocytes are also associated with increased risk of IPD. Diabetes mellitus, chronic renal failure, and cirrhosis of the liver are good examples. Two specialized circumstances are also worth noting. Because the spleen plays a central role in removing nonopsonized bacteria from the bloodstream, persons who do not have a functioning spleen are at a high risk of overwhelming infection caused by *S. pneumoniae*. Persons with chronic CSF leak or cochlear implants have

a greatly increased risk of pneumococcal meningitis.[134–138] Ascites predisposes to pneumococcal peritonitis. Alcoholism and prior damage to heart valves predispose to pneumococcal endocarditis.

The degree of risk elevation is markedly greater for the immunocompromising conditions than for the other chronic diseases. For example, in 2000 the rates of IPD cases per 100,000 person-years were nine among healthy adults compared with 51 among adults with diabetes, 63 among adults with chronic lung disease, 94 among adults with chronic heart disease, and 100 among adults who abused alcohol. Among immunocompromised adults, disease rates are even higher, with rates of 300 among adults with solid cancer, 423 among adults with HIV/AIDS, and 503 among adults with hematologic cancer. Among the latter group, another study found that adults with multiple myeloma appear to be at particularly high risk.[116,128]

Reservoirs of Infection: The Carrier State

The human nasopharynx is the only natural reservoir for *S. pneumoniae.* Colonization of the nasopharyngeal epithelium represents the first step in the pathogenesis of pneumococcal infections.[139,140] Carriage studies provide an estimate of the baseline pneumococcal serotypes that are present in the nasopharynx and provide information for vaccine composition and to monitor changes induced by biologic pressure derived from antibiotic therapy or vaccinations. It is important to note that asymptomatic colonization is an active immunizing process leading to antibody production both in children and in adults.[141,142] If the host is relatively healthy and capable of producing antibody (or has antibody already circulating after vaccination), then disease is less likely to occur. In contrast, if the host is debilitated, has poor pulmonary clearance, or is unable to produce antibody, disease is far more likely to occur.

Colonization studies consistently demonstrate much higher rates of carriage among children than adults.[23,143–161] After acquisition, the duration of carriage is also longer in children compared with adults, and *S. pneumoniae* may be introduced into households by children and spread to other family members.[161] Among adults, carriage rates may be elevated among certain populations, including adults with AIDS, military trainees, cigarette smokers, and native Alaskans,[155–159] but lower in elderly persons.[162]

Although PPSVs are not widely regarded as effective in preventing colonization, rates of serotype-specific nasopharyngeal carriage among vaccine recipients in crowded adult settings significantly decreased in PPSV recipients. A study at a U.S. Army technical school found that PPSV4 reduced serotype-specific carriage by 55% (from 3.3% to 1.8%, $P < .01$).[163] Klugman and colleagues calculated carriage reductions among gold miners in South Africa of 70% for PPSV6 (from 23% to 7%, $P < .001$) and 65% for PPSV13 (from 51% to 18%, $P = .005$).[164]

Epidemiologic Impact of Pneumococcal Conjugate Vaccine Use in Children

Since PCV7 was widely adopted in the United States in 2000, IPD caused by those serotypes have nearly vanished in vaccine recipients. More importantly, as an indirect effect of vaccination, there has been a greater than 98% reduction in invasive disease resulting from vaccine serotypes in children and adults who have not received PCV7.[10–13,165–167] The reduction in unvaccinated adults lags behind that in vaccinated children by a few years, but ends up with similar declines. Reductions have been reported from other countries where PCVs are routinely used in infants, including Canada, England, Israel, Germany, and France.[62,168–171] By 2013, widespread adoption of PCV13 for American children since 2010 had already led to a 58% to 72% decline in IPD as a result of the inclusion of six new serotypes not previously included in PCV7.[13] The net effect is for the seven and then 13 serotypes to fall in incidence and proportion among adults, leaving the non-PCV13 serotypes to predominate in circulation.[168]

PASSIVE IMMUNIZATION

Fränkel demonstrated humoral immunity in 1886, by noting that rabbits that recovered from pneumococcal infection were immune to reinfection.[172] In 1891, Georg and Felix Klemperer showed that repeated vaccination of rabbits with killed pneumococci protected rabbits against challenge with *S. pneumoniae* and that transfer of serum (the humoral substance) to unvaccinated rabbits conferred immunity.[4–7,173] These early investigators also discovered that there were at least two different "types" of *S. pneumoniae* based on the absence of cross-protection. On this basis, they are considered the discoverers of serum therapy.

Cecil, Finland, and other investigators explored the value of type-specific serum therapy to treat pneumococcal infections in the late 1920s and 1930s.[7,174,175] These products were used widely in therapy until the advent of antibiotics.

Human intravenous immunoglobulin preparations commercially available in the United States contain varying amounts of antibody to pneumococcal capsular polysaccharides.[7,176–178] Chronic prophylaxis with intravenous immunoglobulin is used to prevent infections with encapsulated bacteria in patients with primary and certain other immunodeficiency disorders.

ACTIVE IMMUNIZATION

Early Developments

In the 1910s, Maynard,[179] Wright,[180] Cecil and Austin,[181] and Lister[182] undertook studies to show that African miners[179,180,182] or U.S. soldiers[181] were protected against pneumococcal pneumonia by repeated vaccination with killed pneumococci. In these studies, whole-cell pneumococcal vaccine appeared to reduce the occurrence of pneumococcal pneumonia by 50–80%,[179–182] although interpretation of some results is limited by methodologic issues, such as small sample size or lack of an appropriate comparison group.[163,183–186] Of interest, a recent reanalysis of data from trials of whole-cell killed bacterial vaccines given during the 1918 influenza pandemic suggests that whole-cell bacterial vaccines containing pneumococci may have reduced the risk of pneumonia and mortality among patients with pandemic influenza infection.[186]

In the 1920s, Heidelberger and Avery showed that humoral protection resulted specifically from antibody to the pneumococcal polysaccharide capsule.[187] In the 1930s, Felton isolated capsule for use as a vaccine.[188] Smillie used Felton's polysaccharide preparation to help abort an outbreak of pneumococcal pneumonia at a state hospital.[189]

Early Controlled Studies on Pneumococcal Polysaccharide Vaccines

Once antibody to capsular polysaccharide was shown to be protective, vaccination trials began in earnest. In two separate

studies beginning in 1937, Kaufman and coworkers randomized a total of 14,500 elderly persons, half of whom received polysaccharide vaccines against serotypes 1, 2, and 3 and half of whom received placebo.[190] They assessed all-cause pneumonia and death, at a time and place where 90% to 95% of all pneumonias were caused by *S. pneumoniae* and most of those were types 1, 2, or 3. They observed a 76% reduction in pneumonia in the first study (approximately 3500 subjects). In the second study (approximately 11,000 subjects), in which 47% of the patients were 70 years of age or older, the incidence of pneumonia was reduced 72% by vaccination.

In the 1930s, Felton and colleagues carried out controlled studies of PPSV among 18,000 U.S. Civilian Conservation Corps volunteers, documenting reductions in pneumonia incidence ranging from 59% to 89% (differences probably reflecting regional variation in prevalent serotypes).[191,192]

During World War II, the U.S. Armed Forces conducted a controlled study of a quadrivalent PPSV against serotypes 1, 2, 5, and 7 in 17,000 soldiers, documenting significant reductions in pneumonia caused by *S. pneumoniae* types 2 (93%) and 7 (100%), and a 75% reduction in pneumonia caused by type 5 (small number of cases, $P > .15$). There were not enough cases to show any decrease in disease caused by type 1. The investigators also monitored pneumonia caused by *S. pneumoniae* types 4 and 12 that were not included in the vaccine and there was no impact.[163] As a result of this body of work, two hexavalent vaccines were marketed in the United States in 1946, only to be voluntarily withdrawn within a few years, largely because physicians had little interest in a vaccine to prevent a disease they believed they now could treat successfully with penicillin.

In 1964, Austrian and Gold[193] showed conclusively that pneumococcal infections were still lethal, despite appropriate antimicrobial therapy. Austrian led efforts to develop a modern pneumococcal capsular polysaccharide vaccine once again. Within a decade, the type-specific efficacy of PPSV was demonstrated in clinical trials conducted among a subsequent cohort of gold miners in South Africa.[194,195] In 1977, a 14-valent capsular polysaccharide vaccine was licensed in the United States for persons 2 years of age and older, which was succeeded by the current 23-valent formulation in 1983.

Development of Contemporary Pneumococcal Polysaccharide Vaccines

Smit and colleagues undertook two vaccine trials in young adult gold miners in South Africa, one with a six-valent and one with a 12-valent PPSV (Table 47.1).[194,195] Vaccination was associated with a significant reduction in the risk of vaccine-type pneumococcal pneumonia; diagnoses were confirmed by radiography plus blood culture. Vaccine efficacy was estimated to be 76% with the six-valent vaccine and 92% with the 12-valent vaccine. The results of three other trials, evaluating either six-valent or 13-valent vaccines, in South African gold miners were reported by Austrian.[194] In an analysis of all three trials combined, PPSV was reported to reduce the risk of vaccine-type pneumococcal bacteremia by 82%.[195]

In the 1970s, a large randomized, double-blind, placebo-controlled clinical trial of a then-new 14-valent polysaccharide vaccine, was conducted in Papua New Guinea.[196] Study participants were rural highlanders who lived in poorly ventilated longhouses and had frequent respiratory infections. A total of 11,958 persons 10 years of age and older were enrolled in the trial and followed for 3 years. The risk of lower respiratory illness with vaccine-type pneumococci isolated from blood culture or lung aspirate was reduced by 86% (see Table 47.1).

The results of the South Africa trials provided the primary evidence supporting licensure of PPSV14 in the United States in 1977. Those trials provided consistent evidence of vaccine efficacy against pneumococcal pneumonia and pneumococcal bacteremia in adults who were at increased risk of pneumococcal infection. Since the mid-1970s, multiple randomized trials of PPSVs have been conducted among adults in the United States, Europe, and Japan. This product was then reformulated, broadening its spectrum of activity by including the most common adult serotypes, in the form of PPSV23 in 1983.

Interpretation of the results of pneumococcal vaccine trials must take into account the adequacy of the trial design, the study outcomes evaluated, the method of ascertaining the etiology of pneumonia, and whether the sample size was sufficient to detect a clinically meaningful reduction in risk of disease. Regarding sample size, Fedson and Liss[207] assessed each of the U.S. and European trials reported before 2004 for their statistical power to detect reductions in risk of all-cause pneumonia. None of the trials had sufficient person-years of observation to have 80% power to detect a 15% or greater reduction in risk of all-cause pneumonia in those trials.

23-Valent Pneumococcal Polysaccharide Vaccine Formulation

The currently available 23-valent vaccines (PPSV23) contain 25 μg of purified pneumococcal capsular polysaccharides from each of the following serotypes: 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F.[14] Selection of the vaccine serotypes was based primarily on the distribution of strains causing IPD in various global case series in the late 1970s and early 1980s.[208,209] Before the introduction of PCV7 for children in the United States, these 23 serotypes accounted for more than 85% of strains that caused IPD in adults in the United States.[165,168] Since the introduction of PCV7 and then PCV13, and the resulting indirect protection, IPD caused by serotypes contained in PPSV23 has declined in older adults.[11,13,168] In 2013, pneumococcal serotypes contained in PPSV23 accounted for approximately 67% of IPD cases in adults 65 years of age and older in the United States, whereas PCV13 serotypes accounted for approximately 23% of adult IPD cases.[13,168]

Producers and Trade Names

Three vaccine manufacturers currently produce PPSV23. Pneumovax 23 (Merck) and Pneumo 23 (Sanofi Pasteur) formulations are available in Canada and Europe. An unbranded version is produced by Chengdu Institute of Biological Products for China. In the United States, only Pneumovax 23 is available. These vaccines consist of polysaccharides dissolved in isotonic saline, with either phenol (0.25%, Pneumovax 23) or thimerosal (0.01%, Pneumo 23) added as a preservative. They contain no adjuvants. Techniques that simultaneously measure the consistency of molecular size and the antigenicity of individual polysaccharides have helped to ensure uniformity between different lots of vaccine.[210]

Dosage and Route

PPSV23 should be administered as a single 0.5-mL dose intramuscularly or subcutaneously.[14] Intramuscular administration

[a]VE is calculated based on the formula VE = 1 – relative risk of disease in vaccinated versus unvaccinated. A negative VE estimate indicates a higher risk in vaccinated compared with unvaccinated persons; a zero VE estimate indicates no difference in risk between vaccinated and unvaccinated persons; and a positive VE indicates a lower risk in vaccinated compared with unvaccinated persons. If the confidence intervals for the VE estimate cross zero, that is, extend from negative to positive, or include zero, the VE estimate is not statistically significant.

CI, confidence interval; COPD, chronic obstructive pulmonary disease; VE, vaccine effectiveness.

is considered less likely to cause injection-site reactions and, thus, is the commonly preferred route. The vaccine should not be administered intradermally. Influenza vaccine commonly is given simultaneously with PPSV23 at separate injection sites.[211] Administration of PPSV23 concomitantly with zoster vaccine (Zostavax) does not adversely affect the response to PPSV23 but, in a trial of concomitant administration, anti–varicella-zoster virus antibody levels were significantly lower after concomitant administration of PPSV23 and zoster vaccine live (Zostavax, Merck) compared with levels after administration of zoster vaccine alone, albeit the two study arms differed in their baseline values.[212] The U.S. Zostavax prescribing information advises that separating administration of the two vaccines by at least 4 weeks should be considered, although an observational study reported no difference in risk of medically attended herpes zoster after Zostavax in persons who received Zostavax concomitant with PPSV23, compared with persons who received Zostavax alone.[213]

If stored at 2°C to 8°C and not allowed to freeze, PPSV23 is stable for 24 months.

IMMUNOGENICITY OF 23-VALENT PNEUMOCOCCAL POLYSACCHARIDE VACCINE

Laboratory Methods to Assess Antibody Response

Two kinds of assays are used to assess antibody responses to pneumococcal vaccines. Enzyme-linked immunosorbent assays (ELISAs) quantify the amount, but not the function, of serum antibody to pneumococcal capsular polysaccharide. Opsonophagocytosis assays (OPAs) measure the degree to which serum antibody opsonizes pneumococci for uptake in vitro by human polymorphonuclear leukocytes and are, therefore, regarded as functional assays. Because ELISA measures total serotype-specific antipneumococcal antibody levels, including both functional and nonfunctional antibodies, the ELISA antibody concentrations may not necessarily correlate with functional antibody activity.[214] The capsular polysaccharide antigens used in assays contain contaminating cell-wall polysaccharide that is common to all pneumococci, and most persons, regardless of vaccination status, have antibodies to

cell-wall polysaccharide. Consequently, absorption of the serum specimen with cell-wall polysaccharide has been used in recent years to remove non–serotype-specific cross-reacting antibodies.[215] Even after removal of cell-wall polysaccharide antibodies, a variable amount of antibody to unrelated epitopes may still be measured by ELISA.[215–219] A heterologous type 22F pneumococcal polysaccharide can also be used to adsorb antibodies to these common epitopes.[220,221] Serotype 22F was chosen for this purpose because the capsular polysaccharide is readily available and at the time was thought not likely to be included in future conjugate vaccines. Other approaches include adsorption with serotypes 25 and 72, instead of 22F.[222,223] Such absorption has improved the correlation between immunoglobulin (Ig) G levels determined by ELISA and opsonophagocytic titers in most,[220,224–226] but not all,[216] studies.

Further insight into functional status can be obtained by ELISA if avidity studies are performed.[214] In these studies, a range of concentrations of sodium thiocyanate is added into the ELISA wells. If low concentrations reduce the amount of antibody measured by ELISA, the antibody is judged to be nonavid; low-avidity antibody correlates with low OPA activity and poor protection of mice following challenge with type-specific *S. pneumoniae*.

Correlates of Protection

The original studies that showed OPA to be a better correlate of protection than ELISA were carried out in mice that were pretreated with a range of concentrations of antibody and then challenged with *S. pneumoniae* of the relevant serotype.[214] There was considerable interest in establishing correlates of protection in children to facilitate evaluation and licensure of new pneumococcal vaccine formulations.

A World Health Organization (WHO) working group used data from three clinical efficacy trials of PCVs in infants to propose a protective threshold in infants of 0.35 μg/mL. The assays used in these trials included adsorption of sera with pneumococcal C polysaccharide, but not *S. pneumoniae* capsular type 22F.[227] It is important to note that the 0.35 μg/mL threshold was arbitrarily assigned to all capsular types, although it is likely that there is substantial variation from one serotype to another. It is unknown whether naturally acquired antibody or antibody that appears after PPSV23 would be protective at the same or different level.

It is important to remember that these pediatric correlates are based on aggregate performance, derived collectively from diverse serotypes; each serotype might be found to have its own pediatric protective value and confidence interval, if sufficient data were available. Furthermore, these data are derived from randomized vaccine trials in young children (who are typically naïve to pneumococci) and may not correlate well with protection for adults and seniors. Adults and seniors generally have baseline antibody levels that exceed the levels that are considered as protective thresholds in young children. There are no published data from randomized controlled trials demonstrating vaccine efficacy in adults to support identification of correlates of protection. Therefore, although the results of ELISA and OPAs can be used to identify the relative magnitude of the immune response to vaccination in adults, these markers cannot be used to define individuals as protected or susceptible to pneumococcal infection.

Immunogenicity in Adults

In immunocompetent adults, vaccination with PPSV23 induces significant increases in serotype-specific anticapsular antibody levels as measured by ELISA, as well as by functional activity as measured by OPA.[214,224–248] The magnitude of the immune response varies by serotype and varies widely from one individual to another. Some of this individual variation may be due to genetic factors.[249–253]

The magnitude of the immune response to vaccination diminishes with age. In general, most studies comparing ELISA IgG antibody responses between younger and older adults report lower postvaccination geometric mean titers (GMTs) in the older group, but these differences tend not to be substantial.[225,231,233,238,239] In contrast, OPA titers after vaccination are generally markedly lower in elderly adults compared with young adults (Fig. 47.4).[214,242,254,255] The lower OPA titers in elderly persons appear to be correlated with lower avidity of the IgG antibody for pneumococcal polysaccharide and lesser protection of mice that were given passive antibody from elderly humans and then challenged with pneumococci.[214] Lower postvaccination concentrations of serotype-specific IgM antibody in the elderly may be, in part, responsible.[255,256] After absorption of IgM antibody, the differences in OPA titers between the young adults and the elderly adult groups disappeared.[255] Older adults also exhibit a diminished clonal expansion of B cells in response to vaccination compared with younger adults.[256,257]

In a randomized clinical trial of hospitalized adults comparing PPSV23 to a regimen of PCV7 then PPSV23, no marked differences in antibody were noted in the two groups.[258] This study included stratification by a validated index of frailty, which found lower point estimates for antibody concentrations with higher levels of frailty, although wide confidence intervals led the differences to not be statistically significant.

In general, the immune response, as measured by ELISA, to PPSV23 in immunocompetent persons with chronic medical conditions, such as heart disease, lung disease, or diabetes, is comparable to that of age-matched healthy control subjects.[259–263] In patients with chronic lung disease, the antibody response to vaccination does not appear to be affected by concurrent treatment with oral or inhaled steroids.[262] Patients with chronic alcoholism and cirrhosis can usually mount an antibody response to PPSV23.[263,264] Older persons with low serum vitamin B_{12} levels may have reduced antibody responses to PPSV23.[265]

Immunogenicity in Children

Pneumococcal capsular polysaccharides are T-cell–independent antigens; consequently, most are traditionally considered poor immunogens in infants and young toddlers. Although highly immunogenic serotypes, such as type 3, can induce antibodies in infants as young as 3 months of age,[266] antibody responses to most other pneumococcal capsular polysaccharides are generally poor in children younger than 2 years of age.[208,266–272] A study of children in Fiji who received PPSV23 indicated that children who were 12 months of age are capable of mounting an adequate response to the polysaccharide antigens, with response varying substantially by serotype.[268] Children 2 years of age or older respond with good antibody production after vaccination with PPSV23,[270,273–276] although responses continue to improve until children are 5 to 8 years of age.[274] As discussed below, the primary vaccine for pediatric vaccination is PCV13; but it is recommended that children 2 years of age and older who are at elevated risk for IPD also receive a dose of PPSV23 for the benefit of its unique serotypes.

Immunogenicity in Immunocompromised Persons

The following section describes immune responses to PPSV23 in immunocompromised persons. The application of PPSV23

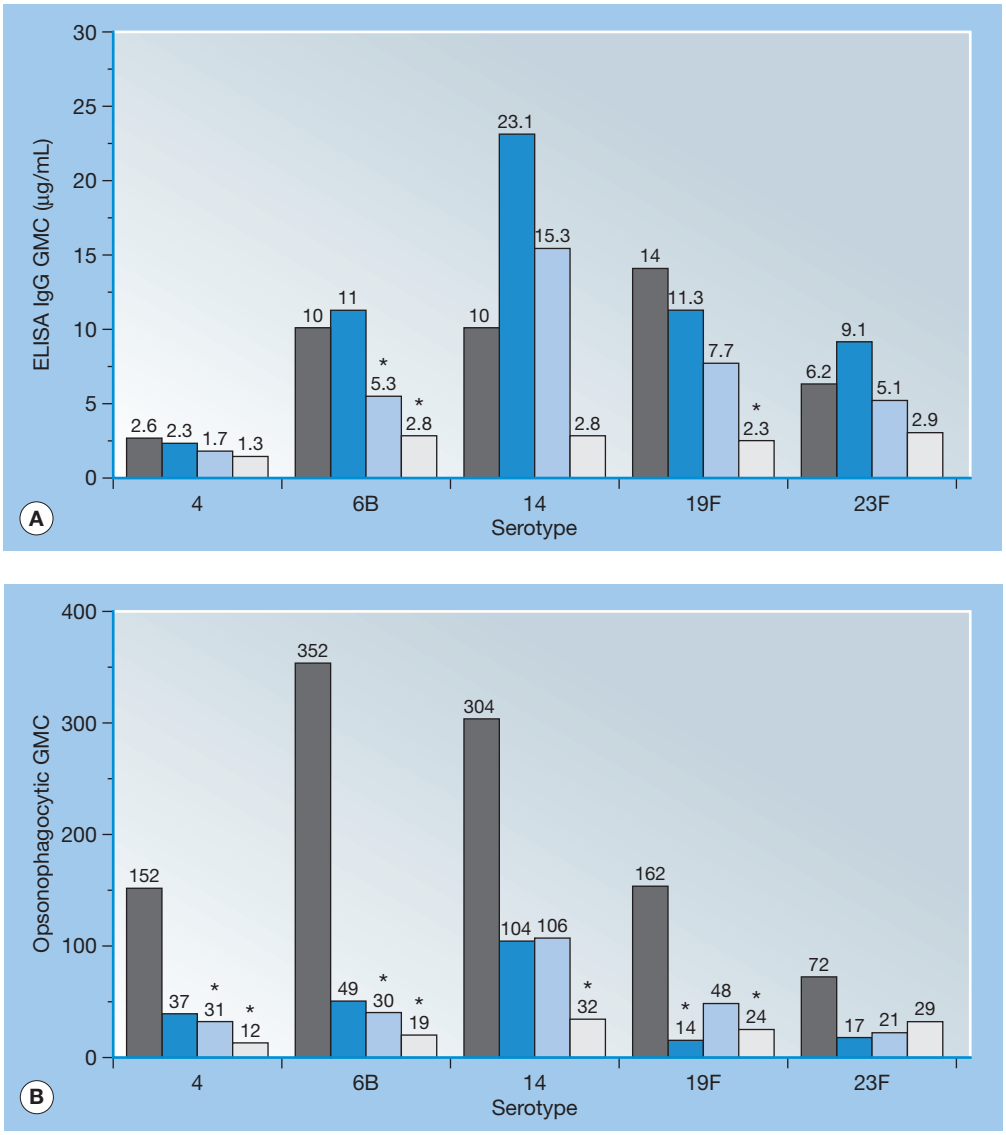

Figure 47.4. Comparison of serotype-specific enzyme-linked immunosorbent assay (ELISA) immunoglobulin (Ig) G geometric mean concentrations and opsonophagocytic antibody geometric mean titers in young adults and elderly adults. **A,** Geometric mean concentration (GMC, µg/mL) of IgG pneumococcal capsular polysaccharide-specific serum antibody, as determined by ELISA, for young control subjects (22–46 years of age; $n = 12$; *gray bars*) and for elderly age groups (63–79 years of age; $n = 10$, *dark blue bars*; 80–89 years of age; $n = 22$, *light blue bars*; and ≥90 years of age; $n = 14$, *white bars*) after vaccination with PPSV23. **B,** Geometric mean opsonophagocytic titer (GMT, reciprocal serum dilution) for the young control subjects and elderly age groups shown in panel **A** after vaccination. An *asterisk* designates a significant difference ($P < .05$) from values for the younger control subjects, per the Wilcoxon sample test. *(From Romero-Steiner S, Musher DM, Cetron MS, et al. Reduction in functional antibody activity against Streptococcus pneumoniae in vaccinated elderly individuals highly correlates with decreased IgG antibody avidity.* Clin Infect Dis. *1999;29:281–288.)*

in context with PCV13 in these patients is described in the later section on vaccination policy and recommendations.

HIV Infection

A large number of studies have evaluated the immunogenicity of PPSV23 in HIV-infected persons.[277–295] In HIV-infected persons who are not receiving highly active antiretroviral therapy (HAART), the response to PPSV23 is poor when compared with healthy control subjects, whether assayed by ELISA or OPA.[214,277–293] In these studies, postvaccination antibody levels in the HIV-infected groups have not consistently correlated with $CD4^+$ T-cell counts at time of vaccination.[283,284,286,288,289,291–293,296] Antibody levels after vaccination decline at about the same rate in HIV-infected and uninfected persons, but, because peak levels are lower in HIV-infected patients, a decline to undetectability could occur sooner in HIV-infected persons.

Preservation or reconstitution of immune function with antiretroviral therapy may be associated with an improved antibody response,[297] although conflicting results have been reported.[291,298,299]

Before the introduction of HAART, HIV-infected children demonstrated poor response to PPSV23.[300] A study in the post-HAART era documented an improved response, although it was still lower than in healthy control subjects.[277] In that study, a better antibody response in the HIV-infected children was correlated with a higher CD4 count at the time of vaccination.

Rodriguez-Barradas and colleagues found that in HIV-infected patients with CD4 cell counts of 200 or higher, delaying PPSV23 until the patient has received 6 or more months of HAART did not improve responses and may lead to missed opportunities for immunization.[301]

Hematopoietic Stem Cell Transplant

Among hematopoietic stem-cell transplant recipients, the antibody response to PPSV23 improves with increasing time after transplantation,[302–304] and so in the past, an initial PPSV23 vaccination was recommended at 12 months after hematopoietic stem-cell transplant, with a second vaccination 12 months later. However, the antibody response to PPSV23 vaccination is limited in this situation,[304–307] particularly in patients receiving corticosteroid treatment for graft-versus-host disease,[308] and is not improved with a second vaccination 12 months later.[309]

Solid-Organ Transplant

Solid-organ recipients can respond to PPSV23,[310–313] but the immune response is of lower magnitude[314] and of shorter duration[264] than in normal control subjects. Antibody levels decline rapidly after such vaccination.[315] Revaccination 2 years later leads to modest increases in antibody levels, but most do not reach levels seen initially.[316] In a randomized trial of adult renal transplant recipients, the opsonophagocytic antibody response to PCV was comparable to that of PPSV23.[313] At 3 years after vaccination, serotype-specific antibody titers had declined significantly compared with 8 weeks postvaccination for both the PCV7 and PPSV23 groups, with the two vaccine groups having comparable antibody concentrations.[317]

Renal Disease

Children with nephrotic syndrome[275,318] and children and adults with other chronic renal diseases and those on dialysis usually respond adequately to PPSV23.[319] However, in most of these patients, antibody levels rapidly decline.[318,320] It is uncertain to what extent this decline reflects poor antibody synthesis or loss of antibody in the urine. Revaccination 1 year later leads to good antibody responses in about one-half of renal disease patients, but antibody levels decline rapidly over the next few months.[319]

Hematologic Neoplasms

Several factors influence the immune responses to PPSV23 among patients with hematologic neoplasms, such as chronic lymphocytic leukemia, Hodgkin disease, and multiple myeloma. These factors include the stage of disease, whether or not a splenectomy has been performed, the extent of previous radiation therapy or chemotherapy, and the time between completion of treatment and vaccination.[321] See also Chapter 69.

Few patients with chronic lymphocytic leukemia respond to pneumococcal vaccine, even when they are not receiving chemotherapy.[322,323] Those who do respond have less-advanced disease and higher levels of IgG, IgG_2, and IgG_4.[323] Administration of granulocyte-macrophage colony-stimulating factor does not improve the immune response to PPSV23 in this population.[324] Children with acute leukemia who are on maintenance chemotherapy have poor antibody responses.[325] In contrast, a small study found that those in remission for 2 or more years responded well to PPSV23 vaccination.[326]

Patients with Hodgkin disease given PPSV23 before the onset of treatment have postvaccination antibody levels (as measured by ELISA) comparable to those of healthy vaccinated persons.[327,328] Once treatment begins, antibody responses to vaccination are reduced.[329] After completion of treatment, antibody responsiveness may be less than in untreated controls. Patients who do not respond to a first dose of PPSV23 tend not to respond to revaccination several months later.[330] These findings imply that Hodgkin disease patients should be vaccinated as soon as possible after the diagnosis is established and before treatment begins.[14,331–333]

Patients with multiple myeloma or Waldenström macroglobulinemia have low pneumococcal antibody levels before vaccination. After vaccination, antibody responses are poor, although some patients respond to a few serotypes.[331–336] The capacity to respond does not correlate with the severity of the disease or the timing of chemotherapy, and antibody levels are seldom sustained.

Functional or Anatomic Asplenia

Antibody responses to PPSV23 in postsplenectomy patients vary, largely because some patients are immunocompromised and others are not. After splenectomy for trauma, in presumably immunocompetent adults, antibody responses to PPSV23 are similar to those in normal control subjects.[337–340] In postsplenectomy trauma patients, opsonophagocytic antibody titers are higher in patients vaccinated 14 or more days after the splenectomy compared with those vaccinated on days 1 or 7 after splenectomy.[338] There is no difference in antibody titers in persons vaccinated at 28 days compared with 14 days.[337,341] In patients who undergo splenectomy for hematologic disease, responses are more variable,[275,327,328] antibody levels may decline rapidly after vaccination, and persons who do not respond to an initial vaccination may also have a poor response to revaccination.[342]

Other Conditions

In one small study, patients with solid tumors had an antibody response to vaccination that was similar to healthy control subjects.[343] The response to PPSV23 vaccination in persons with human T-cell lymphotropic virus II infection is comparable to the response in healthy adults in terms of magnitude, quality, and functional activity.[344]

Patients with systemic lupus erythematosus,[345–347] rheumatoid arthritis,[346] Felty syndrome,[348] and celiac sprue[349] are at increased risk for pneumococcal infections. Patients with systemic lupus erythematosus or rheumatoid arthritis may have a diminished response to PPSV23 compared with healthy persons.[346,350] Those with celiac sprue appear to respond normally.[349]

In patients with rheumatologic conditions, such as rheumatoid arthritis, ankylosing spondylitis, or psoriatic arthritis, treatment with anti–tumor necrosis factor (e.g., adalimumab, etanercept, infliximab) does not appear to impair the antibody response to PPSV23, although methotrexate therapy, given with or without anti–tumor necrosis factor therapy, reduces this response.[351–358] Other immunomodulatory agents used for the treatment of rheumatologic conditions may also influence the immune response to PPSV23. In healthy volunteers, a single dose of abatacept, a selective costimulatory modulator that inhibits CD28-dependent T-cell activation, reduced the immune response to PPSV23.[359] Similarly, rituximab, a monoclonal antibody that targets $CD20^+$ B cells, reduces the immune response to PPSV23 in patients with rheumatoid arthritis.[358,360] Together, these results suggest that, if possible, PPSV23 should be given to patients with rheumatologic disorders before initiation of treatment with agents

that diminish the immune response to vaccination (e.g., methotrexate, abatacept, rituximab).

In a prospective trial, patients with inflammatory bowel disease who were not receiving immunosuppressive therapy responded as well to PPSV23 as healthy control subjects.[361] The response to vaccination was lower in patients who were receiving anti–tumor necrosis factor therapy and concomitant immunomodulator therapy (e.g., 6-mercaptopurine, azathioprine, methotrexate). In one small study of adults with panhypopituitarism who were receiving glucocorticoid replacement as well as other conventional replacement therapy, a lower response to PPSV23 was found, compared with healthy control subjects of similar age.[362]

EFFICACY OF PNEUMOCOCCAL POLYSACCHARIDE VACCINES

Table 47.1[194,195,197–206] and Table 47.2[363–386] summarize key parameters of contemporary PPSV randomized clinical trials and observational studies of efficacy and effectiveness, respectively. Table 47.3 focuses on studies assessing pneumococcal pneumonia,[372,377,386,390–395] many of which were conducted before diagnostic tools to differentiate bacteremic (invasive) and nonbacteremic (noninvasive) pneumococcal pneumonia became available. The metaanalysis updated by the Cochrane Collaboration in 2013 included 25 randomized clinical trials (RCTs) and observational studies of various PPSVs that evaluated vaccine efficacy against pneumococcal outcomes.[396] Because *S. pneumoniae* was the principal cause of pneumonia in early studies, and bacteremia (which now represents approximately 25% of pneumococcal pneumonias) was often not sought by blood culture, some of these studies present data on all-cause pneumonia as well as on pneumococcal pneumonia or even vaccine-type–specific pneumococcal pneumonia. The vaccine-type analyses matched the valences included in the specific vaccines studied.

The primary outcomes of the most recent Cochrane Review included IPD and all-cause pneumonia.[396] The IPD analysis included 11 RCTs (with 18,634 vaccinees and 17,855 controls), yielding an odds ratio (OR) of 0.26 (95% confidence interval [CI], 0.14–0.45), corresponding to a protective vaccine effect of 74%. The corresponding values for seven observational studies were OR 0.48 (95% CI, 0.37–0.61), corresponding to efficacy of 52%. The all-cause pneumonia measure included 16 RCTs (with 22,643 vaccinees and 25,091 controls), yielding an OR of 0.72 (95% CI, 0.56–0.93), corresponding to a vaccine effect of 28%, albeit with statistical heterogeneity. Selected secondary outcomes include the following[396]:

- Vaccine-type IPD: five RCTs (13,889 vaccinees and 17,334 controls), with an OR of 0.18 (95% CI, 0.10–0.31).
- Definitive vaccine-type pneumococcal pneumonia (clinically and radiographically confirmed, with *S. pneumoniae* isolated from usually sterile site): four RCTs (15,583 vaccinees, 14,978 controls), with an OR of 0.13 (95% CI, 0.05–0.38).
- Presumptive vaccine-type pneumococcal pneumonia (clinically and radiographically confirmed, with *S. pneumoniae* isolated from culture of sputum or nasal swab): five RCTs (8,755 vaccinees, 9,813 controls), with an OR of 0.27 (95% CI, 0.08–0.87).

A few selected studies from the 2013 Cochrane metaanalysis are described further below, as examples of the range of published data considered.

In the Veterans Administration Cooperative Study conducted in the United States (see Table 47.1), 2295 immunocompetent veterans, who were defined as high-risk on the basis of age (≥55 years) and/or the presence of chronic cardiac, pulmonary, renal, or hepatic disease, and/or diabetes mellitus or alcoholism, were randomized to receive either PPSV14 or placebo.[199] Only one case of vaccine-type invasive pneumococcal infection occurred in each group. The frequency of probable pneumococcal pneumonia, defined as radiographically confirmed pneumonia with pneumococci isolated from sputum, was also balanced between the groups, although the cohorts were not balanced at baseline for history of prior pneumococcal infection.

Two clinical trials (see Table 47.1) conducted in Finland[202,203] and one conducted in Sweden[201] assessed PPSV23 efficacy against all-cause pneumonia and against an outcome of pneumococcal pneumonia that was largely defined on the basis of serologic testing for antibodies to pneumolysin in circulating immune complexes. These studies showed no protection from pneumococcal vaccine, but the number of disease outcomes was small, the overall rate of pneumonia was far greater than might have been expected for pneumococcal pneumonia, and the method for diagnosing pneumococcal pneumonia was subsequently shown to be invalid.[397] In one of these studies,[201] which was limited to people with a prior history of pneumonia, six cases of bacteremic pneumococcal pneumonia were identified, five of which were in the placebo group, for a 79% reduction in risk of this outcome ($P = .2$).

Most recently, a randomized, placebo-controlled, observer-blind trial was conducted among nursing home residents (mean age: 85 years) in Japan.[205] The study focused on pneumococcal pneumonia, defined by isolation of *S. pneumoniae* from blood, pleural fluid, or sputum, or by a positive BinaxNOW urine antigen test. The incidence of pneumococcal pneumonia per 1000 person years was 32 in the placebo group and 12 in the PPSV23 group ($P < .001$). Death from pneumococcal pneumonia was significantly higher in the placebo group than in the PPSV23 group (35.1% [13/37] vs 0% [0/14], $P < .01$). The Kaplan-Meier survival curves of participants without pneumococcal pneumonia in the placebo and PPSV23 groups generated a hazard ratio of 0.368 (95% CI, 0.199–0.680).

Because the incidence of *S. pneumoniae* as a cause of pneumonia has steadily declined over the past five decades, recent studies looking at all-cause pneumonia are becoming less likely to inform our understanding of pneumococcal-vaccine performance. For example, the U.S. Department of Defense recently conducted a RCT of PPSV23 in 153,000 military trainees, with all-cause pneumonia as one of the principal outcomes.[398] In that study, zero cases of pneumococcal pneumonia were identified in either the vaccine or the control group. The authors concluded that their study found a lack of PPSV23 effectiveness in that setting, but a more reasoned statement would be that PPSV23 was administered in a setting where *S. pneumoniae* disease was uncommon; hence no conclusion about PPSV23 effect could be reached. Their conclusion that PPSV23 is not appropriate for military recruits may be valid because of the apparent rarity of pneumococcal pneumonia in that population, but not because of inadequate vaccine effect.

Other Observational Evidence of Vaccine Effect

Case-control and other types of observational studies have generally shown that PPSVs effectively prevent pneumococcal pneumonia or IPD in immunocompetent adults (see Table 47.2), similar to the findings of the RCTs. In the 2013 iteration of the Cochrane metaanalysis, the OR for vaccine-type IPD in these studies was 0.45 (95% CI, 0.38–0.54).[396]

TABLE 47.2 Observational Studies of Pneumococcal Polysaccharide Vaccine Effectiveness Against Invasive Pneumococcal Disease in Non–HIV-Infected Populations

Reference	Design	Study Population	Subgroup	No. Cases of Invasive Pneumococcal Disease	VE (%)	95% CI

Tsai[386] (2015)	Cohort	Taiwan National Health Insurance Research Database	All >75 yr	57	76	54–88

[a]Chronic illness included sickle cell disease, malignancy, leukemia, nephrotic syndrome, HIV infection, organ transplantation, CSF leak, congenital anomalies, asplenia, and immunosuppressive medications.
[b]Excluded persons with asplenia, hematologic malignancies, and nonhematologic malignancies on chemotherapy.
[c]Higher effectiveness values found for those age 65–74 yr. Other subgroup analyses reported in publication.
CI, Confidence interval; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus; NR, not reported.

A case-control study from Spain identified adults with radiographically confirmed pneumococcal pneumonia, defined by isolation of pneumococcus from blood culture or by sputum culture, or by a positive BinaxNOW *S. pneumoniae* antigen test.[383] PPSV23 was associated with a significantly lower risk of pneumococcal bacteremia caused by vaccine serotypes (OR: 0.24; 95% CI, 0.09–0.66) (see Table 47.2).

Several studies have used an indirect-cohort method to assess vaccine effect.[364,378,379,382] In that design, only cases of IPD are evaluated; there is no comparison group of uninfected

TABLE 47.3 Cohort Studies of 23-Valent Pneumococcal Polysaccharide Vaccine Effectiveness Against Pneumonia in Noninstitutionalized Seniors

Reference	Senior Population	Person-Years of Follow-Up	Outcome	No. of Events	Association of Vaccination and Risk of the Outcome (Relative Risk, 95% CI)

persons. Vaccine effectiveness is estimated in patients with IPD by comparing the distribution of pneumococcal serotypes in vaccinated and unvaccinated subjects. A healthy-user effect should not influence the outcome; however, the method requires a similar proportion of vaccine-type and non–vaccine-type disease in unvaccinated populations.[399,400] For example, using this approach, Broome and colleagues found 64% efficacy in preventing IPD caused by vaccine types but no effect in nonvaccine types.[399] In three studies that used both the indirect-cohort and case-control methods,[365,367,371] the results of the two methods were similar.

A large indirect-cohort study included 2837 persons, 5 years of age and older, with pneumococcus isolated from blood or CSF at one of 58 U.S. hospitals that participated in a CDC surveillance system.[368] The overall vaccine effectiveness estimate was 57% (95% CI, 45–66%). Subgroup analyses showed similar levels of vaccine effectiveness for persons with diabetes mellitus, coronary vascular disease, congestive heart failure, chronic pulmonary disease, and anatomic asplenia, but not for persons with alcoholism/cirrhosis. Vaccination was associated with a significant reduction in risk of IPD in the smaller subgroups of persons with anatomic asplenia, but not for sickle cell disease, chronic renal failure, immunoglobulin deficiency, leukemia/lymphoma, or multiple myeloma, which raises the important issue of whether PPSV is effective in immunocompromised hosts.

In several studies, adults hospitalized with pneumonia have been evaluated to identify an association between prior PPSV23 and subsequent outcomes such as mortality.[394,401–404] Four studies reported that patients who had received PPSV23 were less likely to die, or be admitted to the intensive care unit, or to have a prolonged hospital stay, than unvaccinated patients,[394,401–403] although the possibility of confounding by underlying health status should be considered.[405] Two studies did not find an association between vaccination and length of survival after hospital discharge.[402,404]

In a retrospective cohort study of seniors enrolled in a health maintenance organization in western Washington State,[372] PPSV23 was associated with a 44% reduction in risk of pneumococcal bacteremia (see Table 47.2). Results of a large unrandomized cohort study from Tarragona, Spain, were published in 2013.[395] Cohort members were followed for 76,033 person-years, including 29,065 person-years for vaccinated subjects. After multivariable adjustment, vaccination with PPSV23 within 5 years was associated with reduced risks of bacteremic pneumococcal CAP (hazard ratio [HR], 0.38; 95% CI, 0.09–1.68), nonbacteremic pneumococcal CAP (HR, 0.52; 95% CI, 0.29–0.92), and overall pneumococcal CAP (HR, 0.49; 95% CI, 0.29–0.84).

Effectiveness of 23-Valent Pneumococcal Polysaccharide Vaccine in Immunocompromised Persons

Immunocompromised persons are at disproportionately high risk of IPD, in most instances because they have diminished capacity to make antibody to any vaccine. Not surprisingly, PPSVs are generally less effective or less immunogenic in immunocompromised persons than in relatively normal comparison groups. In most studies of immunocompromised persons, PPSV23 was not associated with a reduction in risk of IPD. The one study to find a significant reduction defined the immunocompromised subgroup as persons with immunodeficiency, asplenia, any solid-organ or hematologic cancer, chronic nephropathy, or long-term corticosteroid therapy.[384] Nearly all the IPD case patients defined as immunocompromised met the definition because of solid-organ cancers (stage not defined) or non–dialysis-dependent chronic renal failure. In the presumptively immunocompromised group (diagnosis not confirmed), PPSV23 vaccine effectiveness was estimated to be 71% (24–89%).

A nonrandomized, nonblinded study of persons 2 to 25 years of age with sickle cell disease evaluated 68 patients who were given a PPSV8 and a nonconcurrently enrolled comparison group of 106 unimmunized patients. During the 2-year follow-up period, eight of the unimmunized patients developed pneumococcal bacteremia compared with none of the immunized patients, which was interpreted as evidence for a protective effect of vaccination.[406]

Table 47.4 summarizes the results of published nonrandomized studies of PPSV23 effectiveness in HIV-infected persons.[392,407–419] Some were very small,[413,414] including only seven or 12 pneumococcal outcome events. The remaining studies evaluated a variety of outcomes, including IPD and noninvasive pneumococcal infection.

Four studies evaluated an outcome of IPD (or pneumococcal bacteremia) in HIV-infected people.[410,415,416,418] Two found no association of receipt of PPSV23 and risk of IPD,[416,418] one found a significant reduction in risk of pneumococcal bacteremia in vaccinated compared with unvaccinated persons,[415] and one found that vaccination was associated with a reduction in risk of IPD in whites but not blacks.[410]

Gebo and Dworkin found a beneficial effect of vaccination that was restricted to subgroups with a higher (≥200 or ≥500) CD4 count at the time of vaccination.[407,411] In contrast, a more recent study by Peñaranda found a significantly lower risk of pneumococcal infection in vaccinated persons, even when persons with a CD4 count of less than 200 were included.[417] That study was limited by definition of vaccination status in cases as vaccine received before the pneumococcal disease onset date, while vaccination status in the control group was defined as receipt at any time during the study period, which may have led to a bias toward a higher vaccination rate in the control group and thus an inflated estimate of vaccine effect. French and colleagues failed to show any benefit from PPSV23 in patients in Uganda who had advanced AIDS and were not being treated for HIV infection.[420,421]

On the one hand, these findings are discouraging: those persons who are at great need of pneumococcal vaccination are least likely to be protected by it. On the other hand, it is not surprising that persons who have conditions in which antibody responses are greatly diminished—for example, multiple myeloma, Hodgkin disease, lymphoma, and untreated AIDS—tend to not respond well to vaccination. The clinical point is that some such persons do respond, and there is no way of predicting who they will be; hence PPSV23 is recommended.[14,331–333]

Association of 23-Valent Pneumococcal Polysaccharide Vaccine and Risk of Myocardial Infarction or Stroke

Pneumococcal pneumonia can precipitate acute myocardial events.[422,423] Therefore, it is plausible that pneumococcal vaccination could indirectly reduce the incidence of myocardial infarction.

Studies evaluating the association of PPSV23 vaccination and risk of cardiovascular events such as myocardial infarction have yielded diverging results. Some studies found no association between PPSV23 and risk of myocardial infarction or stroke.[424–426] Others did find a protective effect.[427,428] A meta-analysis of 11 studies calculated a protective role for PPSV23 for total cardiovascular events (relative risk [RR], 0.86; 95% CI, 0.76–0.97), but not for specific events.[429] A protective effect was more prominent in older persons and those with higher cardiovascular risk in that analysis. Another metaanalysis by

Ren and colleagues found a decreased risk of acute coronary syndrome (OR, 0.83; 95%CI, 0.71–0.97), but not for stroke (OR, 0.96; 95% CI, 0.87–1.05), in people 65 years or older.[430]

Vaccine Evaluations in Children

Clinical Trials in Immunocompetent Children

Several randomized controlled trials in the 1980s assessed the efficacy of eight-valent and 14-valent PPSVs in preventing otitis media in children younger than 6 years of age, an approach now superseded by the availability of PCVs for healthy children.[431–440] In Australia, a randomized, blinded trial showed no difference in the risk of acute otitis media in children younger than age 2 years (RR, 1.01; 95% CI, 0.81–1.25) and a possible trend toward a reduction in risk in children older than age 24 months (RR, 0.83; 95% CI, 0.69–1.01).[431] A metaanalysis of these trials found no evidence for an overall effect across all age groups or for a reduction in risk of otitis in children younger than 24 months of age who received PPSV, but the pooled analysis of children older than 24 months of age showed evidence of a significant vaccine effect (RR, 0.78; 95% CI, 0.63–0.97).[439]

PPSV is associated with a reduction in risk of death attributed solely to acute lower-respiratory infection in young children in Papua New Guinea.[441–443] A clinical trial of more than 7000 children, 4 months to 5 years of age, were randomized either individually or by hamlet cluster to receive PPSV14 or PPSV23 or placebo. Vaccination was reported to have reduced acute lower-respiratory infection mortality by 59% overall (95% CI, 19–79%) and by 50% (95% CI, 1–75%) in children vaccinated at 2 years of age or younger.

Clinical Trials in Children With Sickle Cell Disease

One randomized trial[444] evaluated the efficacy of pneumococcal polysaccharide vaccination for prevention of pneumococcal infection in children with sickle cell disease. No protective effect was demonstrated.[445] Most of the participants were younger than 2 years, so the results are not generalizable to older children, in whom the vaccine may be more immunogenic.

A nonrandomized, nonblinded study of persons with sickle cell disease, 2 to 25 years of age, evaluated 68 patients who were given a PPSV8 and a nonconcurrently enrolled comparison group of 106 unimmunized patients. During the 2-year follow-up period, eight unimmunized patients developed pneumococcal bacteremia compared with none of the immunized patients, which was interpreted as evidence for a protective effect of vaccination.[406]

Observational Studies of Vaccine Effectiveness in Children

Two observational studies of pneumococcal vaccine effectiveness against IPD included both children and adults,[368,369] but neither presented results of subgroup analyses of persons younger than 18 years of age. Two other indirect-cohort studies included only children and have yielded varying estimates of the effectiveness of 23-valent pneumococcal polysaccharide vaccination against invasive pneumococcal infection in children with sickle cell disease in the era before the availability of PCV (see Table 47.2).

The first study, an indirect-cohort analysis of data from a national surveillance system conducted by Fiore and colleagues,[370] included children 2 to 5 years of age with chronic illnesses considered to be a risk factor for pneumococcal infection who had pneumococcus isolated from blood or CSF during 1984 to 1996. Of the 173 children included in the study, 46 had sickle-cell disease, and vaccine effectiveness was not demonstrated in that subgroup. A significant 84% reduction in risk of IPD was, however, found in the subgroup of children without sickle cell disease, the majority (62%) of

whom had malignancy, nephrotic syndrome, HIV infection, or organ transplant.

The second study, conducted in conjunction with a multisite study of regional pediatric sickle-cell programs and which included only children with sickle-cell disease, reported no significant association of ever-receipt of pneumococcal vaccine with risk of IPD.[374] However, an alternate analysis that defined vaccinated children as only those who had received PPSV23 within the previous 3 years compared that group with a combined group of unvaccinated children and children vaccinated 3 or more years earlier and found an estimated effectiveness of 80% (95% CI, 40–94%).

Vaccine Evaluations of Persons With Asplenia

Evidence supporting PPSV efficacy in persons with anatomic asplenia has been provided by one observational study and one ecologic study. In the indirect-cohort study by Butler and colleagues,[368] vaccine efficacy was 77% (95% CI, 14–95%) in persons with asplenia. The characteristics of the patients, in terms of their indication for splenectomy, time since splenectomy, number of previous pneumococcal vaccinations, and time since last vaccination, were not reported. An assessment in Denmark found no cases of pneumococcal bacteremia in 292 children with splenectomies performed in 1979 to 1987, when PPSV was used routinely, compared with six cases per 1000 person-years in children splenectomized in 1969 to 1978, before the availability of PPSV.[446] The possible impact of the recommended use of antimicrobial prophylaxis on the Danish findings could not be determined.

Persistence of Vaccine Effect

In a case-control study involving all cases of IPD reported by 11 major hospitals in Connecticut, Shapiro and colleagues found 56% efficacy for PPSV23, including immunocompetent and immunocompromised adults of all ages. Among adults younger than age 55 years, vaccine efficacy was 93%, 89%, and 85% at less than 3, 3 to 5, and more than 5 years elapsed, respectively, but the initial efficacy declined with age and subsided more rapidly with time following vaccination (Table 47.5).[367] For persons 75 to 84 years old, vaccine was effective for the first 3 years after administration, and for older subjects protection was not statistically significant. This kind of study could be influenced by a so-called healthy-user effect, in which persons who were vaccinated were more likely to take better care of their health needs or have access to care than those who were not vaccinated.

Butler and colleagues conducted an indirect-cohort study that reached the opposite conclusion on persistence of effect (see Table 47.5).[368] In that study, among persons 5 years of age and older (median age, 50–57 years; see Table 47.2), in which the majority of subjects were older than 50 years, vaccine effectiveness 5 to 8 years after vaccination was 71% (95% CI, 24–89%), and 9 or more years after vaccination, it was 80% (95% CI, 16–95%). In a cohort study of persons 65 years of age and older,[372] vaccine effectiveness within 5 years of vaccination was 48% (95% CI, 6–71%); in the 5 to 7 years after vaccination, it was 36% (95% CI, −41% to 71%); and more than 7 years after vaccination, it was 42% (95% CI, −70% to 80%) (author's unpublished data). Bolan and colleagues reached conclusions similar to Butler's (see Table 47.5).[364]

Other studies offer differing findings on whether protection does or does not persist beyond 5 years.[378,395] Additional evidence is needed to describe the hazard (or survival) function for how long clinical protection from PPSV23 persists. Knowing that function would enable evidence-based policy recommendations for PPSV23 revaccination intervals.

Outcomes of Revaccination. Two published studies evaluated the effect of revaccination. In a study of Alaska Native adults, the point estimates of vaccine effectiveness, as determined by the indirect-cohort method, were 73% for the first dose of PPSV23 (95% CI, 19–92%) and 74% for revaccination (95% CI, <0–94%).[378] In a case-control study of Navajo adults, the risk of IPD in persons who had received two or more doses of PPSV23 was compared with that in unvaccinated persons.[371] In that analysis, revaccination reduced the risk of IPD by 40%, but the finding was not statistically significant (95% CI, −27% to 72%). There was no overall effectiveness of PPSV23 in this study, and the estimate of effectiveness after revaccination was not significantly different from that of cohort including people who received either primary or revaccination.

Antibody Persistence in Immunocompetent Adults. In older adults, anticapsular antibody levels induced by a first dose of PPSV23 decline substantially in the year after vaccination,[236,242,447] but mean levels remain above baseline levels through 5 or 10 years of observation (Fig. 47.5).[245] Similarly, functional antibody levels after PPSV23 in adults persist above concentrations in unvaccinated adults for this same time period.[247] The few studies with contrary findings involve populations of nonambulatory adults or those with confounding host-factor issues.[247] There is an inverse association between circulating antibody level just before primary vaccination or revaccination and the antibody increase post-vaccination.[247]

Immune Response to Revaccination in Immunocompetent Adults. PPSV23 induces a T-cell–independent response; as a result, there is no classical anamnestic, or booster, response to revaccination. In fact, in 1950 Heidelberger observed that repeated vaccination of healthy young adults at close intervals was followed by hyporesponsiveness—a lesser response, relative to earlier responses. At present, the precise mechanism for this hyporesponsiveness at short intervals remains unclear, although in mice, the lack of response following rechallenge with capsular polysaccharide from *S. pneumoniae* type 3 has been attributed to the activity of suppressor T cells that persist for varying intervals after the initial challenge.[448]

Older adults who receive a second dose of PPSV23 several years after initial vaccination demonstrate significant increases in anticapsular antibody levels.[225,241,244–246,447,449–454] The relative magnitude of the immune response to a second compared with a first pneumococcal polysaccharide vaccination has been evaluated in several ways. A review of all studies that compared the postvaccination antibody response in persons being revaccinated with a concurrent group of persons being vaccinated for the first time found consistent vigorous, statistically increased antibody responses at intervals of 5 years or more.[247]

In a group of 189 subjects, 60 to 64 years of age, who received a first dose of PPSV23 at study enrollment and a second dose of PPSV23 approximately 3.5 years later,[455] OPA GMTs to 12 of the PPSV23 serotypes were assessed at 1 month after each vaccination. The GMTs after the second PPSV23 were significantly lower than those after the first vaccination for eight of those 12 serotypes. In contrast, Musher and colleagues revaccinated a small group of patients who recovered from pneumococcal pneumonia,[454] showing that persons immunized within the previous year did not respond at all to revaccination. Those who had been vaccinated between 1 and 5 years previously had blunted responses, but those whose first dose of PPSV23 was 5 years or more previously had comparable antibody responses to those seen after the first vaccination.

One large study ($n = 981$) that followed adults 50 years of age and older after either a first or second PPSV23, found that IgG levels at 30 days postvaccination in persons who had been vaccinated 3 to 5 years previously tended to be lower than in those receiving a first dose of PPSV23, although the differences were modest and generally not statistically significant.[244] Antibody levels declined over time, and at 5 years after the study vaccination, geometric mean concentrations were similar in both the primary and revaccinated groups (with both concentrations still greater than at baseline). A substudy that tested samples by OPA, obtained from a subgroup of 120 subjects 65 years of age and older, reported similar findings.[225] When this study was extended to measure antibody responses 10 years after a first vaccination with PPSV23, no blunting of IgG responses was detected (see Fig. 47.4).[245]

A large study of primarily Alaska Native/Native American older adults found that antibody levels, measured by ELISA or an OPA assay, were similar in adults receiving their first PPSV23 ($n = 123$) to those receiving a second ($n = 121$) or a third or fourth PPSV23 ($n = 71$) (minimum interval of 6 years after a previous PPSV23).[246] Taken together, these studies suggest that revaccination with PPSV23 after an interval of 5 years or longer is effective in stimulating IgG responses similar to those observed after an initial vaccination.

Revaccination in HIV-Infected Persons

There are few studies evaluating the response to revaccination with PPSV23 in HIV-infected populations. Revaccination 3 to 8 years after first vaccination is associated with significant increases in serotype-specific IgG concentrations,[290,456] although antibody responses may be lower than those following a first vaccination.[290] In patients who do not respond to a first vaccination, revaccination 6 to 24 months later does not stimulate an antibody response.[457] In HIV-infected adults who received PPSV23, followed several years later by a series of three doses of PCV13, PCV13-type antibody concentrations after each of the PCV13 doses reached repeated peaks of similar magnitude—not a crescendo-like booster effect.[458]

Although two early studies in the pre-HAART era reported transient increases in viral load in HIV-infected children and adults after PPSV23,[459,460] these results were not confirmed. Numerous later studies show that there is no increased viral load and no adverse HIV consequences of HAART-treated HIV-infected patients after PPSV23.[290,291,456,461–464]

VACCINE SAFETY

Common Reactions

The most common adverse event in people vaccinated with PPSV23 in clinical trials were injection-site pain or soreness (60%), injection-site swelling or induration (20%), headache (18%), injection-site erythema (16%), asthenia or fatigue (13%), and myalgia (12%). The details reported in one study in adults appear in Table 47.6.[245] These reactions usually resolved within 2 to 3 days of vaccination and were typically mild. Fever occurred in less than 3% of PPSV23 recipients. Mild systemic adverse experiences (e.g., tiredness, muscle aches, chills) occurred in about one-third of vaccine recipients (compared to approximately 10% of placebo recipients). Such reactions occurred in approximately 20% of elderly adults. The incidence of severe vaccine-related systemic adverse events was less than 5%, including myalgia (2%), fatigue (1%), and headache (1%). Findings were similar in a separate study of adults receiving first, second, third, or fourth doses of PPSV23 (Table 47.7).[246] The safety profile of PPSV23 in children is similar to that in adults.[275,300]

Rare Reactions

There are two published reports of apparent anaphylactic reactions to PPSV23. The first was a 2-year-old nonatopic boy who had small bowel and liver disease and was awaiting liver transplantation and who developed bronchospasm and cutaneous and laryngeal edema immediately after vaccination, which resolved with appropriate treatment.[465] A diagnostic evaluation demonstrated IgE antibodies specific for pneumococcal polysaccharides. The second was a 3-year-old girl who had received three doses of seven-valent PCV before the age of 1 year, and who had a severe anaphylactic reaction within minutes of receipt of PPSV23 at age 3 years.[466]

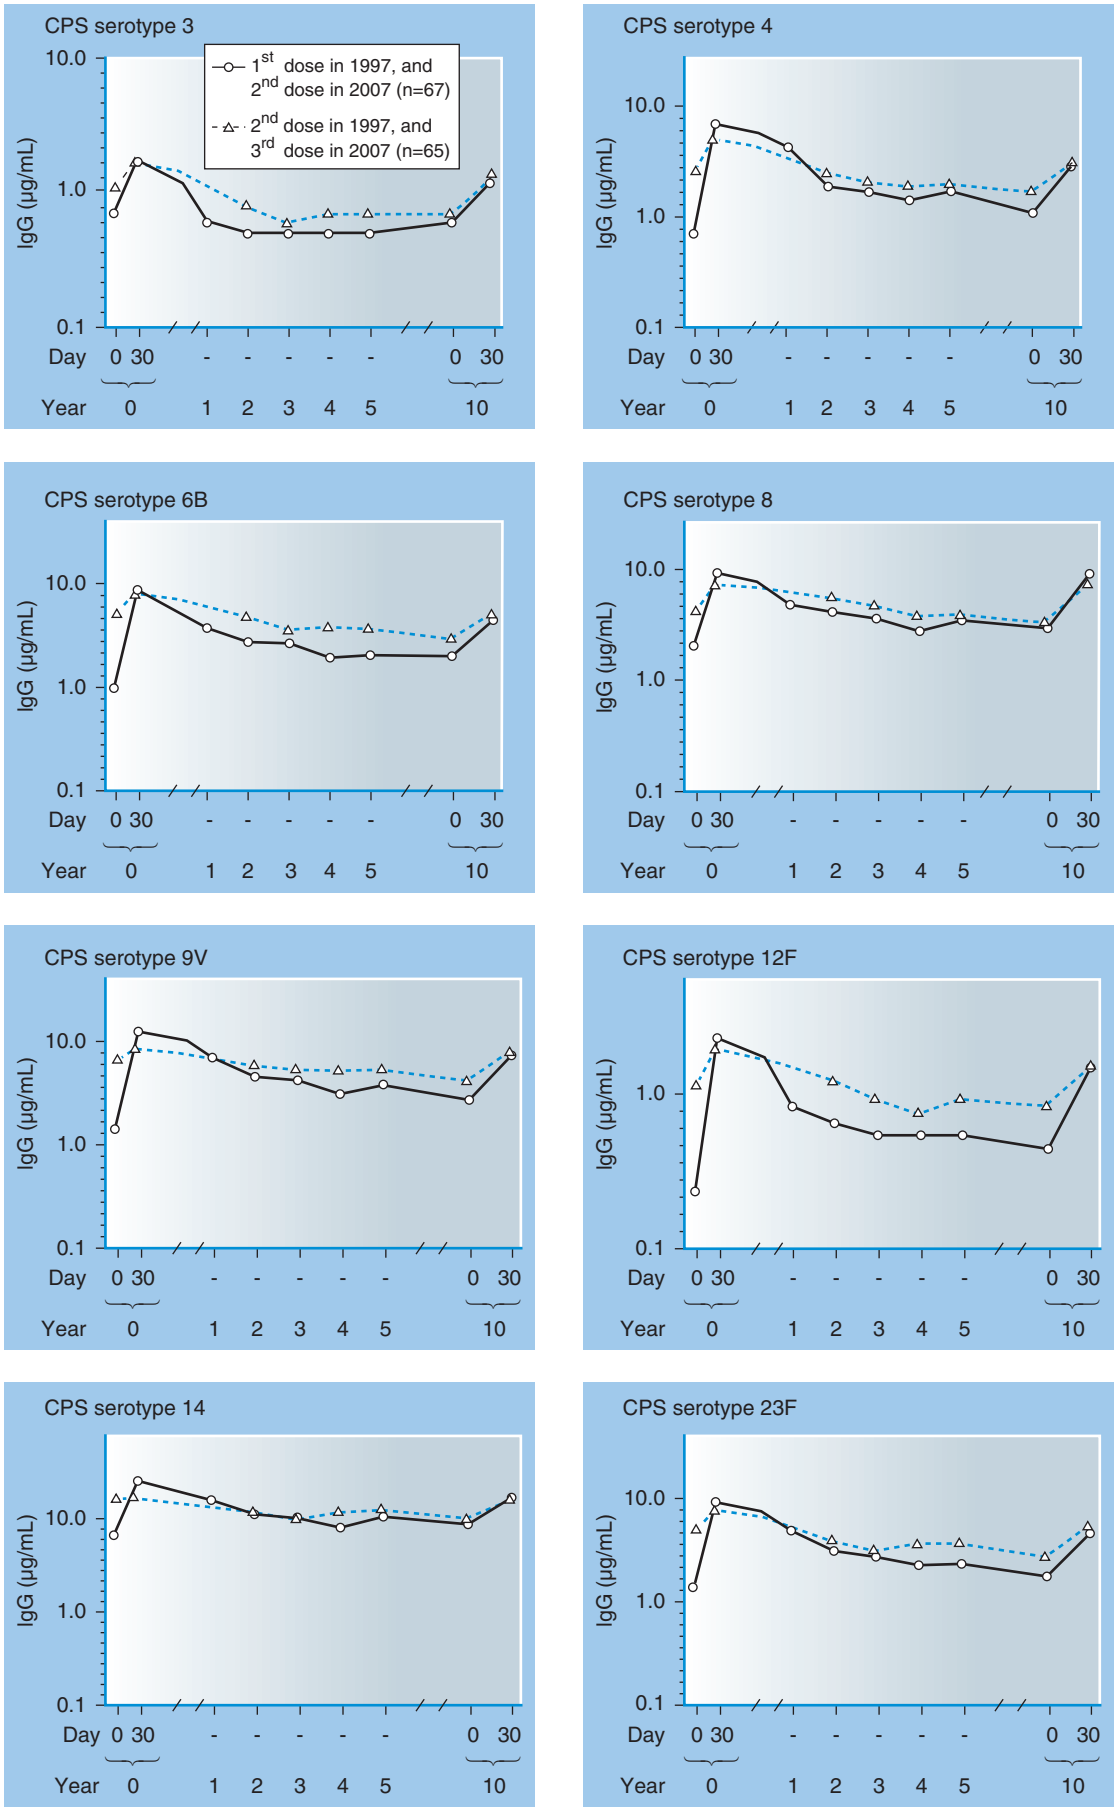

Figure 47.5. Immunoglobulin (Ig) G geometric mean concentrations (GMCs) to pneumococcal polysaccharides as measured by enzyme-linked immunosorbent assay (ELISA). The original protocol called for the annual collection of blood samples only from the first-dose recipients. A protocol amendment permitting the collection of annual blood samples from the second-dose recipients was implemented beginning in Year 2. CPS, capsular polysaccharide. *(From Musher DM, Manoff SB, McFetridge RD, et al. [c]Soreness that completely prevents normal activities.
[d]Unable to raise arm above shoulder level.
N = number in each group who completed the reactogenicity questionnaire.
From Hammitt LL, Bulkow LR, Singleton RJ, et al. Repeat revaccination with 23-valent pneumococcal polysaccharide vaccine among adults aged 55–74 years living in Alaska: no evidence of hyporesponsiveness. Vaccine. *2011;29:2287–2295.*

Safety of Revaccination

In the early 1980s, revaccination was thought to be contraindicated because of concerns about injection-site reactions.[467] Those concerns were prompted by two studies conducted in the 1970s that reported a higher-than-expected frequency and severity of local injection-site reactions after revaccination of healthy adults within 2 years of their first vaccination.[468,469] Other reports documented limb swelling and other large local reactions in healthy adults and children vaccinated within 3 or 4 years of a first vaccination.[470,471]

Those initial policy restrictions have been lifted over time. Several more recent studies indicate that revaccination of older adults at intervals of 5 to 10 years tends to be associated with a higher frequency of injection-site reactions but is generally well tolerated (e.g., see Table 47.6).[245,447,449–451,472–474] These include both clinical trials and studies of large linked databases, summarized in a review article.[247] These injection-site reactions have been seen in individuals with preexisting antibody levels prior to the PPSV23 vaccination with higher preexisting antibody noted in those with shorter intervals between doses. Although injection-site reactions (e.g., pain, swelling, redness) were reported more commonly after PPSV23 revaccination than after primary vaccination in most studies, these reactions were typically mild to moderate in intensity and resolved within 5 days.[247]

The available data from two published retrospective studies indicate that a third dose of PPSV23 is not associated with an increased risk of medically attended adverse events in adults.[475,476]

INDICATIONS FOR 23-VALENT PNEUMOCOCCAL POLYSACCHARIDE VACCINE

In the United States and dozens of other countries, PPSV23 is indicated by the U.S. Food and Drug Administration (FDA) and other national regulators to help prevent pneumococcal disease in persons 50 years of age or older, as well as in persons older than 2 years of age who are at increased risk for pneumococcal disease (most often as a consequence of chronic health conditions).

General Recommendations in the United States

Adults

In the United States, the Advisory Committee on Immunization Practices (ACIP) recommends PPSV23 as the sole pneumococcal vaccine for immunocompetent adults 19 to 64 years of age who are at increased risk of IPD or its consequences (Table 47.8).[14,331–333] These subjects include persons with chronic heart disease (including congestive heart failure and cardiomyopathy, but excluding hypertension), chronic lung disease (including asthma, emphysema, and chronic obstructive pulmonary disease), diabetes mellitus, alcoholism, or chronic liver disease, and those who smoke cigarettes.

Currently,[491] the CDC recommends that immunocompromised adults and those adults 65 years or older receive a combined regimen of PCV13 followed by PPSV23.[14,331,492] A person is immunocompromised if the person has CSF leaks, cochlear implants, sickle cell disease, other hemoglobinopathies, congenital or acquired asplenia (i.e., functional or anatomic asplenia), congenital or acquired immunodeficiencies (including B- or T-lymphocyte deficiency, complement deficiencies [particularly C1, C2, C3, and C4 deficiencies], and phagocytic disorders [excluding chronic granulomatous disease]), HIV infection, chronic renal failure, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, iatrogenic immunosuppression (including glucocorticoids or radiation), solid-organ transplant, or multiple myeloma.

As of 2008, routine use of PPSV23 is no longer recommended for otherwise healthy Native American or Alaska Native persons younger than 65 years of age. This change from the prior recommendation for routine use of PPSV23 in Native American or Alaska Native persons 2 to 64 years of age was made in recognition of the fact that while those groups may have disproportionately higher rates of IPD, the bulk of the disease burden is among those with medical indications for PPSV23.[123,493] However, in special situations, public health authorities may recommend PPSV23 for Native American or Alaska Native adults 50 to 64 years of age who are living in areas where the risk of IPD is increased.

TABLE 47.8 Government-Funded Recommendations for Adult Pneumococcal Vaccination in Selected Countries

Country	People ≥60 or ≥65 Years	Adults With Specified Chronic Diseases, <65 Years	Adults With Immune Suppression	References (Year)
Australia	PPSV23	PPSV23	PPSV23	477 (2015)
Canada	PPSV23	PPSV23	PCV13 then PPSV23	478, 479 (2015)
Germany	PPSV23	PPSV23 or PCV13	PCV13 then PPSV23	480 (2014)
France	–	PPSV23	PCV13 then PPSV23	481 (2015)
Israel	PPSV23	PPSV23	PCV13 then PPSV23	482 (2015)
Japan	PPSV23	PPSV23 for 60–64	PPSV23 for 60–64	483 (2015)
Korea	PPSV23	PPSV23	PPSV23	484, 485 (2013)
Mexico	PPSV23	PPSV23	PPSV23	486 (2013)
Netherlands	–	PPSV23 in asplenia	–	487 (2012)
Sweden	PPSV23	PPSV23	PPSV23	488 (1994)
Taiwan	≥75 years old: PPSV23			489 (2013)
U.K.	PPSV23	PPSV23	PCV13 then PPSV23	490 (2014)
U.S.	PCV13 then PPSV23	PPSV23	PCV13 then PPSV23	14, 331–333 (2014)

PCV13, 13-valent pneumococcal conjugate vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine.

Children and Adolescents

According to current recommendations of the ACIP and the American Academy of Pediatrics, U.S. children younger than 19 years of age with underlying medical conditions that are associated with an increased risk of IPD should receive PCV13 followed by PPSV23.[332,494] Underlying medical conditions that correspond with the recommendation for supplemental use of PPSV23 in children include chronic heart disease, chronic lung disease (including asthma), diabetes mellitus, CSF leaks, cochlear implant, alcoholism, sickle cell disease, other hemoglobinopathies, congenital or acquired asplenia, and immunocompromising conditions.[332,136,494] Receipt of PPSV23 is associated with a diminished immune response to PCV if given within a short interval[241,455]; therefore, all recommended doses of PCV13 should be given before the dose of PPSV23, at a minimum of 8 weeks after the last dose of PCV13.

Routine use of PPSV23 is not recommended for Native American or Alaska Native children. However, in special situations, public health authorities may recommend the use of PPSV23 after PCV13 for Native American or Alaska Native children 24 to 59 months of age who are living in areas in which risk of IPD is increased.[493]

The recommended immunization schedules for U.S. children, adolescents, and adults are updated annually and available at the CDC (http://www.cdc.gov/vaccines).

Revaccination

Revaccination with PPSV23 is recommended for certain subsets of primary vaccinees, such as certain subgroups of immunocompromised persons younger than 65 years. A single revaccination after 5 years is recommended for children and adults younger than 65 years who have chronic renal failure or nephrotic syndrome, functional or anatomic asplenia (e.g., sickle-cell disease or splenectomy), or another immunocompromising condition.[14,331,332,247] Some experts recommend revaccination of splenectomized patients every 6 to 7 years.

Vaccination of Specific Risk Groups

Persons With Functional or Anatomic Asplenia

PPSV23 is recommended for asplenic persons 2 years of age and older, after receiving PCV13. Patients scheduled for elective splenectomy should receive indicated vaccinations, which in children may include PCV13 and PPSV23, at least 2 weeks before the procedure. After emergent splenectomy, pneumococcal vaccination may begin as early as 1 day postoperatively, but there may be an advantage to delaying vaccination for 14 days postoperatively.

Persons With Cochlear Implants

In 2002, the FDA received reports of bacterial meningitis in persons with cochlear implants.[495] A subsequent investigation of 4264 children in the United States who received cochlear implants when they were younger than 6 years of age identified a rate of pneumococcal meningitis in the study population that was more than 30 times higher than that of children in the general U.S. population.[138] The risk of meningitis was significantly higher for patients with implants that included an electrode positioner, and those devices were estimated to account for approximately 50% of the cases of bacterial meningitis. A follow-up study found that children with implants with positioners remain at elevated risk of bacterial meningitis beyond 24 months after implantation, whereas a continued increase in risk was not found in children with implants without positioners.[496] Implant devices with electrode positioners were voluntarily recalled in 2002 and are no longer used.

Because of the increased risk of pneumococcal meningitis, all persons with cochlear implants should receive age-appropriate pneumococcal vaccination with both PCV13 and PPSV23, according to the schedules for persons at exceptionally high risk.[332,136] The dose of PPSV23 should follow at least 8 weeks after the last dose of PCV13. For maximal benefit, the doses of PCV13 and PPSV23 should be completed at least 2 weeks before implant surgery.

Persons Infected With HIV

In the United States, HIV-infected persons should receive PCV13 and then PPSV23 6 to 12 months later.[14,331,332] This approach is supported by the Infectious Diseases Society of America.[333] In patients whose CD4 cell count is greater than 200, there appears to be no benefit to waiting for the patient to receive 6 to 9 months of HAART before vaccinating, even if antiretroviral therapy has just been begun.[301] The Infectious Diseases Society of America recommends a second dose of PPSV23 5 years after the first.

Other Immunocompromised Persons

Pneumococcal vaccination is recommended for immunocompromised persons because of their increased risk of disease, although disease or therapy prevents many of these patients from deriving full benefit from any vaccination.[116,331–333] Persons being considered for immunosuppressive therapy should be vaccinated at least 2 weeks before treatment begins or, if this is not possible, 3 months after treatment stops because the antibody response to vaccination during or shortly after chemotherapy or radiation therapy is poor.

Recommendations in Other Countries

To date, most industrialized countries, including the United States, have retained PPSV23 as the sole recommended pneumococcal vaccine for adults 19 to 64 years old with health conditions predisposing to pneumococcal infection (see Table 47.8).[331–333,477–490] Several countries have adopted the combined PCV13-then-PPSV23 approach for immunocompromised adults, although in France and the Netherlands vaccination is recommended only for adults with high-risk conditions and not for healthy adults 65 years of age and older. In England, a risk group–only policy was implemented in 1992, with recommendations extended in 2003 to include all adults 65 years of age and older and, later, welders.[490] Table 47.8 shows that few countries have adopted government-sponsored recommendations for sequential use of PCV13-then-PPSV23 for people 65 years or older. While other national health authorities do not typically publish rationales for their decisions, the indirect effects among adults of pediatric PCV programs are typically cited as reducing the burden of pneumococcal disease sufficiently, such that they prefer to recommend PPSV23 solely, a product offering broader serotype coverage. Several health-economic models illustrate how this would be so.[497,498]

CONTRAINDICATIONS AND PRECAUTIONS

There are no contraindications to administering PPSV23 other than known hypersensitivity to a vaccine component or a previous severe reaction to the vaccine.

PUBLIC HEALTH CONSIDERATIONS

In the United States, achieving 90% coverage with pneumococcal vaccination of noninstitutionalized adults 65 years of age and older was a Healthy People 2000 and 2010 objective and is now a Healthy People 2020 objective (http://www.healthypeople.gov). Additional Healthy People 2020 objectives for pneumococcal vaccination include achieving 60% coverage for noninstitutionalized high-risk adults 19 to 64 years of age and achieving 90% coverage for institutionalized adults 18 years of age and older. In all recommended groups, actual vaccination levels remain far below target goals.

Among noninstitutionalized adults in the United States who are 65 years of age and older, PPSV23 coverage increased from 14% in 1989 to 60% in 2002 and has plateaued near that level ever since.[499] Vaccination rates among non-Hispanic blacks and Hispanics consistently have been substantially lower than among non-Hispanic whites. Racial disparities in PPSV23 coverage also exist among nursing-home residents.[500]

Coverage rates for PPSV23 are markedly lower among younger adults whose vaccination recommendation is based on underlying disease states. In 2012, the National Health Interview Survey estimated that only 20% of persons 19 to 64 years of age with one or more relevant health conditions had received PPSV23.[499]

Because increased PPSV23 coverage is an important public health goal, evidence-based evaluations of interventions to improve coverage are relevant.[501,502] Both the ACIP and the Task Force on Community Preventive Services recommend the use of standing order programs in both inpatient and outpatient settings to improve pneumococcal vaccination coverage. Standing orders programs, where allowed by state law, authorize nurses and pharmacists to administer vaccinations according to an institution- or physician-approved protocol without the need for a physician's examination or direct order.[503]

The Task Force found evidence that provider-reminder interventions, even when implemented alone, improved targeted vaccination coverage. Provider-reminder interventions are used to inform those who administer vaccinations that individual clients are due for specific vaccinations. The Task Force also recommended combinations of other interventions to improve vaccination rates. These include one or more interventions to enhance access to vaccination services (e.g., expand availability of vaccines in medical or other settings, or reduce out-of-pocket costs) with one or more provider- or system-based interventions and/or one or more interventions to increase client or community demand for targeted vaccination services. Examples include assessment and feedback for vaccination providers, provider education, client reminders, clinic-based education, communitywide education and policies or laws and regulations that require vaccination or other documentation of immunity as a condition of school attendance, residence, or employment.[501]
